Oxygen is necessary for combustion. The amount of oxygen required for complete combustion is known as the stoichiometric or theoretical oxygen, and is determined by the nature and, of course, the quantity of the combustible material to be burned. With the exception of some exotic fuels, combustion oxygen is usually obtained from atmospheric air. Figure 2.3 depicts the concept of complete combustion. It shows that the reaction of oxygen and organics produces only CO<sub>2</sub> and H<sub>2</sub>O (EPA-89/03).

Consider a generalized fuel with a chemical formula C<sub>x</sub>H<sub>y</sub>S<sub>z</sub>O<sub>w</sub>, where the indices *x*, *y*, *z*, and *w* represent the relative number of atoms of carbon, hydrogen, sulfur, and oxygen respectively. Balancing the chemical reaction for the complete oxidation (combustion) of this fuel with oxygen from air gives (EPA-80/02, p. 2):

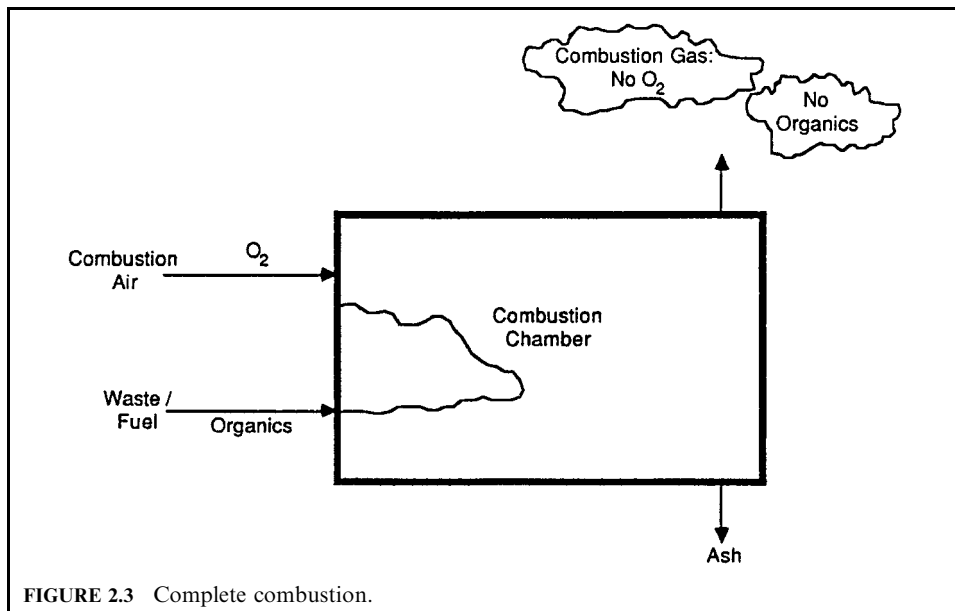

FIGURE 2.3 Complete combustion.

where  $Q$  represents the heat of combustion.

The above reaction assumes that:

1. air consists of 21% by volume of oxygen with the remaining 79% made up of nitrogen and other inert gases;
2. bound oxygen in the fuel is available for combustion, thus reducing air requirements;
3. fuel contains no bound nitrogen, so no “fuel  $\text{NO}_x$ ” is produced;
4. “thermal  $\text{NO}_x$ ” via nitrogen fixation is small, so that it is neglected in stoichiometric air calculations;
5. sulfur in fuel is oxidized to  $\text{SO}_2$  with negligible  $\text{SO}_3$  formation.

Equation (2.1) relates the reactants on a molar basis. One gram-mole of a substance is the mass of that substance equal to its molecular weight in grams. A gram-mole of any substance contains Avogadro’s number of molecules of that substance, i.e., there are  $6.02 \times 10^{23}$  molecules/g-mole. Pound-moles (lb-mole) are also in common use. Since one pound-mole is equivalent to the molecular weight of the substance in pounds, it contains 454 times as many molecules as a gram-mole.

The generalized combustion equation, Eq. (2.1), can be converted to a mass basis simply by multiplying the number of moles of each substance by its respective molecular weight.

Referring to Eq. (2.1), for  $\text{CH}_4$ :  $x = 1$ ;  $y = 4$ ;  $z = w = 0$ . Thus balancing the combustion equation gives

Mole balance (volume balance):

$$1 + 2 + 7.52 \rightarrow 1 + 2 + 7.52 \quad (2.3)$$

= 10.52 moles for both reactants and products.

Mass balance:

$$16 + 64 + 211 \rightarrow 44 + 36 + 211 \quad (2.4)$$

= 291 lb for both reactants and products.

$$\text{Mass/combustibles} = (\text{mass of each component})/(\text{CH}_4 \text{ mass}): \quad (2.5)$$

$$1 + 4 + 13.19 \rightarrow 2.75 + 2.25 + 13.19$$

The above expression gives not only the theoretical air requirements in terms of moles or volume in Eq. (2.3), and mass in Eqs. (2.4) and (2.5), but it also permits the determination of the resulting combustion products which the flue needs to handle.

Chemical reactions take place as a function of the molecular weights of the reactants. Based on the molecular weights of elements, consider the oxygen needed for the following five cases (Hasselriis-98/12).

1. One mole of carbon [12 lb] reacts with one half mole of oxygen (gas) [32/2 lb] to form one mole of carbon monoxide [28 lb].

2. One mole of carbon reacts with one mole of oxygen (gas) to form one mole of carbon dioxide.

3. Two moles hydrogen + one mole oxygen (gas) → two moles water.

4. One mole of sulfur reacts with one mole of oxygen (gas) to form one mole of sulfur dioxide.

5. One mole of oxygen plus one half mole of nitrogen (gas) forms one mole of nitrogen dioxide.

**EXAMPLE 1** combustion of hydrogen

Calculate the weight of oxygen required for combustion of methane CH<sub>4</sub>.

Step 1. Determine the C–H combustion balance equation. The same number of carbons and hydrogens must appear on the left and right sides of the equation. One mole of  $\text{CO}_2$  and two moles of  $\text{H}_2\text{O}$  are produced. Two moles of oxygen are needed to balance the equation.

Step 2. Using the molecular weights of carbon (12), hydrogen (1), and oxygen gas (32), write the weight equation and determine the weights of the reactants.

**EXAMPLE 2** combustion of hydrogen

Calculate how many pounds of oxygen are theoretically required to completely burn (oxidize) a pound of Number 2 fuel oil ( $\text{C}_6\text{H}_{10}$ ).

Step 1. Determine the C–H combustion balance equation.

Five moles of  $\text{H}_2\text{O}$  are produced and 8.5 moles of oxygen are needed to balance the equation.

Step 2. Determine the weights of the reactants.

Use the molecular weights of carbon (12), hydrogen (1), oxygen (16), and oxygen gas (32) to balance and write the weight equation.

Step 3. Divide by weight of fuel.

**EXAMPLE 3** compounds containing hydrogen, carbon, and oxygen

Calculate how many pounds of oxygen are theoretically required to completely burn a pound of cellulose ( $\text{C}_6\text{H}_{10}\text{O}_5$ ).

Step 1. Determine the C-H-O combustion balance equation.

Six moles of oxygen produce 6 moles  $\text{CO}_2$  and five moles of  $\text{H}_2\text{O}$ .

Step 2. Determine the weights of the reactants.

Step 3. Divide by weight of fuel.

## 2.4 Complete Incineration

Parallel to complete combustion, complete incineration is a process where the elements in the waste are generally assumed to follow the reaction patterns listed in Table 2.1. The ultimate goal of incinerating a waste is to convert the waste materials into harmless combustion products so that they can be safely emitted to the environment.

However, complete incineration is solely a theoretical concept. In actual practice, ppm levels of partially oxidized products of incomplete combustion (PICs) are formed. These PICs may include carbon monoxide (CO), soot, and a whole myriad of other organic products. It is always possible to over-design an incinerator or to use extra fuel for higher flame temperatures to ensure sufficiently complete combustion. However, either of these corrective measures increases the cost of incineration.

The organic materials that enter an incinerator with the waste and fuel are primarily made up of carbon, hydrogen, and oxygen. Ideally, these organic materials react with oxygen in the combustion gas to form carbon dioxide (CO<sub>2</sub>) and water vapor (H<sub>2</sub>O). The chemical reaction for this ideal situation is

This ideal reaction represents complete incineration or complete combustion, and is depicted in Fig. 2.4. However, this ideal reaction may or may not occur in actual waste combustion systems. For example, when chlorinated compounds are in the waste, HCl is emitted from the incinerator combustion chamber.

**TABLE 2.1** Complete Incineration Reaction Pattern

Waste elements	Conversion products
Hydrogen, H	H <sub>2</sub> O
Carbon, C	CO <sub>2</sub>
Chloride, Cl	HCl or Cl <sub>2</sub>
Fluoride, F	HF or F <sub>2</sub>
Sulfur, S	SO <sub>2</sub>
Nitrogen, N	N <sub>2</sub>
Alkali metals	Carbonate
Sodium, Na	Na <sub>2</sub> CO <sub>3</sub>
Potassium, K	KOH
Non-alkali metals	Oxides
Copper, Cu	CuO
Iron, Fe	Fe <sub>2</sub> O

## 2.5 Incomplete Combustion and Incomplete Incineration

Incomplete combustion means that the combustion process has not undergone complete combustion. This is depicted in Fig. 2.5. During the incineration of waste, many factors can cause incomplete combustion. Factors that lead to incomplete combustion include poor mixing, too much or too little combustion air, low temperatures, etc. Under these conditions, undesirable toxic combustion byproducts (TCBs) may be discharged with ash or emitted with stack gas. The gaseous TCBs which are emitted with the stack gas are also known as the products of incomplete combustion (PICs). The most common PIC emitted is CO. Concentrations of CO in the stack gas generally increase with any of the poor combustion conditions described above. Soot is another TCB that often is emitted under poor operating conditions. Soot particles are an elemental carbon which is in general very fine and can result in high opacity at the combustion stack. Other PICs that cause concern because of their health impacts are benzene, dioxins, furans, and other hazardous organic compounds.

The main products of waste incineration under either complete or incomplete incineration are combustion gases, solid residue (ash), and energy. The primary objectives of designing or operating an incinerator are to ensure that:

1. the combustion gases contain minimum PICs (products of incomplete combustion);
2. ash or solid residue is free of organic compounds;
3. the energy generated is recovered.

**EXAMPLE:** complete combustion

Methanol (CH<sub>4</sub>O) undergoes incomplete combustion and produces two intermediate compounds, formaldehyde (CH<sub>2</sub>O) and formic acid (CH<sub>2</sub>O<sub>2</sub>). Calculate the volume of air required to combust one pound of methanol at 60°F and 14.6959 psia.

FIGURE 2.5 Incomplete incineration (EPA-89/03).

Solution:

1. Complete the following combustion equations.

2. Calculate the number of moles of methanol  $n$  in one pound of methanol.

$$n = m/M = 1/[12 + 1(4) + 16]$$

$$= 0.0313 \text{ lb-mole}$$

The air needed for each of the three cases above is

3. Calculate the air needed.

The standard volume of one lb-mole of air at  $T = 60^\circ\text{F}$ , and  $p = 14.6959$  psia is

$$\begin{aligned} V &= nR_u T/P \\ &= 1(1545)(460 + 60)/(14.6959(144)) \\ &= 380 \text{ scf} \end{aligned}$$

4. Calculate the volume of air needed for each of the three cases above.

For eq. a, air =  $380(0.0156)(1 + 3.76) = 28.218$  scf

For eq. b, air =  $380(0.0313)(1 + 3.76) = 56.615$  scf

For eq. c, air =  $380(0.0469)(1 + 3.76) = 84.833$  scf

Notes: As shown above, it is possible to create a worse pollution problem if the combustion is incomplete. Incomplete combustion can arise because of:

- low temperatures;
- insufficient air; and
- incomplete mixing.

## 2.6 Combustion Air

The above discussion on basic combustion indicates that oxygen is the essential item in both fuel combustion and waste incineration. It is well known that oxygen can be supplied from the air. Figure 2.6 shows the fate of combustion air. The oxygen component in the air reacts with

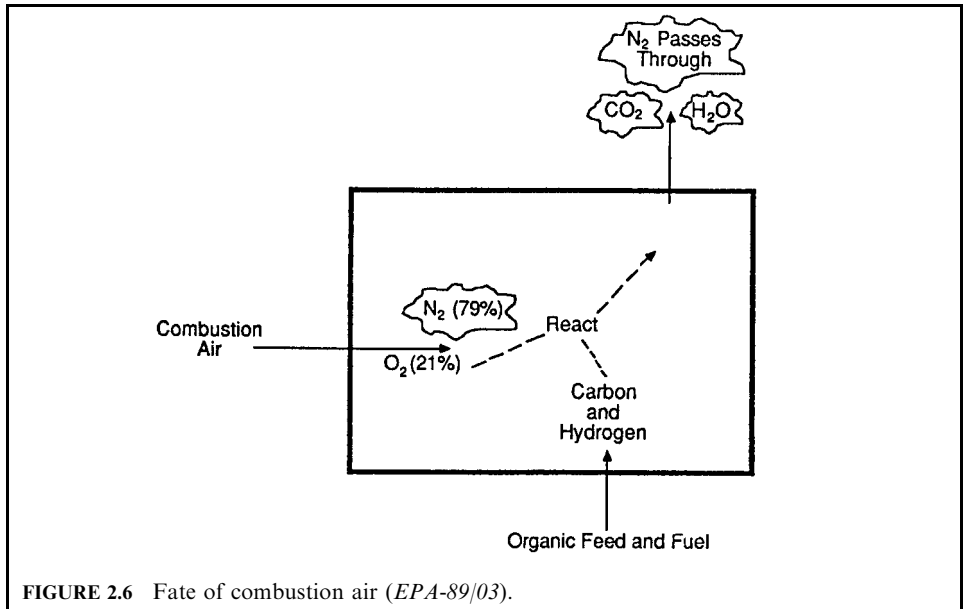

FIGURE 2.6 Fate of combustion air (EPA-89/03).

organics and produces  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . The nitrogen component in the air passes through the combustion chamber and emits to the atmosphere.

**Theoretical air combustion.** The following procedures provide the methods for calculating the amounts of oxygen, nitrogen, and air needed for the theoretical combustion of a hydrocarbon compound. It is assumed that a hydrocarbon compound contains elements of carbon, hydrogen, chlorine, oxygen, nitrogen, and sulfur. The theoretical amount of air needed and the combustion products produced can be derived in terms of the mass of input elements.

- For carbon combustion:  $\text{C} + \text{O}_2 \rightarrow \text{CO}_2$ 
  - Oxygen needs,  $\text{O}_2 = (32/12)(\text{C}) = 2.67(\text{C})$  lb/lb-carbon
  - Combustion products,  $\text{CO}_2 = (44/12)(\text{C}) = 3.67(\text{C})$  lb/lb-carbon
- For hydrogen combustion: hydrogen reacts with chlorine first; the left-over hydrogen then reacts with oxygen. The oxygen needed for this combustion is
  - $\text{H} + \text{Cl} \rightarrow \text{HCl}$ ,  $\text{H}_2 = \text{H}$  left over after Cl reaction;  $\text{H}_2 = \text{H}-\text{Cl}/35.5$
  - $\text{H}_2 + 0.5\text{O}_2 = \text{H}_2\text{O}$
  - Oxygen needs,  $\text{O}_2 = \text{H}_2(0.5)(32/2) = 8(\text{H}-\text{Cl}/35.5)$
  - Combustion products,  $\text{H}_2\text{O} = (18/2)\text{H}_2 = 9(\text{H}_2) = 9(\text{H}-\text{Cl}/35.5)$
- For sulfur combustion:  $\text{S} + \text{O}_2 \rightarrow \text{SO}_2$ 
  - Oxygen,  $\text{O}_2 = (32/32)(\text{S}) = \text{S}$
  - Combustion products,  $\text{SO}_2 = (64/32)\text{S} = 2(\text{S})$
- For bound oxygen ( $\text{B}_o$ ):  $\text{B}_o$  is the oxygen associated with (bound to) fuel or waste, not with air. It is assumed that  $\text{B}_o$  will react with reactant species such as carbon or hydrogen during combustion. Because of the presence of  $\text{B}_o$ , less air is needed.  $\text{B}_o$  will replace the amount of oxygen in the air needed for combustion. Therefore, the net oxygen quantity needed for combustion will be the theoretical oxygen quantity less the  $\text{B}_o$  quantity.  $\text{B}_o$  is used to represent the amount of bound oxygen.
- For bound nitrogen ( $\text{B}_n$ ):  $\text{B}_n$  is the nitrogen associated with (bound to) fuel or waste, not with air. It is assumed that  $\text{B}_n$  will not react with reactant species during combustion. It stays as molecular nitrogen and emits to the atmosphere as part of the combustion products.  $\text{B}_n$  is used to represent the amount of bound nitrogen.

Summing up the five items above results in:

Oxygen amount

$$\text{O}_2 = 2.67(\text{C}) + 8(\text{H}-\text{Cl}/35.5) + \text{S} - \text{B}_o \quad (2.6)$$

Nitrogen amount

$$\begin{aligned} \text{N}_2 &= \text{O}_2(0.79/0.21)(\text{MW of N}_2/\text{MW of O}_2) = \text{O}_2(3.76)(28)/32 \\ &= 3.29(\text{O}_2) \end{aligned} \quad (2.7)$$

Air needed for theoretical combustion  $A_t$

$$\begin{aligned} A_t &= \text{O}_2 + \text{N}_2 \\ &= \text{O}_2 + 3.29(\text{O}_2) \\ &= 4.29(\text{O}_2) \end{aligned} \quad (2.8)$$

Combustion products from theoretical combustion  $P_t$

$$P_t = CO_2 + H_2O + SO_2 + N_2 + B_n$$

$$= 3.67(C) + 9(H-Cl/35.5) + 2(S) + 3.29(O_2) + B_n \tag{2.9}$$

The above results are also summarized in Tables 2.2 and 2.3. Table 2.2 can be used to calculate air requirements during theoretical or complete combustion.

Table 2.3 can be used to calculate combustion products during complete combustion.

**TABLE 2.2** Computing the Reactants of Theoretical Air Combustion ( $R_t$ )

Basic reaction	Oxygen, nitrogen, and air requirements
$C + O_2 \rightarrow CO_2$	$O_2 = C(32/12) = 2.67(C)$
$H_2 + 0.5O_2 \rightarrow H_2O$	$H_2 = H$ left over after Cl reaction; $H_2 = H-Cl/35.5$ $O_2 = H_2(0.5)(32/2) = 8(H-Cl/35.5)$
$S + O_2 \rightarrow SO_2$	$O_2 = S(32/32) = S$
$B_o = \text{bound oxygen}$	$B_o$ is the oxygen associated with waste or fuel. It reacts with reactants and is a negative value if the air amount is positive
$O_2$	$O_2 = 2.67(C) + 8(H-Cl/35.5) + S - B_o$
$N_2$	$N_2 = (O_2)(3.76 \times 28/32)$
$R_t$	$R_t = O_2 + N_2$

**TABLE 2.3** Computing the Products of Theoretical Air Combustion ( $P_t$ )

Basic reaction	Combustion products
$C + O_2 \rightarrow CO_2$	$CO_2 = (C)(44/12)$
$H_2 + 0.5O_2 \rightarrow H_2O$	$H_2 = H$ left over after Cl reaction; $H_2 = H-Cl/35.5$ $H_2O = H_2(18/2) = 9(H-Cl/35.5)$
$S + O_2 \rightarrow SO_2$	$SO_2 = S(64/32) = 2(S)$
$N_2 = 3.29(O_2)$	$N_2$ associated with air, $N_2 = (O_2)(3.76 \times 28/32)$
$B_n = \text{bound nitrogen}$	$N_2$ associated with waste or fuel
$P_t$	$P_t = 3.67(C) + 9(H-Cl/35.5) + 2(S) + 3.29(O_2) + B_n$

**EXAMPLE 1** air for theoretical combustion

Calculate the amounts of  $O_2$  and  $N_2$  needed in the air and the combustion products produced for the complete combustion of 200 pounds  $CH_4$ .

**Given conditions:**

- $CH_4 = 200$  lb
- $Cl = 0$
- $S = 0$
- $B_o = 0$
- $B_n = 0$

*Solution 1* by chemical analysis

1.1. Calculate the ultimate composition of  $CH_4$  in 200 lb (Table 2.4)

where

- $x_i$  = compound element
- $M$  = molecular weight of  $\text{CH}_4$
- $x_i/M$  = mass per pound fuel

**TABLE 2.4** 200 lb  $\text{CH}_4$ 

$x_i$	C	H	Cl	O	M
$\text{CH}_4$	12	4	0	0	16.00
$x_i/M$	0.7500	0.2500	0.0000	0.0000	
200 lb	150.0000	50.0000	0.0000	0.0000	

1.2. Apply results from 1.1 to calculate the oxygen amount.

$$\begin{aligned}
 \text{O}_2 &= 2.67(\text{C}) + 8(\text{H}-\text{Cl}/35.5) + \text{S} - \text{B}_o \\
 &= 2.67(150) + 8(50 - 0) + 0 - 0 \\
 &= 401 + 400 \\
 &= 801 \text{ lb}
 \end{aligned}$$

1.3. Apply results from 1.2 to calculate the nitrogen amount.

$$\begin{aligned}
 \text{N}_2 &= \text{O}_2(3.76)(28)/32 \\
 &= 3.29(\text{O}_2) \\
 &= 3.29(801) \\
 &= 2635 \text{ lb}
 \end{aligned}$$

1.4. Apply results from 1.3 to calculate the theoretical air  $A_t$ .

$$\begin{aligned}
 A_t &= \text{O}_2 + \text{N}_2 \\
 &= 801 + 2635 \\
 &= 3436 \text{ lb}
 \end{aligned}$$

1.5. Calculate the total reactants.

$$\begin{aligned}
 \text{Reactants} &= \text{CH}_4 + \text{air} \\
 &= 200 + 3436 \\
 &= 3636
 \end{aligned}$$

1.6. Apply results of 1.4 to calculate the combustion products  $P_t$ .

$$\begin{aligned}
 P_t &= \text{CO}_2 + \text{H}_2\text{O} + \text{SO}_2 + \text{N}_2 + \text{B}_n \\
 &= 3.67(\text{C}) + 9(\text{H}-\text{Cl}/35.5) + 2(\text{S}) + 3.29(\text{O}_2) + \text{B}_n \\
 &= 3.67(150) + 9(50 - 0/35.5) + 0 + 3.29(801) + 0 \\
 &= 551 + 450 + 2635 \\
 &= 3636 \text{ lb}
 \end{aligned}$$

1.7. Compare the results of reactant and product calculations. Comparing the values of reactants and products shows that the two numbers are identical. This means that the mass input and mass output are balanced and the calculation is correct.

*Solution 2* by tabulation

2.1. Calculate the theoretical combustion air ( $A_t$ ) by the procedures in Table 2.5.

**TABLE 2.5** Computing the Reactants of Theoretical Air Combustion ( $R_t$ )

Basic reaction	Oxygen, nitrogen, and air requirements	Mass
$C + O_2 \rightarrow CO_2$	$O_2 = C(32/12) = 2.67(C) = 2.67(150)$	401
$H_2 + 0.5O_2 \rightarrow H_2O$	$H_2 = H$ left over after Cl reaction; $H_2 = H-Cl/35.5$	400
	$O_2 = H_2(0.5)(32/2) = 8(H-Cl/35.5) = 8(50 - 0)$	
$S + O_2 \rightarrow SO_2$	$O_2 = S(32/32) = S$	0
$B_o =$ bound oxygen	$B_o$ is the oxygen associated with waste or fuel. It reacts with reactants and is a negative value if the air amount is positive	0
$O_2$	$O_2 = 2.67(C) + 8(H-Cl/35.5) + S - B_o$	801
$N_2$	$N_2 = (O_2)(3.76 \times 28/32)$	2635
$R_t$	$R_t = O_2 + N_2$	3436

2.2. Calculate the theoretical combustion products ( $G_t$ ) by the procedures in Table 2.6.

**TABLE 2.6** Computing the Products of Theoretical Air Combustion ( $P_t$ )

Basic reaction	Combustion products	Mass
$C + O_2 \rightarrow CO_2$	$CO_2 = (C)(44/12)$	551
$H_2 + 0.5O_2 \rightarrow H_2O$	$H_2 = H$ left over after Cl reaction; $H_2 = H-Cl/35.5$	450
	$H_2O = H_2(18/2) = 9(H-Cl/35.5)$	
$S + O_2 \rightarrow SO_2$	$SO_2 = S(64/32) = 2(S)$	0
$N_2 = 3.29(O_2)$	$N_2$ associated with air, $N_2 = (O_2)(3.76 \times 28/32)$	2635
$B_n =$ bound nitrogen	$N_2$ associated with waste or fuel	0
$P_t$	$P_t = 3.67(C) + 9(H-Cl/35.5) + 2(S) + 3.29(O_2) + B_n$	3636

2.3. Check the mass input and mass output results. The results shows that the mass input and mass output are identical.

**EXAMPLE 2** weight of air for theoretical combustion

Calculate how many pounds of air are required to completely burn a pound of cellulose ( $C_6H_{10}O_5$ ) [see the previous example in this chapter] (Hasselriis-98/12).

Step 1. Add the nitrogen carried with the theoretical oxygen to both sides. For 1.18 lb oxygen there will be  $1.185(3.31)^*$  or 3.92 lb  $N_2$ :

\* This value is derived elsewhere in this chapter as 3.29, however 3.31 will be used in Examples 2 and 3.

**EXAMPLE 3** weight of air for theoretical combustion

Calculate the products of combustion when 50% excess air is used to burn cellulose. Add 50% more oxygen and nitrogen to both sides of the equation:

This can be written as:

**EXAMPLE 4** volume of air for theoretical combustion

Calculate the volume of air required for complete combustion of methane.

Step 1. Determine and balance the  $\text{CH}_4$  and  $\text{O}_2$  combustion equation.

The equation shows that 1 mole of  $\text{CH}_4$  requires 2 moles of  $\text{O}_2$ . It also shows that 1 scf of  $\text{CH}_4$  requires 2 scf of  $\text{O}_2$ .

Step 2. Calculate the volume of air required.

The oxygen required for combustion carries nitrogen with it. The components of air can be expressed in terms of either moles or standard cubic feet (scf) as follows:

For 2 scf of  $\text{O}_2$ ,  $2 \times 4.76 = 9.52$  scf of air is needed per scf of  $\text{CH}_4$ .

**EXAMPLE 5** calculate the average molecular weight of the products

Calculate the average molecular weight of the *wet* products of combustion of cellulose at 0% excess air.

**EXAMPLE 6** calculate the average molecular weight of the products

Calculate the average molecular weight of the *dry* products from combustion of cellulose at 0% excess air; subtract the moisture ( $\text{H}_2\text{O}$ ).

$$\begin{array}{r r r r} \text{Wt. fraction} \times \text{Mol. wt.} & = & \text{weight} & \\ \text{CO}_2 \ 1.63 & \times \ 44 & = & 71.72 \\ \text{H}_2\text{O} \ (0.555) & \times \ 18 & = & - \\ \text{N}_2 \ 3.92 & \times \ 28 & = & 109.76 \\ \text{Total:} & 5.55 & & 181.48 \\ \text{Average: sum/wt.} & = & 181.48/5.55 & = \ 32.70 \ \text{lb/mole} \end{array}$$

**EXAMPLE 7** calculate the average molecular weight of the products  
 Calculate the average molecular weight of the dry products from combustion of cellulose at 50% excess air.

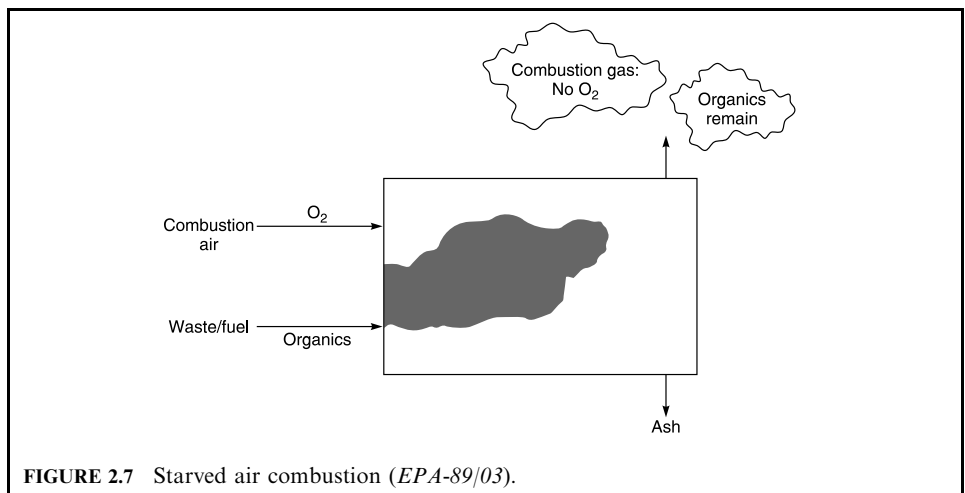

$$\begin{array}{r r r r} \text{Wt. fraction} \times \text{Mol. wt.} & & & \\ \text{CO}_2 \ 1.63 & \times \ 44 & = & 71.72 \\ \text{H}_2\text{O} \ (0.555) & \times \ 18 & = & - \\ \text{O}_2 \ 1.78 & \times \ 32 & = & 56.96 \\ \text{N}_2 \ 5.88 & \times \ 28 & = & 164.64 \\ \text{Wt:} & 9.21 & \text{Average: sum/wt.} & = \ 293.32/9.21 = \ 31.85 \ \text{lb/mole} \end{array}$$

**Deficient (starved) air combustion.** Deficient air combustion is also known as starved air combustion. Deficient air combustion results when the supplied combustion air is less than that required for theoretical combustion. Insufficient air will result in incomplete combustion, with emissions of pollutants such as carbon monoxide, solid carbon particulates in the form of smoke or soot, and unburned and/or partially oxidized hydrocarbons. Figure 2.7 shows the phenomenon of starved air combustion in which the organics in the waste are not completely destroyed and are emitted to the atmosphere (EPA-89/03).

Burning carbon with insufficient oxygen can produce CO.

With additional oxygen the carbon monoxide can be converted to CO<sub>2</sub>.

**FIGURE 2.7** Starved air combustion (EPA-89/03).

Even clean-burning gaseous fuels, such as methane, could produce pollutants when burned with too little oxygen.

The solid carbon particles can agglomerate resulting in smoke and soot. Somewhat more oxygen, but still less than theoretically necessary, could lead to carbon monoxide formation by the following reaction:

Reactions similar to those represented by Eqs (2.10) and (2.13) can occur in the presence of adequate air if (a) the oxygen is not readily available for the burning process, as a result of inadequate mixing or turbulence, (b) the flame is quenched too rapidly, and/or (c) the residence time is too short. These “three T’s of combustion” (i.e., turbulence, temperature, and time) are all interrelated and need to be considered carefully in order to achieve efficient combustion with a minimum of pollutant emissions.

**Excess air combustion.** Excess combustion air or excess air (EA) is the air supplied in excess of that necessary to burn a compound completely and it appears in the products of combustion. The amount of excess air is normally expressed as a percentage of the theoretical (stoichiometric) air required for complete combustion of the compound. Figure 2.8 shows the concept of excess air combustion in that the excess amount of oxygen passes through the combustion chamber and emits to the atmosphere (EPA-80/02, p. 51-4; EPA-89/03).

The excess air ( $A_e$ ) (fractional basis) is defined by two methods.

**METHOD 1**

Theoretical air (stoichiometric air) ( $A_t$ ) = (actual air entering process ( $A_a$ ))/(theoretical air ( $A_t$ ))

$$\%A_t = (A_a/A_t)(100) \quad (2.14)$$

FIGURE 2.8 Excess air combustion (EPA-89/03).

Excess air ( $A_e$ ) = (actual air entering process ( $A_a$ ) – theoretical air ( $A_t$ ))/(theoretical air ( $A_t$ ))

$$\%A_e = [(A_a - A_t)/A_t](100) \quad (2.15)$$

where

- $A_a$  = moles of actual air used in the combustion process
- $A_t$  = moles of theoretical air (stoichiometric air) used at 100% of stoichiometric combustion
- $\%A_t$  = theoretical air
- $\%A_e$  = excess air

#### METHOD 2

For example, for the combustion of methane,  $\text{CH}_4$ :

where

- $e$  = the number of moles of excess  $\text{O}_2$  in the excess air

*Calculations of reactants and products from excess air combustion.* Tables 2.7 and 2.8 were derived from the tables in Section 2.6. The basic steps needed to calculate the quantities of reactants and products are provided. The method can also be used to calculate the reactants and products of theoretical air combustion.

The basic steps needed to perform the calculation of combustion products are provided in Table 2.8, where the mole is the mass divided by its corresponding molecular weight.

**TABLE 2.7** Combustion Reactant Table

Basic reaction	Oxygen, nitrogen, and air requirements
$\text{C} + \text{O}_2 \rightarrow \text{CO}_2$	(1) $\text{O}_2 = \text{C}(32/12)$
$\text{H}_2 + 0.5\text{O}_2 \rightarrow \text{H}_2\text{O}$	(2) $\text{O}_2 = 8(\text{H}-\text{Cl}/35.5)^*$
$\text{S} + \text{O}_2 \rightarrow \text{SO}_2$	(3) $\text{O}_2 = \text{S}(32/32) = \text{S}$
$B_o$ = bound oxygen	(4) Data from waste analysis
$\text{O}_{2t}$ = theoretical $\text{O}_2$	$\text{O}_{2t} = (1) + (2) + (3) - (4)$
$\text{N}_{2t}$ = theoretical $\text{N}_2$	$\text{N}_{2t} = (\text{O}_{2t})(3.76 \times 28/32) = 3.29\text{O}_{2t}$
$A_t$ = theoretical air	$A_t = \text{O}_{2t} + \text{N}_{2t}$
$\%A_e$ = % excess air	Given data
$A_e$ = excess air	$A_e = (\%A_e)(A_t)$
$A_{\text{ada}}$ = actual dry air	$A_{\text{ada}} = A_t + A_e$
$\text{H}_2\text{O}$ from air†	$0.0127(A_{\text{ada}})$
$A_a$ = actual air	$A_a = A_{\text{ada}} + \text{H}_2\text{O}$
Waste feed	Data from waste analysis
$R_a$ = actual reactants	$R_a = A_a + \text{waste feed} + \text{H}_2\text{O}$ from air

\* If  $\text{H}_2$  is the hydrogen left over after Cl reaction, i.e.,  $\text{H}_2 = \text{H}-\text{Cl}/35.5$ , the  $\text{O}_2$  needed to react with  $\text{H}_2$  will be equal to  $\text{H}_2(0.5)(32/2) = 8(\text{H}-\text{Cl}/35.5)$ .

† In general, at room temperature, the humidity ratio is  $0.0127$  (lb- $\text{H}_2\text{O}$ )/(lb-dry-air) or  $0.0127$  (kg- $\text{H}_2\text{O}$ )/(kg-dry-air).

**TABLE 2.8** Combustion Product Table

Component	Combustion product
CO <sub>2</sub>	CO <sub>2</sub> = (C)(44/12)
SO <sub>2</sub>	SO <sub>2</sub> = S(64/32)
HCl	HCl = Cl(36.5/35.5)
O <sub>2e</sub>	(%A <sub>e</sub> )O <sub>2t</sub> , O <sub>2t</sub> from Table 2.7
N <sub>2e</sub>	(%A <sub>e</sub> )N <sub>2t</sub> , N <sub>2t</sub> from Table 2.7
N <sub>2</sub>	N <sub>2e</sub> + N <sub>2t</sub> + from waste
H <sub>2</sub> O from comb.	H <sub>2</sub> O from combustion = 9(H-Cl/35.5)
H <sub>2</sub> O	H <sub>2</sub> O from combustion + from air + from waste
G <sub>a</sub> = actual flue gas	G <sub>a</sub> = CO <sub>2</sub> + SO <sub>2</sub> + HCl + O <sub>2e</sub> + N <sub>2</sub> + H <sub>2</sub> O
Ash	Fly ash + bottom ash
P <sub>a</sub> = actual product*	G <sub>a</sub> + ash

\* In performing the mass balance calculation, the values of reactants ( $R_a$ ) and products ( $P_a$ ) should be equal, i.e., if  $R_a = P_a$ , the mass balance calculation is correct.

**EXAMPLE 1** excess air combustion

Consider the following combustion cases:

	<u>Case</u>
CH <sub>4</sub> + (2)O <sub>2</sub>	1
CH <sub>4</sub> + (3)O <sub>2</sub>	2
CH <sub>4</sub> + (4)O <sub>2</sub>	3

Determine the percent theoretical air and percent excess air for these combustion cases.

*Solution:*

1. Complete the balance of chemical equations.

The above equations can also be expressed as

2. Apply Eq. (2.14), %A<sub>t</sub> = (A<sub>a</sub>/A<sub>t</sub>)(100).

- %A<sub>t</sub> for case (1) = 2/2 = 100% theoretical air
- %A<sub>t</sub> for case (2) = 3/2 = 150% theoretical air
- %A<sub>t</sub> for case (3) = 4/2 = 200% theoretical air

The above cases can further be expressed as

3. Apply Eq. (2.15) to Eqs. (2.23)–(2.25).

$$\%A_c = ((A_a - A_t)/A_t)(100)$$

$$\text{Eq. (2.23): "e" } = (2 - 2)/2 = 0\% \text{ excess air}$$

$$\text{Eq. (2.24): "e" } = (3 - 2)/2 = 50\% \text{ excess air}$$

$$\text{Eq. (2.25): "e" } = (4 - 2)/2 = 100\% \text{ excess air}$$

4. In summary, apply Eqs. (2.14)–(2.15) to each case.

$$\%A_t = 2/2 = 1 = 100\%$$

$$\%A_c = (2 - 2)/2 = 0$$

$$\%A_t = 3/2 = 1.5 \text{ or } 150\%$$

$$\%A_c = (3 - 2)/2 = 0.5 \text{ or } 50\%$$

$$\%A_c \text{ can also be expressed by } 2(1 + e) = 3, e = 0.5 \text{ or } 50\%$$

$$\%A_t = 4/2 = 2 \text{ or } 200\%$$

$$\%A_c = (4 - 2)/2 = 1 \text{ or } 100\%$$

$$\%A_c \text{ can also be expressed by } 2(1 + e) = 4, e = 1 \text{ or } 100\%$$

**EXAMPLE 2** excess air combustion

Consider the following combustion cases:

Determine the theoretical air, excess air, and actual combustion air.

*Solution:*

1. Write the chemical balance equations.

2. Determine theoretical combustion air  $A_t$ .

Equation (2.26) is a theoretical combustion. The air needed for this combustion is the theoretical combustion air  $A_t$ .

$$\begin{aligned} A_t &= 2 + 2(3.76) \\ &= 9.52 \text{ mole, or} \end{aligned}$$

$$\begin{aligned} A_t &= 2(32) + 2(3.76)(28) \\ &= 64 + 210.56 \\ &= 274.56 \text{ lb} \end{aligned}$$

3. Determine the excess combustion air  $A_e$ .

For Eq. (2.26),  $A_e = 0$

Equation (2.27) is an excess air combustion. The % excess air, %  $A_e$ , is

$$\begin{aligned}\%A_e &= (A_a - A_t)/A_t \\ &= (3 - 2)/2 \\ &= 50\%\end{aligned}$$

$$\begin{aligned}A_e &= \%A_e(A_t) \\ &= 0.5(9.52) \\ &= 4.76 \text{ mole, or}\end{aligned}$$

$$\begin{aligned}A_e &= 0.50(274.56) \\ &= 137.28 \text{ lb}\end{aligned}$$

4. Determine actual combustion air  $A_a$ .

For Eq. (2.26), actual combustion air is equal to its theoretical combustion air. Hence,  $A_a = A_t$ .

For Eq. (2.27), actual combustion air is

$$\begin{aligned}A_a &= A_t + A_e \\ &= 9.52 + 4.76 \\ &= 14.28 \text{ mole, or}\end{aligned}$$

$$\begin{aligned}A_a &= 274.56 + 137.28 \\ &= 411.84 \text{ lb}\end{aligned}$$

**EXAMPLE 3** more excess air combustion

Consider propane gas ( $C_3H_8$ ) combustion at different levels of air supply.

At 100% theoretical air or 0% excess air combustion,

At 80% theoretical air or 20% deficient air combustion,

At 150% theoretical air or 50% excess air combustion,

Consequently, 150% of theoretical air is equivalent to 50% excess air. The above reactions show that at 100%  $A_t$  (theoretical air) of propane ( $C_3H_8$ ) combustion, the reaction is a complete combustion, and at both 80% and 150%  $A_t$ , the reactions are an incomplete combustion which results in compounds other than  $H_2O$ ,  $CO_2$  and  $N_2$  in their products.

## 2.7 Combustion Components and Incineration Components

### *Combustion process*

Fundamentally, for a combustion system, there are four major combustion components. They are:

- (1) fuel
- (2) oxidizer
- (3) heat
- (4) diluent

### *Incineration process*

For an incineration system, there are five major components. They are:

- (1) fuel
- (2) oxidizer
- (3) heat
- (4) diluent
- (5) organic material

### *Description*

**FUEL:** A fuel is a mixture of hydrocarbons containing energy-rich bonds such as the carbon-carbon and carbon-hydrogen bonds. These hydrocarbons are a common source of chemical potential energy. Some important families of hydrocarbons are summarized in Table 2.9. During combustion, fuels are oxidized and their chemical potential energy is transformed into thermal energy. Relative to their chemical structures, fuels can be composed of the following items.

1. Unsaturated hydrocarbons. Unsaturated hydrocarbons are those compounds which have two or more adjacent carbon atoms joined by a double or triple bond. For example, the molecular structure of  $\text{H}-\text{C}=\text{C}-\text{H}$  is an unsaturated hydrocarbon.
2. Saturated hydrocarbons. Saturated hydrocarbons are those compounds whose carbon atoms are each joined by a single bond. For example, the molecular structure of  $\text{H}-\text{C}-\text{C}-\text{H}$  is a saturated hydrocarbon.
3. Isomers. Two hydrocarbons with the same number of carbon and hydrogen atoms but different structures are called isomers. For example, there are several different octanes, the  $\text{C}_8\text{H}_{18}$  series, each having 8 carbon atoms and 18 hydrogen atoms, but each has a different structure; these different structures are called the isomers of octane.

**TABLE 2.9** Characteristics of Some of the Hydrocarbon Families

Family	Formula	Structure	Saturated?
Paraffin	$\text{C}_n\text{H}_{2n+2}$	Chain	Yes
Olefin	$\text{C}_n\text{H}_{2n}$	Chain	No
Diolefin	$\text{C}_n\text{H}_{2n-2}$	Chain	No
Naphthene	$\text{C}_n\text{H}_{2n}$	Ring	Yes
Aromatic benzene	$\text{C}_n\text{H}_{2n-6}$	Ring	No
Aromatic naphthalene	$\text{C}_n\text{H}_{2n-12}$	Ring	No

**OXIDIZER:** An oxidizer is the chemical species that reacts with the fuel or waste compounds during incineration. Its function is to transform the chemical potential energy stored in the fuel into thermal energy or to convert heavy-molecule waste compounds into light, simple compounds such as  $\text{CO}_2$ ,  $\text{H}_2\text{O}$  and  $\text{HCl}$ . Most commonly, the oxidizer is molecular oxygen, a constituent of air.

The oxygen needed for the combustion reaction is supplied by the ambient combustion air. Combustion air is supplied to the combustion chambers through air ports by a forced draft fan, by an induced draft fan, or by natural draft. In general, this air contains about 21 percent oxygen ( $\text{O}_2$ ) and 79 percent nitrogen ( $\text{N}_2$ ), so about 21 percent of the total combustion air fed to the incinerator is oxygen that is available to react with the organic material in the waste and fuel.

The combustion reaction between the organic material and oxygen that causes the organics to burn occurs only after the temperature of the organic material is raised to the point that combustion can begin. Each specific organic compound has its own temperature at which the reaction occurs, but temperatures in the range of 1000 to 1800°F generally are considered to provide “good combustion conditions.” Energy in the form of heat is required to raise the temperatures of the incinerator chamber and organic material and  $\text{O}_2$ . Initially this energy usually is supplied by the pilot and auxiliary fuel burners. After the system is in full operation, the energy released from the burning waste is often sufficient to maintain these high temperatures.

**HEAT:** Heat provides the elevated temperatures needed to start and to maintain incineration.

**DILUENT:** A diluent is a substance that does not participate chemically in the combustion reaction either as a fuel substance or as an oxidizer. It is physically present and often does influence the combustion process. For example, diluents have heat capacity, and while they do not make a positive contribution to the total energy released, they do act as a thermal sink and limit the temperature rise achieved by combustion. A diluent can be thought of as a substance that participates principally in the physical aspects of the combustion process. There are several possible diluents in an incineration system, and some are listed below.

- Nitrogen. Nitrogen, which comprises almost 79% of air, is the most common diluent.
- Excess amount of oxygen. Incineration normally takes place at about 150–200% of the amount of theoretical air needed for combustion. The excess oxygen (the amount over 100% of theoretical air) will act as a diluent. That is, its participation in the combustion process will be physical but not chemical.
- Water contents. Water contained either in combustion air or in the waste feed (or, for that matter, the amount formed during the incineration process).
- Inorganic ash compounds. Inorganic ash compounds such as trace heavy metals present in the waste or in the fuel. The waste feed generally includes inorganic materials which are not involved in the combustion reaction. The inorganic materials in the waste feed are either retained in the ash or are emitted as particulate matter in the combustion gas. Air velocities in the combustion bed are controlled to reduce the amount of inorganic material entrained (picked up) by the combustion gas and emitted with the effluent gas.

**ORGANIC MATERIAL:** The waste streams that are incinerable include hazardous waste, municipal waste, toxic substances (PCB), medical waste, spent pesticides, sludges from both municipal and industrial wastewater treatment processes, and other unclassified waste such as nonhazardous military waste. The organic material used in the reaction comes from two sources, waste and auxiliary fuel. Some organic material is contained in most medical waste. Depending on the fraction of organics and the specific organic composition, the waste may be adequate to sustain combustion. The other source of organic material is auxiliary fuel. Auxiliary fuel is always used to preheat the incinerator and to start combustion;

auxiliary fuel may be used to maintain combustion if the waste material does not contain enough organic material to maintain high temperatures.

In general, solid waste contains two types of organic materials. They are:

- volatile matter
- fixed carbon

These two types of materials are involved in distinct types of combustion reactions, and the operating variables that control the two types of reaction are different.

**VOLATILE MATTER:** Volatile matter is the portion of the waste that is vaporized (or evaporated) when the waste is heated. Combustion occurs after the material becomes a gas. The combustion variables that influence this reaction are gas temperature, residence time, and mixing. A minimum temperature is needed to start and sustain the chemical reaction. Residence time is the length of time, generally measured in seconds, that the combustion gas spends in the high temperature combustion chamber. The residence time must be long enough for the reaction to be completed before it leaves the high temperature zone. Turbulent mixing of the volatile matter and combustion air is required to ensure that the organic material and oxygen are well mixed.

**FIXED CARBON:** Fixed carbon is the nonvolatile organic portion of the waste. For fixed carbon, the combustion reaction is a solid-phase reaction that occurs primarily in the waste bed (although some materials may burn in suspension). Key operating parameters are bed temperature, solids retention time, and mechanical turbulence in the bed. The solids retention time is the length of time that the waste bed remains in the primary chamber. Mechanical turbulence of the bed is needed to expose all the solid waste to oxygen for complete burnout. Without mechanical turbulence, the ash liberated during combustion can cover the unburned waste and prevent the oxygen necessary for combustion from contacting the waste.

## 2.8 Combustion Constants

The American Gas Association (AGA) constructed a table which was included on page 2-14 of reference EPA-80/02. The table contains various constants of basic combustion. Examples of the constants include the amount of theoretical air and the amount of 150% excess air needed for the combustion of one mole or one pound of methane. The following two calculations show how some of the constants are obtained. Case 1 is for theoretical combustion and case 2 for 150% theoretical air combustion. It is understood that 150% of theoretical combustion air is equivalent to 50% excess air.

### *Combustion constants: theoretical air combustion*

(1) Molar analysis (mole/mole-CH<sub>4</sub>)

CH<sub>4</sub> = 1; O<sub>2</sub> = 2; N<sub>2</sub> = 7.52; CO<sub>2</sub> = 1; H<sub>2</sub>O = 2; N<sub>2</sub> = 7.52; Air = 9.52

(2) Mass analysis (lb/lb-CH<sub>4</sub>)

$\text{CH}_4 = 1$ ;  $\text{O}_2 = 4$ ;  $\text{N}_2 = 13.16$ ;  $\text{CO}_2 = 2.75$ ;  $\text{H}_2\text{O} = 2.25$ ;  $\text{N}_2 = 13.16$ ;  $\text{Air} = 17.16$

**Combustion constants: excess air combustion**

Write the chemical balance equation with 150% theoretical combustion air.

(1) Molar analysis (mole/mole- $\text{CH}_4$ )

$\text{CH}_4 = 1$ ;  $\text{O}_2 = 3$ ;  $\text{N}_2 = 11.28$ ;  $\text{CO}_2 = 1$ ;  $\text{H}_2\text{O} = 2$ ;  $\text{N}_2 = 11.28$ ;  $\text{Residual O}_2 = 1$ ;  $\text{Air} = 14.28$

(2) Mass analysis (lb/lb- $\text{CH}_4$ )

$\text{CH}_4 = 1$ ;  $\text{O}_2 = 6$ ;  $\text{N}_2 = 19.74$ ;  $\text{CO}_2 = 2.75$ ;  $\text{H}_2\text{O} = 2.25$ ;  $\text{N}_2 = 19.74$ ;  $\text{Residual O}_2 = 2$ ;  $\text{Air} = 25.74$

The same approach can be used to calculate the data from the combustion of the following compounds:

Paraffin series

- ethane,  $\text{C}_2\text{H}_6$
- propane,  $\text{C}_3\text{H}_8$
- *n*-butane,  $\text{C}_4\text{H}_{10}$
- isobutane,  $\text{C}_4\text{H}_{10}$
- *n*-pentane,  $\text{C}_5\text{H}_{12}$
- isopentane,  $\text{C}_5\text{H}_{12}$
- neopentane,  $\text{C}_5\text{H}_{12}$
- *n*-hexane,  $\text{C}_6\text{H}_{14}$

Olefin series

- ethylene,  $\text{C}_2\text{H}_4$
- propylene,  $\text{C}_3\text{H}_6$
- *n*-butene,  $\text{C}_4\text{H}_8$
- isobutene,  $\text{C}_4\text{H}_8$
- *n*-pentene,  $\text{C}_5\text{H}_{10}$

Aromatic series

- benzene,  $\text{C}_6\text{H}_6$
- toluene,  $\text{C}_7\text{H}_8$
- xylene,  $\text{C}_8\text{H}_{10}$

## 2.9 Combustion Correction Factor

For comparison purposes, it is sometimes necessary to correct a measured value of a compound's concentration at the stack to a certain desired concentration. The way to make such a correction follows.

The correction factor (CF) for oxygen is defined as

$$CF = (21 - \text{desired } O_2) / (21 - \text{measured } O_2)$$

### EXAMPLE 1 combustion correction factor

Consider the following combustion cases:

Equation (2.28) depicts combustion at 0% excess air, and Eq. (2.29) shows 150% of theoretical air combustion.

Determine how  $CO_2$  measured at 150% of theoretical air combustion (50% excess air) is converted to 0% excess air combustion.

*Solution:*

$O_2$  measured at the wet condition (with  $H_2O$ ) of Eq. (2.29) =  $1 / (1 + 2 + 1 + 11.28) = 6.5\%$ .

$O_2$  measured at the dry condition (without  $H_2O$ ) of Eq. (2.29) =  $1 / (1 + 1 + 11.28) = 7.5\%$ .

To correct the measured (dry)  $O_2$  value to a desired level (0%  $O_2$  in products):

$$\begin{aligned} CF &= (21 - 0) / (21 - 7.5) \\ &= 1.55 \end{aligned}$$

$CO_2$  measured at the dry condition of Eq. (2.29) =  $1 / (1 + 1 + 11.28) = 7.5\%$

To correct the measured  $CO_2$  to a desired  $O_2$  level of 0% excess air (i.e., at the theoretical air condition):

$$C = CF \times C_m$$

where  $C$  = corrected parameter value at the desired  $O_2$  level  
 $C_m$  = measured parameters such as  $CO$  or  $CO_2$  which are required to be corrected to a desired  $O_2$  level

For this example,

$$\begin{aligned} CO_2 \text{ (at 0\% } O_2 \text{ level)} &= CF \times (CO_2)_m \\ &= 1.55 \times 7.5\% \\ &= 11.625\% \end{aligned}$$

This number can be checked with the dry  $CO_2$  level from the theoretical air combustion of  $CH_4$  from Eq. (2.28). That is,

$$CO_2 = 1 / (1 + 7.52) = 11.73\%$$

The discrepancy between the 11.625% and 11.73% values is probably due to rounding off certain values; in any case, the values are very close.

**EXAMPLE 2** combustion correction factor

This example is to show the conversion between two correction factors. Assume that CO concentration at 7% O<sub>2</sub> is 150 ppm. Determine CO concentration at 10% O<sub>2</sub> level.

*Solution:*

CO concentration at 7% O<sub>2</sub> is

$$(\text{CO})_7 = ((21 - 7)/(21 - O_m))(\text{CO})_m \quad (2.30)$$

where subscript m refers to the measured value.

CO concentration at 10% O<sub>2</sub> is

$$(\text{CO})_{10} = ((21 - 10)/(21 - O_m))(\text{CO})_m \quad (2.31)$$

From the ratio of these two equations:

$$\begin{aligned} (\text{CO})_{10} &= (11/14) \times (\text{CO})_7 \\ &= 0.7857(150) \\ &= 117.86 \text{ ppm} \end{aligned}$$

**EXAMPLE 3** combustion correction factor

Consider the following two equations. Equation (2.32) is a theoretical air combustion of carbon tetrachloride (CCl<sub>4</sub>) with methane (CH<sub>4</sub>), and Eq. (2.33) is a 150% of theoretical air combustion of the same carbon tetrachloride with methane.

Determine:

1. Correction factor
2. Corrected CO<sub>2</sub> value
3. Prove that the corrected CO<sub>2</sub> value under 150% theoretical air combustion in Eq. (2.33) is equal to the CO<sub>2</sub> molar fraction in Eq. (2.32) for a theoretical air combustion

*Solution for question (1)*

- 1.1. Determine O<sub>2</sub> molar fraction ((O<sub>2</sub>)<sub>m</sub>) in Eq. (2.33)

$$\begin{aligned} (\text{O}_2)_m &= 1/(2 + 4 + 1 + 11.28) \\ &= 0.0547 \end{aligned}$$

- 1.2. Calculate correction factor (CF)

CF for correcting the measured O<sub>2</sub> in Eq. (2.33) to a 0% excess air is

$$\begin{aligned} \text{CF} &= (0.21 - 0)/(0.21 - 0.0547) \\ &= 1.35 \end{aligned}$$

*Solution for question (2)*

2.1. Determine CO<sub>2</sub> molar fraction ((CO<sub>2</sub>)<sub>m</sub>) in Eq. (2.33)

$$\begin{aligned}(\text{CO}_2)_m &= 2/(2 + 4 + 1 + 11.28) \\ &= 0.11\end{aligned}$$

2.2. Calculate the corrected CO<sub>2</sub>

$$\begin{aligned}\text{CO}_2 \text{ (at 0\% O}_2 \text{ level)} &= \text{CF} \times (\text{CO}_2)_m \\ &= 1.35 \times 0.11 \\ &= 0.15\end{aligned}\tag{2.34}$$

*Solution for question (3)*

3.1. Determine CO<sub>2</sub> molar fraction ((CO<sub>2</sub>)<sub>m</sub>) in Eq. (2.32)

$$\begin{aligned}(\text{CO}_2)_m &= 2/(2 + 4 + 7.52) \\ &= 0.15\end{aligned}\tag{2.35}$$

The results in Eqs. (2.34) and (2.35) are identical. This means that the corrected CO<sub>2</sub> value under 50% excess air combustion in Eq. (2.33) is equal to the CO<sub>2</sub> molar fraction in Eq. (2.32) for a theoretical air combustion.

## 2.10 Combustion Efficiency

### *Definition*

In fossil fuel combustion or solid waste incineration, carbon monoxide (CO) represents one of the most stable products of incomplete combustion. It is therefore used to indicate the extent of incomplete combustion in the combustion system. Combustion efficiency (CE) is defined as

$$\text{CE} = \text{CO}_2/(\text{CO}_2 + \text{CO})$$

where CO<sub>2</sub> = carbon dioxide  
CO = carbon monoxide

Equation (2.32) shows that if CO = 0, the combustion efficiency would be equal to 100% combustion. Thus, the less CO that is produced, the better the combustion efficiency is. In general, the concentration of CO and CO<sub>2</sub> is obtained from a continuous emission monitor (CEM). The concentration often has a unit of “parts per million by volume, or ppm by weight.”

### **EXAMPLE** combustion efficiency

Consider that propane gas (C<sub>3</sub>H<sub>8</sub>) is under combustion at 80% theoretical air, or 20% deficient air supply.

Determine the combustion efficiency

*Solution 1: By the volume of product species*

Because the volume of product species is proportional to the coefficient of each species in the chemical reaction equation, the combustion efficiency of the propane gas can be expressed as

$$\begin{aligned}
 \text{CE} &= (\text{coefficient of CO}_2)/(\text{coefficient of CO}_2 + \text{coefficient of CO}) \\
 &= 1/(1 + 2) \\
 &= 33\% \text{ (by volume)}
 \end{aligned}$$

*Solution 2: By the mass of product species*

If the mass of product species is used to calculate combustion efficiency, CE can be expressed as

$$\begin{aligned}
 \text{CE} &= (\text{mass of CO}_2)/(\text{mass of CO}_2 + \text{mass of CO}) \\
 &= (12 + 32)/((12 + 32) + 2(12 + 16)) \\
 &= 44/(44 + 56) \\
 &= 44/100 \\
 &= 44\% \text{ (by mass)}
 \end{aligned}$$

### ***Factors affecting combustion performance***

The factors that may affect the combustion performance include:

- combustion air
- combustion temperature
- waste characteristics

**COMBUSTION AIR:** Combustion air is usually the ambient air associated with the oxygen needed for burning a fuel or waste materials. The two key questions about combustion air are: (1) How much combustion air is needed to sustain the combustion reaction? and (2) What happens if there is too much or too little combustion air?

Ambient air is a typical source of oxygen for combustion, and is considered as an ideal gas in many incineration calculations. It is, of course, a mixture of oxygen, nitrogen, and small amounts of water vapor, carbon dioxide, argon, and other elements. For the purposes of combustion calculations, the last four items are usually included with the nitrogen.

In a chemical reaction between organic materials and oxygen, the amount of oxygen required under ideal or “perfect” conditions to burn all of the organic materials into CO<sub>2</sub> and H<sub>2</sub>O with no oxygen left over is called the *stoichiometric* (or *theoretical*) *oxygen level* and the process is called *complete combustion*. The amount of combustion air associated with that oxygen level is called the stoichiometric air level. Air flows greater than those required at stoichiometric levels are called the *excess air levels*, and airflows less than those required at stoichiometric levels are called the *deficient air* or *substoichiometric starved air levels*. Typically, an incinerator operates with an overall 150–200 percent of the stoichiometric air level. That is, the incinerator operates with about 1.5-2 times more air than is required at stoichiometric levels. Excess air is used to assure that enough oxygen is available for complete combustion.

Computation of exact stoichiometric air requirements for a waste incinerator is difficult because it depends on the chemical composition of the waste and fuel. However, stoichiometric air requirements can be estimated on the basis of the energy input (or heat input) to the incinerator. Heat input is a measure of the energy released when the waste and fuel are burned. It is measured in British thermal units (Btu’s). Generally about 1 standard cubic foot of combustion air is required per 100 Btu’s of heat input to the incinerator.

Maximum combustion temperatures are always attained at stoichiometric conditions. As the amount of excess air is increased above the stoichiometric point, the temperature in the incinerator drops because energy is used to heat the extra combustion air. If the amount of combustion air is too great, the temperature can drop below “good combustion temperature,” and undesirable combustion products are generated as a result of incomplete combustion. As

the amount of excess air is decreased, the combustion temperature increases until it becomes maximum at the stoichiometric point. Below the stoichiometric point, the temperature decreases because complete combustion has not occurred. A graphical representation of the relationship between combustion temperature and excess air level is shown in Fig. 2.9 (EPA-89/03). At air levels below the stoichiometric point, some of the organic compounds are not reacted, and pollutants are emitted as a result of incomplete combustion.

**COMBUSTION TEMPERATURE:** Temperature plays an important role in the combustion of solid waste. Temperatures should be maintained at the level specified by combustor manufacturers to sustain the combustion reaction. However, temperatures that are too high may cause problems. Continuous operation at high temperatures is generally not desirable because it can cause the ash to fuse and cause thermal damage to the refractory.

**WASTE CHARACTERISTICS:** The primary characteristics of the waste that affects the combustion reaction are:

- heating value
- chlorine content
- ultimate composition
- moisture content

#### (1) Heating value

The heating value of a waste is a measure of the energy released when the waste is incinerated. It is measured in units of Btu/lb (1 Btu/lb = 2.324 J/g). In general, a heating value of about 5000 Btu/lb (11,620 J/g) or greater is needed to sustain combustion. Wastes with lower heating values can be burned, but they will not maintain adequate temperature without the addition of auxiliary fuel. The heating value of the waste is needed to calculate total heat input to the incinerator, where

$$\text{Heat input (Btu/h)} = \text{Feed rate (lb/h)} \times \text{Heating value (Btu/lb)}$$

The heating value of waste varies from nearly zero for some pathological wastes and other materials with very high moisture contents to around 15,000 Btu/lb (35,000 J/g) for plastic packaging materials.

**High heating value (HHV)**

HHV is the heating value produced from the combustion of a waste under the condition that the water vapor in the combustion gas has condensed into the liquid state. Any fuel containing hydrogen yields water as one product of combustion. At atmospheric pressure, the partial pressure of the water vapor in the resulting combustion gas mixture is usually sufficiently high to cause water to condense out if the temperature of the exhaust gas is allowed to fall below 120–140°F. This causes liberation of the heat of vaporization of any water condensed. Thus, HHV is the heat transfer with liquid water in the products. HHV is also referred to as higher heating value or gross heating value. It is usually expressed as Btu/lb fuel or Btu/scf fuel (Lee-89/09).

**Low heating value (LHV)**

Similar to HHV, LHV is the heating value produced from the combustion of a waste under the condition that the water vapor in the combustion gas is not condensed into the liquid state. It is also referred to as the lower heating value or net heating value (Lee-89/09).

**(2) Chlorine content**

Most chlorine in plastics or solvents in the waste feed react with hydrogen during incineration to form hydrochloric acid (HCl), which mostly requires a downstream scrubbing system to remove it. This HCl is an emission problem which can create corrosion problems downstream from the incinerator.

**(3) Ultimate composition**

The ultimate composition of a compound is the chemical elements in the compound such as C, O, H, Cl, S, etc. The ultimate composition provides information relative to (1) the quantity of combustion air needed during incineration, and (2) the quantity of ash to be produced after incineration.

**(4) Moisture content**

Moisture is evaporated from the waste as the temperature of the waste is raised in the combustion chamber; it passes through the incinerator, unchanged, as water vapor. This evaporation of moisture uses energy and reduces the temperature in the combustion chamber. The water vapor also increases the combustion gas flow rate, which reduces combustion gas residence time.

**2.11 Combustion of Chlorinated Compounds**

Compounds containing carbon and chlorine rather than hydrogen require a source of hydrogen in order to attain complete destruction (hydrogen is used to react with chlorine for chemical balance). For example, methane gas (CH<sub>4</sub>) can be used to completely destroy (incinerate) carbon tetrachloride (CCl<sub>4</sub>) in an incinerator.

Consider the combustion of a mixture of methane and carbon tetrachloride in air. The balanced chemical reaction for the combustion is

The result shows that 1 lb CCl<sub>4</sub> requires 0.1 lb CH<sub>4</sub>, and 1.78 lb air for complete combustion. In other words, one mole of methane reacts with one mole of carbon tetrachloride and two moles of oxygen to form two moles of carbon dioxide and four moles of HCl. The nitrogen does not participate in the main combustion reaction. It is carried along with the oxygen. The coefficient 7.52 for nitrogen is obtained by multiplying the number of moles of oxygen participating in the chemical reaction by the volumetric ratio of nitrogen and oxygen in air (79/21).

Under standard temperature and pressure (STP) conditions ( $^{\circ}\text{C}$  and 1 atm), 1 lb-mole occupies a standard volume of  $359\text{ ft}^3$  and 1 g-mole  $0.0224\text{ m}^3$ .

- The combustion requires 2 moles of air. If the calculations are performed in lb-moles, the combustion will require  $2(359) = 718$  scf (standard cubic feet).
- The combustion produces  $(2 + 4 + 7.52) = 13.52$  moles of flue gas. If the calculations are performed in lb-moles, the combustor will produce  $13.52(359) = 4854$  scf of flue gas.
- If the calculation were performed in metric units and the equations were read as g-moles, the 13.52 g-moles of flue gas would occupy  $0.303\text{ m}^3$  at STP.

The air volume can also be computed by applying the ideal gas law. For this example, the above equation shows that 2 moles of air are needed for the complete incineration of  $\text{CCl}_4$ .

Assume that the standard conditions are  $P = 1$  atm and  $T = 32^{\circ}\text{F}$ ; the volume of air can be obtained by applying the ideal gas equation:

$$PV = nR_u T$$

where  $P =$  pressure  
 $V =$  volume  
 $n =$  moles  
 $R_u =$  universal gas constant  
 $T =$  absolute temperature

$$\begin{aligned} V &= nR_u T / P \\ &= 2(1544)(32 + 460) / [14.6959(144)] \\ &= 718 \text{ scf (standard cubic feet)} \end{aligned}$$

The air volume (718 scf) that was calculated from the ideal gas equation and the air volume (718 scf) that was calculated from the standard volume are identical.

Mass balances on more complex systems are performed in the same way. No matter how complex the system is, the calculations can be based on the elemental feed rates of the streams.

In this example, chlorine consumes the hydrogen preventing its reaction with oxygen to form water. The thermodynamics of HCl formation will always result in chlorine consuming the hydrogen to form HCl before any of the hydrogen forms water. In addition, the only time that more than trace quantities of chlorine gas ( $\text{Cl}_2$ ) will be formed is when insufficient hydrogen of any form is present in the combustion chamber—a virtual impossibility in an actual combustor.

## 2.12 More Examples of Basic Combustion

### EXAMPLE 1 basic combustion

Propane ( $\text{C}_3\text{H}_8$ ) is burned with 100 percent theoretical air. Calculate:

- (1) air/fuel ratio
- (2) molar analysis of the products of combustion
- (3) dew point of the products for a total pressure of 14.696 psia
- (4) volume of air required to burn gaseous propane to completion, if the ambient air temperature is  $80^{\circ}\text{F}$
- (5) volume of air per pound of fuel on the basis of per pound of fuel
- (6) volume of air per pound of fuel on the basis of per mole of fuel

**Given conditions**

The data in question are:

- fuel: propane
- total pressure: 14.696 psia
- temperature: 80°F

*Solution:*

*Solution for question (1)*

1.1. Write the theoretical air combustion equation.

1.2. Write the equation for mass calculation.

$$m = nM$$

where  $m$  = mass  
 $n$  = number of moles  
 $M$  = molecular weight

1.3. Calculate air mass ( $m_a$ ) and fuel mass ( $m_f$ ).

$$m_f = 1(44) = 44$$

$$m_a = 5(32 + (3.76)(28)) = 686.4$$

1.4. Calculate the air/fuel ratio (mass base).

$$\text{AF} = 686.4/44 = 15.6$$

1.5. Calculate the air/fuel ratio (mole base).

$$\text{AF} = 5/1 = 5$$

*Solution for question (2)*

2.1. Calculate the total number of moles of products.

$$\begin{aligned} n &= 3 + 4 + 5(3.76) \\ &= 25.8 \text{ mole/(mole-fuel)} \end{aligned}$$

2.2. Calculate the mole fraction of product components.

$$y(\text{CO}_2) = 3/25.8 = 0.1163$$

$$y(\text{H}_2\text{O}) = 4/25.8 = 0.1550$$

$$y(\text{N}_2) = (5)(3.76)/25.8 = 0.7287$$

The sum of  $y$  values = 1.

*Solution for question (3)*

3.1. Write the partial pressure equation for  $\text{H}_2\text{O}$ .

$$\begin{aligned} p(\text{H}_2\text{O}) &= y(\text{H}_2\text{O})p(\text{total}) \\ &= (0.1550)(14.696) \\ &= 2.28 \text{ psia} \end{aligned}$$

3.2. Find the saturation temperature (from a steam table).

- The temperature corresponding to 2.28 psia is the dew point temperature, which is roughly 138°F. Thus moisture would condense if the products were cooled below 138°F.
- This explains, of course, why water drips from the tailpipe of an automobile on a cold morning before the exhaust system has warmed up.

*Solution for question (4)*

4.1. Write the ideal gas equation.

$$\begin{aligned} V &= nR_u T/p \\ &= (m/M)R_u T/p \\ v &= V/m \\ &= R_u T/(pM) \end{aligned}$$

4.2. Calculate the specific volume of air.

$$\begin{aligned} v &= (1544)(460 + 80)/((14.696)(144)(29)) \\ &= 13.59 \text{ ft}^3/(\text{lb-air}) \end{aligned}$$

*Solution for question (5)*

Because the air/fuel ratio (mass basis) is 15.6, the volume of air required per pound of fuel is

$$\begin{aligned} V &= (13.59)(15.6) \\ &= (212.00 \text{ ft}^3/(\text{lb-fuel})) \end{aligned}$$

*Solution for question (6)*

$$\begin{aligned} V &= (212.00)(\text{ft}^3/(\text{lb-fuel}))(44)(\text{lb-fuel})/(\text{mole-fuel}) \\ &= 9328 \text{ ft}^3/(\text{mole-fuel}) \end{aligned}$$

### EXAMPLE 2 basic combustion

Propane ( $\text{C}_3\text{H}_8$ ) is burned with 150 percent theoretical air. Calculate:

- (1) the air/fuel ratio
- (2) molal analysis of the products of combustion
- (3) the dew point of the products for a total pressure of 14.696 psia
- (4) the volume of air required to burn gaseous propane to completion, if the ambient air temperature is 80°F
- (5) volume of air per pound of fuel on the basis of per pound of fuel
- (6) volume of air per pound of fuel on the basis of per mole of fuel

#### Given conditions

The data in question are:

- fuel: propane
- total pressure: 14.696 psia
- temperature: 80°F
- excess air: 50 percent

*Solution:*

*Solution for question (1)*

1.1. Write the theoretical air combustion equation.

1.2. Write the 150% theoretical air combustion equation.

1.3. Write the equation for mass calculation.

$$m = nM$$

where  $m$  = mass  
 $n$  = number of moles  
 $M$  = molecular weight

1.4. Calculate air mass ( $m_a$ ) and fuel mass ( $m_f$ ).

$$\begin{aligned} m_f &= 1(44) \\ &= 44 \end{aligned}$$

$$\begin{aligned} m_a &= 1.5(5)(32 + (3.76)(28)) \\ &= 1029.6 \end{aligned}$$

1.5. Calculate the air/fuel ratio (mass base).

$$\begin{aligned} \text{AF} &= 1029.6/44 \\ &= 23.4 \end{aligned}$$

1.6. Calculate the air/fuel ratio (mole base).

$$\begin{aligned} \text{AF} &= 1.5(5)/1 \\ &= 7.5 \end{aligned}$$

*Solution for question (2)*

2.1. Calculate the total number of moles of products.

$$\begin{aligned} n &= 3 + 4 + (1.5)(5)(3.76) + 0.5(5) \\ &= 37.7 \text{ mole/(mole-fuel)} \end{aligned}$$

2.2. Calculate the mole fraction of product components.

$$y(\text{CO}_2) = 3/37.7 \\ = 0.0796$$

$$y(\text{H}_2\text{O}) = 4/37.7 \\ = 0.1061$$

$$y(\text{O}_2) = (0.5)(5)/37.7 \\ = 0.0663$$

$$y(\text{N}_2) = (1.5)(5)(3.76)/37.7 \\ = 0.7480$$

The sum of mole fractions equals 1, i.e.,  $y(\text{CO}_2) + y(\text{H}_2\text{O}) + y(\text{O}_2) + y(\text{N}_2) = 1$

*Solution for question (3)*

3.1. Write the partial pressure equation for H<sub>2</sub>O.

$$p(\text{H}_2\text{O}) = y(\text{H}_2\text{O})p(\text{total}) \\ = 0.1061(14.696) \\ = 1.56 \text{ psia}$$

3.2. Find the saturation temperature corresponding to 1.56 psia (from a steam table).  
Dew point temperature is roughly 117°F

*Solution for question (4)*

4.1. Write the ideal gas equation.

$$V = nR_u T/p \\ = (m/M)R_u T/p \\ v = V/m \\ = R_u T/(pM)$$

4.2. Calculate the specific volume of air.

$$v = 1544(460 + 80)/((14.696)(144)(29)) \\ = 13.59 \text{ ft}^3/(\text{lb-air})$$

*Solution for question (5)*

Because the air/fuel ratio (mass basis) is 23.4, the volume of air required per pound of fuel is

$$V = 13.59(23.4) \\ = 318.01 \text{ ft}^3/(\text{lb-fuel})$$

*Solution for question (6)*

$$V = 318.01(\text{ft}^3/(\text{lb-fuel}))(44)(\text{lb-fuel})/(\text{mole-fuel}) \\ = 13,992 \text{ ft}^3/(\text{mole-fuel})$$

**EXAMPLE 3** basic combustion

Propane ( $C_3H_8$ ) is burned with 80 percent theoretical air. Calculate:

- (1) the air/fuel ratio
- (2) molal analysis of the products of combustion
- (3) the dew point of the products for a total pressure of 14.696 psia.
- (4) the volume of air required to burn gaseous propane to completion, if the air temperature is  $80^\circ F$
- (5) volume of air per pound of fuel on the basis of per pound of fuel
- (6) volume of air per pound of fuel on the basis of per mole of fuel

**Given conditions**

The data in question are:

- fuel: propane
- total pressure: 14.696 psia
- temperature:  $80^\circ F$
- theoretical air: 0.8

*Solution:*

*Solution for question (1)*

1.1. Write the theoretical air combustion equation.

1.2. Write the 80% of theoretical air combustion equation.

1.3. Write the mass balance equation for each component.

For carbon:  $3 = a + b$

For oxygen:  $8 = 2a + b + 4$

The solution to these two equations is:

$$a = 1$$

$$b = 2$$

1.4. Write the 80% theoretical air combustion equation.

1.5. Write the equation for mass calculation.

$$m = nM$$

where  $m = \text{mass}$   
 $n = \text{number of moles}$   
 $M = \text{molecular weight}$

1.6. Calculate air mass ( $m_a$ ) and fuel mass ( $m_f$ ).

$$\begin{aligned} m_f &= 1(44) \\ &= 44 \\ m_a &= 0.8(5)(32 + (3.76)(28)) \\ &= 549.12 \end{aligned}$$

1.7. Calculate the air/fuel ratio (mass base).

$$\begin{aligned} \text{AF} &= 549.12/44 \\ &= 12.48 \end{aligned}$$

1.8. Calculate the air/fuel ratio (mole base).

$$\begin{aligned} \text{AF} &= (0.8)(5)/1 \\ &= 4 \end{aligned}$$

*Solution for question (2)*

2.1. Calculate the total number of moles of products.

$$\begin{aligned} n &= 1 + 2 + 4 + (0.8)(5)(3.76) \\ &= 22.04 \text{ mole/(mole-fuel)} \end{aligned}$$

2.2. Calculate the mole fraction of product components.

$$\begin{aligned} y(\text{CO}_2) &= 1/22.04 \\ &= 0.0454 \\ y(\text{CO}) &= 2/22.04 \\ &= 0.0907 \\ y(\text{H}_2\text{O}) &= 4/22.04 \\ &= 0.1815 \\ y(\text{N}_2) &= 0.8(5)(3.76)/22.04 \\ &= 0.6824 \end{aligned}$$

The sum of mole fractions equals 1, i.e.,  $y(\text{CO}_2) + y(\text{CO}) + y(\text{H}_2\text{O}) + y(\text{N}_2) = 1$

*Solution for question (3)*

3.1. Write the partial pressure equation for  $\text{H}_2\text{O}$ .

$$\begin{aligned} p(\text{H}_2\text{O}) &= y(\text{H}_2\text{O})p(\text{total}) \\ &= 0.1815(14.696) \\ &= 2.67 \text{ psia} \end{aligned}$$

3.2. Find the saturation temperature corresponding to 2.67 psia (from a steam table).  
Dew point temperature is roughly 129.41°F.

*Solution for question (4)*

4.1. Write the ideal gas equation.

$$\begin{aligned} V &= nR_u T/p \\ &= (m/M)R_u T/p \\ v &= V/m \\ &= R_u T/(pM) \end{aligned}$$

4.2. Calculate the specific volume of air.

$$\begin{aligned} v &= 1544(460 + 80)/((14.696)(144)(29)) \\ &= 13.59 \text{ ft}^3/(\text{lb-air}) \end{aligned}$$

*Solution for question (5)*

Because the air/fuel ratio (mass basis) is 12.48, the volume of air required per pound of fuel is

$$\begin{aligned} V &= 13.59(12.48) \\ &= 169.60 \text{ ft}^3/(\text{lb-fuel}) \end{aligned}$$

*Solution for question (6)*

$$\begin{aligned} V &= (169.60)[\text{ft}^3/(\text{lb-fuel})](44)(\text{lb-fuel})/(\text{mole-fuel}) \\ &= 7462.4 \text{ ft}^3/(\text{mole-fuel}) \end{aligned}$$

**EXAMPLE 4** basic combustion

Propane ( $\text{C}_3\text{H}_8$ ) is burned with 150 percent theoretical air. Air has an initial relative humidity of 60%. Calculate:

- (1) the air/fuel ratio
- (2) molal analysis of the products of combustion
- (3) the dew point of the products for a total pressure of 14.696 psia
- (4) the volume of air required to burn gaseous propane to completion, if the air temperature is 80°F
- (5) volume of air per pound of fuel on the basis of per pound of fuel
- (6) volume of air per pound of fuel on the basis of per mole of fuel

**Given conditions**

The data in question are:

- fuel: propane
- total pressure: 14.696 psia
- temperature: 80°F
- excess air: 50 percent
- relative humidity: 60%

*Solution:*

*Solution for question (1)*

1.1. Write the theoretical air combustion equation.

where

- humidity ratio (HR) at temperature = 80°F
- relative humidity = 60% from psychrometric chart, HR = 0.01315 (lb-water)/(lb-dry-air)\*

1.2. Write the 150% of theoretical air combustion equation.

1.3. Write the equation for mass calculation.

$$m = nM$$

where  $m$  = mass  
 $n$  = number of moles  
 $M$  = molecular weight

1.4. Calculate air mass ( $m_a$ ) and fuel mass ( $m_f$ ).

$$\begin{aligned} m_f &= 1(44) \\ &= 44 \end{aligned}$$

$$\begin{aligned} \text{Dry air mass} &= 1.5(5)(32 + (3.76)(28)) \\ &= 1029.6 \text{ lb} \end{aligned}$$

$$\begin{aligned} \text{Water vapor associated with dry air} &= 0.01315(1029.6) \\ &= 13.54(\text{lb-water}) \end{aligned}$$

$$\begin{aligned} \text{Moles of water} &= 13.54/18 \\ &= 0.7522(\text{mole-water}) \end{aligned}$$

Actual air mass,  $m_a$

$$\begin{aligned} m_a &= 1029.6 + 13.54 \\ &= 1043.14 \end{aligned}$$

1.5. Calculate the air/fuel ratio (mass base).

$$\begin{aligned} \text{AF} &= 1043.14/44 \\ &= 23.71 \end{aligned}$$

1.6. Calculate the air/fuel ratio (mole base).

$$\begin{aligned} \text{AF} &= 1.5(5)/1 \\ &= 7.5 \end{aligned}$$

\*Theoretically, the (HR) (air mass) term should appear on both sides of the equation.

*Solution for question (2)*

2.1. Calculate the total number of moles of products.

$$\begin{aligned} n &= 3 + 4 + (1.5)(5)(3.76) + 0.5(5) + 0.7522 \\ &= 38.45 \text{ mole/(mole-fuel)} \end{aligned}$$

2.2. Calculate the mole fraction of product components.

$$\begin{aligned} y(\text{CO}_2) &= 3/38.45 \\ &= 0.0780 \end{aligned}$$

$$\begin{aligned} y(\text{H}_2\text{O}) &= (4 + 0.7522)/38.45 \\ &= 0.1236 \end{aligned}$$

$$\begin{aligned} y(\text{O}_2) &= 0.5(5)/38.45 \\ &= 0.0650 \end{aligned}$$

$$\begin{aligned} y(\text{N}_2) &= (1.5)(5)(3.76)/38.45 \\ &= 0.7334 \end{aligned}$$

The sum of mole fractions equals 1, i.e.,  $y(\text{CO}_2) + y(\text{H}_2\text{O}) + y(\text{O}_2) + y(\text{N}_2) = 1$

*Solution for question (3)*

3.1. Write the partial pressure equation for  $\text{H}_2\text{O}$ .

$$\begin{aligned} p(\text{H}_2\text{O}) &= y(\text{H}_2\text{O})p(\text{total}) \\ &= 0.1236(14.696) \\ &= 1.82 \text{ psia} \end{aligned}$$

3.2. Find the saturation temperature corresponding to 1.82 psia (from a steam table).  
Dew point temperature is roughly 129°F.

*Solution for question (4)*

4.1. Write the ideal gas equation.

$$\begin{aligned} V &= nR_u T/p \\ &= (m/M)R_u T/p \\ v &= V/m \\ &= R_u T/(pM) \end{aligned}$$

4.2. Calculate the specific volume of air.

$$\begin{aligned} v &= 1544(460 + 80)/((14.696)(144)(29)) \\ &= 13.59 \text{ ft}^3/(\text{lb-air}) \end{aligned}$$

*Solution for question (5)*

Because the air fuel ratio (mass basis) is 23.71, the volume of air required per pound of fuel is

$$\begin{aligned} V &= 13.59(23.71) \\ &= 322.21 \text{ ft}^3/(\text{lb-fuel}) \end{aligned}$$

*Solution for question (6)*

$$\begin{aligned}
 V &= 322.21[\text{ft}^3/(\text{lb-fuel})](44)(\text{lb-fuel})/(\text{mole-fuel}) \\
 &= 14,177 \text{ ft}^3/(\text{lb-fuel})
 \end{aligned}$$

**EXAMPLE 5** basic combustion

Assume that 200 lb of methane gas (CH<sub>4</sub>) is used to incinerate 100 lb of carbon tetrachloride (CCl<sub>4</sub>) in an incinerator. Determine the quantity of theoretical air needed for complete incineration.

*Solution 1: By chemical analysis*

1. Analyze chemical composition.

1.1 Calculate the ultimate composition of CCl<sub>4</sub> on a 100 lb basis (Table 2.10)

where  $x_i$  = compound element

$M$  = the molecular weight of the compound

$x_i/M$  = mass per pound fuel

1.2. Calculate the ultimate composition of CH<sub>4</sub> on a 200 lb basis (Table 2.11).

1.3. Calculate the ultimate composition of compounds by combining items 1.1 and 1.2 (Table 2.12).

2. Determine theoretical combustion air.

2.1. Calculate oxygen needs for theoretical combustion.

Apply the method in Section 2.6 (Table 2.13).

**TABLE 2.10** Composition of CCl<sub>4</sub>

$x_i$	C	H	Cl	O	M
CCl <sub>4</sub>	12	0	142	0	154.00
$x_i/M$	0.0779	0.0000	0.9221	0.0000	
100 lb	7.7900	0.0000	92.2100	0.0000

**TABLE 2.13** Combustion Reactant Table

Basic reaction	Oxygen, nitrogen, and air requirements	Mass (lb/h)	Mole (mol/h)
$C + O_2 \rightarrow CO_2$	(1) $O_2 = C(32/12)$	420.77	13.15
$H_2 + 0.5O_2 \rightarrow H_2O$	(2) $O_2 = 8(H-Cl/35.5)^*$	379.22	11.85
$S + O_2 \rightarrow SO_2$	(3) $O_2 = S(32/32) = S$	0.00	0.00
$B_o =$ bound oxygen	(4) Data from waste analysis	0.00	0.00
$O_{2t} =$ theoretical $O_2$	$O_{2t} = (1) + (2) + (3) - (4)$	799.99	25.00
$N_{2t} =$ theoretical $N_2$	$N_{2t} = (O_{2t})(3.76 \times 28/32)$	2631.98	94.00
$A_t =$ theoretical air	$A_t = O_{2t} + N_{2t}$	3431.97	119.00
$\%A_e =$ % excess air	Given data	0	
$A_e =$ excess air	$A_e = (\%A_e)(A_t)$	0.00	0.00
$A_{ada} =$ actual dry air	$A_{ada} = A_t + A_e$	3431.97	119.00
$H_2O$ from air†	$0.0127(A_{ada})$	43.59	2.42
$A_a =$ actual air	$A_a = A_{ada} + H_2O$	3475.56	121.42
Waste feed	Data from waste analysis	300.00	
$R_a =$ actual reactant	$R_a = A_a +$ waste feed $+ H_2O$ from air	3775.56	

\* If  $H_2$  is the hydrogen left over after Cl reaction, i.e.,  $H_2 = H-Cl/35.5$ , the  $O_2$  needed to react with  $H_2$  will be equal to  $H_2(0.5)(32/2) = 8(H-Cl/35.5)$ .

† In general, at room temperature, the humidity ratio is 0.0127 (lb- $H_2O$ )/(lb-dry-air) or 0.0127 (kg- $H_2O$ )/(kg-dry-air).

Table 2.13 shows that the oxygen, nitrogen and air needed for the complete combustion of 200 lb of  $CH_4$  and 100 lb of  $CCl_4$  are:

- oxygen = 799.99 lb
- nitrogen = 2631.98 lb
- water produced = 43.59 lb
- combustion air = 3475.56 lb
- total reactants = 3775.56 lb

*Solution 2: By chemical balance*

1. Determine  $CH_4$  and air needed for  $CCl_4$  incineration.

$$\begin{aligned}
 \text{Theoretical nitrogen, } N_2 &= O_2(3.76)(28)/32 \\
 &= 42(3.76)(28)/32 \\
 &= 138
 \end{aligned}$$

$$\begin{aligned}
 \text{Theoretical dry air} &= O_2 + N_2 \\
 &= 42 + 138 \\
 &= 180
 \end{aligned}$$

This calculation shows that 100 lb  $CCl_4$  requires 10 lb  $CH_4$  and 180 lb air for complete incineration.

2. Determine air needed to react with unreacted CH<sub>4</sub>.

$$\begin{aligned}
 \text{Theoretical nitrogen, N}_2 &= \text{O}_2(3.76)(28)/32 \\
 &= 760(3.76)(28)/32 \\
 &= 2500
 \end{aligned}$$

$$\begin{aligned}
 \text{Theoretical dry air} &= \text{O}_2 + \text{N}_2 \\
 &= 760 + 2500 \\
 &= 3260
 \end{aligned}$$

This calculation shows that the unreacted 190 lb CH<sub>4</sub> needs 3260 lb air.

3. Determine the total theoretical air needed.

The total air needed is the sum of air found in 1 and 2 above, which is equal to 180 + 3260 = 3440 lb. This amount is approximately equal to the amount obtained by method 1, which is 3476 lb. The numerical difference between the two methods is due to rounding off certain values.

**EXAMPLE 6** basic combustion

Assume that a waste fuel consists of several components with the following volume fraction composition:

$$\text{N}_2 = 0.05$$

$$\text{CH}_4 = 0.81$$

$$\text{C}_2\text{H}_6 = 0.10$$

$$\text{C}_3\text{H}_8 = 0.04$$

Determine:

- (1) The volumetric flow rate of air required for complete combustion of 1.0 lb-mole/h of the above fuel with 100% theoretical air. Assume that the standard volume at the standard conditions is 387 scf (standard cubic feet) per lb-mole.
- (2) The volumetric flow rates of the combustion products (EPA-86/03, p. 55).

First, the nitrogen in the feed is  $(0.05)(28) = 1.40$  lb.

*Solution 1 for question (1)*

1.1. Analyze chemical composition.

1.1.1. Calculate the ultimate composition of CH<sub>4</sub> (Table 2.14).

**TABLE 2.14** Composition of CH<sub>4</sub>

$x_i$	C	H	Cl	O	$M$
CH <sub>4</sub>	12	4	0	0	16.00
$x_i/M$	0.7500	0.2500	0.0000	0.0000	
$(0.81) \times (M) = 12.96$	9.7200	3.2400	0.0000	0.0000	

- 1.1.2. Calculate the ultimate composition of  $C_2H_6$  (Table 2.15).
- 1.1.3. Calculate the ultimate composition of  $C_3H_8$  (Table 2.16).
- 1.1.4. Calculate the ultimate composition by combining items 1.1.1, 1.1.2, and 1.1.3 (Table 2.17).
- 1.2. Determine the theoretical combustion air (Table 2.18).  
Apply the method in Section 2.6.  
Table 2.18 shows that the oxygen, nitrogen, and air needed for this combustion are:

- oxygen = 69.44 lb/(lb-waste)
- nitrogen = 228.46 lb/(lb-waste)
- combustion air = 297.90 lb/(lb-waste)
- total reactants = 315.62 lb

1.3. Determine the air volumetric flow rate.  
From Table 2.18, the air flow rate  $A_a$  is 10.33 mol/h, and from the standard volume given in the question the volumetric flow rate  $V_r$  is:

$$V_r = 387(10.33) = 3997.71 \text{ scfh}$$

**TABLE 2.15** Composition of  $C_2H_6$

$x_i$	C	H	Cl	O	$M$
$C_2H_6$	24	6	0	0	30.00

$A_e =$ excess air	$A_e = (\%A_e)(A_t)$	0.00	0.00
$A_{ada} =$ actual dry air	$A_{ada} = A_t + A_e$	297.90	10.33
$H_2O$ from air†	$0.0127(A_{ada})$ , not considered for this case	0.00	0.00
$A_a =$ actual air	$A_a = A_{ada} + H_2O$	297.90	10.33
Waste feed	Data from waste analysis (17.72 + 1.40)	19.12	
$R_a =$ actual reactant	$R_a = A_a +$ waste feed + $H_2O$ from air	317.02	

\* If  $H_2$  is the hydrogen left over after Cl reaction, i.e.,  $H_2 = H-Cl/35.5$ , the  $O_2$  needed to react with  $H_2$  will be equal to  $H_2(0.5)(32/2) = 8(H-Cl/35.5)$ .

† In general, at room temperature, the humidity ratio is  $0.0127 \text{ (lb-H}_2\text{O)/(lb-dry-air)}$  or  $0.0127 \text{ (kg-H}_2\text{O)/(kg-dry-air)}$ .

### Solution 1 for question (2)

2.1. Analyze the combustion products (Table 2.19).

Apply the method in Section 2.6.

2.2. Calculate the volumetric flow rate of combustion products.

Table 2.19 shows that the combustion flue gas  $G_a = 11.37 \text{ mol/h}$ . The volumetric flow rate of the combustion products is

$$\begin{aligned} V_p &= 387(11.37) \\ &= 4400.19 \text{ scfh} \end{aligned}$$

### Solution 2: by the chemical balance of each individual compound

1. Determine the mass of each compound by multiplying the molecular weight with its corresponding compound.

**TABLE 2.19** Combustion Product Table

Component	Combustion product	Mass (lb/h)	Mole (mol/h)
$CO_2$	$CO_2 = (C)(44/12)$	49.72	1.13
$SO_2$	$SO_2 = S(64/32)$	0.00	0.00
HCl	$HCl = Cl(36.5/35.5)$	0.00	0.00
$O_{2e}$	$(\%A_e)O_{2t}$ , $O_{2t}$ from Table 2.18	0.00	0.00
$N_{2e}$	$(\%A_e)N_{2t}$ , $N_{2t}$ from Table 2.18	0.00	
$N_2$	$N_{2e} + N_{2t} +$ from waste (0 + 228.46 + 1.40)	229.86	8.21
$H_2O$ from combustion	$H_2O$ from combustion = $9(H-Cl/35.5)$	37.44	
$H_2O$	$H_2O$ from combustion + from air + from waste	37.44	2.08
$G_a =$ actual flue gas	$G_a = CO_2 + SO_2 + HCl + O_{2e} + N_2 + H_2O$	315.62	11.37
Ash	Fly ash + bottom ash	0.00	
$P_a =$ actual product*	$G_a +$ ash	317.02	

\* In performing the mass balance calculation, the values of reactants ( $R_a$ ) and products ( $P_a$ ) should be equal, i.e., if  $R_a = P_a$ , the mass balance calculation is correct.

$$\text{Mass of N}_2 = 0.05(28) = 1.40 \text{ lb/h}$$

$$\text{Mass of CH}_4 = 0.81(16) = 12.96 \text{ lb/h}$$

$$\text{Mass of C}_2\text{H}_6 = 0.10(30) = 3.00 \text{ lb/h}$$

$$\text{Mass of C}_3\text{H}_8 = 0.04(44) = 1.76 \text{ lb/h}$$

2. Determine the chemical reaction balance equation for each compound.

These calculations show that the total oxygen  $\text{O}_2$  required is:

$$\begin{aligned} \text{O}_2 &= 51.84 + 11.20 + 6.40 \\ &= 69.44 \text{ lb/h} \end{aligned}$$

3. Calculate the theoretical air amount ( $m_{\text{air}}$ ).

$$\begin{aligned} \text{Theoretical nitrogen, N}_2 &= \text{O}_2(3.76)(28)/32 \\ &= 69.44(3.76)(28)/32 \\ &= 228.46 \text{ lb} \end{aligned}$$

$$\begin{aligned} \text{Theoretical dry air} &= \text{O}_2 + \text{N}_2 \\ &= 69.44 + 228.46 \\ &= 297.90 \text{ lb} \end{aligned}$$

This air mass flow rate is identical to that in Solution 1.

Following the same procedures as in Solution 1, the volumetric flow rate of combustion air and the volumetric flow rate of combustion products can be found.

*Solution 3: by total chemical balance*

1. Write the balanced chemical equation for complete combustion.

2. Determine the chemical balance.

For carbon balance

$$\begin{aligned}
 0.81(12) + 0.1(12)(2) + 0.04(12)(3) &= 12v \\
 13.56 &= 12v \\
 v &= 1.13 \text{ lb-mole/h}
 \end{aligned} \tag{2.37}$$

For hydrogen balance

$$\begin{aligned}
 0.81(4) + 0.1(6) + 0.04(8) &= 2w \\
 4.16 &= 2w \\
 w &= 2.08 \text{ lb-mole/h}
 \end{aligned} \tag{2.38}$$

For oxygen balance

$$\begin{aligned}
 32u &= 32v + 16w \\
 32u &= 32(1.13) + 16(2.08) \\
 u &= 2.17 \text{ lb-mole/h}
 \end{aligned} \tag{2.39}$$

3. Summarize the calculated coefficients from Eqs. (2.37)–(2.39).

$$u = 2.17 \tag{2.40}$$

$$v = 1.13 \tag{2.41}$$

$$w = 2.08 \tag{2.42}$$

4. Write the complete balance reaction for Eq. (2.36).

5. Calculate the volumetric flow rate of air required.

From Eq. (2.43), the air component is

$$\text{Air} = 2.17(\text{O}_2 + 3.76\text{N}_2)$$

Air flow rate is the sum of the coefficients from  $\text{O}_2$  and  $\text{N}_2$ .

Therefore, air flow rate =  $2.17(1 + 3.76) = 10.33 \text{ lb-mole/h}$

$$\text{Air mass flow rate} = 2.17(32 + 3.76(28)) = 297.9 \text{ lb/h}$$

Again this air mass flow rate is identical to that in Solution 1.

Following the same procedures as in Solution 1, the volumetric flow rate of combustion air and the volumetric flow rate of combustion products can be found.

**EXAMPLE 7** basic combustion**Given conditions**

- A waste is incinerated in an incinerator. The waste feeding rate is 300 lb/h with the following components:

$$\begin{aligned} C &= 219.00 \text{ lb/h} \\ H_2 &= 50.00 \\ Cl &= 2.00 \\ O_2 &= 5.00 \\ N_2 &= 16.00 \\ S &= 2.00 \\ H_2O &= 3.00 \\ \text{bottom ash} &= 2.00 \\ \text{fly ash} &= 1.00 \end{aligned}$$

- Air humidity ratio = 0.0127 (lb-H<sub>2</sub>O/lb-air)
- Excess air = 150% = 250% theoretical air = 1.5 (as a fraction)

The waste consists of several components, as shown below.

Determine:

- (1) The air flow rate required for 150% excess air combustion.
- (2) The flow rate of combustion products.

*1. Solution for question (1)*

1.1. Calculate the combustion air flow rate.

Apply the method in Section 2.6 (Table 2.20).

From Table 2.20, the air flow rate for 150% excess air combustion is 10,649.95 lb/h.

**TABLE 2.20** Combustion Reactant Table

Basic reaction	Oxygen, nitrogen, and air requirements	Mass (lb/h)	Mole (mol/h)
$C + O_2 \rightarrow CO_2$	(1) $O_2 = C(32/12)$	584.00	18.25
$H_2 + 0.5O_2 \rightarrow H_2O$	(2) $O_2 = 8(H-Cl/35.5)^*$	399.55	12.49
$S + O_2 \rightarrow SO_2$	(3) $O_2 = S(32/32) = S$	2.00	0.06
$B_o = \text{bound oxygen}$	(4) Data from waste analysis	5.00	0.16
$O_{2t} = \text{theoretical } O_2$	$O_{2t} = (1) + (2) + (3) - (4)$	980.55	30.64
$N_{2t} = \text{theoretical } N_2$	$N_{2t} = (O_{2t})(3.76 \times 28/32)$	3226.01	115.21
$A_t = \text{theoretical air}$	$A_t = O_{2t} + N_{2t}$	4206.56	145.86
$\%A_e = \%$ excess air	Given data (use $\% A_e$ as a fraction)	1.5	
$A_e = \text{excess air}$	$A_e = (\%A_e)(A_t)$	6309.83	218.79
$A_{ada} = \text{actual dry air}$	$A_{ada} = A_t + A_e$	10,516.39	364.65
$H_2O \text{ from air}^\dagger$	$0.0127(A_{ada})$	133.56	7.42
$A_a = \text{actual air}$	$A_a = A_{ada} + H_2O$	10,649.95	372.07
Waste feed	Data from waste analysis	300.00	
$R_a = \text{actual reactant}$	$R_a = A_a + \text{waste feed} + H_2O \text{ from air}$	10,949.95	

\* If H<sub>2</sub> is the hydrogen left over after Cl reaction, i.e.,  $H_2 = H-Cl/35.5$ , the O<sub>2</sub> needed to react with H<sub>2</sub> will be equal to  $H_2(0.5)(32/2) = 8(H-Cl/35.5)$ .

† In general, at room temperature, the humidity ratio is 0.0127 (lb-H<sub>2</sub>O)/(lb-dry-air) or 0.0127 (kg-H<sub>2</sub>O)/(kg-dry-air).

2. *Solution for question (2)*

Calculate the combustion products flow rate by applying the method in Section 2.6 (Table 2.21).

From Table 2.21 the flow rate of combustion products for 150% excess air combustion is 10,949.96 lb/h.

**TABLE 2.21** Combustion Product Table

Component	Combustion product	Mass (lb/h)	Mole (mol/h)
CO <sub>2</sub>	CO <sub>2</sub> = (C)(44/12)	803.00	18.25
SO <sub>2</sub>	SO <sub>2</sub> = S(64/32)	4.00	0.06
HCl	HCl = Cl(36.5/35.5)	2.06	0.06
O <sub>2e</sub>	(%A <sub>e</sub> )O <sub>2t</sub> , O <sub>2t</sub> from Table 2.20	1470.83	45.96
N <sub>2e</sub>	(%A <sub>e</sub> )N <sub>2t</sub> , N <sub>2t</sub> from Table 2.20	4839.02	172.82
N <sub>2</sub>	N <sub>2e</sub> + N <sub>2t</sub> + from waste	8081.03	288.61
H <sub>2</sub> O from combustion	H <sub>2</sub> O from combustion = 9(H-Cl/35.5)	449.49	24.97
H <sub>2</sub> O	H <sub>2</sub> O from combustion + from air + from waste	586.05	32.56
G <sub>a</sub> = actual flue gas	G <sub>a</sub> = CO <sub>2</sub> + SO <sub>2</sub> + HCl + O <sub>2e</sub> + N <sub>2</sub> + H <sub>2</sub> O	10,946.96	385.50
Ash	Fly ash + bottom ash	3.00	
P <sub>a</sub> = actual product*	G <sub>a</sub> + ash	10,949.96	

\*In performing the mass balance calculation, the values of reactants ( $R_a$ ) and products ( $P_a$ ) should be equal, i.e., if  $R_a = P_a$ , the mass balance calculation is correct.

### 3 BASIC MASS AND ENERGY BALANCE CALCULATIONS

The purpose of this section is to provide readers with a universally applicable, step-by-step, and easy-to-follow procedure to perform mass and energy balance calculations on thermal treatment operations. Examples will be included to illustrate the procedure in different applications (Ho-98/12).

#### 3.1 Solid Waste Thermal Treatment

There are a variety of solid wastes which can be managed through thermal treatment processes. These wastes may include medical waste, municipal waste, hazardous waste, and sludge waste from the treatment of domestic and industrial wastewater. Although these different types of waste may have different chemical compositions, energy levels, water contents, and so on, and they may be burned in different types of combustors, e.g., rotary kiln, fixed hearth, liquid injection, fluidized bed, etc., the procedures of performing the mass and energy balance calculations are essentially identical.

Thermal treatment (or combustion/incineration) is an effective method for treating solid wastes. Under normal operations, a properly designed thermal treatment unit is capable of destroying more than 99.99% of the incoming organic wastes. Depending on the heating values of the wastes, the treatment process may or may not require auxiliary fuels. Energy recovery during and after the treatment process is also possible if the unit is equipped with waste heat recovery systems. The amounts of auxiliary fuels required and potential heat recovery can theoretically be estimated through mass and energy balance calculations.

**Combustion fundamentals.** The combustion/incineration process is the burning of waste with air or pure oxygen. Theoretically, it is the conversion of elemental constituents in the organic waste, e.g., carbon (C), hydrogen (H), oxygen (O), nitrogen (N), chlorine (Cl), and sulfur (S), into both nontoxic combustion products such as carbon dioxide (CO<sub>2</sub>), water (H<sub>2</sub>O), oxygen (O<sub>2</sub>) and nitrogen (N<sub>2</sub>), and potentially toxic products such as carbon monoxide (CO), hydrochloric acid (HCl), chlorine (Cl<sub>2</sub>), nitrogen oxides (NO<sub>x</sub>, or NO and NO<sub>2</sub>), and sulfur oxides (SO<sub>x</sub>, or SO<sub>2</sub> and SO<sub>3</sub>). These combustion phenomena can be represented by the following simplified stoichiometric equations:

where C, H, O, N, Cl, and S in the above equations represent the elemental constituents in the waste, and O<sub>2</sub> represents the supplied oxygen from air or other oxygen sources. Note that reactions A, C, D, and F represent the major combustion reactions and are commonly the only reactions considered in the material and energy balance calculations.

**Theoretical oxygen requirement.** One of the important steps in performing material and energy balance calculations is to determine the *theoretical oxygen requirement* ( $n_{s,\text{O}_2}$ ) for the waste to be combusted, i.e., the minimum amount of oxygen (O<sub>2</sub>) which is required to be supplied to completely combust the waste according to combustion stoichiometry. This theoretical oxygen requirement can be calculated by the equation

$$n_{s,\text{O}_2} = n_{\text{C}} + (n_{\text{H}} - n_{\text{Cl}})/4 + n_{\text{S}} - n_{\text{O}}/2 \quad (2.44)$$

where  $n_{\text{C}}$ ,  $n_{\text{H}}$ ,  $n_{\text{Cl}}$ ,  $n_{\text{S}}$ , and  $n_{\text{O}}$  represent the number of pound-moles of carbon, hydrogen, chlorine, sulfur, and oxygen atoms in the waste. Note that this equation reflects the combustion stoichiometry that each pound-mole of carbon and sulfur atoms requires one pound-mole of oxygen gas (reactions A and F) for complete combustion; and each two pound-moles of available hydrogen atoms ( $n_{\text{H}} - n_{\text{Cl}}$ ) requires one-half pound-mole of oxygen gas (reaction D). It also reflects the reaction that each pound-mole of chlorine atoms will consume one pound-mole of hydrogen atoms to form one pound-mole of hydrochloric acid (reaction C), which reduces the amount of hydrogen available for reacting with oxygen. The existence of oxygen atoms in the waste also reduces the theoretical oxygen requirement as reflected in the equation.

**Excess oxygen supply.** In combustion/incineration practice, the actual amount of oxygen supply is normally greater than the theoretical oxygen requirement to ensure sufficient oxygen for combustion. In such practice, the amount of oxygen supply in excess of that of the theoretical requirement is called the excess oxygen, and the fraction in excess is called the fractional excess. The fractional excess ( $f$ ) is thus defined as

$$f = (n_{\text{O}_2} - n_{\text{s,O}_2})/n_{\text{s,O}_2} \quad (2.45)$$

where  $n_{\text{O}_2}$  represents the actual amount of oxygen supply in pound-moles and  $n_{\text{s,O}_2}$  is the theoretical amount of oxygen requirement in pound-moles as calculated in Eq. (2.44). In cases where the fractional excess is to be fixed, Eq. (2.45) can be rearranged to determine the actual amount of oxygen supply, i.e.,

$$n_{\text{O}_2} = (1 + f)n_{\text{s,O}_2} \quad (2.46)$$

**Theoretical and excess air supply.** When air is used as the oxygen source, the following two equations can be derived based on a common assumption that air is composed of 21 mole% oxygen and 79 mole% nitrogen, i.e.,

$$n_{\text{O}_2} = 0.21n_{\text{air}} \quad \text{or} \quad n_{\text{air}} = n_{\text{O}_2}/0.21 \quad (2.47)$$

and

$$n_{\text{s,O}_2} = 0.21n_{\text{s,air}} \quad \text{or} \quad n_{\text{s,air}} = n_{\text{s,O}_2}/0.21 \quad (2.48)$$

where  $n_{\text{air}}$  represents the actual amount of air supply in pound-moles and  $n_{\text{s,air}}$  is the theoretical amount of air requirement in pound-moles. Substituting Eqs. (2.47) and (2.48) into Eqs. (2.45) and (2.46), the corresponding two equations in terms of  $n_{\text{air}}$  and  $n_{\text{s,air}}$  will have the following forms:

$$f = (n_{\text{air}} - n_{\text{s,air}})/n_{\text{s,air}} \quad (2.49)$$

and

$$n_{\text{air}} = (1 + f)n_{\text{s,air}} \quad (2.50)$$

All the above equations are commonly involved in the material and energy balance calculations.

### 3.2 Mass and Energy Balance Principle

**Material balance principle.** The material balance principle for a combustion system is simply that, under steady state operations, the inlet molar flow rate of any elemental species must be equal to the total molar flow rate of that particular element in the outlet, which may appear in one or more flue gas species. Note that the inlet molar flow rate of a particular elemental species is the sum of that species from all inlet streams. Normally, an inlet stream is considered to be composed of moisture ( $\text{H}_2\text{O}$ ), combustible substances, and noncombustible (ash) materials. In the calculations, the moisture and noncombustible materials are considered to pass through the unit with only physical changes, i.e., temperature changes and the vaporization of water. For the combustible portion, the elemental species commonly considered are carbon (C), hydrogen (H), chlorine (Cl), sulfur (S), oxygen (O), and nitrogen (N). The following sequence of assumptions are generally involved in determining the outlet species from the inlet combustible substances.

**Carbon element.** All the incoming carbon (C) is either converted to carbon dioxide ( $\text{CO}_2$ ) according to reaction A, i.e.,

or remains unburned and exits as solid elemental carbon. Note that the conversion of carbon to carbon monoxide (CO) is generally not considered in material balance calculations because

carbon monoxide is not expected to be present in any significant amount in a well-designed and well-operated combustion system.

*Hydrogen element.* All the incoming hydrogen (H) will either react with chlorine to form hydrochloric acid (HCl) according to reaction C, i.e.,

or is converted to water (H<sub>2</sub>O) according to reaction D, i.e.,

*Chlorine element.* Essentially all of the incoming chlorine (Cl) is converted to hydrochloric acid (HCl) according to reaction C.

*Sulfur element.* Essentially all of the incoming sulfur (S) is converted to sulfur dioxide (SO<sub>2</sub>) according to reaction F, i.e.,

*Oxygen element.* All the incoming oxygen, including that in the inlet combustible materials and that from the air or oxygen supply, will be in either carbon dioxide (CO<sub>2</sub>), water (H<sub>2</sub>O), sulfur dioxide (SO<sub>2</sub>), or oxygen gas (O<sub>2</sub>).

*Nitrogen element.* All the incoming nitrogen, including that in the inlet combustible materials and that from the air supply, will be in nitrogen gas (N<sub>2</sub>). Note again that the formation of nitrogen oxides (NO<sub>x</sub>) is generally in small amounts and is not considered in the material and energy balance calculations.

In summary, the outlet species considered in the material balance calculations are carbon dioxide (CO<sub>2</sub>), water (H<sub>2</sub>O), hydrochloric acid (HCl), sulfur dioxide (SO<sub>2</sub>), oxygen gas (O<sub>2</sub>), nitrogen gas (N<sub>2</sub>), and solid ash, including noncombustible materials and unburned carbon.

Based on the above assumptions, the following material balance equations are derived to determine the molar flow rate of each outlet species:

$$n_{\text{carbon dioxide}} = n_C \quad (2.51)$$

$$n_{\text{water}} = (n_H - n_{Cl})/2 + n_{\text{moisture}} \quad (2.52)$$

$$n_{\text{hydrochloric acid}} = n_{Cl} \quad (2.53)$$

$$n_{\text{sulfur dioxide}} = n_S \quad (2.54)$$

$$n_{\text{oxygen}} = n_{O_2} + n_{O_2} - n_C - n_S - (n_H - n_{Cl})/4 \quad (2.55)$$

$$n_{\text{nitrogen}} = n_{N_2}/2 + n_{N_2} \quad (2.56)$$

where

$$n_{N_2} = 0.79n_{\text{air}} \quad (2.57)$$

Equations (2.49)–(2.57) completely describe the material balance calculations for waste combustion processes.

**Energy balance principle.** The energy balance principle for a combustion system is simply that, under steady state operations, the difference in total energy content between the outlet and inlet streams must be equal to the amount of heat transfer. In formula, it is expressed as

$$Q = (H_{\text{total}})_{\text{outlet}} - (H_{\text{total}})_{\text{inlet}} \quad (2.58)$$

Note that the  $(H_{\text{total}})_{\text{outlet}}$  is generally less than  $(H_{\text{total}})_{\text{inlet}}$  in combustion processes, and therefore the amount of heat transfer ( $Q$ ) appearing in the equation is always negative, indicating

that energy is transferring out of the combustion process. This heat transfer can be in the forms of energy recovery through generating useful steam or energy lost to the surroundings.

In performing energy balance calculations, the following equation, derived from Eq. (2.58), is usually involved, i.e.,

$$Q = -(\text{HHV})_{\text{total}} + (H_{\text{sensible}})_{\text{outlet}} - (H_{\text{sensible}})_{\text{inlet}} \quad (2.59)$$

where  $(\text{HHV})_{\text{total}}$  is the sum of the higher heating values from all the inlet streams,  $(H_{\text{sensible}})_{\text{outlet}}$  is the sum of the sensible heat from all the outlet flue gas species (plus the heat of vaporization of water), and  $(H_{\text{sensible}})_{\text{inlet}}$  is the sum of the sensible heat from all the inlet streams. The three terms in Eq. (2.59) can be calculated by the following equations, respectively:

$$(\text{HHV})_{\text{total}} = \sum \{w(\text{HHV})\}_i, \quad i = \text{each inlet stream} \quad (2.60)$$

$$(H_{\text{sensible}})_{\text{outlet}} = \sum \{nC_{\text{pm}}(T - 77)\}_i + n_{\text{water}}(\Delta H_{\text{v}})_{\text{water}}, \quad i = \text{each flue gas species} \quad (2.61)$$

and

$$(H_{\text{sensible}})_{\text{inlet}} = \sum \{wC_{\text{pm}}(T - 77)\}_i, \quad i = \text{each inlet stream} \quad (2.62)$$

where  $w$  is the mass or molar flow rate of each inlet stream, HHV is the higher heating value of each inlet stream on either a per mass or per mole basis,  $n$  is the molar flow rate of each flue gas species,  $n_{\text{water}}$  is the molar flow rate of water in the flue gas,  $(\Delta H_{\text{v}})_{\text{water}}$  is the heat of vaporization of water at 77°F (= 1050 Btu/lbm),  $C_{\text{pm}}$  is the mean specific heat again on either a per mass or per mole basis, and  $T$  is temperature in degrees Fahrenheit.

In the application, the HHV for each inlet stream can either be looked up from thermodynamic tables, measured experimentally, or estimated using the following equation:

$$\text{HHV} = 14,545X_{\text{C}} + 62,031(X_{\text{H}} - 0.125X_{\text{O}}) - 760X_{\text{Cl}} + 4500X_{\text{S}} \quad (2.63)$$

where HHV is in the unit of Btu/lbm and  $X_{\text{C}}$ ,  $X_{\text{H}}$ ,  $X_{\text{O}}$ ,  $X_{\text{Cl}}$  and  $X_{\text{S}}$  are mass fraction of carbon, hydrogen, oxygen, chlorine, and sulfur, respectively, in the combustible portion of an inlet stream. For the mean specific heat appearing in Eqs (2.61) and (2.62), Table 2.22 lists the corresponding values at different temperatures.

### 3.3 Mass and Energy Balance Calculational Procedure

**Calculational procedure.** The step-by-step procedure for performing material and energy balance calculations is described below.

- Step 1. Break down each inlet stream into moisture, noncombustible material and various elemental species; then add up all the inlet streams to determine the total flow rate of moisture, noncombustible material, and each elemental species in terms of carbon, hydrogen, chlorine, sulfur, hydrogen, and nitrogen.
- Step 2. Determine the theoretical oxygen requirement based on Eq. (2.44) and the results from step 1.
- Step 3. Determine the actual oxygen (or air) supply under a given value of fractional excess ( $f$ ) based on either Eq. (2.46) or Eq. (2.50).
- Step 4. Perform the material balance calculation by identifying the flue gas species and determine the corresponding molar flow rate based on Eqs. (2.51)–(2.56).
- Step 5. Perform the energy balance calculation based on Eqs. (2.59)–(2.62).

**TABLE 2.22** Mean Specific Heat ( $C_{pm}$ ) of Various Flue Gas Species (Reference Temperature 77°F)

$T(^{\circ}\text{F})$	$C_{pm}$ (Btu/lb-mole $^{\circ}\text{F}$ )

### 3.4 Example Calculation

**EXAMPLE 1** combustion of pure methane gas (CH<sub>4</sub>)  
Determine the amount of heat transfer ( $Q$ ) = ? Btu/h.

**Given conditions**

- methane flow rate = 5000 ft<sup>3</sup>/h @ 1 atm, 77°F
- fractional excess air = 0.15 @ 77°F
- flue gas temperature = 1800°F
- higher heating value of methane = 383,109 Btu/lb-mole

*Solution:*

Step 1. Determine the molar flow rate of methane and the corresponding molar flow rates of C and H based on the ideal gas law and the following equations:

$$\begin{aligned}
 n_{\text{CH}_4} &= (PV)/(RT) \\
 &= (14.7 \times 5000)/(10.73 \times 537) \\
 &= 12.76 \text{ (lb-mole/h)}
 \end{aligned}$$

Therefore,

$$n_{\text{C}} = 1 \times n_{\text{CH}_4} = 12.76 \text{ lb-mole/h}$$

and

$$n_H = 4 \times n_{\text{CH}_4} = 51.04 \text{ lb-mole/h}$$

Step 2. Determine the theoretical air requirement based on Eq. (2.44), i.e.,

$$\begin{aligned} n_{\text{s,O}_2} &= n_C + (n_H - n_{\text{Cl}})/4 + n_S - n_{\text{O}}/2 \\ &= 12.76 + (51.04 - 0)/4 + 0 - 0 \\ &= 25.52 \text{ (lb-mole/h)} \end{aligned}$$

Therefore,

$$n_{\text{s,air}} = 25.52/0.21 = 121.52 \text{ (lb-mole/h)}$$

Step 3. Determine the actual air supply based on the given value of fractional excess according to Eq. (2.50), i.e.,

$$\begin{aligned} n_{\text{air}} &= (1 + f)n_{\text{s,air}} \\ &= (1 + 0.15)(121.52) \\ &= 139.75 \text{ (lb-mole/h)} \end{aligned}$$

Therefore

$$\begin{aligned} n_{\text{O}_2} &= 0.21n_{\text{air}} \\ &= 29.35 \text{ (lb-mole/h)} \end{aligned}$$

and

$$\begin{aligned} n_{\text{N}_2} &= 0.79n_{\text{air}} \\ &= 110.40 \text{ (lb-mole/h)} \end{aligned}$$

Step 4. Determine the molar flow rate of flue gas based on Eqs. (2.50)–(2.56), i.e.,

$$\begin{aligned} n_{\text{carbon dioxide}} &= n_C \\ &= 12.76 \text{ lb-mole/h} \end{aligned}$$

$$\begin{aligned} n_{\text{water}} &= (n_H - n_{\text{Cl}})/2 + n_{\text{moisture}} \\ &= (51.04 - 0)/2 + 0 \\ &= 25.52 \text{ lb-mole/h} \end{aligned}$$

$$\begin{aligned} n_{\text{hydrochloric acid}} &= n_{\text{Cl}} \\ &= 0.0 \text{ lb-mole/h} \end{aligned}$$

$$\begin{aligned} n_{\text{sulfur dioxide}} &= n_S \\ &= 0.0 \text{ lb-mole/h} \end{aligned}$$

$$\begin{aligned} n_{\text{oxygen}} &= n_{\text{O}}/2 + n_{\text{O}_2} - n_C - n_S - (n_H - n_{\text{Cl}})/4 \\ &= 0 + 29.35 - 12.76 - 0 - (51.04 - 0)/4 \\ &= 3.83 \text{ lb-mole/h} \end{aligned}$$

$$\begin{aligned} n_{\text{nitrogen}} &= n_{\text{N}}/2 + n_{\text{N}_2} \\ &= 0 + 110.40 \\ &= 110.40 \text{ lb-mole/h} \end{aligned}$$

Step 5. Determine  $Q$  based on the given  $(\text{HHV})_{\text{methane}}$  and Eq. (2.60), i.e.,

$$Q = -(\text{HHV})_{\text{total}} + (H_{\text{sensible}})_{\text{outlet}} - (H_{\text{sensible}})_{\text{inlet}}$$

(a) For  $(\text{HHV})_{\text{total}}$ :

$$\begin{aligned} (\text{HHV})_{\text{total}} &= \sum \{w(\text{HHV})\}_i, \quad i = \text{each inlet stream} \\ &= (12.76 \times 383,109)_{\text{methane}} \\ &= 4.89 \times 10^6 \text{ (Btu/h)} \end{aligned}$$

(b) For  $(H_{\text{sensible}})_{\text{outlet}}$  at 1800°F based on Table 2.22:

$$\begin{aligned} C_{\text{pm,CO}_2,1800^\circ\text{F}} &= 11.88 \text{ (Btu/lb-mole}^\circ\text{F)} \\ C_{\text{pm,H}_2\text{O},1800^\circ\text{F}} &= 9.22 \text{ (Btu/lb-mole}^\circ\text{F)} \\ C_{\text{pm,O}_2,1800^\circ\text{F}} &= 7.95 \text{ (Btu/lb-mole}^\circ\text{F)} \\ C_{\text{pm,N}_2,1800^\circ\text{F}} &= 7.48 \text{ (Btu/lb-mole}^\circ\text{F)} \end{aligned}$$

Then

$$\begin{aligned} (H_{\text{sensible}})_{\text{outlet}} &= \sum \{nC_{\text{pm}}(T - 77)\}_i + n_{\text{water}}(\Delta H_v)_{\text{water}} \\ &= \{nC_{\text{pm}}(T - 77)\}_{\text{CO}_2} + \{nC_{\text{pm}}(T - 77)\}_{\text{H}_2\text{O}} + \{nC_{\text{pm}}(T - 77)\}_{\text{O}_2} \\ &\quad + \{nC_{\text{pm}}(T - 77)\}_{\text{N}_2} + n_{\text{water}}(\Delta H_v)_{\text{water}} \\ &= \{12.76C_{\text{pm}}(1800 - 77)\}_{\text{CO}_2} + \{25.52C_{\text{pm}}(1800 - 77)\}_{\text{H}_2\text{O}} \\ &\quad + \{3.83C_{\text{pm}}(1800 - 77)\}_{\text{O}_2} + \{110.40C_{\text{pm}}(1800 - 77)\}_{\text{N}_2} \\ &\quad + 25.52 \times 18 \times 1050 \\ &= 2.62 \times 10^6 \text{ (Btu/h)} \end{aligned}$$

(c) For  $(H_{\text{sensible}})_{\text{inlet}}$  at 77°F:

$$\begin{aligned} (H_{\text{sensible}})_{\text{inlet}} &= \sum \{nC_{\text{pm}}(T - 77)\}_i \quad i = \text{each flue gas species} \\ &= \{nC_{\text{pm}}(T - 77)\}_{\text{methane}} + \{nC_{\text{pm}}(T - 77)\}_{\text{air}} \\ &= \{12.76C_{\text{pm}}(77 - 77)\}_{\text{methane}} + \{139.75C_{\text{pm}}(77 - 77)\}_{\text{air}} \\ &= 0 \text{ (Btu/h)} \end{aligned}$$

Therefore,

$$\begin{aligned} Q &= -(\text{HHV})_{\text{total}} + (H_{\text{sensible}})_{\text{outlet}} - (H_{\text{sensible}})_{\text{inlet}} \\ &= -4.89 \times 10^6 + 2.62 \times 10^6 - 0 \\ &= -2.27 \times 10^6 \text{ (Btu/h)} \end{aligned}$$

**EXAMPLE 2** co-combustion of liquid benzene and No. 2 oil  
Determine the amount of heat transfer ( $Q$ ) = ? Btu/h.

**Given conditions**

- Stream 1: liquid benzene ( $C_6H_6$ )

$$\begin{aligned}\text{benzene flow rate} &= 100 \text{ lbm/h at } 77^\circ\text{F} \\ \text{HHV (benzene)} &= 18,026 \text{ Btu/lbm}\end{aligned}$$

- Stream 2: No. 2 oil (C: 0.872; H: 0.123; S: 0.005 by mass)

$$\begin{aligned}\text{oil flow rate} &= 300 \text{ lbm/h at } 77^\circ\text{F} \\ \text{fractional excess air} &= 0.1 \text{ at } 77^\circ\text{F} \\ \text{flue gas temperature} &= 1800^\circ\text{F}\end{aligned}$$

*Solution:*

Step 1. Determine the combined molar flow rate of C, H, and S.

(a) Stream 1 (benzene)

$$\begin{aligned}M_{\text{benzene}}(\text{benzene molecular weight}) &= 12 \times 6 + 1 \times 6 = 78 \\ n_{\text{benzene}} &= 100/M_{\text{benzene}} = 100/78 = 1.28 \text{ (lb-mole/h)}\end{aligned}$$

Therefore

$$\begin{aligned}n_C &= 6 \times n_{\text{benzene}} = 7.68 \text{ lb-mole/h} \\ n_H &= 6 \times n_{\text{benzene}} = 7.68 \text{ lb-mole/h}\end{aligned}$$

(b) Stream 2 (No. 2 oil)

$$\begin{aligned}n_C &= (300 \times 0.872)/12 = 21.8 \text{ lb-mole/h} \\ n_H &= (300 \times 0.123)/1 = 36.9 \text{ lb-mole/h} \\ n_S &= (300 \times 0.005)/32 = 0.047 \text{ lb-mole/h}\end{aligned}$$

(c) Total input (benzene and No. 2 oil)

$$\begin{aligned}n_C &= 7.68 + 21.8 = 29.48 \text{ lb-mole/h} \\ n_H &= 7.68 + 36.9 = 44.58 \text{ lb-mole/h} \\ n_S &= 0 + 0.047 = 0.047 \text{ lb-mole/h}\end{aligned}$$

Step 2. Determine the theoretical air requirement based on Eq. (2.44), i.e.,

$$\begin{aligned}n_{s,O_2} &= n_C + (n_H - n_{Cl})/4 + n_S - n_O/2 \\ &= 29.48 + (44.58 - 0)/4 + 0.047 - 0 \\ &= 40.672 \text{ (lb-mole/h)}\end{aligned}$$

Therefore

$$n_{s,air} = 40.672/0.21 = 193.68 \text{ (lb-mole/h)}$$

Step 3. Determine the actual air supply based on the given value of fractional excess according to Eq. (2.50), i.e.,

$$\begin{aligned}n_{\text{air}} &= (1 + f)n_{\text{s,air}} \\ &= (1 + 0.1)(193.68) \\ &= 213.05 \text{ (lb-mole/h)}\end{aligned}$$

Therefore,

$$\begin{aligned}n_{\text{O}_2} &= 0.21n_{\text{air}} \\ &= 44.74 \text{ (lb-mole/h)}\end{aligned}$$

and

$$\begin{aligned}n_{\text{N}_2} &= 0.79n_{\text{air}} \\ &= 168.31 \text{ (lb-mole/h)}\end{aligned}$$

Step 4. Determine the molar flow rate of flue gas based on Eqs. (2.50)–(2.56), i.e.,

$$\begin{aligned}n_{\text{carbon dioxide}} &= n_{\text{C}} \\ &= 29.48 \text{ lb-mole/h} \\ n_{\text{water}} &= (n_{\text{H}} - n_{\text{Cl}})/2 + n_{\text{moisture}} \\ &= (44.58 - 0)/2 + 0 \\ &= 22.29 \text{ lb-mole/h} \\ n_{\text{hydrochloric acid}} &= n_{\text{Cl}} \\ &= 0.0 \text{ lb-mole/h} \\ n_{\text{sulfur dioxide}} &= n_{\text{S}} \\ &= 0.047 \text{ lb-mole/h} \\ n_{\text{oxygen}} &= n_{\text{O}}/2 + n_{\text{O}_2} - n_{\text{C}} - n_{\text{S}} - (n_{\text{H}} - n_{\text{Cl}})/4 \\ &= 0 + 44.74 - 29.48 - 0.047 - (44.58 - 0)/4 \\ &= 4.07 \text{ lb-mole/h} \\ n_{\text{nitrogen}} &= n_{\text{N}}/2 + n_{\text{N}_2} \\ &= 0 + 168.31 \\ &= 168.31 \text{ lb-mole/h}\end{aligned}$$

Step 5. Determine  $Q$  based on the given  $(\text{HHV})_{\text{benzene}}$ , the estimated  $(\text{HHV})_{\text{oil}}$ , and Eq. (2.60), i.e.,

$$Q = -(\text{HHV})_{\text{total}} + (H_{\text{sensible}})_{\text{outlet}} - (H_{\text{sensible}})_{\text{inlet}}$$

(a) For  $(\text{HHV})_{\text{total}}$ :

(1) Estimated  $(\text{HHV})_{\text{oil}}$  based on Eq. (2.63), i.e.,

$$\begin{aligned}(\text{HHV})_{\text{oil}} &= 14,545X_{\text{C}} + 62,031(X_{\text{H}} - 0.125X_{\text{O}}) - 760X_{\text{Cl}} + 4500X_{\text{S}} \\ &= 14,545(0.872) + 62,031(0.123 - 0) - 0 + 4500(0.005) \\ &= 20,335.6 \text{ (Btu/lbm)}\end{aligned}$$

(2) Determine  $(\text{HHV})_{\text{total}}$

$$\begin{aligned} (\text{HHV})_{\text{total}} &= \sum \{w(\text{HHV})\}_i, \quad i = \text{each inlet stream} \\ &= (100 \times 18,026)_{\text{benzene}} + (300 \times 20,335.6)_{\text{oil}} \\ &= 7.90 \times 10^6 \text{ (Btu/h)} \end{aligned}$$

(b) For  $(H_{\text{sensible}})_{\text{outlet}}$  at  $1800^\circ\text{F}$ , based on Table 2.22:

$$\begin{aligned} C_{\text{pm,CO}_2,1800^\circ\text{F}} &= 11.88 \text{ (Btu/lb-mole}^\circ\text{F)} \\ C_{\text{pm,steam,1800}^\circ\text{F}} &= 9.22 \text{ (Btu/lb-mole}^\circ\text{F)} \\ C_{\text{pm,O}_2,1800^\circ\text{F}} &= 7.95 \text{ (Btu/lb-mole}^\circ\text{F)} \\ C_{\text{pm,N}_2,1800^\circ\text{F}} &= 7.48 \text{ (Btu/lb-mole}^\circ\text{F)} \\ C_{\text{pm,SO}_2,1800^\circ\text{F}} &= 12.81 \text{ (Btu/lb-mole}^\circ\text{F)} \end{aligned}$$

Then

$$\begin{aligned} (H_{\text{sensible}})_{\text{outlet}} &= \sum \{nC_{\text{pm}}(T - 77)\}_i + n_{\text{water}}(\Delta H_v)_{\text{water}} \\ &= \{nC_{\text{pm}}(T - 77)\}_{\text{CO}_2} + \{nC_{\text{pm}}(T - 77)\}_{\text{H}_2\text{O}} + \{nC_{\text{pm}}(T - 77)\}_{\text{O}_2} \\ &\quad + \{nC_{\text{pm}}(T - 77)\}_{\text{N}_2} + n_{\text{water}}(\Delta H_v)_{\text{water}} \\ &= \{29.48C_{\text{pm}}(1800 - 77)\}_{\text{CO}_2} + \{22.29C_{\text{pm}}(1800 - 77)\}_{\text{H}_2\text{O}} \\ &\quad + \{4.07C_{\text{pm}}(1800 - 77)\}_{\text{O}_2} + \{168.31C_{\text{pm}}(1800 - 77)\}_{\text{N}_2} \\ &\quad + \{0.047C_{\text{pm}}(1800 - 77)\}_{\text{SO}_2} + 22.29 \times 18 \times 1050 \\ &= 3.60 \times 10^6 \text{ (Btu/h)} \end{aligned}$$

(c) For  $(H_{\text{sensible}})_{\text{inlet}}$  at  $77^\circ\text{F}$ :

$$\begin{aligned} (H_{\text{sensible}})_{\text{inlet}} &= \sum \{nC_{\text{pm}}(T - 77)\}_i, \quad i = \text{each flue gas species} \\ &= \{nC_{\text{pm}}(T - 77)\}_{\text{benzene}} + \{nC_{\text{pm}}(T - 77)\}_{\text{oil}} + \{nC_{\text{pm}}(T - 77)\}_{\text{air}} \\ &= \{100C_{\text{pm}}(77 - 77)\}_{\text{benzene}} + \{300C_{\text{pm}}(77 - 77)\}_{\text{oil}} \\ &\quad + \{213.05C_{\text{pm}}(77 - 77)\}_{\text{air}} \\ &= 0 \text{ (Btu/h)} \end{aligned}$$

Therefore,

$$\begin{aligned} Q &= -(\text{HHV})_{\text{total}} + (H_{\text{sensible}})_{\text{outlet}} - (H_{\text{sensible}})_{\text{inlet}} \\ &= -7.90 \times 10^6 + 3.60 \times 10^6 - 0 \\ &= -4.30 \times 10^6 \text{ (Btu/h)} \end{aligned}$$

**EXAMPLE 3** combustion of MSW with No. 2 oil  
Determine the required oil flow rate = ? (lbm/hr)

**Given conditions**

- Stream 1: municipal solid waste (MSW) at MSW flow rate = 500 lbm/h at 77°F  
 proximate analysis: moisture 32%  
                                   noncombustible 44%  
                                   combustible 24%  
 ultimate analysis (combustible portion):  
     C: 55 wt%  
     H: 20 wt%  
     Cl: 5 wt%  
     O: 10 wt%  
     N: 5 wt%  
     S: 5 wt%  
 higher heating value (HHV) = 4756 Btu/lbm MSW
- Stream 2: No. 2 oil (C: 0.872; H: 0.123; S: 0.005 by mass, HHV = 20,335.6 Btu/lbm)  
 Fractional excess air = 1.2 (at 77°F)  
 Flue gas temperature = 2000°F

*Solution*

The solution to this problem requires a trial and error approach. First, it will be assumed that no auxiliary fuel is required and the standard procedure will be followed to determine  $Q$ . If  $Q$  is less than or equal to 0, then the assumption is correct. If not, then the assumption is not correct and an oil flow rate will be guessed to repeat the trial and error procedure.

(A) Assume no auxiliary fuel is required, i.e., oil flow rate = 0 lbm/h.

Step 1. Determine the flow rate of moisture and noncombustible materials (inert), and molar flow rate of C, H, Cl, O, N, and S.

$$\begin{aligned}
 n_{\text{moisture}} &= 500 \times 0.32/18 = 8.89 \text{ lb-mole/h} \\
 n_{\text{inert}} &= 500 \times 0.44 = 220 \text{ lbm/h} \\
 n_{\text{C}} &= (500 \times 0.24 \times 0.55)/12 = 5.5 \text{ lb-mole/h} \\
 n_{\text{H}} &= (500 \times 0.24 \times 0.2)/1 = 24.0 \text{ lb-mole/h} \\
 n_{\text{Cl}} &= (500 \times 0.24 \times 0.05)/36.5 = 0.16 \text{ lb-mole/h} \\
 n_{\text{O}} &= (500 \times 0.24 \times 0.1)/16 = 0.75 \text{ lb-mole/h} \\
 n_{\text{N}} &= (500 \times 0.24 \times 0.05)/14 = 0.43 \text{ lb-mole/h} \\
 n_{\text{S}} &= (500 \times 0.24 \times 0.05)/32 = 0.19 \text{ lb-mole/h}
 \end{aligned}$$

Step 2. Determine the theoretical air requirement based on Eq. (2.44), i.e.,

$$\begin{aligned}
 n_{\text{s},\text{O}_2} &= n_{\text{C}} + (n_{\text{H}} - n_{\text{Cl}})/4 + n_{\text{S}} - n_{\text{O}}/2 \\
 &= 5.5 + (24.0 - 0.16)/4 + 0.19 - 0.75/2 \\
 &= 11.275 \text{ (lb-mole/h)}
 \end{aligned}$$

Therefore,

$$n_{\text{s},\text{air}} = 11.275/0.21 = 53.69 \text{ (lb-mole/h)}$$

Step 3. Determine the actual air supply based on the given value of fractional excess according to Eq. (2.50), i.e.,

$$\begin{aligned} n_{\text{air}} &= (1 + f)n_{\text{s,air}} \\ &= (1 + 1.2)(53.69) \\ &= 118.12 \text{ (lb-mole/h)} \end{aligned}$$

Therefore,

$$\begin{aligned} n_{\text{O}_2} &= 0.21n_{\text{air}} \\ &= 24.81 \text{ (lb-mole/h)} \end{aligned}$$

and

$$\begin{aligned} n_{\text{N}_2} &= 0.79n_{\text{air}} \\ &= 93.31 \text{ (lb-mole/h)} \end{aligned}$$

Step 4. Determine the molar flow rate of flue gas based on Eqs. (2.50)–(2.56), i.e.,

$$\begin{aligned} n_{\text{carbon dioxide}} &= n_{\text{C}} \\ &= 5.5 \text{ lb-mole/h} \\ n_{\text{water}} &= (n_{\text{H}} - n_{\text{Cl}})/2 + n_{\text{moisture}} \\ &= (24.0 - 0.16)/2 + 8.89 \\ &= 20.81 \text{ lb-mole/h} \\ n_{\text{hydrochloric acid}} &= n_{\text{Cl}} \\ &= 0.16 \text{ lb-mole/h} \\ n_{\text{sulfur dioxide}} &= n_{\text{S}} \\ &= 0.19 \text{ lb-mole/h} \\ n_{\text{oxygen}} &= n_{\text{O}}/2 + n_{\text{O}_2} - n_{\text{C}} - n_{\text{S}} - (n_{\text{H}} - n_{\text{Cl}})/4 \\ &= 0.75/2 + 24.81 - 5.5 - 0.19 - (24.0 - 0.16)/4 \\ &= 13.54 \text{ lb-mole/h} \\ n_{\text{nitrogen}} &= n_{\text{N}}/2 + n_{\text{N}_2} \\ &= 0.43/2 + 93.31 \\ &= 93.53 \text{ lb-mole/h} \end{aligned}$$

Step 5. Determine  $Q$  based on the given  $(\text{HHV})_{\text{MSW}}$  and Eq. (2.60), i.e.,

$$Q = -(\text{HHV})_{\text{total}} + (H_{\text{sensible}})_{\text{outlet}} - (H_{\text{sensible}})_{\text{inlet}}$$

(a) For  $(\text{HHV})_{\text{total}}$ :

$$\begin{aligned} (\text{HHV})_{\text{total}} &= \sum \{w(\text{HHV})\}_i, \quad i = \text{each inlet stream} \\ &= (500 \times 4756)_{\text{MSW}} \\ &= 2.38 \times 10^6 \text{ (Btu/h)} \end{aligned}$$

(b) For  $(H_{\text{sensible}})_{\text{outlet}}$  at  $2000^\circ\text{F}$ , based on Table 2.22:

$$C_{\text{pm,CO}_2,2000^\circ\text{F}} = 12.07 \text{ (Btu/lb-mole}^\circ\text{F)}$$

$$C_{\text{pm,H}_2\text{O},2000^\circ\text{F}} = 9.37 \text{ (Btu/lb-mole}^\circ\text{F)}$$

$$C_{\text{pm,HCl},2000^\circ\text{F}} = 7.70 \text{ (Btu/lb-mole}^\circ\text{F)}$$

$$C_{\text{pm,SO}_2,2000^\circ\text{F}} = 12.97 \text{ (Btu/lb-mole}^\circ\text{F)}$$

$$C_{\text{pm,O}_2,2000^\circ\text{F}} = 8.02 \text{ (Btu/lb-mole}^\circ\text{F)}$$

$$C_{\text{pm,N}_2,2000^\circ\text{F}} = 7.55 \text{ (Btu/lb-mole}^\circ\text{F)}$$

and, assuming

$$C_{\text{pm,inert},2000^\circ\text{F}} = 0.24 \text{ (Btu/lbm}^\circ\text{F)}$$

then

$$\begin{aligned} (H_{\text{sensible}})_{\text{outlet}} &= \sum \{nC_{\text{pm}}(T - 77)\}_i + n_{\text{water}}(\Delta H_v)_{\text{water}} \\ &= \{nC_{\text{pm}}(T - 77)\}_{\text{CO}_2} + \{nC_{\text{pm}}(T - 77)\}_{\text{H}_2\text{O}} + \{nC_{\text{pm}}(T - 77)\}_{\text{HCl}} \\ &\quad + \{nC_{\text{pm}}(T - 77)\}_{\text{SO}_2} + \{nC_{\text{pm}}(T - 77)\}_{\text{O}_2} + \{nC_{\text{pm}}(T - 77)\}_{\text{N}_2} \\ &\quad + \{nC_{\text{pm}}(T - 77)\}_{\text{inert}} + n_{\text{water}}(\Delta H_v)_{\text{water}} \\ &= \{5.5C_{\text{pm}}(2000 - 77)\}_{\text{CO}_2} + \{20.81C_{\text{pm}}(2000 - 77)\}_{\text{H}_2\text{O}} \\ &\quad + \{0.16C_{\text{pm}}(2000 - 77)\}_{\text{HCl}} + \{0.19C_{\text{pm}}(2000 - 77)\}_{\text{SO}_2} \\ &\quad + \{13.54C_{\text{pm}}(2000 - 77)\}_{\text{O}_2} + \{93.53C_{\text{pm}}(2000 - 77)\}_{\text{N}_2} \\ &\quad + \{220C_{\text{pm}}(2000 - 77)\}_{\text{inert}} + 20.81 \times 18 \times 1050 \\ &= 2.18 \times 10^6 + 0.39 \times 10^6 \\ &= 2.57 \times 10^6 \text{ (Btu/h)} \end{aligned}$$

(c) For  $(H_{\text{sensible}})_{\text{inlet}}$  at  $77^\circ\text{F}$ :

$$\begin{aligned} (H_{\text{sensible}})_{\text{inlet}} &= \sum \{nC_{\text{pm}}(T - 77)\}_i, \quad i = \text{each inlet stream} \\ &= \{nC_{\text{pm}}(T - 77)\}_{\text{MSW}} + \{nC_{\text{pm}}(T - 77)\}_{\text{air}} \\ &= \{500C_{\text{pm}}(77 - 77)\}_{\text{MSW}} + \{118.12C_{\text{pm}}(77 - 77)\}_{\text{air}} \\ &= 0 \text{ (Btu/h)} \end{aligned}$$

Therefore,

$$\begin{aligned} Q &= -(\text{HHV})_{\text{total}} + (H_{\text{sensible}})_{\text{outlet}} - (H_{\text{sensible}})_{\text{inlet}} \\ &= -2.38 \times 10^6 + 2.57 \times 10^6 - 0 \\ &= 0.19 \times 10^6 \text{ (Btu/h)} \end{aligned}$$

Discussion: since  $Q$  is positive, the assumption that no auxiliary fuel is required is not correct. To continue the trial and error procedure, assume oil flow rate = 100 lbm/h.

(B) Assume oil flow rate = 100 lbm/h

- Step 1. Determine the combined flow rate of moisture and noncombustible materials (inert), and molar flow rates of C, H, Cl, O, N, and S.  
 (a) MSW

$$\begin{aligned}
 n_{\text{moisture}} &= 500 \times 0.32/18 = 8.89 \text{ lb-mole/h} \\
 n_{\text{inert}} &= 500 \times 0.44 = 220 \text{ lbm/h} \\
 n_{\text{C}} &= (500 \times 0.24 \times 0.55)/12 = 5.5 \text{ lb-mole/h} \\
 n_{\text{H}} &= (500 \times 0.24 \times 0.2)/1 = 24.0 \text{ lb-mole/h} \\
 n_{\text{Cl}} &= (500 \times 0.24 \times 0.05)/36.5 = 0.16 \text{ lb-mole/h} \\
 n_{\text{S}} &= (500 \times 0.24 \times 0.05)/32 = 0.19 \text{ lb-mole/h} \\
 n_{\text{O}} &= (500 \times 0.24 \times 0.1)/16 = 0.75 \text{ lb-mole/h} \\
 n_{\text{N}} &= (500 \times 0.24 \times 0.05)/14 = 0.43 \text{ lb-mole/h}
 \end{aligned}$$

- (b) No. 2 oil

$$\begin{aligned}
 n_{\text{C}} &= (100 \times 0.872)/12 = 7.27 \text{ lb-mole/h} \\
 n_{\text{H}} &= (100 \times 0.123)/1 = 12.3 \text{ lb-mole/h} \\
 n_{\text{S}} &= (100 \times 0.005)/32 = 0.016 \text{ lb-mole/h}
 \end{aligned}$$

- (c) Combined (MSW + oil)

$$\begin{aligned}
 n_{\text{moisture}} &= 8.89 + 0 = 8.89 \text{ lb-mole/h} \\
 n_{\text{inert}} &= 220 + 0 = 220 \text{ lbm/h} \\
 n_{\text{C}} &= 5.5 + 7.27 = 12.77 \text{ lb-mole/h} \\
 n_{\text{H}} &= 24.0 + 12.3 = 36.30 \text{ lb-mole/h} \\
 n_{\text{Cl}} &= 0.16 + 0 = 0.16 \text{ lb-mole/h} \\
 n_{\text{S}} &= 0.19 + 0.016 = 0.21 \text{ lb-mole/h} \\
 n_{\text{O}} &= 0.75 + 0 = 0.75 \text{ lb-mole/h} \\
 n_{\text{N}} &= 0.43 + 0 = 0.43 \text{ lb-mole/h}
 \end{aligned}$$

- Step 2. Determine the theoretical air requirement based on Eq. (2.44), i.e.,

$$\begin{aligned}
 n_{\text{s},\text{O}_2} &= n_{\text{C}} + (n_{\text{H}} - n_{\text{Cl}})/4 + n_{\text{S}} - n_{\text{O}}/2 \\
 &= 12.77 + (36.3 - 0.16)/4 + 0.21 - 0.75/2 \\
 &= 21.64 \text{ (lb-mole/h)}
 \end{aligned}$$

Therefore

$$n_{\text{s},\text{air}} = 21.64/0.21 = 103.05 \text{ (lb-mole/h)}$$

- Step 3. Determine the actual air supply based on the given value of fractional excess according to Eq. (2.50), i.e.,

$$\begin{aligned}
 n_{\text{air}} &= (1 + f)n_{\text{s},\text{air}} \\
 &= (1 + 1.2)(103.05) \\
 &= 226.71 \text{ (lb-mole/h)}
 \end{aligned}$$

Therefore,

$$\begin{aligned}n_{\text{O}_2} &= 0.21n_{\text{air}} \\ &= 47.61 \text{ (lb-mole/h)}\end{aligned}$$

and

$$\begin{aligned}n_{\text{N}_2} &= 0.79n_{\text{air}} \\ &= 179.10 \text{ (lb-mole/h)}\end{aligned}$$

Step 4. Determine the molar flow rate of flue gas based on Eqs. (2.50)–(2.56), i.e.,

$$\begin{aligned}n_{\text{carbon dioxide}} &= n_{\text{C}} \\ &= 12.77 \text{ lb-mole/h} \\ n_{\text{water}} &= (n_{\text{H}} - n_{\text{Cl}})/2 + n_{\text{moisture}} \\ &= (36.3 - 0.16)/2 + 8.89 \\ &= 26.96 \text{ lb-mole/h} \\ n_{\text{hydrochloric acid}} &= n_{\text{Cl}} \\ &= 0.16 \text{ lb-mole/h} \\ n_{\text{sulfur dioxide}} &= n_{\text{S}} \\ &= 0.21 \text{ lb-mole/h} \\ n_{\text{oxygen}} &= n_{\text{O}}/2 + n_{\text{O}_2} - n_{\text{C}} - n_{\text{S}} - (n_{\text{H}} - n_{\text{Cl}})/4 \\ &= 0.75/2 + 47.61 - 12.77 - 0.21 - (36.3 - 0.16)/4 \\ &= 25.97 \text{ lb-mole/h} \\ n_{\text{nitrogen}} &= n_{\text{N}}/2 + n_{\text{N}_2} \\ &= 0.43/2 + 179.1 \\ &= 179.32 \text{ lb-mole/h}\end{aligned}$$

Step 5. Determine  $Q$  based on the given  $(\text{HHV})_{\text{MSW}}$  and Eq. (2.60), i.e.,

$$Q = -(\text{HHV})_{\text{total}} + (H_{\text{sensible}})_{\text{outlet}} - (H_{\text{sensible}})_{\text{inlet}}$$

(a) For  $(\text{HHV})_{\text{total}}$ :

$$\begin{aligned}(\text{HHV})_{\text{total}} &= \sum \{w(\text{HHV})\}_i, \quad i = \text{each inlet stream} \\ &= (500 \times 4756)_{\text{MSW}} + (100 \times 20,335.6)_{\text{oil}} \\ &= 4.41 \times 10^6 \text{ (Btu/h)}\end{aligned}$$

(b) For  $(H_{\text{sensible}})_{\text{outlet}}$  at 2000°F, based on Table 2.22:

$$C_{\text{pm,CO}_2,2000^\circ\text{F}} = 12.07 \text{ (Btu/lb-mole}^\circ\text{F)}$$

$$C_{\text{pm,H}_2\text{O},2000^\circ\text{F}} = 9.37 \text{ (Btu/lb-mole}^\circ\text{F)}$$

$$C_{\text{pm,HCl},2000^\circ\text{F}} = 7.70 \text{ (Btu/lb-mole}^\circ\text{F)}$$

$$C_{\text{pm,SO}_2,2000^\circ\text{F}} = 12.97 \text{ (Btu/lb-mole}^\circ\text{F)}$$

$$C_{\text{pm,O}_2,2000^\circ\text{F}} = 8.02 \text{ (Btu/lb-mole}^\circ\text{F)}$$

$$C_{\text{pm,N}_2,2000^\circ\text{F}} = 7.55 \text{ (Btu/lb-mole}^\circ\text{F)}$$

and, assuming

$$C_{\text{pm,inert},2000^\circ\text{F}} = 0.24 \text{ (Btu/lbm}^\circ\text{F)}$$

Then

$$\begin{aligned} (H_{\text{sensible}})_{\text{outlet}} &= \sum \{nC_{\text{pm}}(T - 77)\}_i + n_{\text{water}}(\Delta H_v)_{\text{water}} \\ &= \{nC_{\text{pm}}(T - 77)\}_{\text{CO}_2} + \{nC_{\text{pm}}(T - 77)\}_{\text{H}_2\text{O}} + \{nC_{\text{pm}}(T - 77)\}_{\text{HCl}} \\ &\quad + \{nC_{\text{pm}}(T - 77)\}_{\text{SO}_2} + \{nC_{\text{pm}}(T - 77)\}_{\text{O}_2} + \{nC_{\text{pm}}(T - 77)\}_{\text{N}_2} \\ &\quad + \{nC_{\text{pm}}(T - 77)\}_{\text{inert}} + n_{\text{water}}(\Delta H_v)_{\text{water}} \\ &= \{12.77C_{\text{pm}}(2000 - 77)\}_{\text{CO}_2} + \{26.96C_{\text{pm}}(2000 - 77)\}_{\text{H}_2\text{O}} \\ &\quad + \{0.16C_{\text{pm}}(2000 - 77)\}_{\text{HCl}} + \{0.21C_{\text{pm}}(2000 - 77)\}_{\text{SO}_2} \\ &\quad + \{25.97C_{\text{pm}}(2000 - 77)\}_{\text{O}_2} + \{179.32C_{\text{pm}}(2000 - 77)\}_{\text{N}_2} \\ &\quad + \{220C_{\text{pm}}(2000 - 77)\}_{\text{inert}} + 26.96 \times 18 \times 1050 \\ &= 3.90 \times 10^6 + 0.51 \times 10^6 \\ &= 4.41 \times 10^6 \text{ (Btu/h)} \end{aligned}$$

(c) For  $(H_{\text{sensible}})_{\text{inlet}}$  at  $77^\circ\text{F}$

$$\begin{aligned} (H_{\text{sensible}})_{\text{inlet}} &= \sum \{nC_{\text{pm}}(T - 77)\}_i, \quad i = \text{each inlet stream} \\ &= \{nC_{\text{pm}}(T - 77)\}_{\text{MSW}} + \{nC_{\text{pm}}(T - 77)\}_{\text{air}} \\ &= \{500C_{\text{pm}}(77 - 77)\}_{\text{MSW}} + \{226.71C_{\text{pm}}(77 - 77)\}_{\text{air}} \\ &= 0 \text{ (Btu/h)} \end{aligned}$$

Therefore

$$\begin{aligned} Q &= -(\text{HHV})_{\text{total}} + (H_{\text{sensible}})_{\text{outlet}} - (H_{\text{sensible}})_{\text{inlet}} \\ &= -4.41 \times 10^6 + 4.41 \times 10^6 - 0 \\ &= 0 \text{ (Btu/h)} \end{aligned}$$

Discussion: this calculation result indicates that the guessed oil flow rate, i.e., 100 lbm/h, is exact for the combustion process. Note that if there is heat loss involved in the process, then the oil flow rate must be increased correspondingly.

**EXAMPLE 4** combustion of MSW with preheated air  
Determine the required oil flow rate = ? (lbm/h).

**Given conditions**

- Stream 1: municipal solid waste (MSW)
  - MSW flow rate = 500 lbm/h at 77°F
  - proximate analysis: moisture 32%
  - noncombustible 44%
  - combustible 24%
  - ultimate analysis (combustible portion):
    - C: 55 wt%
    - H: 20 wt%
    - Cl: 5 wt%
    - O: 10 wt%
    - N: 5 wt%
    - S: 5 wt%
  - higher heating value (HHV) = 4756 Btu/lbm MSW
- Stream 2: No. 2 oil (C: 0.872; H: 0.123; S: 0.005 by mass, HHV = 20,355.6 Btu/lbm)
  - Fractional excess air = 1.2 (preheated to 300°F)
  - Flue gas temperature = 2000°F

*Solution:*

This problem is exactly identical to Example 3 except that the supplied air is preheated to 300°F instead of 77°F. Similar to that for Example 3, the solution to this problem requires a trial and error approach. First, it will be assumed that no auxiliary fuel is required.

(A) Assume no auxiliary fuel is required, i.e., oil flow rate = 0 lbm/h.

Step 1. Determine the flow rate of moisture and noncombustible materials (inert), and molar flow rate of C, H, Cl, O, N, and S.

$$\begin{aligned}
 n_{\text{moisture}} &= 500 \times 0.32/18 = 8.89 \text{ lb-mole/h} \\
 n_{\text{inert}} &= 500 \times 0.44 = 220 \text{ lbm/h} \\
 n_{\text{C}} &= (500 \times 0.24 \times 0.55)/12 = 5.5 \text{ lb-mole/h} \\
 n_{\text{H}} &= (500 \times 0.24 \times 0.2)/1 = 24.0 \text{ lb-mole/h} \\
 n_{\text{Cl}} &= (500 \times 0.24 \times 0.05)/36.5 = 0.16 \text{ lb-mole/h} \\
 n_{\text{O}} &= (500 \times 0.24 \times 0.1)/16 = 0.75 \text{ lb-mole/h} \\
 n_{\text{N}} &= (500 \times 0.24 \times 0.05)/14 = 0.43 \text{ lb-mole/h} \\
 n_{\text{S}} &= (500 \times 0.24 \times 0.05)/32 = 0.19 \text{ lb-mole/h}
 \end{aligned}$$

Step 2. Determine the theoretical air requirement based on Eq. (2.44), i.e.,

$$\begin{aligned}
 n_{\text{s},\text{O}_2} &= n_{\text{C}} + (n_{\text{H}} - n_{\text{Cl}})/4 + n_{\text{S}} - n_{\text{O}}/2 \\
 &= 5.5 + (24.0 - 0.16)/4 + 0.19 - 0.75/2 \\
 &= 11.275 \text{ (lb-mole/h)}
 \end{aligned}$$

Therefore,

$$n_{\text{s},\text{air}} = 11.275/0.21 = 53.69 \text{ (lb-mole/h)}$$

Step 3. Determine the actual air supply based on the given value of fractional excess according to Eq. (2.50), i.e.,

$$\begin{aligned} n_{\text{air}} &= (1 + f)n_{s,\text{air}} \\ &= (1 + 1.2)(53.69) \\ &= 118.12 \text{ (lb-mole/h)} \end{aligned}$$

Therefore,

$$\begin{aligned} n_{\text{O}_2} &= 0.21n_{\text{air}} \\ &= 24.81 \text{ (lb-mole/h)} \end{aligned}$$

and

$$\begin{aligned} n_{\text{N}_2} &= 0.79n_{\text{air}} \\ &= 93.31 \text{ (lb-mole/h)} \end{aligned}$$

Step 4. Determine the molar flow rate of flue gas based on Eqs. (2.50)–(2.56), i.e.,

$$\begin{aligned} n_{\text{carbon dioxide}} &= n_{\text{C}} \\ &= 5.5 \text{ lb-mole/h} \\ n_{\text{water}} &= (n_{\text{H}} - n_{\text{Cl}})/2 + n_{\text{moisture}} \\ &= (24.0 - 0.16)/2 + 8.89 \\ &= 20.81 \text{ lb-mole/h} \\ n_{\text{hydrochloric acid}} &= n_{\text{Cl}} \\ &= 0.16 \text{ lb-mole/h} \\ n_{\text{sulfur dioxide}} &= n_{\text{S}} \\ &= 0.19 \text{ lb-mole/h} \\ n_{\text{oxygen}} &= n_{\text{O}}/2 + n_{\text{O}_2} - n_{\text{C}} - n_{\text{S}} - (n_{\text{H}} - n_{\text{Cl}})/4 \\ &= 0.75/2 + 24.81 - 5.5 - 0.19 - (24.0 - 0.16)/4 \\ &= 13.54 \text{ lb-mole/h} \\ n_{\text{nitrogen}} &= n_{\text{N}}/2 + n_{\text{N}_2} \\ &= 0.43/2 + 93.31 \\ &= 93.53 \text{ lb-mole/h} \end{aligned}$$

Step 5. Determine  $Q$  based on the given  $(\text{HHV})_{\text{MSW}}$  and Eq. (2.60), i.e.,

$$Q = -(\text{HHV})_{\text{total}} + (H_{\text{sensible}})_{\text{outlet}} - (H_{\text{sensible}})_{\text{inlet}}$$

(a) For  $(\text{HHV})_{\text{total}}$ :

$$\begin{aligned} (\text{HHV})_{\text{total}} &= \sum \{w(\text{HHV})\}_i, \quad i = \text{each inlet stream} \\ &= (500 \times 4756)_{\text{MSW}} \\ &= 2.38 \times 10^6 \text{ (Btu/h)} \end{aligned}$$

(b) For  $(H_{\text{sensible}})_{\text{outlet}}$  at  $2000^\circ\text{F}$ , based on Table 2.22:

$$C_{\text{pm,CO}_2,2000^\circ\text{F}} = 12.07 \text{ (Btu/lb-mole}^\circ\text{F)}$$

$$C_{\text{pm,H}_2\text{O},2000^\circ\text{F}} = 9.37 \text{ (Btu/lb-mole}^\circ\text{F)}$$

$$C_{\text{pm,HCl},2000^\circ\text{F}} = 7.70 \text{ (Btu/lb-mole}^\circ\text{F)}$$

$$C_{\text{pm,SO}_2,2000^\circ\text{F}} = 12.97 \text{ (Btu/lb-mole}^\circ\text{F)}$$

$$C_{\text{pm,O}_2,2000^\circ\text{F}} = 8.02 \text{ (Btu/lb-mole}^\circ\text{F)}$$

$$C_{\text{pm,N}_2,2000^\circ\text{F}} = 7.55 \text{ (Btu/lb-mole}^\circ\text{F)}$$

and assuming

$$C_{\text{pm,inert},2000^\circ\text{F}} = 0.24 \text{ (Btu/lbm}^\circ\text{F)}$$

then

$$\begin{aligned} (H_{\text{sensible}})_{\text{outlet}} &= \sum \{nC_{\text{pm}}(T - 77)\}_i + n_{\text{water}}(\Delta H_v)_{\text{water}} \\ &= \{nC_{\text{pm}}(T - 77)\}_{\text{CO}_2} + \{nC_{\text{pm}}(T - 77)\}_{\text{H}_2\text{O}} + \{nC_{\text{pm}}(T - 77)\}_{\text{HCl}} \\ &\quad + \{nC_{\text{pm}}(T - 77)\}_{\text{SO}_2} + \{nC_{\text{pm}}(T - 77)\}_{\text{O}_2} + \{nC_{\text{pm}}(T - 77)\}_{\text{N}_2} \\ &\quad + \{nC_{\text{pm}}(T - 77)\}_{\text{inert}} + n_{\text{water}}(\Delta H_v)_{\text{water}} \\ &= \{5.5C_{\text{pm}}(2000 - 77)\}_{\text{CO}_2} + \{20.81C_{\text{pm}}(2000 - 77)\}_{\text{H}_2\text{O}} \\ &\quad + \{0.16C_{\text{pm}}(2000 - 77)\}_{\text{HCl}} + \{0.19C_{\text{pm}}(2000 - 77)\}_{\text{SO}_2} \\ &\quad + \{13.54C_{\text{pm}}(2000 - 77)\}_{\text{O}_2} + \{93.53C_{\text{pm}}(2000 - 77)\}_{\text{N}_2} \\ &\quad + \{220C_{\text{pm}}(2000 - 77)\}_{\text{inert}} + 20.81 \times 18 \times 1050 \\ &= 2.18 \times 10^6 + 0.39 \times 10^6 \\ &= 2.57 \times 10^6 \text{ (Btu/h)} \end{aligned}$$

(c) For  $(H_{\text{sensible}})_{\text{inlet}}$  at  $77^\circ\text{F}$  and  $300^\circ\text{F}$ :

$$\begin{aligned} (H_{\text{sensible}})_{\text{inlet}} &= \sum \{nC_{\text{pm}}(T - 77)\}_i, \quad i = \text{each inlet stream} \\ &= \{nC_{\text{pm}}(T - 77)\}_{\text{MSW}} + \{nC_{\text{pm}}(T - 77)\}_{\text{air}} \\ &= \{500C_{\text{pm}}(77 - 77)\}_{\text{MSW}} + \{118.12C_{\text{pm}}(300 - 77)\}_{\text{air}} \\ &= 0 + 118.12 \times 7.04 \times 223 \\ &= 0.19 \times 10^6 \text{ (Btu/h)} \end{aligned}$$

Therefore,

$$\begin{aligned} Q &= -(\text{HHV})_{\text{total}} + (H_{\text{sensible}})_{\text{outlet}} - (H_{\text{sensible}})_{\text{inlet}} \\ &= -2.38 \times 10^6 + 2.57 \times 10^6 - 0.19 \times 10^6 \\ &= 0 \text{ (Btu/h)} \end{aligned}$$

Discussion: this calculation result indicates that no auxiliary fuel is required if the air is preheated to  $300^\circ\text{F}$ . Note that its effectiveness is equivalent to adding 100 lbm/h of the No. 2 oil as auxiliary fuel, as calculated in Example 3.

## Nomenclature for this example

- $C_{\text{pm,CO}_2}$  = heat capacity of  $\text{CO}_2(\text{g})$ , Btu/lb-mole $^\circ\text{F}$
- $C_{\text{pm,HCl}}$  = heat capacity of  $\text{HCl}(\text{g})$ , Btu/lb-mole $^\circ\text{F}$
- $C_{\text{pm,H}_2\text{O}}$  = heat capacity of  $\text{H}_2\text{O}(\text{g})$ , Btu/lb-mole $^\circ\text{F}$
- $C_{\text{pm,inert}}$  = heat capacity of inert materials, Btu/lbm $^\circ\text{F}$
- $C_{\text{pm,N}_2}$  = heat capacity of  $\text{N}_2(\text{g})$ , Btu/lb-mole $^\circ\text{F}$
- $C_{\text{pm,O}_2}$  = heat capacity of  $\text{O}_2(\text{g})$ , Btu/lb-mole $^\circ\text{F}$
- $C_{\text{pm,SO}_2}$  = heat capacity of  $\text{SO}_2(\text{g})$ , Btu/lb-mole $^\circ\text{F}$
- $f$  = fractional excess of oxygen or air supply
- $H_{\text{sensible}}$  = enthalpy relative to process species at  $77^\circ\text{F}$ , Btu
- $(H_{\text{sensible}})_{\text{inlet}}$  = total inlet rate of  $H_{\text{sensible}}$  defined in Eq. (2.62), Btu/h
- $(H_{\text{sensible}})_{\text{outlet}}$  = total outlet rate of  $H_{\text{sensible}}$  defined in Eq. (2.61), Btu/h
- $H_{\text{total}}$  = enthalpy relative to atomic species at  $77^\circ\text{F}$ , Btu
- $(H_{\text{total}})_{\text{inlet}}$  = total inlet rate of  $H_{\text{total}}$ , Btu/h
- $(H_{\text{total}})_{\text{outlet}}$  = total outlet rate of  $H_{\text{total}}$ , Btu/h
- HHV = higher heating value, Btu/lbm or Btu/lb-mole
- $(\text{HHV})_{\text{methane}}$  = HHV of methane, Btu/lb-mole
- $(\text{HHV})_{\text{total}}$  = total inlet rate of HHV, Btu/h
- $M$  = molecular weight, lbm/lb-mole
- $M_{\text{benzene}}$  = molecular weight of benzene, 78 lbm/lb-mole
- $n_{\text{air}}$  = molar flow rate of air supply, lb-mole/h
- $n_{\text{C}}$  = molar flow rate of C in an inlet stream, lb-mole/h
- $n_{\text{CH}_4}$  = molar flow rate of methane, lb-mole/h
- $n_{\text{Cl}}$  = molar flow rate of Cl in an inlet stream, lb-mole/h
- $n_{\text{carbon dioxide}}$  = molar flow rate of  $\text{CO}_2(\text{g})$  in the outlet stream, lb-mole/h
- $n_{\text{H}}$  = molar flow rate of H in an inlet stream, lb-mole/h
- $n_{\text{hydrochloric acid}}$  = molar flow rate of  $\text{HCl}(\text{g})$  in the outlet stream, lb-mole/h
- $n_{\text{inert}}$  = molar flow rate of inert, lbm/h
- $n_{\text{moisture}}$  = molar flow rate of water in an inlet stream, lb-mole/h
- $n_{\text{nitrogen}}$  = molar flow rate of  $\text{N}_2(\text{g})$  in the outlet stream lb-mole/h
- $n_{\text{N}}$  = molar flow rate of N in an inlet stream, lb-mole/h
- $n_{\text{N}_2}$  = molar flow rate of  $\text{N}_2$  in air supply, lb-mole/h
- $n_{\text{O}}$  = molar flow rate of O in an inlet stream, lb-mole/h
- $n_{\text{O}_2}$  = molar flow rate of  $\text{O}_2$  in air supply, lb-mole/h
- $n_{\text{oxygen}}$  = molar flow rate of  $\text{O}_2(\text{g})$  in the outlet stream, lb-mole/h
- $n_{\text{S}}$  = molar flow rate of S in an inlet stream, lb-mole/h
- $n_{\text{s,air}}$  = theoretical air required for complete combustion, lb-mole/h
- $n_{\text{s,O}_2}$  = theoretical oxygen required for complete combustion, lb-mole/h
- $n_{\text{sulfur dioxide}}$  = molar flow rate of  $\text{SO}_2(\text{g})$  in the outlet stream, lb-mole/h
- $n_{\text{water}}$  = molar flow rate of  $\text{H}_2\text{O}(\text{g})$  in the outlet stream, lb-mole/h
- $P$  = pressure, psia

- $Q$  = rate of heat transfer, Btu/h
- $R$  = gas constant, 10.73 (psia-ft<sup>3</sup>)/lb-mole-°R
- $T$  = temperature, °F or °R
- $V$  = volume flow rate, ft<sup>3</sup>/h
- $X_C$  = mass fraction of carbon in an inlet stream
- $X_{Cl}$  = mass fraction of chlorine in an inlet stream
- $X_H$  = mass fraction of hydrogen in an inlet stream
- $X_O$  = mass fraction of oxygen in an inlet stream
- $X_S$  = mass fraction of sulfur in an inlet stream
- $w$  = mass or mole flow rate of an inlet stream, lbm/h or lb-mole/h
- $(\Delta H_v)_{\text{water}}$  = heat of vaporization of water at 77°F, Btu/lb-mole

## 4 BASIC INCINERATOR DESIGN

---

This section describes the key items needed for the design of waste incinerators. These include:

- adiabatic temperature
- waste properties
- auxiliary fuel
- incinerator design calculation
- system design feature
- refractory selection
- exhaust gas monitoring
- acid gas corrosion

### 4.1 Adiabatic Temperature

The temperature at which a waste will burn without considering process losses is its adiabatic temperature. These process losses would include radiation losses from the furnace walls and heat lost in the ash discharge. The adiabatic temperature is a function of the waste combustible heating value, waste combustible content, moisture content and excess air requirement. As a first-order approximation of adiabatic temperature for any combustible material, the as-received waste heating value can be used. Figure 2.10 is a graph of adiabatic temperature versus gross (as-received or as-fired) heating value for various values of excess air. It is applicable for any material, liquid, solid, or gas. Excess air values for typical furnaces are given in Table 2.23 (OME-88/12, p. 4-12).

Using Fig. 2.10, for example, a waste with an as-received heating value of 8000 kJ/kg (3440 Btu/lb) is burned in a fluid bed incinerator using 60% excess air. As an example, the combustion of this waste is assumed to require 1000°C (1830°F) for effective destruction. From the graph, the adiabatic temperature is approximately 900°C (1650°F), and therefore supplemental fuel is required to achieve a combustion temperature of 1000°C (1830°F).

This graph gives an approximate temperature of combustion and provides an indication of whether or not to proceed with a detailed analysis of incinerator parameters.

FIGURE 2.10 Adiabatic temperature vs. excess air (OME-88/12, p. 4-11).

TABLE 2.23 Typical Excess Air Values

Incinerator type	Excess air range
Fluid bed	40-60
Gaseous waste	10-15
Liquid waste	15-30
Multiple chamber (retort, in-line)	100-200
Multiple hearth	100-125
Rotary kiln	100
Waterwall	65-100

## 4.2 Incinerator Step-by-step Calculation

There are a number of incinerator parameters that are normally of interest, including:

- furnace temperature
- supplemental fuel requirement
- combustion air requirement
- flue gas discharge quantity
- residence time
- turbulence/mixing

From these parameters, the sizes of equipment associated with the incinerator system can be calculated.

Table 2.24 (OME-88/12, p. 4-14) represents a step-by-step method of analysis for an incinerator system (see sludge incineration sample calculations in Chapter 2.3). It is a simplified mass and heat balance calculation. The feed quantity, moisture fraction, noncombustible fraction, and combustible heating value must be known. An excess air and humidity figure must be selected, as well as a reasonable radiation loss figure (from 1% to 5% of the total heat release) and an ash heat content (as will normally represent a heat loss in the range 160–340 kJ/kg [69–146 Btu/lb] of ash). The required gas temperature for destruction of the waste stream must be selected.

This analysis is a detailed heat balance based on the principle that the total heat leaving (exiting) a system is equal to the heat entering that system. Heat entering a system includes the potential heat release of a waste, and/or fuel, that is fired within that system.

One important assumption made in this analysis is that flue gas from an incinerator is composed of moisture plus dry air. Actual incinerator off-gas contains more carbon dioxide and less oxygen than is found in air. The assumption that dry flue gas has the properties of air, however, greatly simplifies calculations while introducing a relatively small error (less than 3%) in calculated temperatures and heat requirements.

The air quantities required to support combustion must be determined to perform these calculations. If the exact waste composition is known, the air requirements can be determined by calculation from the equilibrium equations, as follows:

- for combustion of carbon,  $C + O_2 \rightarrow CO_2$
- for combustion of hydrogen,  $H_2 + 0.5O_2 \rightarrow H_2O$
- for sulfur,  $S + O_2 \rightarrow SO_2$

With each kilogram of oxygen, nitrogen is present in air:

- 1 kg air = 0.2315 kg  $O_2$  + 0.7685 kg  $N_2$
- 1 kg oxygen carries 3.3197 kg nitrogen from air

Usually there is some uncertainty about the range of waste composition and properties. The curves in Figs. 2.11 and 2.12 were generated based on the DuLong equation. Using this equation, a relationship between the composition and heating value was established and plotted. Figure 2.11 relates the stoichiometric air requirements to heating value; Fig. 2.12 relates moisture produced from combustion to heating value. These values are approximate, recognizing that the DuLong equation represents only an estimate of heating value.

Figures 2.13 and 2.14 and Table 2.25 indicate the net heat available from supplemental fuel combustion in an incineration process. As the temperature of the process (the incinerator exit temperature) increases, the heat required to raise the temperature of the products of combustion of supplemental fuel to the incinerator exit temperature increases. The heat available for process heating (the net heating value) is the heat of combustion of the fuel less heat lost to the

**TABLE 2.24** Incinerator Analysis

Step	Description	Calculation	Unit
1	Waste feed rate (given)		kg/h
2	Water fraction in waste (given)		
3	Water quantity in waste (step 1 $\times$ 2)		kg/h
4	Solid quantity (step 1 – step 3)		kg/h
5	Noncombustible fraction (given)		
6	Noncombustible quantity (step 4 $\times$ 5)		kg/h
7	Combustible quantity (step 4 – step 6)		kg/h
8	Heating value of combustibles (given)		kJ/kg
9	Total heat generated (step 7 $\times$ 8)		kJ/h
10	Theoretical (stoichiometric) air ratio (Fig. 2.11)		
11	Theoretical air (step 7 $\times$ 10)		kg/h
12	Excess air fraction (given)		
13	Excess air required (step 11 $\times$ 12)		kg/h
14	Total air required (steps 11 + 13)		kg/h
15	Water formed due to combustion of combustible waste (Fig. 2.12)		kg-water/ kg-combustible
16	Total water due to combustion (step 7 $\times$ 15)		kg/h
17	Humidity in air (given)		kg-water/kg-air
18	Water due to humidity (step 14 $\times$ 17)		kg/h
19	Total water in flue gas (steps 3 + 16 + 18)		kg/h
20	Dry flue gas (steps 7 + 14–16)		kg/h
21	Radiation loss fraction (given)		
22	Radiation heat loss (step 9 $\times$ 21)		kJ/h
23	Ash heating value (given)		kJ/kg
24	Ash heat loss (step 6 $\times$ 23)		kJ/kg
25	Humidity correction due to latent heat (step 18) $\times$ 2186		kJ/h
26	Miscellaneous heat loss (given)		kJ/h
27	Heat in flue gas (steps 9 – 22 – 24 + 25 – 26)		kJ/h
28	Estimate flue gas temperature*		$^{\circ}\text{C}$
29	Required gas temperature (given)		$^{\circ}\text{C}$
30	Required enthalpy of flue gas <sup>†</sup>		kJ/h
31	Net heat required (step 30 – step 27)		kJ/h
32	Fuel excess air (given)		
33	Fuel heating value at required temperature (Fig. 2.13 or 2.14)		kJ/L
34	Fuel required (step 31/33)		L/h
35	Air for fuel (Table 2.25)		kg air/L
36	Total air required for fuel (step 35 $\times$ 34)		kg/h
37	Moisture from fuel (Table 2.25)		kg/L
38	Moisture generated (step 37 $\times$ 34)		kg/h
39	Dry flue gas from fuel combustion (Table 2.25)		kg/L
40	Dry gas generated (step 39 $\times$ 34)		kg/h
41	Total dry gas flow (steps 40 + 20)		kg/h
42	Total moisture flow (steps 38 + 19)		kg/h
43	Fuel gross heating value (Table 2.25)		kJ/L
44	Heat generated from fuel (step 43 $\times$ 34)		kJ/h
45	Total heat at exit (steps 44 + 27)		kJ/h

\* Calculation for step 28. The flue gas temperature can be calculated from the heat in the flue and Figs. 2.15 and 2.16. The procedure involves estimating a temperature, calculating the flue gas enthalpy, and comparing the calculated enthalpy with the enthalpy in step 27. Repeat these steps until the calculated enthalpy and the enthalpy in step 27 are nearly equal. Actual calculations are as in the next footnote.

<sup>†</sup> Calculation for step 30. The required enthalpy of the flue gas can be calculated from the required temperature, 760 $^{\circ}\text{C}$ , and Figs. 2.15 and 2.16. The procedures are similar to those in the previous footnote.

FIGURE 2.11 Air required from theoretical combustion (OME-88/12, p. 4-16).

FIGURE 2.12 Water produced from combustion (zero humidity) (OME-88/12, p. 4-17).

FIGURE 2.13 Net heat available from No. 2 fuel (OME-88/12, p. 4-18).

TABLE 2.25 Supplemental Fuel Combustion

No. 2 fuel oil, heat content 39,100 kJ/L, density 0.91 kg/L

Percent excess air	10	20	30
kg air/L	13.78	15.03	16.29
kg dry gas/L*	13.84	15.09	16.34
kg water/L*	1.04	1.05	1.07

Natural gas, heat content 37,256 kJ/m<sup>3</sup>, density 0.80 kg/m<sup>3</sup>

Percent excess air	5	10	15
kg-air/m <sup>3</sup>	12.09	12.66	13.24
kg-dry-air/m <sup>3</sup> *	11.4	11.97	12.55
kg-water/m <sup>3</sup> *	1.65	1.65	1.66

\* Products of combustion.

products of combustion of supplemental fuel. The available heat, therefore, decreases with increasing temperature, as shown in Figs. 2.13 and 2.14 for No. 2 fuel oil and natural gas, respectively. The net heating value must be used in incinerator calculations.

### 4.3 Incinerator Residence Time

Residence time means the length of time that the combustion gas is exposed to the combustion temperature in an incinerator. It can be expressed as:

$$t = V/q$$

where  $t$  = residence time  
 $V$  = combustion chamber volume  
 $q$  = combustion gas flow rate

Time and temperature affect combustion in much the same manner as temperature and pressure affect the volume of a gas. When one variable is increased, the other may be decreased with the same end result. With a higher temperature, a shorter residence time can achieve the same degree of oxidation. The reverse is also true; a higher residence time allows the use of a lower temperature. In describing an incinerator operation, these two terms are always mentioned together. One has little meaning without specifying the other.

The choice between higher temperature or longer residence time is based on economic considerations. Increasing residence time involves using a larger combustion chamber, resulting in a higher capital cost. Raising the operating temperature increases fuel usage which also adds to the operating costs. Fuel costs are the major operating expense for most incinerators. Within certain limits, lowering the temperature and adding volume to increase residence time can be a cost-effective alternative method of operation.

Once again, the residence time of gases in the combustion chamber may be calculated from

$$t = V/Q$$

where  $t$  = residence time  
 $V$  = volume of incinerator chamber  
 $Q$  = gas volumetric flow rate at combustion conditions

$Q$  is the total flow of hot gases in the combustion chamber. Adjustments to the flow rate must include any outside air added for combustion.

References used in this section: EPA-81/09, p. 4-98; EPA-81/12, p. 3-7.

**EXAMPLE 1** residence time

Calculate the maximum achievable gas residence time in an incinerator after the desired operating temperature has been achieved.

Case 1. Use the following given conditions to calculate:

- (1) the maximum achievable gas residence time after the desired operating temperature has been achieved;
- (2) the required volume of the incinerator chamber.

Case 2. If the operating temperature  $T_2 = 2000^\circ\text{F}$ , answer the same questions.

Case 3. If the incinerator requires a minimum residence time of 2 s, calculate the required volume of the incinerator for cases 1 and 2.

**Given conditions**

The data in question are summarized below:

- standard volumetric flow rate in the combustion chamber,  $Q_1 = 1000$  scfm
- standard conditions  $T_1 = 60^\circ\text{F}$  and  $P_1 = 1$  atm
- combustion chamber temperature  $T_2 = 1500^\circ\text{F}$
- volume of incinerator chamber  $V = 120$  ft<sup>3</sup>

*Solution for case 1*

1.1 Write the ideal gas equation for the actual volumetric flow rate (acfm) calculation.

$$Q_2 = Q_1(T_2/T_1)(P_1/P_2)$$

where

- $Q_2$  = actual volumetric flow rate
- $Q_1$  = standard volumetric flow rate
- $T_2$  = actual operating temperature, °R or K
- $T_1$  = standard temperature, °R or K
- $P_2$  = actual operating pressure
- $P_1$  = standard pressure

Note: in general,  $P_1 = P_2$  for an incinerator.

1.2. Calculate the actual volumetric flow rate,  $Q_2$ .

$$\begin{aligned} Q_2 &= (1000)[(460 + 1500)/(460 + 60)] \\ &= 3769 \text{ acfm (actual cubic feet per minute)} \\ &= 62.82 \text{ acfs (actual cubic feet per second)} \end{aligned}$$

1.3. Write the residence time equation.

$$\begin{aligned} t &= V/Q_2 \\ &= 120/62.82 \\ &= 1.91 \text{ s} \end{aligned}$$

*Solution for case 2*

2.1. Write the ideal gas equation for the actual volumetric flow rate (acfm) calculation.

$$Q_2 = Q_1(T_2/T_1)(P_1/P_2)$$

2.2. Calculate the actual volumetric flow rate  $Q_2$ .

$$\begin{aligned} Q_2 &= (1000)[(460 + 2000)/(460 + 60)] \\ &= 4731 \text{ acfm} \\ &= 78.85 \text{ acfs} \end{aligned}$$

2.3. Write the residence time equation.

$$\begin{aligned} t &= V/Q_2 \\ &= 120/78.85 \\ &= 1.52 \text{ s} \end{aligned}$$

*Note:* the results of cases 1 and 2 show that the higher the operating temperature, the shorter the residence time.

*Solution for case 3*

3.1. Write the volume equation from either sub-section 1.3 or 2.3.

$$V = Q_2 t$$

3.2. Calculate the incinerator volume for case 1.

$$\begin{aligned} V &= 62.82(2) \\ &= 126 \text{ ft}^3 \end{aligned}$$

3.3. Calculate the incinerator volume for case 2.

$$\begin{aligned} V &= 78.85(2) \\ &= 158 \text{ ft}^3 \end{aligned}$$

#### 4.4 Incinerator Retention Time

Retention time means the length of time that solid materials remain in the primary combustion chamber during incineration. It can be expressed as

$$t = 0.19(L)/(DSN)$$

where  $t$  = retention time in minutes  
 $L$  = kiln length in ft  
 $D$  = kiln diameter in ft  
 $S$  = slope of kiln ft/ft  
 $N$  = rotation velocity in rpm

References used in this section: EPA-81/09, p. 4-104; EPA-86/03, p. 98.

##### **EXAMPLE** retention time

A rotary kiln is used to incinerate solid waste. Calculate:

- (1) retention time
- (2) if the solid waste requires at least 60 min of retention time, determine the rotational velocity with kiln slope remaining unchanged, or
- (3) determine the kiln slope with rotational velocity remaining unchanged.

**Given conditions**

The data in question are summarized below:

- kiln length,  $L = 20$  ft
- kiln diameter,  $D = 6$  ft
- kiln slope,  $S = 0.02$  ft/ft
- rotation velocity,  $N = 1.5$  rpm

*Solution for question (1)*

1.1. Write the retention time equation.

$$t = 0.19(L)/(DSN)$$

1.2. Calculate the retention time.

$$\begin{aligned} t &= 0.19(20)/[6(0.02)(1.5)] \\ &= 21.11 \text{ min} \end{aligned}$$

*Solution for question (2)*

2.1. Write the rotational velocity equation.

$$N = 0.19(L)/(DS t)$$

2.2. Calculate the rotational velocity.

$$\begin{aligned} N &= 0.19(20)/(6(0.02)(60)) \\ &= 0.53 \text{ rpm} \end{aligned}$$

*Solution for question (3)*

3.1. Write the rotational velocity equation.

$$S = 0.19(L)/(DNt)$$

3.2. Calculate the rotational velocity.

$$\begin{aligned} S &= 0.19(20)/[6(1.5)(60)] \\ &\cong 0.01 \text{ rpm} \end{aligned}$$

## 4.5 Duct Sizing

Ducts convey air and are normally sized to provide no more than 12 m/s (40 ft/s) air flow velocity. Higher velocities result in excessive noise and excessive pressure drop.

## 4.6 Flue Sizing

Flues carry gaseous products of combustion (flue gas) from an incinerator. They are generally sized to allow no more than 9 m/s (30 ft/s) gas flow. At higher velocities the particulate normally present in the exhaust will tend to accelerate flue erosion.

## 4.7 Chamber Sizing

Chamber sizing is based on heat release. There is a limit to the quantity of heat that can be released in a particular furnace chamber. Heat release is that amount of heat generated when combustible material burns. When combustible gases burn or when liquids burn in suspension, the volume of the furnace chamber will limit the total amount of heat released within that chamber. The furnace volume must be large enough to allow release of the heat generated by the anticipated waste and the supplemental fuel.

When a solid or sludge waste is fired, the heat release (heat generated per chamber volume or hearth area per hour) of that waste is characterized by the area of the surface on which it is placed, i.e., the hearth or grate.

Table 2.26 (OME-88/12, p. 1-22) lists typical heat release values for some common incinerator systems. The calculated heat release is determined by dividing the value in step 45 of Table 2.24 (which includes heat released from the waste plus the heat released from supplemental fuel) by the hearth or grate area (or chamber volume).

As an example of the use of this information, a reasonable size of a rotary kiln used for destruction of 2000 kg/h (4410 lb/h) waste with a heat content of 17,000 kJ/kg (7309 Btu/lb) is calculated as described below.

$$(2000 \text{ kg/h})(17,000 \text{ kJ/kg}) = 34,000,000 \text{ kJ/h}$$

Using a 1,000,000 kJ/m<sup>3</sup>-h heat release rate,

$$(34,000,000 \text{ kJ/h}) / (1,000,000 \text{ kJ/m}^3\text{-h}) = 34 \text{ m}^3 (1200 \text{ ft}^3) \text{ volume}$$

For a kiln with a 2.5 m internal diameter (unit cross sectional area = 4.91 m<sup>2</sup>), the required length is 34 m<sup>3</sup>/4.91 m<sup>2</sup> = 6.93 m (22.7 ft).

The kiln for this application would have an internal diameter of 2.5 m (8.2 ft) and a length of 7.0 m (23 ft).

In general, an incinerator volume can be calculated by two approaches.

Approach 1: by incinerator dimensions. For example, the volume of a rotary kiln can be calculated by the equation

$$V = \pi(r^2)(L)$$

where  $r$  = radius of the kiln  
 $L$  = length of the kiln

Approach 2: by heat release rate.

**TABLE 2.26** Typical Heat Release Rates

Incinerator	Heat release
Fluid bed*	350,000–500,000 kJ/m <sup>2</sup> -h (bed-area)
Multiple chamber	300,000–400,000 kJ/m <sup>3</sup> -h
Multiple hearth	300,000–400,000 kJ/m <sup>3</sup> -h
Multiple hearth heat release*	250,000–350,000 kJ/m <sup>2</sup> -h (hearth area)
Gaseous waste incinerator	3,000,000–10,000,000 kJ/m <sup>3</sup> -h
Liquid waste incinerator	1,000,000–3,000,000 kJ/m <sup>3</sup> -h
Rotary kiln	500,000–1,500,000 kJ/m <sup>3</sup> -h
Solid waste grate*	150,000–300,000 kJ/m <sup>2</sup> -h (grate area)

\*These heat release values are based on surface area, not volume.

**EXAMPLE 1** incinerator volume

An incinerator is used to incinerate waste with the following given conditions. Calculate the maximum waste burning rate.

**Given conditions**

- incinerator energy release rate  $Q_r = 30,000 \text{ Btu}/(\text{h}\cdot\text{ft}^3)$
- combustion chamber volume  $V = 800 \text{ ft}^3$
- waste heating value  $H = 9500 \text{ Btu}/\text{lb}$

*Solution:*

1. Calculate the incinerator maximum heat capacity  $Q$ .

$$\begin{aligned} Q &= Q_r V \\ &= 30,000(800) \\ &= 2.40 \times 10^7 \text{ Btu/h} \end{aligned}$$

2. Calculate the maximum waste burning rate  $W$ .

$$\begin{aligned} W &= Q/H \\ &= 2.40 \times 10^7 / 9500 \\ &= 2526 \text{ lb/h} \end{aligned}$$

**EXAMPLE 2** incinerator volume

A rotary kiln was designed to have an average energy release rate of  $28,500 \text{ Btu}/\text{h}\cdot\text{ft}^3$  in the combustion chamber. It is anticipated that the kiln will be used to incinerate  $4000 \text{ lb}/\text{h}$  of solid waste which has heating value as high as  $9500 \text{ Btu}/\text{lb}$ . Assume that the length-to-diameter ratio of the kiln is 3.5. Determine (1) the volume of the kiln, and (2) the diameter of the kiln.

**Given conditions**

- energy release rate:  $Q_r = 28,500 \text{ Btu}/\text{h}\cdot\text{ft}^3$
- waste feed rate  $W = 4000 \text{ lb}/\text{h}$
- heating value of the waste  $H = 9500 \text{ Btu}/\text{lb}$
- length-to-diameter ratio  $L/D = 3.5$

*Solution:*

1. Calculate the amount of heat released by the waste  $Q$ .

$$\begin{aligned} Q &= (4000 \text{ lb}/\text{h})(9500 \text{ Btu}/\text{lb}) \\ &= 3.80 \times 10^7 \text{ Btu/h} \end{aligned}$$

2. Calculate the combustion chamber volume.

$$\begin{aligned} V &= Q/Q_r \\ &= 3.80 \times 10^7 / (28,500 \text{ Btu}/\text{h}\cdot\text{ft}^3) \\ &= 1333 \text{ ft}^3 \end{aligned}$$

3. Calculate the diameter of the kiln.

$$\begin{aligned} V &= \pi(D/2)^2(L) \\ D^3 &= 1333(4)/[\pi(3.5)] \\ &= 485 \text{ ft}^3 \\ D &= 7.86 \text{ ft} \end{aligned}$$

4. Calculate the length of the kiln.

$$\begin{aligned} L &= 3.5D \\ &= 3.5(7.86) \\ &= 27.51 \text{ ft} \end{aligned}$$

## 4.8 Turbulence and Mixing

In order to achieve high combustion efficiency in incinerators, it is particularly important to achieve good mixing between the primary combustion products (primarily CO and organics) and a stoichiometric excess secondary combustion air. This mixing can be promoted by a range of physical parameters as well as by promoting highly turbulent flow of the gases. Physical parameters which are used to promote mixing include:

- location and direction of secondary air jets
- volume and pressure of secondary air addition
- changes in flow direction(s)
- other baffling techniques

As well as the provision of overall mixing using the above methods, the eddies formed by turbulent flow promote local mixing of the combustible gases and air. The degree of turbulence is typically assessed by use of the Reynolds number  $Re$ :

$$Re = VD/K$$

where  $V$  = average velocity, m/s  
 $D$  = diameter (or equivalent diameter) of flow stream, m  
 $K$  = kinematic viscosity, m<sup>2</sup>/s.

Figure 2.17 shows the relationship between the kinematic viscosity and temperature. When the Reynolds number is below 2300 (defined as the critical Reynolds number), flow is generally considered laminar with no significant turbulence.

As a guide, the gas flow within an incinerator chamber or flue should have a Reynolds number well above 10,000. As an example of this calculation, assume a flue exiting a furnace has an internal diameter of 2 m (6.6 ft). The gas flow is at a temperature of 1000°C (1832°F), and is at a velocity of 10 m/s (33 ft/s). From the figure,  $K = 140 \times 10^{-6}$  m<sup>2</sup>/s at 1000°C. Therefore,

$$Re = VD/K = 10(2)/140 \times 10^{-6} = 143,000$$

A Reynolds number of 143,000, in combination with good mixing, should be ample to provide high combustion efficiency and burnout.

For a rectangular or other shape of flue, the equivalent diameter ( $D_e$ ) should be used. For example, for a rectangle,  $D_e$  is equal to four times the cross-sectional area divided by the wetted perimeter, i.e.,

$$D_e = 2ab/(a + b)$$

where  $a$  and  $b$  are the dimensions of the sides of the rectangle. For example,  $a = 2$  m and  $b = 3$  m. Therefore,  $D_e = 2(2)(3)/(2 + 3) = 2.4$  m. This value of  $D_e$  would be used in lieu of  $D$  when applied to a noncircular cross section.

#### 4.9 Fan Sizing

The fan power requirement is a function of air or gas flow rate (cubic meter per second), the pressure developed across the fan (kilopascals), and the fan efficiency. The efficiency of fans located downstream of air pollution control systems (clean gas) is normally in the range 80–85%; fans located upstream of control devices (dirty gas) require specific designs which may be limited to the range 60–75% efficiency. Efficiency will also drop as the fan becomes dirty, or when fan material erodes with wear. The fan power consumption is calculated as follows:

$$S = QW_p/h$$

where  $Q$  = flow rate, m<sup>3</sup>/s  
 $Wp$  = pressure across fan, kPa  
 $h$  = fan efficiency  
 $S$  = fan power consumption, kW

The flow rate of air or gas is determined from the incinerator calculations procedure described above. Typical pressure drops for fans associated with incinerator systems are listed in Table 2.27 (OME-88/12, p. 4-28). These pressure values are values developed across the fan and should be used as  $Wp$  in the above equation.

#### 4.10 Induced Fan Sizing

An induced draft fan (ID fan) is the fan at the discharge of an incinerator that draws flue gas from the incinerator and discharges the gas through a stack to the atmosphere. Many incinerators such as multiple hearth furnaces, grate type systems, and rotary kilns, use ID fans.

Hot exhaust gases leaving incinerators may first be cooled by passage through a heat recovery section and/or passage through a water quench. Normally, sufficient water will be added to the hot gas stream to saturate that gas stream before entering the ID fan. When a fabric filter or an electrostatic precipitator is included within the system, only a limited amount of water is added; the gas flow would not be saturated and less water would be required.

Figure 2.18 relates the gas flow rate of saturated gas to dry air flow as a function of temperature. Determination of this ratio is necessary to allow a determination of the fan size. As noted previously, the assumption that flue gas has a dry component with the properties of dry air is used in these calculations.

As an example, if an ID fan is placed downstream of a wet scrubber which passes 18,000 kg/h (39,683 lb/h) of dry gas at a temperature of 50°C (122°F) entering the ID fan, the flow rate is calculated as follows.

From Fig. 2.18, at 50°C (122°F), 1 kg of dry air will have a volume of 1.03 m<sup>3</sup> (36 ft<sup>3</sup>) when saturated with water. The 18,000 kg/h dry gas will therefore produce (18,000 kg/h) (1.03 m<sup>3</sup>/kg), or 18,540 m<sup>3</sup>/h of flue gas entering the ID fan. The ID fan can be sized on the basis of this flow.

#### 4.11 Electric Power Requirements

As a general rule, when an ID fan is used in an incineration system, the total electric power requirements of that system can be approximated as double the ID fan rated kW. If an ID fan is not used, the power rating of each of the major items of equipment must be determined and totaled to obtain the facility power requirement.

**TABLE 2.27** Typical Fan Pressure Drop Values

Fan type	Pressure drop
Forced draft	1.0–1.5 kPa
Heated gas recirculation	1.0–2.0 kPa
Induced draft	5.0–15.0 kPa
Supplemental fuel combustion air	0.2–0.5 kPa
Fluidizing air blower	1.2–5.0 kPa

*Note:* The above values are typical of the pressure drop across a particular fan usage that should be used in determining fan power requirements.

#### 4.12 Refractory Selection

Refractory selection involves the following factors:

- refractory parameters
- castables (refractory concrete)
- firebrick
- incinerator refractory selection

**Refractory parameters.** There are a wide variety of refractory and insulation products available. Their significant properties include those listed below.

- Abrasion: the washing away or physical destruction of material under forces due to physical contact with the gaseous, liquid, or solid materials on the hot face.
- Resistance to slagging or corrosion (chemical processes that destroy the refractory bond or the chemical integrity of the insulation).

- Mechanical shock or cold crushing strength: the ability to withstand handling and shipping without damage and impact strength at low temperature operations.
- Modulus of rupture: a standard measure of structural strength provided by load testing (ASTM Methods C16 and C216), providing another measure of mechanical shock resistance.
- Spalling: a deterioration of the surface of the refractory by flaking caused by abrasion, corrosion, or mechanical or thermal shock.
- Porosity: the susceptibility to penetration by slags or gases, indicative of fly ash adherence.
- Maintaining strength under high temperature conditions.
- Insulating value: the ability to provide resistance to the flow of heat.
- Reheat (ASTM Method C113): a measure of irreversible changes in linear dimensions under repeated heating and cooling.
- Specific heat: the amount of heat required to raise the temperature of a refractory material.
- Thermal expansion: the reversible change in linear dimensions under heating and cooling. Where the refractory is used as a liner in a flue, for instance, the expansion of the refractory must be evaluated with respect to thermal expansion of the flue; if the expansions do not match, provision for material expansion must be considered.
- Resistance to the operating environment: of particular interest is the performance of refractory in an oxidizing or reducing atmosphere. A reducing atmosphere, one deficient in oxygen, will tend to degrade refractory material containing iron or silicon components.

**Castables (refractory concrete).** These materials are supplied dry and are to be mixed with water before installation. They are installed by either pouring (casting in place), troweling, pneumatic gunning (as with gunned fireproofing), or ramming. A castable refractory should provide a smooth, continuous, monolithic mass. Castable materials are normally placed in an area with pins, mesh, or other anchor devices to hold the refractory in place during placement and curing. Mesh, grid, studs, or needles may also be used to enhance the strength of the refractory installation.

Castable refractories are classified as dense or lightweight (insulating). Dense castables have excellent mechanical strength and low permeability. Their insulating properties, however, are relatively poor. As dense materials, over  $1600 \text{ kg/m}^3$  ( $100 \text{ lb/ft}^3$ ) specific weight, they offer good resistance in wet service such as quencher linings.

Lightweight castables are excellent insulators. Castable materials have the advantage of relatively easy installation in irregular areas such as furnace transitions, burner openings, etc. Lightweight castable service temperatures are generally limited to below  $1650^\circ\text{C}$  ( $3000^\circ\text{F}$ ), whereas other castable refractories can sustain higher temperatures.

**Firebrick.** Conventional firebrick is kiln-baked to uniform, controlled consistency and quality. The term firebrick refers to dense brick, over  $1600 \text{ kg/m}^3$  ( $100 \text{ lb/ft}^3$ ), containing up to 44% alumina, normally placed in direct contact with the hot gas stream. Conventional firebrick has relatively poor insulating qualities.

Insulating firebrick (IFB) is a lightweight, porous brick, normally less than  $800 \text{ kg/m}^3$  ( $50 \text{ lb/ft}^3$ ), which can be placed in direct contact with the gas stream and which provides good insulating characteristics. IFB is machined to its final shape, providing excellent dimensional control as compared with conventional firebrick which is used as cast.

IFB is lower in structural strength than firebrick and, because of its porosity, is a soft material not suitable for erosive gas streams, i.e., gas streams with high particulate components. This low abrasion resistance limits the maximum velocities allowed adjacent to it.

Where refractory brick is required and high abrasive resistance is necessary, firebrick will often be provided with an insulation block as backup between the firebrick and the furnace/flue wall.

Silicon carbide refractory has relatively good thermal conductivity, good mechanical resistance, and abrasion resistance.

There are numerous types and grades of firebrick such as super-duty (high alumina content, improved strength and stability properties at high temperature), high-duty (good thermal shock resistance), low-duty (applicable for lower temperature and low abrasion service), and silicon carbide (excellent resistance to chemical attack), etc.

**Incinerator refractory selection.** Table 2.28 (OME-88/12, p. 4-35) describes typical refractory applications for various incinerator sections.

### 4.13 Exhaust Gas Monitoring

Permanently mounted instrumentation is required for the measurement of temperatures, total hydrocarbons (or carbon monoxide), and opacity. Additionally, oxygen, carbon dioxide, and nitrogen oxides monitoring may be required.

As a minimum, temperature should be monitored and recorded for the gas leaving the furnace and the exhaust gas exiting the stack. Gaseous monitors should be located as close as practicable to the furnace exhaust point.

Special care must be exercised in locating opacity meters on systems which incorporate wet gas cleaning devices (such as a venturi scrubber). Entrained and/or condensing moisture downstream will appear and will affect the opacity reading. An upstream location will provide an indication of particulate and other carryover from the incinerator.

### 4.14 Acid Gas Corrosion

The exhaust gases from incinerators usually contain HCl, SO<sub>2</sub>, and other acidic gases. Special design considerations may be necessary where:

- gas temperatures will be below 150°C (300°F; potential for acid gas condensation), and/or
- heat recovery media (e.g., boiler tubes) will be above 370°C (700°F; potential for acid gas corrosion).

## 5 SYSTEM CALCULATIONS

---

### 5.1 Sludge Incineration

A stream of dewatered sludge is fed to a multiple hearth incinerator (Fig. 2.19) at the rate of 5000 kg/h. The sludge is 75% water and has 12.5% noncombustible (ash). The heating value of the combustible fraction has been determined to be 23,000 kJ/kg. This is to be burned using 100% excess air with fuel oil (20% excess air) as auxiliary fuel. Standard air is available at 15.5°C and 60% relative humidity, which is equivalent to a humidity of 0.00657 kg moisture per kg of dry air. Radiant heat losses are estimated at 1% of the heat released from the waste. The ash is estimated to remove 200 kJ/kg ash from the incinerator. The exhaust gas temperature is to be maintained at 760°C (OME-88/12, p. C.3-1).

The solution to this problem is provided below by using the information (tables and figures) in Section 4.2 and Table 2.29.

**TABLE 2.28** Refractory Selection for Incinerators

Incinerator part	Temperature range (°C)	Abrasion	Slagging	Mechanical shock	Spalling	Fly ash adherence	Recommended refractory
Charging gate	20–1400	Severe, very important	Slight	Severe	Severe	None	Super-duty
Furnace walls, grate to 2 m above	20–1400	Severe	Severe, very important	Severe	Severe	None	Silicon carbide or super-duty
Furnace walls, upper portion	20–1400	Slight	Severe	Moderate	Severe	None	Super-duty
Stoking doors	20–1400	Severe, very important	Severe	Severe	Severe	None	Super-duty
Furnace ceiling	20–1400	Slight	Moderate	Slight	Severe	Moderate	Super-duty
Flue from combustion chamber	650–1400	Slight	Severe, very important	None	Moderate	Moderate	Silicon carbide or super-duty
Combustion chamber	650–1400	Slight	Moderate	None	Moderate	Moderate	Super-duty
Combustion chamber ceiling	650–1400	Slight	Moderate	None	Moderate	Moderate	Super-duty
Breeching walls	650–1650	Slight	Slight	None	Moderate	Moderate	Super-duty
Breeching ceiling	650–1650	Slight	Slight	None	Moderate	Moderate	Super-duty
Subsidence chamber walls	650–1650	Slight	Slight	None	Slight	Moderate	Firebrick or super-duty
Subsidence chamber ceiling	650–1650	Slight	Slight	None	Slight	Moderate	Firebrick or super-duty
Stack	260–540	Slight	None	None	Slight	Slight	Firebrick or super-duty

**TABLE 2.29** Sludge Incinerator Analysis

Step	Description	Calculation	Unit
1	Waste feed rate (given)	5000	kg/h
2	Water fraction in waste (given)	0.75	
3	Water quantity in waste (step 1 $\times$ 2)	3750.00	kg/h
4	Solid quantity (step 1 – step 3)	1250.00	kg/h
5	Noncombustible fraction (given)	0.125	
6	Noncombustible quantity (step 4 $\times$ 1)	625.00	kg/h
7	Combustible quantity (step 4 – step 6)	625.00	kg/h
8	Heating value of combustibles (given)	23,000	kJ/kg
9	Total heat generated (step 7 $\times$ 8)	14,375,000.00	kJ/h
10	Theoretical (stoichiometric) air ratio (see Fig. 2.11)*	7	
11	Theoretical air (step 7 $\times$ 10)	4375.00	kg/h
12	Excess air fraction (given)	1	
13	Excess air required (step 11 $\times$ 12)	4375.00	kg/h
14	Total air required (steps 11 + 13)	8750.00	kg/h
15	Water formed due to combustion of combustible waste (see Fig. 2.12)*	0.52	kg-water/ kg-combustible
16	Total water due to combustion (step 7 $\times$ 15)	325.00	kg/h
17	Humidity in air (given)	0.00657	kg-water/kg-air
18	Water due to humidity (steps 14 $\times$ 17)	57.49	kg/h
19	Total water in flue gas (steps 3 + 16 + 18)	4132.49	kg/h
20	Dry flue gas (steps 7 + 14 – 16)	9050.00	kg/h
21	Radiation loss fraction (given)	0.01	
22	Radiation heat loss (step 9 $\times$ 21)	143,750.00	kJ/h
23	Ash heating value (given)	200	kJ/kg
24	Ash heat loss (step 6 $\times$ 23)	125,000.00	kJ/h
25	Humidity correction due to latent heat (step 18) $\times$ 2186	125,673.14	kJ/h
26	Miscellaneous heat loss (given)	0	kJ/h
27	Heat in flue gas (steps 9 – 22 – 24 + 25 – 26)	14,231,923.14	kJ/h
28	Estimate flue gas temperature (see note 1 calculation below)	258	°C
29	Required gas temperature (given)	760	°C
30	Required enthalpy of flue gas (see note 2 calculation below)	23,547,625	kJ/h
31	Net heat required (step 30 – step 27)	9,315,701.99	kJ/h
32	Fuel excess air (20% excess air, given)	0.2	
33	Fuel heating value at required temperature (Figs. 2.13 or 2.14)	22,000	kJ/L
34	Fuel required (step 31/33)	423.44	L/h
35	Air for fuel (see Table 2.25)*	15.03	kg air/L
36	Total air required for fuel (step 35 $\times$ 34)	6364.30	kg/h
37	Moisture from fuel (see Table 2.25)*	1.05	kg/L
38	Moisture generated (step 37 $\times$ 34)	444.61	kg/h
39	Dry flue gas from fuel combustion (see Table 2.25)*	15.09	kg/L
40	Dry gas generated (step 39 $\times$ 34)	6389.71	kg/h
41	Total dry gas flow (steps 40 + 20)	15,439.71	kg/h
42	Total moisture flow (steps 38 + 19)	4577.10	kg/h
43	Fuel gross heating value (Table 2.25)	39,100	kJ/L
44	Heat generated from fuel (step 43 $\times$ 34)	16,556,504.00	kJ/h
45	Total heat at exit (steps 44 + 27)	30,788,427.14	kJ/h

\* See Section 4.2.

FIGURE 2.19 Multiple hearth incinerator (DOE-93/03, p. C-5).

NOTE 1: Calculation for step 28

The flue gas temperature can be calculated from the heat content (enthalpy) in the flue gas (step 27) and the enthalpy in Figs. 2.15 and 2.16. The procedure involves estimating a temperature and calculating the flue gas enthalpy by using the enthalpy values obtained from the figures and the water mass in step 19 and dry flue gas in step 20. The calculated gas enthalpy is then compared with the enthalpy in step 27. Repeat these steps until the calculated enthalpy and the enthalpy in step 27 are nearly equal. Actual calculations are given in detail below.

Assume that the flue gas exit temperature is 200°C.

- From Fig. 2.15, moisture enthalpy = 2790 kJ/kg
- From Fig. 2.16, dry air enthalpy = 190 kJ/kg
- Total enthalpy = 190(9050) + 2790(4132) = 13,249,140.13 kJ/h. This value is less than the value of 14,231,923.14 in step 27.

Assume that the exit temperature is 400°C.

- From Fig. 2.15, moisture enthalpy = 3200 kJ/kg
- From Fig. 2.16, dry air enthalpy = 380 kJ/kg
- Total enthalpy = 380(9050) + 3200(4132) = 16,662,960 kJ/h. This value is greater than the value of 14,231,923.14 in step 27.

The kiln temperature ( $x$ ) is estimated by the following interpolation method.

$x_1$	200°C	$1.32E + 07$ kJ/h	$y_1$
Estimate	$x$	$1.42E + 07$	$y$
$x_2$	400°C	$1.67E + 07$	$y_2$

$$(x - x_1)/(y - y_1) = (x_2 - x_1)/(y_2 - y_1)$$

$$x = x_1 + (y - y_1)(x_2 - x_1)/(y_2 - y_1)$$

$$x = 257.58^\circ\text{C}$$

NOTE 2: Calculation for step 30

The required enthalpy of flue gas can be calculated from required temperature 760°C and Figs. 2.15 and 2.16.

- From Fig. 2.15, moisture enthalpy = 3990 kJ/kg
- From Fig. 2.16, dry air enthalpy = 780 kJ/kg
- Total enthalpy =  $780(9050) + 3990(4132) = 23,547,625.13$  kJ/h

## 5.2 Refuse Incineration

Refuse at 50 tonnes per day (2083 kg/h) is to be incinerated. It has a moisture content of 24%, a heating value of 11,000 kJ/kg as received and an ash (noncombustible) content of 11% as received. The incinerator is of grate design, and requires 85% excess air for complete combustion. A minimum temperature of 980°C is required for effective burnout. Assume an ash content of 250 kJ/kg, 2% radiation heat loss, and a humidity of 0.00657 kg/kg dry air. Calculations follow and are summarized in Table 2.30, this refuse incinerator analysis (OME-88/12, p. 3-7).

The solution to this problem is provided below by using the information (tables and figures) in Section 4.2.

NOTE 1: Calculation for step 28

The flue gas temperature can be calculated from the heat content (enthalpy) in the flue gas (step 27) and the enthalpy in Figs. 2.15 and 2.16. The procedure involves estimating a temperature and calculating the flue gas enthalpy by using the enthalpy values obtained from these figures and the water mass in step 19 and dry flue gas in step 20. The calculated gas enthalpy is then compared with the enthalpy in step 27. Repeat these steps until the calculated enthalpy and the enthalpy in step 27 are nearly equal. Actual calculations are given in detail below.

Assume that the flue gas exit temperature is 1000°C.

- From Fig. 2.15, moisture enthalpy = 4590 kJ/kg
- From Fig. 2.16, dry air enthalpy = 1070 kJ/kg
- Total enthalpy =  $1165.84(4590) + 13,542.06(1070) = 19,841,209$  kJ/h. This value is less than the value of 22,580,760.35 in step 27.

Assume that the exit temperature is 1200°C.

- From Fig. 2.15, moisture enthalpy = 5060 kJ/kg
- From Fig. 2.16, dry air enthalpy: 1300 kJ/kg
- Total enthalpy =  $1165.84(5060) + 13,542.06(1300) = 23,503,828.40$  kJ/h. This value is less than the value of 22,580,760.35 in step 27.

**TABLE 2.30** Refuse Incinerator Analysis

Step	Description	Calculation	Unit
1	Waste feed rate (given)	2083	kg/h
2	Water fraction in waste (given)	0.24	
3	Water quantity in waste (step 1 $\times$ 2)	499.92	kg/h
4	Solid quantity (step 1 – step 3)	1583.08	kg/h

44	Heat generated from fuel (step 43 $\times$ 34)	0.00	kJ/h
45	Total heat at exit (steps 44 + 27)	22,580,760.35	kJ/h

\* See Section 4.2.

The furnace temperature ( $x$ ) is estimated by the following interpolation method.

$x_1$	1000°C	1.98 E + 07 kJ/h	$y_1$
Estimate	$x$	2.26 E + 07	$y$
$x_2$	1200	2.35 E + 07	$y_2$

$$(x - x_1)/(y - y_1) = (x_2 - x_1)/(y_2 - y_1)$$

$$x = x_1 + (y - y_1)(x_2 - x_1)/(y_2 - y_1)$$

$$x = 1149.60^\circ\text{C}$$

### 5.3 Starved Air Incineration

For the previous example (heating value = 11,000 kJ/kg), it was assumed that the waste was incinerated in a starved air unit consisting of two chambers, and the total gas flow and heat release from the system would be the same. Conditions at the exit of the primary chamber could be calculated as follows, assuming 60% of the stoichiometric air requirement was provided in the primary chamber.

The heating value of the combustible content would not be fully realized in the primary chamber because only 60% of the stoichiometric air requirement is provided. From Fig. 2.20, at 60% of stoichiometric, 72% of the total heat capacity of the combustibles is released, which is  $0.72(16,928.33) \text{ kJ/kg} = 12,188.40 \text{ kJ/kg}$ . The air requirement is based on 16,928.33 kJ/kg, while moisture generation is based on 12,188.40 kJ/kg actual heat release. Calculations follow, and are summarized in Table 2.31 for the analysis of a starved air refuse incinerator.

The solution to this problem is provided by using the information (tables and figures) in Section 4.2.

NOTE 1: Calculation for step 28

The flue gas temperature can be calculated from the heat content (enthalpy) in the flue gas (step 27) and the enthalpy in Figs. 2.15 and 2.16. The procedure involves estimating a temperature and calculating the flue gas enthalpy by using the enthalpy values obtained from these figures and the water mass in step 19 and dry flue gas in step 20. The calculated gas enthalpy is then compared with the enthalpy in step 27. Repeat these steps until the calculated enthalpy and the enthalpy in step 27 are nearly equal. Actual calculations are given in detail below.

Assume that the exit temperature is 1200°C.

- From Fig. 2.15, moisture enthalpy = 5060 kJ/kg
- From Fig. 2.16, dry air enthalpy: 1300 kJ/kg
- Total enthalpy =  $960.26(5060) + 5062.20(1300) = 11,439,775.60 \text{ kJ/h}$ . This value is less than the value of 16,169,511.31 in step 27. The temperature exiting the primary chamber is therefore in excess of 1200°C.

### 5.4 Furnace

The combustion chamber is a volume where the fuel and air mixture (in proper proportions) is exposed to an ignition source and burned. The residence time needed to achieve complete oxidation of the fuel depends on the temperature maintained in the combustion chamber, commonly referred to as the *furnace*. From the temperature effect on the reaction rate, the higher the furnace temperature, the faster the oxidation reaction and hence the smaller the furnace would need to be. This size reduction, however, is limited by Charles' Law.

Adiabatic flame temperatures, which are the highest temperatures which may theoretically be attained in the furnace, are for most fuels considerably higher than the commonly used

furnace materials can tolerate. Uncooled furnace walls constructed of refractory materials normally require the furnace gas temperatures not to exceed 1800–2200°F. Furnace temperature control, therefore, takes on primary importance. This can be accomplished by:

1. using excess air in quantities sufficient to produce the desired temperature;
2. heat removal across heat transfer surfaces;
3. some combination of (1) and (2).

**EXAMPLE 1** furnace temperature

Consider a furnace burning No. 6 fuel oil having a specific gravity of 0.986, a HHV of 18,640 Btu/lb, and an ultimate analysis of 85.7% C, 10.5% H<sub>2</sub>, 0.92% O<sub>2</sub>, 2.8% S, 0.08% ash, and a net heating value, NHV, of 17,620 Btu/lb (EPA-80/02, p. 4-3).

**TABLE 2.31** Starved Air Incinerator Analysis

Step	Description	Calculation	Unit
1	Waste feed rate (given)	2083	kg/h
2	Water fraction in waste (given)	0.24	
3	Water quantity in waste (step 1 × 2)	499.92	kg/h
4	Solid quantity (step 1 – step 3)	1583.08	kg/h
5	Dry base of noncombustible fraction = (wet fraction)/ (1-water fraction) = 0.11/(1 – 0.24)	0.145	
6	Noncombustible quantity (step 4 × 5)	229.55	kg/h
7	Combustible quantity (step 4 – step 6)	1353.53	kg/h
8	Heating value of combustibles = 11,000(2083/1353.53) = 16,928.33. From Fig. 2.11, at 60% of stoichiometric air, 72% of the total heat capacity is released, i.e., 0.72(16,928.33) = 12,188.40	12,188.4	kJ/kg
9	Total heat generated (step 7 × 8)	16,497,365.05	kJ/h
10	Theoretical (stoichiometric) air ratio (based on 16,928.33 from Fig. 2.11)*	5.1	kg-air/ kg-combustible
11	Theoretical air (step 7 × 10)	6903.00	kg/h
12	Excess air fraction (60% stoichiometric air = –40% excess air, given)	–0.4	
13	Excess air required (step 11 × 12)	–2761.20	kg/h
14	Total air required (steps 11 + 13)	4141.80	kg/h
15	Water formed due to combustion of combustible waste (based on 12,188.40 from Fig. 2.12)*	0.32	kg-water/ kg-combustible
16	Total water due to combustion (step 7 × 15)	433.13	kg/h
17	Humidity in air (given)	0.00657	kg-water/kg-air
18	Water due to humidity (step 14 × 17)	27.21	kg/h
19	Total water in flue gas (steps 3 + 16 + 18)	960.26	kg/h
20	Dry flue gas (steps 7 + 14 – 16)	5062.20	kg/h
21	Radiation loss fraction (given)	0.02	
22	Radiation heat loss (step 9 × 21)	329,947.30	kJ/h
23	Ash heating value (given)	250	kJ/kg
24	Ash heat loss (step 6 × 23)	57,387.50	kJ/kg
25	Humidity correction due to latent heat (step 18) × 2186	59,481.06	kJ/h
26	Miscellaneous heat loss (given)	0	kJ/h
27	Heat in flue gas (steps 9 – 22 – 24 + 25 – 26)	16,169,511.31	kJ/h
28	Estimate flue gas temperature (see note 1 calculation below)	>1200	°C
29	Required gas temperature (given)	–	°C
30	Required enthalpy of flue gas	–	kJ/h
31	Net heat required (step 30 – step 27)	–	kJ/h
32	Fuel excess air (20% excess air, given)	–	
33	Fuel heating value at required temperature (Figs. 2.13 or 2.14)*	–	kJ/L
34	Fuel required (step 31/33)	None	L/h
35	Air for fuel (see Table 2.25)*	–	kg air/L
36	Total air required for fuel (step 35 × 34)	–	kg/h
37	Moisture from fuel (see Table 2.25)*	–	kg/L
38	Moisture generated (step 37 × 34)	–	kg/h
39	Dry flue gas from fuel combustion (see Table 2.25)*	–	kg/L
40	Dry gas generated (step 39 × 34)	–	kg/h
41	Total dry gas flow (steps 40 + 20)	5062.20	kg/h
42	Total moisture flow (steps 38 + 19)	960.26	kg/h
43	Fuel gross heating value (Table 2.25)*	–	kJ/L
44	Heat generated from fuel (step 43 × 34)	–	kJ/h
45	Total heat at exit (steps 44 + 27)	16,169,511.31	kJ/h

\* See Section 4.2.

Determine:

- The furnace gas temperature with the following system design alternatives.
  - Adiabatic combustion (no loss or useful heat transfer) with stoichiometric air.
  - Stoichiometric air, and 5% energy loss from the furnace to the surroundings.
- Excess air or heat transfer necessary to achieve 2200°F furnace temperature.
  - Excess air but no heat transfer other than 5% energy loss.
  - Excess air limited to 10%, 5% energy loss, and heat transfer is needed to limit the temperature to 2200°F.

**Given conditions**

The data in question are summarized below.

- specific gravity of No. 6 oil  $S_g = 0.986$
- high heating value (HHV) = 18,640 Btu/lb
- net heating value (NHV) = 17,620 Btu/lb
- ultimate analysis of No. 6 oil:

$$C = 0.857$$

$$H_2 = 0.105$$

$$O_2 = 0.0092$$

$$S = 0.028$$

$$\text{Ash} = 0.0008$$

- sum of the ultimate analysis = 1.00

*Solution for Case 1*

First we need to determine the amount of stoichiometric (theoretical) air required for complete combustion (Table 2.32). The amount of combustion air can be found by applying the method in Section 2.6. Assume 1.0 lb/h of No. 6 fuel oil fed.

For the No. 6 fuel oil given here, air required for complete combustion from the calculation contained in Table 2.32 is

$$A_t = 13.4883 \text{ lb-air/lb-oil}$$

When a fuel is burned, mass must be conserved. It is possible then to predict the mass of combustion gas from the air required and the combustible matter actually burned (Table 2.33). The mass of flue gas produced is calculated by applying the method in Section 2.6.

**CHECK ON MASS BALANCE:** The above calculations show that the flow rate of total reactants ( $R_a$ ) and total products ( $P_a$ ) are considered to be equal (14.5, accurate to one decimal point). Also from the above calculations, the actual combustion flue gas  $G_a$  becomes the theoretical combustion flue gas because there are no excess air components in the calculation. Let  $G_t$  be the theoretical combustion flue gas, so that

$$G_t = G_a$$

The noncombustibles here are either the ash in the fuel or the ash together with the unburned combustibles in solid form. Gaseous unburned components would remain part of the flue gas. With one pound of fuel as a basis,  $G_t$  for the No. 6 oil specified here becomes

$$G_t = 14.5 \text{ lb-air/lb-oil}$$

The mass of each individual gas in the product can be calculated, and an average or effective specific heat ( $C_p$ ) for the mixture can be computed. A value applicable to oil combustion gas temperatures is approximately 0.25 Btu/lb-°F. With this value, one can estimate the adiabatic flame temperature  $t_{ad}$  from

$$H = G_t C_p (t_{ad} - t_a) \tag{2.64}$$

- where  $H$  = net heating value
- $G_t$  = theoretical combustion flue gas
- $t_{ad}$  = adiabatic combustion temperature
- $t_a$  = combustion air intake temperature, initial temperature (100°F)

Substitute the proper numbers into the above equation and solve for  $t_{ad}$ .

**TABLE 2.32** Combustion Reactant Table

Basic reaction	Oxygen, nitrogen, and air requirements	Mass (lb/h)	Mole (mol/h)
$C + O_2 \rightarrow CO_2$	(1) $O_2 = C(32/12)$	2.2853	0.0714
$H_2 + 0.5O_2 \rightarrow H_2O$	(2) $O_2 = 8(H-Cl/35.5)^*$	0.8400	0.0263
$S + O_2 \rightarrow SO_2$	(3) $O_2 = S(32/32) = S$	0.0280	0.0009
$B_o =$ bound oxygen	(4) Data from waste analysis	0.0092	0.0003
$O_{2t} =$ theoretical $O_2$	$O_{2t} = (1) + (2) + (3) - (4)$	3.1441	0.0983
$N_{2t} =$ theoretical $N_2$	$N_{2t} = (O_{2t})(3.76 \times 28/32)$	10.3442	0.3694
$A_t =$ theoretical air	$A_t = O_{2t} + N_{2t}$	13.4883	0.4677
$\%A_e =$ % excess air	Given data	0.0000	
$A_e =$ excess air	$A_e = (\%A_e)(A_t)$	0.0000	0.0000
$A_{ada} =$ actual dry air	$A_{ada} = A_t + A_e$	13.4883	0.4677
$H_2O$ from air†	$0.0127(A_{ada}) = N/A$	0.0000	0.0000
$A_a =$ actual air	$A_a = A_{ada} + H_2O$	13.4883	0.4677
Waste feed	Data from waste analysis	1.0000	
$R_a =$ actual reactant	$R_a = A_a +$ waste feed + $H_2O$ from air	14.4883	

\* If  $H_2$  is the hydrogen left over after Cl reaction, i.e.,  $H_2 = H-Cl/35.5$ , the  $O_2$  needed to react with  $H_2$  will be equal to  $H_2(0.5)(32/2) = 8(H-Cl/35.5)$ .

† In general, at room temperature, the humidity ratio is 0.0127 (lb- $H_2O$ )/(lb-dry-air) or 0.0127 (kg- $H_2O$ )/(kg-dry-air).

**TABLE 2.33** Combustion Product Table

Component	Combustion product	Mass (lb/h)	Mole (mol/h)
$CO_2$	$CO_2 = C(44/12)$	3.1423	0.0714
$SO_2$	$SO_2 = S(64/32)$	0.0560	0.0009
HCl	$HCl = Cl(36.5/35.5)$	0.0000	0.0000
$O_{2e}$	$(\%A_e)O_{2t}$ , $O_{2t}$ from Table 2.32	0.0000	0.0000
$N_{2e}$	$(\%A_e)N_{2t}$ , $N_{2t}$ from Table 2.32	0.0000	
$N_2$	$N_{2e} + N_{2t} +$ from waste	10.3400	0.3693
$H_2O$ from combustion	$H_2O$ from combustion = $9(H-Cl/35.5)$	0.9450	
$H_2O$	$H_2O$ from combustion + from air + from waste	0.9450	0.0525
$G_a =$ actual flue gas	$G_a = CO_2 + SO_2 + HCl + O_{2e} + N_2 + H_2O$	14.4833	0.4941
Ash	Fly ash + bottom ash	0.0008	
$P_a =$ actual product*	$P_a = G_a +$ ash	14.4841	

\* In performing the mass balance calculation, the values of reactants ( $R_a$ ) and products ( $P_a$ ) should be equal, i.e., if  $R_a = P_a$ , the mass balance calculation is correct.

$$\begin{aligned}
 17,620 &= 14.5(0.25)(t_{\text{ad}} - 100) \\
 t_{\text{ad}} &= 100 + 17,620/(14.51(0.25)) \\
 &= 4957^\circ\text{F}
 \end{aligned}$$

Note that this temperature is considerably greater than the furnace materials of construction can tolerate. Therefore, case 1 is not a viable option.

*Solution for Case 2*

A second approach involves predicting the gas temperature when the system has heat transfer losses to the structure and surroundings. Equation (2.64) must be modified by the loss term  $Q_L$  to yield the nonadiabatic furnace temperature  $t_f$  as given by

$$H - Q_L = G_t C_p (t_f - t_a) \quad (2.65)$$

Here, with  $Q_L = 0.05H$ , the furnace temperature is

$$\begin{aligned}
 H - 0.05H &= G_t C_p (t_f - t_a) \\
 0.95H &= G_t C_p (t_f - t_a) \\
 t_f &= 100 + 0.95(17,620)/(14.51(0.25)) \\
 &= 4714^\circ\text{F}
 \end{aligned}$$

This gas temperature, while lower than that calculated for the adiabatic situation (case 1), is still too high to be practical.

*Solution for Case 3*

The third alternative proposes imposing a limit to the furnace temperature, with a 5% energy loss and no other heat transfer. This can be realized only through the use of excess air ( $A_e$ ). The quantity of excess air needed is determined by a calculation of the mass of combustion product gas  $G_f$  required to absorb the net heating value of the fuel  $H$  with the gases leaving the furnace at the specified temperature (2200°F). The gas per pound of fuel is

$$G_f = (A_e + G_t)$$

Equation (2.65) is modified as given by

$$H - Q_L = G_f C_p (t_f - t_a) \quad (2.66)$$

Now if the  $t_f = 2200^\circ\text{F}$  condition is imposed on the system and assuming  $C_p = 0.25$  Btu/lb°F as before,  $G_f$  can be calculated from

$$\begin{aligned}
 H - 0.05H &= G_f(0.25)(2200 - 100) \\
 0.95(17,620) &= G_f(525) \\
 16,739 &= G_f(525) \\
 G_f &= 31.88 \text{ lb}
 \end{aligned}$$

The excess air needed to reduce the temperature is then

$$\begin{aligned}
 A_e &= G_f - G_t \\
 &= 31.88 - 14.51 \\
 &= 17.37 \text{ lb-air/lb-fuel}
 \end{aligned}$$

Percent excess air ( $A_e/A_t$ ):

$$\begin{aligned} A_e/A_t &= 17.37/13.51 \\ &= 128\% \end{aligned}$$

This is substantially greater than the excess air normally found necessary for proper combustion of No. 6 oil.

*Solution to Case 4*

The logical next alternative is to limit the temperature by transferring energy to some useful purpose while limiting the excess air to the amount required for complete combustion. The energy equation for this case becomes

$$H = G_f C_p (t_f - t_a) + Q_L + Q_u \quad (2.67)$$

where  $Q_u$  is the energy to be transferred in order to maintain the furnace temperature at  $t_f$ . Rearranging Eq. (2.67) gives

$$Q_u = H - Q_L - G_f C_p (t_f - t_a) \quad (2.68)$$

Recall that case 4 prescribes 10% excess air. For this case, Eq. (2.69) becomes

$$Q_u = H - Q_L - G_{f10} C_p (t_f - t_a) \quad (2.69)$$

$$\begin{aligned} A_{e10} &= 0.10(13.51) \\ &= 1.35 \text{ lb-air/lb-fuel} \\ G_{f10} &= G_t + A_{e10} \\ &= 14.51 + 1.35 \\ &= 15.86 \text{ lb-air/lb-fuel} \end{aligned}$$

where  $G_{f10}$  = flue gas for combustion with 10% excess air (lb/lb-fuel)  
 $A_{e10}$  = 10% excess air (lb/lb-fuel)

Substituting the appropriate numerical values into Eq. (2.69) gives

$$\begin{aligned} Q_u &= 17,620 - 0.05(17,620) - (15.86)(0.25)(2200 - 100) \\ &= 16,739 - 8327 \\ &= 8412 \text{ Btu/lb fuel} \end{aligned}$$

Percent available energy for recovery:

$$\begin{aligned} Q_u/H &= 8412/17,620 \\ &= 47.74\% \end{aligned}$$

Here  $Q_u$  represents 47.74% of the net heating value of the fuel. Useful application of this energy obviously depends upon the primary purpose of the combustion system. Steam generation would dictate water walls in the furnace to absorb this energy. Other systems would have to utilize this energy in some other appropriate manner with the heat transfer surface and medium compatible with the intended end use.

Summarizing the design process to this point, the primary alternatives for controlling the furnace temperature are to use a great deal of excess air, or to use some appropriate heat transfer surface to remove sufficient energy from the combustion gas to effect a control of

temperature. The use of excess air alone as a control is wasteful of energy and should be avoided whenever possible.

This potentially wasteful aspect is also evident when considering the utilization of the energy remaining in the combustion products after they leave the furnace.

Nomenclature for this example

- $A_c$  = excess air (lb/lb-fuel)
- $A_{c10}$  = 10% excess air (lb/lb-fuel)
- $A_t$  = theoretical (stoichiometric) air (lb/lb-fuel)
- $C_p$  = constant pressure specific heat (Btu/lb-°F)
- $G_t$  = theoretical combustion flue gas (lb/lb-fuel)
- $G_f$  = flue gas for combustion with excess air (lb/lb-fuel)
- $G_{f10}$  = flue gas for combustion with 10% excess air (lb/lb-fuel)
- $H$  = net heating value (Btu/lb-fuel) = HHV -  $Q_v$
- HHV = high heating value (Btu/lb-fuel)
- $Q_L$  = energy transfer losses to structure and surrounding (Btu/lb-fuel)
- $Q_u$  = useful energy transferred in the furnace (Btu/lb-fuel)
- $t_a$  = combustion air temperature (°F)
- $t_{ad}$  = adiabatic flame temperature (°F)
- $t_f$  = furnace temperature (°F)

## 5.5 Energy Utilization in the Nonfurnace Region

Further utilization of energy, represented by the elevated temperatures of gases leaving a furnace, has a significant impact on the overall combustion system thermal efficiency  $E$ . The efficiency and its related equations are provided below (EPA-80/02, p. 4-6).

$$E = Q_s/Q_h \quad (2.70)$$

$$Q_h = m_f(\text{HHV}) \quad (2.71)$$

$$Q_s = m_f(q_s) = Q_h - \text{sum}(Q_{\text{loss}}) \quad (2.72)$$

where

- $E$  = overall combustion efficiency
- HHV = high heating value
- $m_f$  = fuel firing rate
- $Q_s$  = total energy transferred for a useful purpose
- $q_s$  = energy to useful purpose per lb of fuel
- $Q_h$  = total energy input to the system

Losses identified earlier were limited to the energy transferred to the structure and the surroundings in the furnace  $Q_L$ . Additional losses occur in the regions through which the gas must flow upon leaving the furnace. A major loss is due to the heat content of flue gas leaving the system. This loss  $Q_{fg}$  arises from the fact that the flue gas stack temperature  $t_{fg}$  is higher than ambient temperature, and is expressed as

$$Q_{fg} = G_f(C_p)(t_{fg} - t_{\text{amb}}) \quad (2.73)$$

Equation (2.73) indicates that  $Q_{fg}$  is directly proportional to the total mass of the flue gases  $G_f$ , the specific heat of the gas, and the difference between the flue gas and the ambient. Increasing excess air beyond that which is required to ensure proper combustion increases  $G_f$ , which tends to increase the flue losses. The desirability of reducing the flue gas temperature  $t_{fg}$  is also apparent. In almost all combustion energy utilization devices, it is impractical to reduce  $t_{fg}$  to  $t_{amb}$ . Design, material, and economic factors prevent this and, in fact, dictate limits for various cases. Flue gas temperatures in steam boilers are limited to a low of about 250–300°F because of the potential dew-point and  $SO_x$ -associated corrosion problems which can develop at lower temperatures. Achieving even these flue gas exit temperatures requires considerable energy recovery equipment such as economizers and air preheaters.

The overall energy utilization pattern is summarized in Fig. 2.21, and by the following terms of the energy balance relationship (see the Nomenclature at the end of this sub-section).

FIGURE 2.21 Energy distribution (EPA-80/02, p. 4-12).

Input: HHV

Losses:  $\text{sum}(Q_{\text{loss}}) = Q_L + Q_{fg} + Q_v$

Available (utilized) energy:  $Q_s = Q_u + Q_{nf}$

$Q_s = \text{HHV} - \text{sum}(Q_{\text{loss}})$

Note that in terms of the net heating value of the fuel  $H$ , the energy balance would become

$$\begin{aligned} H &= \text{HHV} - Q_v \\ &= Q_L + Q_{fg} + Q_s \end{aligned}$$

The interaction of these several energy quantities is illustrated by the next example, which presumes a steam boiler where the fuel is already identified.

**EXAMPLE** furnace system thermal efficiency

A steam generator is to be designed for firing the No. 6 fuel oil from the previous example. Its rated output is to be 60,000 lb/h, output steam at  $p = 650$  psia,  $t = 800^\circ\text{F}$ , with the feedwater at  $320^\circ\text{F}$  (EPA-80/02, p. 4-8). No. 6 fuel oil has a specific gravity of 0.986, a HHV of 18,640 Btu/lb, and an ultimate analysis of 85.7% C, 10.5%  $\text{H}_2$ , 0.92%  $\text{O}_2$ , 2.8% S, 0.08% ash, and a net heating value (NHV) of 17,620 Btu/lb (EPA-80/02, p. 4-3).

Determine the distribution of the available energy utilization in this steam generator.

*Solution:*

The design begins with a determination of  $Q_s$  for this unit. This is done by accounting for the energy which is added to the working fluid (water) as it passes through the unit. Figure 2.22 shows the energy distribution in question (EPA-80/02, p. 4-8).

Letting  $m_s$  represent the steaming rate,  $Q_s$  becomes

$$Q_s = m_s(h_2 - h_1)$$

- where
- $h_1$  = enthalpy of the entering water
  - $h_2$  = enthalpy of the output steam
  - $m_s$  = steam rate
  - $Q_s$  = total energy transferred for a useful purpose

FIGURE 2.22 Energy distribution (EPA-80/02, p. 4-8).

$$\begin{aligned}
 h_1 &= 290.3 \text{ Btu/lb at } p = 650 \text{ psia, } T = 320^\circ\text{F (data from a steam table)} \\
 h_2 &= 1406.0 \text{ Btu/lb at } p = 650 \text{ psia, } T = 800^\circ\text{F (data from a steam table)} \\
 Q_s &= 60,000(1406.0 - 290.3) \\
 &= 66.9 \times 10^6 \text{ Btu/h}
 \end{aligned}$$

This is the available useful energy represented by  $m_f(Q_u + Q_{nf})$ .

The fuel supply rate needed to provide this energy depends on the overall efficiency  $E$ , which in turn depends on the energy recovery devices incorporated into the design.

$$\begin{aligned}
 q_s &= Q_s/m_f \\
 &= \text{HHV} - Q_v - Q_L - Q_{fg} \\
 &= H - Q_L - Q_{fg} \\
 &= 17,620 - Q_L - Q_{fg}
 \end{aligned} \tag{2.74}$$

where

- $H$  = net heating value (Btu/lb-fuel)
- HHV = high heating value (Btu/lb-fuel)
- $Q_{fg}$  = energy loss as sensible heat in flue gas (Btu/lb-fuel)
- $Q_L$  = energy transfer losses to structure and surroundings (Btu/lb-fuel)
- $Q_v$  = energy loss due to latent heat of the water vapor formed by combustion (Btu/lb-fuel)

Suppose that  $Q_L$  can be limited to a maximum of 5% of HHV. Before the remaining loss term  $Q_{fg}$  can be determined, it is in order to consider some of the temperatures in the system.

- Gas leaves the furnace at  $t_f = 2200^\circ\text{F}$ , while steam leaves the
- Steam superheater at  $t_s = 800^\circ\text{F}$
- Steam boiler temperature  $t_b = 495^\circ\text{F}$  (saturation temperature at 650 psia)

The reason for listing these temperatures is to emphasize the limitations imposed by thermodynamic and heat transfer considerations. Energy exchange by heat transfer requires a temperature difference between the energy source and the heated medium. The superheater, if located in the convection zone, might reduce the gas temperature typically from  $2200^\circ\text{F}$  to say  $1000^\circ\text{F}$ , which will still allow a  $200^\circ\text{F}$  temperature difference for heat transfer requirements. The boiler operating at the  $495^\circ\text{F}$  boiling temperature can remove enough energy to bring the gas temperature to about  $700^\circ\text{F}$ . These temperatures are practical values, that is, they recognize the need for a finite temperature difference for heat exchange at realistic rates. In any event, temperatures lower than  $800^\circ\text{F}$  for the superheater outlet and  $495^\circ\text{F}$  for the boiler cannot be realized even with infinite heat transfer areas.

If the steam generator design does not include either an economizer or an air preheater, the gas temperature leaving the system would be approximately  $700^\circ\text{F}$ . For this case, the energy loss in the flue gas is given by

$$\begin{aligned}
 Q_{fg} &= G_{f10}(C_p)(t_{fg} - t_{amb}) \\
 &= 15.86(0.25)(700 - 100) \\
 &= 2379 \text{ Btu/lb-fuel} \\
 Q_L &= 0.05(\text{HHV}) \\
 &= 0.05(18,640) \\
 &= 930 \text{ Btu/lb}
 \end{aligned} \tag{2.75}$$

The useful energy per pound of fuel  $q_s$  is calculated by solving Eq. (2.74).

$$\begin{aligned}
 q_s &= 17,620 - Q_L - Q_{fg} \\
 &= 17,620 - 930 - 2379 \\
 &= 14,300 \text{ Btu/lb-oil}
 \end{aligned}$$

The efficiency  $E$ , with  $Q_s$  and  $Q_h$  each based on one pound of fuel, is

$$E = Q_s/Q_h$$

where  $E$  = overall combustion efficiency  
 $Q_s$  = total energy transferred for a useful purpose  
 $Q_h$  = total energy input to the system

Substituting the appropriate numerical values into the above equation gives

$$\begin{aligned}
 E &= 14,300/18,640 \\
 &= 76.7\%
 \end{aligned}$$

The fuel firing rate can now be determined noting that the total useful energy  $Q_s$  is  $66.9 \times 10^6$  Btu/h and solving for  $m_f$  from equation

$$\begin{aligned}
 m_f &= Q_s/q_s \\
 &= (66.9 \times 10^6)/14,300 \\
 &= 4680 \text{ lb-oil/h}
 \end{aligned}$$

The specific gravity of this No. 6 fuel oil was specified to be 0.986, and therefore a required fuel flow of approximately 569 gal/h is indicated.

The efficiency obtainable with a unit which extracts useful energy only in the furnace water walls, superheater, and boiler is not as high as could be realized. Continuing the design process, one would seek means to reduce the flue gas temperature still further, thereby reducing the flue losses and increasing the thermal efficiency. Recall that the feedwater temperature was specified to be 320°F. This is 175°F lower than the boiler temperature of 495°F. It would therefore appear to be possible to insert a heat exchange surface in the flue gas stream to extract energy by transferring energy to the colder feedwater. Such an exchange surface is called the *economizer*, and with temperatures as hypothesized here, flue gas temperature could be reduced to 500°F. With this lower flue gas temperature, the flue loss  $Q_{fg}$  would be reduced to 1590 Btu/lb,  $q_s$  would increase to 15,100 Btu/lb, and the efficiency would increase to 81.0%.

Continuing the design analysis, one would note that the flue gas leaves the economizer at 500°F and that the ambient air enters at 100°F. Why not preheat combustion air? A decision to do so or not should, at least in part, be based upon economics. The additional hardware would have a higher first-cost and operating cost, which would have to be balanced against the value of the energy saved. An air preheater could certainly be expected to reduce flue gas temperatures to 350°F.

At 350°F flue gas temperature, Eq. (2.75) is used to calculate the loss  $Q_{fg}$ :

$$\begin{aligned}
 Q_{fg} &= G_{f10}(C_p)(t_{fg} - t_{amb}) \\
 &= 15.86(0.25)(350 - 100) \\
 &= 991 \text{ Btu/lb-fuel}
 \end{aligned}$$

Now, from Eq. (2.74)

$$\begin{aligned}
 q_s &= 17,620 - 932 - 991 \\
 &= 15,697 \text{ Btu/lb fuel}
 \end{aligned}$$

The efficiency  $E$  would be

$$\begin{aligned} E &= 15,697/18,640 \\ &= 84.21\% \end{aligned}$$

The fuel firing rate  $m_f$  would be

$$\begin{aligned} m_f &= Q_s/q_s \\ &= (66.9 \times 10^6)/15,697 \\ &= 4262 \text{ lb-oil/h} \end{aligned}$$

Nomenclature for this example

- $A_a$  = actual combustion air (lb/lb-fuel)
- $A_c$  = excess air (lb/lb-fuel)
- $A_{c10}$  = 10% excess air (lb/lb-fuel)
- $A_t$  = theoretical (stoichiometric) air (lb/lb-fuel)
- $C_p$  = constant pressure specific heat (Btu/lb-°F)
- $G_t$  = theoretical combustion flue gas (lb/lb-fuel)
- $G_f$  = flue gas for combustion with excess air (lb/lb-fuel)
- $G_{f10}$  = flue gas for combustion with 10% excess air (lb/lb-fuel)
- $h$  = specific enthalpy (Btu/lb-fuel)
- $h_1$  = enthalpy of the entering water (Btu/lb-fuel)
- $h_2$  = enthalpy of the output steam (Btu/lb-fuel)
- $H$  = net heating value (Btu/lb-fuel) = HHV -  $Q_v$
- HHV = high heating value (Btu/lb-fuel)
- $m_f$  = fuel firing rate (lb/h)
- $m_{nc}$  = noncombustibles in fuel (lb/h)
- $m_s$  = steam rate (lb/h)
- $Q_{fg}$  = energy loss as sensible heat in flue gas (Btu/lb-fuel)
- $Q_h$  = total energy input to the system (Btu/h)
- $Q_L$  = energy transfer losses to structure and surroundings (Btu/lb-fuel)
- $Q_{nf}$  = useful energy (Btu/lb-fuel), transferred in nonfurnace region
- $q_s$  = total energy transferred for a useful purpose (Btu/lb)
- $Q_s$  = total energy transferred for a useful purpose (Btu/h)
- $Q_u$  = useful energy transferred in the furnace (Btu/lb-fuel)
- $Q_v$  = energy loss due to latent heat of the water vapor formed by combustion (Btu/lb-fuel)
- $t_a$  = combustion air temperature (°F)
- $t_b$  = steam boiler temperature (°F)
- $t_{ad}$  = adiabatic flame temperature (°F)
- $t_{amb}$  = ambient air temperature (°F)
- $t_f$  = furnace temperature (°F)
- $t_{fg}$  = flue gas temperature (°F)

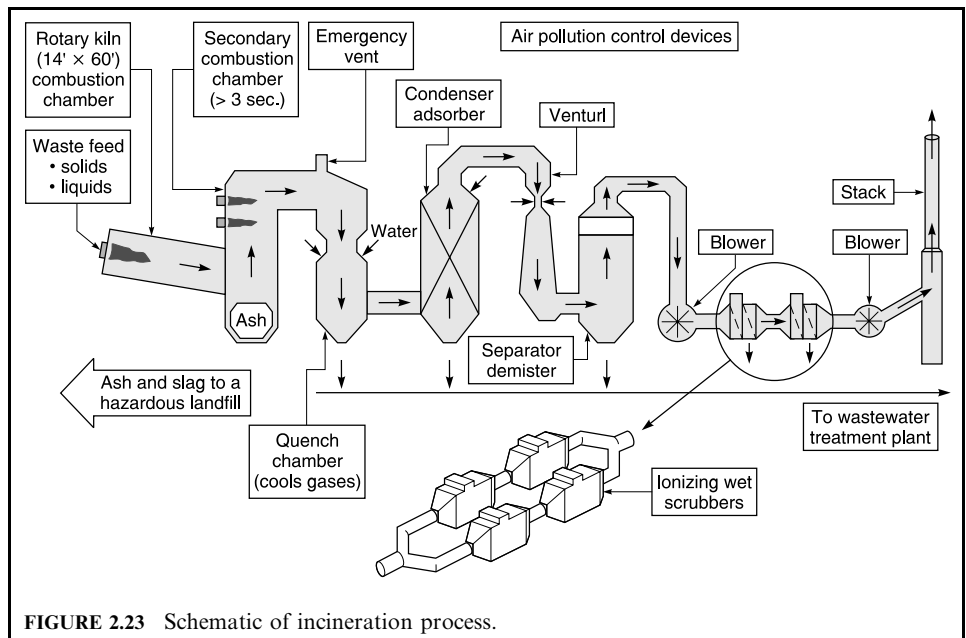

## 5.6 Rotary and Afterburner System

A computer program was developed by the Energy and Environmental Research Corporation (EER) under a contract to the US EPA to perform energy and mass balance calculations on rotary kiln incinerators for hazardous waste incineration (EPA Contract 68-CO-0094, 92/10). A typical rotary kiln incineration system is shown in Fig. 2.23. The calculations are performed for a single-zone incinerator or for an incinerator system composed of single zones in series. The composition of gases and solids in a zone is assumed to be the same as the exit composition—that of complete reaction, the temperature in a zone is assumed to be the same as the exit temperature, and the residence time within a zone is assumed to be the mean residence time. Products of one zone enter the next zone at the exit temperature of the first zone. In cases where there is a significant heat loss between the incinerator units, a transition zone is included between the units to allow the products to enter the second unit at a lower temperature than they exit the first.

Inputs to the energy and mass balance calculation include:

- feed rate, temperature, heating value, heat capacity, heat of vaporization, and composition of all input streams to each unit including wastes, fuels, water, air, and oxygen;
- incinerator design specifications including the thickness and conductivity of the refractory, the volume of the unit, the area of the refractory and any cooled surfaces, and the outer shell temperature;
- the air pollution control devices (APCD) design specifications including gas volumetric capacity, acid gas capacity, quench water capacity and temperature, and the temperature to which the gas must be quenched.

Tables 2.34–2.37 show typical blank input forms.

Others

Feed rates are in the form of mass flows. Preheat denotes the temperature at which a stream enters the incinerator. Proximate analysis is a standard analytical procedure used to characterize fuel/waste consisting of mass percentages of fixed carbon, volatiles, ash, and moisture. Elemental analysis consists of the dry mass percentages of carbon, hydrogen, nitrogen, sulfur, ash, oxygen, and chlorine. Halogens other than chlorine should be treated as chlorine by multiplying their mass percentage by the ratio of atomic weight of chlorine to the atomic weight of the halogen and renormalizing so that the total mass percentage is 100.

Heating value is input as the higher or gross heating value (HHV) the way it is typically measured and reported. The higher heating value is defined as the heat of complete combustion of the fuel/waste at 76.4°F (298 K) with all product water in liquid form and all product chlorine in the form of HCl. If the heating value is unknown, it can be estimated from the fuel/waste composition by the following equation (EPA-92/10):

$$\text{HHV} = 1.8(100 - \text{ash} - \text{moisture})/100\{83.2(\text{C}) + 275.15(\text{H}) + 25.0(\text{S}) + 15.0(\text{N}) - 25.8(\text{O}) - 568.4[1 - \exp(-0.582(\text{Cl}/\text{C}))]\} \text{ Btu/lb}$$

**EXAMPLE** energy and mass balance calculation for a rotary kiln and afterburner system  
A rotary kiln burns 3000 lb/h of typical medical waste with a higher heating value of 8724 Btu/lb. The waste has about 36% moisture on a wet basis, and about 15% ash and 4% chlorine on a dry basis. No auxiliary fuel is required for the rotary kiln. Almost 50,000 lb/h of air is used to burn the waste. Heat loss from the kiln is a little more than 5%. There is no preheat of either the waste or the air. The hot combustion products from the rotary kiln pass directly into the afterburner except that 98% of the ash drops out in the kiln.

The afterburner burns about 550 lb/h of No. 2 fuel oil in almost 8000 lb/h of additional air. Heat loss from the afterburner is almost 6%.

In this example, the rotary kiln is also referred to as the primary combustion chamber (PCC) and the afterburner as the secondary combustion chamber (SCC). More detailed inputs for the example are provided in Tables 2.38 and 2.39.

*Solution:*

1. Calculate mass balance on PCC

1.1. Convert each input stream to composition on a wet, as-fired basis

From the proximate analysis, the waste consists of 36.32% moisture by mass and  $100 - 36.32 = 63.68\%$  dry components by mass.

**TABLE 2.38** PCC Energy and Mass Balance Input Data\*

	Feed rate (lb/h)	Preheat (°F)	Proximate analysis (as received)					Elemental analysis (dry)						
			Fixed carbon (%)	Volatiles (%)	Ash (%)	Moisture (%)	HHV (Btu/lb)	C (%)	H (%)	N (%)	S (%)	O (%)	Ash (%)	Cl (%)
Waste stream	3000	76.4	0	53.65	10.03	36.32	8724	63	9.37	0.12	0	7.47	15.76	4.27
Fuel														
Air	49,439	76.4												
Water	0													
Oxygen	0													
Ash dropout	98%													

\* PCC = primary combustion chamber; PCC heat loss = 5.34%; PCC unit volume = 1525 ft<sup>3</sup>.

**TABLE 2.39** SCC Energy and Mass Balance Input Data\*

	Feed rate (lb/h)	Preheat (°F)	Proximate analysis (as received)					Elemental analysis (dry)							
			Fixed carbon (%)	Volatiles (%)	Ash (%)	Moisture (%)	HHV (Btu/lb)	C (%)	H (%)	N (%)	S (%)	O (%)	Ash (%)	Cl (%)	
Waste stream															
Fuel (No. 2 oil)	554	76.4	0	100	0	0	25,296	87.13	12.6	0.01	0.22	0.04	0	0	
Air	7,932	76.4													
Water	0														
Oxygen	0														
Ash dropout	0%														

\* SCC = secondary combustion chamber; SCC heat loss = 5.96%; SCC unit volume = 2113 ft<sup>3</sup>.

Converting the elemental analysis from a dry mass to a wet mass basis, the dry components are

$$\begin{aligned}
 C &= (63.00/100)(63.68) = 40.12\% \\
 H &= (9.37/100)(63.68) = 5.97\% \\
 N &= (0.12/100)(63.68) = 0.08\% \\
 S &= (0.00/100)(63.68) = 0.00\% \\
 O &= (7.47/100)(63.68) = 4.76\% \\
 \text{Ash} &= (15.76/100)(63.68) = 10.04\% \\
 \text{Cl} &= (4.27/100)(63.68) = 2.72\%
 \end{aligned}$$

1.2. Calculate individual component flowrates

$$\begin{aligned}
 \text{mass}_C &= 3000(40.12)/100 = 1203.60 \text{ lb/h} \\
 \text{mass}_H &= 3000(5.97)/100 = 179.10 \text{ lb/h} \\
 \text{mass}_N &= 3000(0.08)/100 = 2.40 \text{ lb/h} \\
 \text{mass}_S &= 3000(0.00)/100 = 0.00 \text{ lb/h} \\
 \text{mass}_O &= 3000(4.76)/100 = 142.80 \text{ lb/h} \\
 \text{mass}_{\text{ash}} &= 3000(10.04)/100 = 301.20 \text{ lb/h} \\
 \text{mass}_{\text{Cl}} &= 3000(2.72)/100 = 81.60 \text{ lb/h} \\
 \text{mass}_{\text{H}_2\text{O}} &= 3000(36.32)/100 = 1089.60 \text{ lb/h}
 \end{aligned}$$

1.3. Calculate the O<sub>2</sub> and N<sub>2</sub> amount from the given air flowrate

$$\begin{aligned}
 \text{mass}_O &= 49,439(23.2)/100 = 11,470 \text{ lb/h} \\
 \text{mass}_N &= 49,439(76.8)/100 = 37,969 \text{ lb/h}
 \end{aligned}$$

1.4. Calculate combustion air

Calculate the combustion air by applying the method in Section 2.6 and using Table 2.40.

**TABLE 2.40** Combustion Air in PCC

Basic reaction	Oxygen, nitrogen, and air requirements	Mass (lb/h)	Mole (mol/h)
$C + O_2 \rightarrow CO_2$	(1) $O_2 = C(32/12)$	3209.60	100.30
$H_2 + 0.5O_2 \rightarrow H_2O$	(2) $O_2 = 8(H-Cl/35.5)^*$	1414.41	44.20
$S + O_2 \rightarrow SO_2$	(3) $O_2 = S(32/32) = S$	0.00	0.00
$B_o =$ bound oxygen	(4) Data from waste analysis	142.80	4.46
$O_{2t} =$ theoretical $O_2$	$O_{2t} = (1) + (2) + (3) - (4)$	4481.21	140.04

$R_a =$ actual reactant	$R_a = A_a +$ waste feed $+ H_2O$ from air	52,439.38	

\* If  $H_2$  is the hydrogen left over after Cl reaction, i.e.,  $H_2 = H-Cl/35.5$ , the  $O_2$  needed to react with  $H_2$  will be equal to  $H_2(0.5)(32/2) = 8(H-Cl/35.5)$ .

† In general, at room temperature, the humidity ratio is 0.0127 (lb- $H_2O$ )/(lb-dry-air) or 0.0127 (kg- $H_2O$ )/(kg-dry-air).

1.5. Calculate excess air amount  $\%A_e$

For this example,  $A_a = 49,439$  lb/h (given condition).

The excess air amount is

$$\begin{aligned}
 A_e &= A_a - A_t \\
 &= 49,439 - 19,224 \\
 &= 30,215 \text{ lb/h} \\
 \%A_e &= A_e/A_t(100\%) \\
 &= 30,215/19,224(100\%) \\
 &= 157.17\%
 \end{aligned}$$

1.6. Calculate actual combustion products  $P_a$

$P_a$  can be calculated from the method in Section 2.6 and using Table 2.41.

1.7 Check on mass balance

The above calculations show that the flow rate of reactants and products are checked. They are both equal to 52,439 lb/h.

2. Calculate mass balance on secondary combustion chamber

The mass balance on the secondary combustion chamber is performed first on a local basis (i.e., ignoring the primary effluent), and then on an overall basis (i.e., combining secondary with primary combustion gas products).

2.1. Convert each input stream to composition on a wet, as-fired basis

From the proximate analysis, No. 2 fuel oil consists of 0% moisture by mass and  $100 - 0 = 100\%$  dry components by mass.

Converting the elemental analysis from a dry mass to a wet mass basis, the dry components are

**TABLE 2.41** Combustion Product in PCC

Component	Combustion product	Mass (lb/h)	Mole (mol/h)
CO <sub>2</sub>	CO <sub>2</sub> = (C)(44/12)	4413.20	100.30
SO <sub>2</sub>	SO <sub>2</sub> = S(64/32)	0.00	0.00
HCl	HCl = Cl(36.5/35.5)	83.90	2.30

Ash	Fly ash + bottom ash	301.20	
P <sub>a</sub> = actual product*	G <sub>a</sub> + ash	52,439.69	

\* In performing the mass balance calculation, the values of reactants (R<sub>a</sub>) and products (P<sub>a</sub>) should be equal, i.e., if R<sub>a</sub> = P<sub>a</sub>, the mass balance calculation is correct.

$$C = (87.13/100)(100) = 87.13\%$$

$$H = (12.60/100)(100) = 12.60\%$$

$$N = (0.01/100)(100) = 0.01\%$$

$$S = (0.22/100)(100) = 0.22\%$$

$$O = (0.04/100)(100) = 0.04\%$$

$$\text{Ash} = (0.00/100)(100) = 0.00\%$$

$$Cl = (0.00/100)(100) = 0.00\%$$

2.2. Calculate individual component flowrates

$$\text{mass}_C = 554(87.13)/100 = 482.70 \text{ lb/h}$$

$$\text{mass}_H = 554(12.60)/100 = 69.80 \text{ lb/h}$$

$$\text{mass}_N = 554(0.01)/100 = 0.0554 \text{ lb/h}$$

$$\text{mass}_S = 554(0.22)/100 = 1.22 \text{ lb/h}$$

$$\text{mass}_O = 554(0.04)/100 = 0.22 \text{ lb/h}$$

$$\text{mass}_{\text{ash}} = 554(0.00)/100 = 0.00 \text{ lb/h}$$

$$\text{mass}_{Cl} = 554(0.00)/100 = 0.00 \text{ lb/h}$$

$$\text{mass}_{H_2O} = 554(0.00)/100 = 0.00 \text{ lb/h}$$

2.3. Calculate the O<sub>2</sub> and N<sub>2</sub> amount from the given air flowrate

$$\text{mass}_O = 7932(23.2)/100 = 1840 \text{ lb/h}$$

$$\text{mass}_N = 7932(76.8)/100 = 6092$$

2.4. Calculate theoretical combustion air (A<sub>t</sub>)

Calculate the combustion air by applying the method in Section 2.6 and using Table 2.42.

**TABLE 2.42** Combustion Air in SCC

Basic reaction	Oxygen, nitrogen, and air requirements	Mass (lb/h)	Mole (mol/h)
$C + O_2 \rightarrow CO_2$	(1) $O_2 = C(32/12)$	1287.20	40.23
$H_2 + 0.5O_2 \rightarrow H_2O$	(2) $O_2 = 8(H-Cl/35.5)^*$	558.72	17.46
$S + O_2 \rightarrow SO_2$	(3) $O_2 = S(32/32) = S$	1.22	0.04
$B_o =$ bound oxygen	(4) Data from waste analysis	0.22	0.01
$O_{2t} =$ theoretical $O_2$	$O_{2t} = (1) + (2) + (3) - (4)$	1846.92	57.72
$N_{2t} =$ theoretical $N_2$	$N_{2t} = (O_{2t})(3.76 \times 28/32)$	6076.37	217.01
$A_t =$ theoretical air	$A_t = O_{2t} + N_{2t}$	7923.29	274.73
$\%A_e =$ % excess air	See step 2.5	0.0011	
$A_e =$ excess air	$A_e = (\%A_e)(A_t)$	8.72	0.30
$A_{ada} =$ actual dry air	$A_{ada} = A_t + A_e$	7932.00	275.03
$H_2O$ from air†	$0.0127(A_{ada}) = N/A$	0.00	0.00
$A_a =$ actual air	$A_a = A_{ada} + H_2O$	7932.00	275.03
Waste feed	Data from waste analysis	554.00	
$R_a =$ actual reactant	$R_a = A_a +$ waste feed $+ H_2O$ from air	8486.00	

\* If  $H_2$  is the hydrogen left over after Cl reaction, i.e.,  $H_2 = H-Cl/35.5$ , the  $O_2$  needed to react with  $H_2$  will be equal to  $H_2(0.5)(32/2) = 8(H-Cl/35.5)$ .

† In general, at room temperature, the humidity ratio is 0.0127 (lb- $H_2O$ )/(lb-dry-air) or 0.0127 (kg- $H_2O$ )/(kg-dry-air).

2.5. Calculate excess air amount  $\%A_e$

For this example,  $A_a = 7932$  lb/h (given condition)

$$\begin{aligned}
 A_e &= A_a - A_t \\
 &= 7932 - 7923 \\
 &= 9 \text{ lb/h} \\
 \%A_e &= A_e/A_t(100\%) \\
 &= 9/7923(100\%) \\
 &= 0.11\%
 \end{aligned}$$

2.6. Calculate actual combustion products  $P_a$

$P_a$  can be calculated from the method in Section 2.6 and using Table 2.43.

**TABLE 2.43** Combustion Product in SCC

Component	Combustion product	Mass (lb/h)	Mole (mol/h)
$CO_2$	$CO_2 = C(44/12)$	1769.90	40.23
$SO_2$	$SO_2 = S(64/32)$	2.44	0.04
HCl	$HCl = Cl(36.5/35.5)$	0.00	0.00
$O_{2e}$	$(\%A_e)O_{2t}$ , $O_{2t}$ from Table 2.42	2.03	0.06
$N_{2e}$	$(\%A_e)N_{2t}$ , $N_{2t}$ from Table 2.42	6.68	
$N_2$	$N_{2e} + N_{2t} +$ from waste	6083.11	217.25
$H_2O$ from combustion	$H_2O$ from combustion = $9(H-Cl/35.5)$	628.20	
$H_2O$	$H_2O$ from combustion + from air + from waste	628.20	34.90
$G_a =$ actual flue gas	$G_a = CO_2 + SO_2 + HCl + O_{2e} + N_2 + H_2O$	8485.68	292.48
Ash	Fly ash + bottom ash	0.00	
$P_a =$ actual product*	$P_a = G_a +$ ash	8485.68	

\* In performing the mass balance calculation, the values of reactants ( $R_a$ ) and products ( $P_a$ ) should be equal, i.e., if  $R_a = P_a$ , the mass balance calculation is correct.

## 2.7. Check on mass balance

The above calculations show that the flow rate of reactants and products are close enough.

## 3. Combine combustion products from both primary and secondary combustion chambers

3.1. Calculate the composite combustion gas from the PCC and the SCC (Table 2.44)

3.2. Calculate the overall excess oxygen (Table 2.45)

## 4. Energy balance on PCC (rotary kiln) (EPA-92/10)

The energy balance equates the energy released in combustion to the energy required to vaporize all moisture, the energy required to heat the combustion products to the exit temperature, and the energy lost in the process. The energy balance can be expressed as

$$(\text{heat of combustion}) - (\text{heat of vaporization}) - (\text{sensible heat}) - (\text{heat loss}) = 0$$

or

$$(\text{heat of combustion}) = (\text{heat of vaporization}) + (\text{sensible heat}) + (\text{heat loss})$$

## 4.1. Calculate heat of combustion

The heat of combustion is the chemical heat released as the reactants are converted to products at the reference state of 76.4°F with the product H<sub>2</sub>O in liquid form. It is calculated by the following equation:

$$\text{heat of combustion} = \text{HHV}(\text{mass flow}) - (\text{heat of solution})$$

where HHV is the higher heating value of the fuel/waste, and the heat of solution is the energy released when gaseous HCl dissolves in water. The heat of solution is calculated by the following equation:

$$\text{heat of solution} = (\text{mass flow})(\text{Cl})(1 - \text{moisture})(887.36)(1 - \exp(-\text{H}_2\text{O}/\text{HCl})^{0.77}/1.92))$$

where H<sub>2</sub>O/HCl is the molar ratio of H<sub>2</sub>O to HCl produced in the oxidation of the fuel/waste. The molar values of H<sub>2</sub>O and HCl can be calculated from the following equations:

$$\text{Molar value of H}_2\text{O} = 1590/18 = 88.33$$

$$\text{Molar value of HCl} = 84/36.5 = 2.30$$

where the values of 1590 and 84 are obtained from Table 2.41, and the values of 18 and 36.5 are the molecular weight of H<sub>2</sub>O and HCl, respectively.

**TABLE 2.44** PCC and SCC Composite Combustion Products (lb/h)

Combustion products	PCC (lb/h)	SCC (lb/h)	PCC + SCC (lb/h)	Molar weight	PCC + SCC (mole/h)
CO <sub>2</sub>	4413	1769.9	6182.90	44	140.52
SO <sub>2</sub>	0	2.44	2.44	64	0.04
HCl	84	0	84.00	36.5	2.30
O <sub>2c</sub>	7043	2.03	7045.03	32	220.16
N <sub>2</sub>	37,917	6083.11	44,000.11	28	1571.43
H <sub>2</sub> O	2681	628.2	3309.20	18	183.84
Fly ash	6	0	6.00	—	—
	52,144.00	8485.68	60,629.68		2118.29

**TABLE 2.45** PCC and SCC Composite Oxygen Flowrate (lb/h)

Combustion products	PCC	SCC	PCC + SCC
O <sub>2t</sub>	4481	1847	6328.00
O <sub>2e</sub>	7043	2.03	7045.03
O <sub>2a</sub>	11,524	1849.03	13,373.03
Excess %O <sub>2</sub> = (7045/6328)100% = 111.33%			

Thus, the molar ratio (H<sub>2</sub>O/HCl) = 88.33/2.30 = 38.40 and the heat of solution is

$$\begin{aligned} \text{Heat of solution} &= 3000(4.27/100)(1 - 36.32/100)(887.38)(1 - \exp((-38.40)^{0.77}/1.92)) \\ &= 72,000 \text{ Btu/h} \end{aligned}$$

Thus, the heat of combustion = 8724(3000) - 72,000 = 26.10 *E* + 06 Btu/h where the values of 3000, 4.27, 36.32, and 8724 were given conditions provided in Table 2.38.

#### 4.2. Calculate heat of vaporization

As shown in the preceding section, the higher heating value is used for the heat of combustion. This is based on the assumption that the product water is in liquid form. However, in combustion, the product water is in vapor form. Therefore, the heat required to vaporize that water must be factored into the energy balance.

The heat of vaporization is the heat required to vaporize all moisture and combustion water. It is calculated according to the equation

$$\begin{aligned} \text{Heat of vaporization} &= (\text{water flowrate})(\text{heat of vaporization}) \\ &= 2681(1050.54) \\ &= 2.82 \text{ E} + 06 \text{ Btu/h} \end{aligned}$$

where the value of 2681 lb/h was from Table 2.41 and 1050.54 Btu/lb is the water latent heat, that is, the heat needed to vaporize one pound of water to vapor form.

#### 4.3. Calculate heat loss

The heat loss can be rigorously calculated based on the radiative and convective heat transfer, or it can be prescribed. For this calculation, assume that the heat loss is 5.34% of the heat entering the kiln. Since there is no preheat, the heat entering the kiln is the heat of combustion.

$$\begin{aligned} \text{Heat loss} &= 26.10 \text{ E} + 06(5.34/100) \\ &= 1.39 \text{ E} + 06 \text{ Btu/h} \end{aligned}$$

#### 4.4. Calculate sensible heat

The sensible heat is the energy required to heat the combustion gas from the reference temperature to the combustion chamber exit temperature. It is the sum of the sensible heat from the components of combustion gases.

$$\text{Sensible heat} = \text{sum}(m_i(Cp_i)(T - T_{\text{ref}}))$$

where  $m_i$  = mass flowrate of component *i* of combustion gases  
 $Cp_i$  = heat capacity of component *i* of combustion gases  
 $T$  = combustion chamber exit temperature (this is the unknown variable which the energy balance is being used to calculate)  
 $T_{\text{ref}}$  = reference temperature = 76.4°F (298 K)

$Cp_i$  is the mean heat capacity of each component of the combustion gas. For gaseous species, the mean heat capacity is calculated according to the equation below.

$$Cp_i = (a_i(T - T_{ref}) + b_i(T^2 - T_{ref}^2)/2 + c_i(T^3 - T_{ref}^3)/3 + d_i(T^4 - T_{ref}^4)/4)(T - T_{ref})$$

where  $T$  is the combustion chamber exit temperature in degrees Kelvin. This is the unknown variable which the energy balance is being used to calculate. It is solved by iteration, calculating the sensible heats and performing the energy balance until it closes. For simplification, in this example we will fortuitously choose the correct combustion exit temperature of 1600°F (1144.4 K) as a first guess. Thus, only one iteration will be required.  $T_{ref}$  is the reference temperature of 76.4°F (298 K).

The constants  $a$ ,  $b$ ,  $c$ , and  $d$  for the gaseous species are provided in Table 2.46 (EPA-92/10).

Using the above equation, the mean heat capacities for the gaseous species are provided in Table 2.47.

For ash, heat capacity is calculated from an integration of a formula from Perry (1973):

$$\begin{aligned} C_{p_{ash}} &= (0.18(T - T_{ref}) + 0.00003(T^2 - T_{ref}^2))/(T - T_{ref}) \\ &= 0.2303 \text{ Btu}/(\text{lb}\cdot^\circ\text{F}) \end{aligned}$$

Thus, the sensible heat of the various species is expressed in Table 2.48

where the values of column “mass flow” were calculated in Table 2.41 of this example  
 temperature difference = combustion chamber exit temperature – reference  
 temperature = 1600°F – 76.4°F = 1523.6°F

4.5. Calculate the total energy balance for a PCC (rotary kiln)

The energy balance terms are combined according to the equation

$$\begin{aligned} &\text{Heat of combustion} - \text{heat of vaporization} - \text{heat loss} - \text{sensible heat} \\ &26.10 E + 06 - 2.82 E + 06 - 1.39 E + 06 - 21.89 E + 06 = 0 \text{ Btu/h} \end{aligned}$$

Since the sum of the heats is zero, the energy balance is closed. If the sum had come out positive, it would have been an indication that the sensible heat was too low. In such a case, the guess for the combustion chamber exit temperature should be revised upward, and the energy balance should be iterated until closure is achieved.

5. Energy balance on a SCC (afterburner)

The energy balance equates the energy released in combustion with the energy required to vaporize all moisture, the energy required to heat the combustion products to the exit temperature, and the energy lost in the process. The energy balance can be expressed as

$$\begin{aligned} &(\text{Heat passed on from kiln}) + (\text{heat of combustion}) - (\text{heat of vaporization}) - (\text{heat loss}) \\ &\quad - (\text{sensible heat}) = 0 \end{aligned}$$

**TABLE 2.46** Constants for Heat Capacity Calculation

Species	$a$	$b$	$c$	$d$
CO <sub>2</sub>	5.316	$1.4284 \times 10^{12}$	$-8.362 \times 10^{-6}$	$1.784 \times 10^{-9}$
SO <sub>2</sub>	6.157	$1.3840 \times 10^{-2}$	$-9.103 \times 10^{-6}$	$2.057 \times 10^{-9}$
HCl	7.244	$-1.8200 \times 10^{-3}$	$3.170 \times 10^{-6}$	$-1.036 \times 10^{-9}$
O <sub>2</sub>	6.085	$3.6310 \times 10^{-3}$	$-1.709 \times 10^{-6}$	$3.133 \times 10^{-10}$
N <sub>2</sub>	6.903	$-3.7530 \times 10^{-4}$	$1.930 \times 10^{-6}$	$-6.861 \times 10^{-10}$
H <sub>2</sub> O	7.7	$4.5940 \times 10^{-4}$	$2.521 \times 10^{-6}$	$-8.587 \times 10^{-10}$

**TABLE 2.47** Heat Capacity

Species	Mole base		Mass base
	$C_p$ (Btu/(mole-°F))	Molar weight ( $M$ )	$C_p$ (Btu/(lb-°F)) = $C_p$ (Btu/(mole-F))/ $M$
CO <sub>2</sub>	11.67	44	0.2652
SO <sub>2</sub>	11.9	64	0.1859
HCl	7.25	36.5	0.1986
O <sub>2</sub>	7.87	32	0.2459
N <sub>2</sub>	7.41	28	0.2646
H <sub>2</sub> O	9.06	18	0.5033

or

$$(\text{Heat passed on from kiln}) + (\text{heat of combustion}) = (\text{heat of vaporization}) + (\text{heat loss}) + (\text{sensible heat})$$

The heat passed on from the kiln includes the sensible heat and the heat of vaporization of the combustion gas entering the afterburner.

The sensible heat entering the afterburner is the same as the sensible heat exiting the rotary kiln except that a portion of that sensible heat is lost due to the ash which drops out in the kiln:

$$\begin{aligned} \text{Sensible heat entering the afterburner} &= \text{sensible heat exiting kiln} \\ &\quad - \text{sensible heat of ash drop out} \end{aligned}$$

Since 98% of the ash drops out in the kiln, 98% of the sensible heat of the ash also drop out:

$$\begin{aligned} \text{Sensible heat of ash dropout} &= 105,616(0.98) \\ &= 103,504 \text{ Btu/lb} \end{aligned}$$

$$\begin{aligned} \text{Sensible heat entering the afterburner} &= 21,890,000 \text{ (from Table 2.48)} - 103,504 \\ &= 21.78 \text{ E} + 06 \text{ Btu/lb} \end{aligned}$$

The heat of vaporization of the combustion gas entering the afterburner is the same as the heat of vaporization of the gas exiting the kiln as calculated in step 4.2 of this example.

**TABLE 2.48** Sensible Heat Exiting PCC

Species	Mass flow	$C_p$ (Btu/(lb-°F))	Temperature difference	Sensible heat of species (Btu/h)
CO <sub>2</sub>	4413	0.2652	1523.6	1,783,111
SO <sub>2</sub>	0	0.1859	1523.6	0
HCl	84	0.1986	1523.6	25,417
O <sub>2e</sub>	7043	0.2459	1523.6	2,638,683
N <sub>2</sub>	37,917	0.2646	1523.6	15,286,032
H <sub>2</sub> O	2681	0.5033	1523.6	2,055,866
Ash	301	0.2303	1523.6	105,616
Sum of sensible heat is roughly equal to 21.89 E + 06				21,894,725

$$\begin{aligned}
 \text{Heat passed on from kiln} &= \text{sensible heat entering afterburner} \\
 &\quad + \text{heat of vaporization entering afterburner} \\
 &= 21.78 E + 06 + 2.82 E + 06 \\
 &= 24.60 E + 06 \text{ Btu/h}
 \end{aligned}$$

### 5.1. Calculate heat of combustion

The heat of combustion is the chemical heat released as the reactants are converted to products at the reference state of 76.4°F with the product H<sub>2</sub>O in liquid form. It is calculated by the following equation:

$$\text{Heat of combustion} = \text{HHV}(\text{mass flow}) - (\text{heat of solution})$$

where HHV is the higher heating value of the fuel/waste, and heat of solution is the energy released when gaseous HCl dissolves in water. The heat of solution is calculated by the following equation:

$$\text{Heat of solution} = (\text{mass flow})(\text{Cl})(1 - \text{moisture})887.36(1 - \exp((-H_2O/HCl)^{0.77}/1.92))$$

Since the No. 2 fuel oil charged to the afterburner has no chlorine, Cl = 0, the heat of solution is 0.

$$\begin{aligned}
 \text{Thus, heat of combustion} &= 25,296(554) - 0 \\
 &= 14.01 E + 06 \text{ Btu/lb}
 \end{aligned}$$

where the values of 25,296 and 554 were given in Table 2.39.

### 5.2. Calculate heat of vaporization

As shown in the preceding section, the higher heating value is used for the heat of combustion. This is based on the assumption that the product water is in liquid form. However, in combustion, the product water is in vapor form. Therefore, the heat required to vaporize that water must be factored into the energy balance.

The heat of vaporization is the heat required to vaporize all moisture and combustion water. It is calculated according the equation

$$\begin{aligned}
 \text{Heat of vaporization} &= (\text{H}_2\text{O in kiln} + \text{H}_2\text{O in afterburner})(\text{heat of vaporization}) \\
 &= 3309(1050.54) \\
 &= 3.48 E + 06 \text{ Btu/h}
 \end{aligned}$$

where the value of 3308 is from Table 2.44 of this example.

### 5.3. Calculate heat loss

The heat loss can be rigorously calculated based on the radiative and convective heat transfer, or it can be prescribed. For this calculation, assume that the heat loss is 5.96% of the heat entering the afterburner. The heat load to the afterburner includes the heat of combustion and the heat passed on from the kiln.

$$\begin{aligned}
 \text{Heat loss} &= (14.01 E + 06 + 24.60 E + 06)(5.96/100) \\
 &= 2.30 E + 06 \text{ Btu/h}
 \end{aligned}$$

### 5.4. Calculate sensible heat

The sensible heat exiting the afterburner is the energy required to heat the combustion gas (including both kiln and afterburner combustion products) from the reference temperature to

the combustion chamber exit temperature. It is the sum of the sensible heats from the components of combustion gases:

$$\text{Sensible heat} = \text{sum}(m_i(Cp_i)(T - T_{\text{ref}}))$$

where  $m_i$  = mass flowrate of component  $i$  of combustion gases  
 $Cp_i$  = heat capacity of component  $i$  of combustion gases  
 $T$  = combustion chamber exit temperature (this is the unknown variable which the energy balance is being used to calculate)  
 $T_{\text{ref}}$  = reference temperature = 76.4°F (298 K)

$Cp_i$  is the mean heat capacity of each component of the combustion gas. For gaseous species, the mean heat capacity is calculated according to the equation below.

$$Cp_i = (a_i(T - T_{\text{ref}}) + b_i(T^2 - T_{\text{ref}}^2)/2 + c_i(T^3 - T_{\text{ref}}^3)/3 + d_i(T^4 - T_{\text{ref}}^4)/4)/(T - T_{\text{ref}})$$

where  $T$  is the combustion chamber exit temperature in degrees Kelvin. This is the unknown variable which the energy is being used to calculate. It is solved by iteration, calculating the sensible heats, and performing the energy balance until it closes. For simplification, in this example we will fortuitously choose the correct combustion exit temperature of 2000°F (1366.7 K) as a first guess. Thus, only one iteration will be required.  $T_{\text{ref}}$  is the reference temperature of 76.4°F (298 K).

The constants  $a$ ,  $b$ ,  $c$ , and  $d$  for the gaseous species are given in Table 2.46 (EPA-92/10).

Using the above equation, the mean heat capacities for the gaseous species are provided in Table 2.49.

For ash, heat capacity is calculated from an integration of a formula from Perry (1973):

$$\begin{aligned} C_{p_{\text{ash}}} &= (0.18(T - T_{\text{ref}}) + 0.00003(T^2 - T_{\text{ref}}^2))/(T - T_{\text{ref}}) \\ &= 0.2423 \text{ Btu}/(\text{lb}\cdot^\circ\text{F}) \end{aligned}$$

Thus, the sensible heat of the species is given in Table 2.50.

where the values of the column “mass flow” were calculated in Table 2.41 of this example.

Temperature difference = combustion chamber exit temperature  
 – reference temperature = 2000 – 76.4 = 1923.6°F

5.5. Calculate the total energy balance for the SCC (afterburner)

The energy balance terms are combined according to the equation

**TABLE 2.49** Heat Capacity

Species	Mole base		Mass base
	$Cp$ (Btu/(mole-°F))	Molar weight ( $M$ )	$Cp$ (Btu/(lb-°F)) = $Cp$ (Btu/(mole-F))/ $M$
CO <sub>2</sub>	12.07	44	0.2743
SO <sub>2</sub>	12.18	64	0.1903
HCl	7.38	36.5	0.2022
O <sub>2</sub>	8.02	32	0.2506
N <sub>2</sub>	7.55	28	0.2696
H <sub>2</sub> O	9.37	18	0.5206

**TABLE 2.50** Sensible Heat Exiting Afterburner

Species	Mass flow	$C_p$ (Btu/(lb-°F))	Temperature difference	Sensible heat of species (Btu/h)
CO <sub>2</sub>	6183	0.2743	1923.6	3,262,420
SO <sub>2</sub>	2.44	0.1903	1923.6	893
HCl	84	0.2022	1923.6	32,672
O <sub>2e</sub>	7045	0.2506	1923.6	3,396,072
N <sub>2a</sub>	44,000	0.2696	1923.6	22,818,513
H <sub>2</sub> O	3309	0.5206	1923.6	3,313,719
Ash	6	0.2423	1923.6	2797
Sum of sensible heat is roughly equal to $32.83 E + 06$				32,827,086

Heat passed on from PCC + heat of combustion – heat of vaporization – heat loss  
–sensible heat = 0

$$24.60 E + 06 + 14.01 E + 06 - 3.48 E + 06 - 2.30 E + 06 - 32.83 E + 06 = 0$$

Since the sum of the heats is zero, the energy balance is closed. If the sum had come out positive, it would have been an indication that the sensible heat was too low. In such a case, the guess for the combustion chamber exit temperature should be revised upward, and the energy balance should be iterated until closure is achieved.

#### 6. Calculate residence time

##### 6.1. Calculate the standard condition flow volumetric flowrate

Mean residence time in a combustion chamber is calculated from the temperature, volume, and volumetric flow of the combustion chamber.

$$\text{Volumetric flow at } 70^\circ\text{F} = (\text{molar flow})(386.7 \text{ sft}^3/\text{mole})$$

where the value of  $386.7 \text{ sft}^3$  is the gas volume at standard conditions.

$$\begin{aligned} \text{Volumetric flow (at } 70^\circ\text{F)}_{\text{PCC}} &= (\text{molar flow in Table 2.41})(386.7 \text{ sft}^3/\text{mole}) \\ &= 1825.83(386.7) \\ &= 706,048.46 \text{ sft}^3/\text{h} \text{ (standard cubic feet per hour)} \\ &= 196.12 \text{ sft}^3/\text{s} \end{aligned}$$

$$\begin{aligned} \text{Volumetric flow (at } 70^\circ\text{F)}_{\text{SCC}} &= (\text{molar flow in Table 2.44})(386.7 \text{ sft}^3/\text{mole}) \\ &= 2118.29(386.7) \\ &= 819,142.74 \text{ sft}^3/\text{h} \\ &= 227.54 \text{ sft}^3/\text{s} \end{aligned}$$

##### 6.2. Calculate the actual condition flow volumetric flowrate

By the ideal gas law:

$$\begin{aligned} \text{Volumetric flow (at } T) &= \text{volumetric flow (at } 70)(T + 460)/(70 + 460) \\ \text{Volumetric flow (at } T)_{\text{PCC}} &= 196.12(1600 + 460)/(70 + 460) \\ &= 762.27 \text{ ft}^3/\text{s} \\ \text{Volumetric flow (at } T)_{\text{SCC}} &= 227.54(2000 + 460)/(70 + 460) \\ &= 1056.13 \text{ ft}^3/\text{s} \end{aligned}$$

6.3. Calculate the residence time

$$\begin{aligned} \text{Residence time} &= \text{volume}/(\text{volumetric flow}) \\ \text{Residence time}_{\text{PCC}} &= 1525/762.27 = 2.00 \text{ s} \\ \text{Residence time}_{\text{SCC}} &= 2113/1056.13 = 2.00 \text{ s} \end{aligned}$$

## 5.7 Stationary Hearth System

This section provides the application of a stationary hearth to the incineration of medical waste (OME-86/10, p. 28). This type of incinerator is also known as a starved air incinerator or a controlled air incinerator. The purpose of this section is to compare the difference between a stationary hearth and a rotary kiln provided in Section 5.6.

Figure 2.24 shows the operating principle of a stationary hearth (or controlled air) incinerator. Figure 2.25 shows the major components of a stationary hearth incinerator.

Figure 2.26 shows a typical feeding system for a stationary hearth incinerator.

Figure 2.27 shows a typical staged hearth and automatic ash removal system for a stationary hearth incinerator.

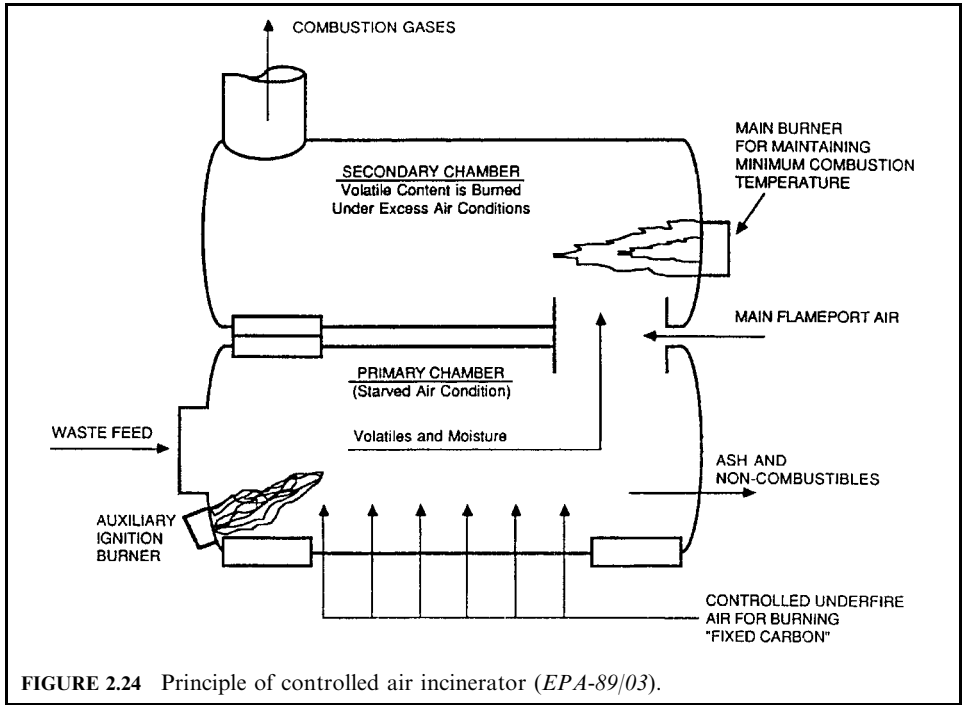

Figure 2.28 shows a waste heat recovery boiler and a bypass stack for emergency use.

The design criteria for this type of incinerator are briefly discussed under the following headings:

- Feed system
- Primary chamber
- Secondary chamber
- Turbulence
- Combustion air
- Burners
- Process monitoring/control
- Quenching
- Ash disposal
- Operating procedure
- Incinerator stack

### FEED SYSTEM

- All feed systems should be designed to prevent leakage of liquids that may be contained in the waste, and should be sloped towards the opening of the incinerator.
- Provision should be made to disinfect the hopper sides and containers when mechanical feed systems are used. Cleaning fluids should be drained to a controlled area or container and properly disposed of.

FIGURE 2.26 Hopper ram assembly (EPA-89/03).

FIGURE 2.27 Staged hearth and automatic ash removal (EPA-89/03).

FIGURE 2.28 Incinerator with waste heat boiler and bypass stack (EPA-89/03).

- Mechanical feed systems should be interlocked with the charging mechanism to facilitate lock-out of the waste feed if the temperature in the secondary chamber falls below  $1000^{\circ}\text{C}$  ( $1830^{\circ}\text{F}$ ).
- Automated mechanical feed systems are desirable to maintain steady operation.

#### PRIMARY CHAMBER

- The rate at which waste is fed into the incinerator is critical to the successful operation of the unit because the feed rate determines the heat release rate of the medical waste and the size of the primary chamber. Medical waste contains low-density, high heating value wastes (e.g., plastics) as well as high-density, low heating value wastes (e.g., tissue, bones). Therefore, the primary chamber should be sized to accommodate the variation in the waste composition.
- The volume of the primary chamber should be designed to allow for a total heat release rate of between  $445,000 \text{ kJ}/(\text{h m}^3)$  ( $12,000 \text{ Btu}/(\text{h ft}^3)$ ) and  $930,000 \text{ kJ}/(\text{h m}^3)$  ( $25,000 \text{ Btu}/(\text{h ft}^3)$ ). A heat release rate of over  $930,000 \text{ kJ}/(\text{h m}^3)$  ( $25,000 \text{ Btu}/(\text{h ft}^3)$ ) is not recommended for use in the design as this may lead to uncontrolled conditions, resulting in high particulate emissions, poor micro-organism destruction, and the discharge of incomplete combustion products to the environment.
- The hearth area should be designed to allow a burning rate of  $58.5\text{--}68.5 \text{ kg}/(\text{h m}^2)$  ( $12\text{--}14 \text{ lb}/(\text{h ft}^2)$ ).
- The primary chamber should be designed to operate continuously under negative pressure to prevent fugitive emissions.

- The temperature in the primary chamber should be maintained in the range 400–760°C (750–1400°F). Avoiding temperature peaks above 760°C will minimize excursions in gas velocities, thereby reducing ash carry-over and particulate emissions.
- The external casing of the chamber should be designed to maintain a maximum temperature of 70–90°C (160–195°F). This can be accomplished with the use of refractory and/or insulation materials. Where appropriate, an expanded metal shield or other suitable means of shielding should be installed for the protection of personnel.
- The primary chamber hearth should have an adequate grease containment lip at the opening to prevent escape or leakage of fluids from the chamber. The lip should be a minimum of 5 cm (2 inches) deep.
- A “hot hearth” is recommended for use in all primary chambers where economically feasible.

#### SECONDARY CHAMBER

- The temperature in the secondary chamber should be designed for a minimum of 1100°C (2010°F) with an operating temperature of not less than 1000°C (1830°F) at all times.
- The incinerator should be designed to provide no less than 6% residual oxygen in the flue gas exhaust from the secondary chamber.
- The secondary chamber should be designed for a gas residence time of not less than 1 s at 1000°C (1830°F). This residence time is to be based on the volume of the secondary chamber from the flame front to the location of the temperature sensing device.
- The temperature in the secondary chamber should be controlled by a thermocouple or other temperature sensor located at a point representing 1-s retention time at the exit of the secondary chamber or at the breaching. The thermocouple should be connected to a system to provide automatic temperature control, and it should also regulate the modulating secondary chamber burner.
- The refractory surface of the secondary chamber should be heated over a minimum period of half an hour prior to feeding waste into the incinerator to ensure optimum conditions for the destruction of micro-organisms.
- The external casing of the secondary chamber should be designed to maintain a maximum temperature of 70–90°C (160–195°F) by means of insulation and refractory. For protection of personnel, an expanded metal shield or other suitable means of protection should also be installed on the casing.

#### TURBULENCE

- Gas turbulence is an important parameter in the design of incinerators and can be achieved by high combustion gas velocity, tangential air injection, abrupt changes in flow direction, and the installation of combustion gas restrictions (e.g., orifices, checkerwork, or baffles).
- Turbulence is difficult to quantify; however, use of the Reynolds number ( $Re$ ) has been suggested to provide an indication of the gas-phase turbulence in the incinerator.
- The calculated Reynolds number in the secondary chamber should be over 10,000 to ensure turbulent flow.

#### COMBUSTION AIR

- For starved air incinerators, air into the primary chamber should be supplied at 30–80% of that required for stoichiometric combustion.
- The air supply in the secondary chamber of all incinerators should be able to provide excess air at 40–250% of that theoretically required during the peak burning rate.

- The combustion air supply should be automatically adjustable with a temperature recorder control system to maintain the set temperatures in the primary and secondary chambers of the incinerator.

#### BURNERS

- The burners must be able to maintain a stable flame throughout the range of pressures, input rates, and fuel/air ratios experienced in the primary and secondary chambers.
- The burners should be designed to supply a minimum of 80% of the total heat input of the incinerator design capacity. The burners must also be capable of modulating down to 15% of the total heat input requirement.
- The burner(s) in the primary chamber should be:
  - located at a downward angle to provide maximum impingement of the flame onto the wastes. The alignment of the burner(s) should not allow the flame to impinge on the refractory walls or on other burner(s)
  - set to maintain a temperature of 400–760°C (750–1400°F) in the primary chamber once the burn cycle is initiated
  - constructed with a sealed casing to eliminate the flow of tramp air into the chamber
- The burner(s) in the secondary chamber should be:
  - mounted to promote thorough mixing throughout the whole chamber. The alignment of the burner(s) should not allow the flame to impinge on the refractory walls or on other burner(s)
  - designed to automatically lock out the primary chamber charging mechanism in the event of burner(s) failure
  - set to maintain a temperature of not less than 1000°C (1830°F) in the secondary chamber at all times
  - fully modulating with a low “hold fire” setting to ensure a flame throughout the incineration cycle

#### PROCESS MONITORING/CONTROL

- One, or preferably two, viewports should be installed in the primary chamber immediately behind the burners to facilitate visual inspection of the burn. The location should be selected to reduce particulate impingement, so that the viewport will remain relatively clean.
- A temperature recorder/controller (TRC) should be used to control primary and secondary temperatures by:
  - turning off or reducing heat input from the burners
  - turning off, throttling back, or increasing the air supply
  - turning on the quench water system where used

The TRCs should provide a graphical recording of the temperature variations and feedback of the operating fluctuations. A TRC should be used to monitor the temperature at the exit of the primary chamber and also control the air supply to the primary chamber and its auxiliary burners. A second TRC should be installed to monitor the temperature at the exit of the secondary chamber or at the base of the stack, and also to control the secondary air supply and its auxiliary burners.

- All incinerators should be equipped with continuous total hydrocarbon or carbon monoxide monitoring equipment. An opacity meter should also be provided in the incinerator stack.

### QUENCHING

- A water quench system should be provided in the primary chamber of the incinerator to prevent the temperature from developing into runaway conditions and/or to reduce flue gas temperatures at the exit of the secondary chamber.
- The quench system should be activated by the primary chamber TRC and sized to reduce the temperature in the primary chamber by 2000°C (3630°F) within 60 s.

### ASH DISPOSAL

- Ash resulting from the incineration of medical waste may contain significant quantities of sharps, needles, and glass; therefore, care should be exercised in the removal and disposal of incinerator ash.
- The incinerator ash should be wetted prior to handling to minimize the potential for generating airborne dust.
- All personnel handling the ash should wear or use dust masks, gloves, and protective clothing as a safety precaution.
- The incinerator ash should be stored in enclosed containers and transported to an approved landfill site for disposal.

### OPERATING PROCEDURE

- Waste should not be charged into the incinerator during the start-up period until the refractory surface of the secondary chamber has been heated to the operating temperature.
- The initial charges to the incinerator should be noninfectious waste; infectious waste should be fed later in the incineration cycle.
- The waste should be weighed and logged prior to charging to ensure that the design feed rate is not exceeded and to maintain a record of the quantities of waste processed.
- Incinerator operators should be properly trained and be familiar with all the manufacturer's operating procedures for the unit.
- The ash in the primary chamber should be discharged on a batch basis at the end of each incineration cycle to ensure complete destruction of the micro-organisms.

### INCINERATOR STACK

- For natural draft systems, calculations for stack design should be based on a gas temperature of 1000°C (1830°F). If substantial heat losses through the stack are expected, such losses should be taken into account in determining the average stack temperature and the available draft.
- The stack height should be calculated to provide a minimum available draft of 6.3 mm (0.25 in.) water gauge (WG) at the breaching. The latter is an absolute minimum draft provision for all natural draft medical waste incinerators and must result in a draft of at least 2.5 mm (0.1 in.) WG at the burner air inlets. Perry's Chemical Engineers' Handbook outlines procedures for calculating stack draft.

### EXAMPLE stationary hearth system

An energy and material balance is an important part of designing and/or evaluating incinerators. The following example entails a mathematical evaluation of the input and output conditions of a medical waste incinerator. It determines the combustion air and auxiliary fuel requirements for incinerating a given medical waste, and the limitations of an existing incinerator when charged with a known waste.

An incinerator is to be designed to incinerate a mixture of 30% red bag and 70% yellow bag (with a PVC content of 4%) medical waste. Throughput is to be 100 kilogram per hour

(kg/h). The auxiliary fuel is natural gas, the waste has been ignited, and the secondary burner is modulating. Design requirements are summarized as follows:

- secondary chamber temperature: 1100°C
- flue gas residence time at 1000°C: 1 s
- residual oxygen in flue gas: 6% minimum (OME-86/10, p. 42)

For comparison purposes, this example provides both the metric system and the British system in the process of solution calculation.

**Given conditions**

- waste throughput = 100 kg/h or 220 lb/h
- input temperature of waste, fuel, and air is 15.5°C or 60°F
- air contains 23% by weight O<sub>2</sub> and 77% by weight N<sub>2</sub>
- air contains 0.0132 kg-H<sub>2</sub>O/kg-dry-air at 60% relative humidity, and 26.7°C dry bulb temperature, or 0.0132 lb-H<sub>2</sub>O/kg-dry-air at 60% relative humidity and 80°F dry bulb temperature
- for any ideal gas, 1 kg-mole is equal to 22.4 m<sup>3</sup> at 0°C and 101.3 kPa
- latent heat of vaporization of water is 2460.3 kJ/kg at 15.5°C or 1057.35 Btu/lb at 60°F
- 1 Btu = 1.0551 kJ
- 1 Btu/lb = 2.3269 kJ/kg = 0.5557 kcal/kg
- 1 Btu/lb-°F = 4.1883 kJ/kg-°C
- 1 lb = 453.5 g = 0.4535 kg
- 1 ft<sup>3</sup> = 0.02832 m<sup>3</sup>

*Solution:*

1. Analyze waste throughput

Waste throughput = 100.00 kg/h or 220.51 lb/h

Red bag throughput = 30%(100) = 30 kg/h or 66.15 lb/h

Yellow bag throughput = 70%(100) = 70 kg/h or 154.36 lb/h

1.1. Analyze red bag waste components for 30 kg/h throughput

	%	kg/h	lb/h
Tissue	0.15	4.50	9.92
Water	0.80	24.00	52.92
Ash	0.05	1.50	3.31
	1.00	30	66.15

1.2. Analyze yellow bag waste components for 70 kg/h throughput

	%	kg/h	lb/h
Polyethylene	0.35	24.50	54.02
PVC	0.04	2.80	6.17
Cellulose	0.51	35.70	15.44
Ash	0.10	7.00	15.44
	1.00	70	154.36

## 2. Calculate theoretical combustion components

## 2.1. Write chemical reaction equations for combustible organics

For tissue ( $C_5H_{10}O_3$ ) incinerationFor polyethylene ( $C_2H_4$ ) incinerationPolyvinyl chloride ( $C_2H_3Cl$ ) incinerationCellulose ( $C_6H_{10}O_5$ ) incineration

## 2.2. Calculate theoretical combustion air

$$\text{Theoretical oxygen (kg base)} = 7.32 + 84.00 + 3.58 + 42.31 = 137.22 \text{ kg/h}$$

$$\text{Theoretical oxygen (lb base)} = 16.15 + 185.23 + 7.90 + 93.30 = 302.57 \text{ lb/h}$$

$$\text{Theoretical nitrogen (kg base)} = 3.29(137.22) = 451.44 \text{ kg/h}$$

$$\text{Theoretical nitrogen (lb base)} = 3.29(302.57) = 995.47 \text{ lb/h}$$

$$\text{Theoretical air (kg base)} = \text{theoretical oxygen} + \text{theoretical nitrogen}$$

$$\text{Theoretical air (kg base)} = 137.22 + 451.44 = 588.66 \text{ kg/h}$$

$$\text{Theoretical air (lb base)} = 302.57 + 995.47 = 1298.04 \text{ lb/h}$$

2.3. Calculate  $CO_2$  formed

$$CO_2 \text{ products (kg base)} = 8.39 + 77.00 + 3.94 + 58.18 = 147.51 \text{ kg/h}$$

$$CO_2 \text{ products (lb base)} = 18.50 + 169.79 + 8.69 + 128.29 = 325.27 \text{ lb/h}$$

2.4. Calculate moisture ( $\text{H}_2\text{O}$ ) formed

$$\text{H}_2\text{O products (kg base)} = 3.43 + 31.50 + 0.81 + 19.99 = 55.73 \text{ kg/h}$$

$$\text{H}_2\text{O products (lb base)} = 7.57 + 69.46 + 1.78 + 44.08 = 122.89 \text{ lb/h}$$

## 2.5. Calculate HCl formed

$$\text{HCl products (kg base)} = 1.64 \text{ kg/h}$$

$$\text{HCl products (lb base)} = 3.61 \text{ lb/h}$$

## 2.6. Calculate ash dropout

$$\text{Ash from waste feed (kg base)} = 8.50 \text{ kg/h}$$

$$\text{Ash from waste feed (lb base)} = 18.75 \text{ lb/h}$$

## 3. Calculate actual combustion components

## 3.1. Calculate actual dry combustion air

By given conditions at the 150% excess air combustion,

$$\text{Excess air amount (kg base)} = 588.66(1.5) = 882.99 \text{ kg/h}$$

$$\text{Excess air amount (lb base)} = 1298.04(1.5) = 1947.06 \text{ lb/h}$$

Actual air amount = theoretical oxygen + excess oxygen

$$\begin{aligned} \text{Actual air amount (kg base)} &= \text{theoretical oxygen} + \text{excess oxygen} \\ &= 588.66 + 882.99 = 1471.65 \text{ kg/h} \end{aligned}$$

$$\text{The actual air amount (lb base)} = 1298.04 + 1947.06 = 3245.10 \text{ lb/h}$$

## 3.2. Calculate the moisture from actual dry combustion air

By given conditions, the humidity = 0.0132 kg- $\text{H}_2\text{O}$ /kg-dry-air, or 0.0132 lb- $\text{H}_2\text{O}$ /lb-dry-air

Moisture = humidity (dry air)

$$\text{Moisture (kg base)} = 0.0132(1471.65) = 19.43 \text{ kg/h}$$

$$\text{Moisture (lb base)} = 0.0132(3245.10) = 42.84 \text{ lb/h}$$

## 4. Calculate material balance

## 4.1. Calculate mass in

Mass in = waste feed rate + actual dry combustion air + moisture from combustion air

$$\text{Mass in (kg base)} = 100.00 + 1471.65 + 19.43 = 1591.08 \text{ kg/h}$$

$$\text{Mass in (lb base)} = 220.51 + 3245.10 + 42.84 = 3508.44 \text{ lb/h}$$

## 4.2. Calculate dry combustion products

Dry combustion products = excess air + theoretical nitrogen +  $\text{CO}_2$  from combustion

$$\text{Dry combustion products (kg base)} = 882.99 + 451.44 + 147.51 = 1481.94 \text{ kg/h}$$

$$\text{Dry combustion products (lb base)} = 1947.06 + 995.47 + 325.27 = 3267.80 \text{ lb/h}$$

4.3. Calculate  $\text{H}_2\text{O}$  in products

$$\begin{aligned} \text{H}_2\text{O in products} &= \text{H}_2\text{O from waste} + \text{H}_2\text{O from combustion reaction} \\ &\quad + \text{H}_2\text{O from actual combustion air} \end{aligned}$$

$$\text{H}_2\text{O in products (kg base)} = 24.00 + 55.73 + 19.43 = 99.16 \text{ kg/h}$$

$$\text{H}_2\text{O in products (lb base)} = 52.92 + 122.89 + 42.84 = 218.65 \text{ lb/h}$$

4.4. Calculate flue gas flowrate ( $W_{\text{pec}}$ )

Flue gas flowrate ( $W_{\text{pec}}$ ) = dry combustion products (step 4.2) + moisture in products (step 4.3)

$$W_{\text{pcc}} = 1481.94 + 99.16 = 1581.10 \text{ kg/h in kg base}$$

$$W_{\text{pcc}} = 3267.80 + 218.65 = 3486.45 \text{ lb/h in lb base}$$

## 4.5. Calculate total mass out

Total mass out = the sum of (dry combustion products (step 4.2) + H<sub>2</sub>O in products (step 4.3) + HCl (step 2.5) + ash (step 2.6))

$$\text{Total mass out (kg base)} = 1481.94 + 99.16 + 1.64 + 8.50 = 1591.24 \text{ kg/h}$$

$$\text{Total mass out (lb base)} = 3267.80 + 218.65 + 3.61 + 18.75 = 3508.81 \text{ lb/h}$$

## 4.6. Check on material balance

Comparing data in steps 4.1 and 4.4, the results should be identical if the combustion materials are balanced. However, for this example, the discrepancy between the values of 1591.08 kg/h and 1591.24 kg/h or between the values of 3508.44 lb/h and 3508.81 lb/h is probably due to rounding off of certain values; in any case, the values are considered to be very close.

## 5. Calculate heat balance

5.1. Calculate heat input ( $Q_i$ )

Combustible components	Waste (kg/h)	Hc (kJ/kg)	Heat input (kJ/h)
Tissue	4.50	20,471.00	92,119.50
Polyethylene	24.50	46,304.00	1,134,448.00
PVC	2.80	22,630.00	63,364.00
Cellulose	35.70	18,568.00	662,877.60
	67.50		1,952,809.10 kJ/h or 1,850,828.45 Btu/h

$$Q_i = 1,952,809.10 \text{ kJ/h or } 1,850,828.45 \text{ Btu/h}$$

where Hc = HHV (high heating value)

$$1 \text{ Btu} = 1.0551 \text{ kJ}$$

5.2. Calculate total heat out based on an equilibrium temperature of 1100°C ( $Q_o$ )5.2.1. Calculate radiation loss ( $Q_r$ )

$$\begin{aligned} Q_r &= 5\% \text{ of total heat available} \\ &= 0.05(1,952,809.10) \\ &= 97,640.46 \text{ kJ/h or } 92541.42 \text{ Btu/h} \end{aligned}$$

5.2.2. Calculate heat loss to ash ( $Q_a$ )

$$\begin{aligned} Q_a &= mC_p\Delta T \\ &= 8.5(0.831)(1100 - 15.5) \\ &= 8.5(0.831)(1084.5) \\ &= 7660.37 \text{ kJ/h or } 7260.32 \text{ Btu/h} \end{aligned}$$

where  $m$  = weight of ash = 8.5 kg/h

$$C_p = \text{heat capacity} = 0.831 \text{ kJ/kg}\cdot^\circ\text{C}$$

$$\Delta T = 1100 - 15.5 = 1084.5^\circ\text{C}$$

5.2.3. Calculate heat loss to dry combustion products ( $Q_g$ )

$$\begin{aligned} Q_g &= mC_p\Delta T \\ &= 1481.94(1.086)(1100 - 15.5) \\ &= 1481.94(1.086)(1084.5) \\ &= 1,745,380.03 \text{ kJ/h or } 1,654,231.85 \text{ Btu/h} \end{aligned}$$

where  $m$  = weight of combustion products = 1481.94 kg/h  
 $C_p$  = heat capacity of combustion products = 1.086 kJ/kg-°C  
 $\Delta T$  = 1100 - 15.5 = 1084.5°C

5.2.4. Calculate heat loss to moisture ( $Q_m$ )

$$\begin{aligned} Q_m &= mC_p\Delta T + mH_v \\ &= 99.16(2.347)(1100 - 15.5) + 99.16(2460.3) \\ &= 99.16(2.347)(1084.5) + 99.16(2460.3) \\ &= 252,394.08 + 243,963.35 \\ &= 496,357.43 \text{ kJ/h or } 470,436.39 \text{ Btu/h} \end{aligned}$$

where  $m$  = weight of water = 99.16 kg/h  
 $C_p$  = heat capacity of water = 2.347 kJ/kg-°C  
 $\Delta T$  = 1100 - 15.5 = 1084.5°C  
 $H_v$  = latent heat of water vaporization = 2460.3 kJ/kg

5.2.5. Calculate total heat out ( $Q_o$ )

$$\begin{aligned} Q_o &= \text{sum of (5.2.1 + 5.2.2 + 5.2.3 + 5.2.4)} \\ &= 2,347,038.29 \text{ kJ/h or } 2,224,469.98 \text{ Btu/h} \end{aligned}$$

5.2.6. Calculate net heat balance ( $Q_n$ )

$$\begin{aligned} Q_n &= Q_i - Q_o \\ &= 1,952,809.10 - 2,347,038.29 \\ &= -394,229.19 \text{ kJ/h (deficiency)} \end{aligned}$$

The negative sign indicates that auxiliary fuel must be supplied to achieve the design temperature of 1100°C.

6. Calculate auxiliary fuel required to reach 1100°C

6.1. Calculate total heat required from fuel ( $Q_f$ )

$$\begin{aligned} Q_f &= 394,229.19 + 5\% \text{ radiation loss} \\ &= 413,940.65 \text{ kJ/h or } 392,323.62 \text{ Btu/h} \end{aligned}$$

6.2. Calculate natural gas requirements

Available heat (net) from natural gas at 1100°C and 20% excess air = 15,805.2 kJ/m<sup>3</sup> (Gordon-79/09)

$$\begin{aligned} \text{Natural gas required: } &413,940.65/15,805.2 \\ &= 26.19 \text{ m}^3/\text{h or } 26.19/0.02832 = 924.79 \text{ ft}^3/\text{h} \end{aligned}$$

7. Calculate the products of combustion from auxiliary fuel

Dry products density from fuel at 20% excess air =  $16.0 \text{ kg/m}^3\text{-fuel}$  (Gordon-79/09)

Dry products from fuel at 20% excess air =  $16.0(26.19) = 419.04 \text{ kg/h}$

Moisture quantity from fuel at 20% excess air =  $1.59 \text{ kg/m}^3\text{-fuel}$  (Gordon-79/09)

Moisture from fuel at 20% excess air =  $1.59(26.19) = 41.64 \text{ kg/h}$

8. Calculate the secondary combustion chamber volume required to achieve 1 s residence time at  $1000^\circ\text{C}$

8.1. Calculate the total dry products from waste and fuel

Total dry products from waste (step 4.2) and fuel (step 7)

$$= 1481.94 + 419.04$$

$$= 1900.98 \text{ kg/h}$$

Assuming that dry products have the properties of air and using the ideal gas law, the volumetric flow rate ( $V_p$ ) of dry products at  $1000^\circ\text{C}$  can be calculated as follows:

$$V_p = 1900.98[(22.4)/29][1273/273][1/3600] = 1.9019 \text{ m}^3/\text{s}$$

where  $22.4 \text{ m}^3$  = standard volume at standard conditions

29 kg = air molar weight

1273 K =  $1000^\circ\text{C} + 273$

273 K =  $0^\circ\text{C} + 273$

3600 s = 1 h

8.2. Calculate the moisture from waste and fuel that is in the products

Total water in products (step 4.3) and from the fuel (step 7)

$$= 99.16 + 41.64 = 140.80 \text{ kg/h}$$

Using the ideal gas law, the volumetric flow rate ( $V_m$ ) of moisture at  $1000^\circ\text{C}$  can be calculated as follows:

$$V_m = 140.80[(22.4)/18][1273/273][1/3600] = 0.2270 \text{ m}^3/\text{s}$$

where  $22.4 \text{ m}^3$  = standard volume at standard conditions

18 kg = moisture molar weight

1273 K =  $1000^\circ\text{C} + 273$

273 K =  $0^\circ\text{C} + 273$

3600 s = 1 h

8.3. Calculate the volumetric flow rate

Total volumetric flow rate =  $\sum$  of steps 8.1 and 8.2

$$= 1.9019 + 0.2270 = 2.1289 \text{ m}^3/\text{s}$$

Therefore, the active chamber volume required to achieve 1 s retention is  $2.1289 \text{ m}^3$  (void areas with retention volume). This should not be included in the secondary chamber to meet the 1 s retention time required; the length of chamber should be calculated from the flame front to the location of the temperature-sensing device.

9. Calculate oxygen in the flue gas

The residual oxygen (%O<sub>2</sub>) can be determined using the following equation:

$$\begin{aligned} EA \text{ (excess air)} &= \%O_2 / (21\% - \%O_2) \\ 1.50 &= \%O_2 / (21\% - \%O_2) \\ \%O_2 &= 12.60\% \end{aligned}$$

10. Calculate gas velocity in the rotary kiln (primary combustion chamber)

At standard conditions, i.e., temperature  $T_1 = 0^\circ\text{C}$ , the flue gas flow rate (step 4.4)

$$W_{\text{pcc}} = 1481.94 + 99.16 = 1581.10 \text{ kg/h in kg base}$$

Assuming that the flue gas has a molecular weight similar to air molecular weight, which is equal to 29 kg/kg-mole, the molar flow rate ( $n$ ) =  $W_{\text{pcc}}/29 = 54.52$  kg-mole/h.

Because the volume at standard conditions per kg-mole is 22.4 m<sup>3</sup>, the volumetric flow rate ( $V_{\text{std}}$ ) =  $54.52(22.4) = 1221.26$  m<sup>3</sup>/h.

The actual flue gas volumetric flow rate ( $V_{\text{act}}$ ) can be calculated from the equations below.

$$\begin{aligned} V_{\text{act}} &= T_{\text{act}}(V_{\text{std}}/T_{\text{std}}) \\ &= (1000 + 273)(1221.26/(0 + 273)) \\ &= (1273)(1221.26/273) \\ &= 5694.74 \text{ m}^3/\text{h} \\ &= 1.582 \text{ m}^3/\text{s} \end{aligned}$$

11. Calculate flue gas velocity ( $v$ )

Assuming that the internal cross-sectional area ( $A_i$ ) of the kiln = 4 m<sup>2</sup>, the internal diameter ( $D_i$ ) of the kiln can be calculated from

$$\begin{aligned} D &= (4A_i/3.1416)^{0.5} \\ &= (4(4)/3.1416)^{0.5} \\ &= 2.26 \text{ m} \end{aligned}$$

The flue gas velocity ( $v$ ) can be calculated from

$$\begin{aligned} v &= V_{\text{act}}/A_i \\ &= 1.582/4 \\ &= 0.3955 \text{ m/s} \end{aligned}$$

12. Calculate the residence time in the kiln (last half only)

Assuming that the kiln length = 2 m

Use half the length for residence time calculation, i.e., = 1 m

$$\begin{aligned} \text{Residence time } (t) &= \text{length/velocity} \\ t &= 1/0.3955 \\ &= 2.53 \text{ s} \end{aligned}$$

13. Calculate the kiln volume

$$\begin{aligned}\text{Kiln useful volume} &= (\text{useful length})(\text{cross-sectional area}) \\ &= 1(4) = 4 \text{ m}^3 \\ \text{Total kiln volume} &= (\text{kiln length})(\text{cross-sectional area}) \\ &= 2(4) = 8 \text{ m}^3\end{aligned}$$

14. Gas flow turbulence

$$\text{Reynolds number} = Re = VD/ki$$

where

$$\begin{aligned}V &= \text{average velocity, m/s} \\ D &= \text{diameter of flow} \\ Ki &= \text{kinematic viscosity} = 0.00014 \text{ m}^2/\text{s}\end{aligned}$$

$$Re = 0.3955(2.26)/0.00014 = 6385$$

i.e., probably sufficiently turbulent because the  $Re$  is above 5000.

In accordance with Perry's *Chemical Engineers' Handbook*, p. 5-4, the critical Reynolds number corresponds to the transition from turbulent to laminar flow as the velocity is reduced. Its value is in the range 2000–3000 for a circular pipe.

15. Calculate the specific heat release

$$\begin{aligned}\text{Kiln volume} &= 8 \text{ m}^3 \\ \text{Heat input} &= 1,952,809.10 \text{ kJ/h (step 5.1)} \\ \text{Specific heat release} &= (\text{heat input})/(\text{kiln volume}) \\ &= 1,952,809.10/8 \\ &= 244,101.13 \text{ kJ/m}^3\text{-h}\end{aligned}$$

## 5.8 Evaluation of Trial Burn Data

The operation of an incinerator is subject to the regulations developed under the Resource Conservation and Recovery Act and the Clean Air Act. Federal and State permit writers are responsible for implementing the regulations. One of the major problems that the permit writers often encounter is the uncertainty of determining whether data submitted are adequate or accurate. For example, if an applicant's data show that his incinerator can reach a certain temperature by burning certain wastes at certain combustion air levels, the question is, "Are the claimed data dependable?"

To help answer this question, the authors developed a simple calculational computer model on a Lotus 1-2-3 program in the mid-1990s to calculate an energy and mass balance for a rotary kiln incinerator (Lee-98). The main purpose of the model is to assist the permit writers in evaluating the adequacy of the data submitted by applicants seeking incinerator permits. Key parameters that the model can calculate include theoretical combustion air, excess air needed for actual combustion cases, flue gas rate, and exit temperature.

Because the model is considered to be of interest to the readers, the calculational procedure has been simplified and provided here for the readers' reference.

**EXAMPLE** application of energy and mass balance model to evaluate Ciba–Geigy trial burn data

**Statement of the problem.** The Ciba–Geigy Corporation conducted a trial burn on their rotary kiln incinerator on November 12–17, 1984. The measured data were later summarized in an EPA report (EPA-86/09, p, B-11) and key aspects of it appear below. A schematic of the Ciba–Geigy incinerator is shown in Fig. 2.29.

#### EQUIPMENT INFORMATION

- Type of unit: private incinerator—rotary kiln with secondary chamber
- Capacity: 50 tpd (tons per day) with 10% excess capacity ( $30 \times 10^6$  Btu/h for each burner)
- Pollution control system: quench tower, polygon venturi scrubber (25-in. pressure drop), and packed tower scrubber
- Waste feed system:
  - Liquid: Hauck Model 780 wide-range burners (kiln and secondary burners)
  - Solid: ram feed
- Residence time: 5.05 s (kiln); 3.09 s (secondary chamber)

#### TEST CONDITIONS

- Waste feed data: hazardous liquid and nonhazardous solid wastes usually burned; for this run only, synthetic hazardous liquid waste was tested
- Length of burn: 6–9 h (2-h sampling time)
- Total amount of waste burned: 480 gal (liquid) and 0 lb (solid)
- Waste feed rate: 4 gpm (liquid); 0 lb/h (solid)
- POHCs (principal organic hazardous constituents) selected and percent concentration in waste feed:
  - hexachloroethane 4.87
  - tetrachloroethene 5.03
  - chlorobenzene 29.52
  - toluene 60.58

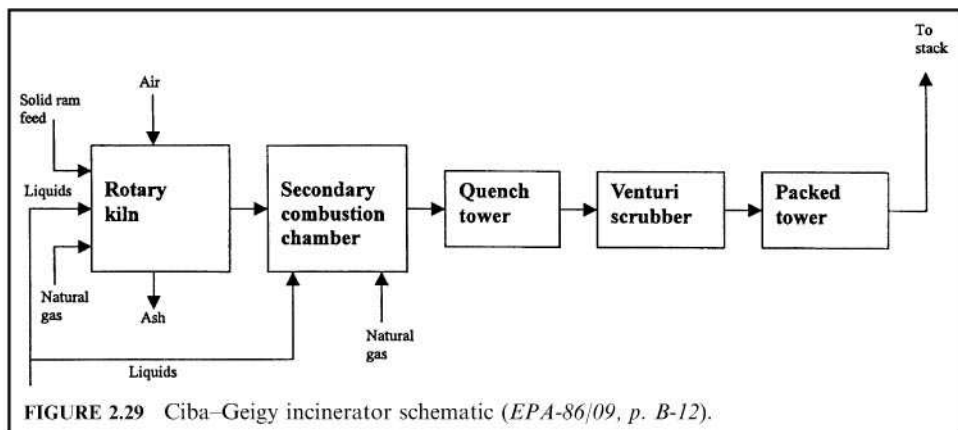

FIGURE 2.29 Ciba–Geigy incinerator schematic (EPA-86/09, p. B-12).

- Btu content: 15,200 Btu/lb
- ash content: not measured
- chlorine content: 20.8% (calculated)
- moisture content: not measured

## OPERATING CONDITIONS

- Temperature: range 1750–1850°F (kiln); 1950-2050°F (secondary chamber)
- Average 1800°F (kiln); 2000°F (secondary chamber)
- Auxiliary fuel used: natural gas (1200 scfh to the kiln)
- Airflow:
  - primary air to kiln 2200 cfm
  - secondary air to kiln 1400 cfm
- Flue gas oxygen content: 10.3%

*Energy and mass balance calculations for primary chamber (kiln) (Table 2.51)*

- A. GIVEN CONDITIONS: the data in question are
- Waste feed rate (gpm): 4 gpm  
Assume that 1 gal = 5 lb  
Waste feed rate in lb/h: 1200 lb/h
  - Fly ash (% of waste feed): 0 (assumed)
  - % of ash due to unburned carbon: 0 (assumed)
  - Ash quench temperature: undefined
  - Exit temperature: unspecified
  - Reference temperature: 70°F
  - Radiation loss (assumed): 0.05 (5%)
  - Excess air rate (EAR) (assumed), by weight: 0.885 (i.e., 88.5% excess air)
  - Humidity at 60% relative humidity (RH), 80°F: 0.0127 kg-H<sub>2</sub>O/kg-dry-air; 0.0127 lb-H<sub>2</sub>O/lb-dry-air
  - Standard volume: 24.04 scm/kg-mol; 386.9 scf/lb-mol
  - Water latent heat: 2460 kJ/kg; 1054 Btu/lb
  - Ash specific heat: 0.83 kJ/kg-°C; 0.25 Btu/lb-°F
  - Flue gas specific heat: 1.09 kJ/kg-°C; 0.26 Btu/lb-°F
  - Water specific heat: 2.35 kJ/kg-°C; 0.49 Btu/lb-°F
  - 1 kcal/g = 4187 kJ/kg = 1799 Btu/lb; 2.33 kJ/kg = 1 Btu/lb; 1 kJ/kg = 0.43 Btu/lb; 1.06 kJ = 1 Btu; 1 m = 3.28 ft
  - Natural gas (heat of combustion): 13.3 kcal/g = 23,932 Btu/lb
  - Waste analysis

**TABLE 2.51** Primary chamber

POHC name	POHC ratio	Waste feed (lb/h)	$\Delta H$ (kcal/g)	$\Delta H$ (Btu/lb)	Mixture (Btu/h)
Hexachloroethane, C <sub>2</sub> Cl <sub>6</sub>	0.0487	58.44	0.46	828	4.84 E + 04
Tetrachloroethene, C <sub>2</sub> Cl <sub>4</sub>	0.0503	60.36	1.19	2141	1.29 E + 05
Chlorobenzene, C <sub>6</sub> H <sub>5</sub> Cl	0.2952	354.24	6.6	11873	4.21 E + 06
Toluene, C <sub>7</sub> H <sub>8</sub>	0.6058	726.96	10.14	18242	1.33 E + 07
Total	1	1200	18.39	33084	1.76 E + 07
Therefore, the heat value of the POHC mixture is (in Btu/lb)					1.47 E + 04

## a18. Chemical analysis

 a18.1. Calculate the ultimate composition of hexachloroethane,  $C_2Cl_6$  (Table 2.52).

 a18.2. Calculate the ultimate composition of tetrachloroethene,  $C_2Cl_4$  (Table 2.53).

 a18.3. Calculate the ultimate composition of chlorobenzene,  $C_6H_5Cl$  (Table 2.54)

 a18.4. Calculate the ultimate composition of toluene,  $C_7H_8$  (Table 2.55).

 a18.5. Calculate the ultimate composition of fuel (natural gas),  $CH_4$  (Table 2.56).

- Fuel (natural gas,  $CH_4$ ) to kiln: 1200 scf/h
- Fuel density = molecular wt/std volume (a10) =  $16/386.9 = 0.04135$  lb/scf
- Fuel weight flow rate = fuel density  $\times$  fuel volume flow rate =  $0.04135(1200) = 49.62$  lb/h

a18.6. Calculate the ultimate composition of compounds by combining items a18.1–a18.5 (Table 2.57).

 a19. Fuel heat input = weight rate  $\times$  HHV =  $(49.62)(23932) = 1.188 E + 06$  Btu/h

 a20. Total heat in = waste input (a17) + fuel input (a19):  $1.88 E + 07$  Btu/h

Total average heating value = a20/(waste + fuel): 15,045 Btu/lb

Because the test data gave 15,200 Btu/lb, it shows that the calculated results and test data are consistent.

**TABLE 2.52** Composition of  $C_2Cl_6$

$CH_4$	37.22	12.40	0.00	0.00	49.62
Total	942.29	91.38	215.95	0.00	1249.62

**B. COMBUSTION AIR**

The combustion air with 88.5% excess air needed to incinerate the following compounds is shown in Table 2.58 (88.5% excess air is an assumed value).

- C = 942.29 lb/h
- H = 91.38
- Cl = 215.95

The format of Table 2.58 was given in Section 2.6.

Calculate the combustion products flow rate (Table 2.59).

Apply the method in Section 2.6.

Check on mass balance.

The above calculations show that the mass of reactants and the mass of products are balanced because  $R_a = P_a = 27,415.81$  lb/h.

**C. COMBUSTION AIR FLOW RATE AND OXYGEN CONTENT****C1. Combustion air flow rate**

From Table 2.58, the actual combustion air is

**TABLE 2.58** Combustion Reactant Table

Basic reaction	Oxygen, nitrogen, and air requirements	Mass (lb/h)	Mole (mol/h)
$C + O_2 \rightarrow CO_2$	(1) $O_2 = C(32/12)$	2512.77	78.52
$H_2 + 0.5O_2 \rightarrow H_2O$	(2) $O_2 = 8(H-Cl/35.5)^*$	682.38	21.32
$S + O_2 \rightarrow SO_2$	(3) $O_2 = S(32/32) = S$	0.00	0.00
$B_o =$ bound oxygen	(4) Data from waste analysis	0.00	0.00
$O_{2t} =$ theoretical $O_2$	$O_{2t} = (1) + (2) + (3) - (4)$	3195.15	99.85
$N_{2t} =$ theoretical $N_2$	$N_{2t} = (O_{2t})(3.76 \times 28/32)$	10,512.04	375.43
$A_t =$ theoretical air	$A_t = O_{2t} + N_{2t}$	13,707.19	475.28
$\%A_e =$ % excess air	Given data (as a fraction)	0.885	
$A_e =$ excess air	$A_e = (\%A_e)(A_t)$	12,130.86	420.62
$A_{ada} =$ actual dry air	$A_{ada} = A_t + A_e$	25,838.05	895.90
$H_2O$ from air†	$0.0127(A_{ada})$	328.14	18.23
$A_a =$ actual air	$A_a = A_{ada} + H_2O$	26,166.19	914.13
Waste feed	Data from waste analysis	1249.62	
$R_a =$ actual reactant	$R_a = A_a +$ waste feed + $H_2O$ from air	27,415.81	

\* If  $H_2$  is the hydrogen left over after Cl reaction, i.e.,  $H_2 = H-Cl/35.5$ , the  $O_2$  needed to react with  $H_2$  will be equal to  $H_2(0.5)(32/2) = 8(H-Cl/35.5)$ .

† In general, at room temperature, the humidity ratio is 0.0127 (lb- $H_2O$ )/(lb-dry-air) or 0.0127 (kg- $H_2O$ )/(kg-dry-air).

$$A_a = 26166.19 \text{ lb/h} = 914.13 \text{ mol/h}$$

$$\begin{aligned} \text{Air flow rate} &= \text{std. volume}(a_{10})(\text{mol/h}) \\ &= 386.9(914.13) \\ &= 353,676.90 \text{ scfh} \\ &= 5894.61 \text{ scfm} \end{aligned}$$

The test result was 3600 scfm with primary air 2200 scfm and secondary air 1400 scfm. When this test result is compared with the calculated result, there is a considerable difference. See the discussion of results that follows.

**TABLE 2.59** Combustion Product Table

Component	Combustion product	Mass (lb/h)	Mole (mol/h)
$CO_2$	$CO_2 = (C)(44/12)$	3455.06	78.52
$SO_2$	$SO_2 = S(64/32)$	0.00	0.00
HCl	$HCl = Cl(36.5/35.5)$	222.03	6.08
$O_{2e}$	$(\%A_e)O_{2t}$ , $O_{2t}$ from Table 2.58	2827.71	88.37
$N_{2e}$	$(\%A_e)N_{2t}$ , $N_{2t}$ from Table 2.58	9303.16	
$N_2$	$N_{2e} + N_{2t} +$ from waste	19,815.20	707.69
$H_2O$ from combustion	$H_2O$ from combustion = $9(H-Cl/35.5)$	767.67	
$H_2O$	$H_2O$ from combustion + from air + from waste	1095.81	60.88
$G_a =$ actual flue gas	$G_a = CO_2 + SO_2 + HCl + O_{2e} + N_2 + H_2O$	27,415.81	941.54
Ash	Fly ash + bottom ash	0.00	
$P_a =$ actual product*	$G_a +$ ash	27,415.81	

\* In performing the mass balance calculation, the values of reactants ( $R_a$ ) and products ( $P_a$ ) should be equal, i.e., if  $R_a = P_a$ , the mass balance calculation is correct.

c2. Calculate oxygen content in flue gas

Table 2.59 shows that the excess oxygen  $O_{2e} = 2827.71$  lb/h and the product flue gas,  $P_a = 27,416$  lb/h

$$\begin{aligned}\text{Therefore, the oxygen content in the flue gas} &= 2827.71/27,416 \\ &= 10.31\%\end{aligned}$$

The test result was 10.3%. This shows that the test result and the calculated result are consistent (and that the calculated air rate is more dependable than the measured one).

c3. Total water vapor in flue gas from Table 2.59: 1095.8 lb/h

c4. Total dry flue gas =  $P_a - H_2O = 27,416 - 1096 = 26,320$  lb/h

#### D. CALCULATION OF EXIT TEMPERATURE FROM KILN

d1. Total heat in = waste heat input (a18) + fuel heat input (a19) = a20:  $1.88 E + 07$  Btu/h

d2. Overall heat loss (assumed as 5%, see a7):  $0.0940 E + 07$

Unburned carbon = 0 (not measured)

d3. Unreleased heat (due to unburned carbon): 0

Trial 1

Assumed exit temperature:  $1500^\circ\text{F}$

Reference temperature:  $70^\circ\text{F}$

d4. Temperature difference ( $\Delta T$ ):  $1430^\circ\text{F}$

$$\begin{aligned}\text{d5. Heat in dry flue gas} &= mCp\Delta T \\ &= [c4 \times a13 \times d4] \\ &= 26,320(0.26)(1430) \\ &= 9.79 E + 06\end{aligned}$$

$$\begin{aligned}\text{d6. Heat in water} &= mCp\Delta T \\ &= (c3 \times a14 \times d4) \\ &= 1096(0.49)(1430) \\ &= 0.0768 E + 07\end{aligned}$$

$$\begin{aligned}\text{d7. Total latent heat} &= (c3 \times a11) \\ &= 1096(1054) \\ &= 0.1158 E + 07\end{aligned}$$

$$\begin{aligned}\text{d8. Heat in ash} &= mCp\Delta T \\ &= (a2 \times a12 \times d4) \\ &= 0.0000\end{aligned}$$

$$\begin{aligned}\text{d9. Total heat accounted for} &= (d2 + d3 + d5 + d6 + d7 + d8) \\ &= 1.2660 E + 07\end{aligned}$$

$$\begin{aligned}\text{d10. Net heat balance} &= (d1 - d9) \\ &= 0.6140 E + 07 \text{ Btu/h}\end{aligned}$$

Trial 2

Assumed exit temperature:  $2500^\circ\text{F}$

Reference temperature:  $70^\circ\text{F}$

d11. Temperature difference ( $\Delta T$ ):  $2430^\circ\text{F}$

$$\begin{aligned}\text{d12. Heat in dry flue gas} &= mCp\Delta T \\ &= [c4 \times a13 \times d4] \\ &= 26,320(0.26)(2430) \\ &= 1.6643 E + 07\end{aligned}$$

$$\begin{aligned}\text{d13. Heat in water} &= mCp\Delta T \\ &= (c3 \times a14 \times d4) \\ &= 1096(0.49)(2430) \\ &= 0.1305 E + 07\end{aligned}$$

- d14. Total latent heat =  $(c3 \times a11)$   
 $= 1096(1054)$   
 $= 0.1158 \ E + 07$
- d15. Heat in ash =  $mCp\Delta t$   
 $= (a2 \times a12 \times d11)$   
 $= 0.0000$
- d16. Total heat accounted for =  $(d2 + d12 + d13 + d14 + d15)$   
 $= 2.0046 \ E + 07 \ \text{Btu/h}$
- d17. Net heat balance =  $(d1 - d16)$   
 $= -0.1246 \ E + 07 \ \text{Btu/h}$
- d18. Using the interpolation method to estimate kiln temperature, we have:

$x_1$	1500°F	0.6140 E + 07 Btu/h	$y_1$
$x$		0.00	$y(y = 0)$
$x_2$	2500	-0.1246 E + 07	$y_2$

$$(x - x_1)/(0 - y_1) = (x_2 - x_1)/(y_2 - y_1)$$

$$x = x_1 - y_1(x_2 - x_1)/(y_2 - y_1)$$

- d19.  $x = 2331^\circ\text{F}$   
 Test data were at 1800°F (average kiln exit temperature).

**Summary/discussion of results.** Based on the calculations contained here and information provided by the trial burn results, a summary of key data is provided in Table 2.60.

Table 2.60 shows that the differences between the calculated and the measured results are small, with the exception of the kiln exit temperature and the air flow rate. The calculated value of the air flow rate is about 63% greater than that of the trial burn (measured) value. The difference is due to the fact that the measured (upstream-from-the-combustor) air rate values neglected to account for the amount of air in-leakage which has to occur in any actual (negative pressure) kiln combustion operation. The measured data relative to oxygen content (taken downstream of the combustor) show that the calculated air in the system (the 5855 scfm amount) is reasonable because the oxygen content measured downstream of the kiln matches the calculated oxygen concentration (the 10.3%). The calculation therefore confirms that the air needed is much more than the 3600 cfm measured value (which, of course, proves that the air in-leakage phenomenon does occur). The fact that the measured kiln exit temperature is also much lower (about 530°F lower) than the calculated kiln exit temperature indicates that the assumed amount of heat loss (the 5%) is probably too low.

**TABLE 2.60** Summary of Calculated and Trial Burn Results

	Calculated results	Measured results
O <sub>2</sub> content in flue gas	10.31%	10.3%
Heating value, Btu/lb	15,045	15,200
Exit kiln temperature	2331°F	1800°F (average)
Air flow rate	5855 scfm	3600 cfm

## 6 EVALUATION OF PERMIT APPLICATION DATA

---

The permit writer may receive incinerator performance data requiring detailed evaluation from the results of a trial burn conducted in accordance with an approved plan. The purpose of this example is to provide numerical methods for interpretation and validation of these data. Sample calculations are provided for:

- computation of destruction and removal efficiencies (DRE)
- scrubber efficiencies
- particulate loadings in the stack gas

The purpose of these calculations is to ensure compliance with the regulatory performance requirements. Guidance is presented to evaluate the routine process monitoring, safety systems inspections, and incinerator effluent management described in a permit application. Finally, the permit writer is presented with guidance for the specification of the regulatory operating requirements under 40CFR Parts 264.345 which are incorporated into an operating permit (EPA-80/12, p. 87).

### 6.1 Evaluation of Compliance with Performance Standards

An owner or operator of a hazardous waste incinerator must submit a computation of the destruction and removal efficiency (DRE), particulate emissions, and scrubber efficiency, if applicable, derived from data accompanying a permit application. The permit writer must ensure that these values are computed correctly and are within the regulatory performance standards specified under 40CFR Parts 264.343. These calculations must be provided for each different set of data or for each trial test conducted. Only in those situations during which the waste feed composition and incinerator operating conditions were exactly the same may these calculated values be averaged. Otherwise, each set of data will be judged independently and only those demonstrating compliance with the performance standards may be used to establish incinerator operating conditions in a permit. A permit application may be recommended for rejection if any of the performance standards are not attained.

#### *Destruction and removal efficiency*

**EXAMPLE** calculation of destruction and removal efficiency (DRE)

Incinerators burning hazardous waste must achieve a destruction and removal efficiency (DRE) of 99.99% for each principal organic hazardous constituent (POHC) in the waste feed as required under 40CFR Parts 264.343(a). The DRE is determined from the following equation:

$$\text{DRE} = [(W_{\text{in}} - W_{\text{out}}) / W_{\text{in}}](100)$$

where DRE = destruction and removal efficiency

$W_{\text{in}}$  = mass feed rate of the principal organic hazardous constituent (POHC) in the waste stream feeding the incinerator

$W_{\text{out}}$  = mass emission rate of the principal organic hazardous constituent (POHC) present in exhaust emissions prior to release to the atmosphere

$W_{\text{in}}$  is calculated using the formula

$$W_{\text{in}} = (\text{concentration of POHC in waste})(\text{waste feed rate})$$

POHCs are given as concentrations and must be expressed in percentages when applying this formula. The waste feed rate is expressed in mass per unit time and must be consistent with the units used to express  $W_{\text{out}}$ . If a waste is cofired with auxiliary fuel, the auxiliary fuel feed rate does not affect the calculation of  $W_{\text{in}}$ .

$W_{\text{out}}$  is calculated from stack sampling data and involves three steps:

- computation of stack gas sample volume
- computation of POHC concentration in stack sample
- computation of stack gas volume flow rate

Stack gas sample volume and stack gas volume flow rate may be determined by EPA methods 2 and 5 or ASTM method D2928. Stack emissions of POHCs may be determined using a modified EPA method 5 apparatus, and includes collection and analysis of particulate matter, gas phase organics, and water present in the stack gas.

Methods of laboratory analysis of a stack sample for POHCs are presented in *Test Methods for Evaluating Solid Waste*, EPA, SW-846, 1980. Sampling and analytical data should be included with a permit application. The following sample calculation of DRE will identify the necessary data and provide methods of computation allowing the permit writer to verify a DRE claimed by an applicant.

#### Given conditions

- POHC = hexachlorobenzene
- concentration of POHC in waste feed = 14.5%
- waste feed rate = 1000 lbs/h

#### Calculation:

Step 1. Computation of  $W_{\text{in}}$

$$\begin{aligned} W_{\text{in}} &= (\text{concentration of POHC in waste})(\text{waste feed rate}) \\ &= 0.145(1000 \text{ lb/h}) \\ &= 145 \text{ lb/h} \end{aligned}$$

Step 2. Computation of stack gas sample volume

This sample volume must include water collected during sampling and be expressed under standard conditions (293 K, 760 mm Hg or 528 °R, 29.92 in. Hg). The following formula from EPA method 5 may be used to compute the corrected dry gas volume  $V_{\text{m}}(\text{std})$ :

$$V_{\text{m}(\text{std})} = K_1 V_{\text{m}} Y [P + (H/13.6)] / T_{\text{m}}$$

where  $V_{\text{m}(\text{std})}$  = sample volume under standard conditions

$K_1$  = 0.3858 K/mm Hg = 17.64 °R/in Hg

$V_{\text{m}}$  = volume of gas measured by dry gas meter, corrected if necessary

$Y$  = dry gas meter calibration factor

$P$  = barometric pressure

$H$  = average pressure differential across sampler orifice meter

$T_{\text{m}}$  = absolute average dry gas meter temperature

**Given conditions**

- $K_1 = 0.3858 \text{ K/mm Hg} = 17.64 \text{ }^\circ\text{R/in. Hg}$
- $V_m = 31.153 \text{ ft}^3$
- $Y = 1.12$
- $P = 29.82 \text{ in. Hg}$
- $H = 0.705 \text{ in. H}_2\text{O}$
- $T_m = 554 \text{ }^\circ\text{R}$

*Calculation:*

$$\begin{aligned} V_{m(\text{std})} &= K_1 V_m Y [P + (H/13.6)] / T_m \\ &= (17.64 \text{ }^\circ\text{R/in. Hg})(31.153 \text{ ft}^3)(1.12)[29.82 \text{ in. Hg} + 0.705 \text{ in. H}_2\text{O}/13.6] / (554 \text{ }^\circ\text{R}) \\ &= 33.19 \text{ scf} \end{aligned}$$

This volume must be corrected for the volume of water collected during sampling using the formula

$$V_{W(\text{GAS})} = 0.0472(V_w - \text{grams SO}_2 - \text{grams H}_2\text{S})$$

where  $V_{W(\text{GAS})}$  = volume of water vapor at standard conditions, scf  
 $V_w$  = volume of water collected in impingers and silica gel, ml

**Given conditions**

- $V_w = 90.4 \text{ ml}$
- $\text{grams SO}_2 = \text{grams H}_2\text{S} = 0$

*Calculation:*

$$\begin{aligned} V_{W(\text{GAS})} &= 0.0472(90.4) \\ &= 4.267 \text{ scf} \end{aligned}$$

The volume of water vapor is added to  $V_{m(\text{std})}$  to obtain the sample volume.

$$\begin{aligned} \text{Sample volume} &= V_{W(\text{GAS})} + V_{m(\text{std})} \\ &= 4.27 + 33.19 \\ &= 37.46 \text{ scf} \end{aligned}$$

Step 3. Computation of POHC concentration in stack sample

The concentration of the POHC in the stack gas ( $C_g$ ) is determined from the following equation:

$$C_g = (\text{total weight of POHC in sample}) / (\text{volume of sample at standard conditions})$$

The total weight of POHC is obtained from laboratory analysis.

**Given conditions**

- $3.5 \text{ } \mu\text{g}$  hexachlorobenzene extracted from water
- $12.3 \text{ } \mu\text{g}$  hexachlorobenzene extracted from particulate matter
- $26.0 \text{ } \mu\text{g}$  hexachlorobenzene extracted from gas-phase trap

Total 41.8  $\mu\text{g}$  hexachlorobenzene  
 or  $4.18 \times 10^{-5}$  grams hexachlorobenzene

Calculation:

$$\begin{aligned} C_g &= (4.18 \times 10^{-5} \text{ g}) / (37.46 \text{ scf}) \\ &= 1.12 \times 10^{-6} \text{ g/scf} \\ &= 2.46 \times 10^{-9} \text{ lb/scf} \end{aligned}$$

#### Step 4. Computation of stack gas volume flow rate

This value is determined by a pitot tube which measures the difference between the total and static pressures in a flue. Gas velocity determinations are made at several locations during sampling and the values are averaged. EPA method 2 or ASTM method D2928 may be used to obtain data. The gas velocity  $V_g$  in feet per minute may be calculated using the formula

$$V_g = 174(C)[(29.92/P_s)(1.00/G_s)(h)(T_s)]^{0.5}$$

where  $V_g$  = gas velocity  
 $C$  = Pitot tube correction factor (usually 0.85 for Type S and 1.00 for others)  
 $P_s$  = absolute pressure in flue, inches of mercury  
 $h$  = velocity pressure at sampling point, inches of water. If the velocities differ greatly from one sampling point to another, the averages of the square roots of the velocity pressures must be used (see ASTM D2928 Section 5.6)  
 $T_s$  = absolute temperature of stack gas,  $^{\circ}\text{R}$   
 $G_s$  = specific gravity of flue gas with respect to air

$G_s$  can be computed by the formulas

$$\begin{aligned} G_s &= M_s / (387)(0.0749) \\ M_s &= M_d [(100 - W) / 100] + 0.18(W) \\ M_d &= 0.44[\%(\text{CO}_2)] + 0.28[9.00(\text{CO})] + 0.32[9.00(\text{O}_2)] + 0.28[\%/\text{N}_2] \end{aligned}$$

where  $W$  = water content of flue gas

#### Given conditions

- $C = 0.835$
- $P_s = 29.81 \text{ in. Hg}$
- $G_s = 0.850$
- $h = 0.202 \text{ in. Hg}$
- $T_s = 582 \text{ }^{\circ}\text{R}$

Calculation:

$$\begin{aligned} V_g &= 174(0.835)[(29.92/29.81)(1.00/0.85)(0.202)(582)]^{0.5} \\ &= 1700 \text{ ft/min} \end{aligned}$$

The stack gas volume flow rate at standard conditions  $Q$  is determined by the formula

$$Q = V_g A_s (530/T_s)(P_s/29.92)$$

where  $A_s$  = cross-sectional area of stack,  $\text{ft}^2$

**Given conditions**

- $A_s = 55.0 \text{ ft}^2$

*Calculation:*

$$\begin{aligned} Q &= V_g A_s (530/T_s)(P_s/29.92) \\ &= (1700 \text{ ft/min})(55.0 \text{ ft}^2)(530/582)(29.81/29.92) \\ &= 84,833 \text{ scf/min} \end{aligned}$$

Step 5. Computation of  $W_{\text{out}}$   
 $W_{\text{out}}$  may be calculated using the formula

$$\begin{aligned} W_{\text{out}} &= C_g Q \\ &= (2.46 \times 10^{-9} \text{ lb/scf})(84,833 \text{ scf/min})(60 \text{ min/h}) \\ &= 0.0125 \text{ lb/h} \end{aligned}$$

Step 6. Computation of DRE  
 The DRE is computed from the equation

$$\begin{aligned} \text{DRE} &= [(W_{\text{in}} - W_{\text{out}})/W_{\text{in}}](100\%) \\ &= \{[(145 \text{ lb/h}) - (0.0125 \text{ lb/h})]/(145 \text{ lb/h})\}(100\%) \\ &= 99.9914\% \end{aligned}$$

Note: the expression of the DRE to 5 or 6 decimal places is justified because an error by as much as 25% in the  $W_{\text{out}}$  would often affect only the fifth decimal place.

If a DRE of 99.99% is not demonstrated, the permit writer must recommend rejection of a permit application for this reason. If the DRE is 99.99% or better, the permit writer must evaluate the scrubber efficiency and particulate emission values submitted by the applicant.

**Hydrogen chloride control efficiency.** An incinerator destroying hazardous waste having an organically bound chlorine concentration greater than 0.5 percent must be equipped with emission control equipment capable of removing at least 99 percent of hydrogen chloride from the exhaust gases, as required under 40CFR Parts 264.343(b). Waste and stack gas sample analyses are usually generated in terms of chloride ( $\text{Cl}^-$ ) concentrations, and the scrubber efficiency (SE) may be defined as

$$\text{SE} = [Cl_{\text{in}} - Cl_{\text{out}}]/Cl_{\text{in}}(100\%)$$

where SE = scrubber efficiency  
 $Cl_{\text{in}}$  = mass feed rate of organically bound chlorides entering the scrubber system  
 $Cl_{\text{out}}$  = mass emission rate of chlorides in the scrubber exhaust gas prior to emission to the atmosphere

In the above definition for scrubber efficiency the words “scrubber system” are used, as opposed to the word “scrubber.” The former term is used on purpose, since many incinerator facilities do indeed have a scrubber system, and rarely have only a single scrubber. A scrubber system is usually composed of a prescrubber quench section (to precool the hot gases, and prevent excess evaporation of scrubber water), and one or more scrubbers installed in a series-flow arrangement. In some installations, the first scrubber is a venturi scrubber which eliminates most particulates and some of the acid gases. Subsequent scrubbers remove acid gases as their primary function. Residual water from the quench section is generally recycled to the quench or to one of the scrubbers. Thus, where the term “scrubber efficiency” is used, the acid

gas removal efficiency of the whole scrubber system is usually the parameter being considered. The efficiency of individual scrubber units can be determined, but a high efficiency for the total scrubber system is the fundamental desired parameter.

Since the gases exiting the scrubber are generally cool (180°F), sampling and analysis of this gas is comparatively easy and safe. Sampling of the hot incinerator exhaust gases is not simple and it may be a somewhat hazardous procedure. A more common basis for estimating  $Cl_{in}$  is to base this quantity on the waste feed rate to the incinerator and the average organic chlorine analysis of this feed. If this method for estimating  $Cl_{in}$  overstates the “true” chlorine content of the unscrubbed exhaust gas (and it may), then the calculated value for scrubber efficiency may also be slightly overstated. Two sources of error, which may be considered negligible for calculation of the scrubber efficiency, derived from using a calculated  $Cl_{in}$  value are as follows:

- Some chlorine may react with alkaline metal components of the feed and end up in any slag or fly-ash.
- Some chlorine may exit the combustion chamber in elemental form ( $Cl_2$ ). This will not dissolve in scrubber water to any large extent, but some will react with alkaline components of scrubber liquid to form hypochlorites. The remainder will exit the system via the stack.

A sample calculation is presented below demonstrating the use of this equation for scrubber efficiency.

**EXAMPLE** hydrogen chloride emissions

Step 1.  $Cl_{in}$  is calculated from the information below

**Given conditions**

- Organic (free) chlorine content of incinerator feed = 25.0%. Chlorine content must be expressed as chloride ( $Cl^-$ ). If it is expressed as free chlorine ( $Cl_2$ ),  $Cl^- = Cl_2/2$ .
- Incinerator feed rate = 2000 lb/h hazardous waste

*Calculation:*

$$\begin{aligned} Cl_{in} &= (\text{concentration of chlorine in feed})(\text{feed rate}) \\ &= (0.250)(2000 \text{ lb/h}) \\ &= 500 \text{ lb/h} \\ &= 8.33 \text{ lb/min} \end{aligned}$$

$Cl_{out}$  is computed from stack monitoring data. Necessary data include:

- volume of the stack gas sample at standard conditions
- total chlorides ( $Cl^-$ ) collected during sampling
- stack gas volume flow rate at standard conditions

The method for computing the volume of the stack gas sample ( $V_{m(\text{std})}$ ) employed for the DRE calculation may be used to compute the scrubber efficiency. Assume sampling conditions are the same for this sample calculation as for the DRE example (immediately preceding).

Step 2. Total chlorides are determined by laboratory analysis of the impinger solution using the formula

$$\text{mgCl}^- = 35.45ANV_1/V_A$$

where

- $A$  = ml of titrant for sample
- $N$  = normality of mercuric nitrate titrant
- $V_1$  = volume of impinger solution
- $V_A$  = volume of sample aliquot

**Given conditions**

- $A = 3.12$  ml
- $N = 0.01$
- $V_1 = 40$  ml
- $V_A = 10$  ml

Calculation:

$$\begin{aligned} \text{mgCl}^- &= 35.45(3.12)(0.01)(40)/10 \\ &= 4.43 \\ &= 9.77 \times 10^{-6} \text{ lb} \end{aligned}$$

Step 3. The concentration of chlorides ( $C_{\text{Cl}}$ ) in the stack gas is

$$\begin{aligned} C_{\text{Cl}} &= \text{lb of Cl}^- / (\text{sample volume}) \\ &= 9.77 \times 10^{-6} \text{ lb} / 37.46 \text{ scf} \\ &= 2.61 \times 10^{-7} \text{ lb/scf} \end{aligned}$$

The stack gas volume flow rate ( $Q$ ) may be calculated by the method used to compute the DRE. The same conditions exist as for the DRE example,  $Q = 84,833$  scf/min.

Step 4.  $Cl_{\text{out}}$  may be computed by the formula

$$\begin{aligned} Cl_{\text{out}} &= Q(C_{\text{Cl}}) \\ &= (84,833 \text{ scf/min})(2.61 \times 10^{-7} \text{ lb/scf}) \\ &= 0.0221 \text{ lb/min} \end{aligned}$$

Step 5. The scrubber efficiency (SE) may be computed from the equation

$$\begin{aligned} \text{SE} &= [(Cl_{\text{in}} - Cl_{\text{out}}) / Cl_{\text{in}}](100\%) \\ &= [(4.17 \text{ lb/min} - 0.0221 \text{ lb/min}) / 4.17 \text{ lb/min}](100\%) \\ &= 99.47\% \end{aligned}$$

If the scrubber efficiency is less than 99 percent, the permit writer must recommend rejection of a permit application for this reason. If the scrubber efficiency is 99 percent or better, the permit writer must evaluate incinerator particulate emissions.

**Particle emission control efficiency.** As of 1991, incinerators destroying hazardous wastes must not emit particulate matter at concentrations greater than 180 milligrams of particulates per dry standard cubic meter of stack gas (0.08 grains per dry standard cubic foot) when the stack gas is corrected to a 12 percent carbon dioxide concentration as required under 40CFR Parts 264.343(c). Two stack sampling methods for particulate emissions are the EPA method 5 and ASTM method D2928. A sample calculation of particulate matter concentration in the stack gas is presented using the Subpart E, 40CFR Parts 60.50 methods referenced in the regulations. The calculation involves the following steps:

- determination of the stack gas sample volume
- determination of the weight of collected particulate matter
- calculation of the particulate concentration in the stack gas
- determination of the carbon dioxide concentration in the stack gas
- correction of the particulate concentration to 12% carbon dioxide

**EXAMPLE** particulate emissions

## Step 1. Calculation of sample volume

The stack gas sample volume may be computed in a manner similar to that in EPA method 5 or ASTM method D2928. The method for computing the volume of the stack gas sample ( $V_{m(\text{std})}$ ) employed for the DRE calculation may be used for this example. Assume that the sampling conditions are the same for this sample calculation as for the DRE example. For this example, the same sample volume will be used,  $V_{m(\text{std})} = 33.19$  scf.

## Step 2. Calculation of sample weight

The weight of the collected particulate matter is determined gravimetrically. For this example, a particulate matter weight of 137.0 milligrams (2.113 grains) will be assumed.

## Step 3. Calculation of sample concentration

The concentration of particulate matter ( $P$ ) in the stack gas is obtained by dividing the weight of the collected particulate matter by the stack gas sample volume.

$$P = 2.113 \text{ grains}/33.19 \text{ scf} = 0.0637 \text{ grains/scf}$$

## Step 4. Calculation of carbon dioxide concentration

The carbon dioxide concentration in the stack gas may be determined by the method presented in 40CFR Parts 60.521(c). This method involves a  $\text{CO}_2$  determination by EPA method 3 and a measurement of the stack gas volumetric flow rate by EPA method 2. The stack gas volume flow rate ( $Q$ ) may be calculated by the method used to compute the DRE.

Alternatively, continuous monitoring equipment may be used to measure  $\text{CO}_2$  concentrations. If an incinerator is equipped with a scrubber, volumetric flow rates and  $\text{CO}_2$  concentrations must be determined in the flue gas prior to a scrubber as well as in the stack after the scrubber in order to allow for  $\text{CO}_2$  absorption in the scrubber. A sample calculation of the corrected  $\text{CO}_2$  concentration  $(\text{CO}_2)_{\text{adj}}$  in the stack gas of an incinerator equipped with a scrubber is presented below. The following equation is used:

$$(\text{CO}_2)_{\text{adj}} = (\text{CO}_2)_b(Q_b/Q_a)$$

where  $(\text{CO}_2)_{\text{adj}}$  = adjusted (corrected)  $\text{CO}_2$  concentration  
 $(\text{CO}_2)_b$  =  $\text{CO}_2$  concentration in the stack gas measured before the scrubber  
 $Q_b$  = volumetric gas flow rate before the scrubber, dry basis  
 $Q_a$  = volumetric gas flow rate after the scrubber, dry basis

**Given conditions**

- $(\text{CO}_2)_b = 17.10\%$
- $Q_b = 80,259$  scfm
- $Q_a = 84,833$  scfm

*Calculation:*

$$\begin{aligned} (\text{CO}_2)_{\text{adj}} &= 17.10(80,259/84,833) \\ &= 16.18\% \end{aligned}$$

Step 5. Calculation of particulate matter concentration adjusted to 12%  $\text{CO}_2$ 

The particulate matter concentration is adjusted to 12%  $\text{CO}_2$  using the formula

$$P_{12} = 12P/(\text{CO}_2)_{\text{adj}}$$

where  $P_{12}$  = particulate matter concentration in the stack gas adjusted to 12% CO<sub>2</sub>

$$\begin{aligned} P_{12} &= 12(0.0637)/16.18 \\ &= 0.047 \text{ gr/dscf} \end{aligned}$$

Rather than follow the procedure provided in this example, an applicant may submit particulate emission monitoring data from an in-stack instrument in order to demonstrate compliance with the performance requirements. The permit writer must ensure that such instruments are properly calibrated and are functioning properly. The permit writer may request instrument calibration data from the applicant for this purpose. The permit writer should be aware that continuous particle emission monitoring equipment must operate near its sensitivity limit in order to detect 180 mg/dscm. Equipment response is dependent upon particle size distribution and particle color, and requires calibration for each different waste fed to an incinerator.

If the particulate emissions are greater than 180 mg/dscm (0.08 gr/dscf), the permit writer may recommend rejection of a permit application for this reason. If the particulate emissions are less than 180 mg/dscm, the permit writer must evaluate a permit application for compliance with regulatory monitoring and inspection requirements. [Be aware that these particulate emissions limits became much more stringent in 1999.]

## 6.2 Evaluation of Compliance with Monitoring and Inspection

The routine incinerator monitoring and inspection requirements are defined in 40CFR Parts 264.346 and 264.347 of the regulation. The owners and operators of hazardous waste incinerators must include routine monitoring and inspection data in the operating record required under 40CFR Parts 264.73 and 264.74. These records must be furnished upon request and made available for inspection by officers, employees, or representatives of EPA who are duly designated by the Administrator. The following sections provide the permit writer guidance to evaluate information on monitoring, inspection, safety systems, and effluent management included in a permit application.

**Required process monitoring.** An owner or operator of a hazardous waste incinerator must continuously monitor

- combustion temperature
- waste feed rate
- air feed rate
- carbon monoxide concentration in the stack gas

Instrument capabilities are described in the *Engineering Handbook for Hazardous Waste Incineration* (EPA-81/09, p. 5-102). It is recommended that these instruments should be equipped with continuous recorders in order to ease the record-keeping burden and determination of compliance with regulatory operating requirements. The permit writer must ensure that provisions to continuously monitor these parameters are included in the facility description.

**Supplementary process monitoring.** An applicant may monitor parameters other than those required under the regulations, and the permit writer may wish to evaluate this supplementary process monitoring. Pressure drops across major incinerator unit components are frequently monitored. Monitoring of the pressure drop is important because it is sensitive to changes in the gas flow rate, liquid flow rate, and clogging phenomena in the system. During the design phase, a proper pressure drop value or range to maintain design removal efficiency is specified.

Monitoring this parameter provides a continuous check on the normal operation of the scrubber. A change in the pressure drop or gage pressure is an indication that other measured parameters in the system need to be observed immediately to find the cause of any malfunction in order to take corrective action.

Many kinds of pressure measurement devices are commercially available to measure pressure drop across a device; however, a differential pressure gage calibrated in inches of water is usually recommended for this purpose. In selecting a pressure measuring device, the following items are considered:

- pressure range
- temperature sensitivity
- corrosivity of the fluid
- durability and ease of maintenance
- frequency response

Another parameter that may be monitored is the current draw of blower motors. Rapid fluctuations in the current draw indicates upset operating conditions of the incinerator unit. Pressure drop and current monitoring instruments may be connected to the incinerator safety system, as described in the next section.

Stack gases may be continuously monitored for a variety of parameters including sulfur dioxide, nitrogen oxides, nitrogen dioxide, unburned hydrocarbons, carbon dioxide, and oxygen. Capabilities of instruments available for monitoring of these parameters are discussed in the *Engineering Handbook for Hazardous Waste Incineration* (EPA-81/09, p. 5-102). Composition of the waste feed to an incinerator, as well as any state or local laws, will govern supplemental stack monitoring. Incinerators destroying wastes with a high sulfur content may monitor the stack for sulfur dioxide, and those destroying wastes with a high nitrogen content may monitor nitrogen oxides.

**Safety system.** The objective of an incinerator safety system is to stop waste feed when normal operating conditions are upset. If an incinerator is not equipped with a safety system, hazardous waste could be emitted to the environment and the combustion chamber may become filled with an explosive mixture. Every hazardous waste incinerator must be equipped with a safety shut-off system under 40CFR Parts 264.346(e).

A pilot does not offer sufficient protection and may not be considered a safety system. It may be extinguished or be unable to relight the main flame. Automatic feed shut-off valves are recommended. Automatic shut-off valves should close upon the failure of the:

- combustion or atomizing air blower
- elements of input control systems
- response from the flame detector
- response from other safety devices
- electrical power to the facility

Often, two shut-off valves are placed in series because a leak or failure of one valve may be extremely dangerous. Shut-off valves are often connected to flame detectors. Several types of flame detectors are available. Only ultraviolet detectors are suitable for use in hazardous waste incinerators. Unacceptable types include:

- thermopiles and bimetal warping devices — used in low-input heating applications
- photocells (cadmium sulfide and lead sulfide) — respond to light sources other than the flame and are not suitable for hazardous waste incinerators
- flame electrodes — suitable only for clean gas flames

Use of flame supervising systems is strongly recommended on each operating burner on any hazardous waste incinerator operating below 1400°F (760°C). Even when such combustion chambers are normally operated above 1400°F (760°C), it must be remembered that they are not above this temperature level during start-up and warm-up, which is a particularly hazardous time. The 1400°F level is a generally agreed upon temperature at which accidental fuel input would be ignited by the hot furnace interior before dangerous accumulation could occur. For installations that run continuously above 1400°F for long periods, it may be desirable to electrically bypass flame supervising equipment after the furnace is above 1400°F.

Additional potential incinerator malfunctions are identified and appropriate safety system responses are summarized in Table 2.61 (EPA-80/12, p. 105).

**Evaluation of incinerator effluent management.** All effluents, except for air emissions, from a hazardous waste incinerator must be managed as hazardous wastes under RCRA, unless analyzed by the methods specified in Subpart C of 40CFR 261 and found to be nonhazardous. Major incinerator effluents will most likely be ash and APCD (air pollution control device) wastewater and sludges. Management of incinerator effluents is regulated under 40CFR Parts 264, and specific restrictions are imposed for the operation of tanks, surface impoundments, waste piles, land treatment, landfills, chemical, physical, and biological treatment, and underground injection.

**Inspection.** An incinerator facility inspection plan should be included with a permit application. The plan must include, at a minimum as required under 40CFR Parts 264.347(d), daily inspection of the complete incinerator and associated equipment (pumps, valves, conveyors, pipes, etc.) for leaks, spills, and fugitive emissions, and checks of all emergency shut-down controls and system alarms to ensure proper operation. The results of these daily inspections must be included in the operating record maintained at a facility. Because facility diagrams vary, the inspection plans may not be similar. However, the permit writer must ensure that inspection of all facility components shown on a facility diagram are included in an inspection plan.

### 6.3 Specification of Operating Requirements

The permit writer must specify incinerator operating requirements based upon acceptable performance data submitted with an application. These operating requirements are incorporated with the facility operating permit recommendation, and an incinerator must operate in accordance with the requirement when permitted, as specified in 40CFR Parts 264.345. In this section the permit writer will find guidance to check the validity of incinerator operating data and to specify the operating requirements for carbon monoxide level in the stack exhaust gas, waste feed rate, combustion temperature, air feed rate and allowable variations in waste composition and incinerator operating conditions.

**Carbon monoxide level in the stack gas.** The measurement of CO has been selected as a combustion control parameter for the following reasons:

- well developed, reliable, and rugged instrumentation exists that can measure the concentration of CO in exhaust gases in a range from a very few parts per million to a 100% basis;
- response time of the equipment is rapid (1–90 s, depending on the instrument);
- measurement of CO maintains its meaningfulness as the excess air is lowered toward stoichiometric, or as combustion temperatures are lowered;
- instrumentation does not need to be mounted inside the gas stream, and a nonsampling noncontacting methodology for measuring the CO content of a flowing gas stream can be utilized; and

- the cost of the instrumentation (~\$1500–\$3000) is nominal considering the capital required to build a complete hazardous waste incinerator.

The amount of CO present in any combustion exhaust gas is a function of many factors, including:

- (a) combustion temperatures,
- (b) residence time of the combusting gases at the combustion temperature
- (c) degree of mixing of fuel(s) and air,
- (d) amount of air used in excess of stoichiometric requirements.

To some extent, these factors are interdependent. However, residence time and the degree of mixing of air and fuel(s) are largely fixed after the designs of the combustion chambers and the burners are selected. Therefore in any given facility, any changes of CO concentration will primarily reflect changes in excess air usage and in combustion temperatures. CO concentration does increase as combustion temperatures are decreased. With other factors constant, CO concentration will be fairly uniform over a wide range of excess air levels, but with continued decrease in excess air there will be a point where the CO content will very rapidly increase with further decreases in excess air. Thus, the monitoring of CO concentration, with temperature monitoring, is an excellent basis to gauge the proper operating range of combustion temperatures and excess air usage.

Some consideration has been given to the concept of a correlation between CO concentration of an exhaust gas and the destruction and removal efficiency (DRE) of a POHC. Correlations have been attempted with no significant measure of success. In general, time and temperature considerations are primary for a high DRE, but temperature and excess air considerations are more important for a low CO value.

Although monitoring CO in an exhaust gas is more convenient in an exhaust stack (where temperatures are low), measurements of CO at other points within the system (for example, in the take-off ducting immediately after the combustion chamber, or any afterburner) are also acceptable.

An upper limit of CO concentration in the exhaust gas has not been specified, and for the present, the matter will be left to the discretion of the EPA Regional Administrator. As a guide, CO levels for a number of circumstances are given in Table 2.62.

The maximum CO concentration monitored in the stack during a trial burn in compliance with the regulatory performance standards should be designated as the operating requirement for the maximum CO concentration allowable.

**Waste feed rate.** In order to achieve stable operating conditions, the waste feed should remain relatively constant during a trial test or during a trial burn. The permit writer should specify as an operating requirement that the waste feed rate should not vary more than ten percent from the average value established during a trial test which complies with the regulatory performance standards (unless incinerator operating data demonstrate that greater excursions still allow compliance).

**Combustion temperature.** The permit writer must verify the operating combustion zone temperature included in a permit application prior to specifying an operating requirement. The following information is necessary for this calculation:

- mass feed rates of waste and any auxiliary fuel to the incinerator,
- chemical composition of the waste and fuel, plus the proportion of any free or bound water,
- gross heat of combustion of the waste and the fuel, and
- amount of excess air to be used for incineration.

**TABLE 2.61** Hazardous Waste Incinerator Malfunctions, and Remedial or Emergency Responses

No.	Malfunction	Type*	Malfunction indication	Response
1	Partial or complete stoppage of liquid waste feed delivery to all liquid burners	L, C	(a) Flow meter reading out of specified range (b) Pressure build-up in feed lines (c) Change in combustion zone temperature (d) Feed pump failure, zero amps	Halt waste feed, start trouble-shooting and maintenance in affected system. Reinitiate or increase auxiliary fuel feed to maintain combustion zone temperatures; continue operation of air pollution control devices (APCD)
2	Partial or complete stoppage of liquid waste to only one burner	L, C	As in (a), (b), and (c), above	Halt waste feed to affected burner only
3	Partial or complete stoppage of solid wastes feed to rotary kiln	RK, C	(a) Drop in RK combustion temperature (b) Power loss in waste feed conveyor or other feed system	As in 1, above
4	Puffing, or sudden occurrence of fugitive emissions from RK due to thermal instability or excessive feed rate of wastes to RK or failure of seals	RK, C	(a) Pressure surge in kiln (rapid change in manometer level) (b) Visible emission from air seals at either end of kiln	(a) Halt feeding of any solid waste to kiln for 10–30 min, but continue combustion (b) Evacuate unneeded personnel from immediate vicinity of kiln (c) Re-evaluate waste prior to further incineration
5	Failure of forced air supply to liquid waste feed or fuel burners	L, RK, C	(a) Flowmeter reading for air supply off scale (b) Automatic flame detector alarm activated (c) Zero amps or excessive current draw on blower motor(s)	(a) Halt waste and fuel feed immediately (b) Start trouble-shooting immediately and restart as possible (c) Continue operation of APCDs but reduce air flow at induced draft fan by “damping accessory”
6	Combustion temperature too high	L, RK, C	(a) Temperature indicator(s) at instrument control panel (b) Annunciator, or other alarm sounded	(a) Check fuel or waste feed flow rates; reduce if necessary (b) Check temperature sensors (c) Check other indicators in combustor if multiple sensors used (d) Automatic or manual activation of combustion chamber vent (sometimes called an “emergency stack cap”)
7	Combustion temperature too low	L, RK, C	(a) as above; (b) as above	(a) Check other indicators in combustor if multiple sensors are used (b) Check fuel or waste feed flow rates; increase if necessary (c) Check sensor accuracy
8	Sudden loss of integrity of refractory lining	L, RK, C	(a) Sudden loud noise (b) Partial stoppage of air drawn into combustor, resulting in decreasing combustion temperatures, increased particulate emissions, and development of hot spots on external combustor shell	Shut down facility as quickly as possible

9	Excess opacity of stack plume	L, RK, C	Visual or instrument opacity readings which are above maximum allowable operating point	(a) Check combustion conditions, especially temperatures and O <sub>2</sub> (excess air) and CO monitor (b) Check APCD operation (c) Check nature and feed rates of wastes being burned (d) Check ESP rapping interval, cycle duration, and intensity Check and adjust combustion conditions, especially temperature and excess air (O <sub>2</sub> in stack gas), and adjust accordingly
10	CO in exhaust gas in excess of 100 ppm, or in excess of normal CO values	L	CO indicator	
11	Indication of, or actual failure of, induced draft fan	L, RK, C	(a) Motor overheating (b) Excessive or zero current (amps) (c) Total stoppage of fan (d) $\Delta p$ drop across blower inlet and outlet	(a) Switch to stand-by fan, if available (b) If two induced draft fans are used in series, reduce operational levels immediately, stop the failing unit, and operate at reduced rate on one fan only until maintenance can be completed (c) If there is only one fan, and the fan failure appears serious, shift into an emergency shutdown mode for entire incinerator
12	Increase in gas temperature after quench zone, affecting scrubber operation	L, RK, C	(a) Partial or total loss of water supply to quench zone (b) Increase of combustion temperatures	(a) Check water flow to quench zone. Prepare for limited operation rate until water supply is restored (b) Check combustion conditions, especially temperature
13	Partial or complete stoppage of water or caustic solution to scrubber(s)	L, RK	(a) Decrease in $\Delta p$ across scrubber, as indicated by manometers or other instruments (b) Zero or increased amps on water or solution pumps (c) Flowmeter readings out of specified range (d) Large increase in acid components in stack gas as detected by NDIR or other type instruments	(a) Halt waste feed, start trouble-shooting and maintenance in affected system (b) Start-up redundant pumps, if available (c) Check recycle water or solution tank levels (d) If using alkaline solution, switch to water supply if available (e) Check for deposition of solids from recycled liquors in pump lines (f) Use emergency (stand-by) water supply which will feed water by gravity until the whole system can be shut down
14	Deposition of solids in scrubber from recycled wastes or caustic solution, or from excess solids emissions from combustor	L, RK, C	(a) Build-up of $\Delta p$ across scrubber as indicated by manometers or other instruments (b) Increased hold-up of liquor in packed or tray towers, up to and including flooded condition. This can also be detected by liquid level indicators	This requires a shut-down to clean out the tower and internals. The shut-down can be scheduled if the deposit build-up is gradual and is monitored
15	pH of recycled scrubber liquor not within specifications	L, RK, C	(a) Continuous, or spot-checking pH indicator shows actual pH to be outside of desired operating range (b) Drop in scrubber efficiency with excess acid gas in stack gas	(a) Check for adequate supply and metering of alkaline agent (b) Check accuracy of pH meter and alkaline solution metering pump associated with recycling of scrubber liquor
16	Failure of demister operation	L, RK, C	Increased $\Delta p$ , as measured by manometer, due to solids accumulation in demister element	Back-wash element

\*L, liquid injection; RK, rotary kiln; C, combination liquid injection and rotary kiln.

**TABLE 2.62** CO Levels in Exhaust Gas

CO level (ppm) in exhaust gas	Source
30–40	Most coal-burning utility boilers
>1	Commercial hazardous waste incinerators
5–50	Trial burns of miscellaneous hazardous wastes at several test facilities sponsored by EPA

In any theoretical system, heat in = heat out. However, heat is lost from the incinerator by radiation and conductive/convective means, and this loss is estimated to be about 5 percent of the heat input. Assuming that all remaining heat input is available to increase product gas temperatures, the permit writer may use the equation

$$(0.95)(\Delta H \text{ gross}) = \sum (W_n)(Cp_n)(T_c - 60)$$

where  $\Delta H \text{ gross}$  = sum of the total Btu's from the combustion of the waste materials and any auxiliary fuel, per unit time,

$\sum$  = sum of the products of  $(W)(Cp)(T_c - 60)$  for each individual gas in the combustion (flue) gases,

$W_n$  = weight, in pounds, of each gaseous product, per unit time,

$Cp_n$  = specific heat (at constant pressure) of each gaseous product, in Btu/lb-°F. (For approximation purposes, the  $Cp$  of water vapor is 0.49, and 0.26 for most other combustion gases including  $O_2$ ,  $N_2$ ,  $CO_2$ , and  $HCl$ .)

$T_c$  = combustion temperature in °F, which is the parameter to be calculated.

If the permit writer is not prepared to perform this calculation, the simple method of estimation presented at the end of this section may be used to verify the combustion zone temperature.

A sample calculation for the determination of combustion temperatures is given in the following paragraphs.

**Given conditions**

- waste heat content = 6000 Btu/lb
- fuel heat content = 17,500 Btu/lb
- waste feed rate = 1000 lb/h-waste
- fuel feed rate = 1000 lb/h-fuel
- nominal combustion zone temperature = 2200°F
- incinerator diameter = 5 ft
- incinerator length = 26 ft
- excess air = 30%
- composition of waste and fuel:

	Waste	Fuel
%C	30	92
%H	7	8
%Cl <sub>2</sub>	63	—
%H <sub>2</sub> O	—	—

*Calculation:*

Step 1. Analyze waste and fuel (Table 2.63).

Step 2. Calculate the pound-moles of each element per hour.

$$\begin{aligned} \text{C: } & 1220/12 = 101.7 \text{ lb-mole/h} \\ \text{H}_2: & 150/2 = 75 \\ \text{Cl}_2: & 630/(2)(35.45) = 8.9 \end{aligned}$$

Step 3. Calculate total heat input per hour.

$$\begin{aligned} \text{Heat from waste: } & (1000 \text{ lb-waste/h})(6000 \text{ Btu/lb}) = 6 \times 10^6 \text{ Btu/h} \\ \text{Heat from fuel: } & (1000 \text{ lb-fuel/h})(17,500 \text{ Btu/lb}) = 17.5 \times 10^6 \text{ Btu/h} \\ \text{Total heat input} & = 6 \times 10^6 \text{ Btu/h} + 17.5 \times 10^6 \text{ Btu/h} = 23.5 \times 10^6 \text{ Btu/h} \\ \text{Heat available after loss} & = (0.95)(23.5 \times 10^6) = 22.3 \times 10^6 \text{ Btu/h} \end{aligned}$$

Step 4. Calculate oxygen needed for complete combustion.

The combustion equation for stoichiometric air is (in lb-moles/h)

O<sub>2</sub> requirements are 134.8 moles, of which 101.7 moles are for C → CO<sub>2</sub> and 33.05 moles are for H → H<sub>2</sub>O; 33.05 moles was calculated from (75 – 8.9)/2.

With 30% excess air, we obtain the equation

The heat output (heat absorbed by the gaseous products of combustion) is the sum of the equations given below (Table 2.64).

**TABLE 2.63** Analysis of Waste and Fuel

Item	Rate (lb/h)	Elemental composition	%, by wt.	lb element/h
Waste	1000	C	30	300
Fuel	1000	C	92	920
Total C				1220
Waste	1000	H	7	70
Fuel	1000	H	8	80
Total H				150
Waste	1000	Cl	63	630
Total				2000

**TABLE 2.64** Heat Output

	lb-mol	lb/mol	Sp. heat	$\Delta T$ (°F)
CO <sub>2</sub>	101.7	44	0.26	$(T_c - 60)$
HCl	17.8	36.46	0.26	$(T_c - 60)$
H <sub>2</sub> O	66.1	18	0.49	$(T_c - 60)$
O <sub>2</sub>	40.4	32	0.26	$(T_c - 60)$
N <sub>2</sub>	658.9	28	0.26	$(T_c - 60)$
Total flue gas	884.9			

For heat input = heat output,

$$22.3 \times 10^6 = (101.7)(44)(0.26)(T_c - 60) + (17.8)(36.46)(0.26)(T_c - 60) \\ + (66.1)(18)(0.49)(T_c - 60) + (40.4)(32)(0.26)(T_c - 60) \\ + (658.9)(28)(0.26)(T_c - 60)$$

$$22.3 \times 10^6 = 7048(T_c - 60)$$

$$T_c = 3224^\circ\text{F}$$

The calculated combustion temperature of 3224°F is considerably higher than the proposed temperature of 2200°F, and therefore it appears that there is excessive use of fuel. If the same total combined flow of waste and fuel is maintained, then the proportion of waste can possibly be increased. By so doing, residence time and turbulent flow in the combustion chamber would remain essentially unchanged, but one should not allow the load imposed on the downstream scrubber (to remove HCl) to exceed the scrubber's capacity.

An internal check of these calculations can be made at this point. A total of 885 lb-moles of flue gas have been produced. The volumetric flow rate at 2200°F is calculated as follows:

$$\begin{aligned} \text{Standard volumetric flow rate} &= (885 \text{ lb-mol/h})(359 \text{ ft}^3/\text{lb-mol}) \\ &= 317,715 \text{ ft}^3/\text{h} \\ &= 88.25 \text{ ft}^3/\text{s} \\ \text{Actual volumetric flow rate} &= 88.25[(460 + 2200)/(460 + 60)] \\ &= 451 \text{ ft}^3/\text{s} \end{aligned}$$

An alternative useful set of data, illustrating the relationship between the gross heating value of wastes, percent excess air, and adiabatic temperature attained in the combustion gases, is shown in Figs. 2.30 and 2.31. These figures apply to liquid wastes (in Btu/lb) and to gaseous wastes (in Btu/ft<sup>3</sup>). The curves in these figures were based on theoretical considerations of the average combustion temperatures attained in combustion gases burned under adiabatic (no heat loss) conditions. Thus, these calculated temperatures would be somewhat higher than would be encountered in actual practice.

The use of these figures may be demonstrated by the following example. Using the same values presented in the previous example, the heating value of the incinerator feed is 11,750 Btu/lb and the excess air is 30%. Locating these values on Fig. 2.30, the corresponding adiabatic temperature is about 2900°F. This value agrees fairly well with the value of 3224°F obtained from stoichiometric calculations.

After the permit writer has ensured that the combustion temperature is consistent with the other incinerator operating data, the operating requirements must be specified. The minimum allowable temperature should be the minimum average temperature attained during incinera-

tion occurring within the regulatory performance standards. If only one set of data or test burn results are in compliance, the minimum operating temperature allowable is the average temperature of that run determined from continuous monitoring. An incinerator may be operated at temperatures higher than this minimum operating temperature at the discretion of an owner or operator. The maximum operating temperature is limited by the refractory lining material in the combustion chamber.

**Air feed rate.** It is suggested that the permit writer consider four factors when evaluating air feed rates prior to specifying an operating requirement:

- agreement of the air feed rate with excess air values and other operating data,
- residence time in the combustion chamber
- capacities and ratings of air moving equipment, and
- turbulence or mixing in the combustion chamber.

FIGURE 2.31 Adiabatic combustion temperature from a typical gas (*EPA-80/12, p. 121*).

The amount of excess air used in a given application determines the degree of air/waste mixing achieved in the primary combustion zone, process-dependent secondary combustion requirements, and the desired degree of combustion gas cooling. Since excess air acts as a diluent in the combustion process, it reduces the temperature in the incinerator (e.g., maximum theoretical temperatures are achieved at zero percent excess air). This temperature reduction is desirable to limit refractory degradation when readily combustible, high heating value wastes are burned. When highly aqueous or other low heating value waste is being burned, however excess air should be minimized to keep the system temperature as high as possible. Even with combustible waste, it is desirable to limit excess air to some extent so that the combustion chamber volume and the downstream air pollution control system capacities can be minimized.

The percentage of excess air used during incineration may be estimated from the stack gas composition under standard conditions, waste and auxiliary feed rates, and net heating value of the feed. Excess air is defined as that air supplied in addition to the quantity required for stoichiometric (perfect) combustion and may be expressed as

$$\begin{aligned} & \% \text{ excess air} \\ & = [(\text{air feed rate per pound of feed})/(\text{stoichiometric air feed rate per pound of feed})] \times 100 \end{aligned}$$

Excess air may be determined from stack monitoring data by EPA method 3B, Appendix A, 40CFR Part 60. The following equation is used for that computation:

$$\% \text{ excess air} = [(O_2 - 0.5CO)/(0.264N_2 - O_2 + 0.5CO)] \times 100$$

where  $O_2$  = percent oxygen in the stack gas by volume, dry basis  
 $N_2$  = percent nitrogen by volume, dry basis  
 $CO$  = percent carbon monoxide by volume, dry basis

The stoichiometric air (SA) volume may be estimated from the approximation that 1 scf of air is required for each 100 Btu of incinerator feed material. This estimate is true only for stoichiometric combustion (zero excess air). This relation may be expressed as

$$(\text{scf of SA}) = (\text{gross heating value of feed, Btu})/100$$

If auxiliary fuel is co-fired with the waste, the heating value (HV) of the feed may be expressed as

$$HV(\text{feed}) = HV(\text{waste}) \times (\text{fraction of waste in feed}) + HV(\text{fuel}) \times (\text{fraction of fuel in feed})$$

It should be noted that this approximation is valid for estimating the volume of flue gas generated during combustion (see Section 6.1).

The volume of stack gas measured under operating conditions, or actual cubic feet (acf), may be converted to the volume under standard conditions, or standard cubic feet (scf), by use of the ideal gas law. Since both conditions are essentially at atmospheric pressure, this law simplifies to

$$\begin{aligned} (\text{acf})/(\text{scf}) &= (\text{stack gas temperature in } ^\circ\text{R})/492 \\ &= (\text{stack gas temperature in K})/273 \end{aligned}$$

Another useful and approximate relationship converts the volume of combustion gas obtained with stoichiometric air to the total volume of gas generated with a known percentage of excess air. The calculation is as follows:

$$(\text{stoichiometric gas volume}) \times [1 + (\% \text{ excess air})/100] = (\text{total gas volume})$$

This approximation is adequate for most fuels or waste/fuel mixtures and for excess air values to 200%, with differences from theoretical calculations seldom exceeding  $\pm 10\%$ . The utility of these approximations is presented in the following sample calculation.

**EXAMPLE** standard volumetric flow rate and actual volumetric flow rate  
 An applicant claims that the volume flow rate of stack gas is 5525 scf/min when using 22% excess air. The permit writer finds the following data to check these values (Table 2.65).

**TABLE 2.65** Gross Heating Values of Several Fuels

	Btu/lb	Btu/scf	Btu/gal
Natural gas	21,830	1020	—
No. 2 distillate oil	18,993	—	137,000
No. 6 residual oil	18,126	—	153,000

**Given conditions**

- waste feed rate = 17 lb/min
- heating value of waste = 5000 Btu/lb
- auxiliary fuel feed rate (No. 6 residual oil) = 17 lb/min
- heating value of fuel = 18,126 Btu/lb

*Calculation:*

Calculate the flue gas volume flow rate for stoichiometric air.

$$[(17 \text{ lb/min})(5000 \text{ Btu/lb}) + (17 \text{ lb/min})(18,126 \text{ Btu/lb})]/(100 \text{ Btu/scf}) = 3931 \text{ scf/min}$$

*Note:* 1 scf of air is required for each 100 Btu of waste incinerated at standard conditions (see previous statement).

Calculate the flue volume gas flow rate including excess air.

$$(3931 \text{ scf/min})(1 + 22/100) = 4796 \text{ scf/min}$$

Because this calculated value differs by more than 10% from the volume flow rate claimed by the applicant, the permit writer should check the applicant's calculation of the excess air value and volume flow rate.

In liquid injection incinerators, two air rates must be considered: (1) the air present in the primary combustion air mixed with the feed in the burner, and (2) the total air, which includes secondary combustion air brought in around the burner.

Normally, 10 percent to 20 percent excess air (e.g. 1.1–1.2 times the stoichiometric requirement) must be supplied to the burner to prevent smoke formation in the flame zone. When relatively homogeneous wastes are being burned in high efficiency burners, 5 percent excess air may be adequate. Too much excess air through the burner is undesirable, since this can extinguish the flame. Burner manufacturer specifications are the best source of information for case-by-case analysis.

In general, the total excess air rate in liquid injection incinerator units should exceed 20 percent to 25 percent to ensure adequate waste/air contact in the secondary combustion zone. In rotary kiln/afterburner incineration units, three air levels must be considered: (1) air present in the primary combustion air introduced through liquid waste burners in the kiln, (2) total air fed to the kiln, and (3) the air percentage maintained in the afterburner.

High excess air rates are needed in rotary kilns because the efficacy of air/solids contact is less than that for air and atomized liquid droplets. Typical excess air rates range from 140 percent to 210 percent or greater, depending on the desired operating temperature and the heating value of the waste. When high aqueous wastes are being burned, lower excess air rates may be needed. However, less than 100 percent excess air in the kiln may not provide adequate air/solids contact.

The residence time in the combustion zone may be estimated if the volume of the combustion gas is known. The residence time is approximated by dividing the volume of the combustion chamber by the flue gas volume flow rate. A sample calculation is provided below.

**EXAMPLE** residence time

The combustion zone is cylindrical with a diameter of 5 feet and a length of 26 feet.

$$\begin{aligned} \text{Volume of combustion} &= \pi d^2 L / 4 \\ &= 3.14(5^2)(26) / 4 \\ &= 510 \text{ ft}^3 \end{aligned}$$

The volume flow rate is the same as was calculated in the previous example: 4796 scf/min. This volume flow rate must be corrected to combustion zone conditions using the ideal gas law,  $V_1/T_1 = V_2/T_2$ . If the combustion zone is 2200°F,

$$(\text{acf flue gas})/(460 + 2200) = (4796 \text{ scf})/(460 + 32)$$

$$\text{acf flue gas} = 25,930 \text{ acf/min}$$

$$\text{Residence time} = (510 \text{ ft}^3)/(25,930 \text{ acf/min})$$

$$= 0.0197 \text{ min}$$

$$= 1.18 \text{ s}$$

In rotary kiln/afterburner incinerators, residence time is dependent on the physical state of the waste. Finely-divided solids may incinerate within a fraction of a second; dense, bulky materials may require up to an hour. Waste liquids with a high heating value may be co-incinerated with solids, slurries, or tarry materials, but will be injected into a space above the kiln bed. Residence times for these injected materials would generally be much shorter than for the denser materials.

## 1 INTRODUCTION

---

Waste combustion systems may be classified in accordance with the nature of the wastes which they are designed to burn, i.e., municipal refuse, commercial or industrial waste, medical waste or biomedical waste, and the wide range of wastes classified as hazardous. The form of the wastes, such as gaseous, liquid or solid, and the size of the combustion system are also important factors.

---

## 2 COMBUSTION PROCESS CALCULATIONS

---

### 2.1 Heat Balance

As the heat of combustion is released, the temperature of the air supplied for combustion combined with the gaseous products of combustion rises. The temperature achievable when

only the stoichiometric or “ideal” air is supplied is above that which the refractory materials used to form combustion chambers can withstand without slagging and rapid deterioration. From this standpoint alone, at least 50% and up to 150% excess air must be provided in the combustion process, resulting in “total air” of 150% to 250% of ideal air required for complete combustion. The amount of excess air which must be supplied is determined by the desired final temperature, usually in the range from 1800°F to 2200°F, and can be calculated by performing a heat balance between the heat released and the quantity of gases generated by the combustion process, taking into account the specific heats of the gases generated throughout the temperature range between supply and exhaust of the gases.

The following is the heat balance equation:

$$Q = WC_p \Delta t$$

where  $Q$  = heat transferred, Btu per hour (Btu/h) or calories/h  
 $W$  = mass flow of gas, pounds per hour (lb/h) or mol/h  
 $C_p$  = specific heat of gas, Btu per pound per degree F (Btu/(lb · °F)) or calories per degree per mole (cal/(deg · mol))  
 $\Delta t$  = temperature difference

## 2.2 Specific Heat and Enthalpy

Heat balance calculations can be made by using the mean specific heat of each component of the products of combustion over the range of temperatures; alternatively, the enthalpy (Btu per pound) of the gases at the temperatures involved may be used.

The specific heats of the products of combustion vary with temperature. The overall specific heat over the range of temperatures is somewhat difficult to calculate because the variation with temperature is not linear. Table 3.1 gives specific heats at constant pressure ( $C_p$ ) of gases in the products of combustion versus temperature. In addition, the average specific heat is given for ranges of temperatures, assuming combustion air at 70°F is used.

**TABLE 3.1** Specific Heats of Gases versus Temperature

$T$ (°F)	H <sub>2</sub> O	CO <sub>2</sub>	N <sub>2</sub>	O <sub>2</sub>	$T$ (K)*

\* $T(K) = T(^{\circ}C) + 273$

From *Chemical Engineers' Handbook*, McGraw Hill:

$$C_p \text{ of CO}_2 = 10.34 + 0.00274T - 19,550/T^2 \text{ cal/(deg}\cdot\text{mol)}$$

$$\text{O}_2 = 8.27 + 0.000258T - 187,700/T^2 \text{ cal/(deg}\cdot\text{mol)}$$

$$\text{N}_2 = 6.50 + 0.00100T \text{ cal/(deg}\cdot\text{mol)}$$

Figure 3.1 graphs the specific heats of the main components of products of combustion and air. The substantial range of the specific heat of water vapor (H<sub>2</sub>O) makes it important to consider this highly variable factor, especially when there is a wide range of temperature.

Table 3.2 shows the enthalpy *H*, the product of specified heat and temperature (*C<sub>p</sub>* × *T*) of the combustion products versus temperature, assuming theoretical (stoichiometric) air, using the average specific heats of the products.

### 2.3 Temperature Calculations

The heat released by combustion (*Q*) raises the temperature of the flow stream (*W*) of the products of combustion. The temperature rise ( $\Delta T$ ) of the products is dependent on the specific heat (*C<sub>p</sub>*) of the mixture of gases.

**TABLE 3.2** Average Enthalpy (*C<sub>p</sub>* × *T*) of Products vs. Temperature

<i>T</i> (°F)	cal/g	Btu/(lb · mol)	Btu/scf	cal/(g · mol)	cal/scm	<i>T</i> (°C)
32	-5.1	-265	-0.69	-143	-5941	0
70	0	0	0	11	439	21
150	12	572	1.48	338	14,071	66
<b>212</b>	21	1,025	2.65	596	24,800	100
400	50	2,437	6.3	1,390	57,960	205
1000	145	7,201	18.61	4,060	168,845	538
1500	228	11,400	29.46	6,400	266,216	816
1800	280	14,014	36.21	7,853	326,681	982
2000	315	15,792	40.81	8,843	367,829	1,094
2500	406	20,364	52.62	11,386	473,608	1,371

$$Q = W \times C_p \times \Delta T = W \times C_p \times (T_2 - T_1)$$

where  $Q$  = heat released, Btu/h  
 $W$  = flow rate, lb/h  
 $C_p$  = specific heat, Btu/(lb·°F)  
 $T_1, T_2$  = temperature of the gases entering and leaving the heat exchange zone  
 $T_2 = T_1 + Q/(W \times C_p)$

The heat capacity of the gases varies with temperature, as is seen in Fig. 3.1. Over the range from 70°F to 2000°F the  $C_p$  of nitrogen averages 0.282 Btu/(lb·°F) (see Table 3.1), for carbon dioxide it is 0.282, for water vapor 0.528, and for oxygen 0.257 Btu/(lb·°F). For a mixture of combustion gases from municipal waste, the specific heat is typically about 0.30 Btu/(lb·°F), dominated by the major component, nitrogen, but substantially influenced by the water vapor. This typical value of  $C_p$  can be used to make a fairly accurate estimate of the theoretical flame temperature and the final temperature of the gases after adding excess air.

Note that the heat released from combustion is the *lower* heating value (LHV), because the moisture content is not condensed in order to absorb the latent heat of condensation.

**EXAMPLE:** Calculate theoretical flame temperature of municipal waste. Assume that the heat input is the LHV of 4600 Btu/lbf, and the weight of gaseous products is 4.6 pounds of products per pound of fuel (lbp/lbf).

The theoretical flame temperature

$$T_f = 70 \text{ (}^\circ\text{F)} + 4600 \text{ (Btu/lbf)} / (0.30 \text{ (Btu/(lb} \cdot \text{}^\circ\text{F)}) \times 4.6 \text{ (lbg/lbf)}) = 3403^\circ\text{F}$$

**Theoretical air required for complete combustion.** When the ultimate analysis is known, the following equation may be used to determine the theoretical or “stoichiometric” air required for complete combustion, using the weight composition of the waste. Note that moisture and ash are not included, so the component total is less than 100%.

$$\begin{aligned} \text{TA (lba/lbf)} &= 11.50 \times (\%C) + 34.5 \times ((\%H) - (\%O_2/10) - (\%Cl/35.5) - (\%F/19)) \\ &+ 4.32 \times (\%S) \end{aligned}$$

The air required for the complete combustion of fuels and wastes depends upon the heating value, since this determines the amount of oxygen required and hence the corresponding nitrogen and air. The weight of air to weight of fuel ranges from as little as 3.31 lb air per lb fuel for municipal refuse to almost 16 lb/lb for natural gas. On the other hand,

*the volume of air required for complete combustion, per unit of heat, 9450 to 10,200 std ft<sup>3</sup> / (MBtu), or 1062 to 1150 std m<sup>3</sup> / (Mcal) is little affected by the fuel type, and thus may be used when no other information is available.*

**Addition of excess air to control furnace exit temperature.** The temperature resulting from combustion with stoichiometric air is high enough to cause damage to the chamber in which the combustion takes place. Additional air, called excess air, is therefore required in order to bring the final gas temperature down to acceptable levels. Excess air is also required to assure complete combustion.

The temperature of the mixture of gases at the theoretical maximum temperature with excess air is calculated by a heat and mass balance. For example, assume that the oxygen demand for complete combustion was found to be 0.882 lb/lbf. Adding the 3.31 lb N<sub>2</sub> associated with 1 lb oxygen, we get 4.192 lb air per lb fuel, plus 1 lb fuel to get 5.192 lbp per lbf. Adding 100% excess air, we add another 4.192 lb/lbf for a total of 9.384 lbp/lbf. Assume an average specific heat of 0.30 Btu/(lb·°F). The temperature of the mixture is thus

$$T_{\text{mix}} = 70^\circ\text{F} + 4378 \text{ (Btu/lbf)} / (9.384 \times 0.3) = 70 + 1555 = 1625^\circ\text{F}$$

For other amounts of excess air, we can include a factor  $n$  = fraction excess air (%xsa/100), as follows

$$T_{\text{mix}} = T_1 + Q / (W_s + (n \times W_s) \times 0.3) = T_1 + \frac{Q}{W_s \times (1 + n) \times 0.3}$$

where  $W_s$  = lb stoichiometric air per lb of fuel

This can be solved for  $n$ , given  $T_{\text{mix}} = 2000^\circ\text{F}$  and  $T_1 = 70^\circ\text{F}$ :

$$n = \left( \frac{Q}{(T_{\text{mix}} - T_1) \times W_s \times 0.3} \right) - 1$$

$$= (4378 / ((2000 - 70) \times 4.6 \times 0.3)) - 1 = 1.64 - 1 = 0.64 = 64\%$$

After obtaining  $T_{\text{mix}}$  using the above approximate values of  $C_p$ , we can refine these estimates and obtain a more exact calculation of  $T_{\text{mix}}$ , or  $n$ . Then

$$T_{\text{mix}} = \frac{(W_h \times T_h + W_c \times T_c)}{(W_h + W_c)}$$

where  $W_h$  = mass flow of hot fluid  
 $W_c$  = mass flow of cold fluid  
 $T_h$  = temperature of hot fluid  
 $T_c$  = temperature of cold fluid  
 $T_{\text{mix}}$  = temperature of the mixture

**Mass balance to achieve 1800°F gas temperature.** A simple way to estimate the amount of excess air needed to achieve a gas temperature such as 1800°F is to calculate how much cold combustion air would have to be blended with the gases at the flame temperature theoretically achieved under stoichiometric conditions.

*Mixing calculation:*

Input (hot) + input (cold) = output (mixture)

$$(1 - X) \times (T_h)$$

$$\downarrow$$

$$X \times (T_c) \rightarrow [\text{MIX}] \rightarrow (1) \times (T_m)$$

or

$$X \times T_h + (1 - X)T_c = 1 \times T_m$$

where  $X$  = fraction of cold gas  
 $1 - X$  = fraction of hot gas  
 $T_h$  = hot temperature  
 $T_c$  = cold temperature  
 $T_m$  = mixed temperature

For  $T_h = 3600^\circ\text{F}$   
 $T_c = 100^\circ\text{F}$   
 $X = 0.4$

$$T_m = X \times T_c + (1 - X) \times T_h = 0.4 \times 100(^\circ\text{F}) + (1 - 0.4) \times 3600(^\circ\text{F}) = 2200^\circ\text{F}$$

How much excess air would be required to control the mixed temperature to  $T_m = 2000^\circ\text{F}$ ?

$$X = (T_h - T_m)/(T_h - T_c)(3600 - 2000)/(3600 - 100) = 0.457 = 45.7\%$$

To take into account heat losses from the furnace, we can subtract the losses from  $Q$ , the net heating value (NHV), or apply a factor  $Q = \text{NHV} - \text{losses}$ . Losses are probably less than 5%, so we can safely use  $Q = 0.95 \times \text{NHV}$  to take the losses into account. In addition, it must not be forgotten that a supplementary fuel burner may have to remain ignited at a minimum low fire position which may contribute about 5%, canceling out the heat losses.

Figure 3.2 shows the percentage of excess air and excess oxygen needed to obtain a given gas temperature, based on combustion of municipal waste having a heating value of 5500 Btu/lb. Note that excess oxygen is linear with the temperature, but excess air is not.

**Estimating heat losses.** Heat losses from the casings of furnaces can be estimated by assuming that the outer surfaces of the primary and secondary furnaces are at  $170^\circ\text{F}$ , and assuming a heat transfer coefficient of  $5 \text{ Btu}/(\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F})$ . Then each square foot of surface will have a loss of  $5 \times (170 - 70)$  or  $500 \text{ Btu}/(\text{h} \cdot \text{ft}^2)$ .

**EXAMPLE:** An incinerator has a primary chamber 10 ft diameter by 30 ft long, and a secondary chamber 10 ft diameter by 20 ft long. The outside surface is approximately  $1500 \text{ ft}^2$ , so the losses will be about  $750,000 \text{ Btu}/\text{h}$ . If this incinerator had a capacity of  $2000 \text{ lb}/\text{h}$  of  $6000 \text{ Btu}/\text{lb}$  waste, or  $12 \text{ million Btu}/\text{h}$ , the heat loss would be  $0.75/12 = 6\%$  of the HHV.

Many refractory-lined furnaces are constructed with double-wall jackets, and the combustion air is passed through this annular volume to recover heat. Typically, the air is heated from room temperature to about  $140^\circ\text{F}$ . This rise of about  $70^\circ\text{F}$  represents about 4% of the  $1800^\circ\text{F}$  final temperature. Together with the reduced skin temperature, typically about  $140^\circ\text{F}$ , the surface differential may be reduced from  $100^\circ\text{F}$  to  $70^\circ\text{F}$ , the outside loss to  $750,000 \times 70/100 = 500,000 \text{ Btu}/\text{h}$ , or about 4%. Thus most of the heat is recovered, and any loss may be neglected.

### 2.4 Heat Balance of Waste Combustion

**Combustion of waste of known composition.** Given the approximate analysis of a waste, a heat balance calculation can be carried out.

- Step 1. For the given fuel composition, as shown in Table 3.3, determine the oxygen required for complete combustion of the carbon and hydrogen (stoichiometric oxygen),  $(O_2)_{st}$ , to be 0.816 lb per lb fuel, and the products of combustion at zero excess air to be 4.314 lbp/lbf. The final temperature is set at 1800°F.
- Step 2. Calculate additional  $N_2$  and  $O_2$  due to excess air (EA), where EA is assumed to be 1.4 times stoichiometric air:

$$(O_2)_{ea} = EA \times (O_2)_{st} = 1.4 \times 0.816 = 1.14 \text{ lb } O_2/\text{lbf}$$

$$(N_2)_{ea} = 4.31 \times (O_2)_{st} = 4.31 \times 0.816 = 3.76 \text{ lb } N_2/\text{lbf}$$

Stoichiometric products =	4.31 lbp/lbf
Total product with excess air =	9.21 lb/lbf

- Step 3. Calculate the heating value of the fuel, using the modified DuLong formula:

$$HHV = 144.55[C] + 610 [H - Cl/35.5 - F/19 - O/10.5] + 40[S] + 25[N]$$

$$= 5003 \text{ Btu/lbf}$$

- Step 4. Calculate the net heating value (NHV)\* by subtracting  $1050 \times$  ("already formed compounds"):

$$NHV = HHV - [1050 \times (H_2O + 9(H - Cl/35 - F/19))]$$

$$4336 \text{ Btu/lbf}$$

\*The quantity of heat released in the combustion chamber(s) is derived from the net heating value (NHV). The higher heating value (HHV) includes the heat of condensation of the water present in the waste plus the heat formed in the combustion of hydrogen. The lower heating value (LHV) represents the heat formed in the combustion reaction; the net heating value (NHV) is the higher heating value minus the energy necessary to vaporize any moisture present and react with Cl and F, as noted in the heating value equation.

**TABLE 3.3** Oxygen Required for Complete Combustion of MSW

Fuel composition	lb/lbf	Mult. factor	Stoichiometric oxygen, lb/lbf	Products	Mult. factor	Stoichiometric products, lbp/lbf
Carbon	0.2633	2.67	0.703	CO <sub>2</sub>	3.67	0.966
Hydrogen	0.0372	8	0.297	H <sub>2</sub> O	9	0.334
Oxygen	0.186	-1	-0.186	O <sub>2</sub>		0
Nitrogen	0.0038					2.704
Chlorine	0.0031	-0.225	-0.0007	HCl	1.03	0.003
Fluorine	0.001	-0.421	-0.0003	HF	1.05	0.001
Sulfur	0.0019	1	0.002	SO <sub>2</sub>	2	0.004
Moisture	0.3			H <sub>2</sub> O	1	0.302
Ash	0.2					
Totals	1		$(O_2)_{st} = 0.816$		lbp/lbf =	4.314

Step 5. Calculate input enthalpy from preheated air and from the net heating value:

$$\Delta H_1 = \text{enthalpy of combustion air above } 77^\circ\text{F} = 0 \text{ Btu/lbf}$$

$$\Delta H_2 = \text{NHV} = 4336 \text{ Btu/lbf}$$

Step 6. Calculate the change in enthalpy for the products of combustion at the specified final temperature of 1800°F, using appropriate average specific heats:

$$0.315 \times (\text{CO}_2 = 0.974) \times (T - 77) = 528.6 \text{ Btu/lbf}$$

$$0.276 \times (\text{N}_2 = 2.704) \times (T - 77) = 1285.9 \text{ Btu/lbf}$$

$$0.515 \times (\text{H}_2\text{O} = 0.337 + 0.303) \times (T - 77) = 567.9$$

$$0.20 \times (\text{SO}_2 + \text{HCl} = 0.007) \times (T - 77) = \underline{2.4}$$

$$\text{Total } \Delta H_3 = 2384.8 \text{ Btu/lbf}$$

Step 7. Calculate the enthalpy change of the excess air supplied to control the temperature. Note that the oxygen plus nitrogen in air is 4.31 times the oxygen:

$$\Delta H_4 = 0.26 \times 4.31 (\text{lba/lb oxygen}) \times (T - 77) \times (\text{O}_2)_{\text{st}} = 1575 \text{ Btu/lbf}$$

Step 8. Determine the additional air needed to provide a heat balance between input enthalpy and the enthalpy change of the excess air plus products, expressed as a percentage of the stoichiometric air (note:  $Q$  = heat lost from the furnace):

$$\text{EA} = 100 \times (\Delta H_1 + \Delta H_2 - Q - \Delta H_3) / (\Delta H_4 - \Delta H_1) = 143\%$$

*Note that the excess air determined here is the same as that assumed in Step 2. This is a trial-and-error calculation, which is solved in a spreadsheet calculation by a simple loop in which the answer of Step 8 is supplied as the input to Step 2.*

Step 9. Calculate the products of combustion on a volumetric basis. As seen in Table 3.4, conversion from weight (mass) basis to volumetric basis is accomplished by dividing the weight of each compound by the appropriate molecular weight. The factor 386/MW converts the result to standard cubic feet of gaseous product per pound of fuel

**TABLE 3.4** Products of Combustion of MSW with Excess Air for 1800°F

Products at excess air	lbp/lbf	Molecular weight	Factor 386/MW	Products (scfg/lbf)	Vol.% wet	Vol.% dry
CO <sub>2</sub>	0.969	44	8.77	8.54	7.26	8.3
H <sub>2</sub> O (from H <sub>2</sub> )	0.335	18	21.44	7.27	6.14	0
O <sub>2</sub>	1.148	28	12.06	79.26	67.35	77.2
N <sub>2</sub>	6.488	32	13.79	16.10	13.68	15.7
HCl	0.0032	36	10.58	0.034	0.03	0.03
HF	0	19	19.3	0.002	0.002	0.002
SO <sub>2</sub>	0.004	44	6.03	0.024	0.02	0.023
H <sub>2</sub> O (moisture)	0.301	18	21.44	6.47	5.52	0
Totals	9.25			117.68	100%	100%

(sfg/lbf). The percent volume (wet) is converted to (dry) by subtracting the volume of moisture from combustion of  $H_2$  and from moisture in the fuel.

Step 10. Determine parts per million by dry volume:

$$\begin{aligned} \text{HCl} &= (0.03/100) \times 1,000,000 = 300 \text{ ppmdv} \\ \text{SO}_2 &= (0.023/100) \times 1,000,000 = 230 \text{ ppmdv} \end{aligned}$$

**Combustion of a mixture of aqueous waste and auxiliary fuel.** Aqueous waste is water contaminated with combustible materials which cannot be removed readily. To burn aqueous wastes, an auxiliary fuel having a substantial heating value is needed. To calculate a heat and mass balance for a mixture of wastes or, specifically, for a mixture of fuel and an aqueous waste which does not support combustion, the first step determines the composition of a mixture which can be burned with sufficient excess air to assure complete combustion, generally no less than 50% excess air.

A few heat and mass balance trials found that 13.1 lb of fuel oil per 100 lb of aqueous waste and fuel, as shown in Table 3.5, resulted in a furnace temperature of 1800°F at 50% excess air. Table 3.6 determines the products of combustion, and Table 3.7 shows the products of combustion on a mass and volume basis.

Step 1. Calculate additional  $N_2$  and  $O_2$  due to excess air

$$(O_2)_{EA} = EA \times (O_2)_{EA} = 0.34 \text{ lb } O_2/\text{lbf}$$

$$(N_2)_{EA} = 4.31 \times (O_2)_{EA} = 1.13 \text{ lb } N_2/\text{lbf}$$

$$\text{Stoichiometric products} = 3.95$$

$$\text{Total} = 5.42 \text{ lb/lbf}$$

Step 2. Calculate heating values

$$\text{HHV} = 4164$$

$$\begin{aligned} \text{NHV} &= \text{HHV} - [1050 \times (H_2O + 9(H - Cl/35 - F/19))] \\ &= 2988 \text{ Btu/lbf} \end{aligned}$$

**TABLE 3.5** Composition of Mixture of Auxiliary Fuel Oil and Aqueous Waste

	Composition		Fraction composition		Mixture
	Fuel oil	Aqueous waste	Fuel oil	Aqueous waste	
Carbon	88.6	8.98	11.61	7.80	19.41
Hydrogen	9.54	1.19	1.26	1.03	2.28
Oxygen	0.58	1.57	0.08	1.36	1.44
Nitrogen	0.14	2.48	0.02	2.15	2.17
Chlorine	0	0	0.00	0.00	0.00
Fluorine	0	0	0.00	0.00	0.00
Sulfur	1.14	0.39	0.16	0.34	0.49
Moisture	0	81.48	0.00	70.81	70.81
Ash/inerts	0	3.92	0.00	3.40	3.40
Totals	100	100	13.1	86.9	100

Step 3. Calculate enthalpy of products

$$\Delta H_1 = \text{enthalpy of products above } 77^\circ\text{F} = 0 \text{ Btu/lbf}$$

$$\Delta H_2 = \text{NHV} = 4164 \text{ Btu/lbf}$$

Step 4. Calculate enthalpy of combustion products at 1800°F

$$\Delta H = C_p \times W_p \times (T_{\text{out}} - T_{\text{in}})$$

$$0.26 \times (\text{CO}_2 + \text{N}_2) \times (T - 77) = 1354 \text{ Btu/lb}$$

$$0.49 \times (\text{H}_2\text{O}) \times (T - 77) = 771$$

$$0.20 \times (\text{SO}_2 + \text{HCl})(T - 77) = 3$$

$$\text{Total } \Delta H_3 = 2129$$

**TABLE 3.6** Oxygen Required for Complete Combustion of Mixture of Fuel Oil and Aqueous Waste

Fuel composition	lb/lbf	Multiplying factor	Oxygen, lb/lbf	Products	Multiplying factor	Products, lbp/lbf

Totals			77.4	100%	100%

Step 5. Calculate enthalpy of excess air

$$\Delta H_4 = 0.26 \times 4.31 \times (T - 77) \times (\text{O}_2)_{\text{xs}} = 1315 \text{ Btu/lbf}$$

Step 6. Calculate excess air percentage

$$\text{EA} = 100 \times (\Delta H_1 + \Delta H_2 - Q - \Delta H_3) / (\Delta H_4 - \Delta H_1) = 50\%$$

## 2.5 Calculation of *F*-Factor for Stoichiometric Combustion

When converting stack test data from a volumetric basis (as measured) to a mass basis, it is useful, indeed necessary, to use a factor relating stack gas flow to the heat released in combustion. This factor, expressed as standard cubic feet per million Btu, depends upon the composition of the fuel. The US EPA has used a factor of 9750 scf per million Btu for conversions when no information was available about the composition of the waste. The method which can be used to determine the *F*-factor from the chemical composition of the waste is presented below, using a composition typical of municipal solid waste (MSW). The factor determined in Table 3.8 is 10,968 scf/(MBtu), which is about 12% higher than the standard EPA factor, thus showing that it is not exact.

## 2.6 Air Required for Combustion

**Starved-air combustion.** The principle of “starved-air” or “controlled-air” combustion is used in incinerators having refractory primary chambers as a means of keeping the temperature in this chamber below the temperatures at which glassy materials melt and cause slagging. By starving the air, that is, keeping the stoichiometric ratio below one, the flame temperature is reduced accordingly, as CO is produced rather than CO<sub>2</sub>.

Figure 3.2 showed the relationship between excess air or oxygen and the theoretical flame temperature in the excess-air region.

Figure 3.3 shows both the starved-air and excess-air regions. In the starved-air region, where less than half the air required to achieve the maximum flame temperature is supplied, the temperature is less than half the flame temperature. In spite of typical maximum flame temperatures as high as 3600°F, target temperatures of 1400 to 1600°F can be maintained, to minimize slagging. The air needed to complete combustion is provided in the secondary chamber where temperatures in the 1800°F to 2200°F range are achieved, and are controlled by modulating the quantity of combustion air added to the secondary chamber.

The air requirement for a given temperature depends upon the heating value of the waste, such as Types 0, 1 and 2, and typical municipal wastes, which have heating values ranging from 4300 to 8500 Btu/lb. The properties of these wastes are shown in Table 3.9. The oval in Fig. 3.3 marked “primary chamber” shows the starved-air conditions at temperatures from 1300°F to 1500°F, at about 45 to 65% of theoretical air. The oval marked “secondary chamber” shows the temperatures resulting from 125 to 200% of theoretical air (25 to 100% excess air), which range from 1750° to 2000°F. A heat loss of 10% has been assumed. Under these conditions, the peak flame temperature ranges from 2200 to 3000°F.

**EXAMPLE:** Estimate the combustion air required to maintain the primary chamber at 1500°F and the secondary chamber at 1800°F, assuming the theoretical flame temperature is 3600°F.

Step 1. Calculate combustion air needed to maintain starved-air conditions and 1500°F in the primary chamber. This is done by restricting combustion air (and oxygen) so that, instead of heating the 100°F combustion air to 3600°F, a rise of

**TABLE 3.8** Calculation of *F*-Factor for Stoichiometric Combustion of Municipal Waste

MSW	Wt	Wt. %	× mult. factor	Stoichiometric O <sub>2</sub> (lbp/lbf)	Prod.	Mult. factor	Stoichiometric product (lb/lbf)	Mol. wt	Wet products (scfw/lbf)	Dry products (scfd/lbf)	Volume percent wet	Volume percent dry
Carbon	0.263	26.33	2.67	0.703	CO <sub>2</sub>	3.67	0.966	44	8.48	8.48	15.44%	20.58%
Hydrogen	0.037	3.72	8	0.298	H <sub>2</sub> O	9	0.335	18	7.18		13.08%	
Oxygen	0.186	18.60	-1	-0.186	O <sub>2</sub>			28				
Nitrogen	0.004	0.38			O <sub>2</sub> × 3.31 + N <sub>2</sub>		2.706	32	32.64	32.64	59.45%	79.22%
Chlorine	0.003	0.31	-0.0225	-0.000	HCl	1.03	0.003	36	0.03	0.03	0.06%	0.08%
Fluorine	0.001	0.06	-0.421	-0.000	HF	1.05	0.001	19	0.01	0.01	0.02%	0.03%
Sulfur	0.002	0.19	1	0.002	SO <sub>2</sub>	2	0.004	44	0.03	0.03	0.06%	0.08%
Moisture	0.304	30.40		0.000	H <sub>2</sub> O	1	0.304	18	6.52		11.88%	
Ash	0.200	20.00										
Totals	1.000	100.00	Stoic. O <sub>2</sub>	0.816		Stoic. prod.	4.319		54.90	41.20	100%	100%

Notes HHV =  $144.55[C] + 610[H - Cl/35.5 - F/19 - O/10.5] + 40[S] + 25[N]$   
= 5005 Btu/lb

lb/million Btu = 1,000,000 Btu/HHV

*F*-factor (scfd/million Btu) =  $41.2 \times 1,000,000/5005 = 8231$  standard cubic feet per million Btu, dry

*F*-factor (scfw/million Btu) =  $54.9 \times 1,000,000/5005 = 10,968$  standard cubic feet per million Btu, wet.

3600 – 100 = 3500°F, the rise is only 1500 – 100 = 1400°F. The air needed is then 1400/3500 = 0.4 = 40% of theoretical air.

Step 2. Calculate the total combustion air needed to maintain 1800°F in the secondary chamber. This is done by supplying the air needed to complete combustion (100 – 40% = 60% of SA) plus excess cold air at 100°F with gases at the theoretical flame temperature to reduce the temperature to 1800°F.

$$\begin{aligned}
 X &= (T_h - T_m)/(T_h - T_c) \\
 &= (3600 - 1800)/(3600 - 100) \\
 &= 0.51 = 51\% \text{ excess air}
 \end{aligned}$$

$$\begin{aligned}
 \text{Total air} &= \text{primary air plus secondary air} \\
 &= (0.40 + 0.60 + 0.51) \\
 &= 1.51 \times \text{stoichiometric air}
 \end{aligned}$$

TABLE 3.9 Properties of Types of Medical Waste and Trash

Type	HHV	Excess air at 1800°F	Theoretical flame temp. (°F)	%O <sub>2</sub> in dry gas
0	8500	168	4060	13.2
1 + 0	7500	133	3510	12
1	6500	146	3690	12.5
2	4300	90	2800	9.5
MSW	5000	139	3490	12.2

**Heat release in primary furnace.** The primary furnace is used to “release” the heat, and the secondary chamber is used to complete the combustion process. In order to minimize slagging of refractory-lined furnace walls, experience indicates that heat release rates should be 15,000 Btu/(h·ft<sup>3</sup>) or less.

**EXAMPLE:** What would be the maximum amount of heat which would be released within a rectangular primary furnace, 9 ft high, 9 ft wide and 30 ft long, based on a limit of 15,000 Btu/(h·ft<sup>3</sup>) for a refractory-lined chamber?

$$\text{Volume} = (9 \times 9 \times 30) = 2430 \text{ ft}^3$$

$$\text{Heat release} = 15,000 \text{ (Btu/(h} \cdot \text{ft}^3)) \times 2430 \text{ (ft}^3) = 37 \text{ million Btu/h}$$

**Secondary chamber volume and retention or residence time.** An essential criterion in the design of combustion systems, especially those designed to burn difficult-to-burn wastes, is the time provided for the combustion process to be completed while the gases are maintained, calculated at the typically mandated 1800° or 2000°F. This time period is variously called “retention time” and “residence time,” and is typically measured from the location where the last overfire air ports are placed.

Retention time is determined by the velocity of the gases and the distance they travel through the combustion chamber. By multiplying the velocity and distance by the cross-section of the chamber we obtain the volume flow rate of the gases and the volume of the chamber. Retention time is thus determined by the equation:

$$t = (\text{chamber length, ft})/(\text{gas velocity, ft/s}) = s$$

or

$$t = (\text{chamber volume, ft}^3)/(\text{gas volume, ft}^3/\text{s}) = s$$

**EXAMPLE:** A chamber having a volume of 1000 cubic feet passes 60,000 cubic feet per minute of gas. The retention time is then  $1000/(60,000/60) = 1000/1000 = 1$  second.

The gas volume must be calculated at the required temperature (i.e. 1800°F).

**EXAMPLE:** Calculate the secondary furnace volume required for burning 10,000 pounds per hour of the waste at a temperature of 1800°F.

*Solution:*

Based on a heat and mass balance calculation, the volume of gas produced from burning 1 pound of this waste is 13.6 cubic feet, at standard conditions of 70°F and atmospheric pressure

$$\text{Cubic feet per second at standard conditions} = 13.6 \times 10,000 \text{ (lb/h)}/3600 \text{ (s/h)} = 38 \text{ ft}^3/\text{s}$$

Correcting to 1800°F:

$$\text{Actual CFS} = 38 \times [1800 + 460]/[460 + 70] = 38 \times 4.26 = 160 \text{ ft}^3/\text{s}$$

For a retention time of one second, a chamber of 160 cubic feet would be required.

**Retention time and induced-draft fan capacity.** The capacity of the waste combustor is thus determined by the volume of the secondary chamber or afterburner needed to provide one second retention time. The gas flow which provides 1 s retention time thus becomes the design gas flow for the system.

Since it is necessary to heat up the combustion chambers to the required temperature of 1600°F to 1800°F before introducing wastes, whether liquid or solid, clean waste or auxiliary fuel must be used for this purpose. Hence the calculation of the design capacity of the system should be based on the startup operation using clean fuel. The example which follows uses distillate #2 oil as the basis. A similar calculation based on natural gas was found to require less chamber volume and fan capacity, hence the oil basis was selected as being more conservative.

The capacity of the induced-draft fan which will provide the gas flow associated with the retention time is determined by whether water injection or a boiler is used to reduce the temperature of the gases from 1800°F. If a boiler is used, the fan will carry the same mass flow, but the fan capacity will be based on the temperature of the gases leaving the boiler. Typically, the boiler cools the gases to about 450°F. A water quench or a spray-dry scrubber could then reduce the gas temperature to about 300°F, or alternatively, if a wet scrubber is used, to about 130°F. If a wet scrubber is used, without a boiler, typically the gases are cooled to the adiabatic saturation temperature of about 180°F. In any case, the water so evaporated must be added to the products of combustion.

The following calculation determines the gas flow associated with a chamber temperature of 1800°F and a retention time of one second, at a heat release of one million Btu per hour. Then the induced-draft fan capacity is determined on the basis of use of a water quench and scrubber which reduces the gas temperature to 180°F. The basic steps in this calculation are as follows:

- (a) Perform a heat balance using the auxiliary fuel properties to determine the excess air required to achieve a furnace temperature of 1800°F.
- (b) Calculate the volume of the products of combustion. Use this volume and the excess air obtained to determine the volume of the furnace per million Btu of heat release.
- (c) Calculate the quantity and volume of water evaporated in reducing the gas temperature from 1800°F to 180°F.
- (d) The capacity of the fan is the sum of the combustion products and the water evaporated. The chamber volume and fan capacity, based on one million Btu/h, is multiplied by the desired heat release to determine the design capacity of the furnace and fan.
- (e) The capacity of the furnace and fan to burn wastes having different compositions can be estimated closely by using the heat release rate. However, if the waste, or one of several wastes fed to the furnace, contains a large amount of water, a complete calculation will have to be made.

**EXAMPLE:** Calculate secondary chamber volume, and fan capacity for startup.

Step 1. Identify auxiliary fuel and operating conditions:

Auxiliary fuel type	distillate #2 oil
Fuel heating value, NHV	18,300 Btu/lb
Desired operating temperature, $T_{out}$	1800°F
Stoichiometric oxygen required for fuel	3.32 lb/lbf

Step 2. Identify stoichiometric oxygen requirements and combustion product yields for auxiliary fuel

	Combustion products, lbp/lbf				Net heat value
	(O <sub>2</sub> ) stoic(f), lb/lbf	CO <sub>2</sub>	H <sub>2</sub> O	N <sub>2</sub>	
Residual fuel #6	3.16	3.18	0.92	10.5	17,500
Distillate fuel #2	3.32	3.2	1.11	11	18,300
Natural gas	3.67	2.54	2.04	12.2	19,700

Step 3. Calculate enthalpy of the fuel combustion gases:

$$\begin{aligned} \Delta H_1 &= [0.26(\text{CO}_2 + \text{N}_2) + 0.49 \text{H}_2\text{O}] (T_{\text{out}} - 77) \\ &= [0.26(3.2 + 11) + 0.49 \times 1.11](1800 - 77) \\ &= 7298 \text{ Btu/lbf} \end{aligned}$$

Step 4. Calculate the enthalpy of excess air leaving combustion:

$$\begin{aligned} \Delta H_2 &= (4.31 \times 0.26) \times (\text{O}_2)_{\text{stoic}}(f) \times (T_{\text{out}} - 77) \\ &= (4.31 \times 0.26) \times (3.32) \times (1800 - 77) \\ &= 6410 \text{ Btu/lbf} \end{aligned}$$

Step 5. Calculate the heat of fuel combustion, less 5% heat loss through walls:

$$\Delta H_3 = 0.95 \times 18,300 = 17,385 \text{ Btu/lbf}$$

Step 6. Calculate heat loss through chamber walls  $Q$ :

$$Q = 5\% \text{ loss} = 0.05 \times 18,300 \text{ Btu/lbf} = 915 \text{ Btu/lbf}$$

Step 7. Calculate excess air percentage:

$$\begin{aligned} \text{EA} &= 100 \times (\Delta H_3 - Q - \Delta H_1) / (\Delta H_2) \\ \text{EA} &= 100 \times (17,385 - 915 - 7298) / (6410) = 143 \text{ percent} \end{aligned}$$

Step 8. Calculate products with excess air:

	lb/lbf	Molecular weight	(lb/lbf) $\times$ 387/MW = ft <sup>3</sup> /lbf
CO <sub>2</sub>	2.54	44	22.34
H <sub>2</sub> O	2.04	18	43.86
N <sub>2</sub>	12.20	28	168.62
O <sub>2</sub> 1.43 $\times$ (O <sub>2</sub> ) <sub>stoic</sub>	5.25	32	63.47
N <sub>2</sub> 1.43 $\times$ N <sub>2</sub> =	17.45	28	241.13
Total	39.47		539.42

Step 9. Correct volume to 1800°F:

$$539.42 \text{ (lbm/lbf)} \times (1800 + 460) / (77 + 460) = 2270 \text{ ft}^3/\text{lbf}$$

Step 10. Calculate chamber volume needed for one second retention time:

$$\text{For 1 million Btu/h, we need } 1000,000/18,300 = 54.64 \text{ lbf/h}$$

$$\text{For 1 second, } 2270 \text{ (ft}^3/\text{lbf)} / 3600 \text{ (s/h)} = 0.63 \text{ ft}^3/(\text{MBtu/h})$$

$$\text{For 40 million Btu/h, we need } 40 \times 54.645 \times 0.631 = 1378 \text{ ft}^3/\text{s}$$

$$\text{Select 8 ft diam. } \times 27 \text{ ft: Volume} = 1358 \text{ ft}^3$$

Step 11. Calculate water needed to cool gases to 180°F at 1 million Btu/h:

$$\begin{aligned} @ 1 \text{ million Btu/h : products} &= 54.645 \text{ (lb/h)} \times 39.47 \text{ (lb/lbf)} = 2157 \text{ lb/h} \\ \text{Heat to be removed, } Q &= 2157 \text{ (lb/h)} \times 0.26 \times (1800 - 180) = 908,551 \text{ Btu/h} \\ \text{At 1000 Btu/lb water, water added} &= 908,000/1000 = 909 \text{ lbw/h} \\ \text{Volume of water at STP} &= 386/18 = 21.44 \text{ ft}^3/\text{lbw} \\ \text{Volume of water at 180}^\circ\text{F} &= 21.44 \times (460 + 180)/(460 + 70) = 25.89 \text{ ft}^3/\text{lbw} \end{aligned}$$

Step 12. Calculate volume at fan:

$$\begin{aligned} \text{Specific volume of products at STP} &= 386/30 = 12.87 \text{ ft}^3/\text{lbp} \\ \text{Volume of products at STP} &= 2157 \times (386/30)/60 = 463 \text{ ft}^3/\text{min} \\ \text{Volume of products @ 180}^\circ\text{F} &= 462.57 \times (460 + 180)/(460 + 70) = 525 \text{ ft}^3/\text{min} \\ \text{Add volume of water vapor} &= 909 \times 21.44/60 = \underline{325 \text{ ft}^3/\text{min}} \\ \text{Fan capacity} = \text{Total} &= 850 \text{ ft}^3/\text{min} \\ \text{Fan capacity at 40 million Btu/h} &= 850 \times 40 \text{ million Btu/h} = 34,000 \text{ ft}^3/\text{min} \\ \text{Fan capacity per million Btu/h} &= 850 \text{ ft}^3/(\text{min} \cdot \text{MBtu}) \end{aligned}$$

### 3 WASTE COMBUSTION SYSTEMS

---

Systems designed to burn fuels and wastes must feed the fuels and wastes to the combustion chambers, supply combustion air where and as needed, agitate or mix the fuel with this air, remove the ash and flyash residues, measure and control combustion temperatures, and cool the combustion products. Finally, the system must process and clean the combustion gases before discharge through the stack to the atmosphere. The functions of a complete system are controlled by computer systems which measure, record and display operating temperatures and other data and control grate operation, and by fans and dampers which adjust combustion air and furnace draft, among other variables.

*Combustion systems* must be designed to accommodate the special characteristics of the wastes to be burned. While the principles are common, evolution of the designs has found that certain designs and configurations are most suitable for specific fuels and wastes. Given a design and configuration, there are limitations as to what types, quantities and mixtures of fuels and wastes can be burned satisfactorily.

*Combustion of wastes* generally requires these stages:

- Preparation of fuel or waste for feeding
- Feeding fuel or waste under control
- Drying: removing moisture from outer surface of waste
- Evaporating liquids to volatile gases
- Volatilizing solids to gases
- Raising volatile gases to ignition temperature
- Supplying combustion air sufficient to establish flame
- Adding “underfire” combustion air as combustion process continues
- Adding “overfire” combustion air to continue combustion process
- Adding “secondary” air to maintain secondary chamber temperatures.

*The combustion process* is controlled so that, in the progression of fuel and air through the chambers, the optimum amount of air is supplied to combustibles (or, alternatively, the right amount of waste is fed to match the air) at all times and all places: how well this is accomplished is the measure of success. If too much air is supplied too soon, ignition may not take place where desired, and the flame temperature can be too low to assist rapid combustion. Too little air can result in insufficient combustion in the primary chamber, or in excessively high temperatures which can cause slagging and other damage.

*Emission control devices* are an integral part of a complete system. The induced-draft fan at the stack end of the process must be controlled by a damper and/or speed control to maintain the draft in the combustion chambers so that hot gases do not leak into the atmosphere, and so that too much cold air is not sucked into the chambers.

### 3.1 Types of Wastes to be Burned

*Liquid and gaseous wastes* can be burned in relatively simple refractory combustion chambers provided with a burner suitable for burning conventional fuels (gas and oil) and one or more burners designed to atomize and burn the liquid, or to atomize essentially non-combustible liquids, which will be destroyed at the temperatures provided by high-energy fuels or wastes. Heating values of liquid wastes can range from negative to 23,000 Btu per pound. The combustion process is easy to control because the fuel has consistent properties and the combustion air can be controlled in direct proportion to the combustible feed, or vice versa.

*Solid wastes* are more difficult to burn due to the highly variable nature of the waste material. Solid wastes vary widely in composition and physical characteristics, spanning a wide range of bulk densities and moisture contents, resulting in heating values ranging from negative to as high as 22,000 Btu/lb. Solid materials require complex handling, feeding, firing, and residue removal equipment. Municipal and medical wastes, while highly variable in composition and heating value, have a fairly consistent range in their properties.

*Hazardous waste incinerators* may be dedicated to the wastes of a specific facility, or to wastes from a wide range of generators. They are generally capable of processing wastes that include aqueous liquids with negative heating value, high energy liquids, sludges which are difficult to pump, solids which are slow to ignite and burn, and in general wastes containing potentially hazardous chemicals and compounds.

*Note:* the term “incinerator” has been associated with small waste combustors which often lacked emission controls. To avoid this connotation, the term “waste combustor” is preferred.

### 3.2 Types of Combustion System

*Municipal, commercial and medical waste combustion systems* may be classified by size (throughput capacity) and application:

Small refractory-lined incinerators have capacities from 20 to 750 lb/h:

- Single-chamber incinerators, batch feed, 8 to 16-hour operation
- Multiple-chamber incinerators, batch or intermittent feed, 8 to 16-hour operation.

Medium-size refractory-lined two-chamber combustors with capacities from 500 to 2000 lb/h (50 tpd), capable of 24-hour continuous operation.

*For municipal and commercial wastes:*

Small mass-burn combustors with capacities from 50 to 250 tpd:

- Refractory-wall, continuous feed
- Water-cooled wall, continuous feed

Large-scale combustors, water-wall, continuous feed, with capacities from 250 to 1000 tpd:

- Mass-burn stoker
- Suspension-fired RDF stoker
- Fluidized-bed RDF

For hazardous wastes:

- Refractory-lined furnaces
- Rotary kiln refractory furnaces
- Cement kilns
- Lightweight aggregate kilns
- Boilers and industrial furnaces

**Mass burn combustors.** Mass burn combustion systems burn solid wastes such as municipal solid waste (MSW) and biomedical medical wastes (BMW) without preprocessing other than removal of items too large to go through the feed system.

**Small refractory-wall combustors.** Figure 3.4 shows a multiple-chamber rectangular refractory-wall combustor, representing units which have been installed in many hospitals and crematoriums, commonly called incinerators. These are used for capacities in the range of 500 to 2000 lb/h. They may be charged manually through the charging door and, after ignition of the waste, allowed to burn out before recharging. Normally, however, they are fitted with

feed hoppers with tight-closing doors and ram feeders so that they can receive additional charges during the course of the 8 to 12-hour working day, while maintaining the air seal needed to keep the combustion under control and avoiding flash-backs when the charging door is opened.

Waste is fed through the charging door onto the stationary grate, which may be perforated so that combustion air can be supplied from under the waste as it burns in the ignition chamber; alternatively, combustion air may be injected from nozzles in the chamber walls. An ignition burner is provided to ignite the waste and maintain a minimum temperature (such as 1200°F) in the chamber. Flames and hot gases exit through the flame port to the mixing chamber where mixing with secondary air occurs. A secondary burner maintains the temperature when the wastes do not provide enough energy. The gases pass under the curtain wall into the secondary combustion chamber where combustion is completed before exiting to the stack. Not shown is a barometric damper which controls the chamber draft by adding cold air before the gases enter the stack. Air ports are provided in the secondary combustion chamber and in the mixing chamber. A supplemental fuel burner is provided in the primary chamber for ignition and heating up of this chamber. Another burner in the secondary chamber is used for heat up, to maintain the flame, and to assure that the required chamber temperature is maintained at all times that waste is being fed, regardless of the energy supplied by the waste. Ash is removed only after the waste has burned out overnight.

**Modular refractory combustors.** Small two-chamber refractory-wall combustors having capacities ranging roughly from 20 to 750 lb/h are illustrated in Fig. 3.5. A ram feeder pushes the waste from the feed hopper into the lower chamber. The waste is agitated by the internal ram, progressing it toward the ash quench pit, into which ash residues fall and are pulled out by an ash hoe, in this case, into an ash cart. A primary burner (not shown) is used to preheat the primary chamber and maintain temperature, while primary combustion air is introduced through ports in the chamber walls. Secondary combustion air is introduced in the throat between the lower and upper chambers. The secondary burner maintains the temperature in the upper chamber, in which combustion is completed before the gases leave through the stack.

With intermittent feeding, each charge produces an upset in the combustion conditions. The size and frequency of charging determine the degree of upset, and challenge the ability of the control system to adjust the combustion air to maintain essentially constant furnace temperatures. The size of the feed hopper determines the maximum volume of the charge, but neither its weight nor its thermal value; hence it is the duty of the operator to keep weight and quality in mind while charging the hopper.

The time between charges may be automatic, with the operator option to extend it. Generally charges should not follow more closely than 10–15 minutes apart, in order not to exceed the capacity of the combustion air fans during the spike in heat release which occurs about one minute after the charge enters.

The incinerator shown in Fig. 3.5 has a hydraulically operated feed hopper with cover, guillotine shutoff door, charging ram, and reciprocating grates for agitating the waste and moving the burning waste to the ash discharge. The ash discharges into a water-quench tank. An ash conveyor retrieves the ash and places it in containers.

**Continuous feed two-chamber waste incinerator with heat recovery boiler.** Figure 3.6 shows a complete incinerator for continuous feeding of medical waste. A waste cart with tipping mechanism is used to load the feeder while the feeder lid is open and the shrouded feeder door is closed. After loading, the feeder lid closes, the feeder door opens, and the ram feeder pushes the waste into the primary chamber. A refractory ram in the primary chamber pushes the ash to the ash quench pit, where it is removed and discharged into ash carts. The inducted draft fan draws gases from the secondary chamber through the breeching to the heat recovery boiler, generating steam or hot water, and discharges the cooled gases to the boiler exhaust stack.

**Pathological and crematory waste incinerators.** These combustors are specially designed to burn high-moisture wastes which do not support combustion; hence they rely entirely on the supplemental fuel burners to raise and maintain the furnace temperature until the charge has been totally burned to ash. They are generally fed in batches which are allowed to burn down before a new charge is introduced.

**Larger two-chamber modular refractory combustors.** Large two-chamber combustors, shop fabricated for the capacity range of 5–120 tpd of MSW throughput, are illustrated in Fig. 3.7. They were developed to serve the need for smaller, less costly refractory systems which could be shipped in modules for assembly on the site. The refractory is brick or castable, depending on the application. They burn waste that has not been preprocessed other than to remove oversize objects. They are usually fed from a tipping floor by front-loaders.

Multiple hearths are provided, each having a transfer ram to progress the waste down the hearths and into the residue sump and into the water pit, from which they are removed by conveyors. The hot gases from the secondary chamber are generally cooled by a waste heat boiler before discharge through an emission control system to the stack.

**Modular starved air combustors.** These units are designed to operate in starved air (also called controlled air) mode. Air is supplied at levels below that required for complete combustion (sub-stoichiometric level) in order to assist combustion while maintaining temperatures

**FIGURE 3.6** Two-chamber modular incinerator with feeder, ash removal and heat recovery (Simonds Mfg Corp., Auburndale, Florida).

below the levels which cause slagging. Refractory or water-cooled reciprocating rams agitate the waste and move it along the refractory floor to the ash discharge. The incompletely oxidized combustion products (CO and organic compounds) pass into the secondary combustion chamber, where additional air is added to control temperature while providing sufficient retention time for completion of combustion.

**Modular excess air combustors.** A few modular refractory combustors, limited to a capacity of 120 tpd per unit, have been designed to operate in the excess air mode, using recirculating flue gas to control the temperatures in the primary and secondary combustion chambers. Waste is batch-fed by hydraulically operated feed rams to the refractory-lined primary chamber, typically on a 6–10 minute cycle between charges, adjustable to compensate for waste composition. The waste is moved through the primary chamber by hydraulically operated refractory hearths. The ash residue is discharged to a wet quench pit. The refractory secondary combustion chamber provides residence time for burnout.

**Medical waste combustion systems.** Medical wastes have been burned in systems similar to those shown in Figs. 3.4–3.6 without emission controls, discharging the hot gases directly to

FIGURE 3.7 Large two-chamber refractory combustor.

the stack, or passing them through a boiler for heat recovery before discharge to the stack. More recently, these systems have been provided with wet scrubbers or baghouses for emission control.

More stringent regulations have required that medical waste combustors be provided with emission controls to remove not only particulate matter but acid gases. Figure 3.8 shows a complete system including a waste hopper (1), an auger feeder (2), a rotating primary chamber (3), a secondary chamber (4), an emergency bypass stack (5), a heat recovery boiler (6) to reduce the temperature of the gases, a baghouse (7) to remove particulates, a wet scrubber (8) to remove acid gases, an induced-draft fan (9) to provide system draft requirements and maintain furnace draft, and a stack (10) discharging to the atmosphere. Some systems of this type have been provided with dry activated carbon injection systems to remove mercury and dioxins.

**Large refractory-wall combustion systems.** Early designs of mass-burn combustors for municipal solid waste built in unit sizes ranging from 90 to 270 Mg/d (100–300 tpd) had refractory chambers which were constructed in the field from refractory brick, generally anchored to structural steel frames, and often air cooled. They were generally fed from waste storage pits by cranes using grapples to pick up and discharge the waste into feed hoppers.

To permit continuous duty, large refractory-chamber combustors were provided with rocking or reciprocating grates which stir and aerate the waste bed as it advances through the combustion chamber, thereby improving contact between the waste and combustion air and increasing the burnout of combustibles. The ash is discharged at the end of the grate into a water quench pit for collection and disposal in a landfill. Most of these plants, that were built in the 1970s and 1980s, used water quench towers in lieu of heat recovery boilers to reduce the gas temperatures and electrostatic precipitators (ESPs) to reduce PM emissions.

Because refractory-walled combustors do not generally have waterwalls to remove heat from the primary combustion chamber, they need to use relatively large amounts of combustion air, typically 150–300 percent more than that required to maintain the desired furnace temperature range of 1600°–2000°F. These excess air levels result in relatively high carryover of PM from the combustion chamber and through the boiler passes before entering the air pollution control device (APCD).

**Mass burn waterwall combustors.** These systems range in capacity from 46 to 900 Mg/d (50–1000 tpd) of MSW throughput per unit. They are usually erected at the site (as opposed to being prefabricated at another location), and employ from one to three units per plant. This category includes mass burn waterwall (MB/WW), mass burn rotary waterwall combustor (MB/RC) and mass burn refractory wall (MB/REF) designs. These capacities are possible due to the cooling effect of the water-cooled walls of the combustion chamber.

As seen in Fig. 3.9, the waste is discharged from trucks from the tipping floor (2) to a pit (4) where a crane (5) transfers it to the feed hopper (6) from which it is injected onto the stoker grate in the primary combustion chamber (7). The ash residues pass through a quench tank (8) and into an ash hopper (9). In some plants these residues are passed under a magnet to separate ferrous metals, and screened to producing an aggregate for beneficial use. Otherwise the ash residues are sent to landfill.

The hot gases leaving the combustion chamber pass through a waterwall furnace (10) and through a boiler, superheater and economizer (11) and (12). In the conditioning tower (13) the gases are cooled before entering the lime reactor (14). The gases then pass through the fabric filter (15) and the induced draft fan which discharges them to the stack (16). Facilities with spray-dry scrubbers use the vessel (14) to cool the gases and evaporate the lime slurry before they enter the fabric filter. The flyash removed from the boiler hoppers is combined with the bottom ash residue. The flyash removed from the baghouse may be either mixed with the bottom ash or disposed of separately. The flyash is stored for use as a cement supplement, or mixed with the quench tank ash for discharge to the landfill.

The combustor walls are constructed of steel tubes that contain circulating pressurized water used to recover heat from the combustion chamber. In the lower, actively burning region of the chamber, where corrosive conditions may exist, the walls are generally lined with refractory. Heat continues to be recovered in the convective sections, superheater and economizer of the boiler.

Modern MB/WW facilities utilize hydraulically controlled reciprocating stoker grates or roller grates to move the waste through the combustion chamber. The grates typically include three or more sections which can be controlled separately. On the drying grate the moisture content of the waste is reduced prior to ignition. The next set of grates, referred to as the burning grates, is where the majority of active burning takes place. The third grate section, referred to as the burnout grates, is where remaining combustibles in the waste are burned. Bottom ash is discharged from the burnout grate into a water-filled ash quench pit. From there, the wet ash is discharged by a ram or drag conveyor to a conveyor system which transports the ash to a load-out or storage area prior to disposal. Dry ash systems, which have been used in some designs, require a suitable dust collection system to prevent discharge of dust to the environment.

The stoker grates transport the refuse through the furnace and, at the same time, promote combustion by adequate agitation and good mixing with combustion air, while being cooled by the underfire air. Abrupt tumbling caused by the dropping of burning solid waste from one tier to another promotes combustion. This action, however, also contributes to carryover of particulate matter with the exiting flue gases.

Combustion is initiated by radiation from the active combustion areas onto the incoming waste, resulting in drying the exposed surface and raising it to the ignition temperature. Combustion air is added from beneath the grate sections through underfire air plenums, usually one per grate section, to permit proportioning of the air supply as needed to control burning and heat release from the waste bed. Air injected below the grates is also needed to cool the grates. The grates may be divided into multiple parallel sections, each with a con-

trollable air supply. Underfire air may be preheated to compensate for moisture in the MSW. The tendency for slagging waste components (ash and glass) causes fouling and deterioration of the furnace refractory walls. The fusion and melting temperatures of these slags limit the operating temperatures above the grates. With simple refractory walls, flame temperatures may have to be limited to as low as 1800°F. Air-cooled or water-cooled refractory walls permit operation at higher temperatures, up to 2600°, with manageable slagging.

Overfire air is injected through rows of high-pressure nozzles located on the side walls of the chamber to complete the oxidation of the fuel-rich gases evolved from the bed and reduce the temperature of the gases below the theoretical flame temperature. Secondary air is added in the secondary combustion chamber. Properly designed and operated overfire air systems are essential for good mixing and burnout of organics in the flue gas. Typically, 80–100 percent excess air is needed to control the temperature of the gases leaving the combustion chamber.

The flue gas leaving the primary combustion chamber passes through the waterwall-cooled furnace section which cools the gases, from temperatures from 2200°F to 2600°F, generally to about 1500°F before they enter the superheater and/or convection sections, to minimize the formation of slag on the tubes. The superheater and convection sections are followed by economizer sections, altogether cooling the gases to about 450–550°F before they enter the air pollution control device (APCD).

**Mass burn rotary waterwall combustors.** Mass burn rotary combustor (MB/RC) facilities are similar to the units shown in Fig. 3.9 except that the primary chamber is a water-cooled rotary cylinder. These plants have been built in a range of unit capacities from 160 to 800 Mg/d (176–880 tpd), with typically 2 or 3 units per plant. Following removal of objects too large to feed into the combustor, the waste is ram-fed to the inclined cylindrical combustion chamber, which rotates slowly, causing the waste to advance and tumble as it burns. Underfire air is injected through the waste bed, and overfire air is provided above the waste bed. Bottom ash is discharged from the rotary combustor to an afterburner grate and then into a wet quench pit. The wet ash is conveyed to an ash load-out or storage area prior to disposal.

Combustion air is provided along the rotary combustion chamber length, with most of the air provided in the first half of the chamber. The rest of the combustion air is supplied to the afterburner grate and above the rotary combustor outlet in the boiler. The rotary waterwall system normally operates with about 50 percent excess air, compared with 80–100 percent for typical waterwall firing systems, since, due to the effective cooling in the combustor, less cooling air is needed to maintain the desired final combustion temperature of about 1800°–2000°F. Water circulated through the tubes in the rotary chamber recovers heat from combustion. Additional heat recovery occurs in the boiler waterwall, superheater, convector and economizer sections. From the economizer, the flue gas passes to the APCD at a temperature of about 450°F.

**Refuse-derived fuel combustors.** Refuse-derived fuel (RDF) combustors burn processed waste suitable for combustion in stoker-fired boilers, similar to those used to burn granular coal in utility boilers. Combustor sizes range from 290 to 1300 Mg/d (320–1400 tpd). A typical RDF combustion furnace is shown in Fig. 3.10. The waste processing system (not shown) consists of a tipping floor where front-loaders move to the waste after it is dumped from trucks into piles or to the feed conveyor leading to shredding magnetic separation and screening operations. Objectionable items from the waste are placed on a picking floor. Additional steps may remove glass and other non-combustibles, and multiple-stage shredding may provide a more uniform fuel to facilitate feeding to the furnace. Systems doing a high degree of processing to remove glass also produce roughly 20% residue which is normally landfilled, which increases the heating value of the remaining RDF product.

Figure 3.10 shows an RDF-firing system with associated emission controls. The RDF is fed by vibrating feeders and a speed-controlled screw to the air-swept spouts through which it is injected over the traveling-grate spreader-stoker. Underfire air passes through perforations in the stoker grate, and overfire nozzles supply secondary air. The forced-draft fan is followed by

FIGURE 3.10 RDF-firing system with associated emission controls (Palm Beach, Florida).

a steam heater to preheat the combustion air if needed. The RDF is fired in a semi-suspension mode, using an air-swept distributor, which allows a portion of the RDF to burn in suspension and the remainder to be burned out after falling on a horizontal traveling grate. Because the traveling grate moves from the rear to the front of the furnace, distributor settings are adjusted so that most of the waste lands on the rear two-thirds of the grate. This allows more time for combustion to be completed on the grate. Bottom ash drops into a water-filled quench chamber. The speed of the traveling grate can be manually adjusted to accommodate variations in burning conditions. Underfire air is normally preheated and introduced beneath the grate by a single plenum. Overfire air is injected through rows of high-pressure nozzles, providing a zone for mixing and completion of the combustion process.

The combustion gases lose temperature while passing through the waterwall-cooled chamber to the superheater, boiler bank, economizer and tubular air heater which heats the combustion air, thus generating superheated steam for use in the steam turbine-driven generator. Particulate matter (PM) concentrations at the inlet to the pollution control device are approximately double those of mass burn systems and more than an order of magnitude higher than in combustors using starved-air, two-stage combustion.

RDF-fired boilers can totally avoid the use of refractory by extending the water-cooled walls down to the grate level. Corrosion-resistant alloy cladding is used on the waterwalls to provide long life. The boilers have tall furnace chambers, providing retention time to burn out the RDF particles, followed by the superheater, convector and economizer sections, which reduce the gas temperatures to roughly 450°F. Excess air provided is typically 40–80%, similar to that of mass burn waterwall units.

**Fluidized bed combustors.** Fluidized bed furnaces can burn municipal solid waste as well as wood and other suitable wastes. It is necessary to process the waste, reducing particle size to facilitate feeding to the fluid bed, and preferable to remove glass and metals from the waste by preprocessing. This technology requires that the furnace temperature be kept below the melting point of glass and metals such as aluminum and zinc, which are removed from the circulating sand at the bottom.

These furnaces have the ability to add limestone (or other alkali) to the bed to capture halogens (chlorides and fluorides) and other compound, significantly reducing the discharge of acid gases. The ash residues are of a high quality which permits their beneficial use, reducing the costs of ash residue disposal.

In an FBC, illustrated in Fig. 3.11, shredded MSW (RDF) is fed to a turbulent bed of noncombustible material such as limestone, sand or silica, where combustion air is supplied through a gas distribution plate and underfire air windbox. The combustion bed, which lies over the gas distribution plate, is suspended or “fluidized” through the introduction of underfire air at a high flow rate. Other wastes and supplemental fuel may be blended with the RDF outside the combustor or added into the combustor through separate openings. Overfire air is used to complete the combustion process and maintain the furnace temperature below the 1600°F range.

*Bubbling bed combustors* maintain most of the solids near the bottom of the combustor by using relatively low air fluidization velocities to reduce the entrainment of solids from the bed into the flue gas, minimizing recirculation or re-injection of bed particles.

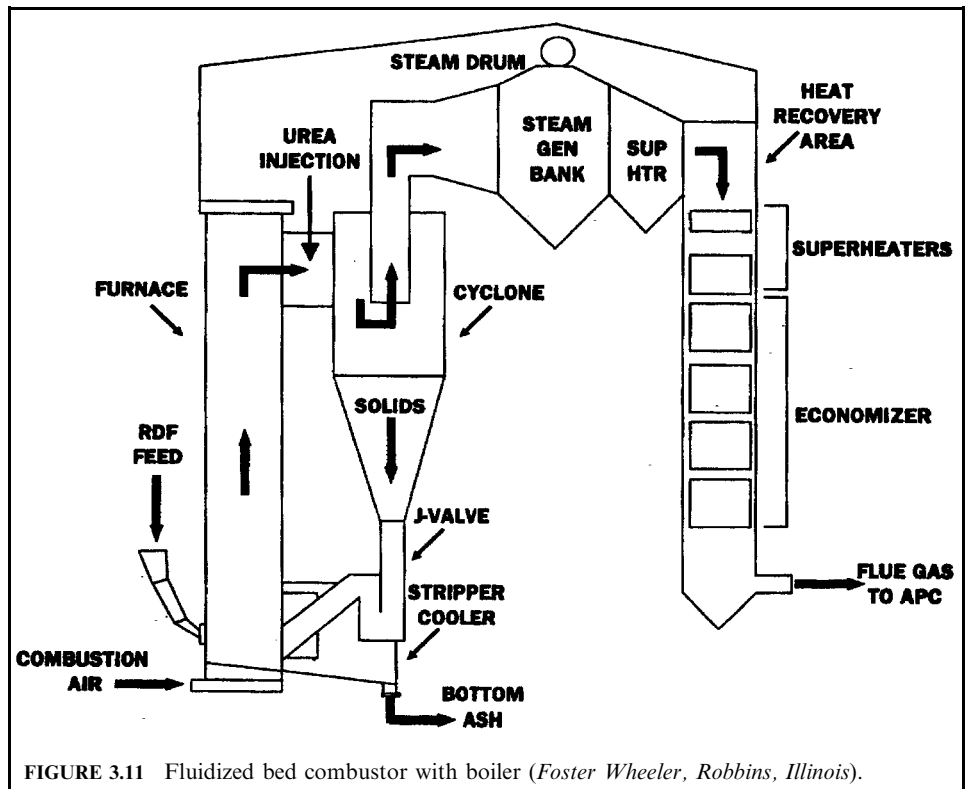

FIGURE 3.11 Fluidized bed combustor with boiler (Foster Wheeler, Robbins, Illinois).

*Circulating bed* combustors operate at higher fluidization velocities to promote carryover of solids into the upper section of the combustor. A cyclone is used to return the entrained bed material to the bed. Combustion occurs in both the bed and the upper section of the combustor. A fraction of the bed material is entrained in the combustion gas and enters a cyclone separator which recycles unburned waste and inert particles to the lower bed.

Good mixing is inherent in the FBC design. Fluidized bed combustors have very uniform gas temperatures in both the bed and the upper region of the combustor. This allows the FBCs to operate at lower excess air and temperature levels than conventional combustion systems. Waste-fired FBCs typically operate at excess air levels between 30 and 100 percent and at bed temperatures around 815°C (1500°F). These low temperatures are necessary for waste-firing FBCs because higher temperatures lead to bed agglomeration. FBCs employ conventional heat recovery boilers including superheaters, convection banks and economizers, and air preheaters to heat the combustion air.

**Other waste combustion systems.** *Sewage sludge* can be burned in a sludge incinerator specially designed for this purpose. Sludge normally has a moisture content in the range of 70–80 percent (conventionally reported as about 50% solids). Municipal solid waste has a moisture content in the range of 20–30 percent. The only effective method of firing these two waste streams together has been by a reduction of the sludge moisture content to that of the MSW.

*Cement kilns* are used to burn a variety of wastes, usually a very small fraction of the weight of material processed by the kiln. The wastes are used as a source of heat, supplementing fossil fuels such as coal and oil, while serving as an efficient way to dispose of these wastes. Generally, organic wastes or components are, essentially, completely destroyed provided the quantities are not excessive. The inorganic components, especially the regulated toxic metals, determine the limitations on the quantity of waste which may be fed to these furnaces.

*Lightweight aggregate kilns*, like cement kilns, are used to burn a variety of wastes, usually a small fraction of the weight of material processed by the kiln. In addition to providing an economical source of heat, they provide an efficient method of disposal of wastes. The difficulty in establishing numerical limits for their emission when burning wastes is that the natural materials being processed into lightweight aggregate also contain naturally occurring organics and inorganic matter, including heavy metals. Generally, organic wastes or components are, essentially, completely destroyed provided the quantities are not excessive. The inorganic components, especially the regulated toxic metals, determine the limitations on the quantity of waste which may be fed to these furnaces.

*Boilers and industrial furnaces* have provided an effective and convenient means of disposal of wastes, especially liquid wastes which could be injected through conventional oil burners. Generally, organic wastes or components are, essentially, completely destroyed provided the quantities are not excessive. The inorganic components, especially the regulated toxic metals, determine the limitations on the quantity of waste which may be fed to these furnaces.

**Hazardous waste combustion systems.** Hazardous waste combustors range from those designed only to burn pumpable liquids to those capable of burning solids as well as liquids. Rotary kilns are usually used for burning solids due to their tolerance of a wide range of solid, liquid and viscous materials. They have thermal capacities up to 100 million Btu/h.

Where hazardous regulations must be complied with, the incinerator design and operation are subject to the Resource Conservation and Recovery Act (RCRA) regulations for handling and disposal. Incineration regulations under RCRA require an extensive analytical compliance process. To obtain construction and operating permits, operating conditions are determined by trial burn tests, which restrict operation. A detailed operator training program must be implemented.

**Rotary kiln technology.** A rotary kiln provides a versatile primary chamber design for combustion of solid wastes, due to the tumbling action which exposes the waste to high temperatures for ignition and continuously exposes the waste to oxygen to continue the combustion

process. A secondary chamber is used to complete the combustion of the gases produced in the kiln. Rotary kilns can be used for the simultaneous combustion of a wide variety of solid and sludge wastes as well as for the incineration of liquid and gaseous waste. Solid and liquid wastes and sludges are burned in the kiln, whereas liquid wastes, especially aqueous wastes, are burned in the secondary chamber.

The rotary kiln system used for waste incineration, as shown in Fig. 3.12, includes provisions for feeding, air supply, kiln, secondary chamber (afterburner), ash collection system, waste-heat boiler and emission control system. The induced-draft (ID) or exhaust fan draws the gases through the system and discharges them through the stack to the atmosphere. The emission control system employs alkali injection for acid gas control. Dry scrubbing may be used in lieu of the wet scrubbing system shown.

The rotary kiln has a horizontal cylinder, lined with refractory, which turns about its horizontal axis. Waste is deposited in the kiln at one end, and burns out to an ash by the time it reaches the other end. The rotation of the kiln is achieved by trunnion rollers, driven by a gear drive around the kiln periphery, or through a chain driving a large sprocket around the body of the kiln. Supplemental fuel is normally injected into the kiln through a conventional burner, to bring the kiln up to operating temperature and to maintain its temperature during incineration of the waste feed and during standby and shutdown periods.

Kilns designed to burn hazardous wastes may be operated in either a non-slugging or a slugging mode. Some kiln designs have a zero or slightly negative rake, with lips at the input and discharge ends so that they can be operated in the slugging mode with the internal kiln geometry designed to maintain a pool of molten slag between the kiln lips. The temperature in a slugging kiln must be sufficiently high to maintain the ash as a molten slag. Temperatures as high as 2600–2800°F are not uncommon. A non-slugging kiln will normally operate at a temperature below 2000°F.

*Solid waste retention time* in a kiln can be varied as a function of kiln geometry and kiln speed, as shown in the following equation:

$$t = \frac{2.28 L/D}{SN}$$

where  $t$  = mean residence time, min  
 $L/D$  = internal length-to-diameter ratio  
 $S$  = kiln rake slope, in/ft of length  
 $N$  = rotational speed, r/min

For a given  $L/D$  ratio and rake, the solids residence time within the unit is inversely proportional to the kiln speed. Doubling the speed halves the residence time. An example of this calculation is as follows.

**EXAMPLE:** Calculate the residence time for a kiln rotating at  $N = 0.75$  r/min with a 1 percent slope ( $S = 0.12$  in/ft of length), with a 4 ft inside diameter and 12 ft length  $L$ .

$$t = \frac{2.28(12/4)}{0.12 \times 0.75} = 76 \text{ min}$$

Doubling of the rotation  $N$  would halve the retention time, and halving the slope rake  $S$  would double the retention time.

### 3.3 Operation of Waste Combustors

**Temperature and combustion control.** Figure 3.13 shows that temperature is directly related to the excess air provided; hence temperature can be used to control fuel supply and/or airflow in both primary and secondary chambers. By providing the primary chamber with less than

FIGURE 3.12 Complete rotary kiln waste combustion system.

stoichiometric air (starved-air conditions), carbon is converted mainly to  $\text{CO}$ , releasing roughly half of the heat of combustion of  $\text{CO}_2$ , so that the process must be completed in the secondary chamber. The temperature can be maintained at about  $1400^\circ\text{F}$ , about half of the theoretical flame temperature, by this method, protecting the furnace refractory from excessive temperatures and restraining the rate of combustion. Setting the primary air supply to a fixed level serves to stabilize combustion in spite of the highly variable heat release rates of some of the components of the waste.

The primary chamber behaves this way with constant air supply:

- To obtain a higher temperature, decrease the solid feed rate.
- To lower the temperature, increase the solid feed rate.

The secondary chamber completes the combustion, using greater than stoichiometric air supplied to control the temperature, by adjusting the secondary combustion air damper and the auxiliary burner as needed. This control behaves this way:

- More air is added to reduce the temperature.
- Air is reduced to increase the temperature.
- Auxiliary fuel is added if needed to keep the temperature up when the waste feed rate or heating value is insufficient.

**Combustion controls.** It is the responsibility of the operator to feed waste in quantities and in mixtures which are within the ability of the combustion air controls to adjust, while maintaining the required primary and secondary furnace temperatures. When the waste has a low heating value, more weight can be fed, and when it has a large quantity of plastics, the weight fed must be reduced. The operator can use the furnace temperatures resulting from each charge to gauge when and how much waste of what type should be fed in the next cycle. Many incinerator controls do this automatically, delaying the next load when the present one indicates a high content, i.e., heating value times weight.

Since much of the waste charged into an incinerator is in opaque bags or boxes, so that the waste cannot be identified, the operator and the controls can only respond after the charge is ignited and starts to burn. The timing and content of the next charge can be varied to compensate for low or high heat release. The impact of each load on the performance of the system is especially great when the charge weight is large compared with the incinerator capacity, since the size of the waste containers and hence the feed hopper cannot be scaled down to the small units.

While similar in requirements, the combustion controls of the three basic systems described above differ in important details.

*Small incinerators* are controlled almost entirely by the furnace temperatures, which modulate the supplemental fuel burners, and the combustion air. Whether or not the furnace is charged, the controls maintain the required temperatures.

*Starved-air combustors* operate best under steady conditions whereby the combustion air fans and induced-draft fans operate at essentially constant capacity while the feed is varied as needed to maintain the necessary heat input. Steam flow may be used to adjust the air supply.

*Municipal waste combustors* including waste-to-energy systems operate best under steady conditions, usually maintaining constant steam flow from the boilers in order to keep the electric generator operating at full capacity. Steam flow adjusts combustion air flow, the time cycle of the waste charging ram, and perhaps the grate cycle, whereas furnace temperature and oxygen are somewhat loosely controlled. The operator watches the grate burnout and may make further adjustments to accommodate the type of waste being burned.

*Hazardous waste combustors* also operate best under steady gas flow conditions so that the emission control system operates at best flow rate. The temperature controls then maintain the primary and secondary chamber temperatures by adjusting the feed of wastes and supplemental fuel. The operators schedule the burning of different types of waste in different locations to optimize the burning of wastes while maintaining the required conditions in the system. Since aqueous wastes do not contribute enough energy to burn, it is necessary to provide sufficient high-energy waste or auxiliary fuel to maintain the required temperatures. Burning of containerized wastes is another special problem since there can be a significant surge in energy release from each container which the controls must be able to accommodate without straying out of the temperature envelope. While this can be a complex process to control, the net result is that the temperatures can be maintained at all times by adjusting the various fuel and waste inputs.

**Draft control.** It is essential for waste combustion systems that excessive air in-leakage not occur, potentially defeating the efforts of the combustion control system to maintain the desired furnace temperatures. The feeding ports as well as the dry ash collection systems must have some clearances to allow for temperature variations. Water-sealed ash quench systems are used to avoid leakage. To ensure that the leakage is into the system, a negative draft must be maintained at all times. Induced-draft fans having damper and/or speed controls actuated by a sensitive draft control are needed to maintain a slight negative pressure in the furnaces so that leakage is always into, not out of, the furnace system, and so that no hot, dirty gases leak out of the furnaces into the surrounding areas, especially into the feed hopper where ignition can take place.

**Ash disposal.** With smaller medical waste units, after burnout the chamber is opened and ash residue is manually raked out. With continuous operating units such as those shown in Figures 3.5 and 3.6, ash is continually discharged, normally into a wet well, then transferred to a container or truck by means of a drag conveyor. It is necessary to quench the dry ash with water to eliminate possible burning embers so that it can be disposed of safely.

**Heat recovery boilers.** Boilers are frequently installed, especially with the larger units, as seen in Fig. 3.7, where there is a use for the heat as steam or hot water and as a means for reducing the combustion gas temperatures to 450°F or less, as is needed before the gas enters the

stack or emission control system. If heat recovery is not used, the gases must be discharged at 1800°F through refractory stacks directly to the atmosphere. Dump stacks, as seen in Fig. 3.7, are generally provided for discharging hot gas during emergency conditions where it is necessary to bypass the boiler or air pollution control device.

### 3.4 Calculation of a Waste-to-Energy Plant

*Assume:* 500 ton/d ( $500/24 = 20.83$  ton/h = 41,666 lb/h MSW)

Higher heating value = 5000 Btu/lb

The plant produces 700 kW·h per ton of MSW (14.6 MW)

Ash residue is 20% of MSW, dry

Ash leaving plant has 50% moisture content

Combustion products are 10 pounds per pound of fuel (lbp/lbf)

The specific heat of combustion products is 0.28 Btu/(lb · °F)

Furnace temperature is 1800°F

Boiler outlet temperature is 450°F

Boiler efficiency is 75%

Water sprays are used to cool the product gases from 450°F to 300°F

The turbine generator produces 14.6 MW of power (equal to 50 MBtu/h)

The steam leaving the turbine is condensed by cooling tower water

The cooling tower removes 106 MBtu/h by evaporating water

The boiler blowdown is 10% of the steam generated by the boiler

The cooling tower blowdown is 10% of the water evaporated by the tower

*Calculate:*

1. Btu/h produced by burning the waste, using higher heating value

$$= 500 \times 5000 \times 2000/24 = 208,000,000 \text{ Btu/h} = 208 \text{ MBtu/h}$$

2. Pounds per hour of combustion products at 10 lb/lb fuel

$$= 41,666 \times 10 = 416,660 \text{ lb/h}$$

3. Heat delivered to steam based on boiler efficiency of 75%

$$= 208 \times 0.75 = 156 \text{ MBtu/h}$$

4. Pounds per hour of steam produced at 1200 Btu/lb of steam

$$= 156,000,000/1200 = 130,000 \text{ lb/h of steam}$$

5. Heat equivalent of 14.6 MW of power at 3416 Btu/(kW · h)

$$= 14,600 \text{ kW} \times 3416 \text{ Btu}/(\text{kW} \cdot \text{h}) = 50 \text{ MBtu/h}$$

6. Heat removed to condense steam leaving the turbine

$$= 156 - 50 = 106 \text{ MBtu/h}$$

7. Water needed to cool gases from 450°F to 300°F

$$= 416,000 \text{ lb/h} \times (450 - 300) \times 0.28 \text{ Btu}/(\text{lb} \cdot ^\circ\text{F})/1000 \text{ (Btu/lb)} = 17,500 \text{ lb/h}$$

8. Water needed for boiler makeup if blowdown is 10% of steam produced

$$= 130,000 \times 0.1 = 13,000 \text{ lb/h}$$

9. Water needed to cool ash from 1600 to 200°F at 1000 Btu/lb water

$$= 41,600 \text{ lb/h} \times 0.20 \times 0.1 \times (1600 - 200)/1000 \text{ Btu}/(\text{lb} \cdot ^\circ\text{F}) = 1164 \text{ lb/h}$$

10. Water needed to wet ash from dry to 50% moisture content

$$= 41,600 \text{ lb/h} \times 0.20 \times (1 \text{ lb water})/(\text{lb dry ash}) = 8320 \text{ lb/h}$$

11. Water evaporated in cooling tower at 1000 Btu/lb water

$$= 106,000,000 \text{ (Btu/h)}/(1000 \text{ Btu/lb water}) = 106,000 \text{ lb/h}$$

12. Water needed to supply 10% blowdown from the cooling tower

$$= 106,000 \times 0.10 = 10,600 \text{ lb/h}$$

13. Total amount of water needed for all of the above uses

$$= 17,500 + 13,000 + 1165 + 8320 + 106,000 + 10,600$$

$$= 156,585 \text{ lb/h} = 313 \text{ gal/min}$$

## 4 CONTROL OF EMISSIONS FROM COMBUSTION

---

Emission control systems are provided to control the various pollutants contained in the products of combustion, including particulate matter, SO<sub>2</sub>, HCl, NO<sub>x</sub>, metals and organics. Each pollutant is subject to a different mechanism of control, however, and a given emission control technique has a different impact on individual pollutants.

### 4.1 Pollutants of Concern

The pollutants of concern which may be found in the combustion products, prior to the air pollution control device (APCD) or in the stack emissions, along with the controls used to reduce their discharge to the atmosphere, are discussed below.

**Particulate matter.** The quantity and concentration of particulate matter (PM) exiting the furnace of a waste combustion system depends on the waste characteristics and the design and operation of the combustion system. While most of the inorganic, non-combustible fraction of MSW and BMW will be discharged as bottom ash, a substantial fraction will be formed from combustion and released into the flue gas. Generally 99% or more of this particulate is captured by the APCD and is not emitted to the atmosphere.

Particulate matter varies in particle diameter from less than 1 micron (μm) to hundreds of microns. Fine particulates, having diameters less than 10 μm (known as PM<sub>10</sub>), and particu-

lates smaller than  $2.5\ \mu\text{m}$  are of concern because of the greater potential for inhalation and passage of these fine particles into the pulmonary region of the lungs. Also, acid gases, metals and toxic organics preferentially adsorb onto particulates in this size range and can therefore be absorbed within the lungs.

The physical properties of the waste being fed, the method of feeding and the distribution of underfire air influence PM concentrations in the flue gas. The concentration of PM emissions at the inlet of the APCD will depend on the combustor design, air distribution and waste characteristics. The higher the underfire/overfire air ratio or the excess air levels, the greater the entrainment of PM in the flue gases, and the higher the PM levels at the APCD inlet. Combustors with boilers that change the direction of the flue gas flow may remove a significant portion of the PM prior to the APCD. For instance, RDF furnaces typically have higher PM carryover due to the suspension firing of the RDF, and starved-air furnaces have substantially lower carryover than excess-air furnaces due to the low gas velocities in the primary furnace.

**Metals.** Metals are present throughout the components of municipal and medical wastes. The metals emitted as components of PM (e.g. arsenic [As], cadmium [Cd], chromium [Cr] and lead [Pb]) and as vapors, such as mercury [Hg], are highly variable and are essentially independent of the combustor type. Most of the metals are vaporized during combustion and condense onto particulates in the flue gas as its temperature is reduced; hence the metal can be effectively removed by the PM control device, at efficiencies greater than 99 percent. Mercury, on the other hand, still has a high vapor pressure at typical APCD operating temperatures, and capture by the PM control device is highly variable. A high level of carbon in the fly ash, or the injection of activated carbon, greatly enhances Hg adsorption onto the particles removed by the PM control device.

**Acid gases.** Combustion of wastes produces HCl and  $\text{SO}_2$ , as well as hydrogen fluoride (HF), hydrogen bromide (HBr) and sulfur trioxide ( $\text{SO}_3$ ) at much lower concentrations. Concentrations of HCl and  $\text{SO}_2$  in flue gases are related directly to the chlorine and sulfur content in the waste, which vary considerably with seasonal and local waste variations. Emissions of  $\text{SO}_2$  and HCl depend partly on the chemical form of sulfur and chlorine in the waste, as well as on the availability of alkali materials in combustion-generated fly ash that act as sorbents, and the type of emission control system used. The major sources of chlorine in MSW are paper, food and plastics. The presence of PVC plastics in BMW results in relatively high HCl emissions. Sulfur in MSW may derive from asphalt shingles, gypsum wallboard, and tires.

**Carbon monoxide.** Carbon monoxide emissions result when not all of the carbon in the waste is oxidized to carbon dioxide ( $\text{CO}_2$ ). High levels of CO indicate that the combustion gases were not held at a sufficiently high temperature in the presence of sufficient oxygen ( $\text{O}_2$ ) for a long enough time to convert CO to  $\text{CO}_2$ . In the first stages of combustion in a fuel bed, waste first releases CO, hydrogen ( $\text{H}_2$ ), and unburned hydrocarbons, then additional air converts these gases to  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . Adding too much air to the combustion zone can lower the local gas temperature and quench (or retard) the oxidation reactions, whereas if too little air is added the probability of incomplete mixing increases, allowing greater quantities of unburned hydrocarbons to escape the furnace, thus increasing CO emissions. Because  $\text{O}_2$  levels, air distribution and the effectiveness of mixing vary among combustor types, CO levels also vary substantially. For example, semi-suspension-fired RDF units generally have higher CO levels than mass burn units, due to the effects of carryover of incompletely combusted materials into low temperature portions of the furnace and, in some cases, due to instabilities that result from fuel feed characteristics and distribution over the fuel bed. Likewise, two-chamber starved-air systems usually have very low CO emissions due to the inherently effective mixing which they can achieve.

Carbon monoxide concentration is a direct indicator of combustion efficiency, and is an important indicator of instabilities and non-uniformities in the combustion process. During unstable combustion conditions when more carbonaceous material is available, serving as precursors, higher CDD/CDF and organic hazardous air pollutant levels are likely to occur. The relationship between emissions of CDD/CDF and CO indicates that high levels of CO (several hundred parts per million by volume [ppmv]), corresponding to poor combustion conditions, frequently correlate with high CDD/CDF emissions. When CO levels are low, however, correlations between CO and CDDs/CDFs may not be found because many mechanisms contribute to CDD/CDF formation, though CDD/CDF emissions are generally lower.

**Nitrogen oxides.** Nitrogen oxides are produced by all combustion processes using air as a source of oxygen. Nitric oxide (NO) is the primary component, but nitrogen dioxide (NO<sub>2</sub>) and nitrous oxide (N<sub>2</sub>O) are also formed in smaller amounts. The combination of these compounds is referred to as NO<sub>x</sub>. Nitrogen oxides are formed during combustion through oxidation at relatively low temperatures (less than 1090°C [2000°F]), and fixation of atmospheric nitrogen occurs at higher temperatures. Because of the relatively low temperatures at which municipal, medical and hazardous waste furnaces operate, 70–80 percent of NO<sub>x</sub> is associated with nitrogen in the waste. Acrylic plastics are a major source of nitrogen in MSW and BMW. Hazardous wastes may contain nitrogen in many forms.

**Organic compounds.** Organic compounds, including chlorinated dibenzodioxins and chlorinated dibenzofurans (CDDs/CDFs), chlorobenzenes (CB), polychlorinated biphenyls (PCBs), chlorophenols (CPs) and polyaromatic hydrocarbons (PAHs), are present in MSW and BMW or can be formed during the combustion and post-combustion processes. Organics in the flue gas exist in the vapor phase or may be condensed or absorbed on fine particulates. Organics are controlled by proper design and operation of both the combustor and the APCDs. Activated carbon injection has been found to be effective in adsorbing CDDs/CDFs and probably other trace organic compounds.

Due to their toxicity levels, emphasis is placed on levels of CDDs/CDFs in the tetra- through octa- homolog groups and specific isomers within those groups that have chlorine substituted in the 2, 3, 7 and 9 positions. The NSPS and emission guidelines for MWCs and BMCs regulate the total tetra- through octa-CDDs/CDFs.

## 4.2 Emission Control Devices

Technologies which are currently available or in use will be discussed below:

- Cyclone separators
- Quench venturi
- Wet venturi scrubber (WVS)
- Packed-bed scrubber (PBS)
- Plate scrubber (PS)
- Electrostatic precipitator (ESP)
- Wet electrostatic precipitator (WESP)
- Dry venturi (DV)
- Dry sorbent injection (DSI)
- Reactor tower (RT)
- Conditioning tower
- Spray-dry reactor (SDR)
- Fabric filter (FF)

*Cyclone separators* use the centrifugal forces attained by forcing the gases through a tangential entry to a cylinder to cause solid particles to follow the walls and drop out of the gas stream, while the gas stream is diverted away without those collected particles. Cyclones are useful for collecting particles larger than 10  $\mu\text{m}$  in diameter, and are still often used to knock out the large particles in gas streams entering scrubbing towers and ESPs, but since they are not effective on smaller particles we will concentrate on the devices which actually collect the fine PM which is of environmental concern.

***Venturi scrubber/packed tower scrubber.*** Medical waste and hazardous waste combustors are often served by venturi scrubbers followed by packed tower scrubbers, due to their effectiveness in removing acid gases and organic vapors and where solid, inorganic particulate matter is not a major contaminant in the flue gases (Hesketh, 1991).

In single-stage scrubbers, the flue gas reacts with an alkaline scrubber liquid to simultaneously remove HCl and SO<sub>2</sub>. In two-stage scrubbers, a low-pH water scrubber for HCl removal is installed upstream of the alkaline SO<sub>2</sub> scrubber. The alkaline solution, typically containing calcium hydroxide (Ca[OH]<sub>2</sub>), reacts with the acid gas to form salts which are generally insoluble and may be removed by sequential clarifying, thickening, and vacuum filtering. The dewatered salts or sludges must then be disposed of in suitable landfills.

*Quench* sections are used to rapidly cool combustion products down to the temperatures at which emission control devices must operate in order to be effective. Water sprays are used for this process, evaporating the water and cooling the gases down to close to the wet bulb temperature. Gases entering at a secondary chamber exit temperature of 1800°F are cooled to about 180°F, whereas those which have been cooled by a heat recovery boiler or heat exchanger will be cooled to about 130°F. Scrubbers which follow a quench section cool the gases closer to the wet bulb temperature by providing more time and surface contact.

*Wet venturi scrubbers* use a converging duct section followed by a diverging section to accelerate and then decelerate the gas stream, while at the same time spraying water into the converging section of the scrubber. As the gases pass through the diverging section, most of the pressure drop lost in the converging section is recovered, resulting in a permanent pressure loss which must be overcome by the fan which moves the gases through the system.

The water droplets, moving at a slower velocity than the gases, take significant time to pass through the venturi, while becoming targets for the particulate matter carried by the gases. The droplets thus absorb fine particulate, at the same time absorbing some of the acid gases such as HCl and HF. As the gases pass through the diverging section, slowing up, the accelerated droplets of water continue to capture dust particles, while agglomerating into larger water droplets which can be dropped out and collected beyond the venturi, typically by cyclonic action.

The effectiveness of wet venturi scrubbers in collecting particulate matter depends mainly on the difference between the entering and the throat gas velocity, which in turn depends upon the relative cross-sectional areas of the duct and the throat. The pressure drop measured between entrance and throat is directly dependent upon these areas and the corresponding velocities achieved.

***Complete hazardous waste incineration system.*** A complete hazardous waste incineration system is illustrated in Fig. 3.14. A solids shredder shreds drums and other large objects which are conveyed to the inlet of the rotary kiln. Liquid wastes, atomized by steam, are also fed to the kiln, where auxiliary fuel burners provide heat-up and temperature maintaining functions. The ash residues leaving the kiln at the end of the kiln are conveyed out to ash storage where they are analyzed to determine suitable disposal procedures. The hot gases at 1000°C go to a secondary chamber, or afterburner, where burners maintain the temperatures at 1200°C for 4 s. The off-gas system consists of a quench tower, used to cool the gases before they enter the venturi scrubber, a packed tower scrubber, and an ionizing wet scrubber which removes the mist. The induced draft fan discharges the cleaned gases to the stack. Water enters

FIGURE 3.14 Complete hazardous waste combustion system with wet scrubber.

the wet scrubber and is drained to the liquid sump, where caustic soda is used to neutralize the acids absorbed by the system. The sump water is recirculated for use in the quench, venturi and column sprays. The liquids from the wet ash system and other wastes are then analyzed, treated, and discharged properly.

**Particle size analysis.** The efficiency of cyclones and venturi scrubbers varies with the size of the particles to be collected. To obtain the overall collection efficiency and the actual quantity and size distribution of the emissions, it is necessary to calculate the efficiency for each size group and obtain the quantities of each size in the emissions.

*Sample calculation:* Pressure drop determination for typical venturi scrubber application

Step 1. Plot the data given in Table 3.10 on a log-log graph to obtain the fractions in each size range for the particle diameter ranges listed.

Step 2. Determine the required collection efficiency:

(a) Inlet loading:

$$1.83 \text{ gr/dscf} \times 183,000 \text{ dscfm} \times (1/7000 \text{ grains}) \times 60 \text{ (min/h)} = 2870 \text{ lb/h}$$

(b) Collection efficiency:

$$[2870 \text{ (lb/h)} - 48.79 \text{ (lb/h)}] \times 100/2870 = 98.3\%$$

(c) Allowable penetration:

$$100.0 - 98.3 = 1.7\% = 0.017 \text{ penetration}$$

Step 3. Plot the penetration from Table 3.11 as a function of pressure drop, and read 36.5" W.G. for 1.7% penetration.

Step 4. To meet the regulation of 0.03 gr/dscf,

$$0.03 \text{ gr/dscf} \times 183,000 \text{ dscfm} \times 60/7000 = 47.057 \text{ lb/h}$$

Select  $\Delta p = 40''$  W.G.

**Collection efficiency.** A venturi scrubber can remove 92 to 99% of particulate in the size range from 0.02 to 5  $\mu\text{m}$ , which makes it effective for smoke and fumes. Since the efficiency is dependent on particle size, it is necessary to obtain the particle size distribution of the PM and perform a fractional efficiency analysis in order to determine the overall efficiency of the venturi for the specific size distribution. Penetration, the fraction passing through, or 1 minus the efficiency/100, is plotted in Fig. 3.15, which plots fractional overall penetration (one minus fractional overall efficiency) against the ratio of the aerodynamic cut diameter  $d_{50}$

**TABLE 3.10** Data Supplied for Pressure Drop Determination

Inlet dust loading to scrubber	1.83 gr/dscf
Inlet gas flow to scrubber	183,000 dscfm
Allowable emission	48.79 lb/h = 0.03 gr/dscfm
Particle diameter ( $\mu\text{m}$ )	Weight less than (%)
10.0	99.0
5.2	89.5
2.0	43.5
1.0	9.7
0.5	1.0

**TABLE 3.11** Determination of Penetration and PM at Outlet of Venturi Scrubber

Particle diameter ( $\mu\text{m}$ )	Fraction in size range	Fractional efficiency = Pt (Dp)		
		$\Delta p = 10$ in.	$\Delta p = 20$ in.	$\Delta p = 40$ in.

to aerodynamic mass mean diameter  $d_g$ . The parameter on this plot is the particle standard geometric deviation  $\sigma_g$ .

**Pressure drop through venturi scrubber.** The pressure drop of a venturi scrubber can be calculated as (Hesketh, 1991)

$$P = v^2 d_g A^{0.122} L^{0.78} / 3870$$

- where  $P$  = venturi scrubber pressure drop, cm H<sub>2</sub>O  
 $v$  = throat velocity of the gas and particles, cm/s  
 $A$  = throat cross-sectional area, cm<sup>2</sup>  
 $L$  = liquid/gas ratio, l/m<sup>3</sup>  
 $d_g$  = gas density, g/cm<sup>3</sup>

or

$$P = v^2 d_g A^{0.122} L^{0.78} / 1270$$

- where  $P$  = venturi scrubber pressure drop, in. H<sub>2</sub>O  
 $v$  = throat velocity of the gas and particles, ft/s  
 $A$  = throat cross-sectional area, ft<sup>2</sup>  
 $L$  = liquid/gas ratio, gallons per 1000 actual cubic feet gas  
 $d_g$  = gas density, lb/ft<sup>3</sup>

*Packed-bed scrubbers* employ a vertical bed of surface-generating shapes through which the gases to be scrubbed pass vertically, while water or recirculated solution enters from the top and contacts the gases. These scrubbers are highly effective in absorbing HCl and SO<sub>2</sub> from the gas stream. Their effectiveness depends upon the temperatures at which the scrubber is operated (usually close to the saturation or wet bulb temperature of the solution), the gas velocity, liquid to gas ratio, and packing height.

Calculations of performance of packed-bed scrubbers are based on tests which determine the performance factors. These are best obtained from the manufacturer who performed the tests and who will guarantee the performance.

Given a specific scrubber, with a set of performance conditions, it is possible to extrapolate its performance under different conditions of operation. For instance, when the number of transfer units (NTU) built into the scrubber is known versus removal efficiency, the efficiency under different conditions can be calculated, or the change in efficiency which would result from an increase in the NTU.

A scrubber used to remove SO<sub>2</sub> from a given concentration of 300 mg/cm to 30 mg/cm has an NTU as follows:

$$NTU = \ln (Y_1(\text{inlet})/Y_2(\text{outlet})) = \ln(300/30) = 2.3$$

The NTU required to reduce the SO<sub>2</sub> from 3000 to 30 mg/cm would be 4.6.

*Plate scrubbers* operate in a similar fashion to packed-bed scrubbers, and are likewise tested and guaranteed by the manufacturer to perform specific functions.

*Wet scrubbers* (Fig. 3.16) perform as a function of the *difference* in concentration between the entering gas and leaving absorbing liquid ( $Y_1$ ) and the leaving gas and the entering absorbing liquid ( $Y_2$ ). This means that the concentration in the liquid is an important factor: the liquid absorbs the acid, accumulating it and increasing its concentration. To control concentration, a portion of the liquid must be “blown down” and discharged from the system. Achieving a high removal efficiency is obtained at the cost of blowing down and probably

FIGURE 3.16 Wet scrubber and tray tower wet scrubbing arrangement.

having to treat the blowdown to make it suitable for discharge to the sewer or publicly operated treatment works (POTW). The ideal method would be to remove the products in a dry benign form, rather than diluted with water, which increases the cost or limitations of disposal.

**EXAMPLE:** Calculate the blowdown rate required to maintain stable concentrations.

$$\text{Makeup} = x = \text{vapor} + \text{blowdown}$$

$$\text{Blowdown} = y$$

$$\text{Makeup concentration} = 250 \text{ ppm}$$

$$\text{Blowdown concentration} = 1000 \text{ ppm}$$

If vapor = 1 gallons per minute (gpm),  $x = 1 + y$

Concentration balance

$$x(250) = 1(0) + y(1000)$$

hence

$$x = 4y, \text{ or } y = x/4$$

Then

$$\text{makeup} = x = 1 + y = 1 + 0.25x$$

$$x - 0.25x = 1 = (0.75)x = 1$$

Then:

$$x = 1/0.75 = 1.33 \text{ gpm}$$

$$y = 1.33/4 = 0.33 \text{ gpm}$$

**Electrostatic precipitators.** Electrostatic precipitators are used to remove dry dust particles from gas streams by employing a series of high-voltage discharge electrodes to charge particulate matter, and attracting the charged particles to grounded metal plates parallel to the direction of gas flow where they are collected and periodically cleaned by rapping the plates, causing the particles to fall off. Although most of the dust is removed in the first stage, upon rapping, some of the collected PM becomes re-entrained in the flue gas, so it is necessary to have two or more sets of charging wires and plates in series so that the next set can pick up the re-entrained particles. In order to meet present standards for PM emissions, ESPs are provided with four or more sets in series. The voltage which may be applied to each bank of the ESP is limited, since sparking, which occurs at some point, varies with the amount and nature of the particulate on the plates. The time intervals between rapping cycles and the voltages which can be maintained for optimum performance are variables which greatly affect the overall collection efficiency of the ESP.

Small particles have lower migration velocities than large particles and are therefore more difficult to collect. As compared to pulverized coal fired combustors, in which only 1–3 percent of the fly ash is generally smaller than  $1 \mu\text{m}$ , 20–70 percent of the fly ash at the inlet of the PM control device for MWCs is reported to be smaller than  $1 \mu\text{m}$ , requiring greater collection areas and lower flue gas velocities than are required for many other combustion types.

The specific collection area (SCA) of an ESP is used as an indicator of collection efficiency. The greater the collection plate area, the greater the ESP's PM collection efficiency. The SCA is expressed as square meters per cubic meter per minute (square feet per cubic feet per minute)

**TABLE 3.13** Electrostatic Precipitator Design Parameters

Particulate load, gr/acf	0.5–9	
Required efficiency, %	98–99.9	
Number of fields	3–4

of flue gas, in effect giving the gas velocity. Most recent ESPs have SCAs in the range of 400 to 600 ft<sup>2</sup>/(1000 acfm).

**ESP efficiency.** The efficiency of an ESP can be estimated by the Deutsch–Anderson equation

$$\eta = 1 - \exp(-Aw/Q)$$

where  $\eta$  = fractional collection efficiency  
 $A$  = area of the collection plates, m<sup>2</sup>  
 $w$  = drift velocity of the charged particles, m/s  
 $Q$  = flow rate of the gas stream, m<sup>3</sup>/s

The drift velocity is the velocity at which a particle approaches the collection surface. It can be estimated from the equation

$$w = ad_p$$

where  $w$  = drift velocity, m/s  
 $a$  = constant, a function of the charging field, the carrier gas properties, and the ability of the particle to accept an electrical charge, s<sup>-1</sup>  
 $d_p$  = particle size,  $\mu\text{m}$

Drift velocities commonly range from 0.02 to 0.2 m/s and can be determined experimentally.

**EXAMPLE:** An electrostatic precipitator is to remove flyash particles of 0.5  $\mu\text{m}$  diameter from a gas stream flowing at 0.7 m<sup>3</sup>/s. Determine the plate area needed to collect these particles at 98% efficiency. The value of the constant  $a$  has been found to be  $0.24 \times 10^6/\text{s}$ .

The drift velocity will be

$$w = 0.24 \times 10^6/\text{s} \times 0.5 \times 10^{-6}\text{m} = 0.12 \text{ m/s}$$

The removal efficiency is then

$$0.98 = 1 - \exp -[(0.12 \text{ (m/s)}/0.7 \text{ (m}^3/\text{s)}) \times A]$$

Then

$$A = 23 \text{ m}^2$$

Considering that both sides of the plate are available for collecting particles, the plate area required is  $23/2 = 11.5 \text{ m}^2$ . A square plate measuring  $3.4 \text{ m} \times 3.4 \text{ m}$  would suffice.

**Wet electrostatic precipitator.** The fine mist which escapes a wet scrubber contains the particulate which has been collected by the scrubber; hence, if allowed to escape to the stack, the same particulate matter which was to be collected will be emitted. In order to collect these droplets of mist, a wet electrostatic precipitator can be used. As seen in Fig. 3.17, the fine droplets of mist are absorbed by a fine spray of water, then the droplets are charged by electrodes kept under high voltage so that they are collected by grounded plates. These units are widely used in hazardous waste incinerators.

**Fabric filters.** Fabric filters (FF), also known as “baghouses,” are widely used for PM, metals and acid gas control. They remove particulate matter by passing the flue gas through a large number of porous cylindrical fabric bags hanging vertically from a tube sheet. Particulate matter is collected on one of the bag surfaces, from which it is periodically removed and

FIGURE 3.17 Wet electrostatic precipitator (Beltran Associates, Inc., Brooklyn, NY).

collected in hoppers. The cleaning process may use either reverse air, with the bags “off line,” or pulse cleaning, with the bags either on or off line.

A fabric filter consists of 4 to 16 individual compartments that can be independently operated and taken off-line for maintenance and/or cleaning. The collected particulate builds up on the bag, forming a filter cake. As the thickness of the filter cake increases, the pressure drop across the bag also increases. Once the pressure drop across the bags in a given compartment reaches a set limit, that compartment is subjected to cleaning, either on-line (pulse cleaning) or off-line.

Figure 3.18 shows a fabric filter (baghouse). Dirty gases enter the enclosure containing the suspended bags and flow through the bags to exit as clean gases, leaving the dust on the outside of the bags. The dust is dropped from the bags after being loosened by pulses of air applied internally to the bags.

In *reverse-air* FFs, flue gas flows through the filter bags, leaving the particulate on the bag. Once the preset pressure drop across the filter cake is reached, air is blown through the filter in the opposite direction, the filter bag collapses, and the filter cake falls off and is collected in a hopper below.

In a *pulse-jet* FF, compressed air is used, pulsed through the inside of the filter bag, to remove the particulate filter cake; the filter bag expands and collapses to its pre-pulsed shape, and the filter cake falls off and is collected in the hopper.

The bags are usually 8 in. in diameter, with lengths ranging from 10 ft to 25 ft. Baghouses are generally provided with a weather-protection house above the tube sheet so that the bags can be removed and replaced.

*Filtering area.* The total filtering area required for a given application is

$$A_f = Q/v_f$$

where  $A_f$  = total filtering area, m<sup>2</sup>  
 $Q$  = volume of gas stream, m<sup>3</sup>/min  
 $v_f$  = filtering velocity (air-to-cloth ratio), m/min

For cylindrical bags,

$A_b$  = filtering area for each bag, m<sup>2</sup>  
 $\pi$  = 3.1416  
 $d$  = diameter of bag, m  
 $h$  = length of bag, m

**TABLE 3.14** Fabric Filter Design Parameters

	Type of fabric filter	
	Reverse air	Pulse jet
Operating temperature, °F	230–450	
Type of fabric	Woven fiberglass	
Fabric coating	10% Teflon B or acid resistant	
Fabric weight, oz/yd <sup>2</sup>	9.5	16 or 22
Bag diameter, in.	8	6
Net air-to-cloth ratio	1.5–2.0:1	3.5–4.0:1
Minimum number of compartments	6	4
Overall pressure drop, in. w.g.	4–6	8–10
Estimated bag life, yr	3–4	1.5–2

FIGURE 3.18 Baghouse (fabric filter) showing tubular filter bags held by bag retainers, dust hopper, and rotary valve through which the dust is discharged.

The number of bags required is

$$N = A_f/A_b$$

*Pressure drop.* The pressure drop for a baghouse filter can be estimated from the equation

$$\Delta P = S_e v_f + k_2 c v_f^2 t$$

where  $\Delta P$  = pressure drop  
 $S_e$  = effective residual drag  
 $v_f$  = gas velocity at filter surface  
 $k_2$  = specific resistance coefficient of collected particles  
 $c$  = concentration of particulate in gas stream  
 $t$  = filtration time, min

Values for  $S_e$  and  $k_2$  can be found in the McGraw-Hill *Chemical Engineer's Handbook* (Perry, 1984). Below is an equation which includes values for  $S_e$  and  $k_2$  which may be suitable. Obviously they will be dependent on the nature of the filter material.

$$\Delta P = 1.6v_f + 8.52cv_f^2 t$$

where  $\Delta P$  = pressure drop, cm  
 $v_f$  = filtering velocity, m/min  
 $c$  = particle concentration in the air stream, kg/m<sup>3</sup>  
 $t$  = time required between cleanings, min

**EXAMPLE:** Determine the filter cloth area and the required frequency of cleaning on the basis of the following data:

Volume of contaminated air stream  $Q = 400 \text{ m}^3/\text{min}$

Filtering velocity  $v_f = 0.8 \text{ m/min}$

Particulate concentration in stream  $c = 0.03 \text{ kg/m}^3$

Diameter of filter bag  $d = 0.2 \text{ m}$

Length of filter bag  $h = 5.0 \text{ m}$

Cleaning occurs when  $\Delta P$  reaches 9 cm water.

$$\text{Total filter area } A_f = 400 (\text{m}^3/\text{min})/0.8 (\text{m/min}) = 500 \text{ m}^2$$

$$\text{Bag filtering area } A_b = 3.14 (0.2) (5.0) = 3.14 \text{ m}^2 \text{ per bag}$$

$$\text{Number of bags } N = 500 \text{ m}^2/3.14 \text{ m}^2 = 160 \text{ bags}$$

At a  $\Delta P$  of 9 cm, the frequency of cleaning is determined as follows:

$$9 \text{ cm} = 1.6 (0.8 \text{ m/min}) + 8.52 (0.03 \text{ kg/m}^3) (0.80 \text{ m/min})^2 t$$

$$t = 47 \text{ min}$$

**Spray dryers.** Spray dryers (SD) are frequently used as the acid gas control technology for waste combustors. When used in combination with an ESP or FF, the system can control CDD/CDF, PM (and metals), SO<sub>2</sub> and HCl emissions. Spray dryer/fabric filter systems have

become favored over SD/ESP systems due to their more efficient metals removal. In the spray drying process, lime slurry is injected into the SD through either a rotary atomizer or dual-fluid nozzles, using steam or air for atomization. The water in the slurry evaporates to cool the flue gas, but, before evaporating, the droplets absorb the acid gases where the acids react with the lime to form calcium salts that can be removed by the PM control device. The SD is designed to provide sufficient contact and residence time to produce a dry product before it leaves the SD adsorber vessel. The residence time in the adsorber vessel is typically 10–15 s, resulting in very large vessel diameters. The particulate leaving the SD contains fly ash plus calcium salts, water, and unreacted hydrated lime.

The SD outlet temperature and lime-to-acid gas stoichiometric ratio are the key design and operating parameters that significantly affect SD performance. The outlet temperature must be high enough to ensure that the slurry and reaction products are adequately dried prior to collection in the PM control device. For MWC flue gas containing significant chlorine, the SD outlet temperature must be higher than about 115°C (240°F) to control agglomeration of PM and sorbent by calcium chloride. To provide a necessary safety margin, the outlet gas temperature from the SD is usually kept around 140°C (285°F). This temperature is controlled by the quantity of water sprayed into the gases. The acid gas concentrations are controlled by the quantity of lime added to the slurry.

A measure of performance of spray-dry scrubbers is the stoichiometric ratio, the molar ratio of calcium in the lime slurry fed to the SD divided by the theoretical amount of calcium required to completely react with the inlet HCl and SO<sub>2</sub>. At a ratio of 1.0, the moles of calcium are equal to the moles of incoming HCl and SO<sub>2</sub>. More than the theoretical amount of lime is generally fed to the SD because of mass transfer limitations, incomplete mixing, and differing rates of reaction (SO<sub>2</sub> reacts more slowly than HCl). The stoichiometric ratio used in SD systems varies depending on the level of acid gas reduction required, the temperature of the flue gas at the SD exit and the type of PM control device used. Lime is fed in quantities sufficient to react with the peak acid gas concentrations expected without severely decreasing performance. The lime content in the slurry is generally about 10 percent by weight, but cannot exceed approximately 30 percent by weight without clogging of the lime slurry feed system and spray nozzles.

**Dry sorbent injection.** Dry sorbent injection is effective in the control of acid gas as well as CDD/CDF and PM emissions from MWCs.

*Duct sorbent injection* (DSI) involves injecting dry alkali sorbents into flue gas downstream of the combustor boiler outlet and upstream of the PM control device.

In DSI, powdered sorbent is pneumatically injected into either a separate reaction vessel or a section of flue gas duct located downstream of the boiler's economizer, or quench tower if no boiler is present. Alkali in the sorbent (generally calcium hydroxide, sodium hydroxide, or sodium bicarbonate) reacts with HCl, HF and SO<sub>2</sub> to form alkali salts (e.g., calcium chloride [CaCl<sub>2</sub>], calcium fluoride [CaF<sub>2</sub>] and calcium sulfite [CaSO<sub>3</sub>]). By lowering the acid content of the flue gas and not evaporating water into the gas stream, downstream equipment can be operated at reduced temperatures while minimizing the potential for acid corrosion of equipment. Solid reaction products, fly ash and unreacted sorbent are collected with either an ESP or an FF.

Acid gas removal efficiency with DSI depends on the method of sorbent injection, flue gas temperature, sorbent type and feed rate, and the extent of sorbent mixing with the flue gas. Flue gas temperature at the point of sorbent injection can range from about 150 to 320°C (300–600°F) depending on the sorbent being used, the means of cooling the gases, and other aspects of the process. Sorbents that have been successfully used include hydrated lime (Ca[OH]<sub>2</sub>), soda ash (Na<sub>2</sub>CO<sub>3</sub>) and sodium bicarbonate (NaHCO<sub>3</sub>). DSI systems can achieve removal efficiencies comparable to those of SD systems. Recirculation towers which increase residence time may be required to achieve comparable acid gas and sorbent efficiencies. Flue gas cooling by dry heat exchange or water injection, combined with DSI, makes it possible to

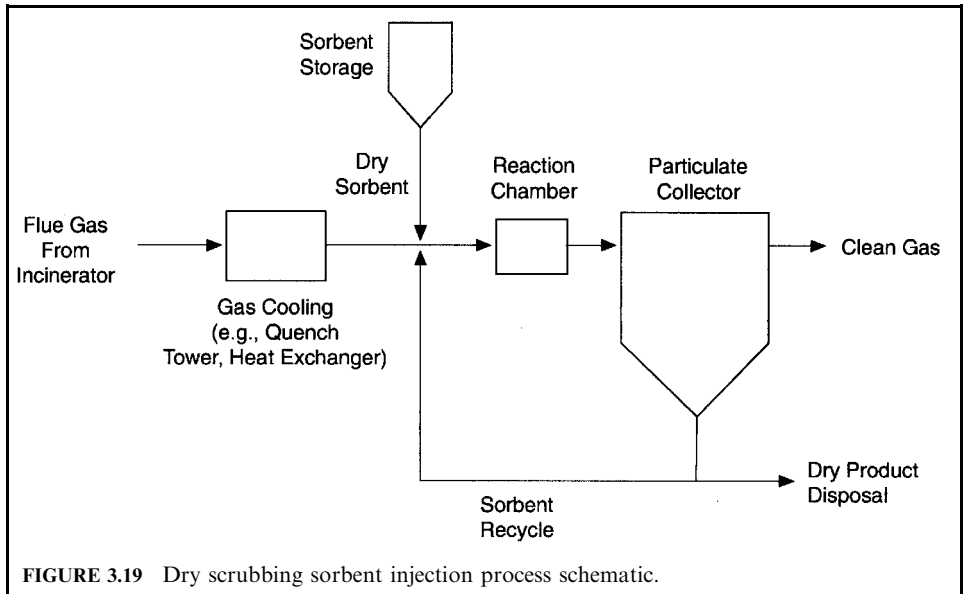

FIGURE 3.19 Dry scrubbing sorbent injection process schematic.

increase CDD/CDF and acid gas removal through a combination of vapor condensation and adsorption onto the sorbent surface.

Furnace injection has been employed to achieve a degree of acid gas control. The basic chemistry of FSI is similar to DSI. Both use a reaction of sorbent with acid gases to form alkali salts. By injecting sorbent directly into the furnace at temperatures of 870–1200°C (1600–2200°F), limestone can be calcined in the combustor to form the more reactive lime, thereby allowing use of less expensive limestone as a sorbent. At these temperatures SO<sub>2</sub> and lime react in the combustor, thus providing a mechanism for effective removal of SO<sub>2</sub>. By injecting sorbent into the furnace rather than into a downstream duct, additional time is available for mixing and reaction between the sorbent and acid gases. Removing a significant portion of the HCl before the flue gas exits the combustor can reduce the formation of CDD/CDF in later sections of the flue gas ducting.

**Acid gas control with alkaline reagents.** Various lime and related alkaline products are used in spray dry and dry injection scrubbers to react with the acid gases, HCl, SO<sub>2</sub> and HF, to convert them into salts which can be collected by the particulate filter.

Calcium oxide (CaO) is called “pebble lime” or “quick lime.” Hydrated lime [Ca(OH)<sub>2</sub>] is made from CaO by adding 32% by weight of water in a hydrator. Ca(OH)<sub>2</sub> is a powder having a mean particle size of 5 μm, and is highly reactive.

CaO is not very reactive with acid gases at the temperatures and conditions that exist in waste combustion facilities, and has to be converted to the hydrate form to be reactive in scrubbing systems. CaO has been demonstrated to remove acid gases in high temperature applications such as furnace injection.

CaO converts to Ca(OH)<sub>2</sub> in the slaking process, in which four parts of water are added to one part of CaO to form Ca(OH)<sub>2</sub> in a slurry that is about 25% solids. This conversion requires two phases and takes place in a slaker. The first phase is to convert the hydrate by mixing 3.96 lb of free water with one part of hydrate (1.32 lb), resulting in a 25% slurry (5.28 lb).

The reactions are as follows:

The capture ratio is  $74/73 = 1.104$ .

1 lb of CaO yields 1.32 lb of Ca(OH)<sub>2</sub>

1.156 lb Ca(OH)<sub>2</sub> captures 1.0 lb SO<sub>2</sub>

1.04 lb Ca(OH)<sub>2</sub> captures 1.0 lb HCl

**EXAMPLE:** The following emission factors are listed for a typical MWC facility:

SO<sub>2</sub> = 5.03 lb/ton (212 ppmv @ 7% O<sub>2</sub>)

HCl = 7.03 lb/ton (532 ppmv @ 7% O<sub>2</sub>)

The characteristic stoichiometric reaction of Ca(OH)<sub>2</sub> is

$5.03 \text{ lb SO}_2/\text{ton MSW} \times 1.156 \text{ lb Ca(OH)}_2/\text{lb SO}_2 = 5.815 \text{ lb Ca(OH)}_2/\text{ton MSW}$

$7.03 \text{ lb HCl}/\text{ton MSW} \times 1.104 \text{ lb Ca(OH)}_2/\text{lb HCl} = 7.761 \text{ lb Ca(OH)}_2/\text{ton MSW}$

Total = 13.575 lb/ton

Pebble lime:

The characteristic stoichiometric reaction of CaO is

$5.03 \text{ lb SO}_2/\text{ton MSW} \times 0.875 \text{ lb CaO}/\text{lb SO}_2 = 4.401 \text{ lb CaO}/\text{ton MSW}$

$7.03 \text{ lb HCl}/\text{ton MSW} \times 0.767 \text{ lb CaO}/\text{lb HCl} = 5.392 \text{ lb CaO}/\text{ton MSW}$

Total = 9.793 lb/ton

Since CaO contains about 7% unreactive material and inerts that are lost in the slaking process, the usage is adjusted to compensate: the adjustment is

$$1.07 \times 9.793 = 10.5$$

Due to the inability to provide absolute contact between the lime and the acid gases, more lime is required in the process. In addition, several unwanted chemical reactions take place that also use some undefined portion of the lime. For example, lime will react with carbon dioxide in the flue gas as follows:

The ratio of the actual amount of lime used to the theoretical amount required is called the stoichiometric ratio. A typical MWC equipped with a spray dryer and an ESP will require about 35 lb pebble lime per ton of MSW, while an MWC with a spray dry baghouse will require about 20 lb per ton, to meet the NSPS standards of 25 ppm VI of HCl (a 93.5% reduction) and 30 ppm of SO<sub>2</sub> (an 85.8% reduction). The stoichiometric ratio for a plant with an ESP would be

$$35 + 10.5 = 45.5 \text{ lb per ton MSW}$$

**Tests of dry sodium bicarbonate injection after a municipal waste combustor.** The refuse combustion unit tested consisted of two identical lines working in parallel, merging before the common electrofilter. Each line consisted of a combustor, a tubular reactor (residence time 5 s) and a cyclone. The bicarbonate was pulverized and then distributed equally into the two lines, being injected into the exit of a venturi tube placed at the entrance to the reactor. The solid residues were trapped by the electrofilter.

The waste combustion plant treating 5 t/h of refuse produced 85 m<sup>3</sup>/h water at 180°C under a 15 bar pressure, corresponding to a power of 8.6 MW. Flue gas flow was 28,000 Nm<sup>3</sup>/h.

The heterogeneous nature of the fuel prevented determination in advance of the exact bicarbonate requirements. The injection rate varied between 50 and 150 kg/h.

*Stoichiometric ratios.* For removal of SO, and HCl, the following global reactions apply:

In other words, 84/36.5 = 2.30 kg of NaHCO<sub>3</sub> are required in order to remove 1 kg of HCl and 2 × 84/64 = 2.625 kg of NaHCO<sub>3</sub> are required in order to remove 1 kg of SO<sub>2</sub>.

*Testing.* The following average values for the two lines together were measured at the bicarbonate injection points at a flue gas temperature of 225°C:

HCL content: 880 mg/Nm<sup>3</sup> (dry) ± 28%

SO<sub>2</sub> content: 143 mg/Nm<sup>3</sup> (dry) ± 34%

HF content: 6 mg/Nm<sup>3</sup> (dry) ± 36%

During testing the composition of the flue gases to be purified fluctuated widely. A range of stoichiometric ratios between 0.9 and 2.03 was covered. On leaving the reactors and cyclones, the gases were already 75% purified compared with levels at the electrofilter outlet.

**Nitrogen oxides control techniques.** Nitrogen oxides emissions derive from two sources: the fuel, and conversion of nitrogen in the air. The conversion from nitrogen takes place in the flame, and depends upon the flame temperature.

The control of NO<sub>x</sub> emissions can be accomplished through either control of the combustion process, injection of reactants, or the use of add-on controls. Combustion controls include use of refractory furnaces (without waterwall cooling), staged combustion, low excess air (LEA), and flue gas recirculation (FGR). Add-on controls which have been used on MWCs include selective noncatalytic reduction (SNCR), selective catalytic reduction (SCR), and natural gas reburning.

Combustion controls involve the control of temperature or  $O_2$  to reduce  $NO_x$  formation. With LEA, less air is supplied, which lowers the supply of  $O_2$  that is available to react with  $N_2$  in the combustion air. In staged combustion, the amount of underfire air is reduced, which generates a starved-air region.

In FGR, cooled flue gas and ambient air are mixed to become the combustion air. This mixing reduces the  $O_2$  content of the combustion air supply and lowers combustion temperatures. Due to the lower combustion temperatures present in MWCs, especially in refractory furnaces, most  $NO_x$  is produced from the oxidation of nitrogen present in the fuel.

SNCR, also known as thermal deNO<sub>x</sub>, is the most common method used for reduction of  $NO_x$ . Injection of ammonia or urea into the furnace in a region having the optimum gas temperature achieves the optimum reduction. With SNCR, ammonia ( $NH_3$ ) or urea is injected into the furnace along with chemical additives to reduce  $NO_x$  to  $NO_2$  without the use of catalysts. MWCs equipped with SNCR have achieved  $NO_x$  reductions of about 45 percent.

With SCR,  $NH_3$  is injected into the flue gas *downstream* of the boiler where it mixes with  $NO_x$  in the flue gas and passes through a catalyst bed, where  $NO_x$  is reduced to  $NO_2$  by a reaction with the  $NH_3$ . Reductions of up to 80 percent have been observed, but problems with catalyst poisoning and deactivation reduce performance over time.

Natural gas reburning involves limiting combustion air to produce an LEA zone. Recirculated flue gas and natural gas are then added to this LEA zone to produce a fuel-rich zone that inhibits  $NO_x$  formation and promotes reduction of  $NO_x$  to  $NO_2$ . Natural gas reburning has achieved  $NO_x$  reductions of 50–60 percent.

Table 3.15 compares the  $NO_x$  emissions from three California MSW combustion systems equipped with thermal deNO<sub>x</sub>.

**TABLE 3.15**  $NO_x$  Emissions from MWCs with Thermal DeNO<sub>x</sub>

Emissions (ppm @ 7% oxygen)	Commerce	Stanislaus		SERRF		
		Unit 1	Unit 2	Unit 1	Unit 2	Unit 3
Uncontrolled $NO_x$	128–217	298	318	–	210	259
Controlled $NO_x$	104	93	112	49	72	54
Ammonia slip	~ 2	3.7	5	–	–	35

*Source:* McDonald *et al.*, 1996.

At Commerce, a study evaluated the two injection levels installed, carrier air injection pressure and ammonia injection rate. The study concluded that optimum performance was achieved by injection of an  $NH_3$ -to- $NO_x$  molar ratio of about 1.5 through the upper elevation of nozzles. Even when there was substantial ammonia slip at the economizer exit, the level at the stack due to the spray dryer-baghouse was held to less than 5 ppm. The lower levels achieved by SERRF are due to a higher rate of ammonia injection as compared with Commerce and Stanislaus. The higher ammonia injection rate also explains the higher ammonia slip numbers, which become the limiting factor in  $NO_x$  control by this method.

**Mercury and dioxins control.** Injection of dry activated carbon (DAC) has been proven to be effective in removing dioxins and mercury from the flue gases produced in municipal waste and medical waste combustion systems. Test data gives an indication of the quantity of DAC required in relation to the concentrations of mercury and/or dioxins present upstream of the point of injection. This quantity is affected by the temperature of the gases and the retention time before the gases enter the particulate collection device, such as ESP or fabric filter (Rigo and Chandler, 1996).

Sodium sulfide has been used for mercury control, using DSI/FF as the APC. Aqueous sodium sulfide will react with mercury to form solid  $HgS$  that can be collected in the PM control device. In this process, a dilute  $Na_2S$  solution is injected into cooled gas ( $< 400^\circ F$ ) prior to injection of hydrated lime used to control the acid gases. Mercury initially in the gas is

absorbed by the solution droplet. As the droplet evaporates, HgS and sodium salts precipitate. Feed rates of  $\text{Na}_2\text{S}$  vary from 0.05 to 0.5 kg/Mg (0.1 to 1 lb/ton) of MSW, depending on site-specific conditions such as the amount of mercury in the flue gas, the level of control required, and the level of carbon in flyash (which also absorbs mercury).

Tests of three WTE facilities in California provide comprehensive data, obtained when the input and output concentrations were measured simultaneously along with operating conditions. Such data are normally available only from government-sponsored tests, such as those carried out by the US EPA.

Uncontrolled mercury levels prior to APCDs range from roughly 200 to 1400 micrograms per dry standard cubic meter ( $\mu\text{g}/\text{dscm}$ ), and average roughly  $650 \mu\text{g}/\text{dscm}$ . Some typical data for various types of APC are shown in Table 3.18. The high variability of mercury levels entering and leaving the APC makes it difficult to obtain anything better than a range of removal efficiency.

Note that the emissions limits for new HWCs were met, except for one PM test and one mercury test. The average of the two PM tests, 0.0282 gr/dscf, does meet the limit of 0.030 gr/dscf. This points out the importance of performing a number of tests and using the average.

\*Inlet = outlet/(1-control efficiency/100).

The high mercury level in one test, in spite of almost equal input, points out the difficulty in controlling mercury emissions. Carbon injection may be indicated.

**Achievable emission limits and averaging times.** Due to the high variability of mercury in the waste and hence in the uncontrolled and controlled emissions, it is necessary to analyze the data statistically in order to make estimates of the future performance of the control system, and to decide on the amount of carbon which should be injected on a continuous basis. On the basis of extensive tests at Stanislaus, it appears that the question of whether to assess compliance based on the average of multiple one-hour tests or on one multiple-hour test appears to be arbitrary from a statistical viewpoint (White, 1993b).

## 5 CONTROLLED AND UNCONTROLLED EMISSION FACTORS

Emission factors (EF), defined as pounds of a pollutant per ton of waste, pounds per million tons, grams/tonne, pounds per million Btu, etc., provide convenient reference numbers for tabulating stack test data, and hence for use in predicting emissions from facilities having similar combustion and emission control configurations.

Table 3.20 is a compilation published by the US EPA in AP-42 (EPA, 1993), providing EFs for uncontrolled emissions and for emissions controlled by ESPs, spray-dryer + ESP, dry sorbent injection + FF, and spray-dry scrubber + FF. AP-42 also expressed emission factors alternatively as  $\mu\text{g}/\text{standard cubic meter}$ . The conversion factor is 8.06 lb/million tons per  $\mu\text{g}/\text{scm}$ , based on the assumption that the heating value of the waste is 4500 Btu/lb. The value in  $\mu\text{g}/\text{scm}$  is presumably based on actual stack measurements, converted to 7% oxygen or 12%  $\text{CO}_2$ , from which the weight units are calculated. The numbers in this table have been calculated by assuming uncontrolled emissions considered to be typical and controlled emissions from selected facilities. It is important to note that the uncontrolled emissions have not been measured at the same facility as the controlled emissions. While the efficiencies determined this way may be useful for general guidance, data from facilities where input and output of the emission controls were measured at the same time should be more reliable. Tables 3.18 and 3.19 present measurements and efficiency calculations which were obtained at the same facility. Table 3.21 shows, for general guidance, uncontrolled emission factors obtained by averaging a number of EPA tests on medical waste incinerators (Walker and Cooper, 1992).

## 5.1 Tracing Metals from Waste to Emissions

It is important to have a clear perspective regarding the fate of air pollutants, especially the heavy metals, starting from concentrations in the waste, in the combustion process, before and after the air pollution control systems, and as concentrations in the stack gases, as they are diluted in the atmosphere before the metals reach the ground. From such analyses the metals concentrations in the stack may be compared with those of regulatory standards, to see whether they comply with the standards, and with what safety factor. Finally, after dilution before they reach ground level, as estimated by modeling studies, comparisons may be made with health standards and with “acceptable ground level concentrations” established by health authorities and amended by state regulatory authorities.

## 5.2 Reduction and Partitioning of Metals

In the combustion of wastes, a substantial fraction of metals is not volatilized but remains in the ash residues, depending upon the volatility of the metals. In the process of emissions control, nearly all of the metals remain in the captured flyash.

Only a few comprehensive studies have been made to measure the “partitioning” of metals from the waste to the various streams leaving the process. Such studies are costly and difficult to run, especially since the samples taken for analysis should be taken as near simultaneously as possible. Three studies are cited below, the first for a European facility having an ESP followed by a scrubbing tower, the second for a Canadian facility having a dry-sorbent injection system and baghouse, and a third for a US facility having a spray-dry scrubber and fabric filter. These facilities represent the major types of air pollution control system in common use at this time.

**TABLE 3.22** Distribution of Emissions from MSW Combustion System

Sampling point	Annual emissions (kg/yr)		
	Lead	Cadmium	Mercury
Waste feed	38,060	434	139
Bottom ash	35,950	272	9

Ratio: stack/backgnd	1,620	5,700	

Source: Sorum *et al.*, 1997.

\*Based on ground level concentrations measured in the New York/New Jersey metropolitan area, 1986 (NYSDEC, 1990).

**EXAMPLE 1:** A study by Sorum *et al.* (1997) analyzed the MSW, bottom ash, ESP ash, scrubber filter cake and drain water, as well as the flue gas leaving the stack. This facility has an ESP followed by a washing tower (wet scrubber). Table 3.22 summarizes the results for cadmium, mercury and lead.

The bottom ash contained  $39,950/38,060 = 94.4\%$  of the lead. The emissions were 0.2% of the MSW, or, in other words, the lead in the MSW was reduced by 99.76%, or by a factor of 413. Likewise, 62.6% of the cadmium stayed in the bottom ash, 24% was removed in the ESP ash, 6% was in the filter cake, and 7.6% was emitted from the stack. Most of the mercury (87%) was collected in the scrubber filter cake, and only 5% was emitted.

The schematic of the facility with annual lead emissions shown is as follows:

The stack emissions for lead are therefore  $92/38,000$  or  $1/413$  of the input, or, stated another way, the removal efficiency is 99.76%.

**EXAMPLE 2:** In another mass-balance test, of a WTE facility, having a dry lime injection scrubber and baghouse (Burnaby), the mass-balance given in Table 3.23 was determined.

Here the ash residues contained  $(326,000 - 1871)/326,000 = 99.4\%$  of the lead, a reduction by a factor of 174. The reduction from waste to stack was  $326,000/363$  or a factor of 898.

Table 3.23 gives a numerical demonstration of the factors by which the metals are reduced, and the efficiency of capture by the emission controls, as measured in extensive tests of the Burnaby facility. With the exception of the highly volatile mercury, of which over 50% reached the stack, the other metals were reduced by factors from 20 times for vanadium to as much as 5000 times for lead. Overall reduction of metals from 4700,000 to only 4720 constitutes a 99.4% reduction. Individual APC control efficiencies for the critical metals, lead and cadmium, were 98.3 and 99.7% respectively.

**TABLE 3.23** Reduction and Partitioning of Metals in Municipal Waste

*Source:* Teller, 1994.

**EXAMPLE 3:** The Commerce facility, having a spray-dry scrubber and fabric filter (baghouse) provided the data for Table 3.24. Stack emissions are compared with boiler outlet concentrations to obtain control efficiencies ranging from 91% for mercury to 99.99% for lead. The stack emissions for lead are 1/1133 of the stack emissions. The emission factors, in lb per million tons, are also shown. The overall collection efficiency is found to be  $(684,756 - 5962)/684,756 = 99.1\%$ . The input is thus 115 times the stack emissions.

### 5.3 Emissions from WTE versus Fossil Fuels

Table 3.25 gives a comparison between the emissions from waste-to-energy facilities and those from fossil-fuel-fired utility boilers. Note that, based on equivalent electric power generation, WTE facilities generally have much lower emissions than those of the fossil fuels (not including distillate oil and gas). This calculation is, of course, for illustration purposes only. Individual comparisons, while more accurate, would show the same general tendencies.

### 5.4 Recycling and Pollution Prevention

Table 3.26 lists the components of MSW analyzed at Burnaby, and the concentrations of the metals in each component.

It is notable that the highest concentrations of mercury were found in certain paper fractions, plastic film, lawn waste, unfinished wood, textiles, food, fiberglass, and, as expected, in batteries. The use of mercury as an anti-fungal agent in corrugated cardboard has essentially ceased. Mercury in printing inks has also been eliminated by use of organic colors. Mercury in batteries has been phased out. It has been found that the levels measured at Burnaby were declining at the time of the tests, and have declined further. Therefore these emission factors are no longer valid. In any case, concentrating on elimination of batteries would not have resulted in a substantial reduction: the total of 0.73 parts per million of MSW would be reduced by only 0.03 (4%) to 0.70 ppm if the battery fraction were eliminated, assuming that there was a direct relationship. It is not known whether the mercury in the batteries reports to the ash residues or to the stack gases. It is known that most of the lead goes to the ash residues (Rigo *et al.*, 1993).

**TABLE 3.25** Comparison of Emissions from WTE Facilities with those from Fossil Fuels (lb/1000 MWh)

## 6 CONVERSIONS AND CORRECTIONS

### 6.1 Correction of Emission Factors for Heating Value

The EPA has listed emission factors for MSW in AP-42, using a higher heating value (HHV) of 4500 Btu/lb as a reference value. When the heating value is different than 4500 Btu/lb, a correction must be made, as follows:

**EXAMPLE:** AP-42 lists emissions of nitrogen oxides (NO<sub>x</sub>) as 2.86 kg/mg of fuel, and as 358 ppm<sub>d</sub> at 4500 Btu/lb.

Correct these emissions to the actual higher heating value of 5000 Btu/lb:

Calculate lb/ton and lb/million Btu:

*multiply 2.86 kg/mg by 5000/4500 to get 3.18 kg/mg at 5000 Btu/lb*

*multiply 3.18 kg/mg by 2 to get 6.36 lb/ton*

Convert from lb/ton to lb/million Btu:

One ton at 4500 Btu/lb × 2000 lb/ton = 9 million Btu/ton

2.86 kg/mg @ 4500 Btu/lb multiplied by 2 = 5.72 lb/ton

5.72 lb/ton divided by 9 MBtu = 0.64 lb/MBtu

One ton at 5000 Btu/lb contains 2000 lb = 10 million Btu/ton

6.36 lb/ton divided by 10 MBtu/ton = 0.64 lb/MBtu

Correct ppm<sub>v</sub> at 4500 Btu/lb to 5000 Btu/lb:

*multiply 358 ppm<sub>d</sub> @4500 Btu/lb by 5000/4500 to get 398 ppm<sub>d</sub>*

## 6.2 Conversions from Volumetric to Other Bases

The US EPA has developed the volumetric emission factors, in grams per cubic meter based on a standardized “F” factor of 9570 ft<sup>3</sup>/MBtu for stoichiometric combustion (zero excess air or zero oxygen). This F-factor is reasonably accurate for combustion of wastes and fuels, but a more precise number may be calculated from the actual composition of the waste, as shown in Section 2.5.

Convert  $\mu\text{g}/\text{dscm}$  to  $(\text{lb pollutant})/(\text{MBtu of waste})$

$$1 \left[ \frac{\mu\text{g}}{\text{m}^3} \right] @ 7\% \text{ O}_2 \times \left[ \frac{21-0}{21-7} \right] \times \left[ \frac{\text{m}^3}{35.3 \text{ ft}^3} \right] \times \left[ \frac{\text{g}}{10^5 \mu\text{g}} \right] \times \left[ \frac{9570 \text{ ft}^3}{10^6 \text{ Btu}} \right] = 0.9 \left[ \frac{\text{lb}}{10^6 \text{ Btu}} \right]$$

Convert ppmv to lb/MBtu

$$1 \text{ [ppmv]} @ 7\% \text{ O}_2 \times \text{MW} \left[ \frac{\text{lb}}{[\text{lb} \cdot \text{mol}]} \right] \times \left[ \frac{21-0}{21-7} \right] \times \frac{1}{35.3} \left[ \frac{\text{lb} \cdot \text{mol}}{\text{ft}^3} \right] \\ \times 9570 \left[ \frac{\text{ft}^3}{10^6 \text{ Btu}} \right] = \frac{1}{26,820} \left[ \frac{\text{lb}}{10^6 \text{ Btu}} \right]$$

Convert ppmv to mg/m<sup>3</sup>

$$385/(454 \times 35.3) = 0.24 \left[ \frac{\text{mg}}{\text{m}^3} \right] \times \left[ \frac{1000 \times 0.024}{\text{MW}} \right] = \text{ppmv}$$

or

$$[\text{mg}/\text{m}^3] \times 24/\text{MW} = [\text{ppmv}]$$

**TABLE 3.27** Conversion of ppmv to lb/MBtu and mg/m<sup>3</sup>

Gas	Molecular weight MW	lb/MBtu 100 ppmv =	mg/m <sup>3</sup> 100 ppmv =
CO <sub>2</sub>	28	0.104	116.5
SO <sub>2</sub>	44	0.163	183.1
NO <sub>x</sub>	46	0.172	191.3
HCl	36.5	0.136	151.8
HF	20	0.746	83.2
CH <sub>4</sub>	14	0.060	66.6
NH <sub>3</sub>	32	0.063	112.3

## 6.3 Corrections for Excess Air

Emissions tests performed in the stack of combustion devices are measured at the actual gas flow, but must be reported at “reference” conditions such as 7% oxygen or 12% CO<sub>2</sub> in order to standardize all reported data and relate it to regulated emission standards. Reference standards vary from 3% oxygen, used in California, to 11% oxygen, used in Europe.

Calculate excess air:

$$\%EA = \frac{O_2 - 0.5 CO}{0.266 (N_2 - 0.5 N_f) - O_2} \times 100\%$$

where

$O_2$ ,  $CO_2$  and  $CO$  are the molar or volume fractions of the gases in the flue gas as determined by an Orsat or equivalent analysis

$N_f$  is the mole fraction of fuel nitrogen in the combined waste and fuel feeds to the combustor, determined from the ultimate analysis. This value is usually negligible

Normally  $N_f$  and  $CO$  can be neglected, yielding this simpler expression:

$$\%EA = \frac{O_2}{0.266 (N_2) - O_2} \times 100\%$$

Correction from (concentration)<sub>actual</sub> to (concentration)<sub>standard</sub>:

Since the sum of  $O_2$  plus  $CO_2$  in the *dry* products of combustion is about 20.5, corrections for excess air are usually approximated by this expression:

$$\text{ratio} = \frac{20.5 - (O_2)_{\text{actual}}}{20.5 - (O_2)_{\text{standard}}} \times 100\%$$

## 6.4 Calculation of Destruction and Removal Efficiency

The regulations for emissions from hazardous waste incinerators were based on destruction and removal efficiency (DRE). Essentially, it was required that 99.99% of the principal organic hazardous components (POHC) be removed, and that for critical chlorinated compounds 99.999% removal was required, during trial burn tests. The operating conditions under which these efficiencies were demonstrated were to be the upper limits of operating parameters, such as waste feed rates and furnace temperatures.

In order to calculate DREs, it is necessary to determine the feed rate of the organics or metals, and measure the stack emissions. To predict the necessary feed rate it is necessary to estimate the partitioning of the metals from ash to flyash and the efficiency of the air pollution control system (APC). For organics, the efficiency of the APC is applied to obtain the estimate of stack emissions.

Since the stack emission levels would be extremely low, it is important that they be high enough to measure. Hence the detection limit becomes a controlling factor. The expected emissions must be sufficiently higher than the detection limit to permit demonstration of the required DRE. The procedure for making this calculation is as follows.

Destruction and removal efficiency for an incinerator/air pollution control system is defined by the following formula:

$$DRE = \frac{W_{\text{in}} - W_{\text{out}}}{W_{\text{in}}} (100)$$

where DRE = destruction and removal efficiency, %

$W_{\text{in}}$  = mass feed rate of the principal organic hazardous constituents to the incinerator

$W_{\text{out}}$  = mass emission rate of the principal organic hazardous constituent(s) to the atmosphere as measured in the stack prior to discharge

DRE calculations are based on the combined efficiencies of destruction in the incinerator and removal from the gas stream in the air pollution control system.

USEPA Part 264, Subpart 0 regulations for hazardous waste incineration require a DRE of 99.99% for all principal organic hazardous components of a waste unless it can be demonstrated that a higher or lower DRE is more appropriate on the basis of human health criteria.

Destruction and removal efficiencies are normally measured only during trial burns and occasional compliance tests, and are used as a basis for determining whether or not the operating conditions of the incinerator/air pollution control system are adequate.

**Sample calculation.** A liquid injection incinerator equipped with a quench tower, venturi scrubber and packed bed caustic scrubber has been constructed to burn a mixture of waste oils and chlorinated solvents with the following empirical composition:

73.0 wt% carbon  
16.5 wt% chlorine  
10.5 wt% hydrogen

The principal organic hazardous components are trichloroethylene, 1,1,1-trichloroethane, methylene chloride and perchloroethylene. Each of these compounds constitutes about 5% of the total waste feed to the incinerator.

During a trial burn, the incinerator was operated at a waste feed rate of 5000 lb/h and 50% excess air. The gas flow rate measured in the stack was 19,200 dscm. Under these conditions, the measured concentrations of the principal organic hazardous components were:

trichloroethylene	4.9 pg/dscf
1,1,1-trichloroethane	1.0 pg/dscf
methylene chloride	49 pg/dscf
perchloroethylene	490 pg/dscf

In order to calculate destruction and removal efficiency for each of these compounds using the equation

$$\text{DRE} = \frac{W_{\text{in}} - W_{\text{out}}}{W_{\text{in}}}(100)$$

it is necessary to calculate the mass flow of each component entering and exiting the system. Because each hazardous component constitutes about 5% of the waste and the total waste feed rate is 5000 lb/h,  $W_{\text{in}}$  for each component is

$$W_{\text{in}} = 0.05 (5000 \text{ lb/h}) = 250 \text{ lb/h}$$

The mass flow rate of each component exiting the stack is then calculated by the following equation

$$W_{\text{out}} = C_i \times \frac{(19,200 \text{ dscfm}) (60 \text{ min/h})}{4.54 \times 10^8 \text{ } \mu\text{g/lb}}$$

where  $W_{\text{out}}$  = mass flow rate of component  $i$  exiting the stack, lb/h  
 $C_i$  = concentration of component  $i$  in the stack gas,  $\mu\text{g/dscf}$

Using this equation to calculate  $W_{\text{out}}$  for each component and the previously cited equation for destruction and removal efficiency, the following results are obtained:

Component	$W_{\text{out}}$ (lb/h)	DRE (%)
Trichloroethylene	0.0124	99.995
1,1,1-trichloroethane	0.00254	99.999
Methylene chloride	0.124	99.95
Perchloroethylene	1.24	99.5

These results indicate that the required 99.99% destruction and removal efficiency was achieved in the trial burn for trichloroethylene and 1,1,1-trichloroethane, but not for methylene chloride and perchloroethylene.

## 6.5 Useful Relationships

The stoichiometric combustion air needed per million Btu can be calculated:

$$\text{lb air/MBtu} = \frac{1,000,000 \text{ [Btu] [lbf]}}{7457 \text{ [Btu]}} \times \frac{5.105 \text{ [lba]}}{\text{[lbf]}} = 684.6 \text{ lba/MBtu}$$

The pounds of stoichiometric products per million Btu would be

$$\text{lb products/MBtu} = \frac{1,000,000 \text{ [Btu] [lbf]}}{7457 \text{ [Btu]}} \times \frac{6.105 \text{ [lba]}}{\text{[lbf]}} = 819 \text{ lbp/MBtu}$$

With 50% excess air, we get pounds combustion air per million Btu:

$$\text{lb air/MBtu} = \frac{1,000,000 \text{ [Btu] [lbf]}}{7457 \text{ [Btu]}} \times \frac{7.66 \text{ [lba]}}{\text{[lbf]}} = 713 \text{ lba/MBtu}$$

and the pounds of products at 50% excess air would be

$$\text{lb products/MBtu} = \frac{1,000,000 \text{ [Btu] [lbf]}}{7457 \text{ [Btu]}} \times \frac{8.66 \text{ [lba]}}{\text{[lbf]}} = 1161 \text{ lba/MBtu}$$

Weight and volume of products per million Btu as standard temperature and pressure:

Volume of 1 mole of ideal gas = 387 ft<sup>3</sup>/lb · mol @ 70°F (20°C), 1 atmosphere

1 lb · mol of dry products (see above) weighs 29.51 lb

1 lb · mol of products weighs about 29.75 lb at *zero excess air*

Therefore the volume of wet products *corrected* to 70°F (70 + 460 = 530°R) is

$$\begin{aligned} V_{\text{wp}} &= 387/29.75 = 13.0 \text{ ft}^3/\text{lbf} \\ &= 6.105 \text{ [lbp/lbf]} \times 13 \text{ ft}^3/\text{lbf} = 79.416 \text{ ft}^3/\text{lbf} \end{aligned}$$

The volume of dry products is calculated when reporting emissions. To get the volume of dry products we subtract 0.555 [H<sub>2</sub>O] from 6.105 to obtain

$$V_{dp} = (6.105 - 0.555) [\text{lbdp/lbf}] \times 13.0 \text{ ft}^3/\text{lbf} = 72.15 \text{ ft}^3/\text{lbf}$$

## 1 INTRODUCTION

---

This chapter addresses the procedures which can or must be followed in order to determine that the emissions from the stack (chimney) of a combustion device burning municipal, medical or hazardous wastes can or are expected to comply with regulations permitting operation of the facility, as well as to evaluate the environmental and health impact of these emissions.

The procedures promulgated by the US EPA for performing stack tests are outlined. The emissions determined by these procedures are compared with permit requirements to confirm compliance with the regulations.

The emissions measured by stack tests can be used to determine their impact at ground level or in sensitive areas by the use of modeling methods which are outlined in this chapter, and their environmental and health risk impact compared with health risk standards.

## 2 CALCULATIONS OF EMISSIONS FROM THE STACK

---

Stack testing is performed to measure the discharges to the atmosphere from the combustion system and its emission control equipment. This testing is performed in accordance with the US EPA methods and procedures, which are briefly summarized below.

The US Environmental Protection Agency (EPA) has published sampling and analytical procedures in the Code of Federal Regulations, Title 40, Part 60 (40 CFR 60), Appendix A, and Title 40, Part 61 (40 CFR 61), Appendix B, among others. The following are the “basic specific methods:”

- EPA Method 1 for determination of sampling and traverse points.
- EPA Method 2 for calculating stack gas velocity, volumetric flow rate, density and mass flow rate.
- EPA Method 3 for sampling of flue gas composition and molecular weight determinations. Dry oxygen and dry volume are calculated using the measured percent moisture. The specific volume at measured temperature is calculated as measured on a wet basis and used to determine the actual cubic feet per minute (acfm) and the dry standard cubic feet per minute (scfm) of flue gas, as well as the percent excess air.
- EPA Method 3/4 for flue gas moisture content. Stack gas moisture is determined by condensation of water from the extracted sample. Orsat analysis of an extracted gas sample is used to determine the percent oxygen and CO<sub>2</sub> of the gases in their wet condition.
- EPA Method 5 for determination of total particulate emissions. Particulate matter (PM) and metals mass rate and composition, measured by sampling train, are shown in Fig. 4.1.
- EPA Method 23 is used for determination of the emission of polychlorinated dibenzodioxins (PCDDs), polychlorinated dibenzofurans (PCDFs), and poly-aromated hydrocarbons (PAHs).
- EPA Method 29 is used for determination of metals emissions (arsenic, barium, beryllium, cadmium, chromium, lead, nickel, selenium, vanadium, zinc and mercury).

Oxygen is continuously measured in the stack by instruments which can measure it in the dry or wet condition.

CO is measured by a continuous monitor located in the stack, or by continuous extraction of a gas sample.

SO<sub>2</sub> is measured by the sampling train of EPA Method 6, or by continuous monitoring.

HCl is measured by the sampling train of EPA Method 26A, or by continuous monitoring.

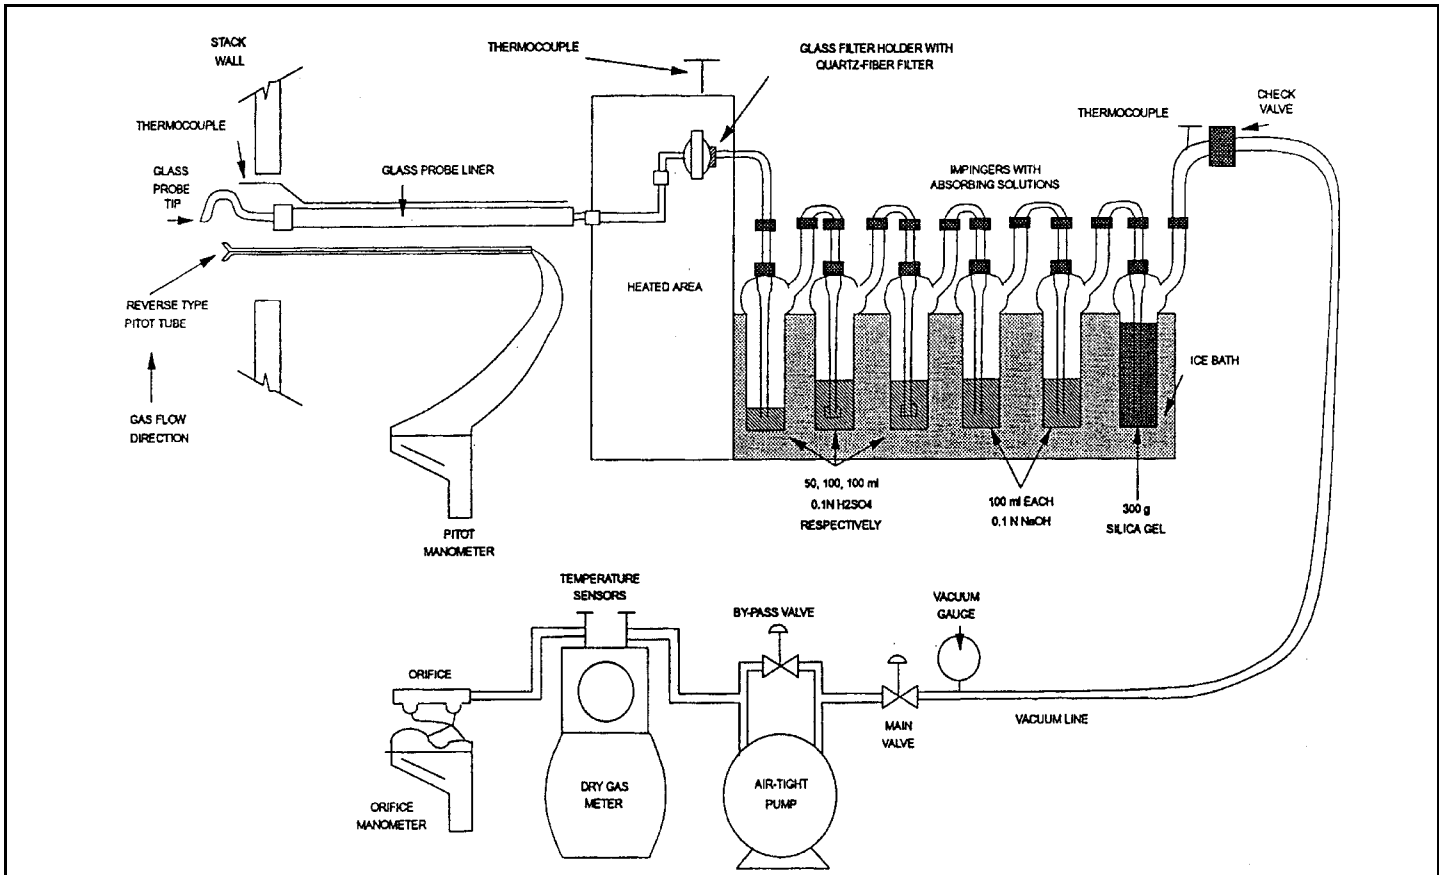

All gas flow measurements are corrected from actual temperature and pressure to standard conditions of one standard atmosphere, 29.92 inches mercury and a temperature of 68°F, and by use of the measured oxygen and moisture.

For analysis of total hydrocarbons and other volatiles, gas samples can be collected in Tedlar bags and taken to the laboratory for analysis.

### 2.1 EPA Method of Calculating Stack Gas

Stack gas flow volume is determined by measuring velocity, temperature and barometric pressure. Velocity is measured by a Pitot tube traverse of equal areas which determine the

NOTE: AT THE INLET LOCATION AN IN-STACK (EPA 17) GLASS FIBER THIMBLE MAY BE USED.

FIGURE 4.1 Combined EPA Method 5 and 26A particulate/anion sampling train.

average velocity. Flow volume is calculated by use of the diameter of the stack at the outlet, and mass flow is determined after calculating the actual gas density.

Step 1. Determine the percentages by volume of oxygen, carbon dioxide and nitrogen, measured on a dry basis by Orsat analysis.

For instance:

%CO <sub>2</sub> =	8.6%
%O <sub>2</sub> =	10.30%
%N <sub>2</sub> =	81.1%
Total =	100.00% dry volume

Step 2. Determine stack gas moisture by Method 4: a sample of stack gas is drawn from the stack through a condenser in the sampling train from which a volume of water condensate ( $V_{lc}$  in ml) is collected and weighed, while the volume of gas extracted ( $V_m$  in ft<sup>3</sup>) is measured by gas meter.

The sample volume is corrected to standard conditions:

$$V_{std} = 17.647 \times V_m \times Y \times (P_b + \Delta H/13.6)/T_m$$

The volume of water vapor sampled is

$$V_w = 0.04707 \times V_{lc}$$

The proportion of water vapor in sampled gas is

$$B_{ws} = V_w / (V_w + V_{std})$$

where  $B_{ws}$  = water vapor in gas stream (proportion by volume)  
 $\Delta H$  = orifice meter differential pressure (inches water column)  
 $P_b$  = barometric pressure (inches Hg)  
 $T_m$  = sampling train meter temperature (°R)  
 $V_{lc}$  = total volume of liquid collected in sampling train (ml)  
 $V_m$  = volume of gas sample measured by gas meter (ft<sup>3</sup> or cf)  
 $V_{std}$  = gas volume corrected to standard conditions (dscf)  
 $V_w$  = volume of water vapor in gas sample (scf)  
 $Y$  = dry gas meter calibration coefficient

For this example, assume that the moisture content has been determined to be

$$\text{moisture content} = B_{ws} \times 100 = 17.3\%$$

Step 3. Determine molecular weight of the stack gas.

In order to calculate the molecular weight of the actual wet gas,  $M_w$ , it is necessary to have the gas composition, measured on a dry basis by an Orsat, and a measurement of the moisture content of the flue gas, obtained by condensing the water vapor in a measured volume of sample gas extracted from the stack.

The *molecular weight* of the *dry gas* is calculated as follows:

$$\begin{aligned} M_d &= (0.44 \times \%CO_2) + (0.32 \times \%O_2) + (0.28 \times (\%N_2 + \%CO)) \\ &= (0.44 \times 8.6) + (0.32 \times 10.30) + (0.28 \times 81.1) = 29.788 \text{ lb}/(\text{lb} \cdot \text{mol}) \end{aligned}$$

The *molecular weight* of the *wet gas* is calculated from  $M_d$  as follows:

$$\begin{aligned} M_s &= M_d \times (1 - B_{ws}) + (18 \times B_{ws}) \\ &= 29.788 \times (1 - 0.1743) + (18 \times 0.1743) = 27.733 \text{ lb}/(\text{lb} \cdot \text{mol}) \end{aligned}$$

Step 4. Calculate stack gas linear velocity.

The *stack gas velocity* is measured by a Pitot tube, which reads the velocity head of impact as the gases impact on the Pitot tube mouth perpendicular to the direction of flow.

A number of readings of velocity pressure  $\Delta P$  are taken over equal areas to represent the total cross-section of the duct. The average of the square roots of these readings  $\sqrt{\Delta P}$  represents the average velocity through the duct. The stack gas velocity  $V_s$  is calculated by a constant 85.49 multiplied by the Pitot calibration coefficient  $C_p$ , the average velocity  $\sqrt{\Delta P}$  times the square root of the flue gas temperature in degrees Rankine  $T_s$ , the static pressure in the duct  $P_s$  and the molecular weight of the flue gas in its wet condition  $M_w$ , as follows:

$$\begin{aligned} V_s &= 85.49 \times C_p \times \sqrt{\Delta P} \times \sqrt{(T_s/P_s \times M_s)} \\ &= 85.49 \times 0.835 \times 0.7843 \times \sqrt{(1004/(28.31 \times 27.733))} = 63.31 \text{ ft/s} \end{aligned}$$

where  $T_s$  = stack temperature =  $544^\circ\text{F} + 460 = 1004^\circ\text{R}$

$P_s$  = barometric pressure + absolute pressure in duct  
=  $28.35 - 0.51 = 28.31$  in.  $H_2O$ .

Step 5. Calculate volumetric flow rates acfm, scfm and dscfm.

The duct area ( $A$ ) for a diameter of 41.5 in. =  $(41.5/12)^2 \times 0.786 = 9.4 \text{ ft}^2$

*Actual volumetric gas flow:*

$$Q = 60 \times V_s \times A = 60 \times 63.31 \times 9.4 = 35,707 \text{ actual ft}^3/\text{min (acfm)}$$

Correct the volumetric stack flow ( $Q$ ) to standard conditions,  $68^\circ\text{F}$  and 29.92 in. Hg:

$$\begin{aligned} Q_s &= Q \times (528/T_s) \times (P_s/29.92) = Q \times 17.647 \times (P_s/T_s) \\ &= 35,707 \times 17.647 \times (28.31/1004) = 17,768 \text{ std. ft}^3/\text{min (scfm)} \end{aligned}$$

Correct  $Q_s$  to dry basis:

$$Q_{sd} = Q_s \times (1 - B_{ws}) = 17,768 \times (1 - 0.1743) = 14,676 \text{ dry std. ft}^3/\text{min (dscfm)}$$

where	$A$ = cross-sectional area of duct at sample point ( $\text{ft}^2$ )	= 9.4 $\text{ft}^2$
	$B_{ws}$ = water vapor in gas stream (proportion by volume)	= 17.43%
	$C_p$ = Pitot tube calibration coefficient	= 0.843
	$G_d$ = flue gas specific gravity relative to air, dimensionless	= $\rho/0.075$
	$m_g$ = mass flow rate of wet flue gas	
	$M_s$ = molecular weight of wet flue gas	
	$M_d$ = molecular weight of dry flue gas	
	$P_s$ = absolute gas pressure of duct (in. Hg)	= 28.31
	$\Delta P$ = velocity pressure measured by Pitot tube (in. WC)	= 0.615
	$Q$ = actual flue gas volumetric flow rate (acfm)	

$$\begin{aligned}
 Q_s &= \text{volumetric gas flow at standard conditions (scfm)} \\
 Q_{sd} &= \text{dry standard volumetric gas flow rate (dscfm)} &= Q_s \times (1 - B_{ws}) \\
 T_s &= \text{flue gas temperature (}^\circ\text{R)} &= 544 + 460 = 1004^\circ\text{R} \\
 V_s &= \text{flue gas linear velocity (ft/s)} &= 63.9 \\
 \rho &= \text{actual flue gas density (lb/ft}^3\text{)} \\
 V_s &= \text{stack gas linear velocity, ft/s} = 85.49 \times C_p \times \sqrt{(\Delta P)} \times \sqrt{(T/(P_s \times M_s))}
 \end{aligned}$$

Step 6. Calculate actual gas density and mass flow rate of wet flue gas.

The *actual gas density* in the *stack*  $\rho$  is calculated at the absolute pressure in the duct  $P_s$ , the actual temperature  $T_s$  and the molecular weight  $M_s$ , as follows:

$$\begin{aligned}
 \rho &= 0.04585 \times P_s \times M_s / T_s = 0.03585 \text{ lb/ft}^3 \\
 &= 0.075(460 + 68)(28.31) / (544 + 460)(29.96) = 0.03721 \text{ lb/ft}^3
 \end{aligned}$$

$$\begin{aligned}
 \text{where } P_s &= 28.35 \text{ in. Hg} \\
 T_s &= 544 + 460 = 1004^\circ\text{R}
 \end{aligned}$$

The *mass flow rate* in the *stack*  $m_g$  is calculated from the volumetric flow  $Q$  and the gas density  $\rho$ :

$$m_g = Q \times 60 \times \rho = 35,707 \times 60 \times 0.03721 = 79,719 \text{ pounds per hour (lb/h)}$$

or

$$m_g = 4.995 \times Q_{sd} \times G_d / (1 - B_{ws})$$

$$\begin{aligned}
 \text{where } P_s &= 28.35 \text{ in. Hg} \\
 T_s &= 1004^\circ\text{R}
 \end{aligned}$$

Step 7. Calculate percent excess air

$$\%EA = 100 \times \left\{ \frac{\%O_2 - (0.05 \times \%CO)}{(0.264 \times \%N_2) - \%O_2 + (0.5 \times \%CO)} \right\}$$

or, neglecting CO (usually very small):

$$\begin{aligned}
 \%EA &= 100 \times (\%O_2) / (0.264 \times \%N_2 - \%O_2) \\
 &= 100 \times (10.3) / (0.264 \times 91.1 - 10.3) = 74.9\% \text{ excess air}
 \end{aligned}$$

$$\begin{aligned}
 \text{where } B_{ws} &= \text{water vapor in gas stream (proportion by volume)} \\
 \%CO &= \text{carbon monoxide in gas stream (percent)} \\
 \%CO_2 &= \text{carbon dioxide in gas stream (percent)} \\
 \%EA &= \text{excess air for combustion (percent)} \\
 F_0 &= \text{correction factor for results comparison} \\
 M_d &= \text{molecular weight of dry flue gas (lb/(lb} \cdot \text{mol))} \\
 M_s &= \text{molecular weight of wet flue gas (lb/(lb} \cdot \text{mol))} \\
 \%N_2 &= \text{nitrogen in gas stream (percent)} \\
 \%O_2 &= \text{oxygen in gas stream (percent)}
 \end{aligned}$$

Step 8. Calculate correction factor, for comparison with standard  $O_2$  or  $CO_2$ .

$$F_0 = (20.9 - \%O_2) / \%CO_2 = (20.9 - \%O_2) / (20.9 - \%O_2)$$

## 2.2 EPA Method 5 Calculations for Particulate Matter (PM)

A sample is extracted from the stack using the sampling train shown in Fig. 4.1.  
Sample volume, correcting to standard conditions

$$V_{\text{std}} = 17.647 \times V_m \times Y \times (P_b + \Delta H/13.6)/T_m$$

Isokinetic variation

$$I = 0.09450 \times (T_s \times V_m)/[P_s \times V_s \times A_n \times \theta \times (1 - B_{\text{ws}})]$$

Particulate concentration

$$C_s = 15.432 \times [m_n/V_{\text{std}}]$$

Particulate mass rate

$$m_p = 0.008571 \times C_s \times Q_{\text{sd}}$$

where  $A_n$  = cross-sectional area of nozzle opening (ft<sup>2</sup>)  
 $B_{\text{ws}}$  = water vapor in gas stream (proportion by volume)  
 $C_s$  = particulate concentration of gas stream (gr/dscf)  
 $\Delta H$  = orifice meter differential pressure (in. WC)  
 $I$  = isokinetic variation of sampling rate (percent)  
 $m_n$  = total particulate collected in sampling train (g)  
 $m_p$  = particulate mass flow rate (lb/h)  
 $P_b$  = barometric pressure (in. Hg)  
 $P_s$  = absolute gas pressure of duct (in. Hg)  
 $Q_{\text{sd}}$  = dry standard volumetric gas flow rate (dscfm)  
 $T_m$  = sampling train meter temperature (°R)  
 $T_s$  = flue gas temperature (°R)  
 $V_m$  = volume of gas sample measured by gas meter (ft<sup>3</sup>)  
 $V_{\text{std}}$  = gas volume corrected to standard conditions (dscf)  
 $V_s$  = flue gas linear velocity (ft/s)  
 $Y$  = dry gas meter calibration coefficient  
 $\theta$  = total sampling time of run (min).

## 2.3 Calculation for Metals

The sample of particulate matter collected on the filter is analyzed for metals. The following calculation is used to relate this data to the concentration and emission rate of the metals:

Step 1. Concentration ( $\mu\text{g}/\text{Nm}^3$ )

$$\mu\text{g}/\text{Nm}^3 = \frac{35.3 \text{ ft}^3}{\text{m}^3} \times \frac{\mu\text{g in sample}}{V_m \text{ (dscf)}}$$

where  $V_m$  = exhaust gas volume through meter (dscf)

Step 2. Emission rate (lb/h)

$$\begin{aligned} (\text{lb/h}) &= \frac{\mu\text{g}}{\text{Nm}^3} \times \frac{\text{lb}}{454} \times \frac{\text{g}}{1000 \text{ mg}} \times \frac{m_g}{1000 \mu\text{g}} \times \frac{\text{dscf}}{\text{min}} \times \frac{60 \text{ min}}{\text{h}} \times \frac{0.0283 \text{ Nm}^3}{\text{dscf}} \\ &= (3.74 \times 10^{-9}) \times \text{dscfm} \times \mu\text{g}/\text{Nm}^3 \end{aligned}$$

where dscfm = volumetric flow rate in the source (stack)

**EXAMPLE:**

$$\text{Sum of metals} = 284 \mu\text{g}/\text{Nm}^3$$

$$\text{dscfm} = 14,676 \text{ Nm}^3$$

$$\begin{aligned} \text{lb/h} &= 3.74 \times 10^{-9} \times 14,676 (\text{Nm}^3) \times 284 (\mu\text{g}/\text{Nm}^3) \\ &= 0.015 \text{ lb/h} \end{aligned}$$

**2.4 Typical Calculation Summary for MSW Incinerator ESP Stack**

Parameter	Run 1	Run 2	Run 3
Date of run	6/14/95	6/14/95	6/14/95
Sample duration (min)	60	60	60
Barometric pressure (in. Hg)	28.35	28.35	28.35
Static pressure of duct (in. H <sub>2</sub> O)	-0.51	-0.51	-0.51

Nozzle diameter (in.)	0.31	0.31	0.31
Area of nozzle opening (ft <sup>2</sup> )	0.000524	0.000524	0.000524
Average $\Delta P$	0.7843	0.7418	0.7846
Average $\Delta H$	2.45	2.52	2.85
Average stack temperature (°R)	1004.00	979.88	981.67
Average meter temperature (°R)	569.38	572.88	583.17
Meter volume (ft <sup>3</sup> )	51.59	52.5	56.45
Dry standard sample volume (ft <sup>3</sup> )	45.70	46.24	48.88
Collected condensate volume (ml)	205.0	222.0	183.0
Volume of water vapor (std. ft <sup>3</sup> )	9.65	10.45	8.61
Moisture content of flue gas (% v/v)	17.43	18.43	14.98
Sum of metals collected (μg)	148.2	208.4	180.2
Sum of metals concentrations (μg/dscm)	284.0	390.1	344.6
Sum of metals mass rates (lb/h)	0.006	0.008	0.007
Source gas velocity (ft/s)	63.9	59.8	63.0
Isokinetic variation (%)	92.2	98.5	95.1

**3 REGULATORY EMISSION STANDARDS AND GUIDELINES****3.1 Technology-based Standards versus Risk-based Standards**

The trend of regulations has been from risk-based standards toward technology-based standards. Before the present federal regulations were in place for municipal waste combustion, many states took the initiative and wrote standards based on the health risk associated with emissions at ground level, and required risk assessments to be prepared on the basis of modeling.

The Clean Air Act Amendments of 1990 required that Maximum Available Control Technology (MACT) standards be developed which would take into account the “best per-

forming” combustion systems, requiring that new facilities meet these more stringent emission standards and that existing facilities be upgraded to higher standards.

In spite of having to comply with the new federal standards and more stringent state standards, permits may continue to be subject to public scrutiny on a one-by-one basis, which means that environmental impact will still be considered for pollutants which are not numerically regulated by federal and state regulations.

New Source Performance Standards (NSPS) are firm for new facilities, but less stringent guidelines are set for existing units. Note that “unit” means a single line of equipment, not the entire facility. All stack emission data is reported after correction to 7% oxygen.

### 3.2 Proposed Guidelines

In addition to stack emission requirements, guidelines have been issued regarding design and operation of waste combustion systems. Guidelines are used for review, but need not necessarily be followed if the performance and compliance tests can be met.

Combustion temperatures are to be maintained at 1800°F for one (or two) seconds after the last injection of secondary combustion air.

To confirm the probability of a given system being able to comply with these regulations, a number of calculations may be made. Some of these will be described and carried out for typical systems in the following sections.

### 3.3 Regulatory Standards

The following summaries greatly simplify the requirements, but are presented in order to point out the differences in general approaches to the various types of systems. More detailed summaries are presented in Tables 4.1–4.5.

**Municipal Waste Combustor (MWC)** emission limits have been established by the US EPA for existing and new units, and for two size categories: between 38.6 tons per day (t/d) and 248 t/d, and greater than 248 t/d, as shown in Table 4.1.

MWCs are required to demonstrate the following in periodic compliance tests:

Particulate matter (PM) emissions are limited to 0.015 grains/dscf at 7% oxygen.

Carbon monoxide (CO) emissions are not to exceed 50 ppm on a rolling average, with exemptions of 150 ppm for refuse-derived fuel (RDF) systems.

Hydrogen chloride (HCl) is limited to 30 ppm at 7% oxygen or 95% control.

Sulfur dioxide (SO<sub>2</sub>) is limited to 50 ppm at 7% oxygen or 80% control.

Nitrogen oxides (NO<sub>x</sub>) are limited to 150 ppm at 7% oxygen.

Mercury, lead and cadmium emissions are limited quantitatively.

The system is permitted to operate at a maximum feed rate, usually specified as tons per day of defined wastes having a specified reference heating value.

**Biomedical Waste Combustor (BWC)** emission limits have been established by the US EPA for existing and for new units for three size categories: small units, < 200 pounds per hour (pph); medium units, 200–500 pph; and large units, > 500 pph. Special consideration has been made for MWCs in rural areas, which have small environmental impact and also cannot support the costs of elaborate controls from an economic point of view. Emission limits for existing BWCs are shown in Table 4.2, and for new BWCs in Table 4.3.

BWCs are required to demonstrate the following:

**TABLE 4.1** US EPA Emission Standards for Municipal Waste Combustors (MWCs)

Pollutant (test method)	Units	Emission limits at 7% oxygen			
		Existing units		New units	
		> 38.6 t/d	> 248 t/d	> 38.6 t.d	> 348 t/d

Source: EPA, July 1999.

Particulate matter (PM) emissions are limited to 0.015 grains/dscf at 7% oxygen. Carbon monoxide (CO) emissions are not to exceed 100 ppm on a rolling average. Hydrogen chloride (HCl) is limited to 30 ppm at 7% oxygen or 95% control. Sulfur dioxide (SO<sub>2</sub>) is limited to 50 ppm at 7% oxygen or 80% control. Nitrogen oxides (NO<sub>x</sub>) are limited to 150 ppm at 7% oxygen. Mercury, lead and cadmium emissions are limited quantitatively.

The system is permitted to operate at a maximum feed rate, usually specified as pounds per hour or tons per day of defined wastes.

**Hazardous Waste Combustor** (HWC) emission limits have been established by the US EPA, as shown in Table 4.4, for existing and new units, with specific limits for hazardous waste incinerators (HWIs), cement kilns (CKs) and lightweight aggregate kilns (LWAKs).

The metals are divided into Hg on the one hand, and semi- and low-volatile groups on the other. Averaging times are different for different pollutants. All data is corrected to 7% oxygen.

HWIs must demonstrate the following in trial burns and periodic compliance tests:

POHCs are required to demonstrate a 99.99% destruction and removal efficiency (DRE). Hydrogen chloride (HCl) emissions are to be less than 5 lb/h or 99% removed. Particulate matter (PM) emissions are limited to 0.03 grains/dscf at 7% oxygen. Carbon monoxide (CO) emissions are not to exceed 150 ppm on a rolling average. Mercury, lead and cadmium emissions are limited quantitatively.

**TABLE 4.4** US EPA Emission Limits for Hazardous Waste Combustors, Final Rule, Sept. 30, 1999

Pollutant	Averaging time	Units	Emission limits					
			Incinerator		Cement kiln		Lightweight aggregate kiln	
			Existing	New	Existing	New	Existing	New
PM	CEM 2 h	mg/dscm (gr/dscf)	34.5 (0.015)	34.5 (0.015)			57 (0.025)	57 (0.025)
CDD/DF	Stack	kg/Mg ng/dscm	0.2 or 0.4 <sup>1</sup>	0.2	0.15	0.15	0.2 or 0.4 <sup>1</sup>	0.2
HC	CEM	ppmdv	10	10	10	10	20	20
CO	CEM	ppmdv	100	100	100	100	100	100
HCl + C <sub>2</sub>	CEM 10 h	ppmdv	77	21	130	86	230	41
Hg	CEM 10 h	μg/dscm	130	45	120	56	47	33
Semivol. metals Pb, Cd, (sum)	CEM 10 h	μg/dscm	240	24	240	180	250	43
Low vol. metals	Stack or CEM	μg/dscm	97	97	56	56	110	110
As, Be, Cr Sb (sum)	10 h							

*Note:* All emission rates corrected to 7% oxygen.

*Note:* If the gas temperature at the inlet of the initial particulate control device is maintained below 400°F.

Critical operating parameters are to be maintained within limits established by the trial burn tests, and may require waste feed shutoffs when these limits are exceeded.

*Waste Incinerator Emission Guidelines for some European countries* are outlined in Table 4.5. They are notably different from the US EPA limits in the averaging times, i.e., 24-h average, maximum  $\frac{1}{2}$  h, weekly mean and 24-h maximum. Also notable is the division of heavy metals into three classes, each class being the sum of a group of like-behaving metals. Note that the Federal Republic of Germany requires correction of the data only when the oxygen level exceeds 11% oxygen, not otherwise, whereas the European Community Directive calls for correcting all data to 11% oxygen.

### 3.4 Good Combustion Practice

US EPA Standards for Good Combustion Practice (GCP) have been developed which apply to all waste combustors: essentially, they require that no waste be fed until the furnace temperature is at least 1600°F, and that the gaseous products of combustion be retained for at least one second at 1800°F or higher for most wastes, or for two seconds at 2000°F for wastes containing large quantities of halogenated compounds which are more difficult to destroy. Hazardous waste incinerators have been subjected to stringent regulation due to the potentially toxic emissions from the wide range of organic and inorganic compounds which may be in the wastes, and which define them as hazardous. These regulations require that trial burns be performed as a permit condition, during which it is demonstrated that the system can achieve 99.99% destruction and removal efficiency (DRE) while burning the principal organic hazardous compounds (POHC) and heavy metals. The assumption behind

**TABLE 4.5** Waste Incinerator Emission Guidelines for Some European Countries

Measurement	Federal Republic of Germany 17.BImSch V, Nov. 1990 All waste plants mg/Nm <sup>3</sup> dry at > 11% oxygen		European Community Directive for new facilities mg/Nm <sup>3</sup> at 11% O <sub>2</sub>	
	24-h avg.	max. $\frac{1}{2}$ h	max. $\frac{1}{2}$ h	24-h max.

Source: Licata *et al.*, 1999.

these tests was that the emissions would be related to the feed materials; hence the feed must be analyzed in normal operation and be anticipated as the basis for the trial burns. In view of the fact that modern combustion and emission control systems which can meet present regulatory standards actually destroy or remove all but traces of the target substances, the tendency has been to focus on the actual emissions and assure that they will not exceed the new, stringent standards.

### 3.5 Stack Testing and Monitoring

An essential part of this focus on actual stack emissions, which applies to all waste combustors, is the requirement that monitoring instruments be installed and operated, providing a continuous record of compliance. Continuous measurement of carbon monoxide (CO) and/or hydrocarbons (HC) and oxygen provides assurance of good combustion. These are useful surrogates for trace organic compounds including dioxins and furans. Measurement of HCl, SO<sub>2</sub> and NO<sub>x</sub> may be required, where applicable. Opacity measurements provide continuous supervision of the combustion process as well as the emission control system.

### 3.6 Ash Residue Management

Ash residues from combustion of wastes are generally required to be tested for toxicity and managed appropriately. If found to fail the toxic characteristic leaching procedure (TCLP) test, they may have to be treated, or disposed in suitable landfills. The source of toxicity is

generally the heavy metals, specifically lead and cadmium, which are not destroyed by the combustion process and hence end up in the flyash or bottom ash residues. The use of alkaline reagents for control of the acid gases adds another component to the disposal problem, since excess alkalinity can increase the solubility of these metals in the ash residues.

### 3.7 Operator Certification and Training

In addition to requiring good combustion practice and regulating emissions, an essential component of the newly promulgated regulations is the requirement for operator training and certification, applied appropriately to municipal, medical and hazardous waste combustion systems.

## 4 CALCULATIONS TO CONFIRM COMPLIANCE WITH STANDARDS

---

Any combustion/emission control system consists of a succession of components which must be designed to operate as a unified system while burning the specified wastes, achieving specified furnace temperatures and meeting the regulatory emission limits, while being fired at a specified heat input, or waste feed rate(s).

Calculations made regarding such unified systems must show that the components can all perform at the required rates, specifically at the rates allowed by the permits. Compliance tests are required to confirm emissions which, in principle, are dependent on the performance of the system.

For example, the gas flows provided by the combustion air fans, passing through the primary and secondary chambers, boilers and, taking into consideration infiltration, the emission control systems and induced draft fan, should be consistent, and provide the desired secondary furnace retention time at the required furnace temperature. In addition, the flow rates of quench water, scrubber blowdown and reagent feed must be sufficient to control the specified temperatures and quantities of acid gases on which the design is based. In order to establish these quantities, a complete mass flow calculation is needed, based on a heat and mass-flow analysis.

In the following sections, example calculations are provided, encompassing the complete system from feed to stack.

The proposer of a waste combustion system must make an application to regulatory authorities which predicts that the system will comply with local, state and federal requirements. The permit writer of the regulatory authority must review this submission and make a judgement as to whether the system will probably comply. Subsequently, the system will have to be tested in order to confirm compliance, and to obtain a permit to operate.

This section will review the basic requirements which must be met by three basic types of combustion system, each of which is subject to substantially different regulatory requirements.

### 4.1 Municipal Waste Combustion System

The following is an approximate calculation for a 1000 ton per day (tpd) municipal waste combustion system with heat and power recovery. A single unit is considered. In most cases, plant capacity is divided into two or even three units. The emission consequences of each of the multiple units would be essentially the same as those of this single unit.

Waste composition—Typical composition of municipal solid waste:

Component	Percent in MSW
Carbon	26.4
Hydrogen	3.74
Oxygen	18.19
Nitrogen	0.40
Chlorine	0.31
Fluorine	0.01
Sulfur	0.20
Moisture	30.0
Ash/inert	20.5

$$\text{Higher heating value (HHV)} = 5000 \text{ Btu/lb}$$

$$\text{Moisture and ash-free HHV (MAFHHV)} = 10,000 \text{ Btu/lb}$$

$$\text{Waste feed rate at 1000 tpd} = 41.7 \text{ tph} = 83,000 \text{ lb/h}$$

$$\begin{aligned} \text{Heat released by waste} &= 83,000 \text{ (lb/h)} \times 5000 \text{ (Btu/lb)} \\ &= 416,600,000 \text{ Btu/h} \end{aligned}$$

The heat and mass balance determines that a furnace temperature of 2200°F requires the use of 88% excess air, assuming zero heat loss from the primary furnace.

The heat and mass balance determines the flow rate of gaseous products for the 2200°F furnace temperature to be 7.48 lbp/lbf.

$$\text{The mass flow of product gases} = 83,000 \text{ (lb/h)} \times 7.48 \text{ (lbp/lbf)} = 620,840 \text{ lb/h}$$

For a typical stoker heat release rate of 350,000 Btu/(h · ft<sup>2</sup>), the grate area would be:

$$416,000,000 \text{ (Btu/h)} / 350,000 \text{ (Btu/(h} \cdot \text{ft}^2)) = 1190 \text{ ft}^2$$

At 25 ft long, width = 46ft

For a furnace volumetric heat release of 8000 Btu/(h · ft<sup>3</sup>), the furnace volume would be:

$$416,600,000 \text{ (Btu/h)} / 8000 \text{ (Btu/(h} \cdot \text{ft}^3)) = 52,000 \text{ ft}^3$$

For a furnace plan area of 25 ft × 46 ft = 1150 ft<sup>2</sup>

$$\text{furnace height} = 52,000 / 1150 = 45 \text{ ft}$$

Determine the volume of combustion chamber equivalent to 1 s retention time:

$$\begin{aligned} \text{Volume of gases at 2200}^\circ\text{F} &= 620,840 \text{ (lbp/h)} \times (460 + 2200) \times 13.5 \text{ (ft}^3\text{/lb)} / (530 \times 3600) \\ &= 11,670 \text{ ft}^3\text{/s} \end{aligned}$$

For a retention time of 1 s

$$\text{volume is } 11,670 \text{ ft}^3$$

For a plan area of 25 × 46 = 1150 ft<sup>2</sup>

$$\text{height} = 11,670 / 1150 = 10 \text{ ft}$$

For actual height of 45 ft

$$\text{retention time} = 4.4 \text{ s}$$

Determine heat recovered by the boiler,  $Q_b$ , assuming the boiler exit temperature is 450°F.

Assuming average specific heat of gases is 0.30 Btu/(lb · °F), the heat absorbed by the boiler,  $Q_b$  is

$$\begin{aligned} Q_b &= wc(T_{\text{in}} - T_{\text{out}}) = 620,840 \text{ [lbp/h]} \times 0.30 \text{ [Btu/(lb} \cdot \text{°F)]} \times (2200 - 450) \text{ [°F]} \\ &= 325,940,000 \text{ Btu/h} \end{aligned}$$

Calculate boiler efficiency = heat absorbed by boiler/heat supplied in fuel:

$$\eta_b = 325,940,000/416,600,000 = 78.5\%$$

Calculate steam generation and power production for typical boiler conditions:

Steam generation at 1200 Btu/lb steam

$$= 325,940,000/1200 \text{ [Btu/lb]} = 27,162 \text{ lb/h}$$

Power generation at 11,000 Btu/(kW · h)

$$= 325,940,000 \text{ [Btu/h]}/11,000 \text{ [Btu/(kW} \cdot \text{h)]} = 29,631 \text{ kW} = 29.6 \text{ MW}$$

Calculate water spray needed to cool gases to 300°F:

$$620,840 \text{ [lbp/h]} \times 0.3 \text{ [Btu/(lb} \cdot \text{°F)]} \times (450 - 300) \text{ [°F]} = 27,900,000 \text{ Btu/h}$$

$$\text{Water evaporated} = 27,900,000 \text{ [Btu/h]}/1000 \text{ [Btu/lb]}$$

$$= 27,900 \text{ lb/h} = 56.5 \text{ gal/min}$$

Gas flow entering fabric filter and handled by the induced-draft fan:

$$620,900 + 27,900 = 648,000 \text{ lb/h}$$

The specific volume of the gases is calculated to be 13.59 std. ft<sup>3</sup>/lb at standard conditions.

$$\begin{aligned} \text{At } 300^\circ\text{F, the actual flow volume} &= 13.59 \text{ [std. ft}^3\text{/lb]} \times [(460 + 300)/530] \\ &\times 648,000 \text{ [lb/h]}/60 \text{ [min/h]} = 210,470 \text{ acfm} \end{aligned}$$

Calculate the volumetric composition of the stack gases:

Gas	Wet basis (%)	Dry basis (%)	
CO <sub>2</sub>	8.47	9.80	(CO <sub>2</sub> + O <sub>2</sub> = 19.73%)
O <sub>2</sub>	8.58	9.93	
N <sub>2</sub>	69.30	80.18	
H <sub>2</sub> O	<u>13.58</u>	<u>0</u>	
	100%	100%	
HCl = 396	ppmv (parts per million by volume)		
HF = 24.5	ppmv		
SO <sub>2</sub> = 406	ppmv		

Calculate factor for correction to composition of stack gases to 7% oxygen, dry. Note the difference between the actual sum of CO<sub>2</sub> + O<sub>2</sub> and the “standard” factor:

$$\begin{aligned}\text{Actual factor} &= [\text{CO}_2 + \text{O}_2 - \text{O}_2\%]/[\text{CO}_2 + \text{O}_2 - 7\%] \\ &= [19.73 - 9.93]/[19.7 - 7] = 0.77\end{aligned}$$

“Regulatory” factor =

$$\begin{aligned}\text{ratio} &= \frac{20.5 - (\text{O}_2)_{\text{actual}}}{20.5 - (\text{O}_2)_{\text{standard}}} = \frac{20.5 - 9.93}{20.5 - 7} = 10.58/13.5 \\ &= 0.78 = 1/1.276\end{aligned}$$

Using the “standard” factor to correct from the higher oxygen content (more excess air) to the “reference” 7% oxygen increases the concentration:

$$(\text{HCl})_{\text{corrected}} = 396 \times 1.276 = 504 \text{ ppm}$$

$$(\text{SO}_2)_{\text{corrected}} = 406 \times 1.276 = 517 \text{ ppm}$$

To comply with 25 ppmv HCl, the removal efficiency must be

$$(500 - 25)/500 = 95\%$$

To comply with 30 ppmv SO<sub>2</sub>, the removal efficiency must be

$$(517 - 30)/640 = 94\%$$

The alternative is 80% removal, reducing 640 to

$$(517 - (0.85 \times 517)) = 103 \text{ ppmv}$$

*Estimate alkaline reagent needed to control SO<sub>2</sub> and HCl to regulatory limits.*

Calculate stoichiometric requirements:

HCl input is 0.31 lb/100 lb, or

$$83,000 \text{ [lbw/h]} \times 0.0031 \text{ [Cl]} = 257 \text{ lb/h} \times [35 + 1]/35 = 264 \text{ lb/h}$$

From Table 4.6, at 300°F, the Ca(OH)<sub>2</sub> required would be

$$1.6 \times 264 = 422 \text{ lb/h}$$

Sulfur input is 0.20 lb/100 lb, or

$$83,000 \times 0.002 = 166 \text{ lb/h [S]} \times [44/12] = 609 \text{ lb/h}$$

From Table 4.6, at 300°F, the Ca(OH)<sub>2</sub> required would be

$$3.7 \times 609 = 2253 \text{ lb/h}$$

In practice, the lime which must be added is greater than the stoichiometric quantity, depending upon the percent removal required. The above numbers should probably be increased by a factor of at least 50%, depending upon the effectiveness of the APC system itself.

*Calculate metals in stack gases after emission controls of MSW facility*

Using the data from the tests of the 650 tpd combustor at Burnaby, a facility with dry lime injection and with reactor tower and fabric filter:

**TABLE 4.6** Calculated Theoretical Reagent Requirements per Tonne of Gaseous Pollutants

Pollutant	Gas temperature		Stoichiometric ratio Ca(OH) <sub>2</sub>	Consumption in tonnes (94%)
	°C	°F		
SO <sub>2</sub>	120–160	250–320	3.0	3.7
	160–220	320–428	3.5	4.3
	220–280	428–536	5.0	6.2
HCl	120–160	250–320	1.5	1.6
	160–220	320–428	1.8	2.0
	220–280	428–536	2.0	2.2
HF	120–280	250–536	1.0	2.1

*Source:* Benson and Licata, 1998.

$$\text{Waste flow} = 650 \times 2000/24 = 54,170 \text{ lb/h} = 27 \text{ t/h}$$

$$\text{Stack gas flow} = 830 \text{ dscm/min} \times 60 = 49,800 \text{ dry std m}^3/\text{h}$$

*Cadmium emissions:*

Cadmium in the waste at Burnaby was estimated to be 27,000 lb/million tons (Mt). (This is 13.5 parts per million parts (ppm) weight of MSW. Assuming ash is 20% of MSW, this is  $13.5/0.2 = 67.5$  ppm in the ash if all goes to ash, or, if 80% goes to ash, 54 ppm cadmium in the dry ash.) The cadmium leaving the boiler was measured to be 5723 lb/Mt, a reduction factor of 5. This means that 80% of the cadmium reported to the ash residues and 20% to the gases entering the emission controls. From the measured stack emissions of 18 lb/Mt, the control efficiency is calculated to be 99.7%.

Cadmium in the stack was

$$18 \text{ [lb/Mt]} \times 27 \text{ [t/h]} \times 454 \text{ [g/lb]} / 1,000,000 \text{ [lb/Mt]} = 0.221 \text{ g/h}$$

Cadmium concentration in stack

$$= 0.221 \text{ [g/h]} / 49,800 \text{ [dry std. m}^3/\text{h]} = 4.43 \text{ }\mu\text{g/dscm}$$

This is 22% of the US EPA standard of 20  $\mu\text{g/dscm}$  for new MWCs. If the control efficiency had been 99.00 instead of 99.70, the result would have been 15  $\mu\text{g/dscm}$ .

European guideline: 200  $\mu\text{g/dscm}$  corrected to 11% for Hg + Cd

US EPA Cd standard:

for small existing MSW units: 100  $\mu\text{g/dscm}$  corrected to 7% oxygen

for large existing MSW units: 40  $\mu\text{g/dscm}$  corrected to 7% oxygen

for new MSW units: 20  $\mu\text{g/dscm}$  corrected to 7% oxygen

*Lead emissions:*

Lead in the stack was

$$363 \text{ [lb/Mt]} \times 27 \text{ [t/h]} \times 454 \text{ [g/lb]} / 1,000,000 \text{ [lb/Mt]} = 4.45 \text{ g/h}$$

Lead concentration in stack

$$= 4.45 \text{ [g/h]} / 49,800 \text{ [m}^3/\text{h]} = 89.4 \text{ }\mu\text{g/dscm}$$

This is 44% of the US EPA standard of 200  $\mu\text{g/dscm}$  for new MWCs. If the control efficiency had been 97.00 instead of 98.3, this would have resulted in 158  $\mu\text{g/dscm}$ .

*Mercury emissions:*

Mercury entering the APC was

$$3630 \text{ [lb/Mt]} \times 27 \text{ [t/h]} \times 454 \text{ [g/lb]} / 1,000,000 \text{ [lb/Mt]} = 44.5 \text{ g/h}$$

Mercury concentration in stack

$$= 44.5 \text{ [g/h]} / 49,800 \text{ [m}^3\text{/h]} = 894 \text{ }\mu\text{g/dscm}$$

This exceeds the standard of 20  $\mu\text{g/dscm}$  for new units and 100  $\mu\text{g/dscm}$  for small existing units. Carbon injection would be required, with a control efficiency of 90%.

#### 4.2 Biomedical Waste Combustion System

The following is an approximate calculation for a 1000 tpd municipal waste combustion system with heat and power recovery. A refractory chamber with 10% heat loss is assumed.

Composition of typical biomedical waste:

Component	Weight percent
Carbon	42.19
Hydrogen	4.20
Oxygen	19.41
Nitrogen	0.74
Chlorine	0.60
Fluorine	0.10
Sulfur	0.36
Moisture	20.76
Ash/inert	9.00

$$\text{HHV} = 7000 \text{ Btu/lb}$$

$$\text{MAF HHV} = 10,000 \text{ Btu/lb}$$

Heat released by waste

$$= 1000 \text{ [lb/h]} \times 7500 \text{ [Btu/lbw]} = 7,500,000 \text{ Btu/h}$$

Determine by heat balance the excess air required to maintain this temperature:

$$141\%$$

By heat and mass balance,

product gas for 1800°F primary furnace temperature is: 9.36 lbp/lbw

$$\text{Product gas flow, } W = 1000 \text{ [lbw/h]} \times 9.36 \text{ [lbp/lbw]} = 9360 \text{ lbp/h}$$

Grate area for heat release of 7,500,000 Btu/h at 150,000 Btu/(h · ft<sup>2</sup>):

$$\text{Grate area} = 7,500,000 \text{ [Btu/h]} / 150,000 \text{ [Btu/(h} \cdot \text{ft}^2\text{)]} = 50 \text{ ft}^2$$

$$\text{For length} = 12 \text{ ft, width} = 4.2 \text{ ft}$$

$$\begin{aligned} \text{Volume of primary chamber for heat release of } 25,000 \text{ Btu}/(\text{h} \cdot \text{ft}^3) \\ = 7,500,000/25,000 = 300 \text{ ft}^3 \end{aligned}$$

For diameter of 5ft,

$$\begin{aligned} \text{area} &= 25 \times 0.786 = 19.65 \text{ ft}^2 \\ \text{length} &= 300 \text{ ft}^3 / 19.65 \text{ ft}^2 = 15.27 \text{ ft} \end{aligned}$$

Determine volume of secondary combustion chamber equivalent to 1 s retention time:

Volume of gases at 1800°F

$$= 9360 \text{ [lb/h]} \times [460 + 1800] \times 13.5 \text{ [ft}^3/\text{lb}]/(530 \times 3600) = 150 \text{ ft}^3/\text{s}$$

For retention time of 2 s,

$$\text{volume is } 300 \text{ ft}^3$$

For diameter of 4.5 ft,

$$\begin{aligned} \text{area} &= 15.92 \text{ ft}^2 \\ \text{length} &= 300/15.92 = 18.8 \text{ ft} \end{aligned}$$

Secondary chamber is about 4.5 ft diam.  $\times$  20 ft long.

Determine heat exchange to boiler, assuming boiler exit temperature is 450°F.

Assuming average specific heat,  $c$ , of gases is 0.30 Btu/(lb  $\cdot$  °F),

$$\begin{aligned} Q &= wc(T_{\text{in}} - T_{\text{out}}) = 9360 \text{ [lb/h]} \times 0.30 \text{ [Btu}/(\text{lb} \cdot \text{°F})] \times (1800 - 450) \\ &= 3,790,000 \text{ Btu/h} \end{aligned}$$

Boiler efficiency

$$= 3,790,000 \text{ [Btu/h output]} / 7,500,000 \text{ [Btu/h input]} = 50.5\%$$

Calculate steam generation and power production for typical boiler conditions.

Steam generation at 1000 Btu/lb steam

$$= 3,790,000/1000 = 3790 \text{ lb/h at } 200 \text{ psig}$$

Power generation at 15,000 Btu/(kW  $\cdot$  h)

$$= 3790/15,000 = 2530 \text{ kW} = 2.53 \text{ MW}$$

Calculate water spray needed to cool gases to 300°F

$$9360 \text{ [lb/h]} \times 0.3 \text{ [Btu}/(\text{lb} \cdot \text{°F})] \times (450 - 300) \text{ [°F]} = 421,200 \text{ Btu/h}$$

Water evaporated

$$\begin{aligned} &= 421,200 \text{ [Btu/h]} / 1000 \text{ [Btu/lb]} = 421 \text{ [lb/h]} / 8.6 \text{ [lb/gal]} \times 60 \text{ [min/h]} \\ &= 0.82 \text{ gal/min} \end{aligned}$$

Gas flow entering fabric filter and handled by the induced-draft fan:

$$9360 + 421 = 9781 \text{ lb/h}$$

The specific volume is calculated to be 13.59 std. ft<sup>3</sup>/lb, at standard conditions.

The actual flow volume

$$= 13.59 \text{ [std. ft}^3\text{/lb]} \times [(460 + 300)/530] \times 9781 \text{ [lb/h]}/60 \text{ [min/h]}$$

$$= 3206 \text{ ft}^3\text{/min.}$$

Calculate volumetric composition of stack gases:

Gas	Wet basis (%)	Dry basis (%)	
CO <sub>2</sub>	6.73	7.54	(CO <sub>2</sub> + O <sub>2</sub> = 7.54 + 12.37 = 19.91%)
O <sub>2</sub>	5.69	12.37	
N <sub>2</sub>	71.39	80.04	
H <sub>2</sub> O	<u>10.80</u>	<u>0.0</u>	
	100%	100%	
HCl = 305 ppmv			
HF = 19 ppmv			
SO <sub>2</sub> = 313 ppmv			

Calculate composition of stack gases corrected to 7% oxygen, dry:

$$\text{Actual factor} = [\text{CO}_2 + \text{O}_2 - \text{O}_2\%]/[\text{CO}_2 + \text{O}_2 - 7\%] = [19.91 - 11.03]/[19.91 - 7]$$

$$= 0.688 = 1/1.454$$

$$\text{Regulatory ratio} = \frac{20.5 - (\text{O}_2)_{\text{actual}}}{20.5 - (\text{O}_2)_{\text{standard}}} = \frac{20.5 - 11.03}{20.5 - 7} = 10.58/13.5 = 0.70 = 1/1.276$$

Correcting from the higher oxygen content (more excess air) to 7% oxygen increases the concentration:

$$(\text{HCl})_{\text{corrected}} = 305 \times 1.276 = 389 \text{ ppm}$$

$$(\text{SO}_2)_{\text{corrected}} = 313 \times 1.276 = 400 \text{ ppm}$$

To comply with 15 ppm HCl, the removal efficiency must be

$$(389 - 15)/389 = 96\%$$

Alternatively, 99% removal

$$= 389 \times (1 - 0.99) = 3.9 \text{ ppmv}$$

To comply with 55 ppm SO<sub>2</sub>, the removal efficiency must be

$$(400 - 55)/400 = 86.3\%$$

Using the alternative of 85% removal would reduce 400 ppm to

$$(400 - (0.85 \times 400)) = 60 \text{ ppm}$$

*Estimate alkaline reagent needed to control SO<sub>2</sub> and HCl to regulatory limits.*

HCl input is 0.31 lb/100 lb, or

$$83,000 \text{ [lbw/h]} \times 0.0031 \text{ [Cl]} = 257 \text{ lb/h} \times [35 + 1]/35 \\ = 264 \text{ lb/h}$$

Sulfur input is 0.20 lb/100 lb, or

$$83,000 \times 0.002 = 166 \text{ lb/h [S]} \times [44/12] = 609 \text{ lb/h}$$

To remove all of the sulfur,

$$\text{Ca(OH)}_2 = 609 \text{ [lb/h]} \times 3.7 \text{ [lb/lb]} = 2253 \text{ lb/h}$$

To remove all of the HCl,

$$\text{Ca(OH)}_2 = 264 \text{ [lb/h]} \times 1.6 \text{ [lb/lb]} = 422 \text{ lb/h}$$

The effectiveness of the emission control system is less than 100%; hence more reagent will actually be required.

### 4.3 Liquid Waste Combustion System

The following is a calculation for a 40 million Btu/h rotary kiln hazardous waste combustion system with heat recovery. A refractory chamber heat loss of 10% is assumed.

Liquid waste composition:

Component	Weight %
Carbon	57.30
Hydrogen	7.56
Oxygen	6.00
Nitrogen	22.52
Chlorine	1.47
Fluorine	0.01
Sulfur	0.01
Moisture	4.21
Ash/inert	0.92

$$\text{HHV} = 12,975 \text{ Btu/lb}$$

$$\text{MAF HHV} = 13,676 \text{ Btu/lbf}$$

Calculate waste feed rate for input of 40 million Btu/h:

$$40,000,000 \text{ [Btu/h]} / 13,676 = 2925 \text{ lbw/h}$$

Determine excess air required to maintain 2200°F furnace temperature:

$$141\%$$

Calculate product gas flow rate for 2200°F secondary furnace temperature:

$$19.33 \text{ lb/g/lbw}$$

Product gas flow

$$\begin{aligned} &= 3083 \text{ lbw/h} \times 19.33 \text{ lbp/lbwf} \\ &= 59,592 \text{ lbp/h} \end{aligned}$$

Determine kiln volume for heat release rate of 35,000 Btu/(h · ft<sup>3</sup>):

$$40,000,000 \text{ [Btu/h]} / 35,000 \text{ [Btu/(h · ft}^3\text{)]} = 11,428 \text{ ft}^3$$

For diameter of 10 ft,

$$\begin{aligned} \text{area} &= 78.6 \text{ ft}^2 \\ \text{length} &= 1142/78.6 = 14.5 \text{ ft} \end{aligned}$$

Determine volume of combustion chamber equivalent to 1 s retention time:

Volume of gases at 2200°F

$$\begin{aligned} &= 59,592 \text{ [lbp/h]} \times (2200 + 460) \text{ [°F]} \times 13.3 \text{ [ft}^3\text{/lbp]} / (530 \times 3600) \\ &= 1105 \text{ ft}^3\text{/s} \end{aligned}$$

For retention time of 2 s,

$$\text{volume is } 2243 \text{ ft}^3$$

For diameter of 10 ft

$$\begin{aligned} \text{area} &= 78.6 \text{ ft}^2 \\ \text{length} &= 2243/78.6 = 28.5 \text{ ft (OK)} \end{aligned}$$

Heat release

$$= 40,000,000/2243 = 17,833 \text{ Btu/(h · ft}^3\text{)}$$

Determine heat exchange to boiler, assuming boiler exit temperature is 450°F.

Assuming average specific heat,  $c$ , of gases is 0.30 Btu/(lb · °F),

$$\begin{aligned} Q &= wc(T_{\text{in}} - T_{\text{out}}) = 59,592 \text{ [lbp/h]} \times 0.30 \text{ [Btu/(lb · °F)]} \times (2200 - 450) \text{ [°F]} \\ &= 31,286,000 \text{ Btu/h} \end{aligned}$$

Boiler efficiency

$$\begin{aligned} &= \text{output/input} = 31,286,000/40,000,000 \\ &= 78\% \end{aligned}$$

Calculate steam generation and power production for typical boiler conditions:

Steam generation at 1000 Btu/lb steam

$$= 31,286,000/1000 = 31,286 \text{ lb/h at 200 psig}$$

Power generation at 13,000 Btu/(kW · h)

$$= 31,286,000/13,000 = 2407 \text{ kW} = 2.4 \text{ MW}$$

Calculate water spray needed to cool gases to 300°F:

$$59,592 \text{ [lb/h]} \times 0.3 \text{ [Btu/(lb} \cdot \text{°F)]} \times (450 - 300) \text{ [°F]} = 2,681,600 \text{ Btu/h}$$

Water evaporated

$$\begin{aligned} &= 2,681,600 \text{ [Btu/h]}/1000 = 2681 \text{ lb/h} \\ &= 2681/8.6 \text{ [lb/gal]} \times 60 \text{ [min/h]} \\ &= 5.24 \text{ gal/min} \end{aligned}$$

Gas flow entering fabric filter and handled by the induced-draft fan:

$$59,592 + 2681 = 62,273 \text{ lb/h}$$

The specific volume is calculated to be 13.3 scf/lb at standard conditions.

$$\begin{aligned} \text{At } 300^\circ\text{F, the actual flow volume} &= 62,273 \text{ [lb/h]} \times 13.3 \text{ [std. ft}^3\text{/lb]} \\ &\times [(460 + 300)/530]/60 \text{ [min/h]} = 19,794 \text{ acfm} \end{aligned}$$

Calculate composition of actual stack gases:

Gas	Wet basis	Dry basis	
CO <sub>2</sub>	7.17	7.63	(CO <sub>2</sub> + O <sub>2</sub> = 18.51)
O <sub>2</sub>	10.23	10.88	
N <sub>2</sub>	76.55	81.42	
H <sub>2</sub> O	<u>5.99</u>	<u>0</u>	
	100%	100%	
HCl = 672	ppmv		
HF = 7.9	ppmv		
SO <sub>2</sub> = 7.2	ppmv		

Calculate composition of stack gases corrected to 7% oxygen, dry:

$$\begin{aligned} \text{Actual factor} &= [\text{CO}_2 + \text{O}_2 - \text{O}_2\%]/[\text{CO}_2 + \text{O}_2 - 7\%] = [18.51 - 10.88]/[18.51 - 7] \\ &= 0.663 = 1/1.51 \end{aligned}$$

$$\text{Regulatory ratio} = \frac{20.5 - (\text{O}_2)_{\text{actual}}}{20.5 - (\text{O}_2)_{\text{standard}}} = \frac{20.5 - 10.88}{20.5 - 7} = 9.62/13.5 = 0.7126 = 1/1.403$$

Correcting from the higher oxygen content (more excess air) to 7% oxygen increases the concentration:

$$(\text{HCl})_{\text{corrected}} = 672 \times 1.4 = 941 \text{ ppmv}$$

$$(\text{SO}_2)_{\text{corrected}} = 7.2 \times 1.4 = 10.1 \text{ ppmv}$$

To comply with 99% control, HCl emissions would be

$$(1 - 0.99) \times 941 = 10 \text{ ppmv}$$

There is no requirement for SO<sub>2</sub> control, but it would absorb reagent, which must be considered.

Estimate alkaline reagent needed to control  $SO_2$  and  $HCl$  to regulatory limits.

$HCl$  input is 1.47 lb/100 lb, or

$$\begin{aligned} 0.0147 \times 3083 \text{ [lbw/h]} &= 45.3 \text{ lb/h} \times [35 + 1]/35 \\ &= 46.6 \text{ lb/h} \end{aligned}$$

The 99% control standard would reduce the emissions to  $(1 - 0.99) \times 46.6 = 0.5$  ppmv. The standard of 5 lb/h could be met with  $(45.3 - 9)/45.3 = 90\%$  control.

In order to remove the  $HCl$  with lime, more than  $1.5 \times 46.6 \text{ lb/h} = 70 \text{ lb/h}$   $Ca(OH)_2$  would be needed, depending on the effectiveness of the acid gas control system.

#### 4.4 Aqueous Waste Combustion System

The following is a calculation for a 40 million Btu/h rotary kiln hazardous waste combustion system with heat recovery. A heat loss of 10% is assumed for this refractory system.

Liquid waste composition: Fuel oil must be burned in order to destroy this aqueous waste. The quantity of oil and the composition of the mixture which would achieve a temperature of  $1800^\circ F$  with 50% excess air has been determined by heat balance and is shown in Table 3.7.

$$HHV = 4194 \text{ Btu/lb}$$

$$MAF \text{ HHV} = 16,392 \text{ Btu/lbf (combustible heating value)}$$

Calculate waste feed rate for input of 40 million Btu/h:

$$40,000,000 \text{ [Btu/h]}/4194 = 9537 \text{ lbf/h}$$

Determine excess air required to maintain this temperature:

$$51\%$$

Calculate product gas flow rate for  $1800^\circ F$  secondary furnace temperature:

$$5.50 \text{ lbg/lbf}$$

Product gas flow

$$= 9537 \text{ [lbw/h]} \times 5.50 \text{ [lbg/lbw]} = 52,456 \text{ lbg/h}$$

Determine kiln volume for a volumetric heat release rate of  $35,000 \text{ Btu}/(\text{h} \cdot \text{ft}^3)$ :

$$40,000,000 \text{ [Btu/h]}/35,000 \text{ [Btu}/(\text{h} \cdot \text{ft}^3)] = 11,428 \text{ ft}^3$$

For diameter of 10 ft

$$\text{area} = 78.6 \text{ ft}^2$$

$$\text{length} = 1142/78.6 = 14.5 \text{ ft}$$

Determine volume of combustion chamber equivalent to 1 s retention time:

Volume at  $1800^\circ F$

$$\begin{aligned} &= 52,456 \text{ [lbg/h]} \times [1800 + 460] \times 14.26 \text{ [ft}^3/\text{lb}]/(530 \times 3600) \\ &= 886 \text{ ft}^3/\text{s} \end{aligned}$$

For retention time of 2 s

$$\text{volume is } 2 \times 839 = 1678 \text{ ft}^3$$

For diameter of 10 ft

$$\text{area} = 78.6 \text{ ft}^2$$

$$\text{length} = 1678/78.6 = 21.3 \text{ ft (OK)}$$

Heat release

$$= 40,000,000/1678 = 23,838 \text{ Btu}/(\text{h} \cdot \text{ft}^3)$$

Determine heat transferred to boiler, assuming boiler exit temperature is 450°F.

Assuming average specific heat of gases is 0.30 Btu/(lb · °F),

$$\begin{aligned} Q = wc(T_{\text{in}} - T_{\text{out}}) &= 52,456 \text{ [lbp/h]} \times 0.30 \text{ [Btu}/(\text{lb} \cdot \text{°F})] \times (1800 - 450) \text{ [°F]} \\ &= 21,245,000 \text{ Btu/h} \end{aligned}$$

Boiler efficiency

$$= \text{output}/\text{input} = 21,245,000/40,000,000$$

$$= 53\%$$

Calculate steam generation and power production for typical boiler conditions:

Steam generation at 1000 Btu/lb steam

$$= 21,245,000/1000 = 21,245 \text{ lb/h at 200 psig.}$$

Power generation at 13,000 Btu/(kW · h)

$$= 21,245,000/13,000 = 1634 \text{ kW} = 1.63 \text{ MW}$$

Calculate water spray needed to cool gases to 300°F:

$$52,456 \text{ [lbp/h]} \times 0.3 \text{ [Btu}/(\text{lb} \cdot \text{°F})] \times (450 - 300) \text{ [°F]} = 2,360,500 \text{ Btu/h}$$

Water evaporated

$$= 2,360,500 \text{ [Btu/h]}/1000 \text{ [Btu/lb]}$$

$$= 2360 \text{ [lb/h]}/8.6 \text{ [lb/gal]} \times 60 \text{ [min/h]}$$

$$= 4.57 \text{ gal/min}$$

Gas flow entering fabric filter and handled by the induced-draft fan:

$$52,456 + 2360 = 54,816 \text{ lb/h}$$

The specific volume is calculated to be 14.26 ft<sup>3</sup>/lb at standard conditions.

$$\begin{aligned} \text{The actual volume at } 300^\circ\text{F} &= 54,816 \text{ [lb/h]} \times 14.26 \text{ [std. ft}^3/\text{lb]} \times [(460 + 300)/530]/60 \text{ [min/h]} \\ &= 18,682 \text{ acfm} \end{aligned}$$

Calculate composition of actual stack gases (see Section 2.4):

Gas	Wet basis (vol %)	Dry basis (vol. %)	
CO <sub>2</sub>	7.99	10.65	(CO <sub>2</sub> + O <sub>2</sub> = 17.94)
O <sub>2</sub>	5.47	7.29	
N <sub>2</sub>	61.44	81.91	
H <sub>2</sub> O	<u>24.99</u>	<u>0</u>	
	100.00	100.00	
HCl =	38 ppmv		
HF =	33 ppmv		
SO <sub>2</sub> =	1465 ppmv		

Calculate composition of stack gases corrected to 7% oxygen, dry:

$$\begin{aligned} \text{Actual factor} &= [\text{CO}_2 + \text{O}_2 - \text{O}_2\%]/[\text{CO}_2 + \text{O}_2 - 7\%] = [17.94 - 7.29]/[17.94 - 7] \\ &= 0.973 = 1/1.027 \end{aligned}$$

$$\text{Regulatory ratio} = \frac{20.5 - (\text{O}_2)_{\text{actual}}}{20.5 - (\text{O}_2)_{\text{standard}}} = \frac{20.5 - 10.88}{20.5 - 7} = 9.62/13.5 = 0.9785 = 1/1.022$$

Correcting from the higher oxygen content (more excess air) to 7% oxygen increases the concentration:

$$(\text{HCl})_{\text{corrected}} = 38 \times 1.022 = 39 \text{ ppm}$$

$$(\text{SO}_2)_{\text{corrected}} = 1465 \times 1.022 = 1497 \text{ ppm}$$

The HCl limit of 67 ppmv is complied with.

There is no SO<sub>2</sub> removal requirement. However, to meet 30 ppmv, (1497 - 30)/1497 = 98% control efficiency would be needed.

*Calculate metals in stack gases after emission controls of HWC:*

Assume the waste has been analyzed for cadmium, and the ash residue has been found to contain 5% lead. The input of cadmium is thus 3.4% ash, of which 5% or 0.17% is lead. The input of cadmium is then 2360 lb/h (waste) × 0.17/100 (lead) = 0.401 lb/h cadmium.

Assume all of the cadmium enters the APC, and that the APC efficiency for cadmium is 99.9%.

Cadmium emissions

$$= (1 - 0.999) \times 0.401 \text{ lb/h} = 4.1 \times 10^{-4} \text{ lb/h}$$

The actual wet volume of gases containing this cadmium is 19,948 acfm at 300°F. Correcting to dry gases, take out the volume of moisture: 24.99%. The dry volume is thus

$$19,948 \text{ acfm} \times (100 - 24.99)/100 = 14,963 \text{ acfm}$$

Correcting to 70°F :

$$\begin{aligned} \text{Standard dry volume} &= 14,963 \text{ acfm} \times (70 + 460)/(300 + 460) \\ &= 10,434 \text{ scfm} \end{aligned}$$

The concentration in the stack gases, corrected for temperature, is

$$\begin{aligned} 4.1 \times 10^{-4} \text{ [lb/h]} \times 434 \text{ [g/lb]} \times [35.3 \text{ ft}^3/\text{m}^3] / (10,434 \text{ [ft}^3/\text{min]} \times 60 \text{ [min/h]}) \\ = 10 \mu\text{g}/\text{m}^3 \end{aligned}$$

This must also be corrected from 7.29% to 7% oxygen using the factor derived above, 1.022:

$$\begin{aligned} \text{Corrected concentration of stack gas} &= 1.022 \times 10 \\ &= 10.22 \mu\text{g}/\text{dscm, corrected to 7\% oxygen} \end{aligned}$$

This concentration can be compared with:

European guideline:	200 $\mu\text{g}/\text{dscm}$ corrected to 11% for Hg + Cd
US EPA standard:	
for small existing MSW units:	100 $\mu\text{g}/\text{dscm}$ corrected to 7% oxygen
for large existing MSW units:	40 $\mu\text{g}/\text{dscm}$ corrected to 7% oxygen
for new MSW units:	20 $\mu\text{g}/\text{dscm}$ corrected to 7% oxygen

## 5 ENVIRONMENTAL IMPACT OF STACK EMISSIONS

---

The environmental impact of incinerator stack emissions depends upon many factors which will be discussed in this section. Concentrations of pollutants emitted by the stack are reduced by dispersion in the atmosphere before the gases reach ground level or elevated receptors of concern. The resulting concentrations are evaluated by comparison with health risk standards which have established “acceptable ground level concentrations” (AGLC).

### 5.1 Stack Emissions Concentrations

**Volume of gases leaving the stack.** The volume of stack gases discharged to the atmosphere depends upon whether or not a heat recovery boiler, heat exchanger, dilution air or water evaporation is used to cool the gases. Hence, for a given mass emission rate, the concentration of the pollutants in the gases leaving the stack will depend upon the actual volume of gases discharged.

Figure 4.2 shows the major alternative emission control systems and the stack temperatures characteristic of each system, ranging from 150°F to 390°F.

Table 4.7 shows the range of actual cubic feet per minute (acfm) discharged *per million Btu* of heat released by the waste, and the corresponding actual cubic meters per second (acms).

At a heat release rate of one million Btu per hour, an incinerator with *no* emission control device would discharge 1510 acfm of gases at 1800°F directly to the atmosphere.

- If the gases are diluted by a draft control device such as a barometric damper, reducing their temperature to 1300°F, the quantity increases to 1730 acfm.
- If a wet scrubber is applied to the 1800°F gases, evaporation of the water will reduce the temperature of the gases to about 180°F and the quantity will be reduced to 660 acfm.
- If a boiler is used to cool the gases, and the gases are then cooled by water to 350°F and passed through a baghouse, the gas flow will be reduced to 520 acfm. If a wet scrubber is used, the gases will be cooled to about 145°F and the quantity reduced to 450 acfm.

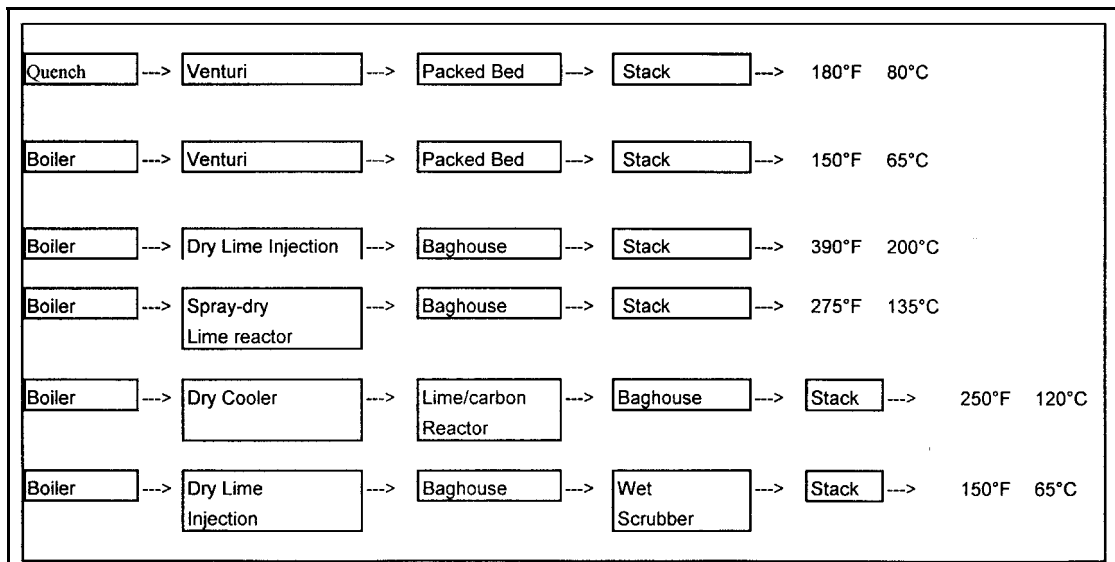

FIGURE 4.2 Alternative emission control systems, with corresponding stack temperatures.

Note that an MWI having *no* boiler or emission controls discharges direct to the stack over *three* times the gas volume of one with a scrubber. For the same pollutant emission *rate*, this results in a reduction in stack pollutant *concentration* by a factor of three.

The actual volume discharged by a typical oil, gas or coal-fired boiler with a stack temperature of 450°F is about 400 acfm per million Btu/h.

*Emission limits* are regulated on the basis of grains per dry standard cubic foot (gr/sdcf), corrected to 7% oxygen (or its equivalent, 12% CO<sub>2</sub>). This represents about 50% excess air, which is typical for operation of fossil fuel-fired boilers. This correction is made in order to use the same regulatory basis for all facilities, eliminating variations in temperature and excess air.

Note that making this correction brings the stack gas flow to 236 *standard* cubic feet per minute (scfm), whereas in reality the various systems actually discharge 450–1500 acfm at temperatures ranging from 145°F to 1800°F. Thus a dilution of 2–6 times actually takes place

TABLE 4.7 Stack Gas Flow at Various Stack Temperatures (per million Btu of heat released in the furnace)

Emission control	Stack temp. (°F)	ACFM (ft <sup>3</sup> /min)	ACMS (m <sup>3</sup> /s)
Direct to stack*	1800	1510	0.71
Diluted with air*	1300	1730	0.82
Boiler only*	450	610	0.29
Boiler and filter*	350	520	0.24
Boiler, spray-dry + filter*	300	490	0.23
Wet scrubber*	180	660	0.31
Boiler and wet scrubber*	145	450	0.21
Fossil-fuel boiler*	450	400	0.19

Based on medical waste at 7500 Btu/lb.

† Based on municipal waste at 5000 Btu/lb/

prior to discharge by the stack, relative to the corrected dry scfm. Making the correction does not change the actual emissions.

If combustors with emission controls are allowed to emit 0.02 gr/dscf of particulate matter, a direct-discharge incinerator logically should be allowed  $1729/450 \times 0.02$  or 0.08 gr/dscf, corrected to 12% CO<sub>2</sub> or 7% O<sub>2</sub>, since they achieve more dilution before the gases are discharged. The original US EPA Federal Standard was 0.08 gr/dscf for all incinerators.

Likewise, if the particulate emissions from an incinerator are the concern, a direct-discharge incinerator without boiler or scrubber with emissions of 0.045 gr/dscf, corrected, would have emissions equivalent to 0.015 gr/dscf for systems with scrubbers, and the stack concentration would actually be the same.

## 5.2 Dispersion in the Atmosphere

**Dispersion of stack gases by the atmosphere.** After the gases leave the stack, dispersion takes place, resulting in substantial dilution of the concentration of pollutants in the plume of gases as it spreads out into the environment by mixing with the ambient air.

Before the plume of gases reaches critical receptors in the environment at ground level or at elevated windows or buildings, the gases have been dispersed and diluted substantially. The environmental and health risk arising from the emission of pollutants from MWIs depends upon how effectively this dispersion process takes place.

The relationship between stack emissions and ground level concentrations (GLC) is determined by computer modeling. The burning capacity of the incinerator, stack diameter, velocity, temperature and height, meteorological (weather) data, the configuration of buildings and the general terrain are taken into account.

Dispersion models provide calculated concentrations of pollutants at ground and elevated levels. Simple models, such as the EPA SCREEN model, produce the average hourly concentration. Concentrations averaged over other time periods can be adjusted by factors roughly like those in Table 4.8. More complex models take into account average meteorological data obtained in the region over a period of years, as well as the effect of local terrain and nearby buildings, arriving at concentrations at various averaging times up to one year. Hourly averages are used to evaluate short-term exposures. The annual average applies to the region of maximum concentration and the most affected individual. Note that the hourly average may be over 20 times the annual average, sometimes over 40 times (Hasselriis, 1990).

**TABLE 4.8** Relative Factors for Various Times of Exposure

8-h average	15
3-h average	20
1-h average	30
30-min average	36

*Source:* Wood and Hasselriis, 1997.

**Modeling calculations.** Modeling calculations are based on the Gaussian plume model, illustrated in Fig. 4.3, showing the stack height, height to plume axis, and two cross sections along the path of the plume.

**Plume rise.** The plume of gases leaving the stack rises, due to its velocity and buoyancy. The distance above the stack outlet that a plume will rise into the atmosphere before leveling off is called the plume rise,  $\Delta h$ . The plume rise is affected not only by the temperature but also by wind speed, physical stack height, its inside diameter, and the ambient pressure.

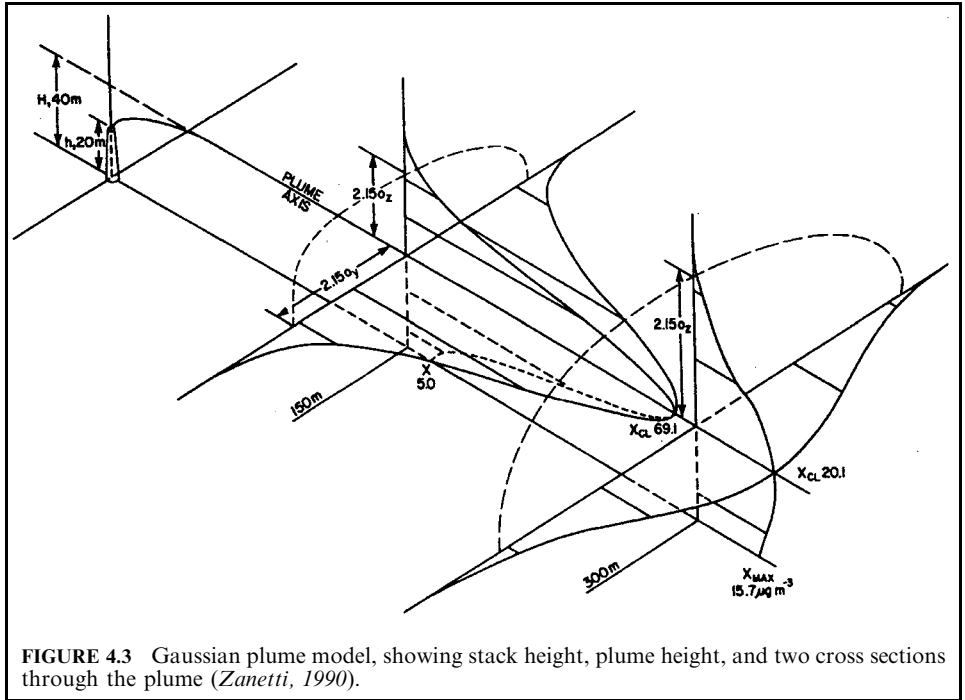

FIGURE 4.3 Gaussian plume model, showing stack height, plume height, and two cross sections through the plume (Zanetti, 1990).

The emission height used in the dispersion models is the effective stack height  $H$  which comprises the physical stack height  $h$  and the plume rise  $\Delta h$ .

**EXAMPLE:** Determine the effective stack height, given the Holland equation and the following data:

$$H = h + \Delta h$$

$$\Delta h = \frac{v_s d}{u} \left\{ 1.5 + 2.68(10)^{-3} p \left[ \frac{T_s - T_a}{T_a} \right] d \right\}$$

- where
- $H$  = effective stack height, m
  - $h$  = physical stack height, m
  - $\Delta h$  = rise of the plume above the stack
  - $v_s$  = stack gas velocity, m/s
  - $u$  = mean wind speed at stack height, m/s
  - $d$  = stack inner diameter, m
  - $p$  = atmospheric pressure mbar
  - $T_s$  = stack temperature, K
  - $T_a$  = atmospheric temperature, K

This equation is valid for neutral stability conditions; however, Holland suggests that the plume rise be adjusted by a factor of 1.1–1.2 for unstable conditions such as stability types A and B, and 0.8–0.9 for stability conditions E and F (see Table 4.9).

To estimate the mean wind speed ( $u$ ) at the top of the stack, an empirical formula can be used, as follows:

**TABLE 4.9** Pasquill Stability Types

Surface wind speed (m/s)	Day Incoming solar radiation (sunshine)			Night	
	Strong	Moderate	Slight	Thinly overcast or = 4/8 low cloud	
				= 3/8 low cloud	
< 2	A	A-B	B		
2	A-B	B	C	E	F
4	B	B-C	C	D	E
6	C	C-D	D	D	D
> 6	C	D	D	D	D

Note: A=extremely unstable, B=moderately unstable, C=slightly unstable, D=neutral, E=slightly stable, F=moderately stable. Neutral class D should be assumed for overcast conditions during day or night.

$$\frac{v}{v_0} = \left(\frac{z}{z_0}\right)^k$$

where  $v$  = wind speed at height  $z$ , m/s  
 $v_0$  = wind speed at anemometer level  $z_0$ , m/s  
 $k$  = exponent or coefficient, dimensionless

The exponent  $k$  has been taken generally as 1/7 but may actually be related to the stability class, ranging from 0.141 for A to 0.414 for G (very stable).

**EXAMPLE:** Determine the effective stack height, given the following data:

- Physical stack height  $h = 183$  m, inside diameter  $d = 6$  m
- Wind velocity at anemometer level (2 m above ground) = 5 m/s
- Air temperature = 10°C
- Atmospheric pressure = 1000 mbar
- Stack gas velocity = 16 m/s
- Stack gas temperature = 135°C
- Class B Pasquill stability type

Determine mean wind speed at the top of the stack:

$$u = (5 \text{ m/s}) [183/(2 \text{ m})]^{0.176} = 11 \text{ m/s}$$

Convert temperatures to K:

$$T_a = 273 + 10 = 283 \text{ K}$$

$$T_s = 273 + 135 = 408 \text{ K}$$

Substitute the given and calculated values in Holland's equation to determine plume rise  $\Delta h$ :

$$\Delta h = \frac{(16 \text{ m/s})(6 \text{ m})}{11 \text{ m/s}} \left\{ 1.5 + 2.68(10^{-3} (1000 \text{ mbar})) \left[ \frac{408 \text{ K} - 283 \text{ K}}{408 \text{ K}} \right] 6 \text{ m} \right\} = 56 \text{ m}$$

Then

$$H = 183 \text{ m} + 56 = 239 \text{ m}$$

**Gaussian dispersion model.** The Gaussian plume model is used to estimate concentrations of pollutants in the plume leaving the stack and in the process of dispersion before it reaches the ground or defined objects. Figure 4.4 shows the concentrations at 150 m and 300 m downwind of a stack having a height of 20 m and a plume rise of 20 m, for a plume axis of 40 m. The concentrations have the shape of the probability curve in the horizontal and vertical directions, but the plume has already intersected the ground prior to the 150 m distance.

The concentration  $\chi$  of a gas or aerosol ( $< 20 \mu\text{m}$ ) calculated at ground level for a distance downwind  $x$  is expressed as follows:

$$\chi(x, y) = \frac{Q}{\pi\sigma_y\sigma_z\bar{u}} \exp\left\{-\frac{1}{2}\left(\frac{y}{\sigma_y}\right)^2\right\} \exp\left\{-\frac{1}{2}\left(\frac{H}{\sigma_z}\right)^2\right\}$$

- where  $(x, y)$  = receptor coordinates, m  
 $\chi$  = ground level concentration,  $\text{g/m}^3$   
 $Q$  = emission rate,  $\text{g/s}$   
 $H$  = effective stack height  
 $\bar{u}$  = mean wind speed,  $\text{m/s}$   
 $\sigma_y, \sigma_x$  = dispersion coefficients, m  
 $\pi = 3.14159$   
 $\text{exp}$  = base of natural logs, 2.7182818

The dispersion coefficients can be obtained as a function of the distance from the source and the stability classes by use of the graphs, Figs. 4.4 and 4.5.

This equation can be simplified if only the ground level downwind concentration along the center line of the plume is needed. In this case,  $y = 0$  and the equation becomes

$$\chi(x, y) = \frac{Q}{\pi\sigma_y\sigma_z\bar{u}} \exp\left\{-\frac{1}{2}\left(\frac{H}{\sigma_z}\right)^2\right\}$$

FIGURE 4.5 Vertical dispersion coefficient  $\sigma_x$  versus downwind distance from the source.

The maximum downwind ground level concentration of a contaminant occurs on the center line of the plume. This concentration can be estimated by taking the differential of a modified version of the equation, resulting in the following expression:

$$\sigma_z = 0.70 H$$

**Wake effects.** Modeling calculations are carried out in accordance with US EPA established procedures. If there is a building within the area of influence of an MWI stack, any such structure must be evaluated for wake effects. The area of influence is five times the lesser of the height or width of the building(s). This building may justify the use of a good engineering practice (GEP) stack height.\* The structure justifying the greatest GEP stack height is then used in the wake effect calculations. It makes no difference whether the stack is upwind, downwind or to the side of a structure. As long as it is within the area of influence, wake effects must be considered (Turner, 1970).

In evaluating wake effects, three zones are considered:

- The cavity zone is considered to be three times the building height  $H_b$ , and is between the stack and the building under consideration. Not much dilution takes place in this zone.
- The wake zone extends beyond the building such that the cavity plus the wake zone is  $10 H_b$ . In this zone dispersion takes place as a result of the building geometry.
- In the reattachment zone stability is regained and the gases gradually become further diluted.

In the case of a short stack in a cavity zone, the area of influence is considered to be five times the lesser of the height or width of the building. The structure justifying the greatest GEP stack height is then used in the wake effect calculations.

If the cavity is entirely on plant property, EPA considers that it may not be necessary to include the concentrations in the cavity region. However, state regulations may require analysis of these on-site conditions, to make certain that the ground level conditions do not exceed safe concentrations of pollutants. The MASC (maximum allowable stack concentration) is calculated using modeling equations. The MASC factor is actually a dilution ratio, which we shall call the dilution factor (DF) below.

The concentration in the cavity is calculated on the basis that the emissions are diluted in a volume equal to the area of the building facing the wind, multiplied by the wind speed and a factor of 1.5. Cavity concentrations are used to determine the one-hour concentrations of pollutants, in accordance with health standards.

The wake region may be three to ten times the lesser of the building height or width. Wake effect may be ignored if the plume elevation at two times  $H_b$  downwind is greater than  $1.2 H_b$ . After the plume passes the wake region it proceeds as if there were no disturbance by the building.

Any stack release height will result in a concentration profile that is zero at the source, increases to some maximum value, and decreases slowly with distance. The decay is logarithmic.

Urban conditions reduce the axial concentrations of the plume and increase the GLC due to the turbulence produced by the buildings and uneven ground conditions. Rural conditions produce the opposite effect. These effects are taken into account in modeling.

\*Note: A good engineering practice (GEP) stack has a height  $H + 1.5L$ , where  $H$  is the height of the worst case building, and  $L$  is the lesser of  $H$  or projected width of the building.

### 5.3 Modeling of Specific Facilities

**Height of the plume.** Figure 4.6 shows, for a typical medical waste combustor, the plume height as a function of the temperature of the gases as they leave the stack. If the gases leave the stack at the temperature of the secondary chamber,  $1800^\circ\text{F}$ , the rise in this illustration is

about twice as high as when emission controls are used, necessarily reducing the stack gas temperature to 145°F for a wet scrubber, or to 350°F when a boiler and spray-dry scrubber are used.

**Plume dimensions.** Figure 4.7 shows the height of upper limit, centerline and bottom of the plume which is achieved, as a function of the size of the incinerator, and the temperature of the gases (resulting from the emission control used). This stack is shorter than a GEP stack, resulting in high concentrations downwind of the building. These graphs, as well as Figs. 4.8 and 4.9, have been calculated by using a US EPA model called SCREEN, which is considered to be quite conservative (Hasselriis, 1990; OAQPS, 1992).

**Ground level concentrations.** Ground level concentrations are calculated from the grams per second (g/s) emission rate, the stack height, diameter and velocity, the temperature of the stack gases, and meteorological data such as temperature, with speed, direction and stability conditions.

The modeling calculations produce the ground or elevated level concentrations in grams of pollutant per cubic meter of air ( $\text{g}/\text{m}^3$ ) resulting from an emission rate of one g/s of pollutant. These “unit” concentrations can be multiplied by the emissions of specific pollutants in g/s to obtain the ground level concentrations of these pollutants.

Ground level concentrations resulting from emissions from a 2000 lb/h incinerator, per g/s of pollutant, are shown in Fig. 4.8. In this case, the concentrations from a stack temperature of 1800° F, without an emission control system, range from a maximum of  $10 \mu\text{g}/\text{m}^3$  down to  $2 \mu\text{g}/\text{m}^3$ , compared with a peak of 100–200  $\mu\text{g}/\text{m}^3$  at 100 m down to about  $30 \mu\text{g}/\text{m}^3$  at 1000 m from the stack.

The impact of particulate emissions of 0.10 gr/dscf of particulate emitted by the uncontrolled emissions would be substantially less than the impact of incinerators with emission controls, in fact less than 1/10th as much, or roughly  $0.010 \text{ gr}/\text{m}^3$ . This finding helps to justify the application of less stringent emission limits to small rural medical waste incinerators and, specifically, waiving of the need for applying scrubbers.

**Dilution factor.** The factor by which the pollutant concentration leaving the stack is diluted by dispersion can be calculated by comparing the stack concentration (in  $\text{g}/\text{m}^3$ ) at 1 g/s of pollutant with the GLC (in  $\text{g}/\text{m}^3$ ) resulting from the same 1 g/s emission rate. This factor may be defined and called the dilution factor (DF), which can conveniently be used to evaluate the phenomenon of dilution *per se* resulting from dispersion (Hasselriis, 1991).

The dilution factor is calculated for a given facility in accordance with these equations:

$$\begin{aligned}
 DF &= \frac{\text{concentration in the stack (g/m}^3\text{)}}{\text{maximum ground level concentration (g/m}^3\text{)}} \\
 &= \frac{(\text{g/s})/(\text{m}^3/\text{s})}{(\text{g/m}^3)/(\text{g/s})}
 \end{aligned}$$

where

$$\begin{aligned}
 \text{m}^3/\text{s} &= \text{actual stack flow volume} \\
 &= (\text{meters/second}) \times (\text{square meters stack area}) \\
 \frac{\text{g/m}^3}{\text{g/s}} &= \text{grams per cubic meter per g/s, by modeling.}
 \end{aligned}$$

The actual cubic meters per second (acms) discharged by the stack depends upon the burning capacity of the incinerator, the composition of the fuel, the excess air used, the type of emission control (if any) used, and the leaving gas temperature, as listed in Table 4.7. The increase in dilution factor with distance from the stack is shown in Fig. 4.9, calculated for a 200 lb/h incinerator having a 45 m stack, discharging 1800°F gases directly (and vertically) from the stack, using the SCREEN model, and ranges from 2000 to 8000.

Dilution factors which have been calculated from modeling data performed for a wide range of combustion facilities are plotted, in Fig. 4.10, against the stack height upon which the modeling was based. The stack concentrations in  $\mu\text{g/m}^3$ , corresponding to a unit emission rate of 1 g/s, have been divided by the maximum annual average ground level concentrations in  $\mu\text{g/m}^3$  in order to obtain the dilution factor for each facility. Most of these modeling studies were performed for the California Air Resources Board (CARB) as part of the board's cadmium and dioxin studies (Fry *et al.*, 1990).

It is interesting to note that, in spite of the fact that this data set includes medical and industrial waste incinerators, asphalt heaters burning waste oil, municipal sludge incinerators, biomass (wood) burners, and municipal waste incinerators, the range of DFs for each category is remarkably similar. Most of the DFs range from 10,000 to 100,000. The small MWIs with short stacks produced DFs which were similar to those of the other categories, even the municipal incinerators with high stacks (Hasselriis, 1990).

**Effect of emission controls on ground level concentration.** Incinerators with greater burning capacities usually have higher stacks. Building heights may vary from as little as 5 m for small incinerators to 30 m for large waste-to-energy power plants. Good engineering practice (GEP)

usually results in a stack height of 2.5 times the height of the building. Large municipal waste-to-energy facilities have stack heights of 90 m or greater.

It appears from Fig. 4.10 that in spite of the fact that the larger MSW incinerators have capacities 50–100 times greater than those of MWIs, their higher stacks result in achieving the same DFs as the small MWIs.

The type of emission control system and the burning capacity of the incinerator affect the ground level concentration for several reasons: the amount of pollutant removed (if controls are used), the dilution before discharge, and the effect of the stack temperature on dispersion. In the following, only the effects of quantity and temperature are discussed.

**Effect of burning capacity and stack temperature on plume rise.** The higher the temperature of the stack gases, and the higher the stack exit velocity, the higher the plume of gases will rise as they blend in with the atmospheric air and become dispersed. Higher temperatures therefore result in lower pollutant concentrations before the gases reach critical “receptors” at ground or elevated levels.

Table 4.10 shows the range of unit dispersion factors (per g/s) and annual average dilution factors resulting from three specific combustion sources, obtained by detailed modeling of the sites. The facilities selected illustrate the fact that two similar MWIs exhibited radically different dispersion and dilution factors. On the other hand, one MWI showed a dilution factor higher than that of a large municipal solid waste (MSW) incinerator (Hasselriis, 1990).

Combustors of a wide range of sizes and types show similar ranges of dilution factors, as stack heights vary with facility burning capacity and size.

## 5.4 Acceptable Ground Level Concentrations

Acceptable ground level concentrations of many pollutants have been determined by various health agencies, such as OSHA. Exposure is expected to take place during 8-hour working days. Some of these standards are listed in Table 4.11. Standards based on health effects use annual averages. Corrections for other exposure times are made in accordance with Table 4.8 above.

Health risks of cancer due to exposure to dioxins and furans, as well as to toxic metals such as cadmium, are based on the annual average, since cancer-based risk involves exposure of the most affected individual (MED) for 70 years at that location.

The health risk impact of incinerator emissions should include not only inhalation but also other pathways. Some studies have concluded that total risk is five times greater than that of inhalation alone (Hahn and Sofaer, 1990). It should not be overlooked that on-site MWIs are generally operated 8 h per day or less, thus contributing only 1/3 the emissions that their capacity implies. The shorter operating time of on-site MWIs reduces the total risk to a factor of two times inhalation alone.

**TABLE 4.10** Dispersion and Dilution Factors for Specific Sources

Facility	Burn rate (lb/h)	Unit dispersion ( $\mu\text{g}/\text{m}^3$ per g/s)	Dilution factor
Cedars Sinai * (MWI, 2 m stack)	980	27	16,000
Kaiser Permanente * (MWI, 7.3 m stack)	980	5	145,000
St Stanislaus† (Municipal waste)	57,000	0.117	133,500

\*Fry *et al.*, 1990.

†Hahn and Sofaer, 1990.

**TABLE 4.11** Acceptable Workplace Concentrations and Unit Risk Values for Pollutants

Pollutant	Ground level concentration* ( $\mu\text{g}/\text{m}^3$ )	Unit risk value for inhalation (cases per million $\dagger\dagger$ at $1 \mu\text{g}/\text{m}^3$ )
Total suspended particulate:

Lead	0.150–1.5	
Mercury	0.012–0.80	
Nickel	0.0033	0.0005
Benzene	0.00042–0.000120	
Dioxin equivalent	$3.0 \times 10^{-8}$	33 @ $1 \text{ pg}/\text{m}^3\dagger$

\*New York State DEC "Air Guide 1," also regulations of Pennsylvania and North Carolina.

$\dagger$  Health Risk Assessment, St Lawrence County, NY, Ram Trac Corp.

$\ddagger$  Unit risk is posed by 70-year exposure to an airborne concentration of  $1 \mu\text{g}/\text{m}^3$  of each substance except for dioxin equivalent 2,3,7,8-TCDD, for which the applicable unit is picograms per cubic meter of air ( $\text{pg}/\text{m}^3$ ), where  $1 \text{ pg} = 10^{-6} \mu\text{g}$ .

Health risks due to cancer are established on the basis of "unit risks." The unit risk is the risk number of additional cancer cases per million caused by exposure to an airborne concentration of  $1 \mu\text{g}/\text{m}^3$ . The unit risk factors for the major cancer causing or promoting pollutants are listed in Table 4.11. For dioxins, a concentration of  $3 \times 10^{-8} \mu\text{g}/\text{m}^3$ , or 30 femtograms per cubic meter, has been adopted by some states.

**Comparison of predicted with acceptable GLC.** Once the hierarchy has been established as above, it is possible to trace through, from waste composition to stack to ground, what happens to individual pollutants, and how they compare with acceptable levels of air contaminants, and what the resulting health effect may be. The influence of alternative emission control devices can be discerned, as well as those of other variables such as burning capacity, stack height and gas velocity and temperature.

One remedy would be to use an emission control capable of removing 90–95% of the HCl. Another might be to raise the stack to increase the DF from the poor level of 500 to 10,000, thus achieving a 20-fold improvement or the equivalent of 95% control. If a DF of 50,000 were achieved, it would be the equivalent of 99% control by the scrubber.

Finally, a reduction in chlorine content from 1% (400 ppm emission) to 0.1% (40 ppm) would achieve a 90% reduction, perhaps eliminating the need for a scrubber.

Table 4.12 shows the effect of stack temperature and type of emission control equipment on the average annual ground level concentration, for the 2000 lb/h MWI with 25 m stack, compared with the acceptable air quality limits established by New York State.

**TABLE 4.12** Comparison of GLCs with Acceptable Air Quality Limits (2000 lb/h MWI with 25 m stack). Units are micrograms per cubic meter ( $\mu\text{g}/\text{m}^3$ )

Pollutant	Temperature leaving stack			Acceptable air quality limit
	Direct discharge* 1800°F	Boiler, no APC 400°F	Wet scrubber† 145°F	
Particulate	0.1	0.4	0.006	50
HCl	1.0	3.0	0.6	7
Cadmium	$3 \times 10^{-4}$	$10 \times 10^{-4}$	$2 \times 10^{-4}$	$6 \times 10^{-4}$
Lead	$2.5 \times 10^{-3}$	$8.8 \times 10^{-3}$	$2 \times 10^{-3}$	1.5
Dioxin T.E.	$2.0 \times 10^{-8}$	$7.4 \times 10^{-8}$	$1 \times 10^{-8}$	$3 \times 10^{-8}$

\*Uncontrolled emissions assumed in this example have been derived from California Air Resources Board data from tests of the St. Agnes MWI (Fry *et al.*, 1990).

† For simplicity, the wet scrubber is assumed to have 90% control efficiency for all listed pollutants, although it is actually much greater.

Particulate concentrations are less than 1% of AAQL *without* emission controls. HCl concentrations range from 15 to 40% of AAQL without emission controls. Lead emissions are insignificant relative to the limit.

Cadmium concentrations in this example range from 50 to 150% of the AAQL, without the use of emission controls. A reduction in cadmium content of plastics in the waste could significantly reduce these percentages.

The TCDD (dioxin) toxic equivalent concentrations are significant in this example. Improvements in combustion could bring these concentrations down. Other MWIs tested by CARB showed TE concentrations were about one-half of those found at St Agnes.

**Dioxin emissions and ground level concentrations.** Dioxins are found in the emissions of wood stoves, automobiles, coal-fired boilers, and medical and municipal waste combustors. Finding that background levels of dioxins in the Los Angeles area occasionally exceeded standards, the California Air Resources Board (CARB) developed guidelines for combustion of medical waste which mandated the use of scrubbers for MWI.

CARB obtained dioxin data from old incinerators which were equipped with no emission controls, or only with the simple devices employed at that time (Fry *et al.*, 1990). Due to the installation of scrubbers, data is now becoming available regarding the effectiveness of modern scrubbers in removing not only heavy metals, but also dioxins, from incinerator emissions.

Table 4.13 lists the toxic equivalent TCDD (dioxin) emissions of *uncontrolled* as well as controlled MWI, based on US EPA data. These are expressed as nanograms per standard cubic meter as well as in pounds per million tons. Controlled TCDD, based on tests of state-of-the-art baghouse and scrubber emission control systems, show the range of emissions measured.

The limit of  $3 \times 10^{-8} \mu\text{g}/\text{g}$  (30 femtograms/gram or  $30 \times 10^{-15} \text{g}/\text{g}$ ) is recognized internationally, and by the US EPA, as a very conservative estimate of a risk of one additional cancer case per million affected persons. Risks at this level are not considered to be significant.

*Sample calculation:*

Assume an uncontrolled MWI has emissions of 300 ng/dscm, and the dilution factor is 10,000. What is the ground level concentration?

$$\text{Ground level concentration} = 300 \times 10^{-9} / 10,000 = 3 \times 10^{-11} \text{ g/dscm}$$

**TABLE 4.13** Uncontrolled and Controlled Toxic Equivalent TCDD Emissions for MWI

Type of control	Range of TEQ emissions	
	(ng/m <sup>3</sup> )	(pounds per million tons)
Uncontrolled	3.24–540	0.04–7.0
Spray-dry + baghouse	0.06	0.0008
Baghouse + wet scrubber	0.14	0.0019
Baghouse	0.15–115	0.002–1.5
Wet scrubber	2.6–41	0.04–0.53

*Note:* conversion factors

1 g/m<sup>3</sup> = 8 lb/ton at 4500 Btu/lb

1 g/m<sup>3</sup> = 13 lb/ton at 7500 Btu/lb

1 ng/m<sup>3</sup> = 0.013 lb/million tons at 7500 Btu/lb

*Source:* Walker and Cooper, 1992.

Compare with  $3 \times 10^{-8}$  µg/m<sup>3</sup>:

$$\text{Safety factor} = 3 \times 10^{-8} [\mu\text{g}/\text{m}^3] / 3 \times 10^{-11} [\text{g}/\text{dscm}] = 1000 \times \text{limit}$$

**Source substitution versus emission controls.** The primary emissions from a medical waste incinerator without emission controls which are likely to fail to meet acceptable ground level pollutant standards are the HCl, heavy metal and dioxin emissions. Hospital purchasing agents can potentially reduce the presence of chlorinated plastics and plastics containing critical metals such as cadmium in the purchased materials.

**Overall effect of various factors on GLC.** A series of factors influence dispersion. Emission controls may achieve a reduction of 10–100 times; dilution before the stack may contribute a factor of 3–5. A change in stack height may produce as much as 3–10-fold reductions if downwash effects are avoided; dispersion factors may range from as low as 500 in the case of high nearby buildings to well over 100,000 with a GEP stack. Finally, removal of pollutants from the waste may result in reductions of perhaps 10–20 times. All of these factors may be considered in planning new or upgraded installations.

Some points to consider:

- Modeling studies show that small refractory-lined incinerators, burning commercial or industrial wastes and medical wastes, have pollutant impacts at ground level which have similar ranges to those of other waste burning incinerators, including municipal waste incinerators. The shorter stacks are compensated for by their relatively low mass emissions and more diluted stack discharges.
- The high stack temperatures of small *uncontrolled* incinerators cause the plume to rise higher than plumes of incinerators equipped with heat recovery boilers and scrubbers, resulting in relatively low ground level concentrations.
- When flue gases are bypassed directly to the atmosphere, the rapid rise and height of the hot gas plume results in very high dilution factors, producing relatively low ground level concentrations in spite of bypassing of emission controls. This assumes that the bypass stack is of equal height. Shorter stacks may still achieve acceptable ground level or elevated level concentrations, at least over the short term of the bypass condition.
- Dilution factors are a useful parameter for relating stack emission concentrations to ground level concentrations. Dilution factors may range from as low as 500 for MWI with short incinerator-mounted stacks and nearby high buildings to well over 100,000 when stacks are

**TABLE 4.14** Uncontrolled and Controlled Emission Factors

Pollutant	Uncontrolled emissions (lb/ton)	Control efficiency (percent)	Controlled emissions (lb/ton or lb/million tons)
<i>Solid matter:</i>			
Particulate	7.35	99	0.02 lb/ton
Arsenic	0.00018	99	2.0 lb/million tons
Cadmium	0.000035	99	3.0 lb/million tons
Chromium	0.00072	99	7.2 lb/million tons
Lead	0.00007	99	0.7 lb/million tons
Manganese	0.0371	99	371 lb/million tons
Mercury	0.00054	50	270 lb/million tons
Nickel	0.000255	99	2 lb/million tons
Zinc	0.0019	99	20 lb/million tons
<i>Acid gases:</i>			
Sulfur dioxide	1.85	90	0.185 lb/ton
Nitrogen oxides	6.02	50	3.0 lb/ton
Carbon monoxide	1.2	0	1.2 lb/ton
Hydrogen chloride	38.3	95	2 lb/ton
<i>Trace organics:</i>			
Benzene	0.41	95	0.02 lb/ton
TCDD toxic equiv.	$1.37 \times 10^{-6}$	95	0.07 lb/million tons
Formaldehyde	0.02	95	0.001 lb/ton
Polyaromatic hydrocarbons (PAHC)	0.001	95	50 lb/million tons

*Source:* Doucet and Mainka, 1991.

GEP and/or higher than adjoining buildings. Municipal incinerators showed DFs ranging from 60,000 to 300,000.

- Detailed modeling helps to obtain the most effective and economic technology for environmental controls. The type of emission control and stack height are essential variables.

## 6 ENVIRONMENTAL RISK ASSESSMENT

### 6.1 Health Risk Assessment

Health risk assessments of waste combustion systems emissions are carried out using air dispersion models and exposure assessment methodologies for estimating atmospheric dispersion to determine the concentrations of pollutants to which the exposed population would hypothetically be exposed. EPA recommends the Industrial Source Complex–Long Term (ISC–LT) model be run, using site-specific meteorology data from local weather stations (Hahn and Sofaer, 1990).

A variety of health risk estimators are used to help quantify the health risks of toxic substances. Past studies have shown that metals pose potentially significant health risks and may be of greater health concern than organics.

Estimates of carcinogen potency factors developed by the US EPA Carcinogen Assessment Group (CAG) are used to calculate excess risk of developing cancer to individuals and populations as a result of exposure to carcinogens detected in the stack emissions (arsenic, beryllium, cadmium, chromium, nickel and PCBs).

Guidelines for evaluating non-carcinogenic effects can use upper limits of “safe” (no observed adverse effect) exposures to derive “acceptable” continuous exposure limits

(CELS), which may reflect realistic exposure conditions as well as additional uncertainty factors which allow for the increased susceptibility of sensitive populations to disease.

Major assumptions and limitations:

- Air dispersion modeling is a source of error, perhaps by a factor of two.
- The flat and urban models used may not account for actual variances in elevation in the area.
- Health effects due to chronic exposures, particularly carcinogenesis, are considered rather than the effects from acute exposures.
- The facility is conservatively assumed to be in operation for 74 years, the average length of a human lifetime, to be consistent with other health risk estimates, although 20 years may be more realistic.
- Emission rates are assumed to be constant and continuous, with the facility running under normal conditions 90% of the year.
- Atmospheric dispersion of stack emissions is assumed to be the primary transport mechanism of pollutants. In fact, the food chain has been shown to be a potentially significant pathway of exposure.
- The combined health effects of various substances are assumed to be additive, in accordance with EPA guidelines, since it is difficult if not impossible to evaluate the synergistic and antagonistic reactions between elements.
- A large margin of safety (perhaps three orders of magnitude) is incorporated into extrapolating the results of animal toxicity testing to prediction of human health effects because of the large degree of uncertainty in predicting these correlations, and in order to protect public health to the greatest extent possible.

## 6.2 Risk Analysis of a Hazardous Waste Facility

The data and calculations provided below show how risk analysis can be calculated on the basis of data on waste composition, uncontrolled emissions of pollutants, controlled emissions, and modeled ground level concentrations obtained by computer modeling, based on a hazardous waste incineration facility (EPA, 1997).

Annual capacity:	52,000–77,000 tons of liquid, solid and semi-solid RCRA wastes.
Types of waste:	Bulk solid wastes, sampled upon arrival; bulk liquid wastes, sampled on arrival; and drummed wastes, at least one out of 10 drums of each waste stream normally sampled. Non-pumpable liquids and sludges are usually mixed with pumpable wastes.
Description:	Rotary kiln, waste feed mechanisms, secondary combustion chamber, heat recovery boiler, air pollution control devices, stack, solid residue removal equipment, and computerized process control and instrumentation systems.
Rotary kiln:	Refractory-lined shell, 15 ft in diameter and 43 ft long, at temperatures of 1800–2200°F.
Secondary chamber:	61 ft high, 21 ft long, 22 ft wide, at 1350–1500°F.
Stack:	150 ft high (45.7 m), 1.83 m inside diameter, exit temperature 201°F.

This facility was subjected to extensive modeling, using the US EPA ISC-COMPDEP atmospheric dispersion model, which incorporates the ISC-ST short-term model and the COMPLEX I screening model for complex terrain, using modeling receptors between stack top elevation and plume height with both the simple and complex terrain models, and using the larger of the two concentration estimates as being the more representative.

The result of these modeling studies was that the maximum annual concentrations in the air were predicted to occur at a location approximately 1 km to the east of the stack. The maximum annual concentration was estimated to be between 0.9108 and 0.9223  $\mu\text{g}/\text{m}^3$  per 1 g/s of emissions.

Taking into account the stack velocity and area, the stack flow was 46.7  $\text{m}^3/\text{s}$ . Dividing 1 g/s by this flow, the stack concentration was 0.0214  $\text{g}/\text{m}^3$ . The dilution factor is then calculated as follows:

$$\text{DF} = 0.0214 / (0.102 \times 10^{-6}) = 209,952$$

### 6.3 Comparison with EPA "Screen" Model

The US EPA screening model, SCREEN, is useful for making a first estimate of ground level concentrations on the basis of site data. This model is shown in Table 4.15.

This model produces the concentration for a one-hour exposure. Using the one-hour concentration of 4.781  $\mu\text{g}/\text{m}^3$ , compared with the 0.101  $\mu\text{g}/\text{m}^3$  calculated with the detailed model indicates a conversion factor of 47 from one-hour to annual. Typically this ratio ranges from 30 to 50, depending upon local conditions. In this case this appears to be a good match with SCREEN.

**EXAMPLE:** Calculate the dilution factor (DF) for one-hour exposure:

The stack concentration for a flow rate of 1 g/s is calculated using the stack diameter and velocity:

$$\text{Stack area} = D^2 \times (\pi/4) = 1.83^2 \times 0.786 = 2.63 \text{m}^2$$

$$\text{Stack volume} = (\text{velocity}) \times (\text{area}) = 17.74 \text{ [m/s]} \times 2.63 \text{ [m}^2\text{]} = 46.7 \text{ m}^3/\text{s}$$

$$\text{Stack concentration} = 1 \text{ [g/s]} / 46.7 \text{ [m}^3/\text{s}\text{]} = 0.0214 \text{ [g/m}^3\text{]} \text{ per 1 g/s}$$

$$\text{GLC} = 4.781 \text{ [g/m}^3\text{]} \text{ per 1 g/s}$$

$$\text{One-hour DF} = (\text{stack concentration}) / (\text{GLC}) = 0.0214 \text{ [g/m}^3\text{]} / 4.781 \text{ [\mu g/m}^3\text{]} = 4480$$

Using the factor of 47 to correct to annual, we get an annual DF of  $4480 \times 47 = 210,500$ .

Comments regarding Table 4.15:

- SCREEN tests each of the stability classes and selects the highest concentration. Hence, as distance from the stack increases, different stability classes are maxima. Stability classes are described in Table 4.9.
- The mixing height varies with the stability class. At distances up to 1200 m the mixing height is as low as 360 at stability 1, but beyond that it is fixed at 5000 m. This illustrates the importance of searching for the maximum at each distance.
- The critical wind velocity at 10 m ranges from 10 m/s at 100 m down to 1 m/s, illustrating its importance in determining ground level concentrations closer to the stack.
- The plume height is highest with stability 1 (260 m), but beyond 1200 m stability 5 results in a plume height of only 124.5 m, bringing the plume closer to the ground.
- $\sigma_y$ , the plume width, is maximum with stability 1 at 900 m, but at stability 5 it increases from 110 m to 165.5 m. At the maximum point it is 161.8 m.
- There is no downwash component for these site conditions, due to the high stack.

**TABLE 4.15** Screen Model Run

Simple Terrain Inputs:

Calculation procedure	Max conc. µg/m <sup>3</sup>	Dist. to max. (m)	Terrain ht. (m)
Simple terrain	4.781	1942	0

The next step in the risk analysis is to determine the relationship between pollutants in the stack emissions, their ground level concentrations, and the comparison with “acceptable” concentrations at ground level.

Table 4.16 lists the stack concentrations of the critical toxic metals and the critical trace organic, toxic equivalent dioxin (TEQ). These were determined from trial burn tests and “normal” emissions, selecting the maximum. These are translated to ground level conditions using the dispersion factor ( $0.9108 \mu\text{g}/\text{m}^3$  per 1 g/s) or the dilution factor (209,952) derived from it, to permit comparison with health risk concentrations.

**TABLE 4.16** Ratio of Acceptable GLC to Annual GLC. Hazardous Waste Incinerator

Pollutant	Feed rate (g/s)	Stack emissions (g/s)	System removal efficiency (%)	Annual average GLC	NY State acceptable GLC	Ratio: AGLC/GLC
Arsenic	0.16	$37 \times 10^{-6}$	99.98	$40 \times 10^{-6}$	$230 \times 10^{-6}$	5.8
Cadmium	0.12	$16 \times 10^{-6}$	99.99	$17.6 \times 10^{-6}$	$560 \times 10^{-6}$	31.8
Chromium	0.10	$0.71 \times 10^{-6}$	99.999	$0.8 \times 10^{-6}$	1.20	126,600
Lead	0.44	$43 \times 10^{-6}$	99.99	$47 \times 10^{-6}$	1.50	21,276
Mercury	0.0014	$210 \times 10^{-6}$	85.0	$230 \times 10^{-6}$	0.12	600

## 6.4 Human Health Risk Assessment

The risk assessment process consists of the following components:

- *hazard identification*: identifying the chemical substances of concern and compiling, reviewing and evaluating data relevant to toxic properties of these substances;
- *dose–response evaluation*: assessing the relationship between dose and response for each chemical of potential concern;
- *exposure assessment*: identification of potential exposure pathways, the fate and transport of chemicals in the environment (including dispersion modeling), and estimation of the magnitude of chemical exposure for the potential exposure pathways;
- *risk characterization*: calculation of numerical estimates of risks for each substance through each route of exposure, using the dose–response information and the exposure estimates.

The general approach used by the EPA guidance provides estimates of:

- individual risks based on exposure within defined subareas surrounding the facility, expressed both as averages across the subareas and at the location of maximum chemical concentrations within each subarea;
- risks to potentially more highly exposed or susceptible subgroups, such as young children, within the general population;
- risks associated with specific activities that may result in elevated exposures, such as subsistence fishing;
- individual risks based on “high end” exposure to subgroups of the population that are believed to be potentially more highly exposed;

- cumulative risks to the population in the vicinity of the incinerator as a result of stack emissions.

This approach allows for the estimation of risk to specific segments of the population, taking into account site-specific activity patterns, the numbers of individuals in each subgroup, and actual locations of individuals within these subgroups.

**Toxicity assessment.** Consistent with US EPA guidance, potential carcinogenic and non-carcinogenic effects are evaluated separately, assuming potentially carcinogenic substances to pose a finite cancer risk at all exposure levels; therefore a “no-threshold” assumption, based on a 70-year lifetime exposure. The US EPA uses a linearized multistage model to develop the cancer slope factor (SF), which is generally believed to overpredict the true potency of a chemical.

Non-cancer effects assume that a minimum threshold level of exposure must be reached before the effect will occur. The estimated level of daily human exposure below which it is unlikely that adverse effects will result is known as the reference dose (RfD). The reference concentration (RfC) reflects the non-carcinogenic effects of certain chemicals, typically derived from experimental animal studies, incorporating uncertainty factors to extrapolate from the high dose exposures in the animal experiments to the low doses likely to be received by humans from environmental sources, and taking into account individuals who are likely to be more susceptible than the general population to the chemical.

For incinerator emissions, exposure to individuals living and working in the vicinity of a facility is evaluated for both inhalation and indirect, multipathway routes of exposure, specifically:

- inhalation of air;
- ingestion of and dermal contact with soil;
- consumption of meat, dairy products and eggs from locally raised livestock;
- consumption of locally grown vegetables;
- ingestion of and dermal contact with surface water during swimming.

**Fate and transport modeling.** The ISC-COMPDEP model is used to estimate chemical concentrations in air associated with the routine emissions from the facility. The results of this modeling can be used directly to assess inhalation exposures, and at the starting point for evaluating exposures through indirect pathways, including the result of wet and dry deposition of particulate matter and vapor onto soil and vegetation, followed by ingestion by livestock, and ingestion of vegetables or livestock grown or raised locally.

**Estimated average cancer risks and health indices.** The final results of the complex analysis performed for the WTI facility are listed in Table 4.17. Cancer risks range from  $1 \times 10^{-6}$  for the theoretical subsistence farmer to  $6 \times 10^{-7}$  for the farmer adult or child. *The US EPA considers these risk levels to be of no significance.* The hazard indices were all less than 0.1.

**Sample calculation.** The following calculation shows the relationship between the ground level exposure for Cd with the inhalation exposure and risk for a rotary kiln with a stack volume of  $50,000 \text{ m}^3/\text{h}$  and a 33 m stack:

**TABLE 4.17** Estimated Area Average Cancer Risks and Hazard Indices Due to Exposure from Direct and Indirect Pathways. WTI Hazardous Waste Incineration Facility

Population subgroup	Cancer risk (per million)	Hazard index
Resident adult	0.2	0.01
Resident child	0.4	0.05
Farmer adult	0.6	0.01
Farmer child	0.6	0.06
School-age child	0.3	0.03
Subsistence farmer adult	1	0.02
Subsistence farmer child	1	0.07

*Source:* EPA, 1997.

Step 1. Cd ground level exposure concentration

$$\begin{aligned}
 &= \text{max. exposure concentration} \times \frac{\text{Cd emission rate}}{\text{Modeled emission rate}} \\
 &= 0.373 \mu\text{g}/\text{m}^3 \times \frac{0.0008 \text{ g}/\text{s}}{1 \text{ g}/\text{s}} = 0.00030 \mu\text{g}/\text{m}^3
 \end{aligned}$$

Step 2.

Inhalation exposure =

$$\begin{aligned}
 &\frac{\text{contaminant concentration} \times \text{inhalation rate} \times \text{exposure duration} \times \text{absorption fraction}}{\text{body weight} \times \text{lifetime}} \\
 &= \frac{3.0 \times 10^{-7} \text{ mg} \times \frac{23 \text{ m}^3}{\text{d}} \cdot 74 \text{ y} \times 1}{70 \text{ kg} \times 74 \text{ y}} \\
 &= 9.9 \times 10^{-8} \text{ mg}/(\text{kg} \cdot \text{d})
 \end{aligned}$$

Step 3.

risk = potency  $\times$  exposure

$$\begin{aligned}
 &= \frac{7.8 \text{ kg} \cdot \text{d}}{\text{mg}} \times \frac{9.9 \times 10^{-8} \text{ mg}}{\text{kg} \cdot \text{d}} \\
 &= 7.7 \times 10^{-7} \text{ increased lifetime risk of developing cancer to the maximum} \\
 &\quad \text{exposed individual, or one chance in 1.3 million (worst case)}
 \end{aligned}$$

## 6.5 Risk Assessment with Failure of Emission Controls

Public concern has been expressed regarding the short-term effects associated with failure of the emission control system and/or bypass of the incinerator emissions directly to the atmosphere. In order to address this issue, short-term health effect risks have been evaluated, and compared with typical uncontrolled stack emissions.

**TABLE 4.18** IDLH versus One-half Hour GLC with APC Failure

Pollutant	Controlled stack emissions (g/s)	Stack emissions if APC fails (g/s)	One-half hour GLC ( $\mu\text{g}/\text{dscm}$ )	IDLH ( $\mu\text{g}/\text{dscm}$ )	Ratio: IDLH/ $\frac{1}{2}$ h GLC)
Arsenic	$37 \times 10^{-6}$	31,268	313	$230 \times 10^{-6}$	29
Cadmium	$16 \times 10^{-6}$	13,523	135	$560 \times 10^{-6}$	37
Chromium	$0.71 \times 10^{-6}$	600	6	1.20	16,663
Lead	$43 \times 10^{-6}$	36,343	363	1.50	41
Mercury	$210 \times 10^{-6}$	150,882	1775	0.12	5.6

*Source:* Wood and Hasselriis, 1997).

The IDLH is the level considered to be “Immediately Dangerous to Life and Health.” Table 4.18 shows the results of this investigation. Modeled GLCs are compared with the IDLH for a half-hour exposure considered possible until the incinerator is brought back under control. The ratio of IDLH to GLC ranges from 5.6 for mercury to 29 to 41 for the other metals except chromium at 16,663. This ratio may be considered to be the safety factor, or even the number of facilities of this size which could fail at one time before the IDLH would be exceeded.

## **1 OVERVIEW OF PROCESSING AND STABILIZING FLY ASH**

### **1.1 Introduction**

What is coal ash? Coal ash is the noncombustible part of the coal which has been burned to produce electrical power or steam. Coal ash also includes flue gas desulfurization residue, and breaks down into the following constituents.

1. *Bottom ash*—This is a coarser particle and is collected at the bottom of the pulverized coal (PC) and stoker-fired boilers.
2. *Fly ash*—This is a fine material collected in a Baghouse or precipitator.
3. *Boiler slag*—This is a coarse ash particle collected at the bottom of cyclone-fired boilers.

Flue gas desulfurization (FGD) develops from the injection of calcium materials into the flue gas for the removal of sulfur.

As stated above, coal ash is divided into three parts. This chapter examines five specific cases.

- The first three examples are for processing fly ash with water only.
- The fourth example is for processing FBC fly and bottom ash with water.
- The fifth example covers hazardous medical waste from an incinerator, stabilizing both fly and bottom ash by chemistry using the silicate treatment.

However, before proceeding let us list some of the variables affecting fly ash:

- type of coal, i.e., bituminous, sub-bituminous, lignite, anthracite, petroleum, coke, etc.;

- co-gen-fired oil, wood, waste materials, mill and industrial sludges, etc.;
- boiler type, i.e., PC, stoker, FBC;
- boiler efficiencies;
- emission controls;
- collection systems.

It is clear that the above variables will have a profound effect upon the type of fly ash the equipment must process to meet legal requirements.

In order to perform in this type of hostile atmosphere, you need properly designed equipment that will wet all the ash particles with water or, if needed, chemical reagents to condition or stabilize the fly ash for disposal. It is imperative to coat all the particles with the proper chemical reagents to maximize the use of the chemicals and at the same time minimize costs without supersaturating the batch. The proper equipment will give you the capabilities to reach this goal. We have developed a large number of applications for our DustMASTER equipment. It is not feasible in this chapter to describe all the applications that are in service. However, we have selected five different applications that will give an idea of the flexibility of this equipment.

The objective of this chapter is to familiarize those who are interested in processing or stabilizing fly and bottom ash with:

- equipment for processing or stabilizing ash;
- how the equipment is controlled and how it operates;
- applications;
- terminologies often used in processing ash.

## 1.2 Understanding the Proper Equipment

Standard fly ash conditioning system specifications

*Mixer.* The “low profile” Turbin Mixer is the mixer utilized. The size used varies with the production requirement. The production rates are based on material weighing fifty (50) pounds per cubic foot and a minimum systems cycle time (charge–mix–discharge) of sixty (60) to ninety (90) seconds (Table 5.1).

The standard mixer is equipped with one (1) swivel discharge door (maximum three (3) discharge doors optionally available). The door is hydraulically operated. The opening and closing of the door is controlled through a single solenoid valve.

The mixer has a dual voltage 230/460 drive motor, 60 Hz, 3 Ph, and is totally enclosed and fan-cooled for long life.

**TABLE 5.1** DustMASTER Capacity

DustMASTER	Turbin	Tons per hour capacity*
Model 20 TPH	Model 50	20
Model 40 TPH	Model 100	40
Model 60 TPH	Model 150	60
Model 80 TPH	Model 200	80
Model 120 TPH	Model 450	120
Model 160 TPH	Model 450	160
Model 200 TPH	Model 500	200

\* Dry material weight.

The mixer cover is a movable, self-supporting assembly that has hinged doors for access to the mixing area inside the mixer. These are used for inspection and clean-out. A heavy rubber seal is fitted around the access door edges as well as the cover to provide a dust-tight seal. Quick release and latch clamps secure the doors to the cover assembly.

*Mixing Process.* The Turbin is a high-intensity mixer. The mixing is produced by a series of paddles which move through the mixer at the rate of six hundred (600) feet per minute.

There are from four (4) to ten (10) mixing arms, depending on the model, with replaceable cast ni-hard paddles plus inner and outer wall scrapers mounted on the rotating mixing assembly. These cast ni-hard wall scrapers are 8 in. wide and provide additional mixing action. The cast ni-hard paddles are right- or left-handed to provide the most effective braiding, mixing action. They have locked mounts with 3/4 in. of vertical wear adjustment.

The mixer is lined with 3/8 in. thick steel segmented liners on the floor and the inner and outer wall. They are bolted in place and can be reversed for longer life.

The mixer discharge door is comprised of a circular segment flush with the floor, pivoted on an external shaft, mounted in a pair of shaft bearings which are sealed and self-lubricated for longer life. The edge of the door matches the floor opening and rides on a machined steel rail to ensure door and floor alignment. The door surface is covered with a bolt in a replaceable 3/8-in.-thick abrasion-resistant liner. The door is externally sealed with a reversible, adjustable steel wiper bar. The door is actuated by a hydraulic cylinder to provide an angular opening of 95°.

The transmission is totally sealed in a lubricant. This prevents foreign materials from entering the transmission causing damage to gears and bearing.

*Air system.* All air cylinders have corrosion-resistant barrels, hard chrome-plated rods, are cushioned at both ends of the stroke, and have repackable piston and nose pieces. The 115-V solenoid valves include a lockable manual operator. The air cylinders, solenoid, and vibrator are piped to a common air supply header which includes an airline filter, pressure regulator, and airline lubricator.

*Hopper for series I.* The weigh-batching hopper is suspended from load cells in a self-supporting frame and is made from all-welded steel. It has a rolling blade-type fill gate and gas-tight butterfly valve discharge gates. All gates are air-cylinder operated through a 115-V, four-way valve. All gates have limit switches to indicate the closed position. The load cells are used for weight measurements. Although we have standard-size hoppers, they can be altered to fit specific space requirements.

*Customer-furnished venting* is required for each hopper. A 12-in.-diameter vent outlet must be provided.

The batching hopper has an access hatch on top for inspection or repair. The hopper utilizes externally replaceable aeration pads to condition the fly ash for uniform flow upon discharge, along with an air vibrator that is activated only when the final empty signal exists.

The hopper includes a flanged vent on top for connecting back to the silo bag house for a fugitive dust collecting system. A cross vent between the weigh hopper and the mixer allows the air in the mixer to be displaced by the incoming fly ash to flow back to the hopper without pressurizing the mixer.

*Water system.* Water volume is measured by weight or a meter which allows the water to pass through a rotary water system into the mixer. A meter controls the water volume per batch. The ash volume is controlled by load cells. The load cells and programmable controller are used to automatically control the batching, mixing, and truck loading. The batching controller is in a NEMA 4x enclosure that serves as the main junction box for all control connections to the DustMASTER.

*Programmable controller.* The principal job of the controller is to obtain a consistent weight of ash per batch. In addition, it provides interlocks, and contains programs designed to allow production in the event of mechanical failure of gates, limit switches, water valves, level probes, and even a breakdown of the master programmable controller.

This controller is housed in a wall-mounted NEMA 4x enclosure with terminal strip wiring. The programmable controller is an industrial modular type complete with a plug-in memory

module that requires no battery back-up. It has a data access and display module. With this arrangement, the program is protected while allowing access and control of all timer and counter set points used in the process. The touch panel interface on the door indicates key functions and proved visual-manual control. With our manual control, it is possible to reach production rates equal to the automatic mode.

Since the number of loads to be cycled into a truck can be pre-set, it is possible to have this function at an optional truck driver start station and the main control. The automatic mode requires someone to start the system. It batches, mixes, and counts the loads into a truck, and then shuts down to a ready condition.

***How the equipment is controlled and works.*** The DustMASTER is a batch system and is controlled by a programmable controller. All the weights of the ingredients are controlled by load cells; the water is controlled by a meter or weight. Any reagents can be weighed cumulatively. When the automatic process is activated by the operator, the following sequence of events takes place.

***DustMASTER system operation:***

- the mixer starts;
- the ash batch gates are open, charging ash into the volumetric or weigh batcher;
- the ash batch gates close when the full signal in the volumetric ash batcher is activated;
- the batcher gates open, discharging fly ash into the mixer;
- the mixer door opens (the timer starts when the batcher gate opens);
- the water start timers begin when the batcher gate opens;
- water starts metering into the mixer when the water start timers expire;
- when the ash in the batcher discharges to the empty level, a batcher discharge gate timer is activated and the ash batcher vibrator is started;
- when another batch is to follow immediately (not the last batch), the ash batcher refills;
- water flow ends when the set volume has been metered into the mixer;
- when the mixer timer expires, the mixer discharge door opens;
- a discharge door-open timer is started;
- when the mixer discharge door-open timer expires (if this is not the last batch), the door closes (if this is the last batch the door stays open for a longer set clean-out time);
- the operator can initiate the stop or last-batch signal or it can be set for automatic shut down when a pre-set number of batches have been loaded onto the haul vehicle;
- when the door closes the volumetric ash batcher gate opens and the mix cycle is repeated unless this is the last batch.

The system will operate in this manner until either it is shut down, or the fly ash storage silo is empty. There are three (3) methods of cleaning the mixer.

1. Hand-scrape the floor, side walls, and paddles (requires two men and approximately 15 min).
2. Pressure water wash (requires high-pressure washer, commercially available).
3. Scour the mixer with small aggregate, fill the mixer, and run it for about 10 min., or as long as required to clean the floor and walls. Discharge aggregate into a container for re-use.

As a result of our batch system we are able to introduce both liquid and powder reagents automatically for stabilizing and fixation during the mixing cycle. The weights of the ingredients are controlled by load cells, and the water addition by time or weight. Neither weight

per cubic foot nor particle size affects the mixing ability of the unit. We have mixed materials from 0#/c.f. up to 287#/c.f. With the programmable controller it is easy to change the cycle times within the sequence of events, giving complete flexibility in the system. In addition, we provide 100% manual override of the control in the event of automatic mode failure.

The design of our system is an accumulation tank process for stabilization. We process and stabilize cupola and electric furnace dust, general foundry sands, sludges, and many other types of hazardous and nonhazardous materials.

## **2 CALCULATIONS OF PROCESSING AND STABILIZING FLY ASH**

---

### **2.1 Applications**

We have a wide variety and range of applications, including both hazardous and nonhazardous materials. During the mixing cycle, the unit has a 99% distribution level. What this statement really means is that all dust particles are coated with moisture, as well as all reagents used in the processing of waste materials, both hazardous and nonhazardous.

It is clear that this type of performance is vital to the conditioning and stabilizing of all waste materials, regardless of application or final use. This is why DustMASTER Enviro Systems issues a money-back performance guarantee on systems designed, engineered, and installed by our company. We have the knowledge and expertise to meet your environmental needs.

### **2.2 Stabilization and Fixation**

As discussed in the districts' proposal for the modification of ash from CREF dated 1989 (CSDLAC, 1989), silicate treatment is by far the largest category of treatment process and has demonstrated the greatest effectiveness in achieving treatment goals. Silicate treatment includes processes which add sodium and potassium silicates as well as those which add calcium silicate (cement). Both published research and research performed by the districts indicate that silicate-based treatment provides the most effective and economically feasible treatment of ash.

As a result of studies and research on alternative treatment technologies, it was ultimately concluded that silicate treatment presented the best opportunity for successful treatment of CREF ash. The districts proposed to employ calcium silicate (cement amendment) as a treatment method.

**SILICATE TREATMENT TECHNOLOGY:** Silicate treatment systems have been found to be effective in reducing the soluble metals levels of a variety of wastes, including incinerator ash. Trezek (1987) has conducted tests on a wide variety of metals and confirmed the efficacy of silicate treatment. Silicate treatment technology utilizes commercially available sodium, potassium, and calcium silicates. Sodium and potassium silicates are normally applied in addition to a calcium silicate in the form of cement, of which calcium silicate is a major constituent. Other cementitious materials may be used which contain, or react to produce, calcium silicates. Cementitious materials include cement kiln dust and natural pozzolans (materials which upon reacting with lime produce calcium silicate). Natural pozzolans include volcanic ash and certain diatomaceous earths. Synthetic pozzolans include flyash and burnt clays. Treatment is achieved by mixing the silicate materials and allowing the mixture to cure.

Several chemical mechanisms are reported to bring about the treatment of heavy metals using silicate treatment. In applications of proprietary silicate blends, there is clear evidence that metasilicate formation stabilizes heavy metals (Trezek, 1987). For example, in the case of lead, an insoluble lead metasilicate ( $\text{PbSiO}_3$ ) precipitate is formed (Zirschy and Pizner, 1988). It is suggested that other insoluble metal complexes are formed by various chemical mechanisms, including absorption by cement hydrates, or substitution and solid solution in the hydrate structure (Poon et al., 1983). Physical mechanisms such as binding and coating of the metal wastes in the cement matrix are also reported to contribute to the stabilization of contaminants.

However, it appears that chemical stabilization resulting in the formation of insoluble, stable complexes which incorporate metals into a crystalline silicate structure serves as the dominant treatment mechanism. The specific chemical reactions involving calcium silicate fixation of metallic ions are discussed below.

The application of portland cement is a form of silicate treatment. Published research demonstrates that calcium silicate, which comprises the majority of cement, behaves similarly to sodium and potassium silicates in chemically stabilizing heavy metals. Zirschky and Pizner (1988), Benson et al. (1985), and Shively et al. (1986) showed that portland cement alone may be effectively applied to wastes as a form of silicate treatment. Results of research conducted by the districts support the efficacy of calcium silicate treatment, and indicate that in the instance of CREF ash, silicate treatment with portland cement achieves the desired treatment objectives more cost-effectively than treatment with proprietary silicate blends.

Portland cement is a hydraulic cement which, when fully cured, achieves stone-like strength. The cement is manufactured by making cement clinker from the raw materials lime (CaO), silica (SiO<sub>2</sub>), and alumina (Al<sub>2</sub>O<sub>3</sub>) in a cement kiln. The two major components of the clinker are tricalcium silicate (3CaO-SiO<sub>2</sub>) and dicalcium silicate (2CaO-SiO<sub>2</sub>), which comprise approximately 70–80% of the portland cement. Tricalcium silicate is the major cementitious phase of most portland cements (Bhatt, 1987). All the constituents of the cement clinker are anhydrous. However, when mixed with water, the anhydrous constituents chemically react and begin to form a dense structure of new, hydrated compounds. This process is most significant during the first 90 days after mixing, but can continue for a year or more. The hydration reaction is usually represented by the following chemical equation (Lea, 1971):

The calcium silicate hydrate comprises approximately 70% of the total amount of the cement hydrated phases, and is believed to play a major role in the fixation of metallic ions [7]. It has been shown that a metallic ion such as sodium can be retained in the structure of calcium silicate hydrates (Poon et al., 1985).

Bhatt (1987) presented four probable mechanisms involved in the fixation of metallic ions in solids formed with portland cement: (1) fixation by addition, (2) fixation by substitution reaction, (3) fixation by formation of a new compound or compounds, and (4) fixation by a combination of the above mechanisms. These mechanisms are discussed below.

**FIXATION BY ADDITION:** In this mechanism, a metallic ion is incorporated into the structure of calcium silicate hydrate by an addition reaction, as follows:

It is likely that calcium silicate hydrates containing low calcium/silicate (C/S) ratios favor fixation of metallic ions by this mechanism.

**FIXATION BY SUBSTITUTION:** In this mechanism, a calcium ion in the calcium silicate hydrate is substituted with a metallic ion in a reaction as follows:

Substitution of calcium ion from the structure of calcium silicate hydrate is generally found to occur with high C/S ratios.

**FIXATION BY FORMATION OF NEW COMPOUNDS:** Insoluble compounds containing metallic ions such as metasilicates may also be formed during hydration of portland cement. These compounds are probably the products of a substitution reaction between the calcium ions in the calcium silicate hydrate and metallic ions.

**FIXATION BY MULTIPLE MECHANISMS:** In a complex system such as cement and ash waste, it is likely that a combination of the above mechanisms operates to fixate metallic ions. These treatment mechanisms begin upon mixing, and continue as the cement cures through a period of months.

Several published studies show that portland cement or cement-based materials can be used to stabilize wastes containing heavy metals. Zirschky and Pizner (1988) shows that contaminated foundry sand having a soluble lead concentration of 79.8 mg/l could be stabilized to meet EP-toxicity criteria of 5.0 mg/l using portland cement. The advantages associated with using cement included achievement of stabilization of hazardous foundry sands at a low cost, and the ease of mixing cement with the waste. Benson et al. (1985) shows that sand-blasting residue containing approximately 0.4 and 9.0 mg of cadmium and lead, respectively, per gram of waste was stabilized when added (up to 15%) as an admixture for concrete. The concrete mixtures were found to retain the heavy metals so that none was detected following the EP-toxicity extraction procedure. Shively et al. (1986) shows that the leaching of industrial sludge containing heavy metals was substantially reduced by solidification with Type II portland cement. All samples met EP-toxicity criteria for nonhazardous wastes. During these studies, the treated wastes were cured for varying periods of time (Appendix A).

*Physical characteristics of ash.* The CREF produces combined ash, which is a mixture of bottom and fly ashes. The bottom ash consists of two fractions, the siftings and the grate ash, of which the latter comprises the greater fraction. Siftings ash consists of the material, generally less than one inch in size, that passes through moving grates on the floor of the furnace. The material that remains on the grates after combustion constitutes the grate ash. The grate ash is very heterogeneous, containing all size fractions from the very fine up to about four feet in length. The larger items may be inerts such as steel or masonry. The fly ashes consist of three distinct fractions: the boiler tube residue, the spray dryer ash, and the baghouse ash. Each of these, though unique in character, is of a relatively uniformly fine particle size. In all ashes, the finer fractions were found to have a greater concentration of the metals cadmium, copper, lead, and zinc. Ash finer than one inch constitutes about 75% of the total waste stream. The balance consists of ordinary uncombusted and inert refuse.

The large items present in the bottom ash (the ash that passes through the furnace) are easily recognizable as nonhazardous and inert material (CCR, 1983). Such items include, but are not limited to, rocks and pebbles, wood and plant pieces, and fragments of manufactured items of metal, plastic, rubber, and glass (CCR, 1983). Large metal and concrete items also occur in the bottom ash. The material larger than one inch in size may be separated by screening. Removal of large items improves the homogeneity of the ash and cement mixture. Treatment becomes more efficient through targeting the ash fraction, which requires treatment and removing large extraneous inert materials.

As we mentioned in the beginning, this chapter will deal with the processing of fly and bottom ash. We have selected the following applications to review.

## 2.3 Scopes and Designs

### 1. Utility

Conditioning fly ash with water only.

Fly ash from Western Coal (powder river basin).

Fly ash contained 26% calcium oxide class C chemical analysis (see Appendix B).

Scope and design

We supplied four 160 TPH Series I DustMASTERS including volumetric hoppers, all valves, 125 hp electric motors, connection chutes, and controls with software.

Batch size 8000 lbs.

Water content 15–18% by weight.

Cycle time 90 s.

The units operate 8 h per day, 5 days per week; at the end of the day shift, two workers clean the units by hand – time required 15 min. These units have been in operation since 1985, and the maintenance cost is \$0.01 per ton. This system was installed in 1985.

## 2. Utility

Conditioning fly ash with water only.

Fly ash type class F (see Appendix C), physical and chemical properties.

Scope and design

One 40 TPH Series I DustMASTER including weigh hopper, all valves, 40 hp electric motor, connection chutes, and controls with software and steel support structure. This was a turn-key project.

Batch size 2000 lbs.

Water content 8–10% by weight.

Cycle time 90 s, 40 batches per hour.

The system operates approximately 2 days per week; at the end of the shift the mixer is washed down with water. This system was installed in 1990.

## 3. Utility

Conditioning fly ash with water only.

Fly ash from western coal PC boiler.

Scope and design

Two 120 TPH Series II DustMASTERS including mixer mounted on load cells, all valves, 100 hp electric motor, connection chutes, and controls with software.

Batch size 6000 lbs.

Water content 15–18% by weight.

Cycle time 90 s, 40 batches per hour, 5 days per week.

At the end of the shift, the mixer is washed down with water.

Maintenance cost \$0.01 per ton.

This system was installed in 1994.

## 4. Utility

Conditioning fly and bottom ash with water only.

Partially hydrated FBC fly ash (see Appendix D) for physical and chemical properties.

Scope and design

One 60 TPH Series II DustMASTER including mixer mounted on load cells, all valves, 50 hp electric motor, connection chutes, and controls with software.

Batch size 3000 lbs.

Water content 20–25% by weight.

Cycle time 90 s, 40 batches per hour, 5 days per week.

At the end of each day, one man used a power wash to clean the mixer, requiring approximately 20 min. This system was installed in 1989.

#### 5. Medical waste incinerator

Stabilizing both fly and bottom ash with the silicate treatment.

Fly and bottom ash from incinerated hazardous medical waste (see Appendices E and F).

Scope and design turn key

One 20 TPH Series II DustMASTER including mixer mounted on load cells, all valves, 20 hp electric motor, connection chutes, and controls with software.

One 535 ft<sup>3</sup> insulated and heat-traced silo.

One dust collector.

One 55-foot-long drag conveyor, heat-traced and insulated.

One cement reagent hopper with delivery screw feeder.

One all-steel support structure.

One recorder and print-out, time-dated by batch and ingredients.

One complete installation of all equipment.

Batch size 800 lbs.

Water content 15% by weight.

Reagent (cement) 10%.

Cycle time 90 s, 40 batches per hour.

This system was installed in 1994.

Flexibility is the norm with our DustMASTER approach to processing all types of waste. With our programmable controller we can adjust all times within the sequence of events, and also change the batch weights. Therefore, if there is a change in the chemical composition of the fly ash requiring more or less process water, the change can be excepted at once via the programmable controller. Furthermore, if at a later date the waste material was declared hazardous, the DustMASTER base equipment would remain the same and a few components would be added to meet the new requirements.

The five examples described above were used as a cross section of the types of fly ash generated from various types of coal-fired boilers in the US, Asia and Europe. The most significant point is that the DustMASTER was able to process with water, or stabilize with chemical reagents, all types of fly ash and dust. Furthermore, our equipment has not encountered a material that could not be processed, up to and including nuclear waste. We do not infer that our unit is a panacea, but to date we have been able to condition all materials submitted to us for processing. In some cases we are conditioning the waste material for recycling to add to another product or application. In some cases we are able to feed it back into the process, eliminating the need for land filling. The ultimate goal for all is recycling. However, in some cases the technology is not in place at this time to accomplish complete recycling of all types of waste material.

## VII. Environmental protection procedures

<i>Spill response</i> Ventilate area. Collect spilled material.
<i>Waste disposal method</i> Dispose of in approved landfill
<i>Other protection</i>

## VIII. Special protection information

<i>Eye protection</i> Dust-resistant goggles	<i>Skin protection</i> Gloves
<i>Respiratory protection (specific type)</i> Dust mask	<i>Ventilation recommended</i>

## IX. Special precautions

<i>Hygienic practices in handling and storage</i> None
<i>Precautions for repair and maintenance of contaminated equipment</i> None
<i>Other precautions</i> None

**APPENDIX B MATERIAL SAFETY DATA SHEET. FLY ASH**

## I. Product identification

Processor's name:	Minnesota Utility
Telephone:	
Address:	
Date prepared:	
Chemical name and synonyms:	Fly ash
Trade name and synonyms:	N/A

## II. Ingredients

Typical analysis (wt. %):	Normal	Design	Upset
CaO	16.5%	20.5	24
CaSO <sub>4</sub>	8.5	11	15
SiO <sub>2</sub>	–	45–50	–
Al <sub>2</sub> O <sub>3</sub>	–	20–25	–
Fe <sub>2</sub> O <sub>3</sub>	–	10–17	–

## III. Physical data

Density for volumetric design:	38 lb/ft <sup>3</sup>
Density for structural design:	80 lb/ft <sup>3</sup>
Normal size:	200 microns × 0 for fly ash
Temperature:	300°F

## IV. Fire and explosion hazard data

Flash point:	–
Flammable limits:	–
Extinguishing media:	–
Special fire-fighting procedures	–
Unusual fire and explosion hazards:	–

V. Health hazard data

Route(s)	Inhalation? Skin? Ingestion?	- - -
Health hazards (acute and chronic):		-
Carcinogenicity: Monographs?	NPT? IARC  OSHA regulated?	- - -
Signs and symptoms of exposure:		-
Medical conditions generally aggravated by exposure:		-
Emergency and first aid procedures:		-

VI. Reactivity data

Stability:	-
Conditions to avoid	-
Incompatibility (materials to avoid):	-
Hazardous decomposition products:	-
Hazardous polymerization:	-
Conditions to avoid:	-

VII. Special or lead procedures

Steps to be taken in case material is released or spilled	-
Precautions to be taken in handling and storing	-
Other precautions:	-

**APPENDIX C MATERIAL SAFETY DATA SHEET. MIXTURES**

## I. Product identification

Processor's name:	Wisconsin Utility
Telephone:	
Address:	
Date prepared:	
Chemical name and synonyms:	Mixture
Trade name and synonyms:	Bituminous and sub-bituminous ash, coal ash, bottom ash, bottom slag, fly ash
Container:	Varies
Use:	Varies

## II. Ingredients

Chemical	%	CAS	TLV/PEL	STEL	CEIL
Amorphous silica	20-50	7631-86-9	6 mg/m <sup>3</sup>	-	-
Aluminum oxide	10-30	1344-28-1	10 mg/m <sup>3</sup>	-	-
Iron oxide	5-30	1309-37-1	10 mg/m <sup>3</sup>	-	-
Crystalline silica**	5-10	14,808-60-7	0.1 mg/m <sup>3</sup>	-	-
Calcium oxide	1-30	1305-78-8	5 mg/m <sup>3</sup>	-	-
Many trace metals	All <0.1	N/A	N/A	-	-

## Section 313. Supplier notification

This product contains the following toxic chemicals subject to the report requirements of Section 313 of the Emergency Planning and Community Right-To-Know Act of 1986 (40 CFR 372)

## III. Physical data

Boiling point:	N/A °F N/A °C
Melting point:	N/A °F N/A °C
Vapor density (air = 1)	N/A
Vapor pressure (mm Hg):	N/A
Bulk density:	N/A °F N/A
Solubility in water:	Slight
Appearance and odor:	Earth-tone powder and granular material
Specific gravity (H <sub>2</sub> O = 1)	2-3
Percent volatile by volume:	N/A
pH/concentration:	N/A N/A
Corrosivity on metals:	No

## IV. Health hazard data

Inhalation: Skin contact: Eye contact: Ingestion:	Little hazard produced by normal operation in open or well-ventilated areas May be abrasive and/or irritating May be irritating and abrasive Mild irritation of throat and GI tract
Health hazards (acute and chronic):	Lung damage. Specifically silicosis** Also see section IX**
Warning properties:	Eye, nose, or throat irritation
Signs and symptoms of exposure:	Skin redness or burning
Emergency and first aid procedures:	
Inhalation	Remove to fresh air. Seek medical help promptly. Use artificial respiration if necessary
Eye contact:	Flush with large amounts of water for at least 15 min. Seek medical attention
Skin contact:	Wash with mild soap and water
Ingestion:	Give milk or water. Do not induce vomiting Seek medical attention promptly

## V. Reactivity data

Stability:	N/A
Conditions to avoid:	N/A
Incompatibility (materials to avoid):	N/A
Hazardous decomposition products:	None
Hazardous polymerization:	Will not occur
Conditions to avoid:	None

VI. Environmental/handling/storage

Spill/disposal procedures:	Collect and dispose per local, state, and federal regulations
Storage requirements:	Contain as appropriate to minimize dusting <b>Keep all containers labeled</b>
Is this product listed or does it contain any chemical listed for the following:	
1. Disposal of product or any residue a hazardous waste? Hazardous waste code:	No N/A
2. An extremely hazardous substance under emergency planning and community right-to-know?	No
3. An EPA hazardous substance requiring spill reporting?	No
4. An OSHA hazardous chemical? Chemical name:	Amorphous silica Aluminum oxide Crystalline silica
5. Does it contain any materials regulated as a hazardous material or hazardous substance by the Department of Transportation? Proper shipping name: Hazard class: Identification No.: Label required: Shipping paper required: Quantity required for placarding: Packing GRP:	N/A N/A N/A N/A N/A N/A N/A

VII. Special protection information

Ventilation requirements: Consider on a case-by-case basis/usually not required	
Personal protective equipment	Respiratory: NIOSH-approved dust respirator based on OSHA PEL Eyes: Safety glasses with dust goggles recommended Skin: Gloves recommended if irritating to skin Special clothing: Cover skin areas as needed/fly ash can be irritating

VIII. Other

**\*\* Listed by IARC as a possible human carcinogen based on laboratory animal test data/no evidence of human carcinogenicity.**

Notice

This information was based upon current scientific literature. Information may be developed from time to time which may render this document incorrect. Therefore, the company makes any warranties to its agents, employees, or contractors as to the applicability of this data to the user's intended purpose.

**APPENDIX D MATERIAL SAFETY DATA SHEET. CFBC ASH**

## I. Product identification

Processor's name:	Midwestern University
Telephone:	
Address:	
Date prepared:	
Chemical name and synonyms:	Partially hydrated CFBC ash
Trade name and synonyms:	Partially hydrated circulating fluidized bed combustor ash
Description:	Inorganic mineral ash
NFPA ratings:	Health, 1; flammability, 1; reactivity, 1

## II. Ingredients

Hazardous ingredients	CAS	%
Calcium oxide	1305-78-8	10-25
Calcium sulfate	7778-18-9	40-60
Crystalline silica	14808-60-7	< 2.5
Magnesium oxide	1309-48-4	0.4-2.0

## Section 313. Supplier notification

The remaining components are not known to be hazardous as defined by OSHA's Hazard Communication Standard, 29 CFR 1910.1200

## III. Physical data

Boiling point:	N/A
Freezing point:	N/A
Solubility in water	Insoluble
Appearance and odor	Gray to white, no odor
Form:	Dust
Bulk density:	Approximately 75 lb/ft <sup>3</sup>
pH (1:1):	12.3 approximately

## IV. Fire and explosion hazard data

Not a fire or explosion hazard under normal conditions

## V. Health hazard data

Route(s) of entry: Inhalation? Skin? Ingestion?	Yes No No
Signs and symptoms of exposure to:	
Calcium oxide:	Calcium oxide is a strong alkali, is corrosive, and is dangerous when improperly handled. Marked corrosive action results from contact with all tissues of the body, and it can cause severe burns to the eyes, resulting in blindness. Since signs and symptoms of irritation are frequently not evident immediately after contact with calcium oxide, injury may result before one realizes that the chemical is in contact with the body. Therefore, adequate protection against such exposure should be provided for all parts of the body
Crystalline silica:	Eye contact may initially include irritation with discomfort, tears, or blurring of vision. Short exposures to very high concentrations of crystalline silica may be lethal. The predominant effect of overexposure to airborne crystalline silica in humans is silicosis. Silicosis is a chronic disease characterized by pulmonary fibrosis and the formation of silica-containing scar tissue in the lungs, with symptoms of coughing, dyspnea, wheezing, and nonspecific respiratory ailments. Individuals with pre-existing diseases of the lungs may have increased susceptibility to the toxicity of excessive exposure to crystalline silica
Carcinogenicity:	Crystalline silica is listed by IARC and NTP as a carcinogen
Applicable exposure limits:	
Calcium oxide:	TLV (ACGIH): 2 mg/m <sup>3</sup> , 8 h TWA PEL (OSHA): 5 mg/m <sup>3</sup> , 8 h TWA
Calcium sulfate:	TLV (ACGIH): 10 mg/m <sup>3</sup> of total dust containing no asbestos and <1% free silica, 8 h TWA PEL (OSHA): 15 mg/m <sup>3</sup> of total dust, 8 h TWA 5 mg/m <sup>3</sup> of respirable dust, 8 h TWA
Silicon dioxide (crystalline silica):	TLV (ACGIH): 0.1 mg/m <sup>3</sup> , or respirable dust 8 h TWA PEL (OSHA): 0.1 mg/m <sup>3</sup> , or respirable dust 8 h TWA
Magnesium oxide:	TLV (ACGIH): 10 mg/m <sup>3</sup> , 8 h TWA PEL (OSHA): 10 mg/m <sup>3</sup> , 8 h TWA

## VI. Reactivity data

Stability:	Stable. Reacts exothermically when water is added.
Incompatibility (materials to avoid):	None known
Hazardous decomposition products:	None
Hazardous polymerization:	Will not occur

## VII. Safe handling and storage

Do not take internally. Excessive inhalation of fine particles may result in respiratory disorders. Treat as a nuisance dust. Clean up with shovel or vacuum, taking steps to minimize fugitive dust. <b>CAUTION:</b> Material is exothermic upon exposure to water; avoid direct contact.	
Shelf life limitations:	N/A
Incompatible materials for packaging:	Non-waterproofed
Incompatible materials for storage or transport:	Non-waterproofed

## VIII. Special protection information

Eye protection:	Close-fitting goggles
Skin protection:	Minimize skin exposure by use of sufficient protective clothing, including gloves. Wash contaminated clothing after use. Wash skin with soap and water to avoid prolonged exposure
Respiratory protection:	Under normal use, use any NIOSH-approved fine particulate filtering mask. Extreme conditions may require the use of a self-contained breathing apparatus
Ventilation to be used:	Local exhaust

## IX. Emergency and first aid procedures

Eye contact:	Flush with water for 15 min or more. Call a physician
Skin contact:	Thoroughly wash skin with soap and water Wash contaminated clothing before re-use. Obtain medical attention if irritation persists
Inhalation:	Remove to area with fresh air. Give oxygen or CPR if necessary. Seek medical attention if needed
Ingestion:	Not considered to be a potential route of exposure

X. Waste disposal

Dispose of in accordance with all local, state, and federal regulations

## **3 OVERVIEW OF FUNDAMENTAL CATALYTIC EXTRACTION PROCESSING**

---

### **3.1 Introduction**

Wastes are typically heterogeneous materials that are an economic burden because value-recovery mechanisms are either unknown or uneconomical (Schung and Realf, 1997). If a technology can view wastes as the elements which comprise the original material, efficient separation and recovery of material from diverse feeds can occur (Nagel, 1990). Catalytic Extraction Processing (CEP) is a technology that uses thermodynamic and solution chemistry principles to achieve the above goal. It provides a means for manufacturing commercial products (i.e., industrial gases, alloys, and ceramics) from heterogeneous low grade materials (including hazardous, radioactive, and mixed waste) using a molten metal bath as both a catalyst for elemental dissociation and a solution for reaction engineering (Nagel et al., 1996).

CEP is able to manufacture products from a wide range of solid, liquid, and gaseous feeds due to its ability to dissociate feeds and dissolve those associated elements into predictable intermediates. Applications that are currently commercially deployed or under development include chlorinated and nonchlorinated organic liquids (Mather et al., 1995), incineration flyash, radioactive ion exchange resins (Castagnacci et al., 1997), mixed wastes from nuclear power plants (e.g., filters, grit blast media, personal protection equipment (PPE), paint, etc.)

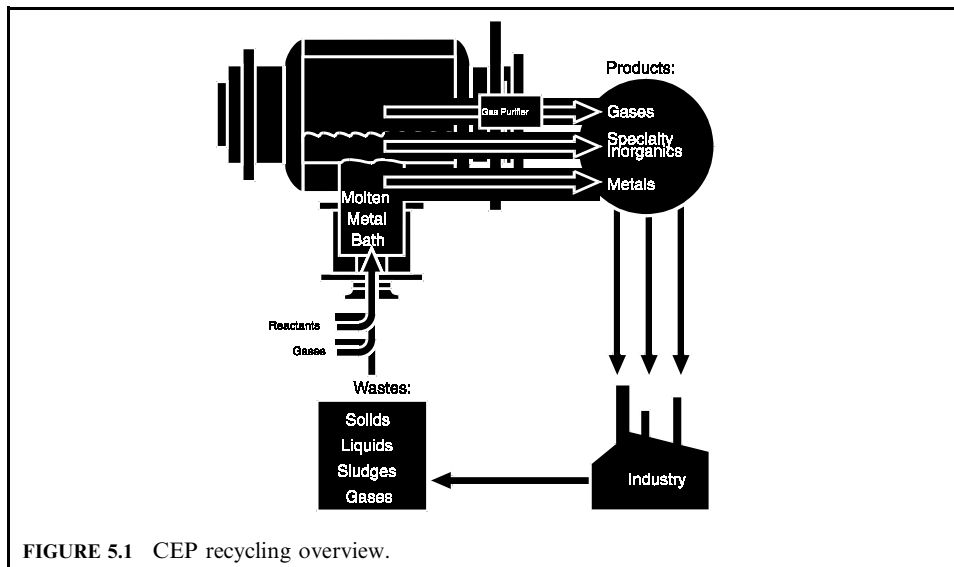

FIGURE 5.1 CEP recycling overview.

(Evans et al., 1997; Centec-XXI, 1997), radioactive nuclear wastes (e.g., supernate sodium nitrate), and chemical weapons (e.g., nerve agent) (Battelle Memorial Institute, 1996). Products that are generated typically include synthesis gas (i.e., carbon monoxide and hydrogen), ceramics (e.g., abrasives, cementitious media, filters, etc.), and metals (e.g., master alloys of iron, nickel, copper, etc.) (ENCORE Technical Resources, Inc., 1997).

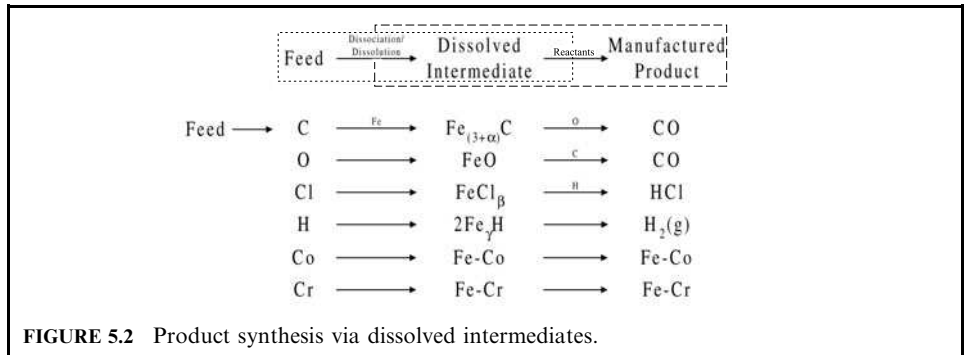

This chapter will cover

1. Catalytic Extraction Processing (CEP) fundamentals
2. standard engineering calculations to predict CEP performances
3. actual waste processing applications.

### 3.2 Understanding Catalytic Extraction Processing

At the core of CEP is a metal bath, operated at temperatures above its liquidus point. The synthesis route to final product involves two simple steps (see also Fig. 5.2):

**Elemental intermediate formation.** The liquid metal contained in the reaction zone, under standard operating conditions, causes feed materials to catalytically dissociate into their basic building blocks (e.g., elements). These constituents form single primary bonded elemental intermediates (e.g.,  $\text{Fe}_{(3+\gamma)}\text{C}$ ) (Bach et al., 1996, Glukhovstev et al., 1997) as a result of the favorable dissolution driving forces governing the metal–element interaction. The parent atom bound to the surrounding metal media (i.e., the dissolved intermediate) exchanges with any given metal atom(s) at diffusion controlled rates. Hence, the formation of the elemental intermediates is affected only by the elemental composition of the feed, not the physical form or molecular structure of the arranged atoms contained therein; and ensures that the resultant products are uncontaminated with their progenitors. This solution property of the CEP system also allows complete conversion of feed constituents and predictability in subsequent product generation.

**Product formation and recovery.** Thermodynamic driving forces govern product formation favorability under reaction conditions. Through the addition of select co-reactants and/or controlling operating conditions, the dissolved elemental intermediate(s) are reacted to form targeted chemical products with commercial utility. Product recovery is facilitated by partitioning the desired species between the metallic, ceramic, and gaseous product streams. Product partitioning between recoverable streams is governing by solution equilibria.

Engineering science calculations which elucidate the utilization of the above reaction pathway are:

1. *process chemistry* basics with attending solution requirements to enable elemental intermediate formation
2. *thermodynamic* basics including Gibbs free energy calculations, elemental partitioning prediction, and cofeed determination
3. *engineering calculations* including mass balance, energy balance, and reactor sizing.

### 3.3 Process Chemistry

With the appropriate choice of operating conditions (e.g., temperature ( $T$ ), pressure ( $P$ ), and moles of species ( $N_i$ )), organic compounds and reducible materials including metals and certain radionuclides can be dissolved in the metal bath. By virtue of the catalytic effect and solution chemistry of the bath, the metal actively participates in the formation of discrete elemental intermediates, creating a chemical-physical separation of feed from products (Glukhovtsev et al., 1997). The change in the Gibbs free energy of solution shows the thermodynamic favorability of elemental intermediate formation as contrasted to dissociation energy requirements in the absence of a solvent (Table 5.2). The relationship between the solubility of elements in molten iron and bond dissociation (Elliot and Gleiser, 1963) is further confirmed by experimental results (Fig. 5.3). The solubility of the element in the metal bath and the bulk concentration of that element in the metal establish dissolution driving forces and conversion performances at constant conditions (Fig. 5.4).

### 3.4 Thermodynamics

**Elemental partitioning.** The reaction of dissolved intermediates creates metallic (alloys), ceramic (inorganic oxides, halides, sulfides), and gaseous (industrial gases) products. Density differentials and immiscibility characteristics enable these products to be separated and recovered in distinct phases. The number of product phases and the final disposition of products are

**TABLE 5.2** Comparison of Dissolution/Dissociation Energetics in the Presence and Absence of a Metal Solvent

<sup>§</sup> C is the dissolved elemental C in the iron bath.

determined by thermodynamics and solution equilibria. The relative likelihood of a reaction can be obtained by comparing the negativity of the Gibbs free energy ( $\Delta G$ ) change upon reaction for the given conditions (Figs. 5.5 and 5.6) (United States Steel, 1985). Targeted product formation can be achieved through manipulation of thermodynamic space ( $T, P, N_i$ ) (Fig. 5.7). This is accomplished by changing bath composition (via modification of feed material addition and bath metal selection) and, to a much lesser extent, pressure of operation.

**FIGURE 5.3** The relationship between the solubility of elements in molten iron ( $\Delta G_{sol}(X)$ ) and their free energy of bond dissociation ( $\Delta G(Fe-X)$ ). (The experimental data on the solubility were taken from Elliot and Gleiser, 1963. The Gibbs free energies of Fe-X bonds were calculated at the BD(T) level.)

**Oxygen thermochemistry.** Synthesis gas is a mixture of carbon monoxide and hydrogen which is widely used in the manufacture of chemicals (e.g., methanol, methyl tertbutyl ether (MTBE), etc.). The end use product determines the syngas specification, including H<sub>2</sub>/CO ratio and the type and level of acceptable contaminants (e.g., metals, N<sub>2</sub>, CO<sub>2</sub>, etc.). In CEP, synthesis gas can be generated from any source of C, H, and O, provided the feed rates are controlled to achieve the targeted product specification. Since the bath carbon activity sets the bath partial pressure of oxygen which in turn bounds the CO/CO<sub>2</sub> and H<sub>2</sub>/H<sub>2</sub>O ratio, the desired product composition can be tailored by modifying the equilibrium position in the defining product forming reaction equations. The reaction of oxygen with carbon monoxide to form carbon dioxide is illustrated by the following reaction:

This reaction equilibrium coupled with assumed ideal gas behavior can be used to derive a very simple expression relating the partial pressure of oxygen to the ratio of the carbon monoxide concentration and carbon dioxide concentration as shown by the expression:

$$P_{\text{O}_2} \cong \left( \frac{y_{\text{CO}}}{y_{\text{CO}_2}} \right)^{-2} K_{\text{eq}}^{-1}$$

where the equilibrium constant,  $K_{\text{eq}}$ , is determined directly using gas phase thermochemical data. It is related to the Gibbs free energy of reaction by the relation:

$$\ln K_{\text{eq}} \equiv \frac{-\Delta G}{RT}$$

where  $R$  is the ideal gas constant and  $T$  is the absolute temperature. The CO/CO<sub>2</sub> ratio as a function of oxygen partial pressure at 1600°C is illustrated in Fig. 5.8. The vertical dashed lines have been added to highlight those conditions consistent with the oxidation of pure iron (Fe), pure nickel (Ni), and pure copper (Cu).

Similarly, the overall oxygen distribution between the various species within the product gas is given by the water-gas-shift reaction as indicated below:

FIGURE 5.8 CO/CO<sub>2</sub> ratio as a function of oxygen partial pressure at 1600°C.

Hence the overall oxygen requirement, represented as a normalized O/C molar ratio, is a function of the CO/CO<sub>2</sub> ratio. In chlorinated organic processing applications, the combined feed (H - Cl)/C molar ratio is assumed to be fixed at a value, for example 2. The overall oxygen requirement for various fixed combined feed (H - Cl)/C molar ratios at a temperature of 1600°C is shown as a function of the CO/CO<sub>2</sub> ratio in Fig. 5.9. These equilibrium data can be used to determine the synthesis gas quality under various operating conditions (e.g., temperature, CO/CO<sub>2</sub> ratio).

### 3.5 Engineering

Based on the above reaction pathways, organic feeds with elemental constituents carbon, hydrogen, oxygen, chlorine, and sulfur will form carbon monoxide, hydrogen, hydrogen chloride, and hydrogen sulfide. The amount of carbon dioxide inerts will be determined by the oxygen potential. Any metallic feeds with elemental constituents cobalt, nickel, copper, etc., will dissolve in the bath metal and form a metal alloy. Inorganic feeds with elemental constituents aluminum, calcium, magnesium, etc., will form an oxide layer based on their affinity to oxygen. Hence, once the elemental composition of feed material is known, the final destination of the elements and the final composition of the three phase products (gas, ceramic, metal) can be determined. A mass balance can be generated once component partitioning is calculated and the cofeed strategy is determined. An energy balance can be determined based on the heat of reaction and heat loss around the reactor. The mass balance, energy balance, throughput required, and targeted conversion performance will be used as baseline information for specifying the reactor sizing: reactor diameter, bath height requirement, headspace requirement, induction coil requirement, and refractory design.

Product development can be engineered through process chemistry, operating conditions optimization, and equipment modifications (shown in Fig. 5.10). For example, synthesis gas quality and contaminants (e.g., CO<sub>2</sub> levels) can be controlled by the oxygen potential and

pressure in the system with subsequent conditioning for end use application. Similarly, ceramic product quality is typically determined by chemical composition and post-process operation procedures; hence by predetermining cofeed addition strategies and post-process product handling mechanisms, targeted ceramic product quality can be achieved.

## 4 ENGINEERING CALCULATIONS OF CATALYTIC EXTRACTION PROCESSING

### 4.1 Process Chemistry

**PROBLEM 1:** Determination of Cofeed Strategies for Processing Chlorinated Organic Wastes

A highly chlorinated organic waste is requested to process in CEP to generate high quality synthesis gas with a CO : H<sub>2</sub> ratio ration 1 : 1 (vol.), and maximum HCl generation. What is the cofeed consumption to achieve the target product distribution? The elemental composition for the chlorinated organic waste is C 25%, H 5%, Cl 70%.

Goal: To complete the stoichiometric consumption of oxygen, and hydrogen cofeeds to achieve targeted product distribution.

*Solution:*

Step 1: To determine the chemical equations of the targeted reactions  
The targeted chemical equation is

Step 2: To determine the cofeed requirement to complete the reactions

Assuming 100 lb of feed materials, the number of lb moles of C, H, and Cl are:  
25/12 = 2.08 lb moles of C, 5/1 = 5 lb moles of H, and 70/35.5 = 1.97 lb moles of Cl.

Based on the above equations: 2.08 lb moles of C require  $2.08/2 = 1.04$  lb moles of  $O_2$  to form 2.08 lb moles of CO (g), 1.97 lb moles of Cl require 1.97 lb moles of H to form 1.97 lb moles of HCl (g),  $5 - 1.97 = 3.03$  lb moles of H form  $3.03/2 = 1.52$  lb moles of  $H_2$  (g).

Hence, without fine-tuning the CO :  $H_2$  ratio, the final product (per 100 lb of feed) has 2.08 lb moles of CO (g), 1.52 lb moles of  $H_2$  (g), 1.97 lb moles of HCl (g), and require 1.04 lb moles of  $O_2$  (g) to complete the reaction.

- Step 3: To determine the cofeed strategy to achieve the target product composition To achieve the target CO :  $H_2$  ratio 1 : 1, an additional hydrogen source is required. Using methane ( $CH_4$ ) as the hydrogen source, the following equation is used.

Let X be the number of moles of  $CH_4$  added per 100 lb feed.

$$\text{CO (lb moles) original} + \text{CO (lb moles) added by } CH_4 = \text{H}_2 \text{ (lb moles) original} + \text{H}_2 \text{ (lb moles) added by } CH_4$$

$$2.08 + X = 1.52 + 2X$$

$$X = 2.08 - 1.52$$

$$= 0.56$$

Hence, 0.56 lb moles of  $CH_4$  and 0.56 lb moles of additional  $O_2$  is required.

To summarize, for 100 lb of feed, the cofeed required is 0.56 lb moles (8.96 lb)  $CH_4$ ,  $0.56 + 1.47 = 2.03$  lb moles (64.96 lb)  $O_2$ , with a final product of 2.64 lb moles (73.92 lb) CO, 2.64 lb moles (2.64 lb)  $H_2$ , and 1.97 lb moles (71.91 lb) HCl.

Alternatively, using a per lb feed basis, the results can be summarized as:

Components	lb/lb feed
$O_2$ (cofeed)	0.65
$CH_4$ (cofeed)	0.09
CO (final product)	0.74
$H_2$ (final product)	0.03
HCl (final product)	0.72

**PROBLEM 2:** Determination of Product Phase for Processing Inorganic Materials

An inorganic-based waste has a composition as shown in the following table:

Component	wt%
$Al_2O_3$	6
CaO	45
$Fe_2O_3$	4
MgO	6
MnO	7
NiO	5
$SiO_2$	20
ZnO	2
C	5
Total	100

The generation rate of this waste stream is 500 tons per year. What is the annual product generation rate:

Goal: To determine the partitioning performance of the elements and calculate the various product phase generation.

*Solution:*

Step 1: To determine the partitioning performance of individual elements  
Using the Gibbs free energy diagram or the calculation procedure as shown in Problem 1 (Section 4.2), the resultant partitioning phases for the elements are:

Component	Partitioning phase	Partitioning form
Al <sub>2</sub> O <sub>3</sub>	Ceramic	Al <sub>2</sub> O <sub>3</sub>
CaO	Ceramic	CaO
Fe <sub>2</sub> O <sub>3</sub>	Metal	Fe
MgO	Ceramic	MgO
MnO	Metal	Mn
NiO	Metal	Ni
SiO <sub>2</sub>	Ceramic	SiO <sub>2</sub>
ZnO	Gas	Zn (g)
C	Gas	CO

Step 2: To determine the mass balance for product generation

Ceramic phase:

$$\text{Al}_2\text{O}_3 + \text{CaO} + \text{MgO} + \text{SiO}_2 = (500/100) \times (6 + 45 + 6 + 20) \text{ ton} = 385 \text{ ton}$$

Metal phase:

$$\begin{aligned} \text{Fe} + \text{Mn} + \text{Ni} &= (500/100) \times (4/(56 \times 2 + 16 \times 3) \times 56 \times 2 + 7/(55 + 16) \\ &\quad \times 55 + 5/(59 + 16) \times 59) \text{ ton} \\ &= (500/100) \times (0.025 \times 56 \times 2 + 0.098 \times 55 + 0.067 \times 59) \text{ ton} \\ &= (500/100) \times 12 \text{ ton} = 61 \text{ ton} \end{aligned}$$

Gas metal phase:

$$\begin{aligned} \text{Zn} &= (500/100) \times 2/(65 + 16) \times 65 \text{ ton} = (500/100) \times 0.025 \times 65 \text{ ton} \\ &= (500/100) \times 1.6 \text{ ton} = 8 \text{ ton} \end{aligned}$$

Gas phase:

$$\text{CO} = (500/100) \times (5/12) \times (12 + 16) = 58 \text{ ton CO}$$

Step 3: To determine oxygen balance and cofeed strategy

Total oxygen input in excess of that used in ceramic phase generation:

$$\begin{aligned} \text{From Fe}_2\text{O}_3 + \text{From MnO} + \text{From NiO} + \text{From ZnO} &= (500/100) \times 16(0.025/2 \times 3 \\ &\quad + 0.098 + 0.067 + 0.025) \\ &= 21 \text{ ton oxygen} \end{aligned}$$

Total oxygen output used in CO formation:

$$58 \text{ ton}/(12 + 16) \times 16 = 33 \text{ ton oxygen}$$

Hence  $33 - 21 = 12$  ton oxygen is required to add to the system to complete the carbon conversion.

The results can be summarized as

Inputs	
Feed	500 ton
Oxygen cofeed	12 ton
<b>Input total</b>	<b>512 ton</b>
Outputs	
CO	58
Ceramic product	385
Metal product	61
Gaseous metal	8
<b>Output Total</b>	<b>512 ton</b>

**CHALLENGE 1:** Determination of the cofeed strategy for an inorganic feed material

Based on the feed composition in Problem 2, what will be the cofeed strategy if the targeted ceramic product requires a composition of CaO 45%, SiO<sub>2</sub> 30%, Al<sub>2</sub>O<sub>3</sub> 20%, MgO 5%?

**CHALLENGE 2:** Determination of the intermediate structures

Why is the Gibbs free energy of solution in Table 5.2 positive for hydrogen and nitrogen but negative for chlorine or oxygen? Explain why  $G(\text{Fe} - \text{X})$  is negative, and  $G_{\text{sol}}(\text{X})$  is positive for  $\text{X} = \text{N}$  in Fig. 5.3? Using Table 5.2 and Fig. 5.3, what is an average energy in a metal parent atom bond? What are the likely chemical structures resulting from the dissolution of carbon, oxygen, and chlorine in iron?

## 4.2 Thermodynamics

**PROBLEM 1:** Determination of the partitioning results for various feeds

Consider a feed containing elements carbon, nitrogen, cobalt, nickel, calcium, and uranium-238. Determine where these elements will partition in a CEP system.

Goal: To determine how the listed elements partition between gas, ceramic, and metal phase.

*Solution:*

Step 1: To calculate the Gibbs free energy of oxide formation for these elements  
The Gibbs free energy for oxide formation is defined as

$$\Delta G = \Delta H - T\Delta S$$

where  $\Delta G$  is the standard Gibbs free energy change,  $\Delta H$  is the standard enthalpy change,  $\Delta S$  is the standard entropy change, and  $T$  is the temperature. The corresponding equations for these elements to be evaluated are:

Based on the thermodynamic equilibrium data from the literature (*Perry's Engineers' Handbook*, 1997), the Gibbs free energy for the above equations at the typical CEP operating temperature (1500°C) are:

**Step 2:** Comparing the Gibbs free energy values

Given that carbon is used as the reducing agent, oxidation reactions with a Gibbs free energy change more negative than that for CO formation will be favorable. Hence, Ca and U-238 will partition to the ceramic phase as metal oxides. The other metals, Co and Ni will remain in the metal and be recovered as ferroalloy. Oxidation byproducts like NO<sub>2</sub> formation is thermodynamically unfavorable under CEP operating conditions. The above evaluation can also be determined based on the standard Gibbs free energy diagram.

*Note:* The partitioning results indicated that radioactive materials can be concentrated into the ceramic phase to achieve significant volume reduction for radioactive final form disposal.

**PROBLEM 2:** Determination of chlorine partitioning

Where does chlorine partition in CEP systems?

**Goal:** To determine the Gibbs free energy of chlorine formation in the presence of various components: primarily with and without a ceramic phase.

**Solution:** Refer to Fig. 5.6: Gibbs free energy of chloride formation at the typical CEP operating temperature 1500°C. In the presence of a ceramic phase (alumina–calcia–silicate based) calcium chloride is highly favorable. Hence chlorine is expected to partition to the ceramic phase. In the absence of a ceramic phase, i.e., absence of Ca, Na, Ca, and other metals, hydrogen chloride will be the favorable product. Hence, hydrogen chloride is the expected product in CEP systems.

*Note:* This manipulation of elemental partitioning based on cofeed strategy is used if the partitioning phase of certain elements is required by the customer.

**PROBLEM 3:** Determination of sodium partitioning

If sodium is present in the inorganic materials as shown in Problem 2 in Section 4.1, what is the expected partitioning of sodium with/without a ceramic phase? What is the expected partitioning of sodium in the presence of chlorine and sulfur?

Goal: To determine the effect of various cofeeds and pressure on sodium partitioning.

*Solution:*

Step 1: To determine the standard sodium partitioning determination

The melting point of pure sodium is 700°C (Lide, 1975); hence in the absence of a ceramic phase, sodium will vaporize and be recovered in the gas phase.

In the presence of a ceramic phase, the Gibbs free energy diagram (Fig. 5.2) for oxide formation is used. The diagram indicated that sodium oxide formation is favorable in CEP conditions. The melting point of sodium oxide is 1500°C; hence in the presence of a ceramic phase, sodium will stay in the bath as sodium oxide.

Step 2: To determine sodium partitioning in the presence of chlorine and sulfur

In the presence of other anions, alternative reactions are considered:

To determine the competing reactions between oxygen, chlorine, and sulfur for sodium, the following equations are considered:

Based on the Gibbs free energy calculations of the above equations, the product distribution is determined by the thermochemistry equilibrium, and NaCl, Na<sub>2</sub>S are the predominant products. Hence in the presence of Cl and S, Na will partition to the gas phase as NaCl and ceramic phase as Na<sub>2</sub>S, respectively.

**PROBLEM 4:** Determination of bath metal for chlorinated organic wastes processing

The R&D scientists are considering the different options of bath metal in processing a highly chlorinated organic feed. The goal is to maximize the generation of hydrogen chloride which will be used as a product. The scientists are considering using a iron, copper, or nickel bath. Based on the Gibbs free energy determination, which bath metal should be used?

Goal: To determine the formation of chlorides in various metal baths and identify the one with minimal chloride formation.

*Solution:* Based on a diagram similar to Fig. 5.6 or Gibbs free energy calculation of the following equations:

By comparing the respective  $\Delta G_f$ , it is apparent that a copper system will minimize metal chloride formation and hence will maximize HCl generation.

**CHALLENGE 3:** Sulfur partitioning

How will sulfur partition in an iron bath system? How will partitioning be affected upon saturation of sulfur in the bath? How will the partitioning be affected if the system is operated at 6 bar? Repeat the previous question for an iron bath system that contains sulfur and sodium.

**CHALLENGE 4:** HCl formation

Which metal systems are reasonable for the formation for anhydrous HCl? Which metal system yields: the highest CO/CO<sub>2</sub> ratio; the lowest operating temperature; the lowest energy costs, least hazardous maintenance; the highest carbon solubility; the highest hydrogen solubility, the highest chlorine solubility? Why can the HCl/C ratio be assumed to be fixed for chlorinated organic processing applications?

**CHALLENGE 5:** UO<sub>2</sub> partitioning

What is the solubility of UO<sub>2</sub> in molten iron, nickel, and copper? If the targeted decontamination potential limit of the metal is 10<sup>-8</sup>, how would the UO<sub>2</sub> be extracted to achieve this level and how should the thermodynamic space be changed to achieve the targeted equilibrium?

### 4.3 Engineering/Product Applications

**PROBLEM 1:** Energy balance for chlorinated organic wastes processing

Determine the energy balance when processing a chlorinated organic waste stream with the following composition:

Element	wt. %
C	72.5%
H	9.76%
O	0.1%
Cl	17.63%

*Solution:*

Consider the reactions that will take place:

The resultant energy balance is:

$$\begin{aligned} & \text{Heat duty} + \text{heating value of feed} - H(\text{CO} \rightarrow \text{CO}_2, 298 \text{ K}) - H(\text{H}_2 \rightarrow \text{H}_2\text{O}, 298 \text{ K}) \\ & = H(\text{CO}, 298 \text{ K} \rightarrow 1800 \text{ K}) + H(\text{H}_2, 298 \text{ K} \rightarrow 1800 \text{ K}) + H(\text{HCl}, 298 \text{ K} \rightarrow 1800 \text{ K}) \end{aligned}$$

Hence

$$\begin{aligned} \text{Heat duty} = & H(\text{CO}, 298 \text{ K} \rightarrow 1800 \text{ K}) + H(\text{H}_2, 298 \text{ K} \rightarrow 1800 \text{ K}) \\ & + H(\text{HCl}, 298 \text{ K} \rightarrow 1800 \text{ K}) + H(\text{CO} \rightarrow \text{CO}_2, 298 \text{ K}) \\ & + H(\text{H}_2 \rightarrow \text{H}_2\text{O}, 298 \text{ K}) - \text{heating value of feed} \end{aligned}$$

The final energy balance can be determined based on feed heating value (9000 Btu/lb), heat of combustion, heat capacity of these products, as shown in the following table:

Compound	Heat of combustion		Enthalpy		Heat capacity polynomial regression constants		
	Btu/lb mol	Btu/lb	Btu/lb mol	Btu/lb	a	b	c
CO (gas)	20.873	745	-47,555	-1,698	2.37E-6	2.8E-2	-8.6588
H <sub>2</sub> (gas)	19.477	9642	0	0	1.70E-6	2.71E-2	-8.15575
CO <sub>2</sub> (gas)	-	-	-169,286	-3,847			
H <sub>2</sub> O (liq)	-	-	-122,964	-6,828			
HCl (gas)	20.184	554	-39,713	-1,089	2.29E-6	2.70E-2	-8.24483

Based on the above equation, the reactor heat duty is -1156 Btu/lb (exothermic reaction), i.e., the energy required to release out of the system is 1156 Btu/lb.

**PROBLEM 2:** Impact of operating conditions on energy requirements

Products resulting from the processing of 10 pounds per minute of allyl chloride (C<sub>3</sub>H<sub>5</sub>Cl) in a copper bath at 1350°C are given below with attending thermodynamic data at operating conditions. Determine the energy requirements if the stoichiometric ratio selected, under conditions of operation, promote the formation of carbon monoxide and hydrogen exclusively. What are the energy requirements if the stoichiometric ratio selected, under conditions of operation, promote only the formation of carbon dioxide and water? What is the percent of oxidation under substoichiometric conditions? How does the percent of oxidation change with varying CO/CO<sub>2</sub> ratio?

$$K_{eq} = y_{CO}y_{H_2O}/y_{CO_2}y_{H_2}$$

$$= 2.96 \text{ (at } 1350^\circ\text{C)}$$

*Solution:*

Product distribution is set by the stoichiometric conditions specified. Since carbon and hydrogen are the only species reactive with oxygen at the conditions specified, stoichiometric conditions favoring the formation of carbon monoxide and hydrogen result in a product distribution of:

C <sub>3</sub> H <sub>5</sub> Cl	CH <sub>4</sub>	O <sub>2</sub>	CO	CO <sub>2</sub>	H <sub>2</sub>	H <sub>2</sub> O	HCl
1.000	1.000	2.000	4.000	0.000	4.000	0.000	1.000

Similarly, stoichiometric conditions favoring the formation of carbon dioxide and water result in a product distribution of:

C <sub>3</sub> H <sub>5</sub> Cl	CH <sub>4</sub>	O <sub>2</sub>	CO	CO <sub>2</sub>	H <sub>2</sub>	H <sub>2</sub> O	HCl
1.000	1.000	6.000	0.000	4.000	0.000	4.000	1.000

The energy requirements are determined by establishing an enthalpy balance on the species formed under the conditions of interest. Using the data provided above, this balance becomes:

$$\begin{aligned}
 \Delta H &= \Delta H_{\text{out}} - \Delta H_{\text{in}} \text{ (kJ)} \\
 &= \left\{ \left[ \alpha \text{CO} \times \Delta H_{\text{CO},1350^\circ\text{C}} + \beta \text{H}_2 \times \Delta H_{\text{H}_2,1350^\circ\text{C}} + \chi \text{HCl} \times \Delta H_{\text{HCl},1350^\circ\text{C}} \right] \right. \\
 &\quad \left. - \left[ \delta \text{C}_3\text{H}_5\text{Cl} \times \Delta H_{\text{C}_3\text{H}_5\text{Cl},25^\circ\text{C}} + \epsilon \text{CH}_4 \times \Delta H_{\text{CH}_4,25^\circ\text{C}} + \phi \text{O}_2 \times \Delta H_{\text{O}_2,25^\circ\text{C}} \right] \right\} \\
 &= \left[ (4 \times -67.73) + (4 \times 39.53) + (1 \times -52.659) \right] - \left[ (1 \times -74.873) + (1 \times -0.628) \right] \\
 &= -89.958 \text{ kJ}
 \end{aligned}$$

Likewise, at stoichiometric conditions favoring the formation of carbon dioxide and water (e.g., the higher oxides) the energy requirement becomes:

$$\begin{aligned}
 \Delta H &= \Delta H_{\text{out}} - \Delta H_{\text{in}} \text{ (kJ)} \\
 &= \left\{ \left[ \gamma \text{CO}_2 \times \Delta H_{\text{CO}_2,1350^\circ\text{C}} + \eta \text{H}_2\text{O} \times \Delta H_{\text{H}_2\text{O},1350^\circ\text{C}} + \kappa \text{HCl} \times \Delta H_{\text{HCl},1350^\circ\text{C}} \right] \right. \\
 &\quad \left. - \left[ \lambda \text{C}_3\text{H}_5\text{Cl} \times \Delta H_{\text{C}_3\text{H}_5\text{Cl},25^\circ\text{C}} + \nu \text{CH}_4 \times \Delta H_{\text{CH}_4,25^\circ\text{C}} + n \text{O}_2 \times \Delta H_{\text{O}_2,25^\circ\text{C}} \right] \right\} \\
 &= \left[ (4 \times -324.674) + (4 \times -187.82) + (1 \times -52.659) \right] - \left[ (1 \times -74.873) + (1 \times -0.628) \right] \\
 &= -2027.134 \text{ kJ}
 \end{aligned}$$

The percent of oxidation is determined by calculating the enthalpic ratio for the condition of interest and comparing it to the condition of full oxidation:

$$\begin{aligned}
 \text{Percent oxidation} &= \Delta H_{\text{partial}} / \Delta H_{\text{full}} \\
 &= (-89.958 / (-2027.134)) \times 100 \\
 &= 4.44\%
 \end{aligned}$$

Now to calculate the percent of oxidation at varying CO/CO<sub>2</sub> ratios. By using the targeted CO/CO<sub>2</sub> ratio in conjunction with the equilibrium relationship provided in the problem statement, the moles of each species at each ratio specified can be calculated. The product distribution at varying CO/CO<sub>2</sub> ratios is:

CO/CO <sub>2</sub>	C <sub>3</sub> H <sub>5</sub> Cl	CH <sub>4</sub>	O <sub>2</sub>	CO	CO <sub>2</sub>	H <sub>2</sub>	H <sub>2</sub> O	HCl
1000	0.098788	1.000	1.987	3.960	0.004	3.970	0.006	0.0988
100	1.000	1.000	2.049	3.960	0.040	3.942	0.058	1.000
10	1	1	2.440	3.636	0.364	3.484	0.516	1.000
1	1	1	4.194	2.000	2.000	1.613	2.387	1.000
0.1	1	1	5.692	0.364	3.636	0.253	3.747	1.000
0.01	1	1	5.967	0.040	3.960	0.027	3.973	1.000
0.001	1	1	5.997	0.004	3.996	0.003	3.997	1.000
0.0001	1	1	6.000	0.000	4.000	0.000	4.000	1.000
0.00001	1	1	6.000	0.000	4.000	0.000	4.000	1.000

By calculating the energy requirements for each CO/CO<sub>2</sub> ratio and comparing it to the conditions at full oxidation, the percent oxidation at each condition can be determined:

Targeted CO/CO <sub>2</sub> ratio	Energy requirements (kJ)	Percent oxidation (%)
1000	-90.1757	4.45
100	-113.3968	5.59
10	-300.6319	14.83
1	-1146.5525	56.56
0.1	-1876.1429	92.55
0.01	-2010.8546	99.20
0.001	-2025.4932	99.92
0.0001	-2026.9698	99.99
0.00001	-2027.1176	100.00

#### CHALLENGE 6: Methane consumption

What is the methane requirement at the balanced energy point ( $\Delta H = 0$ ) for the processing of allyl chloride (C<sub>3</sub>H<sub>5</sub>Cl) at 1350°C? Assume that the allyl chloride feed rate is 10 lb/min. If the natural heat loss rate is 100 kW, what impact does the target CO/CO<sub>2</sub> ratio have on the methane requirement?

#### CHALLENGE 7: Heat duty

What is the resultant heat duty if a CO/CO<sub>2</sub> ratio of 8 is required for the above reaction; what if the required CO/CO<sub>2</sub> ratio is 100? At what CO/CO<sub>2</sub> ratio is the heat duty 0?

#### CHALLENGE 8: Product purity

How does synthesis gas yield and purity, resulting from the CEP processing of hydrocarbons, compare with other alternative approaches? What if the feed contains a substantial amount of chlorine (e.g., a chlorinated organic) or sulfur or phosphorous?

**PROBLEM 3:** Product quality of CEP synthesis gas

The composition of the synthesis gas generated from processing organic liquid sludge is:

Component	vol %
Carbon monoxide	40.0
Hydrogen	41.8
Carbon dioxide	1.0
Nitrogen	8.2
Argon	9

What is the corresponding heating value of the synthesis gas? To meet the synthesis gas product specifications, the targeted CO<sub>2</sub> should be < 1%. What are the potential options to achieve the low CO<sub>2</sub> content? The product is delivered in pressure. What is the impact of pressure on throughput?

*Solution:*

Step 1: To determine the heating value

	Heat of combustion data	MW
Hydrogen	-68.317 kcal/g mol	2
Carbon monoxide	-67.636 kcal/g mol	28

The heating value of the synthesis gas is:

$$\text{Heating of combustion of H}_2 \times \text{H}_2 \text{ vol\%} + \text{heating of combustion of CO} \times \text{CO vol\%} = 263.8 \text{ Btu/SCF}$$

Step 2: To determine the operating conditions

The product specification for synthesis gas is

Criterion	Specifications
H <sub>2</sub> : CO	1 : 1
Total inerts (N <sub>2</sub> , CO <sub>2</sub> , Ar, CH <sub>4</sub> )	< 2-4 vol%
HCN	< 0.1 ppmv
NH <sub>3</sub>	< 0.1 ppmv
Total nitrogen	< 1 ppmv
Total sulfur	< 0.1 ppmv
Oxygen	< 1 ppmv
Total halogen	< 1 ppmv
Total metals	< 1 ppmv
Pressure	60 psig

To consider the partial pressure of oxygen in various metal baths, the CO/CO<sub>2</sub> ratio has to be at least > 8 to achieve CO<sub>2</sub> less than 1 vol%. Given the wider range of operable CO/CO<sub>2</sub> ratio for a nickel and copper bath when compared with an iron bath, Ni and Cu are the preferred bath metal to be used. The other specifications can be achieved through standard purification process design.

Step 3: To evaluate the effect of pressure on product generation  
The synthesis gas is required to be compressed to 60 psig for delivery. By increasing the pressure, the throughput is increased given the maximum off-gas flow rate is kept constant (the off-gas flow rate is determined by the gas handling train design).

**PROBLEM 4:** Environmental performance for processing nerve agent (Battelle Memorial Institute, 1996)

Processing of chemical weapons mustard gas at the bench-scale CEP unit provided the following data:

	Time	Feed weight, g	Product gas, ft <sup>3</sup>
Start	17:50	204.57	834.97
Stop	18:37	172.70	843.77
Difference	47 min	31.87 g	8.8 ft <sup>3</sup>

The XAD resin trap for testing the outlet concentration of mustard shows non-detection to the limit of 0.2 µg/ml. What is the Destruction Removal Efficiency (DRE) of CEP in processing mustard gas?

*Solution:*

$$\text{DRE} = (\text{In} - \text{Out})/\text{In} \times 100\%$$

$$\text{Input} = \text{agent feed rate}/\text{time}$$

$$= 31.87 \text{ g}/47 \text{ min}$$

$$= 0.678 \text{ g}/\text{min}$$

$$\text{Output} = (\text{detection limit}/\text{gas volume}) \times (\text{gas volume}/\text{time})$$

$$\leq (0.2\text{E} - 6 \text{ g}/8.8 \text{ ft}^3) \times (8.8 \text{ ft}^3/47 \text{ min})$$

$$\leq 4\text{E} - 9 \text{ g}/\text{min}$$

Hence,

$$\text{DRE} \geq (0.678 - 4\text{E} - 9)/0.678 \times 100\%$$

$$\geq 99.9999993\%$$

**CHALLENGE 9:** VX processing performance

What is the DRE for VX based on the same above operating conditions, with a non-detection limit of 0.05 µg/ml for the XAD trap?

**CHALLENGE 10:** VX processing optimization

What is the chemical structure of VX? What is the metal system of choice for processing VX and why? What pressure should the system be operated at and why?

**CHALLENGE 11:** DRE determination of organics processing

The processing of chlorinated organics with an off-gas flowrate of 110 SCFM yielded a TO-14 analysis of:

Compound	Reporting limit (ppb)	Results (ppb)
Chloromethane	4.9	ND
Vinyl chloride	3.9	ND
Chloroethane	3.8	ND
Bromomethane	2.6	ND
Acetone	4.2	ND
Trichlorofluoromethane	1.8	ND
1,1-Dichloroethene	2.5	ND
Methylene chloride	2.9	ND
Carbon disulfide	3.2	ND
Trichlorotrifluoroethane	1.3	ND
trans-1,2-Dichloroethene	2.5	ND
cis-1,2-Dichloroethene	2.5	ND
1,1-Dichloroethane	2.5	ND
Methyl tert-butyl ether	2.8	ND
Vinyl acetate	2.8	ND
2-Butanone	3.4	ND
Chloroform	2.1	ND
1,2-Dichloroethane	2.5	ND
1,1,1-Trichloroethane	1.9	ND
Benzene	3.1	ND
Carbon tetrachloride	1.6	ND
1,2-Dichloropropane	2.2	ND
Bromodichloromethane	1.5	ND
Trichloroethene	1.9	ND
cis-1,3-Dichloropropene	2.2	ND
4-Methyl-2-pentanone	2.4	ND
trans-1,3-Dichloropropene	2.2	ND
1,1,2-Trichloroethane	1.9	ND
Toluene	2.7	ND
Dibromochloromethane	1.2	ND
2-Hexanone	2.4	ND
1,2-Dibromoethane	1.3	ND
Tetrachloroethene	1.5	ND
Chlorobenzene	2.2	ND
Ethylbenzene	2.3	ND
Bromoform	0.98	ND
Styrene	2.4	ND
<i>m,p</i> -Xylenes	2.3	ND
<i>o</i> -Xylene	2.3	ND
1,1,2,2-Tetrachloroethane	1.5	ND
1,3-Dichlorobenzene	1.7	ND
1,4-Dichlorobenzene	1.7	ND
1,2-Dichlorobenzene	1.7	ND

What is the appropriate Principal Organic Hazardous Constituent (POHC)(s) and what is the DRE based on EPA BDAT requirements? Feed was injected at a rate of 95 lb/min and the feed composition is shown as:

Volatile organics	µg/L
1,1,2-Trichloroethane	18,000,000
Tetrachloroethane	9,700,000
Chlorobenzene	12,000,000
1,2-Dichloroethane	6,800,000
1,1,2,2-Tetrachloroethane	11,000,000
Trichloroethene	24,000,000
Xylenes	610,000
1,1,1,2-Tetrachloroethane	1,000,000
sec-Butylbenzene	540,000
tert-Butylbenzene	2,000,000
Hexachlorobutadiene	3,600,000
<i>p</i> -Isopropyltoluene	870,000
Naphthalene	900,000
1,2,4-Trimethylbenzene	1,100,000

**PROBLEM 5:** Operating strategies for processing ion exchange resins

Ion exchange resins are processed in a batch mode. Typical throughput per batch is 50,000 lb of resins. The final crucible is disposed in a 42 ft<sup>3</sup> stainless-steel container. The typical composition, radioactivity, and volume of ion exchange resins is shown below. What is the product distribution of ion exchange resins? What is the distribution of radioactivity? What is the volume reduction?

Element	Composition, wt%, dry basis	
C	54.25	
H	6.0	
N	2.7	
S	8.7	
O	25.0	
Other elements, including Fe, Na, Ca, Mg, B, Al, Si, K and Cl	3.35	
Total	100	

Radionuclides	Activity, mCi	% of total
Ni-63	100.34	80.3%
Fe-55	8.53	6.8%
Cs-137	5.48	4.4%
Co-60	4.73	3.8%
Cs-134	2.04	1.6%
H-3	0.94	0.7%
Co-58	0.93	0.7%
Mn-54	0.60	0.5%
Ce-144	0.19	0.2%
Other*	1.25	1.0%
Total	125.02	100%

\* Includes Fe-59, Sb-124, C-14, Nb-95 and Zr-95.

Preprocessed volume of ion exchange resins, ft <sup>3</sup>	
Utility 1	1335
Utility 2	400
Utility 3	570
Utility 4	360
Utility 5	67

*Solution:*

Step 1: To determine the partitioning of bulk elements

The organic constituents (C, H, and O) in the IER feed are partitioned into the gas phase primarily as synthesis gas, which is a mixture of carbon monoxide and hydrogen. Nitrogen partitions to the gas phase as N<sub>2</sub>. Sulfur partitions primarily to the gas phase as H<sub>2</sub>S. The syngas, after purification by removing H<sub>2</sub>S in the GHT, is either ignited in a thermal oxidizer or used as fuel in a steam boiler. About 97 wt% (dry basis) of the IER feed was C, H, N, S, and O. Trace elements, such as Fe, Na, Ca, Mg, B, K, Al and Si which represented about 3 wt%, were captured in the metal bath. Particulates in the reactor off-gases includes carryover from the bath, and volatile metals and compounds. After separation from the off-gases, particulates can be recycled to the CPU. The mass balance for processing ion exchange resin is as shown below:

Stream	Weight, lb	Components/comments
1 Wet resin	50,000	
2 Dry resin	25,000	Composition shown
6 Final bath	1200 + Fe in initial charge	Bath growth due to partitioning of elements from resin feed such as Fe, Na, Ca, Mg, B, Al, and Si
7 Particulates	Recycled or purged as needed	Includes bath carryover and volatile metals
8 Syngas	35,500	CO, H <sub>2</sub> , and inerts
9 Sulfur recovery	1250	Sulfur compounds from caustic scrubbing

Step 2: To determine the distribution of radionuclide  
 For the radionuclide as shown above, the nonvolatile metals, including Ni-63, Fe-55, Co-60, Co-58, Mn-54 and Ce-144, partitioning to the metal bath and disposed in the crucible; and volatile metals, such as Cs-137 and Cs-134, and H-3 partitioning to off-gases. Cs-137 and Cs-134 were removed from the off-gases in the GHT and disposed together with the crucible. Hence all the radionuclides are disposed in the final form. The distribution of radioactivity of final exit are shown below:

Radionuclides	Activity, mCi	% of total	% in bath	% in off-gas and collected for disposal in the final form	% in off-gas
Ni-63	100.34	80.3%	80.3%		
Fe-55	8.53	6.8%	6.8%		
Cs-137	5.48	4.4%		4.4%	
Co-60	4.73	3.8%	3.8%		
Cs-134	2.04	1.6%		1.6%	
H-3	0.94	0.7%			0.7%
Co-58	0.93	0.7%	0.7%		
Mn-54	0.60	0.5%	0.5%		
Ce-144	0.19	0.2%	0.2%		
Other*	1.25	1.0%			1.0%
Total		100.0%	92.3%	6%	1.7%

Step 3: To determine the volume reduction  
 The total volume of wastes processed is per batch

$$= 1335 + 400 + 570 + 360 + 67 = 2732 \text{ ft}^2$$

The final disposal volume is the total ingot = 42 ft<sup>3</sup>  
 Hence, the volume reduction is:

$$2732 \text{ ft}^3 / 42 \text{ ft}^3 = 65$$

**CHALLENGE 12:** Weapon components processing

Devise a flowsheet and operations concept for the manufacture of a copper master alloy resulting from the catalytic extraction processing of 20,000 tons of weapon components (see composition below); repeat for the manufacture of an iron master alloy.

### CHALLENGE 13: UF<sub>6</sub> recycling

Devise a flowsheet and operations concept for the manufacture of anhydrous hydrogen fluoride (HF) and uranium oxide resulting from the catalytic extraction processing of 20,000 tons of uranium hexafluoride (UF<sub>6</sub>). If UO<sub>2</sub> is not wetted by the metal, how might the process flowsheet change?

**CHALLENGE 14:** Biosolids recycling

Devise a flowsheet and operations concept for the manufacture of synthesis gas ( $\text{CO}/\text{H}_2 = 1 \pm 0.1$ ,  $\text{CO}/\text{CO}_2 \geq 18$ ) from 20,000 tons of biosolids (see composition below)

Element	Average composition, wt%
Carbon	45.5
Hydrogen	6.6
Oxygen	26.4
Nitrogen	9.0
Sulfur	1.2
Chlorine	0.9
Ash	10.4
Total	100.0

### 1 INTRODUCTION

---

Incineration is a controlled combustion process used in the treatment of unusable wastes. Careful selection of equipment and processes for the incineration of wastes is essential to ensure that the basic obligations of safe handling and proper ultimate disposal are met in a satisfactory manner. Because of past research and development there are many incineration technologies that are available on the market. For obvious reasons, different waste may

require different treatment technology. In other words, technology A, which is suitable for incinerating waste A, may not be suitable for incinerating waste B. Therefore, proper selection of an adequate technology becomes a very important factor in designing a treatment facility.

This chapter describes a collection of thermal treatment technologies. The technology variation ranges from a very simple technology such as a liquid injection incinerator to a very complicated technology such as the recently developed vitrification process. The intended purpose is for readers, particularly beginners, to be aware of the breadth of technological options. The calculational methods which we provided in previous chapters are generally applicable to the technologies given in this chapter, because every technology has to meet the mass and energy conservation principle.

Construction of an effective system that will satisfy regulatory requirements and meet with the community approval is the ultimate goal of understanding the incineration processes. Accordingly, in the later part of this chapter, key elements that are needed for the design and operation of an incineration facility are provided for reference.

## 2 INCINERATION TECHNOLOGY

---

Because the technologies described in this section are “stand-alone” technologies, they are given in alphabetical order for easy search.

### 2.1 Catalytic Incinerator

**PROCESS DESCRIPTION:** Catalytic incineration is for the destruction of gaseous waste. The objective of catalytic incinerators is to destroy the organic components of a gas stream at lower temperatures than those required by direct combustion, thus effecting significant energy savings for wastes containing low concentrations of combustibles. The catalyst bed (or matrix) in commercial units is typically a metal mesh mat, ceramic honeycomb, or other ceramic matrix structure with a surface deposit or coating of finely divided platinum or other platinum family metals. The finely divided metal deposit is the catalyst for the oxidation reactions, while the matrix serves to support the catalyst on a high geometric surface area and promote good contact between waste stream and catalyst. Figure 6.1 shows a schematic of a catalytic process for fume incineration.

The basic steps of catalytic incineration include:

- gas phase heat and mass transfer of reactants to the surface film on the catalyst. The gas is normally preheated with fired burners and then passed over a catalyst bed where the oxidation reactions proceed;
- diffusion of adsorbed reactants within the surface film;
- oxidation reaction between reactants;
- diffusion and desorption of reaction products;
- gas phase heat and mass transfer of products leaving the catalyst.

At the appropriate temperature and residence time with sufficient oxygen present, 85–95% destruction of hydrocarbons can be achieved with catalytic incinerators.

Catalytic incinerators normally operate at temperatures below 600°C (1110°F) and residence times of approximately 1 s. The catalyst section is normally sized to provide a pressure drop no greater than 1 kPa (4 in WC, water column). It should not be used unless the gas stream constituents are consistent in analysis and contain neither particulate matter, halogens, nor other contaminants listed under Technology Application below.

The gas stream entering the catalyst shall have a minimum temperature of 315°C (600°F) and a maximum inhibitor concentration of 25 ppmv.

Flares or direct flame incinerators can be used with gases above the upper explosive limit (UEL) or below the lower explosive limit (LEL). Catalytic incinerators operate most efficiently when the gas stream concentration is no more than 25% of the LEL. The LEL is the lowest concentration of a gas in air that will sustain combustion. The UEL is that concentration above which there is insufficient air present to sustain combustion. Table 6.1 (OME-88/12, p. 4-92) lists LEL and UEL values for common compounds.

**TECHNOLOGY APPLICATION:** Catalytic incineration is most applicable to the destruction of gaseous wastes with low concentrations of combustibles. The waste stream must be free of particulates and several other contaminants (e.g., heavy metals, phosphates, arsenic compounds, halogens, sulfur compounds, alumina and silica dusts, iron oxides and silicones) which can foul the catalyst materials. Table 6.2 (OME-88/12, p. 91) lists a number of these catalyst inhibitors and their effect on the process. Although commercially available, catalytic incinerators are not widely used for waste gas destruction.

**TECHNOLOGY ADVANTAGE:** The technological advantage is the feature of treating waste containing low concentrations of waste constituents. The efficiency of most catalytic reactors in destroying products of incomplete combustion make catalytic incinerators valuable as secondary afterburners in some applications (DOE-93/03 p. C-9).

**TECHNOLOGY DISADVANTAGE:** The technological disadvantages include:

- the system is only suitable for treating gaseous streams; and
- catalysts will usually degrade over time by mechanical blinding of the active surface by particles and soot, or by deactivation (poisoning) of the surface by certain metals in the waste gas stream, or by internal changes in the catalyst resulting from inadvertent over-heating of the catalyst; common poisons for catalysts are copper, phosphorus, and zinc (DOE-93/03, p. C-10).

## 2.2 Controlled Air Incinerator

**PROCESS DESCRIPTION:** Controlled air incinerators are also known as fixed hearth or starved air incinerators. They typically contain two furnace chambers: a primary and a secondary chamber. Typical fixed hearth systems are shown in Figs. 6.2 and 6.3. Solid and liquid wastes may be charged into the primary chamber. Small units are normally batch-fed, while larger units may be continuously fed with a screw feeder or moving grate, or semicontinuously fed with a ram pusher. In some designs, there may be two or three step hearths on which the ash and waste are pushed with rams through the system. In other designs, rotating rabble arms stir the solid waste material on the grate. A controlled flow of “underfire” combustion air is

**TABLE 6.1.** Combustibility Characteristics of Pure Gases and Vapors in Air

LEL, lower explosive limits; UEL, upper explosive limit; —, not determined.

introduced, usually up through the hearth on which the waste sits. In some designs, combustion air may also be provided from the wall over the waste bed (EPA-94/05, p. 32).

The term starved-air is derived from the principle of combustion. The combustion air to the primary combustion chamber (PCC) into which the waste is fed is strictly controlled, so that the amount of air present is less than that needed for complete combustion, i.e., the chamber is “starved” for air. This type of incinerator is often referred to as a controlled-air incinerator because the amount and distribution of air to each combustion chamber is controlled to meet the design requirements.

**TABLE 6.2** Catalyst Inhibitors

Type of inhibitor	Effect
Fast-acting inhibitors: phosphorus, bismuth, lead, arsenic, antimony, mercury Slow-acting inhibitors: iron, tin, silicon	Irreversible reduction of catalyst activity at a rate dependent on concentration and temperature Irreversible reduction of catalyst activity. Higher concentrations than those of fast-acting catalyst inhibitors may be tolerated
Reversible inhibitors: sulfur, halogens, zinc	Reversible surface coating of active catalyst area. Removed by increasing catalyst temperature
Surface eroders and maskers: inert particulates	Surface coating of active catalyst area. Also erosion of catalyst surface at a rate dependent on particulate size, grain loading, and gas stream velocity

The temperature in the primary chamber is usually maintained in the range 760–870°C (1400–1600°F), whereas the secondary chamber may operate at temperatures as high as 1100°C (2010°F). Typically, 70–80% of the stoichiometric air requirement is introduced into the primary chamber. Approximately 140–200% of the primary chamber’s off-gas stoichiometric requirement is fed to the secondary chamber. The net air flow to the system is in the range 100–200% of the stoichiometric requirement.

**FIGURE 6.2** Fixed hearth incinerators (*EPA-94/05, p. 2-33*).

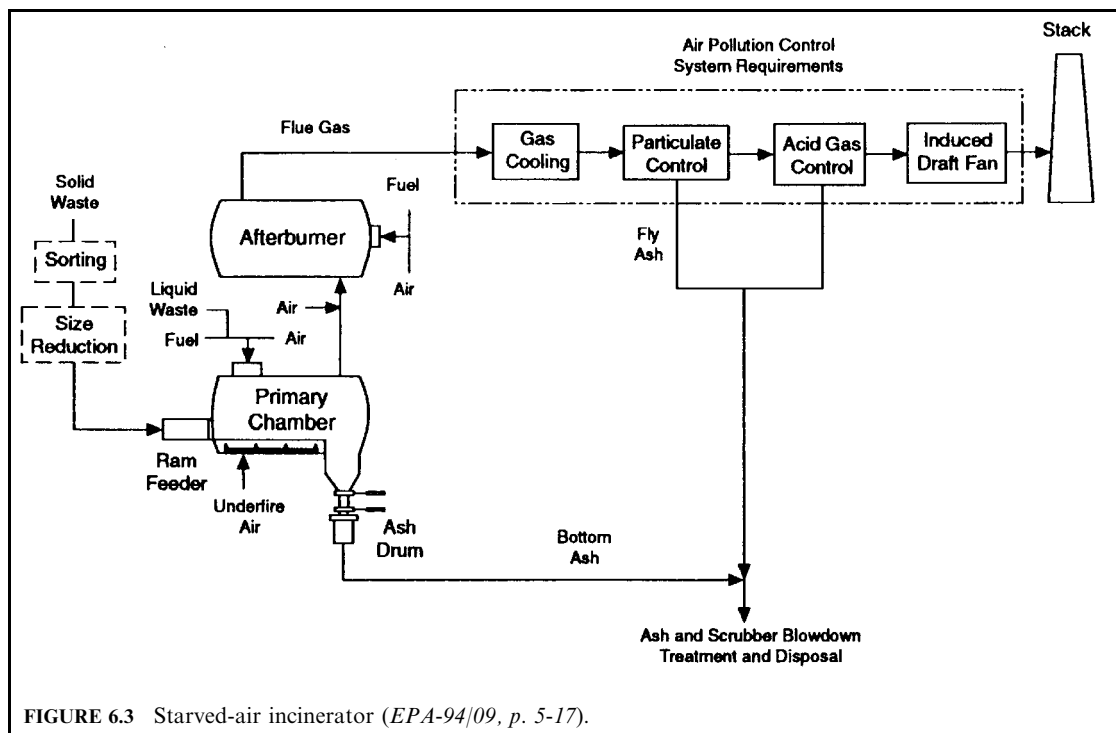

FIGURE 6.3 Starved-air incinerator (EPA-94/09, p. 5-17).

The air feed rate to each chamber is controlled by temperature. Below the stoichiometric air requirement (in the primary chamber) temperatures increase with increasing airflow, whereas in the secondary chamber, where excess air is provided, increasing airflow decreases the operating temperature. Automatic fan damper positioning is normally used to control the airflow, and thus the temperature, in each chamber.

Starved-air incinerators come in all sizes and shapes. Incinerators are available with design capacities ranging from 50 lb/h (23 kg/h) to 4000 lb/h (1800 kg/h). Some are manually controlled and others are automatically controlled. Some use manual waste loading and ash removal, and others are fully automated.

Critical fixed hearth operating parameters include primary chamber and afterburner temperature. Primary chamber temperature is controlled by the underfire air supply. Afterburner temperature can be controlled by auxiliary fuel firing and primary waste feed rate adjustments. Note that the capacity of the afterburner or secondary chamber limits the primary chamber burning rate. The afterburner must have adequate volume to accept and oxidize all volatile gases generated in the primary chamber. Additionally, the afterburner must be kept operating at excess air conditions to ensure complete volatile burnout.

Due to the starved air combustion in the primary chamber, the gas and entrained particulate matter flowing to the afterburner will contain unburned hydrocarbons (including hazardous organics) and high levels of CO and H<sub>2</sub>. In the afterburner, where 140–200 percent of the stoichiometric air required is supplied, these compounds are oxidized to CO<sub>2</sub> and H<sub>2</sub>O. Complete hazardous organic destruction will occur if sufficient time and high enough temperatures are provided in this oxidizing environment. Normally afterburners are sized to provide a minimum of 2 s of residence time in the afterburner at temperatures as high as 2200°F, depending upon the waste composition. An auxiliary natural gas burner in the secondary chamber is used to maintain temperature at the set point.

**TECHNOLOGY APPLICATION:** Controlled air incinerators are capable of treating solid, sludge, liquid and mixed wastes. For example, at DOE's Los Alamos National Laboratory (LANL), all solid waste feed for their starved air incinerator is prepackaged in 1 ft × 1 ft × 2 ft cardboard boxes. In the staging glovebox, which can hold 24-h worth of waste feed, a state-of-the-art multiple energy gamma assay system (MEGAS) and a micro-dose X-ray system are used to screen for large noncombustible waste items and to assay for radioisotopes. Boxes of acceptable waste pass out of the staging glovebox on a conveyor and are individually loaded into the hydraulic feed ram for charging into the primary chamber. For liquid wastes, a high intensity vortex liquid burner was installed on the side of the primary chamber. This burner is also used for heat-up and temperature modulation using natural gas or fuel oil.

**TECHNOLOGY ADVANTAGE:** The technological advantages include:

- the small size of these units, which makes them favorable for onsite treatment of small quantities of solid waste;
- the primary chamber can be operated with a wide variety of wastes with different chemical properties;
- the secondary chamber can be operated with conditions necessary to achieve high destruction efficiencies for organic materials;
- maintenance costs are typically low because there are no moving parts inside the incineration chamber;
- generally, the low combustion air input volume (starved air) in the primary chamber maintains a quiescent environment, resulting in lowered entrained ash or particulate matter in the combustion gases entering the secondary combustion chamber.

**TECHNOLOGY DISADVANTAGE:** The technological disadvantage lies primarily in limitations on acceptance of certain materials which require turbulence for effective combustion. Such materials include powdered carbon, pulp wastes, sludges, and highly viscous wastes.

### 2.3 Direct Flame Incinerator

Direct flame incineration is the most common method of gas incineration. Catalytic incineration uses catalysts to reduce the temperature required for waste destruction. Direct flame incineration includes:

- flare incineration
- fume incineration
- gas combustion
- afterburner.

**FLARE INCINERATOR:** Flaring is the simplest means of disposing of relatively large quantities of waste gas with combustible components. The gas is ignited and discharged to the atmosphere without heat recovery. The process is particularly suited to the disposal of intermittent gas discharges.

Supplemental fuel for flares is required when the gas heating value is less than 5600 kJ/Nm<sup>3</sup> (150 Btu/scf). Radiative heat from flares should be controlled to less than 34,000 kJ/(m<sup>2</sup>-h) [3000 Btu/(ft<sup>2</sup>-h)] for equipment, 5000 kJ/(m<sup>2</sup>-h) [440 Btu/(ft<sup>2</sup>-h)] for personnel on a continuous basis, and 17,000 kJ/(m<sup>2</sup>-h) [1500 Btu/(ft<sup>2</sup>-h)] for personnel on an intermittent basis. Provisions should be included for noise control in flare design.

As illustrated in Fig. 6.4 (OME-88/12, p. 4-87), a flare is basically a stack discharging a combustible gas to the atmosphere. A pilot flame at the end of the stack ignites the gas, the combustion of which is supported by the surrounding atmosphere. Steam is frequently intro-

FIGURE 6.4 Flare burner (*OME-88/12, p. 4-87*).

duced into the flame to generate turbulence and promote mixing with the surrounding air, to aid in cracking complex molecules, and to help oxidize carbon.

**FUME INCINERATOR:** A fume incinerator is one of the gas incineration devices. It is used to destroy gaseous or fume wastes. The combustion chambers are comparable with those of liquid injection incinerators in that they are usually single-chamber units, are vertical or horizontal in configuration, and use nozzles to inject the wastes into the unit for combustion. Wastes are injected by pressure or atomization through the burner nozzles. Using the waste in this manner to maintain combustion requirements reduces secondary fuel requirements. Wastes may be combusted solely by thermal or catalytic oxidation (EPA-86/09 p. 2-7).

Castable and brick refractories are used in the combustion chamber of a fume incinerator. The type used depends on the temperature required to incinerate the waste. For some units, the combustion chamber temperature is maintained at 650–980°C (1200–1800°F), with a fume retention time of 0.3–1.0 s to achieve maximum conversion to carbon dioxide and water. Use of a catalyst such as alumina coated with noble metals (e.g., platinum, palladium, or rhodium) and other materials (e.g., copper chromate, or oxides of copper, chromium, or manganese) can lower the required temperature to 260–480°C (500–900°F) and can also decrease retention time.

Exhaust gas from the incinerator can be passed through a heat exchanger before discharge to recover heat energy for a variety of uses. Fume incinerators may be equipped with air pollution control devices for removing  $\text{SO}_x$  or  $\text{Cl}^-$  gases, depending on the composition of the waste gases. Particulate controls and ash collection equipment are seldom needed because gaseous wastes yield very little ash when completely incinerated.

**TECHNOLOGY APPLICATION:** Direct flame incineration is best applied to waste gas streams rich in combustible constituents. Probably the most common application of flares is the combustion of waste gases and vent gases from petroleum refining operations. Fume incinerators have been successfully applied to control smoke and solvent emissions from surface coating operations and odorous emissions from food facilities, as well as combustible fumes from a wide variety of industries such as printing, food processing, and chemical processing.

**TECHNOLOGY ADVANTAGE:** The technological advantages include:

- flue incinerators can incinerate a wide range of gaseous wastes;
- continuous ash removal and particulate control systems are usually not required; and
- these incinerators have virtually no moving parts.

**TECHNOLOGY DISADVANTAGE:** The technological disadvantages include:

- if the heat content of the burned waste is not adequate to maintain ignition and incineration temperatures, a supplemental fuel must be provided; and
- if a catalyst is used in a fume incinerator, it must be replaced periodically, because of deactivation.

## 2.4 Fluidized Bed Incinerator

**PROCESS DESCRIPTION:** A fluidized bed is essentially a vertical cylinder containing a bed of granular material at the bottom. Combustion air is introduced at the bottom of the cylinder and flows up through the bed material, suspending the granular particles. Solid, liquid, and gaseous waste fuels may be injected into the bed, where they mix with the combustion air and burn. This section provides a process description and a discussion of the process operating parameters (EPA-94/05, p. 2-29; EPA-86/10, p. 4-41; OME-88/12, p. 4-73).

A fluidized bed incinerator consists of a fluidized bed reactor, fluidizing air blower, waste feed system, auxiliary fuel feed system, and an air pollution control device system. One such reactor, as shown in Fig. 6.5, has an inside diameter of 26 ft (8 m) and elevation of 33 ft (10 m). Silica beds are commonly used and have a depth of 3 ft (1 m) at rest and extending up to 6.5 ft (2 m) in height when fluidizing air is passed through the bed. The waste is put in direct contact with the bed media, causing heat transfer from the bed particles. At the proper temperature, waste ignition and combustion occur. The bed media acts to scrub the waste particles, exposing a fresh surface by the abrasion process, which encourages rapid combustion of the waste. Waste and auxiliary fuels are injected radially into the bed and react at temperatures from 840°F to 1500°F (450°C to 810°C). Further reaction occurs in the volume above the bed at temperatures up to 1800°F (980°C). An auxiliary burner is located above the bed to provide heat for start-up, reheat, and maintenance of bed temperature.

Generally, fluidized bed incinerators have two separate waste preparation/feed systems, one for solids and one for liquids. In some cases, four feed systems are employed: wet solids, dry solids, viscous fluids, and nonviscous fluids. Solid wastes are usually fed into a coarse shredder. The coarsely shredded waste falls into a classifier which separates the light and dense particles. The lighter particles are transferred to a secondary shredder, and from there they are conveyed to the hopper to feed the fluidized bed. Liquid waste is pumped into a larger holding tank. To ensure that the mixture is as homogeneous as possible, the liquid waste is continuously pumped through a recirculating loop from the bottom of the tank to the top. A metering pump draws the waste fuel to be burned from the tank to the primary reactor. Nozzles are used to atomize and distribute the liquid waste within the bed.

Critical parameters for optimum performance include fluidized bed temperature, oxygen level in the bed, solids residence time, bed fluidization, and combustion gas residence time.

FIGURE 6.5 Fluidized bed incinerator (EPA-94/05, p. 2-30).

Specifically:

- The fluidized bed temperature must be monitored and controlled by a waste feed and auxiliary burner to ensure that the temperature remains above an established minimum. Operating temperatures are normally maintained in the 1400–1600°F range.
- The oxygen level in the bed must be maintained to ensure the potential for complete combustion. Monitoring the carbon monoxide and total hydrocarbon concentration in the flue gas is also an indication of complete combustion.
- Solids retention time in the bed is a measure of the thorough treatment of the waste. Retention time is especially important for relatively noncombustible wastes.
- Uniform bed fluidization must be maintained to properly treat the waste.
- The combustion gas residence time must be monitored to ensure that the combustion gas has been exposed to a volatiles destruction temperature for a sufficient period of time.

The use of a control system could aid in maintaining fluidized bed temperature and flue gas residence time. The control system would involve the adjustment of waste and auxiliary fuel feed rates, as well as the ratio of oxidation/inert fluidization gases.

**TECHNOLOGY APPLICATION:** Fluid bed furnaces have been used for combustion of many materials, including coal, coke, wood, oil sands, and several other fuels. In incineration applications, fluidized bed systems have been used principally for the combustion of sludges, particularly sewage sludge. The first fluid bed used for incineration of sewage sludge was in 1962. Since that time it has been gaining popularity in North America. A prime requisite for the successful combustion of solid waste is that it be adequately prepared by shredding and sorting.

**TECHNOLOGY ADVANTAGE:** The technological advantages include:

- fluidized bed incinerators are generally applicable for the disposal of combustible solids, liquid, and gaseous wastes;
- the design concept is simple, and no moving parts are required in the combustion zone;
- because of the compact design, a fluidized bed can have a high heating rate per unit volume (100,000–200,000 Btu/h-ft<sup>3</sup>);
- fluctuations in the feed rate and composition are easily tolerated because of the large quantities of heat stored in the bed;
- because of its intimate contact with heated bed particles, waste can be combusted at lower temperatures than those of conventional incinerators;
- relatively low gas temperatures and excess air requirements tend to minimize nitrogen oxide formation and contribute to smaller, lower-cost emission control systems; temperatures in the vessel are reportedly high enough to destroy wastes, but low enough to prevent formation of significant amounts of NO<sub>x</sub>.
- the large active surface area resulting from the fluidizing action increases the combustion efficiency;
- the bed material acts as a scrubber to capture acid gas from the process, reportedly creating a nontoxic solid residue, and selection of proper bed material suppresses acid gas formation, thereby reducing emission control requirements;
- there is the potential for some metals capture in the bed, thereby lowering the emissions to the environment; and
- the fluid bed furnace system is compact, of airtight construction, and with most manufacturers it is maintained as a positive pressure system. By maintaining the entire system under positive pressure, the furnace must be designed to be airtight. This feature is useful in applications where the furnace is called upon to operate on a noncontinuous basis. If the furnace is to operate 5 days per week, for instance, its airtight construction allows it to be sealed fairly effectively. Dampers on its inlet and outlet will hold in its heat, and the refractory and sand within the unit provide significant thermal inertia. As a result of its construction the fluid bed furnace will lose as little as 5°C (9°F) per hour after a shutdown. It can be shut down on a Friday evening and will require only a few hours of heat-up on a Monday morning to be available for waste feeding.

**TECHNOLOGY DISADVANTAGE:** The technological disadvantages include:

- the presence of heavy, noncombustible materials in the waste may cause the bed volume to increase with time, necessitating tapping to prevent excessive agglomeration;
- feed must be selected to avoid bed degradation caused by corrosion or reaction, and waste feed particle size should be controlled to maintain a uniform feed rate;
- removal of the residual materials from the bed is a potential problem area. As waste combustion proceeds, noncombustible ash accumulates in the bed;
- beds with higher than 20 wt% ash are undesirable, since at ash levels of this magnitude, defluidization can occur;
- disposal of the supposedly inert residual bed material may present a problem (if the removed bed materials are considered to be hazardous, they would have to be disposed of at a secure landfill site);

- relatively large amounts of fine particulate matter entrained in the exhaust gases may require elaborate pollution control devices;
- accurate control is needed to ensure that retention time in the bed is sufficient for complete combustion, and that radical increases in the waste's heat value will not drastically boost bed temperatures and adversely affect bed operations;
- sophisticated analytical methodologies for the analysis of hazardous residues in the spent bed materials may be required. The analysis is normally required to determine how much unburned waste remains in the residues and to examine how much waste residue is leachable to the environment. It is quite possible that milligram amounts of hazardous materials may remain in the spent bed materials undetected. Disposal of the spent materials could then recycle the hazardous material back into the environment. This situation would be especially dangerous in the case of chemical warfare agents;
- other problems include corrosion of the combustor and mechanical devices for feeding wastes to the combustor;
- the fluidized bed incineration technique is not well suited for irregular, bulky solids, tarry solids, or wastes with a high fusible ash content. Formation of eutectics (compounds with low melting or fusion temperatures) can result in bed fouling. Problems caused by wastes with low ash fusion temperatures can be avoided by keeping operating temperatures below the ash fusion level or by using chemical additives to raise the ash fusion temperature. Waste containing bulky or irregular solids may require pretreatment in the form of drying, shredding, and sorting prior to entering the reactor (EPA-86/10); and
- labor utilization is high, since regular preparation and maintenance of the fluid bed must be performed. These costs can increase dramatically if it becomes difficult to remove residual materials from the bed (EPA-86/10).

## 2.5 Liquid Injection Incinerator

**PROCESS DESCRIPTION:** For purposes of incinerator design, a material is considered a liquid if it can be pumped to a burner, atomized, and fired in suspension. Liquid injection incinerators are either horizontally or vertically oriented, cylindrical, refractory-lined chambers fitted with nozzles firing axially or tangentially into the furnace. Vertical units may be upfired (i.e., the burner is on the lower end and fires upward), and combustion gases exit at the top of the combustion chamber. Downfired units are equipped with a wet quench at the combustion chamber exits at the bottom of the unit; this feature is especially important when wastes have a high salt content. Figures 6.6 and 6.7 show a horizontal and a vertical liquid injection incinerator, respectively (EPA-94/05, p. 2-27; EPA-86/10, p. 4-32; OME-88/12, p. 4-79).

The typical liquid injection incinerator includes a waste burner system, an auxiliary fuel system, an air supply system, a combustion chamber, and an air pollution control system. Liquid wastes are fed and atomized into the combustion chamber through the waste burner nozzles. These nozzles atomize the waste and mix it with air. Atomization is usually achieved either by mechanical methods such as a rotary cup or pressure atomization systems, or by twin-fluid nozzles which use high-pressure air or steam. With a relatively large surface area, the atomized particles vaporize quickly, forming a highly combustible mix of waste fumes and combustion air. This mixture ignites and burns in the combustion chamber. Typical combustion chamber residence time and temperature ranges are 0.5–2 s and 1300–3000°F (700–1650°C), respectively. Typical liquid feed rates are as high as 200 cubic feet per hour (5600 L/h).

Liquid injection can be used to incinerate virtually any combustible liquid waste, including slurries and sludges with a viscosity of up to 10,000 Saybolt Second Units (SSU). This viscosity represents the upper limit at which atomization can be used to expedite the conversion of liquid waste to a gas before combustion. Atomization is accomplished by

FIGURE 6.6 Liquid injection incinerator (EPA-94/05, p. 2-28).

FIGURE 6.7 Vertical liquid injection incinerator (OME-88/12, p. 4-81).

the use of gas-fluid nozzles with high-pressure air or steam. The waste must be atomized to small droplets of 40  $\mu\text{m}$  or less. Efficient destruction of liquid waste results from minimizing unevaporated droplets and unreacted vapors. Wastes with high solids are filtered prior to entering the feed tank. The liquid waste fuel system transfers waste from drums into a feed tank.

The tank is pressurized with nitrogen, and waste is fed to the incinerator using a control valve and a flow meter. The fuel supply line is purged with nitrogen after use. A recirculation system is used to mix the tank contents.

One of the very important components for liquid injection incinerators is the nozzle. Types of nozzles for liquid injection incinerators include:

- mechanical atomizing nozzle
- rotary cup burner
- external low pressure air atomizing burner
- external high pressure two-fluid burner
- internal mix nozzle
- sonic nozzle

**MECHANICAL ATOMIZING NOZZLE:** These are the most common types of burner nozzles in current use. Fuel is pumped into the nozzle at pressures of 515–1030 kPa (70–140 psig) through a small fixed-orifice discharge. The fuel is given a strong cyclonic or whirling velocity before it is released through the orifice. Combustion air is provided around the periphery of the conical spray of fuel produced. The combination of combustion air introduced tangentially into the burner and the action of the swirling fuel produce effective atomization. Normal turndown ratios are in the range 2.5 : 1 to 3.5 : 1. By utilizing a return flow line for fuel oil, the turndown ratio can be increased to as high as 10 : 1. A major disadvantage of this type of burner/nozzle is its susceptibility to erosion and pluggage from solids components of the fluid stream. Flames tend to be short, bushy, or low velocity, and this results in slower combustion, requiring relatively large combustion chamber volumes. This burner is applicable for fluids with relatively low kinematic viscosity, under  $0.22 \times 10^{-4} \text{ m}^2/\text{s}$  (100 SSU).

**ROTARY CUP BURNER:** Atomization is provided by throwing fuel centrifugally from a rotating cup or plate. Oil is thrown from the lip of the cup in the form of conical sheets which break up into droplets by the effect of surface tension. No air is mixed with fuel prior to atomization. Instead, it is introduced through an annular space around the rotary cup. Normally a common motor drives the oil pump, rotating cup, and combustion air blower. The liquid pressure required for this burner is relatively low, since atomization is a function of cup rotation and combustion air injection, not fuel pressure. This low pressure requirement and the relatively large openings within the burner fuel path allow passage of fluids with relatively high solids contents, as high as 20% by weight. They have a turndown ratio of approximately 5 : 1 and can fire liquids with kinematic viscosity up to  $0.65 \times 10^{-4} \text{ m}^2/\text{s}$  (300 SSU). Rotary cup burners are sensitive to combustion air flow adjustment. Insufficient air flow will result in fuel impingement on furnace walls, while excessive combustion air will cause a flame-out.

**EXTERNAL LOW PRESSURE AIR ATOMIZING BURNER:** The major portion of the combustion air requirement is provided at 7–35 kPa (1–5 psig) near the burner tip. Air is injected externally to the fuel nozzle and is directed to the liquid stream to produce high turbulence and effective atomization. The liquid pressure necessary for operation is only enough for positive delivery, normally less than 10 kPa (1.4 psig). Secondary combustion air is provided around the periphery of the atomized liquid mixture. The flame is relatively short because of the high amount of air provided at the burner (atomization and secondary combustion air). The short flame allows the design of smaller combustion chambers. These burners normally operate with liquids in the range  $0.43\text{--}3.24 \times 10^{-4} \text{ m}^2/\text{s}$  (200–1500 SSU) and can handle solids concentrations in the liquid of up to 30%. A small quantity of the air flow passes around the fuel discharge to aid in optimization of the fuel flow pattern.

**EXTERNAL HIGH PRESSURE TWO-FLUID BURNER:** The atomizing fluid, air or steam (or nitrogen or other gas), impinges the fuel stream at high velocity to generate small particles that encourage quick vaporization and effective atomization of tars and other heavy liquids. The required atomization pressure varies from 200 to 1030 kPa (30 to 140 psig). Turndown is in the range 3:1–4:1. The flame produced is relatively long, requiring appropriately constructed combustion chambers. The fuel viscosity normally handled by these burners ranges from 0.3 to 10.8 m<sup>2</sup>/s (150–5000 SSU) for either air or steam atomization. A solids content of up to 70% can be accommodated by these burners.

**INTERNAL MIX NOZZLE:** Air or steam is introduced within the nozzle to provide impingement of atomization fluid on the fuel stream prior to spraying. Atomization air is provided at pressures less than 200 kPa (30 psig), and steam is normally introduced at 620–1030 kPa (85–140 psig). The turndown ratio for this type of burner is from 3:1 to 4:1. These nozzles cannot tolerate a significant solids content and can handle only low-viscosity fuels, under 0.22 m<sup>2</sup>/s (100 SSU). This burner is used for clean, low-viscosity liquids. Its advantage is in its low cost compared with other burners.

**SONIC NOZZLE:** These nozzles utilize a compressed gas such as air or steam to create high frequency sound waves which are directed at the fuel stream. This acoustic energy is transferred to the liquid stream and creates an atomizing force, breaking the stream into minute particles. The fuel nozzle diameter is relatively large, allowing passage of solid particulate streams such as slurries and sludges with high particulate content. Little fuel pressurization is required. The spray pattern is not well defined, with finely atomized, uniformly distributed droplets travelling at low velocities. These nozzles are difficult to adjust, have low turndown, and generate an extremely high noise level during operation.

**TECHNOLOGY APPLICATION:** Liquid injection incinerators can be used to dispose of almost any combustible liquid waste, including lubrication oils, paints, solvents, and pesticides. With appropriate nozzle design, liquids with kinematic viscosities of up to  $1.62 \times 10^{-4}$  m<sup>2</sup>/s (750 SSU) can be fired in suspension. A wide variety of liquid injection incinerators are marketed today, and these represent probably the most common incinerator type for waste disposal.

**TECHNOLOGY ADVANTAGE:** The technological advantages include (EPA-86/09, p. 2-6):

- they can incinerate a wide range of liquid wastes;
- they are capable of a fairly high turndown ratio;
- they have virtually no moving parts.

**TECHNOLOGY DISADVANTAGE:** The technological disadvantages include:

- they are generally limited to wastes that can be atomized through a burner;
- the burners are susceptible to plugging (burners are designed to accept a certain particle size; thus the particle size of any solids contained in the liquid waste feed is a critical parameter for successful operation);
- burners may not be able to accept a material that dries and cakes as it passes through the nozzles.

## 2.6 Mass Burn Incinerator

**PROCESS DESCRIPTION:** A mass burning incinerator is an incineration process which burns unprocessed, mixed municipal solid waste (MSW) in a single combustion chamber under conditions of excess air, as illustrated in Fig. 6.8 (OME-88/12, p. 4–54).

MSW, which is usually bulky and heterogeneous in nature, is stored in a pit and fed into the incinerator by a crane, which can also remove oversized items. It is burned in a sloping, moving grate. The movement (e.g., vibrating, reciprocating, or pulsing) helps agitate the MSW

FIGURE 6.8 Moving grates for mass burning incinerators (OME-88/12, p. 4-56).

and mix it with air, and causes it to tumble down the slope. Many proprietary grates have been designed. Some systems use a rotating (or rotary) kiln rather than grates to agitate the waste and mix it with air. Many new mass burn incinerators use computer systems to precisely control grate movement, underfire air, and overfire air (OTA-89/10).

An MSW incinerator is normally (in excess of 50 t/d [55 T/d]) a continuously operated installation equipped with heat recovery equipment. Waste is burned in these incinerators without preprocessing.

The features of large central mass burning incinerators are distinguished by the design of the grate system. The grate must transport the MSW through the furnace and promote combustion by providing adequate agitation without contributing to excessive particulate emissions.

As the waste moves progressively through the furnace, it is dried, burned, and combusted to ash. Approximately 40–60% of the total air entering the furnace is provided as underfire air to cool the grates and prevent ash slagging. The balance is supplied as overfire air to completely combust the flue gas and particulates rising from the grates.

Many central waste incineration systems are built with waterwall construction in addition to boiler tubes within the flue gas stream (convection sections) to maximize energy recovery from the incinerator. Refractory-lined combustion chambers with a separate downstream boiler section may also be used in lieu of waterwall construction. If refractory walls are used, higher excess air is required to control the operating temperature.

Operating temperatures in mass burning central waste incinerators are normally maintained in the order of 1000°C (1832°F), and refuse residence time on the grate ranges from 20 to 45 min. Refractory wall systems normally require 100–150% excess air to maintain operating temperatures, whereas waterwall systems require only about 80% excess air. This offers the advantage of a smaller furnace volume and reduced NO<sub>x</sub> formation with the latter system, due to the lower airflow. Waterwalls extract heat from the burning waste. Without waterwalls, where the furnace chamber is lined with refractory, the furnace temperature must be controlled by the injection of cool air. In refractory or waterwall furnaces, the maximum temperatures should be below 1100°C (2010°F), the temperature at which slagging problems will begin to occur.

Underfire air is provided beneath the grates to prevent overheating of the grate system and to supply part of the waste combustion air requirement. Air is also provided above the grates (overfire air) to burn off the products of combustion of the waste and to properly direct flue gas flow within the furnace. Underfire air will comprise from 40% to 60% of the air flow to the furnace, with the overfire air flow inserting the balance of the air required for incineration.

Bulky goods (stoves, refrigerators, etc.) must be removed from the waste feed. With some systems there is a limited ability to handle waste tires, and they must be removed or distributed throughout the daily feed.

There are two types of corrosion mechanisms normally associated with waste burning facilities. One is dew point corrosion and the other is high temperature corrosion. Dew point corrosion occurs when the flue gas stream is reduced in temperature to less than 150°C (302°F). Refuse will contain plastics which, in turn, have a chloride component. In the presence of water vapor, which is always present when burning refuse, the chloride will convert to hydrogen chloride gas. When the gas temperature drops below 150°C (302°F), the hydrogen chloride will begin to condense to a liquid hydrochloric acid, which will produce severe corrosion to steel and other metallic surfaces.

High temperature corrosion of steel occurs when hydrogen chloride is present in the flue gas. At temperatures in excess of 370°C (700°F), ferric chloride will form; this compound is friable, i.e., it will form a series of flakes on the steel surface and the surface will “waste” away. As the temperature increases, this type of corrosion will increase significantly.

To reduce dew point corrosion, the exiting flue gas must never be allowed to drop too low in temperature. This is particularly important when an economizer or an air preheater is used to try to extract relatively low-level heat from the flue gas.

Control of high temperature corrosion is more difficult. By generating steam at a temperature less than 370°C (700°F), the incidence of high temperature corrosion will be greatly reduced (the temperature of the steel boiler tubes is essentially equal to the temperature of the generated steam). The concentration of hydrogen chloride in flue gas is highest just above the grate. To further reduce the corrosion potential of the flue gas, the lower section of a waterwall is normally coated with a refractory material with heat conduction properties, such as carbide brick or cement.

When superheated steam is desired, with temperatures in excess of 370°C (700°C), superheater sections should be placed as far as possible from the burning waste, downstream or immediately upstream of the boiler convection section. By the time the flue gas reaches this area of the incinerator, there should have been sufficient mixing by virtue of the turbulent upstream conditions to reduce the occurrence of concentrated pockets of hydrogen chloride. The hydrogen chloride should be fairly evenly distributed through the gas stream, resulting in a relatively lower concentration.

**TECHNOLOGY APPLICATION:** Central waste incineration systems are used primarily for refuse incineration. The practice has been more prevalent and more long-standing in Europe than in North America.

Mass burning of MSW in central incineration facilities is a commercially demonstrated technology. Due to the relatively large size of such units and unique features of each system with respect to waste handling, energy recovery, etc., these facilities are normally designed and built to meet each customer's specific needs.

## 2.7 Microwave Discharge Reactor

**PROCESS DESCRIPTION:** A microwave discharge, also known as microwave plasma, in the treatment of wastes is a special application in the general field of plasma chemistry. A microwave is an electromagnetic wave that has a wavelength between about 0.3 and 30 cm, corresponding to a frequency of 1–100 GHz. The technology uses microwave energy to excite the molecules of a carrier gas such as helium or air, thus raising electron energy levels and essentially forming very reactive free radicals. The gas in this high energy condition is called plasma. The excited electrons transfer this energy to break the chemical bonds of materials. Carbon-carbon bonds are among those most susceptible. Thus, theoretically, any organic waste (liquid, solid, or gas) placed into the plasma can be degraded to intermediate or ultimate products, perhaps destroying their toxic properties. Residence time within the plasma varies from 0.1 to 1.0 s. The temperature for plasma destruction can be as low as 150°C (300°F).

**TECHNOLOGY APPLICATION:** Lockheed, under the auspices of the US EPA, investigated the microwave plasma decomposition of wastes. The basic elements of Lockheed's microwave discharge reactor were: (a) a microwave generator or source of power; (b) a waveguide which leads the microwave power from the generator to a resonant cavity, which surrounds the reactor; (c) a reaction chamber, which must be made of silica or quartz to minimize dielectric losses; (d) a system for generating or feeding vapors, or reactants or condensed phases into the reaction chamber; (e) a system for controlling pressure and flow; (f) a system for collecting reaction products (EPA-76/11).

## 2.8 Molten Metal

**PROCESS DESCRIPTION:** The Molten Metal Technology Company is currently developing the Quantum Catalytic Extraction Process<sup>TM</sup> (CEP) for treatment of mixed wastes. The CEP is shown schematically in Fig. 6.9 (EPA-94/09, p. 5-100).

Wastes are fed into a molten metal bath where they absorb heat, mix with oxygen, and decompose. The waste organics are partially oxidized. Waste metals are dissolved and assimilated into the molten metal bath. Waste inorganic oxides which are insoluble in the metal bath rise to the top of the molten metal bath and form a distinct vitrified slag layer. The slag layer is tapped and disposed of, theoretically without further processing such as cementation. The metal layer is tapped as required. An afterburner is employed to complete combustion of the flue gas emitted from the surface of the melt. The main subsystems of the CEP are the waste preparation and feeding, the melting chamber, and the air pollution control systems.

FIGURE 6.9 Molten metal technology (EPA-94/09, p. 5-105).

The CEP is capable of treating liquid, shredded solid, slurry, and sludge wastes. These waste forms are introduced at the bottom of the furnace, beneath the molten metal surface. Methods to feed bulk solid wastes are shown in Fig. 6.10.

It may also be most effective to separate organics and nonmetal wastes from metal wastes. Additionally, it may be desirable to segregate metal wastes based upon metal chemistry so they are compatible with thermodynamic considerations, and to segregate them based upon radionuclide contamination. Work on melt refining of uranium-contaminated metal demonstrated the necessity of selecting proper slag and furnace melting procedures based upon the specific metal or alloy. For example, decontamination of aluminum requires a fluoride-type slag; borosilicate and oxidizing slags are most effective for nickel, ferrous metals, and copper; sodium-based fluxes should be used for zinc, lead, and tin.

The heart of the CEP is the bath of molten metal contained in a refractory-lined, enclosed vessel. The bath temperature is maintained between 2500 and 3500°F. Induction heating coils that circle the furnace are used to maintain bath temperature. Alternating current flowing through the coil produces a magnetic field which induces an electric current in the molten metal. The resistance of the metal to the current generates heat. Plasma heating, as described in a later section, may also be used. Partial combustion of waste organics with oxygen (not air) serves as an additional heat source. The molten bath remains well mixed due to natural convection currents and oxygen injection up through the bath.

When the waste comes into contact with the hot molten bath, it disassociates into elements. The catalytic and solvent nature of the molten metal bath assists in the conversion process. Oxygen is added to the bath to gasify waste organics and strip carbon from the molten metal. Oxygen is bubbled up through the bath through three "tuyeres" located at the bottom of the vessel. As in the steelmaking industry, the tuyeres are cooled using methane gas. The tuyeres consist of two concentric tubes; oxygen is transported in the inner tube and methane in the

FIGURE 6.10 Waste feeding techniques for MMT (EPA-94/09, p. 5-106).

outer tube. The methane is endothermically cracked, absorbing heat generated from the oxygen reacting with molten metal. A limited supply of oxygen is provided to create a reducing atmosphere within the melt. The flue gas leaving the melt contains carbon monoxide, hydrogen gas, and hydrocarbons.

The inorganic oxides in the waste which are insoluble in the metal bath rise to the top of the molten metal and form a distinct, vitrified slag layer. The slag layer may act as an insulator to keep the bath hot; it may also prevent emission of some volatilized metals and radionuclides. The slag typically contains silica oxides, iron oxides, magnesium oxides, and sulfur, chlorine, and phosphorus compounds. Controlling the properties of the slag is critical to the success of this process. The slag chemistry, viscosity, melting temperature, and final-form properties such as durability and leachability are controlled by adding different fluxes to the bath. Fluxes may include calcium, silica, alumina, magnesium, sodium, and potassium in the form of raw materials such as limestone, fluorospar, soda ash, borax, and dolomite. For example, borate or calcium fluoride can be added to provide increased slag fluidity, and ferric oxide may be added to increase its oxidative potential.

The accumulated slag and molten metal are to be tapped (removed from the furnace) separately. The slag and metals are poured into containers and allowed to cool and solidify. If the proper chemicals are added, the final slag product is ready for final disposal without further processing. The tapped metal layer may contain radionuclides and leachable metals—it may require stabilization prior to disposal. It is worth noting that because the melt stoichiometry is reducing, the metals do not mix with the slag. This is different from the plasma process, in which the oxidizing hearth stoichiometry allows the metals and other inorganics to be incorporated into one slag material, which is reportedly nonleachable.

**TECHNOLOGY APPLICATION:** The emerging CEP is derived from a metal separation process which has been used in the steelmaking industry for decades. The CEP has treated chlorinated organics, soils, and used electronics.

The CEP has been used to treat homogeneous wastes of known composition. It has not been demonstrated to treat heterogeneous wastes or wastes of unknown composition because the slag and bath properties become more difficult to control. Wastes with high organic content may not be appropriate for the metal melt refining process due to the importance of control of the thermochemistry and chemical make-up of the feed. Of particular concern are the presence of chemicals which cause explosive energy releases or disrupt refining processes when placed in the metal bath. Wet waste materials may cause steam explosions in the molten metal bath.

## 2.9 Molten Salt Oxidation

**PROCESS DESCRIPTION:** The molten salt oxidation (MSO) process is shown schematically in Fig. 6.11. The molten salt bath provides a variety of functions: (1) it provides a thermally stable medium in which the waste and oxygen may mix, (2) it provides a catalyst for the waste oxidation reactions and accelerates destruction of organic materials, (3) it retains soot, char, and ash generated during waste decomposition in the melt, and (4) it acts as an in-situ acid gas scrubber for neutralization and removal of acid gases such as HCl, HF, and  $\text{SO}_x$  formed during waste decomposition. The five main subsystems of the MSO process are the waste pretreatment, molten bath, salt recycle, air pollution control, and ash disposal systems. Each is described below (EPA-94/09 p. 5-7).

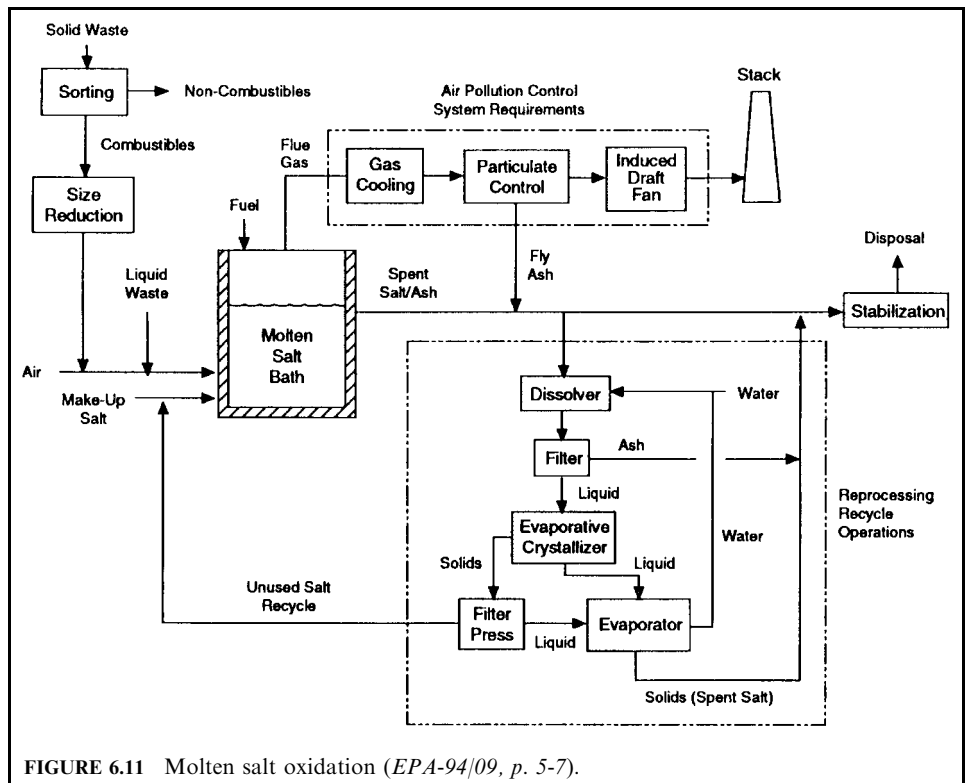

FIGURE 6.11 Molten salt oxidation (EPA-94/09, p. 5-7).

The heart of the MSO system is the refractory-lined vessel containing the molten salt bath. The temperature range of the bath is maintained at 900–1000°C, which is above the nominal salt melting temperature of 650°C. The molten bath is primarily composed of sodium carbonate, but may be supplemented with smaller quantities of other salts such as potassium carbonate, lithium carbonate, and/or sodium sulfate. The addition of lithium carbonate acts to lower the temperature of the melt. Addition of sodium sulfate acts to increase oxygen availability for more efficient waste organics destruction.

The liquid and size-reduced solid wastes are fed via pneumatic or screw-type feeders into the reactor vessel, near the bottom of the molten salt bath. The air may either be utilized as transport fluid for the wastes, or is bubbled up through the molten bath through a dedicated injector. The wastes come up to temperature and oxidize in a uniform fashion as they contact the air in the bubbling molten material. The heat content of the waste acts to maintain melt temperature; auxiliary fuel is used for temperature control. Chlorine and other halides react with the salts to achieve in-situ acid gas capture.

Molten salts near the surface are continuously removed from the reaction vessel and replaced with fresh salts near the bottom. The removed material consists of spent salts, unused salts, and ash. The salts become nonuseful once they have reacted to neutralize waste constituents such as chloride, fluoride, sulfate, or phosphate. The residual ash from thermal treatment of waste material may consist of inorganic metal oxides, aluminates, or silicate oxides, which are present as either dissolved solids or as distinct layers in the melt. For example, lead and aluminum may form separate metallic phases in the salt melt.

A higher melt ash content results in increased bath viscosity, preventing efficient mixing between the waste and the oxygen. Also, a more viscous melt is difficult to remove from the reactor. The rate at which the melt must be replaced depends upon the halide and ash contents of the wastes being treated. Specifically, the replacement rate should be adjusted to maintain an ash to salt ratio of less than 20 percent by weight, or to keep dissolved impurities low enough so that they do not have a negative effect on acid gas retention or other operating parameters. If equal amounts of silicon and aluminum oxides are present in the molten bath, an ash to salt ratio of less than 5 percent by weight must be maintained.

An additional problem is the formation of solid alumina, silica, and iron oxides, which will deposit and remain on the reactor walls until the unit is shut down for cleaning. To avoid this problem the Lawrence Livermore National Laboratory is developing a two-stage molten salt treatment process. The first bath is operated under reducing conditions to limit the formation of oxides. This allows the first bath to accept wastes with higher ash content. The second stage, which has minimal ash buildup due to ash removal in the primary bath, is operated under oxidizing conditions.

**TECHNOLOGY APPLICATION:** Rockwell International developed this technology and has conducted numerous pilot-scale tests. Although all testing results showed excellent destruction and removal efficiency, the technology has not been used commercially (EPA-86/10).

## 2.10 Multiple Chamber Incinerator

**PROCESS DESCRIPTION:** To overcome the problem of incomplete combustion associated with single-chamber incinerators, multiple-chamber units were developed. A primary chamber is used for combustion of the solid waste, while the secondary chamber provides the residence time, temperature, and supplementary fuel for combustion of the unburned products carried over from the primary chamber.

There are two basic types of multiple chamber incinerators:

- retort incinerator;
- in-line incinerator.

**RETORT INCINERATOR:** This unit is a compact incinerator in the form of a cube with multiple internal baffles. The baffles are positioned to guide the combustion gases through 90-degree turns in both lateral (horizontal) and vertical directions. At each turn, ash (soot) drops out of the flue gas flow. The primary chamber has elevated grates for burning of the waste and an ash pit for collection of ash residue. Cut-away views of a typical retort incinerator are shown in Figs. 6.12 and 6.13 (EPA-73/05, p. 438).

**IN-LINE INCINERATOR:** This is a larger unit than the retort incinerator. The flow of combustion gases is straight through the incinerator axially, with abrupt changes in direction, as shown in Fig. 6.14 (EPA-73/05, p. 439). Waste is charged on the grate, which can be either stationary or moving. As with the retort type, changes in the flow path and flow restrictions in an in-line incinerator provide settling out of larger airborne particles and increased turbulence for more efficient burning.

With both types of systems, supplemental fuel burners are provided in both the primary and secondary chambers. Depending upon the nature of the waste burned, the fuel supply in the primary chamber may be unnecessary after start-up although the secondary chamber normally requires a continuous fuel supply (at least a pilot flame). Overfire and underfire air to the primary chamber is normally aspirated through ports in the wall of the furnace, or is supplied at a controlled rate by forced draft fans. Additional air is added to the secondary chamber to ensure complete combustion.

Dimensional data for typical retort and in-line incinerators of varying capacity can be obtained from OME-88/12, p. 4-44 and p. 4-45. Although they represent the product of a single manufacturer, the dimensional data can be considered generic. They are typically operated at a temperature of 760–1000°C (1400–1832°F) in the secondary chamber, and normally use approximately 200% excess air. Approximately half of the required air enters as leakage.

FIGURE 6.12 Retort incinerator (EPA-73/05, p. 438).

Of the balance, 70% should be provided in the primary combustion chamber as overfire air, 10% as underfire air, and 20% in the mixing or secondary chamber.

They are applicable for refuse, trash, rubbish, and biomedical waste, but it is generally difficult to incorporate the air emission control equipment required to meet regulatory emission standards due to space and economic limitations.

**TECHNOLOGY APPLICATION:** Multiple chamber incinerators are commonly used for all types of solid waste as well as for specialty applications such as incineration of medical wastes, crematory incinerators, and metal drum reclamation.

Multiple chamber incinerators are commercially available, many as packaged systems. Retort incinerators are normally used for batch or semicontinuous operation in the capacity range 10–350 kg/h (22–772 lb/h). In-line incinerators are normally provided in the 225–900 kg/h (496–1984 lb/h) range, and may be equipped with automatic charging and/or ash removal equipment on units above 20 kg/h (44 lb/h) capacity.

## 2.11 Multiple Hearth System

**PROCESS DESCRIPTION:** As the name implies, a multiple hearth incinerator is designed with several combustion hearths. It is a vertical cylindrical structure, refractory-lined, with a series of refractory hearths positioned one beneath the other, as shown in Fig. 6.15. The

FIGURE 6.14 In-line incinerator (EPA-73/05, p. 439).

transport of the waste over the hearths is by rabble-arms that stir the waste pile and eventually move the waste to edges or ports in the hearth where the waste drops to the next hearth (DOE-93/03, p. C-4).

The temperature over any hearth can be controlled by direct-fired or indirect-fired auxiliary heat burners. The rabble arms and supporting control shaft are often air-cooled. The air that is heated in this manner can be used as preheated combustion air. The center shaft, which is hollow to allow the passage of cooling air through it, rotates within the incinerator at approximately one revolution per minute, carrying the rabble arms with it sweeping waste across the hearths.

The incinerator is particularly well suited to the combustion of sludge. The upper hearths drive volatiles from the incoming waste, the middle hearths combust the waste, and the lower stages cool the ash before discharge. When burning wastes with an appreciable volatile content, an afterburner chamber is usually included after the multiple hearth incinerator to ensure complete combustion of hazardous components in the exhaust from the “rotary” hearth.

Multiple hearth furnaces range from 2 to 8 m (6.6 to 26.2 ft) in diameter and from 4 to 23 m (13 to 76 ft) in height. The number of hearths is dependent upon the waste feed and processing requirements, but generally varies between 5 and 12 hearths. Waste retention time is controlled by the rabble tooth pattern and the rotational speed of the central shaft.

The upper hearths of the furnace comprise the drying zone where moisture is evaporated from the sludge. Flue gas exits this upper zone of the incinerator at 430–650°C (806–1202°F). Cooling air exiting the top of the center shaft is approximately 90 to 230°C (194–446°F), and is often recirculated to the furnace as preheated combustion air.

FIGURE 6.15 Multiple hearth incinerator (DOE-93/03, p. C-5).

In the center hearths, the combustion zone, temperatures are normally in the 760–980°C (1400–1796°F) range. The lower hearths cool the ash before discharge. Ash exits this system dry from beneath the furnace. It can be collected and disposed of dry, or it can be dropped into a wet hopper, mixed with water, and pumped to a lagoon for dewatering and ultimate disposal.

Sludge or other wastes to be incinerated in the hearth of a multiple hearth furnace should have a solids content of 15–40% for proper movement and rabbling through the furnace. The temperature above at least two hearths should be maintained at approximately 870°C (1600°F) at all times when burning sludge cake.

When burning wastes with an appreciable volatile content, an afterburner chamber is usually included after the multiple hearth incinerator to ensure complete combustion of hazardous components in the exhaust from the rotary hearth, i.e., elimination of smoke and odor.

Feeding a multiple hearth is relatively simple. Feed can be dropped onto the top hearth by gravity. It can also be deposited on the top hearth or a lower hearth by means of a screw conveyor. Attempts to feed sludge to a multiple hearth furnace pneumatically have met with failure. This system necessarily injects air into the furnace in strong discrete bursts, which makes maintenance of constant furnace draft difficult, if not impossible.

Fuel or gas can be used as supplemental fuel. Generally solid fuels, such as coal or wood chips, should not be placed on a hearth and used as supplemental fuel. They are relatively dry and will start burning on the top hearth, encouraging premature release of volatiles from the waste stream and inadequate burnout can result. Similarly, grease (scum) should not be added to sludge feed. If grease is to be incinerated in the multiple hearth furnace, it should be added

at a lower hearth (a burning hearth) through a separate nozzle(s). Grease will volatilize easily, and introducing it too high in the furnace where the temperatures may be below 760°C (1400°F) will not provide effective burnout.

The off-gas temperature can range from 425°C to 760°C (800°F to 1400°F). The oxygen content of the flue gas exiting the furnace should be continuously measured at the breeching leaving the top hearth. A sample should be continuously extracted from the gas stream, passed through a water bath to clean the sample and to reduce its moisture content, and then measured for oxygen content. The oxygen content should be in the range 6–10% by volume.

Excess air of 100–125% must be provided to ensure complete burnout of the sludge to ash. Since approximately 20% of the ash can be entrained in the flue gas, extensive gas cleaning equipment must be provided for its capture.

The multiple hearth furnace should always be run at a negative pressure (draft) to prevent external leakage of hot flue gas. If a separate afterburner is needed and if an emergency discharge stack is provided, the stack should be located downstream of the afterburner.

**TECHNOLOGY APPLICATION:** Multiple hearth incinerators are designed to burn wastes with low heating value such as sewage sludge and other high-moisture-content wastes. Its design includes drying as well as burning sections. Materials with less moisture content, such as coal or solid waste, will start to burn too high in the furnace. There would be insufficient residual time in these cases for effective burnout.

This incinerator system is relatively complex, with fans, burners, shaft speed, and feed charging all within the operator's control, and all affecting combustion efficiency and burnout. Particular attention must be paid to operator training in the proper control of these various equipment items and parameters.

This is the most prevalent incineration system for sewage sludge destruction in North America. Many multiple hearth incinerators have been built in the United States and Canada.

**TECHNOLOGY ADVANTAGE:** The primary technological advantage is the hearth's ability to handle wastes with high moisture and ash content, such as evaporator bottoms and wastewater treatment sludges. This incinerator can even handle sludges in the range 50–85% moisture. Hearths also are energy-efficient because of provisions for reclaiming heat from the ash and the ease of preheating combustion air.

**TECHNOLOGY DISADVANTAGE:** The technological disadvantages of hearths include:

- they are generally not applicable to the incineration of solid materials;
- the designs of the hearths are mechanically intensive and the maximum feed component particle size is limited;
- generally, the multiple hearth furnace cannot accommodate a temperature in excess of 1000°C (1830°F) without damage. If higher temperatures are required, an afterburner must be provided, which represents higher capital costs and higher operating (fuel) costs;
- it is virtually impossible to maintain heat in a multiple hearth furnace without firing supplemental fuel. This furnace, as noted above, has many areas of leakage, and therefore heat cannot be as effectively maintained within the units as in, for example, a fluid bed furnace.

## 2.12 Plasma Arc System

**PROCESS DESCRIPTION:** Plasma arc technology was originally developed for the United States space program. The evaluation of heat shields that protect space vehicles on re-entry required an intense heat source with plasma characteristics.

Plasmas have been referred to as the fourth state of matter since they do not always behave as a solid, liquid, or gas. A plasma may be defined as a conductive gas flow consisting of charged and neutral particles, having an overall charge of approximately zero, and all exhibiting collective behavior.

The plasma, when applied to waste disposal, can best be understood by thinking of it as an energy conversion and energy transfer device. The electrical energy input is transformed into a plasma with a temperature equivalent of up to 10,000°C at the centerline of the reactor. As the activated components of the plasma decay, their energy is transferred to waste materials exposed to the plasma. The wastes are then broken down into atoms, ionized, pyrolyzed, and finally destroyed as they interact with the decaying plasma species. The heart of this technology is that the breakdown of the wastes into atoms occurs virtually instantaneously and no large molecular intermediary compounds are produced during the kinetic recombination.

The most common method of plasma generation is electrical discharge through a gas. A low pressure gas is used as a medium through which an electrical current is passed. The type of gas used is relatively unimportant in creating the discharge, but will ultimately affect the products formed. In passing through the gas, electrical energy is converted to thermal energy by the absorption of gas molecules which are activated into ionized atomic states, losing electrons in the process. Arc temperatures up to 10,000°C may be achieved along the centerline recirculation vortex. Ultraviolet radiation is emitted when molecules or atoms relax from the highly activated states to lower energy levels.

A flow diagram of the plasma pyrolysis system is shown in Fig. 6.16. The plasma device is horizontally mounted in a refractory-lined pyrolysis chamber. Liquid wastes are injected through the colinear electrodes of the plasma device where the waste molecules dissociate into their atomic elements. These elements then enter the pyrolysis chamber, which serves as a mixing zone where the atoms recombine to form hydrogen, carbon monoxide, hydrogen chloride, and particulate carbon. The approximate residence times in the atomization zone and the recombination zone are 500 microseconds and 1 second, respectively. The temperature in the recombination zone is normally maintained at 900–1200°C.

After the pyrolysis chamber, the product gases are typically scrubbed with water and caustic soda to remove hydrochloric acid and particulate matter. The remaining gases, a high percentage of which are combustible, are drawn by an induction fan to the flare stack where they are electrically ignited. In the event of a power failure, the product gases are vectored through an activated carbon filter to remove any undestroyed toxic material.

TECHNOLOGY APPLICATION: Since an EPA/New York State pilot plant was tested in 1986 (Kolak-86), the plasma technology has made considerable progress. Full-scale plasma has

FIGURE 6.16 Plasma arc system (EPA-86/10, p. 4-66).

been installed to treat both liquid and solid waste. The authors call this technology the second generation of thermal treatment systems.

**TECHNOLOGY ADVANTAGE:** The technological advantages include:

- because radiative heat transfer proceeds as a function of the fourth power of temperature, a plasma system has very intense radiative power and therefore is capable of transferring its heat much faster than a conventional flame;
- organic chlorides are known to dehydrogenate when excited by ultraviolet radiation, which is abundant from thermal plasmas;
- because the plasma arc for waste destruction is a pyrolytic process, it requires virtually no oxygen. Compared with conventional incinerators, which normally require about 150% excess air to ensure proper combustion, the plasma arc will save the energy required to heat the excess air to the combustion temperatures, and will also produce significantly less gaseous by-product to be treated downstream;
- the process has a very short on–off cycle; and
- because of its compactness, a plasma arc system has potential for use as a mobile treatment system; the system would be housed in a trailer and moved from site to site.

**TECHNOLOGY DISADVANTAGE:** The technological disadvantages include:

- because the temperatures are so high (about 10,000°C at the arc centerline), the durability of the arc and the refractory materials could be a potential problem (from a corrosion or embrittlement standpoint); and
- because the arc is very sensitive to many factors such as sudden drops in voltage, the operation of the system requires highly trained professionals.

### 2.13 Pyrolysis System

**PROCESS DESCRIPTION:** Pyrolysis is the destruction of carbonaceous material in the presence of heat and substoichiometric oxygen levels. In practice, the heat is provided by combustion of a portion of the waste. Under ideal conditions, the pyrolysis of pure cellulose will produce combustible off-gases (methane and carbon monoxide), water (steam), and a residual char (carbon). The ideal pyrolysis reaction, of which there are many variations, is as follows (DOE-93/03, p. C-1) (Fig. 6.17):

In the actual destruction of waste, the off-gases are a mixture of many simple and complex volatile organic compounds, and the char is often a liquid containing residual carbon or tars and ash. In general, volatile gas production increases with increasing temperature, whereas the generation of tars and other liquors is greatest at lower temperatures.

Pyrolysis reactors typically operate at temperatures of between 500°C and 900°C (930°F and 1650°F), with waste residence times of 12–15 min. Systems designed to generate heat internally by combustion use less than the stoichiometric oxygen requirement. Depending on the waste characteristics and process design features, off-gas will typically have a heating value of between 5000 and 15,000 kJ/m<sup>3</sup> (134–403 Btu/ft<sup>3</sup>) which can represent as high as 80% of the heat energy originally contained within the waste. The solid residue normally represents less than 5% of the original waste volume, although pyrolysis systems will have a higher fixed carbon content than excess air incinerators. Pyrolysis units have been found to be applicable to the destruction of organic industrial sludges.

**TECHNOLOGY APPLICATION:** Pyrolysis has been used as an industrial process for many years for the production of charcoal from wood chips, coke and coke gas from coal, fuel gas

FIGURE 6.17 Pyrolysis reactor (DOE-93/03, p. C-3).

and pitch from heavy hydrocarbon still bottoms, etc. The process has been promoted for waste destruction only since the late 1960s. The only commercial pyrolysis system that has been found to operate successfully in North America is one that handles industrial semiliquid and sludge wastes at a number of pharmaceutical plants in the United States. The use of pyrolysis for the destruction of municipal sludge and solid wastes has not been successfully demonstrated to date on a commercial scale.

## 2.14 Refuse-Derived-Fuel Incinerator

**PROCESS DESCRIPTION:** The refuse-derived-fuel (RDF) incinerator is also known as the semi-suspension incinerator. RDF incineration differs from mass burning in that the waste is pretreated to produce a finer, more homogeneous matter, commonly referred to as refuse-derived-fuel or RDF. The pretreatment steps normally include shredding and ferrous metal recovery by magnetic separation, and can include air classification for removal of other non-combustible material (e.g., nonferrous metal and glass).

RDF can be coarse, fluff, powder, and densified pellets, briquettes, or similar forms and can be burned in two types of boilers. It can be used as the sole or primary fuel in dedicated boilers, or it can be cofired with conventional fossil fuels (e.g., coal and oil) or even wood in existing industrial or utility boilers. Boilers using RDF can recover energy. In addition, materials such as steel and glass recovered during the initial processing can be sold (OTA-89/10).

The RDF is blown into the furnace through a pneumatic charging system. Primary combustion (of approximately 70% of the waste's combustible content) occurs in suspension. Ash and unburned material drop onto a travelling grate where final burnout occurs. The grate discharges the ash to a hopper for removal to final disposal.

The high degree of turbulence in the furnace contributes to high ash carryover in the flue gas stream, necessitating the installation of higher efficiency particulate removal equipment with this type of incinerator than with mass burn units.

These RDF incineration systems require waste preprocessing which, at a minimum, includes shredders and magnetic separators. Although the heating value of the RDF generated by these processes can be 20% higher than the specific heating value of municipal solid waste (MSW), production of this fuel requires a significant investment in capital equipment and high operating costs. Likewise, system reliability is generally lower than for mass burn systems because of the greater amount of process equipment.

**TECHNOLOGY APPLICATION:** Although RDF incineration systems are commercially available, they have not gained the widespread acceptance that mass burning systems currently enjoy, largely due to the additional complexity and cost associated with waste preparation. They do, however, allow the reclamation of salvageable materials from the waste stream (OME-88/12, p. 4-61).

## 2.15 Rollins Rotary Reactor

**PROCESS DESCRIPTION:** The Rollins rotary reactor (RRR) is essentially a cross between a rotary kiln and a fluidized bed. The primary reactor contains a bed of inert media which is effectively fluidized by the rotating action. Shredded solids, liquid, and sludge wastes are injected directly into the inert material and burned. The off-gas flows to an afterburner which ensures complete destruction of the hazardous organics. The RRR provides the capability for in-situ acid gas control by using an alkali agent in the media bed (EPA-94/09, p. 5-33).

The RRR incineration system consists of four major subsystems: waste preparation, primary reactor, afterburner, and air pollution control systems. The RRR system is shown in Fig. 6.18 (EPA-94/09, p. 5-38).

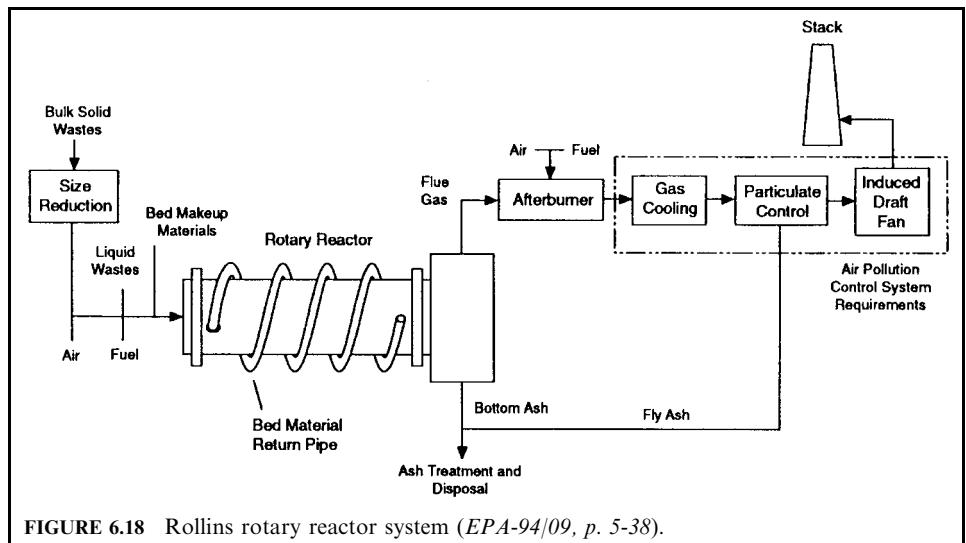

FIGURE 6.18 Rollins rotary reactor system (EPA-94/09, p. 5-38).

The RRR is a rotating horizontal cylindrical combustion chamber which rotates at a rate of five revolutions per minute—approximately ten times faster than a conventional rotary kiln. Externally, the cylinder looks like a rotary kiln with the exception of the helixes attached to the outer shell. Internally, the RRR incinerator is refractory-lined, and equipped with a series of equally spaced lifter assemblies around the circumference. Heat transfer media (such as sand) reside in the combustion chamber and are thoroughly mixed by the mechanical energy imparted by the combination of high speed rotation and the internal mixing devices.

Waste materials are charged through the front wall directly into the noncombustible media, which rapidly heats the waste to combustion conditions. To further enhance mixing, the inert media are recirculated from the exit to the inlet of the combustion chamber. This is accomplished through the use of external helical coils wrapped around the RRR shell which convey media as the unit rotates. Axial movement of the inert solids is driven by gravity due to a slight downward slope and the rapid rotation of the RRR shell. The external helixes are conduits for recirculating the inert bed material from the discharge end of the combustion chamber to the inlet end.

The inert bed is effectively fluidized by the rotation of the incinerator shell. In contrast to stationary fluidized beds, where the combustion air must be supplemented with additional air or nitrogen to effectively fluidize the bed, the quantity of combustion air required by the RRR is set according to the stoichiometric requirements of the waste material being burned without regard to maintaining a minimum gas velocity. This feature allows optimal balancing of combustion air/fuel ratios in the RRR, providing maximum thermal efficiencies. Moreover, the fluidization activity within the RRR is less subject to upsets and channeling caused by improperly sized or sticky feed materials. Conventional pneumatic fluidized beds must be operated with carefully graded and conditioned feed materials to prevent short circuiting and channeling in the bed, which may produce poor destruction efficiencies and operating economies.

The primary combustor operates under excess air conditions, at slightly subatmospheric pressures, and within a temperature range of 1200–1600°F. An alkali reagent is added to the bed material at approximately 1.5 times the stoichiometrically required amount. In the event that the heating value of the waste is not sufficient to allow combustion at these low temperatures, natural gas or fuel oil is fired in a conventional burner, while wood chips are mixed with contaminated soils and fed through the shredder/screw conveyor system. Temperature is monitored at several locations in the primary reactor and a feedback control loop modulates solid, liquid, or auxiliary fuel flows to maintain the temperature at the set point. Excess oxygen is also monitored at the primary chamber exit. This measurement is used to control air flow. If excess O<sub>2</sub> drops below 2 percent, all feeds to the primary chamber are stopped.

At the exit end of the primary combustor, there is a separation zone in which the velocity is reduced so that the larger particles drop to the bottom of the chamber and the flue gas exits through the top. The ash particles are drawn from the bottom in a screw conveyor for final disposal. The flue gas travels from the top of the separation chamber to the afterburner.

A refractory-lined afterburner chamber is sized to provide a 2-s residence time at a minimum temperature of 2000°F. The temperature and oxygen are measured at the secondary chamber exit. Auxiliary fuel is fired to ensure that the temperature is maintained. If oxygen drops below 3 percent, feed to the primary reactor is shut off.

**TECHNOLOGY APPLICATION:** Rollins Environmental tested the RRR in a pilot program using a prototype reactor in the mid-1980s. Since that time, a commercial unit was built and has been operating at their plant in Deer Park, Texas, for more than 4 years. This particular unit is operated in conjunction with a 4.4-m rotary kiln incinerator, both use a common afterburner and wet scrubber system. The reason for this is that the rotary kiln and scrubber were already in place at the plant when the RRR was installed. Because the RRR is capable of in-situ capture of HCl in a stand-alone system, a wet scrubber with its associated waste stream would not be required.

## 2.16 Rotary Kiln System

**PROCESS DESCRIPTION:** Rotary kiln systems used for waste incineration typically consist of two incineration chambers: the kiln and an afterburner. The waste is fed into the rotary kiln chamber and burned. The ash is removed at the end of the chamber. The combustion gases travel to the afterburner and are maintained at a specified temperature for a specified residence time to complete destruction of any remaining organic. A typical rotary kiln incinerator system is shown in Fig. 6.19 (EPA-94/09, p. 5-27).

The rotary kiln itself is a inclined horizontal steel cylinder with an outside diameter typically less than 15 ft, so the kiln can be shipped by rail or truck. On the inside, the kiln is lined with approximately 2–4 in. of insulating refractory covered with 6–10 in. of temperature- and erosion-resistant refractory. The kiln length is generally 2–5 times the diameter dimension. The shell is supported by two or more steel “trundles” that ride on rollers allowing the kiln to rotate about its axis. The inside surface is usually smooth, although recent designs have included internal vanes or paddles to promote mixing of the waste with the combustion air. Sometimes, internal dams are utilized to retard solid waste movement through the kiln.

The kiln is oriented on a slight incline from the horizontal, known as the rake. The rake is normally 2–4 degrees, and the waste is charged on the high side of the kiln. The kiln rotates at rates ranging from 0.5–2 rpm. The incline facilitates ash and slag removal. The rotation of the shell provides transportation of the waste through the kiln and enhances mixing of the waste with combustion air. The rotational speed is used to control waste residence time and mixing. Although increasing the rotation rate can enhance the mixing of waste and air mixing, this also acts to move the solids through the kiln more rapidly, thus reducing their residence time.

Two types of rotary kilns are currently being manufactured: cocurrent and counter-current. In cocurrent rotary kilns, the burner is located at the front end where the waste is fed; in counter-current rotary kilns, the burner is located at the end opposite the feed.

In the kiln, wastes are heated by the primary flame, bulk gases, and refractory walls. Through a series of volatilization and partial combustion reactions, combustible fractions of the wastes are gasified. The solids continue to heat and burn as they travel down the kiln. The solids retention time in the kiln is 0.5–1.5 h, while gas residence time through the kiln is roughly 2 s. Waste feed to the kiln is controlled so that the waste occupies no more than 20 percent of the kiln volume. The typical bulk temperature in the kiln ranges from 1500 to 1900°F.

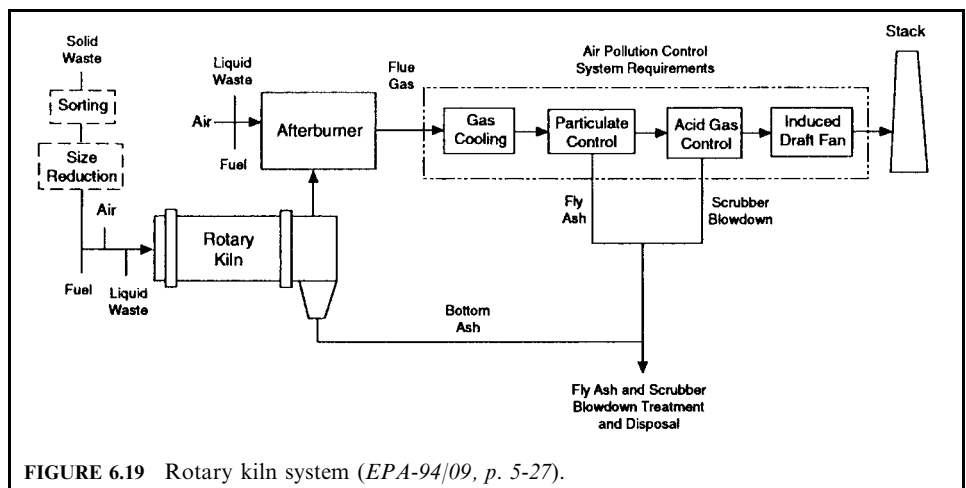

FIGURE 6.19 Rotary kiln system (EPA-94/09, p. 5-27).

An auxiliary burner is located at the feeding end of the kiln, and is used for start-up and to maintain the desired kiln temperature when sufficient heat input is not available from the waste. Wastes with an average heating value of 4500 Btu/lb are adequate to sustain combustion at a kiln temperature between 1600 and 1800°F. Combustion air is provided through ports on the face of the kiln, as well as through rotary seal leaks. The kiln typically operates at 50–300 percent excess air. Kiln operating pressure is maintained slightly below atmospheric (0.5–2 in water) through the use of an induced-draft fan located downstream of the air pollution control system. Operation at negative pressure minimizes fugitive emissions of partially combusted waste gases to the atmosphere through gaps in the rotary seals and any small cracks or holes that may be present. To avoid over-pressurization caused by feeding too much highly combustible waste, an emergency relief vent is typically provided between the afterburner and the air pollution control system to protect the equipment. Use of this valve constitutes a serious release of hazardous and, potentially, radioactive compounds to the environment.

Inorganics, ash, slag, and other noncombustible items that remain when the waste reaches the end of the kiln are removed by gravity into an ash pit. A typical rotary kiln is equipped with a water-filled sump with a drag chain to remove the ash from the sump and discharge it into a container. At the exit of the kiln, there is a separation chamber which serves to reduce the flue gas velocity and separate the gases from the particulate matter.

Rotary kilns which burn waste generally employ an afterburner downstream of the kiln to ensure complete destruction of organic compounds. An afterburner is simply a refractory-lined chamber sized to provide a residence time of 4 s at the maximum firing rate. An auxiliary burner on the front face of the afterburner heats the flue gas to the set-point temperature. Liquid wastes may also be fired directly into the afterburner via a lance or atomizer. A typical afterburner combustion temperature ranges from 1800 to 2200°F. The afterburner supplies an oxidizing environment to ensure complete destruction of hazardous organics.

**TECHNOLOGY APPLICATION:** The rotary kiln system is highly versatile as it is capable of burning solids, sludges, liquids, and gases. Solids are typically ram-fed or dropped by conveyor onto the kiln hearth, while sludges, liquids, and gases are injected through nozzles located in the front or rear face of the kiln or in the afterburner. They are particularly attractive for the destruction of toxic wastes due to their ability to operate at temperatures in excess of 1400°C (2550°F) when fitted with an afterburner.

**TECHNOLOGY ADVANTAGE:** The technological advantages include those listed below.

- The greatest advantage of a rotary kiln incineration system is its ability to retain and tumble the wastes to provide high turbulence and air exposure to solid wastes, thus achieving better combustion efficiency. This ability is especially important when high ash waste is involved.
- The rotary kiln incinerator will incinerate a wide variety of liquid and solid wastes. It is capable of incinerating materials passing through a melt phase. Liquids and solids can be received independently or in combination.
- The rotary kiln incinerator is adaptable to a wide variety of feed mechanism designs. Drums and bulk containers can even be accepted in the feed.
- It incorporates continuous ash removal which does not interfere with the waste oxidation.
- There are no moving parts inside the kiln (except when chains are added to facilitate heat transfer or to enhance mixing).
- The retention time of the waste can be controlled by adjusting the rotational speed.

**TECHNOLOGY DISADVANTAGE:** The technological disadvantages includes those listed below.

- Capital cost for installation is high. The systems are mechanically intensive. They have precise drive mechanisms and large rotating seals. The seals at either end of the kiln cylinder are susceptible to leakage at the interface between the rotating cylinder and the stationary

portions of the system. Seal design is challenging, having to accommodate linear and radial expansion and the imperfect roundness of the heavy, large diameter reactor tube.

- The rotation action of a rotary kiln tends to cause a high degree of solids turbulence resulting in significant particle loadings in the exhaust gas, which must be considered in the design of the off-gas cleaning system.
- Operating care is necessary to prevent refractory damage; thermal shock is a particularly damaging event.
- Spherical or cylindrical items may roll through the kiln before complete combustion.
- Under certain conditions (e.g. temperature, rotation speed, waste feed rate, and composition), molten solids can form and accumulate on the walls of the kiln, forming layers or rings which can restrict the flow of wastes or interfere with the overall operation of the unit.
- Airborne particles may be carried out of the kiln before combustion is complete.
- Problems in maintaining seals at either end of the kiln can result in operating difficulties. Also, the induced-draft fan and air pollution control equipment must be oversized to handle extra flue-gas flow resulting from infiltration of gas through leaking seals.

## 2.17 Shaft-type Incinerator

**PROCESS DESCRIPTION:** The main combustion chamber is a vertically oriented, cylindrical furnace (Fig. 6.20). Waste is fed into the lower third of the furnace tangentially with the combustion air, and burns as it flows up. The flue gas exits the top of the furnace and flows through the air pollution control system, which includes an afterburner. The main

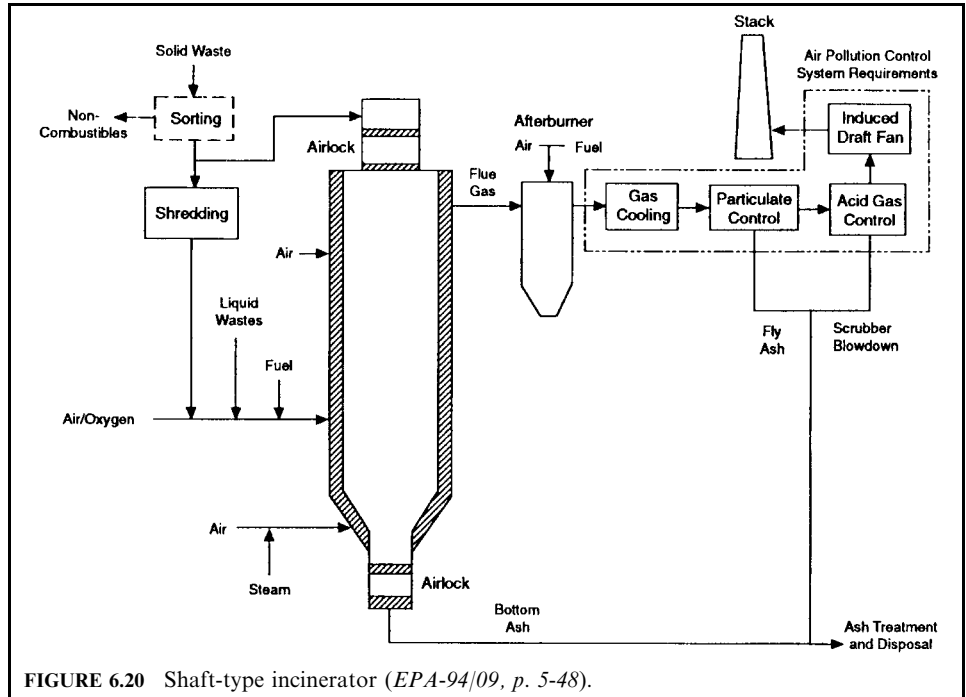

FIGURE 6.20 Shaft-type incinerator (EPA-94/09, p. 5-48).

subsystems of this thermal treatment system are the waste pretreatment, shaft furnace, and off-gas clean-up systems. Each is described below (EPA-94/09).

Combustible liquids, sludge and solids are suitable for treatment in the excess air shaft-type incinerator. The solids are sorted to remove large noncombustibles. Size reduction of solid waste is not strictly required, but, as is true of most incinerators, performance is enhanced with shredding. Shredded waste is pneumatically fed through nozzles into the lower portion of the furnace. If solids are not shredded, they must be batch-fed through an airlock at the top of the reactor. Liquid and sludge wastes are simply injected through nozzles near the bottom of the furnace.

The shaft furnace is a refractory-lined cylinder with a typical height to inside diameter ratio of approximately six. Shredded solid and liquid wastes are introduced near the bottom of the furnace. The primary combustion air is injected tangentially into the reactor at the same elevation as the shredded solid and liquid wastes. Two lesser combustion air flows are also added just above the bottom air lock and just below the top of the furnace. Sufficient combustion air is provided to maintain a set excess oxygen level at the primary reactor exit. The shaft furnace is maintained at a moderate temperature of about 850°C (1562°F) through use of supplemental fuel and solid waste feed rate control.

An induced-draft fan located just upstream of the stack maintains negative pressure in the furnace and allows the shredded waste to burn in suspension as it flows to the top of the furnace. The bottom of the furnace tapers into a small cylindrical volume which serves as a receptacle for the ash and noncombustibles. Steam and air are added at the bottom cone section to prevent the ash from slagging and from adhering to the refractory walls; the temperature of the ash bed is maintained below 800°C. The residual materials that accumulate at the bottom of the reactor are periodically removed in batches through a double enclosure airlock to prevent the release of contamination.

**TECHNOLOGY APPLICATION:** The excess air shaft-type incinerator was originally designed at the Karlsruhe Nuclear Research Center in Germany, and is sometimes referred to as the “Karlsruhe” incinerator. The Karlsruhe system is similar to a starved-air incinerator except that the solids burn in suspension rather than on a grate.

**TECHNOLOGY ADVANTAGE:** The technological advantage is its simplicity. It has been reported that the original Karlsruhe system has treated thousands of tons of low-level mixed waste with only minor interruptions for maintenance of the combustion chamber (DOE-93/03, p. C-6).

**TECHNOLOGY DISADVANTAGE:** The technological disadvantage is the need to sort most metals and glass from the waste feed, and the need to shred the waste in advance.

## 2.18 Supercritical Fluid (SCF)

**PROCESS DESCRIPTION:** SCF is characterized as a form of matter in which the liquid and gaseous states are indistinguishable from one another. It is formed when both temperatures and pressures to which the fluid is subjected exceed the critical point ( $T_c$  and  $P_c$ ), as shown in Fig. 6.21. Under these supercritical states the character of the fluid becomes very unusual compared with that under subcritical conditions. For example, if water is under supercritical conditions (pressures greater than 218 atmospheres combined with temperatures above 374°C), the density, dielectric constant, hydrogen bonding and certain other physical properties are so altered that water behaves much as a moderately polar organic liquid. Thus, *n*-heptane or benzene could become miscible in all proportions with SCW (supercritical water), which cannot happen with water under subcritical conditions. Even some types of wood fully dissolve in SCW. On the other hand, the solubility of sodium chloride (NaCl) could be as low as 100 ppm, and that of calcium chloride can be less than 10 ppm. This is the reverse of the solubilities in water that are encountered under subcritical conditions—under which the two salt solubilities are about 37 wt% and up to 70 wt%, respectively. Thus, organics become

FIGURE 6.21 SCF operating zone (Lee-83/07).

almost completely soluble and inorganic salts become only sparingly soluble and tend to precipitate as shown in Fig. 6.22 (EPA-86/10).

The SCF region can best be visualized with the aid of a reduced pressure and volume diagram, as in Fig. 6.21. The reduced pressure, temperature, and volume are defined as

$$P_r = P/P_c, \quad T_r = T/T_c, \quad V_r = V/V_c$$

where the subscripts r and c denote a reduced property and the property at the critical point, respectively.

In a study of the use of supercritical  $\text{CO}_2$  for the regeneration of activated carbon, Arthur D. Little, Inc., suggested that the SCF region be in the range of 1–1.4 of reduced temperatures and 1–6 of reduced pressures, as shown in Fig. 6.21 (for  $\text{CO}_2$ ,  $P_c = 1071$  psia and  $T_c = 548^\circ\text{R}$ ).

The steps involved in the SCF oxidation process are as follows. Initially, the waste (in the form of an aqueous solution or slurry) is pressurized and heated to supercritical conditions by mixing it with recycled reactor effluent. Compressed air is also mixed with the feed to serve as a source of oxygen for the reactions. Oxygen and air are miscible with water under supercritical conditions, thereby enabling the homogeneous operation of the process. The homogenized mixture is then pumped to the oxidizer where organics are rapidly (residence times average 1 min) oxidized. Oxidation is achieved under homogeneous conditions (single-phase supercritical fluid), and therefore higher effective oxygen concentrations and destruction efficiencies can be achieved with shorter residence times than with other similar processes (i.e., the wet oxidation process) (EPA-86/10).

The release of combustion heat from the oxidation reactions causes temperatures in the oxidizer reactor to rise to 1112–1202°F. The reactor effluent then enters a cyclone (solids separator) where inorganic salts are precipitated out (at temperatures above 450°C). The fluid effluent of the solid separator consists of superheated supercritical water, nitrogen, and carbon dioxide. A portion of the superheated supercritical water is directed to an eductor so that it can be recycled to heat the incoming waste feed (initial step in the process).

The supercritical oxidation process results in conversion of carbon and hydrogen compounds from the organic compound to  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . Chlorine atoms are converted to chloride ions and can be precipitated as sodium chloride with the addition of basic materials to the feed. Gaseous emissions consist primarily of carbon dioxide with smaller amounts of oxygen and nitrogen gas, which do not require auxiliary treatment for off gases. Solid

emissions consist of precipitated inorganic salts (chlorine produces chloride salts, nitro-compounds precipitate as nitrates, sulfur compounds as sulfates, and phosphorus compounds as phosphates). The liquid effluent consists of a purified water stream, which can be used for process water.

Typical operating parameters for a SCF system are:

Waste form	Aqueous solution or slurry of organics
Temperature	450–650°C
Pressure	220–250 atmospheres
Average residence time	Less than 1 min

**TECHNOLOGY APPLICATION:** At the supercritical condition (for water,  $P_c = 3206$  psia and  $T_c = 1165^\circ\text{R}$ ), water acts as a solvent. Therefore it can oxidize many hazardous compounds without extra energy. Similar to the wet air oxidation process, one technological advantage is that since oxidation takes place in the liquid state, it is not necessary to evaporate the water content of the waste. The process can treat the wastes which are too dilute to incinerate economically yet too toxic to treat biologically. This is another advantage of the technology. A technological disadvantage is that at elevated temperatures and pressure, SCF may require the use of high-alloy materials such as titanium to prevent corrosion. This use of high alloys increases capital costs.

## 2.19 Thermal Desorption Process

**PROCESS DESCRIPTION:** Volatile and semivolatile organics are removed from the soil by thermal treatment. Indirect heating of the soil in a rotating chamber volatilizes organic contaminants along with any moisture present in the soil. The soil passes through the chamber and is collected as a dry solid. Condensing of the volatilized organics and water generates separate liquid phases. The organic phase is decanted and removed for disposal. The contaminated aqueous phase is treated by passing it through activated carbon and removing soluble organics before combining it with the thermally treated soil (EPA-96/12, p. 288).

Inorganic contaminants are removed by three physical and chemical separation techniques: (1) gravity separation of high density particles, (2) chemical precipitation of soluble metals, and (3) chelant extraction of chemically bound metals. Gravity separation will be used to separate higher density particles from common soil. Radionuclide contaminants are typically found in this fraction. Selection of the gravity separation device—shaker table, jig, cone or spiral—is based on the distribution of contaminants and the physical properties of the thermally treated soil.

Many of the pollutants (such as radionuclide and other heavy metals) are in a form that makes them partially soluble or suspended in the aqueous media used for separation. These contaminants are separated from the soils and are precipitated. A potassium ferrate formulation is used to precipitate radionuclides. The resulting microcrystalline precipitant is removed, allowing recycling of the aqueous stream, during the process cycle.

Some of the radionuclides that are not in soluble form remain with the soil through the gravity separation process. These radionuclides are removed from the soil via extraction with a chelant. The chelant solution then passes through an ion exchange resin to remove the radionuclides. The chelant solution is recycled back to the soil extraction step.

The contaminants are collected as concentrates from all waste process streams for recovery or off-site disposal at commercial waste or radiological waste facilities. The decontaminated soil is then returned to the site as clean fill.

**TECHNOLOGY APPLICATION:** It was reported that thermal desorption is capable of separating polychlorinated biphenyls (PCB) from soil contaminated with uranium and technetium (EPA-96/12).

## 2.20 Vitrification by Joule Heating

**PROCESS DESCRIPTION:** In a vitrification process, high temperatures are used to convert waste materials into a dense glass which is ready for final disposal. The high temperatures may be achieved through the use of electricity, plasma, microwave, or fossil energy. When the energy source is electricity, the process is referred to as joule heating. A joule-heated vitrification furnace (also known as “melter”) system is shown schematically in Fig. 6.23 (EPA-94/09).

Solid and liquid wastes are fed into a bath of molten glass. Oxidation air is bubbled up through the bottom of the melter. Glass-making additives are also added as required to maintain operations and provide for suitable glass formation. Electrodes immersed in the

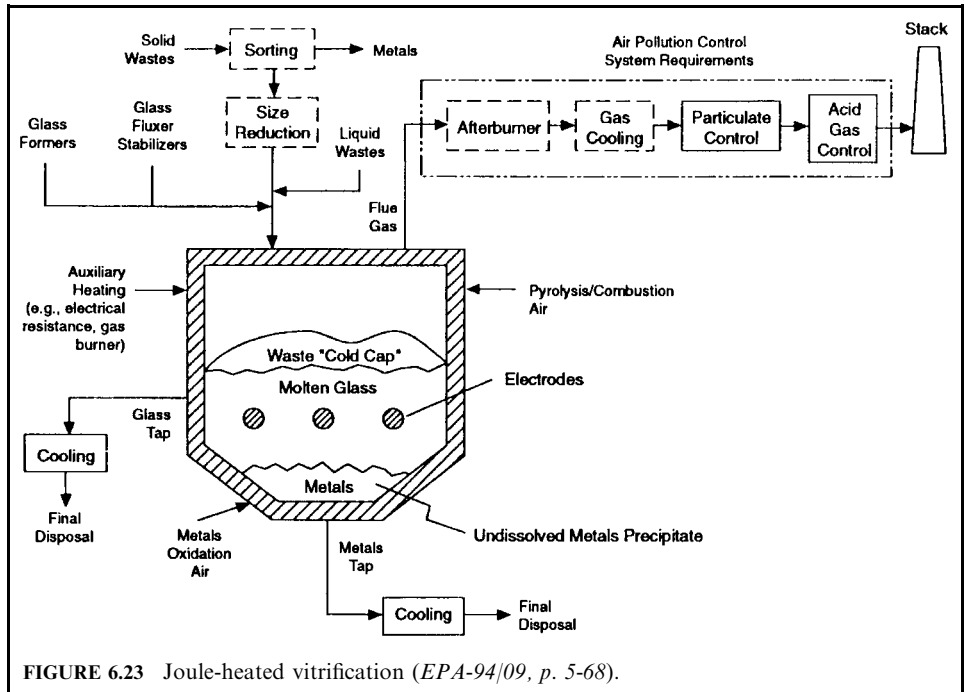

FIGURE 6.23 Joule-heated vitrification (EPA-94/09, p. 5-68).

glass bath provide the melt energy through joule heating. The waste melts and oxidizes when exposed to the air in the high-temperature environment. Waste organics are destroyed, while many of the inorganics are incorporated into the glass melt. The main subsystems of the joule-heated vitrification system are the waste preparation and feeding, melter, glass removal, flue gas clean-up, and automatic control systems. Each is discussed below.

Vitrification furnaces come in a variety of designs, depending on the waste type and the desired operating temperature. Typically, they are rectangular-shaped vessels, lined with high temperature refractory (such as chromium/alumina oxide). Some designs are long tunnels with relatively shallow flat bottoms, while others may have deep or sloped bottoms.

Solid, liquid, slurry, and sludge-type wastes may be fed either semicontinuously with a ram feeder and/or continuously with a screw feeder directly onto the surface of the glass melt. Alternatively, wastes may be introduced below the surface of the glass melt with the use of a drop-tube lance. In some operations a "cold-cap" or "batch-blanket" is maintained over the glass surface. In cold-cap operations, waste is fed at a rate such that a blanket layer over the entire surface of the glass is formed. The waste layer acts as a filter to capture inorganic volatiles released during waste heating and melting and allows for possible reincorporation back into the melt.

Wastes are ignited by the radiant heat of the glass pool and continue to partially oxidize and melt within the pool. Combustion air/oxygen is provided above the glass pool or into the cold cap layer to ensure complete combustion of the partially oxidized flue gas exiting the melt. In some designs, excess oxygen is maintained above the bath. In other designs, reducing conditions are maintained above the bath and an afterburner is utilized to complete combustion of the organics. Auxiliary fuel-fired burners or electric space heaters may also be used to ensure adequate destruction of volatiles.

The melt temperature is typically maintained between 1040°C (1900°F) and 1200°C (2220°F). Temperature is maintained by immersing metal electrodes in the melt, either vertically from the top or horizontally from the sides of the furnace. The electrodes make use of the joule effect, in which alternating electrical current passing between the electrodes and the glass is dissipated in the form of thermal heat due to the glass resistivity. Because the glass conductivity is ionic, alternating current must be used to avoid the risk of electrolysis or anodization of electrodes. Glass has decreased resistivity in its high temperature molten state, making it amenable to conducting and dissipating electricity. Natural convection currents created around and in the region between the electrodes act to stir and mix the molten glass, providing relative homogeneity of the glass melt. Because the burning waste is also a heat source, the electrode voltage is adjusted as necessary to control melt temperature. At start-up, a glass charge is initially melted with auxiliary heating, either by a fuel-fired burner or electrical resistance heating. When the bath reaches a temperature of about 730°C (1350°F), the auxiliary heating is stopped, and heat is provided by the immersed electrodes and the waste.

The electrodes must be designed to withstand corrosion from the glass bath, maintain strength at high temperature, and have low resistivity. Inconel<sup>TM</sup> is commonly selected for electrodes when the design melt temperature is below 1150°C; at higher temperatures, molybdenum electrodes are commonly used. In some designs, the electrodes are internally air-cooled.

In a unique furnace design, a rotating impeller paddle-mixer is submerged in the glass pool and used to stir the glass bath. The stirrer draws unmelted feed into the molten glass, acting to enhance the mixing between the waste and molten glass. This allows for a substantial increase in the melter waste throughput/volume ratio (about eight times higher than that of a conventional melter), while also providing the ability to operate at a lower average melt temperature. The stir-melting furnaces come in two designs depending on the desired operating temperature. In the low temperature design [1050–1150°C (1900–2100°F)], the paddle and furnace are constructed of steel alloy and act as the electrodes to provide the joule heating. In the high temperature design [1350–1500°C (2460–2730°F)], the impeller and electrodes are molybdenum, and the furnace is refractory-lined.

In another unique design used to treat ion-exchange resins, the furnace operates at a high temperature without refractory lining. This is desirable since liquid metals can corrode refractories under reducing conditions. Initially, a thick solidified “skull” of sintered sand is formed on the inside of the water-cooled, steel-lined furnace. The skull crust layer acts as a protective barrier between the molten glass and the steel furnace lining. The furnace can operate at 980–1500°C, and as high as 1650°C for short periods of time.

During operation, the glass is sampled and checked for composition. Depending on the waste composition, additives are fed with the waste to maintain the proper glass viscosity, melt temperature, electrical properties, and residual slag properties. The glass viscosity must be low enough to achieve sufficient convective current mixing in the furnace, allow the required throughput to be met, and facilitate glass pouring operations. Alternatively, the viscosity must be high enough to avoid significant refractory corrosion. The bath temperature must be maintained above the melting point to avoid formation of crystals and deposits in the melter. Electrical resistance must be high enough to promote generation of heat, but low enough to avoid prohibitively high voltage requirements to dissipate current. Finally, the leachability, durability, and stability of the final glass product is ensured by adding the proper compounds to the melt.

Additives may be classified into two main groups based on their impact on the glass physical properties: “network formers” and “network modifiers.” Large amounts of network formers such as silicates, phosphates, and borates are generally required since they are the backbone of the glass structure. Network formers provide the glass with durability, mechanical strength, and resistance to leachability, but tend to increase glass viscosity. Network modifiers include stabilizers and fluxes. Stabilizers such as limestone, dolomite, and feldspar (providing alkali earth elements such as calcium, magnesium, and aluminum) also act to improve glass durability and maintain low melting temperature, but increase melt viscosity and increase the potential for the glass to devitrify when cooled. Fluxes such as soda ash (those

providing alkali metals sodium, potassium, or lithium) are added to decrease melt viscosity and melting temperature; they are incorporated into the glass but break interconnected network bonds. Their addition adversely affects glass leachability and durability and lowers glass resistivity.

For the final glass product to have acceptable durability and resistance to leachability, the glass must have the right proportion of fluxes, formers, and stabilizers. Note that a pure glass has an "amorphous", unordered structure. On the other hand, a ceramic has a crystalline structure, with fused grains, and a highly ordered structure. So-called "slags" are a mixture of both amorphous and crystalline structures. The ultimate glass formation depends on a variety of factors such as melting temperature, glass composition, and glass cooling rate.

The three most common types of glass for waste processing are borosilicate-, aluminosilicate, and sodiumsulfate-based glasses. Borosilicate is almost always chosen for treating high-level radioactive wastes. The presence of boron allows for increased solubility of waste components; additionally, the glass is stable, durable, and has a moderate melt temperature [1150°C (2100°F)]. Aluminosilicate, although the most stable type, is not as popular due to the high melt temperature [1350°C (2500°F)].

Inorganics such as metals, silica, halides, and sulfur which are contained in the waste are either encapsulated (surrounded by glass), melted and incorporated into the glass network, or contained in the flue gas as volatilized vapors or entrained solid particulates. The fate of waste metals in the glass melt depends on factors such as operating temperature, metal type and form, and glass composition. Metal objects will either soften or melt, depending upon the operating temperature and reducing/oxidizing melt conditions. For designs operating at lower temperatures, metals will sink and accumulate at the bottom of the furnace. For higher temperature designs, metals may melt and form a molten layer at the bottom of the melt. In some arrangements, multizone heating is used by positioning electrodes at various depths within the glass melt and powering the electrodes at different levels; higher temperatures are used near the bottom of the melter to accommodate for metals melting.

If the melt operates under reducing conditions, metallic pools will collect at the bottom. However, if oxygen is available, or provided in the melt, a portion of the metal oxides may be absorbed within the glass structure as glass formers or modifiers. In a unique design, an air bubbling and stirring lance is inserted into the glass melt near the floor. Injected air creates a curtain of bubbles between the electrodes, which act to mix the molten bath. The air also provides an oxidizing environment for the oxidation of metals and prevents them from forming a detrimental metallic layer on the bottom of the melter. The bubbler also disrupts the formation of secondary-phase layers on the top of the molten glass, such as sulfides. Glass additives may also enhance the ability to accommodate additional metals in the glass network.

When high level radioactive wastes are treated, the melt temperature is low to minimize the volatilization of radionuclides. To maintain the viscosity at low enough levels to allow processing, the waste loading in the glass is limited to about 30 percent by weight. However, if the waste composition is correct (contains the right amounts of glass formers and fluxes), waste loadings in the glass above 90 percent have been demonstrated, leading to very high waste volume reduction.

Chlorine and sulfur have a low solubility in glass; these constituents are contained primarily in the furnace flue gas. Fluorine has a higher retention in glass than chlorine or sulfur. Any halogens that are incorporated in glass reduce the glass durability and increase glass porosity. Alkali and sulfate salts may also accumulate and form a layer on top of the glass.

The presence of metals in the furnace, as either unmelted or separate melted phases, may lead to degradation of the joule heating due to changes in the conductivity of the metal layer and/or short-circuiting of the electrodes. One solution is to design the furnace with a deep glass bath or slanted bottom. The metals are allowed to accumulate, and periodically, the temperature of the bath is increased enough to melt the metals; the molten metal is then poured from the furnace. Electrodes must be placed a good distance above the metal layer. Other alternatives include sorting metals from the waste feed, or adding metals into the furnace at a slow enough rate to allow all the metal to be incorporated into the glass melt.

The molten glass is drawn off as required to maintain proper glass pool height. Glass may be removed from the furnace in a number of different methods. In most high-level radioactive waste furnace designs, glass is removed through a “teapot spout” or “bottom takeoff overflow weir.” An air lift is used to control glass draining, and ensures consistent, uniform removal of glass from the system. Air is injected into the glass as it rises to the overflow level, acting to control the glass flowrate. In other designs, a tapping hole is located in the side of the furnace; the flow of glass can be controlled with the use of “freeze” valves, which are used to intermittently remove glass. The valve is heated (typically with induction, resistance, or electrode joule heating) to initiate the flow of glass. To stop the flow, the heating is cut off and the glass is solidified. In this arrangement, a slide valve is included for emergency shutoff situations. A bottom drain may also be included for drainage of the entire furnace and removal of accumulated metals. Additionally some furnace designs may include an overflow drain, which is used to ensure a minimum glass level and aid in the removal of unwanted layers that form on the glass surface (such as sulfide salts).

Once removed, the molten glass can be fed directly into canisters or made into small marbles or “gems” depending on storage and disposal requirements. The marble form may be desirable to allow for convenient handling, sampling, repackaging, and/or reprocessing. The furnace may also have an additional separate tap for liquid metals collected at the bottom of the furnace. Tap and drain lines must be heated to ensure proper flow, typically with resistance, induction, or electrode heating.

## 2.21 Vitrification by Plasma Arc

**PROCESS DESCRIPTION:** Plasma arc vitrification occurs in a plasma centrifugal furnace by a thermal treatment process where heat from a transferred arc plasma creates a molten bath that detoxifies the feed material. Organic contaminants are vaporized and react at temperatures of 2000–2500 degrees Fahrenheit (°F) to form innocuous products. Solids melt and are vitrified in the molten bath at 2800–3000°F. Metals are retained in this phase. When cooled, this phase is a nonleachable, glassy residue which meets the toxicity characteristic leachate procedure (TCLP) criteria (EPA-94/09, p. 5-78).

Contaminated soils enter the sealed furnace through the bulk feeder. The reactor well rotates during waste processing. Centrifugal force created by this rotation prevents material from falling out of the bottom and helps to evenly transfer heat and electrical energy throughout the molten phase. Periodically, a fraction of the molten slag is tapped, falling into the slag chamber to solidify.

The term plasma is used to refer to a highly ionized and therefore electrically conductive gas. The types of plasma include dc or ac arc-generated thermal plasmas. The plasma torch utilizes a flowing gas such as nitrogen to maintain an electric discharge or arc between two high voltage electrodes. The first electrode is contained within the torch, and the second electrode is typically the solid material being treated. The electrical resistance of the plasma gas leads to joule heating, which is the conversion of electrical energy into thermal energy. The result is very high plasma gas temperatures and direct heating of the waste.

The primary chamber is a rotating, refractory-lined, and externally water-cooled tub with a central orifice, or copper throat. The copper throat at the bottom of the primary chamber is used to initially strike the arc of the plasma torch. This torch is capable of using air or nitrogen as the stabilizing plasma gas. Once the arc has been struck, the torch is moved slowly up and down the sides of the primary chamber to heat it up. The operator moves the torch remotely, utilizing a video camera to see the furnace condition. Feeding of the waste material begins when the primary chamber’s temperature is greater than 2000°F and the secondary chamber’s temperature is greater than 1800°F.

When the loading of waste begins, the operator moves the torch and monitors the condition and location of the slag in the furnace. The arc heats the waste material by convective heat transfer from the plasma plume, and to a lesser extent joule heating of the waste material itself,

until it is completely molten and at least partially oxidized. The primary chamber may operate under reducing or excess air conditions depending upon the amount of organics in the waste charged. However, the air flow is sufficient to allow oxidation of most of the organics in the primary chamber. The tub spins at approximately 40 rpm to keep the newly fed waste on the sides of the tub, preventing it from rolling down the throat. The slag along the walls of the tub is at approximately 3000°F and actually serves to heat and volatilize the fresh waste as it is fed.

When a sufficient amount of waste has been fed to the tub, the molten material begins to flow down the throat. At this point, the operator halts waste feeding and allows time for destruction of the organics in the latest batch of waste fed to the tub. The rotation of the reaction chamber is then slowed to between 5 and 10 revolutions per minute, allowing gravity to pull the treated glass through the center hole (thimble), falling through the gas/slag separation chamber to be collected in a pig mold below. The slag then pours out through the center opening into a slag collector, where it cools and solidifies. The gases in the separation chamber flow to the second combustion chamber for further treatment.

The primary chamber bulk temperature ranges from 2100°F to 2400°F, and the pressure is slightly below atmospheric (−22 mbar). Typical feedrates range from 45 to 130 kg/h. Typical torch power is 500–750 kW, and the average primary chamber gas residence time is 10–15 s. It is important to note that the centrifuge is a double-walled, water-cooled chamber. As a result, the seals between the various furnace elements can be close to room temperature, and thus they seal very effectively. Also, the system is designed with a relief system and a surge tank, so that even if an explosion occurred, causing a pressure surge of as much as one bar, no untreated material would be released assuming that the seals are truly tight.

The slag separation chamber is sealed off from the receptacles with a simple locking system to prevent untreated material from entering the slag containers. During operation, a refractory-lined collection thimble is sealed to the bottom of the slag separation system by means of a pressure-regulated hydraulic lift in the bottom of the slag lock chamber. Any untreated material will drop into the collection thimble, which can periodically be removed for emptying and recycling of the untreated debris. Prior to slag tapping, all feeding of material is stopped. The slag thimble is lowered and moved from below the slag separation chamber. A slag container is moved into place and sealed to the slag collection system prior to casting. Upon completion of the casting cycle, the slag container is lowered and transferred to its original storage position. The collection thimble is then repositioned and sealed to the slag separation chamber. After the molten slag (in a 48-gallon drum) has cooled sufficiently to be transported to the cooling chamber, the slag lock chamber is purged with air and the slag drum is moved through the slag lock door to the cooling chamber. After 48 h, it is sealed inside a 55-gallon drum and brought to the outside.

**TECHNOLOGY APPLICATION:** Plasma furnaces originated in the metals industry, where high temperatures and controlled environments were required to ensure metal purity. EPA demonstrated its interest in a particular plasma technology for the treatment of waste when it sponsored tests to evaluate Retech's plasma arc centrifugal treatment (PACT) process through the Superfund Innovative Technology Evaluation (SITE) program. Interest in the PACT was also demonstrated by DOE's funding of a test series to evaluate the performance on simulated radioactive and RCRA wastes. The PACT process is shown in Figs. 6.24 and 6.25.

## 2.22 Wet Air Oxidation (WAO)

**PROCESS DESCRIPTION:** A temperature–volume diagram is shown in Fig. 6.26. The figure shows the operating zone of WAO. The water-waste mixture is maintained within the saturated zone within EBCF in the figure. For the particular case shown, total pressure is maintained at 2000 psi, and the temperature varies from 175°C to 320°C.

Wet air oxidation refers to the aqueous-phase oxidation of dissolved or suspended organic substances at elevated temperatures and pressures. Water, which represents the aqueous phase, serves to catalyze the oxidation reactions so that they proceed at relatively low tem-

FIGURE 6.24 Plasma arc centrifugal treatment (PACT) system (EPA-94/09, p. 5-82).

peratures (175–345°C), and at the same time serves to moderate the oxidation rates by removing excess heat by evaporation. Water also provides an excellent heat transfer medium which enables the wet air oxidation process to be thermally self-sustaining with relatively low organic feed concentration.

The oxygen required by the wet air oxidation reactions is provided by an oxygen-containing gas, usually air, bubbled through the liquid phase in a reactor used to contain the process; thus the commonly used term “wet air oxidation.” The process pressure is maintained at a level high enough to prevent excessive evaporation of the liquid phase, generally between 200 and 3000 psi.

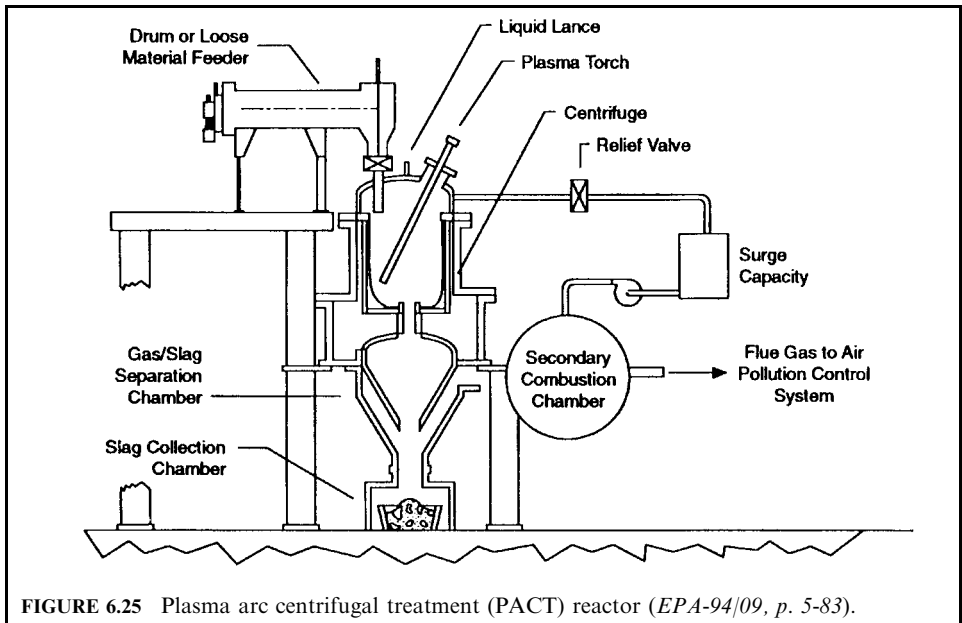

FIGURE 6.25 Plasma arc centrifugal treatment (PACT) reactor (EPA-94/09, p. 5-83).

**TECHNOLOGY APPLICATION:** WAO has been used worldwide to treat both industrial and municipal waste streams for the last 30–40 years. Operating designs vary from low oxidations, for sludge conditioning, to high oxidations, for chemical and power recovery and for carbon regeneration.

**TECHNOLOGY ADVANTAGE:** The technological advantages include:

- since oxidation takes place in the liquid state, it is not necessary to evaporate the water content of the waste. The process is therefore most useful for wastes which are too dilute to incinerate economically yet too toxic to treat biologically; and
- because wet air oxidation reactions take place in the liquid phase, the process can operate without consumption of heat for vaporizing water and organics. The sensible heat required to heat the waste to reaction temperature is recovered from the effluent by heat exchangers.

**TECHNOLOGY DISADVANTAGE:** The principal technological disadvantage is that at elevated temperatures and pressure, WAO may require the use of high alloy materials such as titanium to prevent corrosion. This use of high alloys increases capital costs.

### 3 INCINERATION TECHNOLOGY SUMMARY

Table 6.3 (OME-88/12, p. 4-95) summarizes the qualitative features of major incineration technologies.

### 4 RESOURCE RECOVERY SYSTEM

Combustion systems have been in use for many years burning wastes for energy and material recovery. The systems include:

- Cement kilns for resource recovery. For example, a significant fraction of the waste tires in the United States are fed to cement kilns for disposal and energy and material recovery.

**TABLE 6.3** Incineration System Summary

Incinerator type	Waste Feed				Feed preparation	Agitation of waste	Hazardous waste	Medical waste	Ash discharge		Supplemental fuel			Excess air required	Waste water discharge	Particulate emission

Spent solvents and waste oils are used as fuel in the production of cement and lightweight aggregates.

- Industrial boilers for resource recovery. For example, it is a common practice to fire waste oils in industrial boilers to recover heat for power generation, and to fire spent pulping liquors in alkaline sulfate (kraft) and acid sulfite pulping to recover heat and chemicals in the manufacture of paper and wood cellulose products (EPA-94/05; OME-88/12).

#### 4.1 Cement Kilns for Resource Recovery

In general, cement manufacturing processes that can be used to recover waste energy and materials include:

- cement kilns
- lime kilns
- lightweight aggregate kilns

**Cement kilns.** Cement is made from a carefully proportioned mixture of raw materials containing calcium (typically limestone), silica, and alumina (typically clay, shale, slate, and/or sand), and iron (typically steel mill scale or iron ore). These materials are ground to a fine powder (80% passing 200 mesh), homogenized, and heated to a very high temperature to produce a cement “clinker” product. The raw feed material, known as “meal,” is heated in a kiln which is a large, inclined, rotating cylindrical steel furnace lined with refractory materials. The kilns are operated in a “counter-current” configuration; the gases and solids flow in opposite directions through the kiln, providing for more efficient heat transfer compared with “cocurrent” operations. The raw meal is fed at the upper, “cold” end; the slope (3–6°) and rotation (50–70 revolutions per hour) cause the meal to move toward the “hot” lower end. The kiln is fired at the “hot” end, usually with coal or petroleum coke as the primary fuel; natural gas or fuel oil may also be used as a supplemental fuel. As the meal moves through the kiln and is heated, it undergoes drying and pyroprocessing reactions to form the clinker. The reactions can be categorized into three major stages (EPA-94/05, p. 2-1).

**DRYING AND PREHEATING ZONE:** Residual water is evaporated from the raw meal feed, and clay materials begin to decompose and are dehydrated (removal of bound water) in a temperature range of 70–1100°F.

**CALCINING ZONE:** Material is “calcined”; that is, calcium carbonate in the limestone is dissociated, producing calcium oxide (“burnt lime”) and carbon dioxide in the temperature range 1100–1650°F.

**BURNING ZONE::** In the “burning” zone, also known as the “clinkering” or “sintering” zone, calcium oxide reacts with silicates, iron, and aluminum to form “clinker.” The clinker is a chemically complex mixture of calcium silicates, aluminates, and aluminoferrites. A minimum meal temperature of 2700°F is necessary in the burning zone of the kiln to produce the clinker.

The clinker is removed from the kiln at the hot end. After it passes through the burning zone and by the kiln flame, it enters a short cooling area where the clinker melt begins to solidify; the cooling rate from the burning zone to the kiln exit is important since it determines the microstructure of the clinker. The clinker leaves the kiln at about 2000°F and falls into a clinker cooler. The cooler is typically a moving grate on which the clinker sits. Cooling air is blown through the clinker bed. The cooled clinker consists of grey-colored nodules of variable diameters, typically up to 2 inches. The clinker is blended with gypsum and ground in a ball mill to produce the final product, cement. Hot exhaust air produced from the clinker cooler is either directed to the kiln, where it is used as combustion air, or used to pre-dry the raw feed material in the case of dry-process kilns.

Kiln exhaust flue gases contain significant amounts of entrained particulate matter due to the turbulence in the kiln from the rotary action and from the use of finely ground feed material. The entrained particulate matter, known as “cement kiln dust” (CKD), is removed from the flue gas by some type of air pollution control device. Many plants return a portion of the CKD to the raw feed materials. However, in most cases, some CKD must be removed from the kiln system entirely to lower the build-up of alkali salts. CKD can be used in other industries as neutralizers or additives; however, the excess CKD is usually land-disposed.

In summary, the production of cement involves four steps:

- quarrying and crushing the raw materials;
- grinding and blending these materials into feed in the proper proportions;
- calcining the raw materials at extremely high temperatures to form clinker (an interim product);
- finish-grinding of the clinker, blending the clinker with gypsum, and packaging the finished product.

In the United States, some 200 process kilns are currently in operation across the country. Typical kilns range in size from 18 m (60 ft) long and 1.8 m (6 ft) in diameter to 230 m (760 ft) long and 7.6 m (25 ft) in diameter. These kilns are often larger than those used to incinerate wastes. About 2.9 metric tons (3.2 tons) of raw material (limestone, alumina, silica, and iron) and 6.1 million Btu are required to produce 1 ton of cement. About 90% of the energy is supplied by coal.

Cement can be produced in three major different types of arrangement—wet, dry, or semidry processes—as described below (EPA-94/05, p. 2-2; EPA-86/09, p. 2-12):

- wet process;
- dry process;
- semidry process.

*Wet process.* A schematic of the wet cement-making process is shown in Fig. 6.27. Ground raw materials are mixed with water (about 30% by weight) to form a slurried meal. The slurry is fed to the kiln through a flow-metered pump. Solids in the slurry typically occupy no more than 15–20% of the internal kiln volume. Wet kilns typically have a length-to-diameter ratio of about 30:1 to 40:1, and rotate at from 70 to 80 revolutions per hour. Kiln rotational speed is adjusted to maintain clinker quality and heat transfer. The wet cement making process is the older process, characterized in part by handling, mixing, and blending of the raw materials in the slurry form and lower emissions of kiln dust. However, because all water must be evaporated out of the slurry mixture, wet process kilns require greater energy input than other types of cement kilns; typically, from 5 to 7 MMBtu/ton of clinker product is required (where MM = million =  $10^6$ ).

*Dry process.* In the dry process, the moisture content is reduced to less than 1% before or during grinding, and the ground raw material is pneumatically transported to the kiln, or to a preheater if used. The dry process can be as much as twice as energy-efficient (3.4–4.5 MMBtu/ton of clinker) as the wet process because there is little water to evaporate from the feed. Kiln exhaust flue gases or hot clinker cooler air are typically used for drying the raw materials. There are three different dry process configurations (EPA-94/05, p. 2-7; EPA-86/09):

- long dry kilns
- preheater dry kiln;
- preheater/precalciner kiln.

**LONG DRY KILN:** A long dry process kiln schematic is shown in Fig. 6.27. It has the same flow path as the “dry process”; the raw meal is fed in a dry form. Similar to wet kilns, long dry

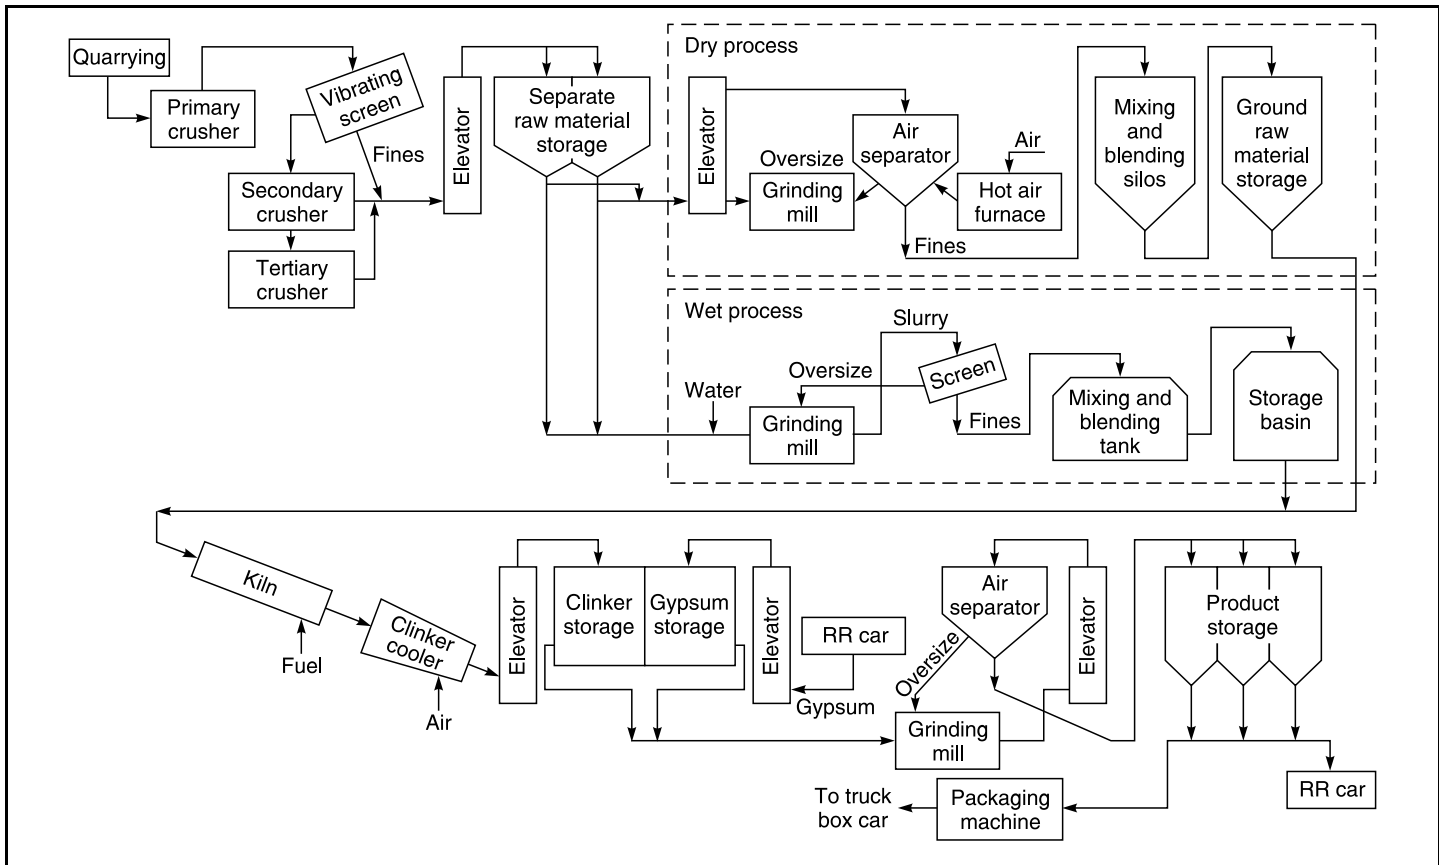

FIGURE 6.27 Long kiln (dry and wet) schematic (EPA-86/09, p. 2-12).

kilns have typical length-to-diameter ratios of about 30 : 1. Note that in comparison to wet kilns, the raw meal feed is heated more rapidly since the energy required for the evaporation of water is small. Kiln gas and solids residence times are similar to those of wet kilns (of order of 10 s and 2–3 h, respectively). Internal chains are also used in dry process long kilns to increase energy efficiency.

**PREHEATER DRY KILN:** A preheater arrangement process schematic is shown in Fig. 6.28. Preheaters are used to further increase the thermal efficiency of the cement-making process. A suspension preheater (“Humboldt” design) consists of a vertical tower containing a series of cyclone-type vessels (typically containing four stages). Raw meal is introduced at the top of the tower. Hot kiln exhaust flue gases pass counter-current through the downward moving meal to heat it prior to introduction into the kiln. The meal is separated from the kiln flue gases in the cyclone, and then dropped into the next stage. Because the meal enters the kiln at a higher temperature than that of the conventional long dry kilns, the length of the preheater kiln is shorter; kilns with preheaters typically have length-to-diameter ratios of about 15 : 1. The kiln has a gas residence time of about 6 s and a solids residence time of about 30 min. The gas residence time through the preheater cyclones (typically four stages) is about 5.5 s.

With preheater systems, it is often necessary to utilize an “alkali” bypass in which a portion of the kiln flue gases are routed away from the preheater tower at a location between the feed end of the rotary kiln and the preheater tower. The bypass is used to remove undesirable components, such as certain alkali constituents, that may accumulate in the kiln due to an internal circulation loop caused by volatilization at high temperatures in the kiln and condensation in the lower temperatures of the preheater. Accumulated alkali salts may cause preheater operating problems such as clogging of the cyclones and an increase in fine NaCl

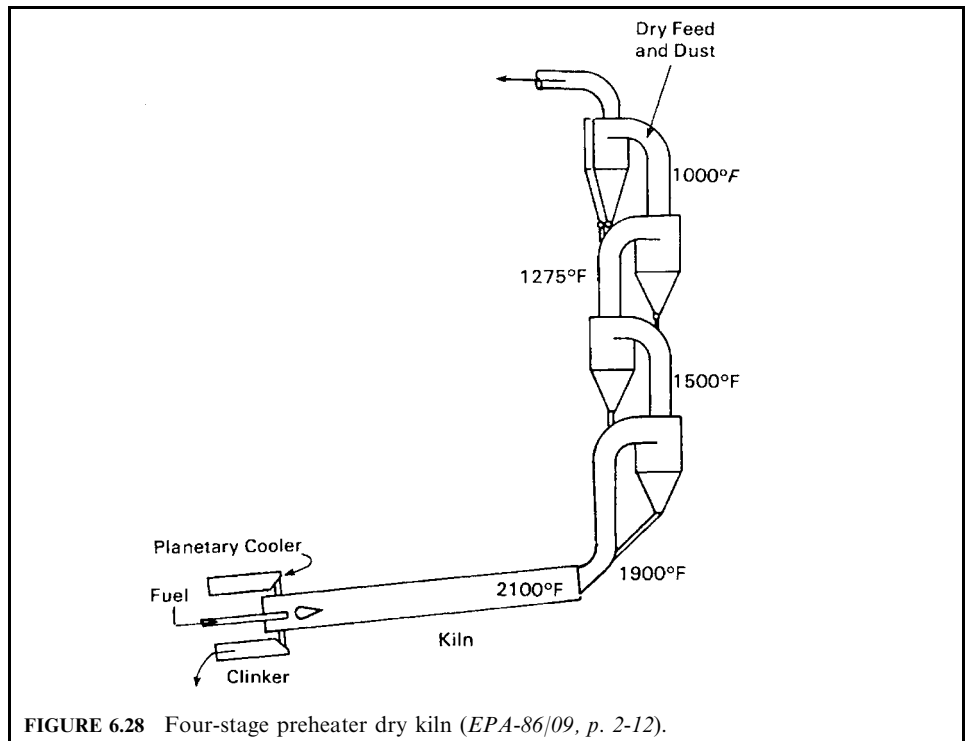

FIGURE 6.28 Four-stage preheater dry kiln (EPA-86/09, p. 2-12).

or KCl fumes in the emission gas. Typically 10–15% of the flue gas is routed through the bypass. Systems without bypasses are limited with respect to raw meal and waste concentrations of alkali metals, chloride (greater than 0.015% Cl by weight), and sulfur that can be tolerated in the raw materials.

The internal circulation of alkali components is greater in systems with preheaters compared to systems without preheaters due to the filtering effect of feed material flow in the preheater cyclones. Systems without preheaters have a kiln dust with a high content of alkali salts, which can be removed from the internal cycle when caught in the air pollution control device. However, for a preheater, a bypass is required to reduce the alkali build-up.

**PREHEATER/PRECALCINER KILN:** A preheater/precalciner process schematic shown in Fig. 6.29. A preheater/precalciner is similar to the preheater arrangement described above, with the addition of an auxiliary firing system to further increase the raw materials temperature prior to introduction into the kiln. An additional precalciner combustion vessel is added to the bottom of the preheater tower. Typical systems use 30–60% of the kiln fuel in the precalciner to release up to 95% of the CO<sub>2</sub> from the raw material. Precalciner air can be supplied either directly with the precalciner fuel, or at the hot end of the kiln. In another arrangement, the kiln flue gas may be routed around the calciner directly to the preheater. Kilns with preheater/precalciners can be even shorter than those with preheaters only (length-to-diameter ratio of 10: 1).

The primary advantage of using the precalciner is that it increases the production capacity of the kiln, since only the clinker burning is performed there. The use of the precalciner also increases the kiln refractory lifetime due to reduced thermal load on the burning zone. These configurations also require a bypass system for alkali control.

*Semi-dry process.* In the semidry process, the ground feed material is pelletized with 12–14% water. The pellets are put on a moving “Lepol” grate on which they are dried and

FIGURE 6.29 Dry preheater/precalciner kiln (EPA-94/05, p. 2-13).

partially calcined by hot kiln exhaust gases before being fed to the rotary kiln. A semidry process schematic is shown in Fig. 6.30.

**Lime kiln.** The United States is the second largest producer of lime in the world. In 1984, lime producers at 137 plants in 38 states sold or used 14.6 million metric tons (16.1 million tons) of lime. The term “lime” is a general term that includes the various chemical and physical forms of quicklime and hydrated lime, the two types generally produced. About 6.7 million Btu of energy is required for each 0.91 metric ton (1 ton) of quicklime produced. The cost of this high energy requirement has led to increased energy efficiency in the industry and to the use of more readily available and lower-cost fuels, especially coal or high-energy content industrial waste. Recent new plant installations and modernization projects have incorporated pulverized-coal-burning systems and energy-saving preheater systems. Figure 6.31 is a schematic of a lime kiln (EPA-86/09, p. 2-13).

The lime manufacturing process is similar to that of cement in that the raw material (usually limestone or dolomite) is quarried, crushed, and sized, and calcined in a kiln at 1093°C (2000°F). Although a variety of kiln types can be used, about 85% of the US producers use the rotary kiln. Kiln sizes vary. The largest is 152 m (500 ft) long and 5.2 m (17 ft) in diameter, and is capable of producing more than 1090 metric tons (1200 tons) of quicklime per day.

The calcining drives off nearly half the limestone’s weight as carbon dioxide (CO<sub>2</sub>) and leaves a soft, porous, highly reactive lime known as quicklime (CaO). Heating beyond this

stage can result in lumps of inert, semivitrified material (known as overburned or dead-burned lime) that is often used in the manufacture of refractory materials. The quicklime is discharged at the lower end of the kiln into the cooling system, where it is air-cooled and then stored in silos. A portion of the quicklime is hydrated before storage. Hydrated lime is produced by combining quicklime with sufficient water to cause the formation of a dry, white powder.

**Lightweight aggregate kiln.** Similar to the cement kiln and lime kiln processes, a lightweight aggregate kiln (Fig. 6.32) is an energy-intensive process to produce concrete products either for structural purposes or for thermal insulation purposes. Because of intensive energy needs, industrial waste is used to supplement the energy requirements (EPA-94/05, p. 2-19).

A lightweight aggregate plant includes a wide variety of raw materials which, combined with cement, form concrete products. The lightweight aggregate concrete is produced either for structural purposes or for thermal insulation purposes. A lightweight aggregate plant is composed of a quarry, a raw material preparation area, a kiln, a cooler, and a product storage area. From there, the material is fed into a rotary kiln.

A rotary kiln consists of a long steel cylinder, lined internally with refractory bricks, which is capable of rotating about its axis and is inclined at an angle of about 5 degrees to the horizontal. The length of the kiln depends in part upon the composition of the raw material to

be processed, but is usually 30–60 meters. The prepared raw material is fed into the kiln at the higher end, while firing takes place at the lower end. The dry raw material fed into the kiln is initially preheated by hot combustion gases.

Once the material is preheated, it passes into a second furnace zone where it melts to a semiplastic state and begins to generate gases which serve as the bloating or expanding agent. In this zone, specific compounds begin to decompose and form gases such as  $\text{SO}_2$ ,  $\text{CO}_2$ ,  $\text{SO}_3$  and  $\text{O}_2$  that eventually trigger the desired bloating action within the material. As temperatures reach their maximum (approximately 2100°F), the semiplastic raw material becomes viscous and entraps the expanding gases. This bloating action produces small, unconnected gas cells, which remain in the material after it cools and solidifies. The product exits the kiln and enters the cooler section of the process, where it is cooled with cold air and then conveyed to the discharge point.

**Waste feed.** The method of feeding waste into a kiln is a primary factor in determining the destruction of the waste, which is dependent on temperature, residence time, and turbulence. The method of introducing the waste also depends on its physical state, including (EPA-94/05, p. 2-14):

- liquid;
- solid;
- containerized solid waste;
- powdered waste.

**LIQUID WASTE:** Liquid wastes are either blended directly with conventional fuels provided at the hot end of the kiln, or they are injected through a separate burner/atomizer into the primary kiln flame.

**SOLID WASTE:**

- For long-type wet and dry kilns and dry kilns with preheaters, a method has been patented by Benoit and Hansen under US Patent No. 4,850,290 for charging solid wastes directly through a hatch on the rotating kiln wall at an intermediate location within the calcining zone. At each rotation, the hatch is opened, and containerized waste solids are fed down a drop tube that is inserted through the hatch and into the rotating kiln. The drop tube prevents hot mineral material from escaping through the port or contacting the enclosure. It is important that the volume of the volatile components do not exceed the capacity for their complete combustion in the gas stream. Thus, wastes are containerized to minimize the potential for overloading the combustion capacity (creating local reducing conditions).
- For preheater or precalcining kilns, the solid waste may be injected directly into the pre-calciner vessel or preheater inlet.

**CONTAINERIZED SOLID WASTE:** Containerized solid wastes may be injected at the hot end of the kiln at a high enough velocity so that they are projected into the calcining zone. An “air cannon,” which is mounted to the kiln hood, is used to propel the waste containers.

**POWDERED WASTE:** If the waste is in powdered form, it may be injected directly into the primary burning-zone coal flame of the cement kiln.

## 4.2 Industrial Boilers for Resource Recovery

In contrast to incinerators, whose main objective is to destroy wastes, boilers are constructed to produce steam for electrical generation (utility boilers) or for onsite process needs (industrial boilers). Also, wastes compose the primary feed to incinerators, whereas they are usually a supplementary fuel for boilers. Fuel inputs to industrial boilers vary with process requirements, which may fluctuate considerably more than the waste feed to a waste incinerator.

Before chlorinated wastes can be fired to boilers, the incompatibility with materials of construction and air pollution control equipment must be considered so as to minimize corrosion problems and hydrogen chloride emissions (EPA-94/05, p. 2-34; EPA-86/09, p. 2-9).

Reportedly there are approximately 2600 fossil-fuel-fired utility boilers and more than 23,000 fossil-fuel-fired industrial boilers (9800 with capacities greater than  $50 \times 10^6$  Btu/h) in the United States. Coal is the primary fuel in both boiler sectors, but oil and gas are also used. The concept of disposing of wastes in boilers has centered around industrial boilers because (1) their operation is more flexible than utility boilers, (2) they offer the potential of destroying wastes generated onsite, and (3) the storage and handling facilities for wastes generated onsite generally already exist.

When burning wastes in boilers, blending and operation plans should be developed to address (OME-88/12, p. 4-99):

- additional gas cleaning requirements necessary to handle the ash content of waste fuels;
- control of hydrogen chloride or other acid gas resulting from the burning of waste fuels;
- increased maintenance of boilers and air-cleaning equipment resulting from the use of waste fuels; and
- installation of ash discharge equipment at the bottom of the boiler to catch and discharge accumulated bottom ash.

In general, criteria for waste firing in a boiler include:

- gross waste heating value  $> 18,000$  kJ/kg, as fired;
- ash content  $< 1.5\%$ , as fired;
- chloride content of the organic matter  $< 0.5\%$ , as fired;
- minimum operation temperature  $870^\circ\text{C}$  ( $1600^\circ\text{F}$ ).

By definition, a boiler is a closed vessel in which water under pressure is transformed into steam by the application of heat. More specifically, EPA has defined the following characteristics of a boiler for regulatory purposes under the Resource Conservation and Recovery Act (RCRA):

- the combustion chamber and primary energy recovery section must be of integral design;
- thermal recovery efficiency must be at least 60%;
- at least 75% of the recovered energy must be “exported” (i.e., not for internal boiler uses).

Boilers come in a variety of sizes, configurations, and designs. The three common boiler design categories which burn hazardous waste are

- fire tube boilers
- water tube boilers
- stoker-fired boilers

**Fire tube boilers.** The fire tube boiler can be described in simple terms as a water-filled cylinder with tubes running through it which provide the escape path for the combustion gases or flue gas (as shown in Fig. 6.33). As the flue gas passes through the tubes, the hot gases heat the tubes which then heat the water to produce steam. The fire tube boiler is primarily used in industrial applications.

Fire tube boilers are compact, low in initial cost, and easy to modularize based on plant requirements. However, they are also slow to respond to changes in demand for steam (load) compared with water tube boilers, and circulation is slower. Also, stresses are greater in boilers because of their rigid design and subsequent inability to expand and contract easily. Fire tube boilers usually range in size from less than 2 to 50 million Btu per hour.

FIGURE 6.33 Fire tube boiler (EPA-94/05, p. 2-35).

**Water tube boiler.** The basic design of a water tube boiler (Figs 6.34 and 6.35) is that the water is circulated through tubes, with the hot combustion gases passing over the outside surfaces of the tubes. Generally, the boiler can be physically divided into two sections, the furnace and the convection pass. Furnaces (fireboxes, combustion chambers) will vary in configuration and size, but their function is to contain the flaming combustion gases and transfer the heat energy to the water-cooled walls. The convection pass contains the superheaters, reheater, economizer and air preheater heat exchangers, where the heat of the combustion flue gases is used to increase the temperature of the steam, water, and combustion air. The superheaters and reheaters are designed to increase the temperature of the steam generated within the tubes of the furnace walls. Steam flows inside the tube, and flue gas passes along the outside surface of the tubes.

The economizer is a counter flow heat exchanger designed to recover energy from the flue gas after the superheater and the reheater. The boiler economizer is a tube bank-type, hot-gas-to-water heat exchanger. It increases the temperature of the water entering the steam drum. The tube bundle is typically an arrangement of parallel horizontal serpentine tubes with the water flowing inside but in an opposite direction to the flue gas. Tube spacing is as small as possible to promote heat transfer while still permitting adequate tube surface cleaning and limiting flue gas side pressure loss. By design, steam is not usually generated inside these tubes.

FIGURE 6.34 Industrial water tube boiler (EPA-94/05, p. 2-35).

FIGURE 6.35 Utility water tube boiler (EPA-94/05, p. 2-41).

The air preheater is not a portion of the steam-water circuit, but serves a key role in the steam generator system to provide heat transfer and efficiency. In many cases, especially in a high pressure boiler, the temperature of the flue gas leaving the economizer is still quite high. The air heater recovers much of this energy and adds it to the combustion air. Heating the combustion air prior to its entrance to the furnace reduces fuel usage.

Water tube boilers are rapid steamers and respond quickly to changes in demand for steam due to improved water circulation. They can withstand much higher operating pressures and

temperatures than fire tube boilers. In addition, the water tube boiler design is safer. They can also burn a wide variety of fuels and have the ability to expand and contract more easily than fire tube boilers. The major drawback is that water tube boilers are more expensive to install. They also require more complicated furnaces and repair techniques.

### ***Stoker boiler***

**STOKER:** Stokers are mechanical devices that feed solid fuels such as coal, wood wastes, and bagasse (as well as residential and commercial refuse) onto a grate at the bottom of the furnace and remove the ash residue after combustion. Stokers are designed to permit continuous or intermittent fuel feed, fuel ignition, air supply for combustion, free passage for the resulting gaseous products, and disposal of noncombustible materials. A stoker firing system typically consists of a fuel supply system, a stationary or moving grate assembly which supports the burning mass of fuel and admits most of the combustion air to the fuel, an overfire air system to complete combustion, and an ash or residual discharge system. Figure 6.36 shows a cross section of an overfeed mass burning traveling grate stoker.

**FUEL FEEDER:** There are three types of fuel feeders utilized in spreader stokers: (1) reciprocating feeder, (2) chain feeder, and (3) drum feeder. In general, fuel feeders have a device which meters the fuel to the combustion control system and delivers it to the built-in rotor.

**GRATE:** The purpose of the grate includes providing

- a floor on which the fuel can burn
- a means of distributing air evenly through the grates
- a method of discharging the ashes that accumulate on the grate from the consumed fuel.

The various grate designs include stationary and dumping grates, reciprocating grates, vibrating grates, traveling grates, and vibrating, water-cooled grates.

## **5 FACILITY DESIGN FEATURE**

The facility design and operation of waste incinerators is significantly influenced by the category of waste involved, i.e., solids, liquids, or sludges. The systematic approach to facility design and operation therefore requires investigation of the composition of each class of waste to define the equipment and operating procedures for each of the following elements. The

overall success of an incinerator facility depends upon the successful integration of these elements.

- Compliance with regulatory requirements.
- Waste characteristics.
- Auxiliary fuel.
- Factors affecting hazardous waste incinerator facility design.
- Site selection.
- Waste receiving area.
- Waste segregation and storage.
- Waste blending and/or processing before incineration.
- Combustion process monitoring.
- Preplanning of facility operation.
- Safety (toxicity, fire explosion).
- Transportation and unloading.
- Fugitive emission control.
- Scrubber/quench water treatment.
- Residue handling and disposal.
- Secondary problems (e.g., stream pollution, runoff, groundwater contamination).
- Permit procedure.

Some of the above items are further described below.

## 5.1 Compliance with Regulatory Requirements

A major consideration in the design and operation of waste combustion systems is the regulatory requirements under which an incineration facility will be permitted and operated. Emissions from combustion of municipal, medical, and hazardous wastes are regulated under entirely different sets of environmental laws, even though many waste types can generally be burned in a given unit, separately or mixed. Key components for the compliance with regulatory requirements include (Hasselriis-98/12):

- environmental laws and environmental regulations;
- pollutants of concern;
- stack emissions and the environment;
- emission standards and guidelines;
- good combustion practice;
- stack testing and monitoring;
- ash residue management;
- operator certification and training.

**ENVIRONMENTAL LAWS AND ENVIRONMENTAL REGULATIONS:** Based on the environmental laws enacted by Congress, US EPA develops detailed environmental regulations and codifies them in 40 Code of Federal Regulations (40CFR). Table 6.4 provides the relationship between the environmental laws and environmental regulations. For the compliance of air emissions, readers are encouraged to refer to the air program in 40 CFR Parts 50 to 90 and for solid waste treatment, the readers should refer to the solid waste program in 40 CFR Parts 240 to 299.

**TABLE 6.4** Major Environmental Laws and Environmental Regulations

Environmental laws	Environmental regulations (CFR cites)
EPA's purpose and functions	Subchapter A—General; 40CFR1-29
Government Performance and Results Act (GPRA) of 1993 (Public Law 103-62)	Web address: <a href="http://www.epa.gov/Indicator/gpra.htm#law">http://www.epa.gov/Indicator/gpra.htm#law</a>
EPA's regulatory authorities	Subchapter B—Grants and Other Federal Assistance; 40CFR30-47
Clean Air Act (CAA) of 1970	Subchapter C—Air Programs; 40CFR50-99
Federal Water Pollution Control Act (FWPCA) of 1972	Subchapter D—Water Programs; 40CFR100-140 (oil discharge and prevention related regulations)
Safe Drinking Water Act (SDWA) of 1974	Subchapter D—Water Programs; 40CFR141-149 (drinking water regulations)
Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) of 1947	Subchapter E—Pesticide Programs; 40CFR150-189
Atomic Energy Act (AEA) of 1954	Subchapter F—Radiation Protection Programs; 40CFR190-192
Noise Control Act (NCA) of 1972	Subchapter G—Noise Abatement Programs; 40CFR201-211
Marine Protection, Research, and Sanctuaries Act (MPRSA) of 1972	Subchapter H—Ocean Dumping; 40CFR220-238
Resource Conservation Recovery Act (RCRA) of 1976	Subchapter I—Solid Wastes; 40CFR240-259 (municipal waste, land disposal, and resource recovery regulations)
Hazardous and Solid Waste Act (HSWA) of 1984	Subchapter I—Solid Wastes; 40CFR260-299 (hazardous waste)
Comprehensive Environmental Response, Compensation, and Liability Act of 1980 (CERCLA)	Subchapter J—Superfund, Emergency Planning, and Community Right-To-Know Programs; 40CFR300-399
Superfund Amendments and Reauthorization Act (SARA) of 1986	
Clean Water Act (CWA) of 1997	Subchapter N—Effluent Guidelines and Standards; 40CFR400-599
Motor Vehicle Information and Cost Savings Act (MVICSA) (15USC1901)	Subchapter P (reserved)
Toxic Substances Control Act (TSCA) of 1976	Subchapter Q—Energy Policy; 40CFR600-699
	Subchapter R—Toxic Substances Control Act; 40CFR700-799
National Environmental Policy Act (NEPA) of 1969	Subchapter V—Council on Environmental Quality; 40CFR1500-1517

**POLLUTANTS OF CONCERN:** The pollutants which are regulated by air programs are particulate matter (PM), carbon monoxide (CO), sulfur dioxide (SO<sub>2</sub>), nitrogen oxides (NO<sub>x</sub>), hydrogen chloride (HCl), lead, cadmium, and mercury. Other pollutants, not expressly regulated, which may need to be investigated in environmental impact studies, may be evaluated by the same calculation procedures.

Permits for hazardous waste combustors (HWCs) have been granted on the basis of demonstrating 99.99% destruction and removal efficiency (DRE) for the principal organic hazardous components (POHC), and for specific metals in the feed, as well as CO limitations. These tests are designed so that the anticipated concentrations of these components are fed to the HWC during the trial burn test while stack emissions are measured. In order to obtain stack emissions high enough to measure with accuracy, sufficiently above the detection limit of the analytical procedures, it is often necessary to feed substantially higher quantities of the target substance than are likely to be encountered in reality. Hence, the measured emissions

may not be appropriate for estimating environmental and health effects resulting from normal operation of the HWC.

The composition of the fuel or the waste determines the potential for emissions of pollutants from the stack, although the chemical forms of the emissions will generally change as a result of the process, and a substantial fraction may be discharged as ash residue. Additives used to alter or control emissions will also affect the composition of the stack gases. These may include water used for cooling of the products of combustion, alkaline reagents to control acid gases, urea or ammonia to control  $\text{NO}_x$ , and activated carbon used to adsorb mercury and dioxins.

**STACK EMISSIONS AND THE ENVIRONMENT:** It is important to understand that the regulated emissions measured at the stack through which they are discharged are expressed as concentrations, weight per unit volume, referred to standard atmospheric temperature and pressure. The regulations express the allowable emissions on a dry basis (water vapor not included), and with an arbitrary standard representing approximately 50% excess air, usually exactly 7% oxygen, and approximately 11% carbon dioxide. The European Union requires correction to 3% oxygen.

These corrected values are used to report and compile emission numbers on a common basis to make valid comparisons of data. The data base of these emission factors, maintained by the US EPA and others, is useful in predicting emissions from facilities yet to be constructed and tested. They do not represent actual emission concentrations which take place at stack temperatures, including the water vapor and excess air. Actual emission concentrations of the pollutants in the actual gaseous emission volumes are used to calculate ground level or other local concentrations resulting from the dilution and dispersion of the stack gases in the ambient atmosphere. These concentrations are appropriate for the estimation of health effects and other environmental impacts.

**EMISSION STANDARDS AND GUIDELINES:** The reader should consult Federal, State, and local emission standards for an incinerator to be designed or operated. The trend of regulations has been from risk-based standards toward technology-based standards. Before present federal regulations were in place for municipal waste combustion, many states took the initiative and wrote standards based on the health risk associated with the emissions at ground level, and required risk assessments to be prepared on the basis of modeling.

The Clean Air Act Amendments of 1990 required that Maximum Available Control Technology (MACT) standards be developed which would take into account the "best performing" combustion systems, requiring that new facilities meet these more stringent emission standards, and that existing facilities be upgraded to higher standards.

In spite of having to comply with the new federal standards, and more stringent state standards, permits may continue to be subject to public scrutiny on a one-by-one basis, which means that environmental impact will still be considered for pollutants which are not numerically regulated by federal and state regulations.

**GOOD COMBUSTION PRACTICE:** Standards for Good Combustion Practice (GCP) have been developed, which apply to all waste combustors: essentially they require that no waste be fed until the furnace temperature is at least  $1600^\circ\text{F}$ , and that the gaseous products of combustion be retained for at least 1 s at  $1800^\circ\text{F}$  or higher for most wastes, or for 2 s at  $2000^\circ\text{F}$  for wastes containing large quantities of halogenated compounds, which are more difficult to destroy. Hazardous waste incinerators have been subjected to stringent regulation due to the potentially toxic emissions from the wide range of organic and inorganic compounds which may be in the wastes, and which define them as hazardous. These regulations require that trial burns be performed as a permit condition, during which it is demonstrated that the system can achieve 99.99% destruction and removal efficiency (DRE) while burning the principal organic hazardous compounds (POHC) and heavy metals. The assumption behind these tests was that the emissions would be related to the feed materials; hence the feed must be analyzed in normal operation, and be anticipated as the basis for the trial burns. In view of the fact that modern combustion and emission control systems which can meet present regulatory standards actually destroy or remove all but traces of the target substances,

the tendency has been to focus on the actual emissions and ensure that they will not exceed the new, stringent standards.

**STACK TESTING AND MONITORING:** An essential part of the focus on actual stack emissions, which applies to all waste combustors, is the requirement that monitoring instruments be installed and operated, providing a continuous record of compliance. Continuous measurement of carbon monoxide (CO) and/or hydrocarbons (HC) and oxygen provides assurance of good combustion. These are useful surrogates for trace organic compounds, including dioxins and furans. Measurement of HCl, SO<sub>2</sub>, and NO<sub>x</sub> may be required, where applicable. Opacity measurements provide continuous supervision of the combustion process as well as the emission control system.

**ASH RESIDUE MANAGEMENT:** Ash residues from combustion of wastes are generally required to be tested for toxicity and managed appropriately. If found to fail the Extraction Procedure Toxicity (TCLP) test, they may have to be treated, or disposed in suitable landfills. The source of toxicity is generally the heavy metals, specifically lead, cadmium, and other metals, which are not destroyed by the combustion process, and hence end up in the flyash or bottom ash residues. The use of alkaline reagents for control of the acid gases adds another component to the disposal problem, since excess alkalinity can increase the solubility of these metals in the ash residues, and carbon, which absorbs dioxins and mercury.

**OPERATOR CERTIFICATION AND TRAINING:** In addition to requiring good combustion practice and regulating emissions, an essential component of the newly promulgated regulations is the requirement for operator training and certification, applied appropriately to municipal, medical, and hazardous waste combustion systems.

## 5.2 Waste Characteristics

Wastes are, by definition, nonuniform in quality. In order to proceed with equipment selection and design, however, waste characteristics must be determined or developed. The objective of undertaking waste characterization is

- to obtain the heating value,
- to obtain the range of the moisture content,
- to determine recyclables,
- to determine ash quantity for disposal,
- to determine the fate of metals,
- to determine the sources of chlorine,
- to determine composition of medical and/or infectious wastes.

A waste material considered as an incineration candidate will normally have a combustible component and a noncombustible component, and may contain moisture. Generally, heating value is stated relative to the waste combustible component. Heating value can be noted as a gross number applied to the total waste quantity, but the combustible, noncombustible, and moisture components must be identified in order to determine the heat content of a material. Key topics related to waste characteristics include (OME-88/12, p. 4-2):

- proximate analysis;
- ultimate analysis;
- calculated heating value.

**PROXIMATE ANALYSIS:** Proximate analysis and ultimate analysis are two important methods for the determination of whether a given waste is suitable for incineration, and how the incineration should take place (OME-88/12, p. 4-2).

Proximate analysis as per ASTM D 3172 is a relatively quick and inexpensive laboratory determination of the percentages of moisture, volatile matter, fixed carbon, and ash. The analytic procedure is as follows:

- heat a sample for 1 h at 105–110°C (221–230°F) and report the weight loss fraction as percent moisture;
- raise the temperature of the dried sample in a covered crucible to 725°C (1337°F) and hold it at this temperature for 7 min, and then report the sample weight loss fraction as volatile matter percentage;
- ignite the remaining sample in an open crucible at 950°C (1742°F) and allow it to burn to a constant weight, then report the sample weight loss as a percent fixed carbon.

The sample residue is to be reported as percent ash. The sum of moisture, volatiles, fixed carbon, and ash should equal 100%.

**ULTIMATE ANALYSIS:** Ultimate analysis is a standard procedure used for a determination of the quantities of elemental components present in a sample (ASTM D 3176). It is required in order to determine the products of combustion of a material, its combustion air requirement, and the nature of the off-gas or combustion products.

In this procedure the following elemental percentages are normally determined:

- carbon
- hydrogen
- sulfur
- oxygen
- nitrogen
- halogens (chlorine, fluorine, etc.)
- heavy metals (mercury, lead, etc.)
- other elements that can affect the combustion process

In addition to these components, analyses may be performed under the heading of ultimate analysis for the presence of certain compounds that may be in the waste, such as chlorobenzene, chlorophenols, PCBs (polychlorinated biphenyls), dioxins, etc.

It must be recognized that wastes are often extremely heterogeneous in nature. The proper selection of a representative sample is at least as important as performing the test itself. Most commonly used methods involve dumping a truckload of material in an enclosed area, and then reducing the truckload to an approximately 100-kg sample by a process of repeatedly quartering the waste and discarding three-fourths. Generally, landfill equipment (a bulldozer or wheeled loader) is used for quartering. Alternative methods include selecting a random sample using a grid method, or treating the entire truckload as the sample.

After sample selection is completed, the material can be sorted into standard components (food wastes, paper, cardboard, plastics, textiles, rubber, leather, garden trimmings, wood, glass, nonferrous metals, ferrous metals, dirt, ashes, etc.) so that each component can be analyzed.

**CALCULATED HEATING VALUE:** If the fractions of the elemental composition such as carbon, hydrogen, oxygen, and sulfur of a waste are given, the DuLong equation can be used to calculate the approximate heating value of the waste. This equation is as follows:

$$Q = 33,829 C + 144,277 (H_2 - 0.125 O_2) + 9420 S$$

where  $Q$  is in kJ/kg and  $C$ ,  $H_2$ ,  $O_2$ , and  $S$  are the weight fractions of carbon, hydrogen, oxygen, and sulfur, respectively. The weight fractions should add to 100% unless an inert

material such as nitrogen is present. With the presence of nitrogen, for instance, the weight fraction (%) of C, H<sub>2</sub>, O<sub>2</sub>, and S will total 100% less the fraction of nitrogen present.

**WASTE AND FUEL DATA:** Tables 6.5–6.10 give a collection of waste data pertinent for incineration references.

Table 6.5 (OME-88/12, p. 4-3) lists properties of various municipal waste materials relative to incineration. Included are heating value, density, and typical ash and moisture components.

Table 6.6 (OME-88/12, p. 4-4) identifies common waste designations.

Table 6.7 (OME 88/12, p. 4-5) lists municipal solid waste composition in the US and Canada on a national average basis.

Table 6.8 (OME-88/12, p. 4-6) lists combustion characteristics of those wastes generated in Hamilton, Canada.

Table 6.9 (Hasselriis-98/12) lists the moisture, ash, heating value, and density of the standard types of municipal, commercial, and medical wastes according to waste types established by the Incinerator Institute of America. The wastes have been classified as Types 0–4 as a simplified definition.

Table 6.10 (Hasselriis-98/12) gives the approximate ultimate analysis of hazardous waste in different combustion chambers.

**TABLE 6.5** Characteristics of Selected Municipal Waste\*

Waste	Heating value as fired (kJ/kg)	Density (kg/m <sup>3</sup> )	% Ash (by weight)	% Moisture
Newspaper	18,600	110	1.5	6
Brown paper	16,900	110	1	6
Magazines	12,200	560	22.5	5

### 5.3 Auxiliary Fuel

Table 6.11 provides the proximate and ultimate analysis and higher heating values of the most commonly used auxiliary fuels, No. 2 light distillate fuel oil, No. 6 heavy residual fuel oil, and natural gas.

### 5.4 Factors Affecting Hazardous Waste Incinerator Facility Design

The overall facility design of hazardous waste incinerators is significantly influenced by the category of waste involved; i.e., solids, liquids, or sludges. The systematic approach to facility design therefore requires investigation of the composition of each class of waste to define the equipment and operating procedures for each of the following elements (EPA-81/09, p. 5-2):

1. safety (toxicity, fire explosion);
2. transportation and unloading;
3. segregation of wastes during storage;
4. storage;
5. handling and feeding;
6. monitoring;

**TABLE 6.7** Composition of Municipal Solid Waste from US and Canada (percent wet weight)

**TABLE 6.9** Standard Types of Municipal, Commercial and Medical Wastes

Waste type	Moisture (%)	Ash (%)	Heating value (Btu/lb)	Density (lb/ft <sup>3</sup> )
Type 0 Trash Highly combustible waste, paper, wood cardboard cartons, including up to 10% treated papers, plastic or rubber scraps; commercial and industrial sources	10	5	8500	8–10
Type 1 Rubbish Combustible waste, paper, cartons, rags, wood scraps, combustible floor sweepings; domestic, commercial, and industrial sources	25	10	6500	8–10
Type 2 Refuse Rubbish and garbage; residential sources	50	7	4300	15–20
Type 3 Garbage Animal and vegetable wastes; restaurants, hotels, markets; institutional; commercial and club sources	70	5	2500	30–35
Type 4 Organic waste Carcasses, organs, solid organic wastes; hospitals, laboratories, abattoirs, animal pounds, and similar sources	85	5	1000	45–55

7. fugitive emission control;
8. scrubber/quench water treatment;
9. residue handling and disposal; and
10. secondary problems (e.g., stream pollution, runoff, groundwater contamination).

The overall success of an incinerator facility depends upon the successful integration of storage, feeding, and firing equipment; often these are areas which do not receive as much attention as is necessary. In the case of hazardous waste incineration, it is crucial that these areas receive special attention.

Figure 6.37 is a block diagram of a typical incinerator facility layout. In an overall facility evaluation the key areas are the facilities and equipment before and after the combustors, i.e., waste receiving, waste storage, waste blending, transfer between these areas, equipment feeding waste to the incinerator, handling and treatment of quench and scrubber waters, and ash disposal.

## 5.5 Site Selection

The selection of a site for a waste incineration facility is a phased decision process which occurs prior to making a permit application. Site screening is the process of identifying and evaluating a parcel of land for its suitability as a waste disposal site. Specific site screening criteria which the permit applicant must address include the following aspects (EPA-81/09, p. 5-2):

- geological
- topographic
- climatic
- ecological
- cultural
- public

**TABLE 6.10** Typical Hazardous Waste Stream Analysis

Component/property	% by weight	Range
Primary combustion chamber (pumpable sludge waste)		
Carbon	24.35	20.52–41.40
Hydrogen	3.22	1.61–5.87
Nitrogen	0	0.00–3.47
Oxygen	0	0.00–4.73
Chlorine	0	1.17–29.48
Fluorine	0	0.00–1.00
Sulfur	0	0.07–1.00
Water	62.43	4.00–70.00
Ash	10	12.63–25.00
HHV (Btu/lb)	5400	3200–9500
Viscosity	500 cp	200–1000
Specific gravity	1.2	1.0–1.71
Primary combustion chamber (solid waste)		
Carbon	13.8	3.39–20.70
Hydrogen	1.95	0.43–2.97
Nitrogen	3.25	0.00–7.80
Oxygen	24	0.00–7.62
Chlorine	15	0.76–16.00
Fluorine	0	0.00–1.00
Sulfur	1	0.07–1.00
Water	16	10.00–22.00
Ash	25	48.33–58.00
HHV (Btu/lb)	3000	700–4500
Secondary combustion chamber (liquid waste)		
Carbon	57.3	48.61–75.90
Hydrogen	7.56	6.42–10.88
Nitrogen	22.52	0.58–28.61
Oxygen	6	7.48–10.26
Chlorine	1.47	1.10–4.68
Fluorine	0.01	0.00–1.00
Sulfur	0.01	0.00–1.00
Water	4.21	0.00–5.02
Ash	0.92	0.54–1.00
HHV	12,000	10,000–20,000
Viscosity	15.2 cp	1.0–20.00
Specific gravity	0.95	1.0–1.10

While many sites may exist which meet technical, economic, and ecological criteria, public acceptance or rejection may ultimately decide the fate of the facility.

**GEOLOGICAL:** The main geological constraints that can render a site unsuitable for a hazardous waste incinerator facility are historical or predicted seismic activity, landslide potential, and volcanic or hot spring activities.

**TOPOGRAPHIC:** The main topographic constraints are susceptibility to flooding, erosion, and offsite drainage runoff. The site will need sufficient area for the construction of a runoff holding pond (or diversion to an existing holding pond) to retain surface runoff which may contain hazardous substances in solution. Because of the holding pond and flood protection criteria, siting in flood plains is not normally acceptable.

**TABLE 6.11** Common Auxiliary Fuels

Component	Residual oil (No. 6)*	Distillate fuel (No. 2)**	Natural gas**
C	0.8852	0.872	0.693

\*\*\* Hasselriis-98/12.

**CLIMATIC:** The primary climatic features which can adversely affect an incineration site are the amount of annual or seasonal precipitation and the incidence of severe storms. Copious precipitation will cause surface runoff and water infiltration through the soil. Runoff, i.e., that amount of rainfall that does not infiltrate the soil, depends on such factors as the intensity and duration of the precipitation, the soil moisture content, vegetation cover, permeability of the soil, and slope of the site. Normally, the runoff from a 10-year storm (recurrence interval of only once in 10 years) or annual spring thaw, whichever is greater, is containable by the site's natural topography. If not, berms, dikes, and other runoff control measures must be constructed to modify the site.

**ECOLOGICAL:** Ecological site features are those elements determined through earlier studies and environmental impact statements (EIS) which determine whether ecosystems at

**FIGURE 6.37** Typical incinerator facility layout (EPA-81/09, p. 5-3).

the site are in a delicate balance. Whether a site is a habitat for rare and endangered species, or used seasonally by migratory wildlife is also a factor in final site selection.

**CULTURAL:** Cultural site features are those elements that are a direct result of human activities which modify and affect the site's desirability as a hazardous waste incineration facility such as access, land use, and aesthetics. Land areas zoned for nonresidential uses and adequate buffer zones are generally preferred for siting a hazardous waste management facility. The site ideally needs to contain sufficient land area to provide a concentric ring of unoccupied space as a buffer zone between active storage, treatment, and disposal areas, and the nearest area of human activity. Vegetation, topography, distance, and artificial barriers are all potential means to screen facility activities from line of sight observations from commercial, residential, or recreational areas.

**PUBLIC:** One of the most difficult problems faced by a hazardous waste incineration facility applicant has been that of gaining public approval from a community for construction of the facility. No matter how thoroughly the above parameters have been examined in the facility site selection, public acceptance or rejection probably decides the fate of the facility. Public awareness of the planned facility, early planning input, and active participation by political leaders, public officials, and environmental groups, as well as other public interest groups and adjacent industry have led to successful facility sitings in the past.

## 5.6 Waste Receiving Area

The type and nature of waste received at an incinerator facility will dictate the design and equipment of the waste receiving area. The physical types of waste which may be received are:

- liquid,
- containerized materials, liquid and solids,
- dry solid materials, and
- wet solid materials:
  - (a) pumpable, and
  - (b) nonpumpable.

The types of receiving equipment for unloading can be divided into three general areas:

- pumpable liquid transfer,
- container transfer, and
- bulk solids transfer.

Careful consideration must be given to the layout, safety, and recordkeeping arrangements of the waste receiving area. Unloading material offers one of the greatest spill or toxic exposure potentials at a waste facility. For recordkeeping, the waste receiving area poses the first interface with the transporter and manifest system. Proper operation of waste receiving areas includes:

- typical operation and layouts,
- laboratory for waste verification and/or characterization,
- liquid unloading, including safety/emergency provisions, and spill and runoff containment,
- container unloading, including drums, barrels, and special bulk units, and
- bulk solids unloading, including mechanical conveyors and pneumatic conveyors.

## 5.7 Waste Segregation and Storage

The manner in which a waste is handled onsite is dependent on:

- the nature of the waste (corrosivity, explosivity, etc.),
- the plant storage facilities, and
- the heat content of the fuel.

Wastes received for incineration at a disposal facility are either incinerated directly (in some cases via pumping directly from the tank truck), or stored until they can be handled more conveniently. A plant operator may want to segregate and store some of the incoming wastes with higher heating values to possibly blend with other wastes which have heating values too low to support combustion alone. At some plants, waste blending occurs prior to storage.

Storage capacity is based on:

- seasonal inventory build-up,
- redundancy or excess incinerator capacity,
- maintenance schedules and downtime,
- operating schedules (i.e., number of shifts vs. in-shipment rates), and
- amounts and nature of waste blending to be done.

Depending on the type of incinerator installation, storage facilities may be required to hold both liquid and solid wastes. If an incinerator cannot burn solids, facilities for solids storage are obviously not necessary.

A waste storage area is designed to address three problem areas:

- segregation of incompatible corrosive and reactive waste types;
- fire hazards due to flammable liquids and solids; and
- toxic hazards to prevent human exposure during storage, transfer, and spill possibilities.

Other factors for consideration for waste storage include:

- types of storage, including liquid storage, bulk solids storage, container storage, and tank cars,
- segregation of waste during storage, and
- safety provisions for storage areas, including fire safety and spill/toxicity safety.

## 5.8 Waste Blending and/or Processing Before Incineration

The methods by which wastes are removed from storage, prepared for incineration, and fed to the incinerator are dependent on the nature of the waste and the type of incinerator. Careful design consideration is given to:

- the layout for liquid waste blending, pumping, and associated pipework; and
- the handling and feeding arrangements for nonpumpable sludges, solids, and containerized wastes, where applicable.

Operating experience has shown that these are areas that do not receive as much attention as is necessary; the overall success of an incineration facility depends upon the successful integration of storage, feeding, and firing equipment.

Other factors for consideration for waste blending and/or processing before incineration include:

- waste compatibilities,
- liquid feed and blending equipment,
- pumps and piping, including positive-displacement pumps, centrifugal pumps, pump emission control, and pump and piping safety,
- valving and controls, including on/off service, throttling service, pressure control, etc.,
- valving and control safety considerations, including safety shutoffs, gages, meters, and gage glasses, operating controls,
- solids feeding equipment, including shredders, explosion suppression and safety consideration for shredders, feeders, container feeding equipment, and
- waste processing instrumentation.

## 5.9 Combustion Process Monitoring

Before incineration process conditions can be controlled automatically they must be measured with precision and reliability. Instrumentation for an incineration process is essential because of the variability of the many factors involved in attaining good combustion. For example, as the heat content of the solid waste rises, changes in the combustion process become necessary. Instrumentation indicates these variations so that automatic or manual control adjustments can be made.

The uses of instrumentation and controls include a means of process control, protection of the environment, protection of the equipment, and data collection. A control system must have four basic elements:

- standard of desired performance;
- sensor (instrument) to determine actual performance;
- capability to compare actual versus desired performance (error); and
- control device to effect a corrective change.

The four major factors governing incineration efficiency for a given waste feed are:

- temperature,
- residence time,
- oxygen concentration, and
- turbulence achieved.

The temperature in the incinerator can be measured directly. Instrumentation is also available to directly monitor CO, CO<sub>2</sub>, and oxygen concentration in the combustion gas to ensure that excess air levels are maintained. Residence time and mixing efficiency cannot be directly measured, however, so other parameters indicative of these conditions need to be measured instead.

Gas residence time in the combustion zone depends upon the volume of the combustion chamber and the volumetric flow rate. Since the volume of the chamber is fixed for a given unit, residence time is directly related to combustion gas volumetric flow rate. Therefore, measuring this flow rate is equivalent to residence time measurement for a given incinerator.

Mixing in liquid waste incinerators or afterburners is a function of burner configuration, gas flow patterns, and turbulence. Burner configuration and gas flow pattern are a function of the incinerator design and will not vary from baseline conditions. Turbulence is determined by gas velocity in the combustion chamber, which is proportional to gas volumetric flow rate. Therefore, combustion gas flow rate is an indicator of mixing as well as residence time in liquid injection incinerators.

In incinerators burning solid wastes, other factors need to be considered to determine solids retention time and degree of agitation. These factors vary from one type of incinerator to another.

**TEMPERATURE MONITORING:** Incinerator temperature is monitored on a continuous basis to ensure that the minimum acceptable temperature for waste destruction is maintained.

This requires one or more temperature sensors in the hot zone and a strip chart recorder or equivalent recording device.

Generally, wall temperatures and/or gas stream temperatures are determined using shielded thermocouples as sensors. Thermocouples are the most commonly used contact sensors for measuring temperatures above 1000°F. Specifically, thermocouples can measure the following thermal parameters:

- Average gas temperature—accomplished using a shielded thermocouple with a relatively large thermal capacity anchored to a relatively large mass. The metering circuit is provided with a 30-s time constant to further smooth and average the readings.
- Instantaneous gas temperature—accomplished using a shielded thermocouple with a very small thermal capacity with the output metered by a circuit with a 1-s time constant. (Nominally, the reaction rates within the hot gas stream are strongly temperature-dependent; they should thus depend on the highest temperature to which the constituents are exposed.)
- Open flame temperature—obtained using an unshielded low thermal mass thermocouple with the output metered by an amplifier with a 30-s time constant.
- Average wall temperature—obtained using a shielded thermocouple imbedded in the refractory wall. (Here, the averaging is accomplished by the thermal inertia of the refractory material.)

Optical pyrometers are not recommended for these measurements owing to spectral bias factors present in the combustion area which can cause unacceptable measurement error.

The location at which temperature measurements are taken is important, owing to possible variations from one point to another in the combustion chamber. Temperatures are highest in the flame and lowest in the refractory wall or at a point of significant air infiltration. Ideally, temperatures are measured in the bulk gas flow at a point after which the gas has traversed the combustion chamber volume that provides the specified residence time for the unit. Generally, temperature measurement at a point of flame impingement or at a point directly in sight of radiation from the flame is not recommended. Figures 6.38 and 6.39 show typical monitoring locations for liquid injection and rotary kiln incinerators, respectively.

Table 6.12 (EPA-81/09, p. 5-80) provides the types of thermocouples used, including J, K, E, R, S, T, and B. The letter symbols identifying the thermocouple types are those defined in ANSI Standard C96.1. These symbols are in common use throughout industry. The table also lists the limits of error for the common thermocouple types; most manufacturers supply thermocouples and thermocouple wire to these limits of error or better.

Since the thermocouple element in a thermocouple assembly is usually expendable, conformance to established emf–temperature relationships is necessary to permit interchangeability. Calibration of a thermocouple consists of the determination of its emf at a sufficient number of known temperatures so that with some accepted means of interpolation, its emf will be known over the entire range in which it is to be used. The process requires a standard thermometer with high-level calibration to indicate temperatures on a standard scale, a means for measuring the emf of the thermocouple, and a controlled environment in which the thermocouple and standard can be brought to the same temperature.

Thermocouples use one of three different types of measuring junctions—grounded, ungrounded, and exposed. The grounded junction is the most popular. The ungrounded junction is the most rugged, but its speed of response is slower than that of the grounded

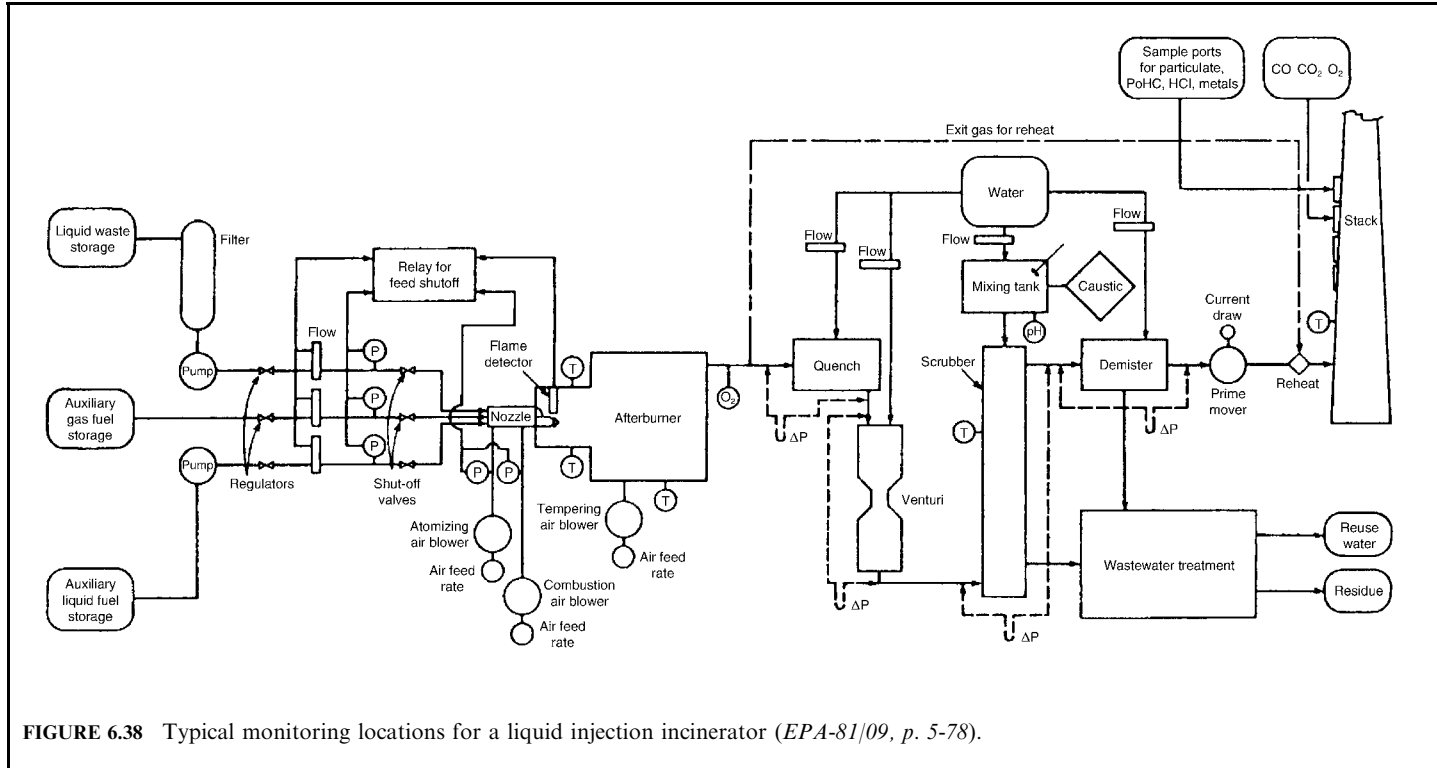

FIGURE 6.38 Typical monitoring locations for a liquid injection incinerator (EPA-81/09, p. 5-78).

FIGURE 6.39 Typical monitoring locations for a rotary kiln incinerator (EPA-81/09, p. 5-79).

**TABLE 6.12** Types and Limits of Error for Thermocouples

Type	Temperature range	Limits of error	
		Standard	Special
Type J—iron versus constantan (modified 1913 calibration)	32–530	±4°F	±2°F
	53–1400	±3/4%	±3/8%
Type K—originally chromel-P versus alumel	32–530	±4°F	2°F
	530–2300	±3/4%	±3/8%
Type R—platinum 13% rhodium versus platinum	32–1000	±5°F	±2.5°F
Type S—platinum 10% rhodium versus platinum	1000–2700	±1/2%	±1/4%
Type T—copper versus constantan	–300 to –75	–	±1%
	–150 to –75	±2%	±1%
	–75 to +200	±1.5°F	±3/4°F
	200–700	±3/4%	±3/8%
Type E—originally chromel-P versus constantan	32–600	±3°F	±2.25°F
	600–1600	±1/2%	±3/8%
Type B—platinum 30% rhodium versus platinum 6% rhodium	1600–3100	±1/2%	–

type. The unprotected exposed junction responds the fastest but is more vulnerable to corrosion and mechanical damage.

A complete thermocouple assembly consists of:

- a sensing element assembly, including in its most basic form two dissimilar wires joined at one end and separated by an electrical insulator;
- a protection tube, either ceramic or metal, or a thermowell. In some cases, both primary and secondary protection tubes are used;
- a thermocouple head or connector; and
- miscellaneous-type hardware such as pipe nipples or adaptors to join the protection tube to the head and thermocouple glands for mounting and pressure sealing.

Protection tubes and thermowells serve the double purpose of guarding the thermocouple against mechanical damage and shielding it from corrosive atmospheres. The choice of the proper material for the protection tube or thermowell is governed by the conditions of use and by the tolerable life of the thermocouple. There may be times when the strength of the protection tube is more important than the long-term stability of the thermocouple. On the other hand, gas tightness, resistance to thermal shock, or chemical compatibility of the protection tube with the process may be the deciding factors.

**OXYGEN MONITORING:** Oxygen concentration in the combustion gas is usually measured at a point of high turbulence after the gas has traversed the full length of the combustion chamber. A good location for measurement is at the inlet to the duct leading from the combustion chamber to the quench zone, immediately after the gas has gone through a 90° turn. Figures 6.38 and 6.39 show such a location.

Oxygen measurements are made on a continuous basis. Commercially available instruments are discussed in Section 5.9. Whichever type of sensor is used, it is typically equipped with a gas conditioning system specified by the manufacturer for the gas environment in which the instrument is used.

When measuring oxygen concentration directly in a high temperature flow, some difficulty can be experienced because of molten slag impingement on the probe. Trial-and-error solutions of location and probe length have minimized this problem. A redundant system for scheduled maintenance is desirable.

**GAS FLOW MEASUREMENT:** Gas flow rates can be measured or approximated in several ways: by insertion in the flue gas duct of an air pressure measuring element (e.g., pitot tube) or by measuring the drop in pressure across a restriction to the gas flow (e.g., baffle plate, venturi section, or orifice) downstream of the combustor. Exhaust gas flow, however, is the most difficult flow measurement application in the incinerator for the reasons given below.

- Because the gas is dusty, moist, and corrosive, pressure taps will tend to plug. For this reason it is extremely important that the connection to the duct be made sufficiently large and with clean-out provision.
- If the two pressure-sensing points are at widely different temperatures, the resulting difference in density of the gas in the connecting lines to the instrument will create an error in measurement. For this reason, avoid measurement across spray chambers or other locations where gas temperature changes radically.
- If taken across a restriction to gas flow, the fouling tendencies of the dirty gas will cause the restriction to increase with time, thereby changing the differential measurement for a given rate of flow.

For the reasons stated above, the usefulness of this measurement as an indication of quantitative flow is limited, and care should be taken in this application.

Flow measurements are performed at either of two locations: (1) in the duct between the combustion chamber and quench zone, or (2) in the stack (Figs. 6.38 and 6.39). Both locations have their advantages and disadvantages. In the combustion chamber outlet duct, a sufficiently long length of duct may not be available for flow pattern development. Access to this location can also be a problem when the incinerator is vertically oriented and because of the necessity to breach the duct at a high temperature point. High temperatures at this location may require special construction materials (e.g., inconel) for measurement elements.

The advantages of flow rate measurement in the stack are relief of the problems associated with high temperature gas flow measurement, increased accessibility to the gas flow, and increased likelihood of having a proper section of duct for the flow measurement. One minor disadvantage associated with this position is the increased possibility that ambient air leaking into the system upstream of the draft fan could bias the flow measurement.

Of the instruments available to measure gas flow in closed conduits, pressure or velocity head meters are among the oldest and most common. The principal shortcomings are the need for elements to be inserted directly into the flow paths (in contact with the gas stream), making them susceptible to corrosion, erosion, and fouling, the requirement for seals, the likelihood that the conduit may have to be opened for inspection or service, and permanent pressure losses caused by restrictions placed in the channels.

Head-type flow meters incorporate primary elements, which interact directly with the streams to induce velocity changes, and secondary elements, which sense the resulting pressure perturbations. The flow rate of interest is a function of the differential pressures which can be detected.

## 5.10 Preplanning of Facility Operation

Preplanning the proper operation of a waste incineration facility is necessary for protection and to prevent adverse effects of the facility on the public health or the environment. Proper facility operation, on a day-to-day basis, includes:

- operation plans including waste classification, waste storage, and disposal procedures, incinerator monitoring, and administrative procedures such as hours of operation per day and days per week;
- operation manuals, including equipment manuals, spare parts, etc.;

- safety at the site, including emergency manual or handbook, leak detection and repair plan, chemical spill handling, facility security, operator practices and training, and a loss prevention program;
- monitoring of operating parameters;
- monitoring to ensure protection of the environment; and
- operator training.

These plans are developed within the operating company (and corporate structure) and are done in cooperation with other neighboring or similar organizations and with governmental agencies. It may not always be possible for all of them to fully cooperate or participate, but through planned action each organization is made aware of certain available assistance.

## 6 SUMMARY OF INCINERATION SYSTEM

This section is a summary of all discussions about solid waste treatment, and is self-explanatory.

Figure 6.40 depicts the hardware and software requirements in operating a treatment facility and in getting a permit to operate one.

Figure 6.41 describes the possible configuration of an incineration system. The PCC can be (1) a rotary kiln for mostly industrial waste combustion, (2) a mass burning combustor for

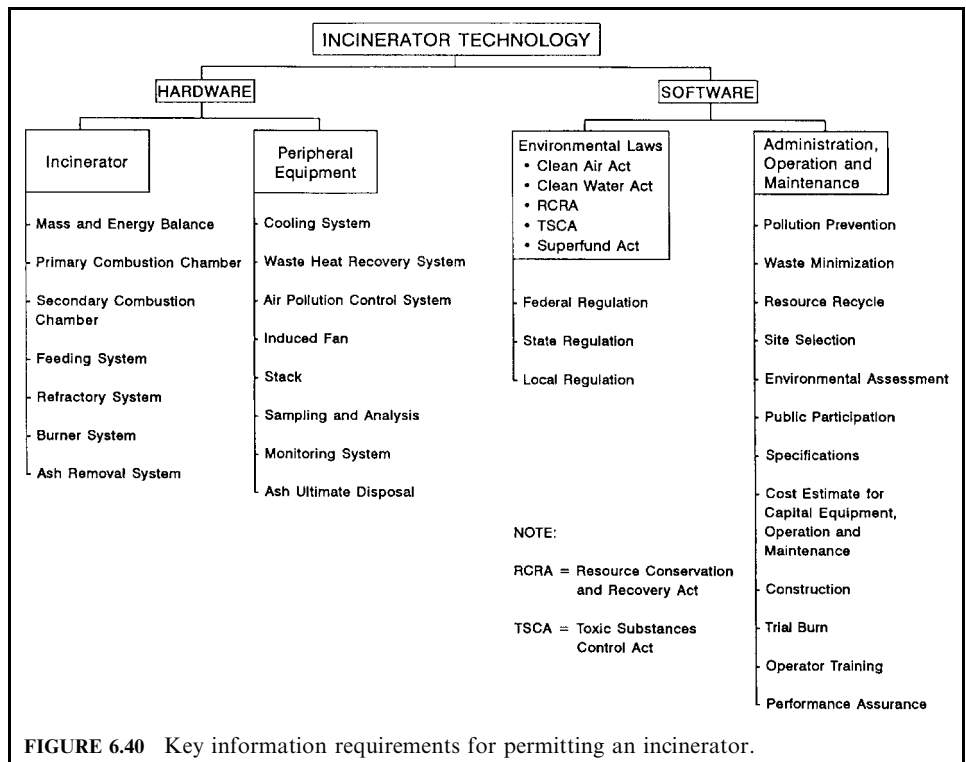

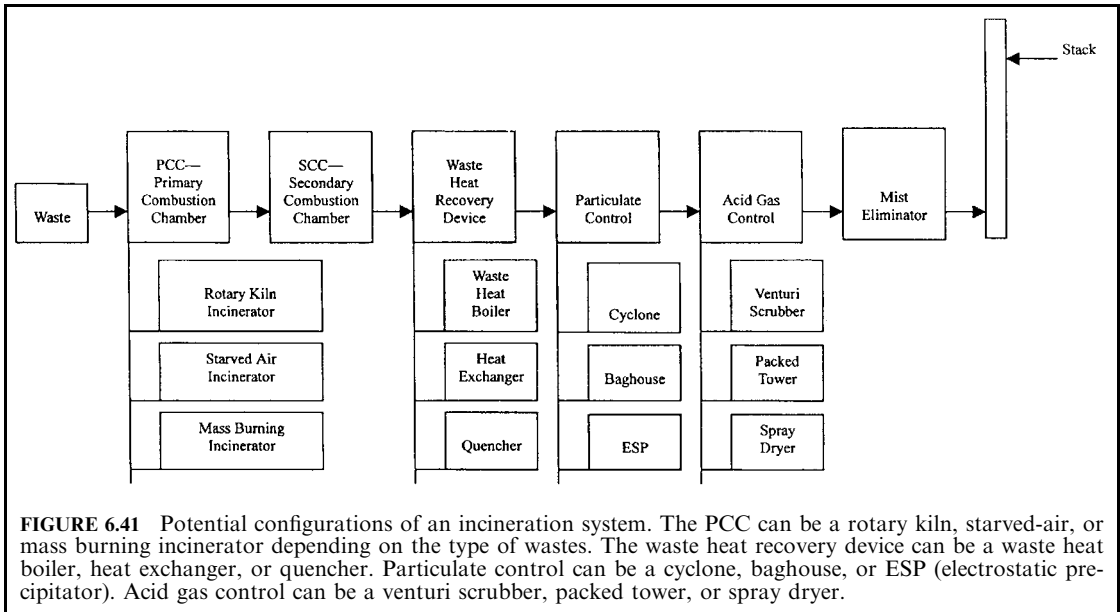

FIGURE 6.40 Key information requirements for permitting an incinerator.

**FIGURE 6.41** Potential configurations of an incineration system. The PCC can be a rotary kiln, starved-air, or mass burning incinerator depending on the type of wastes. The waste heat recovery device can be a waste heat boiler, heat exchanger, or quencher. Particulate control can be a cyclone, baghouse, or ESP (electrostatic precipitator). Acid gas control can be a venturi scrubber, packed tower, or spray dryer.

municipal waste incineration, or (3) a starved-air combustor for mostly medical waste incineration. Other types of PCC may include multihearth combustors and fluidized beds for mostly sludge incineration. The waste heat system is to extract heat from combustion gas for potential reuse and to reduce the combustion gas temperature for air pollution control devices which follow. The particulate control system can be a cyclone, a baghouse, or an ESP (electrostatic precipitator). The acid gas control system can be a venturi scrubber, a packed tower, or a spray dryer. The particulate control system and the acid gas control system are sometimes in reverse order. In other words, after the waste heat recovery device, the system sometimes has acid gas control and then particulate control.

Figure 6.42 shows some typical temperature distributions in different configurations of a rotary kiln incineration system.

The following information summarizes the typical ranges for temperature and residence time in six popular incinerators (EPA-81/09, p. 2-2):

- rotary kiln 1500–2900°F
- liquid injection 1500–2900
- fluidized bed 840–1800
- coincineration 300–2900
- starved air 900–1500
- multiple hearth
  - drying zone 600–1000
  - incinerating zone 1400–1800

In general, for gas or liquid waste, the residence time is less than 2 s. For solid waste, it is in the range of hours, depending on the solids size and nature. This general rule applies to all types of incinerators.

### 1 INTRODUCTION

---

The US EPA considers air pollution control as one of its major research topics and has published a significant amount of air pollution control educational materials and other related reports in the past. This chapter and chapters 3.2 and 3.3 have been heavily excerpted from US EPA publications including those listed in the References. The excerpted materials were then rearranged and edited to make the materials more compact for beginners to understand the basic concepts and basic equipment of air pollution control processes.

Air emissions can result from many sources. The major air emission sources include fossil fuel combustion, waste incineration, and industrial processes. The controls of air emissions include many processes and equipment. The main objective of installing air pollution control equipment (APCE) is to scrub pollutants from contaminated gases to meet regulatory requirements. Many types of equipment are available for use in controlling air emissions from incinerators. Generally speaking, air pollution control processes include:

- Gaseous emission control process: description of this process is provided in this chapter.
- Particulate emission control process: description of this process is provided in later chapters.

Most often, however, one control technique is used more frequently than others for a given source–pollutant combination. For example, absorption is commonly used to remove SO<sub>2</sub> from boiler flue gas. A summary of air emission control is provided in Table 1.1.

Many factors influence the choice of a control device used to reduce air emissions. For example, for particulate matter control, the composition of the particles in terms of concentration, size, and chemical and physical characteristics must be considered. If emitted materials can be re-used in the process, dry collection may be desirable. If the pollutant has little economic value, collection should be accomplished with the safe and economical disposal of the collected pollutants.

The industrial process and potential control devices must both be carefully reviewed. It is very important to not convert an air pollution problem into a water or land pollution problem because of air pollution control activities.

The stringency of air pollution control requirements might also include other methods in addition to the traditional add-on control devices. This calls for the consideration and application of alternative production procedures, modifications of processes, and control techniques that result in minimum emissions from a source.

For example, waste generators who send their waste to industrial furnaces such as cement kilns that act as commercial waste management facilities will have an incentive to reduce the generation of metal- and chlorine-bearing wastes because waste management fees are likely to increase for such waste given that the burner has a fixed metal and chlorine feed rate allotment (due to prescribed feed rates and facility operating conditions). Wastes with extremely high metals content may no longer be acceptable for burning in many cases unless the waste generator reduces the metals content of the waste. Any alternative for the disposal of such wastes may be unavailable or the costs of such treatment may be high enough to create the incentive to reduce waste generation rates at the source. This is a typical scenario for pollution prevention measures to be undertaken by waste generators.

Similarly, generators who burn their wastes onsite also have the incentive to reduce the generation of metal- and chlorine-bearing wastes given that the regulatory rule that they operate under will often require a fixed feed rate allotment of these materials for their boiler or industrial furnace.

## 2 AIR POLLUTION DEFINITION

---

An air pollutant is also known as an air contaminant. It is a substance in air which could, if in high enough concentration, harm human health or the environment. Pollutants may include almost any natural or artificial composition of matter capable of being airborne. Pollutants may be in the form of solid particles, liquid droplets, gases, or in combinations of these forms. Generally, they fall into two main groups: (1) those emitted directly from identifiable sources and (2) those produced in the air by interaction between two or more primary pollutants, or by reaction with normal atmospheric constituents, with or without photoactivation. Table 1.2 shows typical air pollutants, their sources, and their health effects (EPA-73/05).

The common air pollutants discharged from various sources, particularly from waste incineration, include:

- particulate matter including metals
- inorganic gases
- organic gases

## 2.1 Particulate Matter

The terms ‘particulate matter’ and ‘particle’ have been used interchangeably in many air pollution control documents. Particulate matter is defined as any airborne finely divided solid or liquid material with an aerodynamic diameter smaller than 100 micrometers (micro =  $10^{-6}$ ) (40CFR51.100-90). Some examples of particulates are trace metals, smoke, dusts, fumes, mists, and sprays. Control of particulate matter is necessary to maintain or improve air quality in the atmosphere.

The most visible discharge from a burning process is smoke. Smoke is a suspension of solid or liquid particulate matter in a gaseous discharge. The particles range from fractions of a micron to over 50 microns in diameter. One micron ( $\mu\text{m}$ ) is one-millionth of a meter and is commonly used to describe particulate size. The visibility of smoke is related to the quantity of particles present rather than to the weight of the particulate matter. The weight of particulate emissions is, therefore, not necessarily indicative of the density of the emission. Neither is the color of a discharge related to opacity or smoke density. Smoke can be black or can appear non-black; in the latter case, it is termed white smoke. These two types of smoke are discussed below:

*White smoke:* The formation of white or other opaque, non-black smoke is usually due to insufficient furnace temperatures when burning carbonaceous materials. Hydrocarbons will be heated to a level where evaporation and/or cracking will occur within the furnace when white smoke is produced. The temperatures will not be high enough to produce complete combustion of these hydrocarbons. With a stack temperature in the range of 150–260°C (300–500°F),

many of these hydrocarbons will condense to liquid aerosols; with solid particulate present, these will appear as non-black smoke.

A method for controlling white smoke is to increase the furnace/stack temperatures and increase turbulence to help ensure uniformity of this temperature within the off-gas flow.

Excessive airflow may result in excessive cooling. An evaluation of reducing white smoke discharges should include investigating the air quantity introduced into the furnace. Inorganics in the exit gas may also produce a non-black smoke discharge. For instance, sulfur and sulfur compounds will appear yellow in a discharge; calcium and silicon oxides in the discharge will appear light to dark brown.

*Black smoke:* When burned in an oxygen-deficient atmosphere, hydrocarbons will not completely destruct, and carbon particles will be found in the off-gas. Causes of local oxygen deficiency include poor atomization, inadequate turbulence (or mixing), and poor air distribution within a furnace chamber. Each of these factors will generate carbon particles that produce dark, black smoke in the off-gas.

A common method of reducing or eliminating black smoke has been steam injection into the furnace. The carbon present is converted to methane and carbon monoxide as follows:

Hydrocarbons react similarly, and the methane and carbon monoxide produced burn clean in the heat of the furnace, eliminating the black carbonaceous smoke that would have been produced without steam injection:

A number of devices can be used to control the emissions of particulate matter. The devices include:

- mechanical collector
- baghouse
- electrostatic precipitator (ESP)

## 2.2 Inorganic Gas

Inorganic gases produced from the burning process normally include water vapor, carbon dioxide, carbon monoxide, oxides of nitrogen, and, when sulfur is present, oxides of sulfur.

Nitrogen is a reactive substance at the high temperatures of combustion that forms nitrogen oxide (NO) and nitrogen dioxide (NO<sub>2</sub>) from the combustion process.

Sulfur is released into the atmosphere from burning processes in the form of sulfur dioxide, SO<sub>2</sub>, and sulfur trioxide, SO<sub>3</sub>.

## 2.3 Organic Gas

Of the many organic discharges from incinerators, the more significant ones are:

- Oxygenated hydrocarbons, which include aldehydes, ketones, alcohols, and acids. In sufficient quantity they will produce eye irritation, reduce visibility in the atmosphere, and react with other components of the atmosphere to form additional pollutants. Many of these compounds are also odorous.

- Halogenated hydrocarbons, such as carbon tetrachloride, perchloroethylene, etc. These may contribute to atmospheric clarity problems and may also generate odor.
- Polychlorinated dibenzo-*p*-dioxins (PCDD) and polychlorinated dibenzo-furans (PCDF). These compounds may be formed when materials containing chlorine are incinerated. These compounds are of considerable concern due to their toxicity in trace quantities to laboratory animals.
- Olefins, which are a group of unsaturated hydrocarbon compounds that readily react with many other chemical compounds. Olefins take part in photochemical reactions in the presence of nitrogen oxides and several other pollutants.
- Aromatics, including benzene, toluene, xylene, and polycyclic aromatic hydrocarbons (PAH). One of the most toxic of these occurring in industrial processes is benzo(a)pyrene (also written as 3,4,benzopyrene). This compound is relatively simple to detect. A primary source of these compounds is the incomplete combustion of organic materials.

The most apparent effect of organic gas discharges is their effect on the atmosphere. They react with other elements of the atmosphere to form photochemical smog, which is as much a danger to health as it is to the aesthetic quality of an area.

## 2.4 Acid Gas

Industrial waste will often have either a halogen or sulfide component. Municipal wastes have relatively high proportions of plastics, and many of these materials have a significant amount of chlorides. Chlorides and/or sulfides in an incinerator charge will produce hydrogen chloride and/or chlorine, and sulfur dioxide/trioxide gas in the exhaust stream. Acid gas neutralization systems (including water scrubbing followed by water neutralization) should be provided when significant quantities of hydrogen chloride are present in an exhaust. Control of these emissions is often necessary for the protection of downstream equipment (OTA-84/06).

## 2.5 Odor

Odors associated with incineration are normally organic and result from the incomplete combustion of organic matter in the waste feed. The most effective means of dealing with the problem of odor generation is alteration of the burning process to increase burning efficiency, thereby decreasing the occurrence of odor-causing compounds in the exhaust stream.

Since waste streams vary in chemistry or quality, the efficiency of the waste burning process can also change, and incineration parameters must be adjusted to reduce the possibility of odor generation.

Secondary odors may originate from equipment and systems within the incinerator facility such as storage tanks, waste storage pits, etc. Where practical, ventilation systems should be designed to contain such odors and to bring the odorous air to the incinerator for destruction. Other mechanisms of odor control may be required, such as fume incineration, use of a packed tower (absorber), catalytic oxidation system, adsorption (using carbon on silicon beds), dilution, or masking.

## 2.6 Noise

Noises generated by an incineration facility are generally those resulting from the movement of air or gas. Fans and blowers will create the greatest noise levels; of secondary concern is the noise generated by passage of air or gas through ducts, flues, and nozzles.

Local noise can usually be controlled by initial equipment selection, use of sound-absorbing equipment, and provision of sound-deadening or sound-absorbing enclosures around noisy equipment. Exterior noise, however, can be broadcast hundreds of meters, perhaps kilometers. The usual cause of broadcast noise is the pulsation of the ID fan.

Sound control equipment sizing is proportional to the wavelengths of the sound generated. The lower the frequency, the longer the wavelength and the larger the sound control equipment. In controlling ID fan broadcast noise, therefore, it is first necessary to try to increase the beat frequency. If possible, the fan speed should be increased, or if this is impractical, the number of blades should be increased. The ID fan should be close-coupled to the stack. Ductwork with appropriate expansion joints will tend to absorb some of the potential broadcast noise.

Two types of insertion sound control devices are used to reduce broadcast noise. The first is an exhaust silencer, which is placed within the stack or between the ID fan and the stack. Exhaust silencers are resonating devices that tend to balance the generated beat by producing (by static geometry) a frequency that is 180 degrees out of phase from the fan beat. The net result, ideally, is cancellation of the beat frequency plus harmonics. The second type of sound control device is a baffle, usually perforated, that absorbs sound energy with its acoustical fill: fiberglass, mineral wool, or another absorbent.

### 3 POLLUTION EMISSION CALCULATION

---

#### 3.1 Units of Emission Standards

Combustion sources constitute a significant air quality control problem because of the gaseous and particulate emissions which can be produced. With a variety of combustion systems devised for a multitude of end uses, the US EPA has been developing emission standards for the combustion or incineration industry to follow. Accordingly, the emission standards usually establish the maximum allowable limit for the discharge of specific pollutants. These limits are usually based upon volume or mass flows at specified conditions of temperature and pressure. Actual field measurements of gas flow likely would not be made with gas at standard conditions. It is therefore necessary to adjust the observed volume flow to account for difference in pressure and temperature (EPA-80/02, p. 5-1; EPA-89/03).

Emissions can be measured in terms of the concentration of pollutant per volume or mass of flue (stack) gas, the pollutant mass rates, or a rate applicable to a given process. Standards therefore fall into the following general categories:

- pollutant mass rate standards
- process rate standards
- concentration standards
- ambient concentration standards
- reduction standards
- opacity standards

**Pollutant mass rate standards.** Under this general category, the standards are based on the fixed rate of emissions: for example, the mass of pollutant emitted per unit time, lb/h or kg/h.

**Process rate standards.** Process rate standards usually establish the allowable emission in terms of either the input energy or the raw material feed of a process. New source standards for fossil fuel-fired steam power plants are an example of an energy basis standard. Allowable emissions for such operations as acid plants are based upon the mass of acid produced, while a portland cement plant emission standard is in terms of the number of tons of material fed into the kiln.

Where combustion sources are involved, a standard may include not only the allowable concentration but also may specify the quantity of excess air the system may use while achieving this concentration. The standard for solid waste incinerators of 50 T/day (tons/day) or greater is an example of this type of standard (for a calculational example, see Sec. 3.5).

**Concentration standards.** The most common type of emission limit is the concentration standards, which limit either the mass (weight) or volume of the pollutants in the gas exiting the stack. This type of emission limit is expressed as follows and is shown in Figs. 1.1 and 1.2:

- 1 grain per dry standard cubic foot (1 gr/dscf) at 7 percent oxygen
- Milligrams per dry standard cubic meter (mg/dscm)
- Parts per million parts (ppm)

*One grain per dry standard cubic foot (1 gr/dscf) at 7 percent oxygen:* This is a British (Imperial) concentration unit to express the limit of particulate matter (by weight) per unit of stack gas volume. This unit means that no more than 1 grain of particulate matter is allowed to be contained in each cubic foot of gas leaving the stack corrected to 7% oxygen and to standard conditions (20°C and 1 atm) (1 pound = 7000 grains).

*Milligrams per dry standard cubic meter (mg/dscm):* This is a metric concentration unit to express the limit of particulate matter per unit stack gas volume. The conversion factor is

$$1 \text{ gr/dscf} = 2300 \text{ mg/dscm}$$

*Parts per million parts (ppm):* This unit expresses the limit of pollutants (by volume) per stack gas volume. The pollutants under this limit include (1) carbon monoxide; (2) sulfur dioxide; (3) nitrogen oxides; and (4) hydrogen chloride. This unit is applicable to both British and metric systems. By definition, ppm can be expressed as

$$1 \text{ ppm} = (1 \text{ mole of pollutant}) / (10^6 \text{ moles of flue gas})$$

For example, a 100 ppm standard means that no more than 100 cubic feet (cubic meters) of pollutants are allowed to be contained in 1 million cubic feet (cubic meters) of gas leaving the stack.

Because a concentration standard limits the amount of pollutants in a certain amount of stack gas, someone having a problem meeting the standard might be tempted to increase the

FIGURE 1.1 Concentration standards (EPA-89/03).

FIGURE 1.2 Concept of 100 ppm in concentration standards (EPA-89/03).

amount of dilution air to dilute the concentration of the pollutant in the exhaust gas. As air is added, the oxygen concentration in the gas increases because the air contains 21% oxygen. To keep this from happening, regulations usually either forbid the addition of dilution air or require that the concentration be 'corrected' to a standard level of oxygen, usually 7%, or a standard level of carbon dioxide, usually 12%. Figure 1.3 illustrates this concept.

Emission limits are often given for standard conditions, e.g. 0.1 grain/dry standard cubic foot. Standard temperature is often at 68°F (20°C) and standard pressure is 29.92 in. w.c. (760

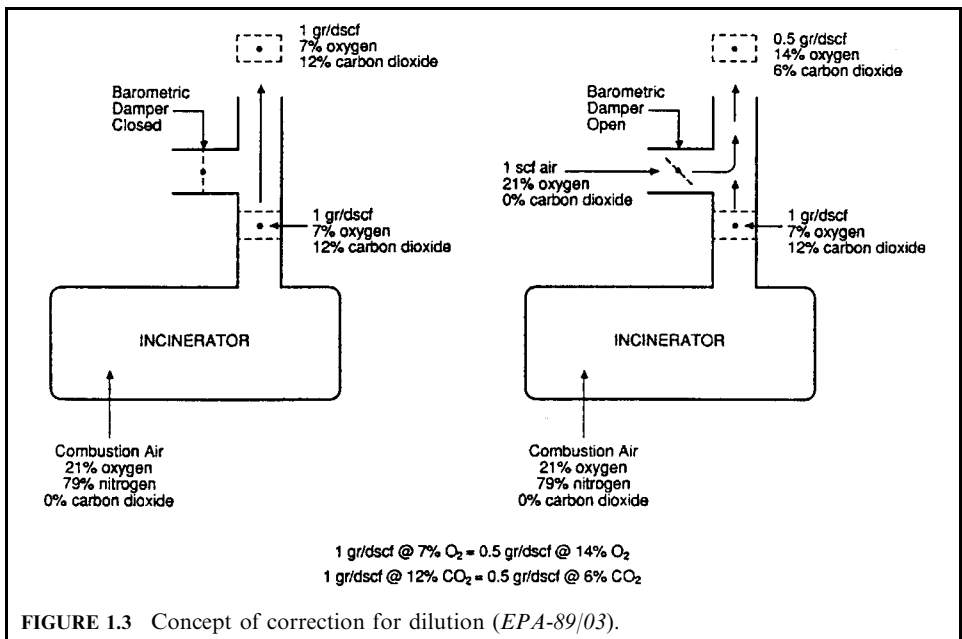

FIGURE 1.3 Concept of correction for dilution (EPA-89/03).

millimeters of mercury). A cubic foot measured at this temperature and pressure is known as a standard cubic foot. When a stack test is performed to check the level of emissions from an incinerator, both temperature and pressure are measured during the test in addition to the pollutant of interest. The test results are then converted to standard conditions (grain/dry standard cubic foot) using the temperature and pressure measured. In this way, all test results of all sources including incinerators can be compared on the same basis; i.e. all results are reduced to standard conditions.

**Ambient concentration standards.** Microgram per cubic meter ( $1\ \mu\text{g}/\text{m}^3$ ) is the unit for this standard category. It is a metric concentration unit to express the limit of pollutant (by weight) per unit ambient air volume. The pollutants under this limit include (1) toxic metals (arsenic, beryllium, cadmium, chromium, nickel, lead, mercury); (2) organics (dioxins/furans, ethylene, propylene); and (3) hydrogen chloride. For example,  $1\ \mu\text{g}/\text{m}^3$  means that no more than 1 microgram of pollutant is allowed to be contained in each cubic meter of ambient air (there are 1 million micrograms in 1 gram).

This unit is sometimes found in state regulations. It limits the amount of pollutants that collect at ground level in areas surrounding the emission source. Usually, the regulations require that the pollutant be measured as it leaves the stack. This measurement information is then used by a computer to calculate the amount of the pollutants at various locations near the source.

**Reduction standards.** Sometimes the emission limit is expressed as a percent reduction of the pollutants. In other words the pollution control device must operate at or above a specified efficiency level (such as 90% removal) to reduce the pollutant emissions. This type of standard frequently is used for acid gases such as HCl. For example, if the emission standard requires at least 90% reduction of HCl, and the HCl in the combustion gas is entering the scrubber inlet at a rate of 20 lb/h (9.1 kg/h), then the allowed emission rate is 2 lb/h (0.9 kg/h), which is 10% of the amount entering the scrubber.

**Opacity standards.** Opacity standards are almost always included in regulations. Opacity standards express the limit on the degree to which the stack emissions are visible and block the visibility of objects in the background. Stack emissions of 100% opacity would totally block the view of background objects and indicate high pollutant levels. Zero percent opacity would provide a clear view of the background and indicate no detectable particulate matter emissions. Opacity may be estimated by taking 'readings' every 15 seconds and averaging the readings over a specified time period. The 'reader' must be a certified opacity reader. The US EPA Reference Method 9 '*Visual determination of the opacity of emissions*' establishes the procedures and criteria for taking opacity readings and for certification. Additionally, opacity may be estimated by comparing the opacity of the smoke to the six sections of a Ringelmann Smoke Chart (Fig. 1.4). The six sections are numbered from 0 to 5 with No. 0 being completely white and No. 5 completely black. Sections 1 through 4 correspond to opacities of 20% (No. 1), 40% (No. 2), 60% (No. 3), and 80% (No. 4). Opacity is estimated by choosing the section which most closely resembles the opacity of the exhaust gas. Opacity may also be measured by an instrument called a transmissometer that is installed in the stack. The following further illustrates an opacity standard: for example, 10% opacity (6-minute average) means that the opacity of the particulate matter emissions cannot average more than 10% for any 6-minute period.

### 3.2 Volume Correction

Because combustion devices always produce flue gas that is at a higher temperature and pressure than those of the standards, corrections for the difference must be made. Consider one cubic foot of gas at some specified condition, say 14.7 psia and 70°F. Does this volume increase or decrease if one raises the gas temperature? Ask a similar question regarding the effect of a pressure increase. What volume would the gas occupy if both pressure and temperature were raised? The answers to these questions can be developed using the ideal gas equation (*EPA-80/02*, p. 5-1).

Consider the combustion gas as an ideal gas. For an ideal gas at states 1 and 2, the following three equations are valid:

$$\text{Volume equation: } V_2/V_1 = (P_1/P_2)(T_2/T_1) \quad (1.1)$$

$$\text{Density equation: } \rho_2/\rho_1 = (P_2/P_1)(T_1/T_2) \quad (1.2)$$

$$\text{Concentration equation: } C_2/C_1 = (P_2/P_1)(T_1/T_2) \quad (1.3)$$

where

- $V_1$  = volume at condition 1
- $V_2$  = volume at condition 2
- $P_1$  = pressure at condition 1
- $P_2$  = pressure at condition 2
- $T_1$  = absolute temperature at condition 1
- $T_2$  = absolute temperature at condition 2
- $\rho_1$  = density at condition 1
- $\rho_2$  = density at condition 2
- $C_1$  = concentration at condition 1
- $C_2$  = concentration at condition 2

The subscript 1 denotes the observed conditions and the subscript 2 the standard conditions or vice versa

**EXAMPLE 1:** volume correction

A volume of  $20\text{ m}^3$  was drawn from a spirometer at  $20^\circ\text{C}$  and  $700\text{ mmHg}$ . What was the standard volume drawn?

*Solution:* Using the ideal gas equation in state 1 and state 2 conditions, the equation  $V_2 = V_1(P_1T_2/P_2T_1)$  can be applied to this case.

where  $V_2$  = volume at condition 2 (standard condition to be determined)

$V_1$  = volume at condition 1 =  $20\text{ m}^3$

$P_1$  = pressure at condition 1 =  $700\text{ mmHg}$

$P_2$  = pressure at condition 2 =  $760\text{ mmHg}$

$T_1$  = temperature at condition 1 =  $20^\circ\text{C} + 273 = 293\text{ K}$

$T_2$  = temperature at condition 2 =  $25^\circ\text{C} + 273 = 298\text{ K}$

$$V_2 = (20 \times 700 \times 298)/(760 \times 293) = 18.7\text{ m}^3$$

*Conversion of ppm into  $\mu\text{g}/\text{m}^3$* 

As an applied example, consider using the ideal gas equation to help develop a conversion factor with which ppm can be converted into  $\mu\text{g}/\text{m}^3$ . Begin with the definition:

$$1\text{ ppm} = (\text{moles of product})/(10^6\text{ moles of air})$$

*Note:* This is basically a volume measure; the definition is based on  $T = 25^\circ\text{C}$  and  $P = 760\text{ mmHg}$ . Recall here that a mole of any gas will occupy a volume of  $22.4$  liters when  $P = 760\text{ mmHg}$  and  $T = 0^\circ\text{C}$ . The definition of ppm is based on  $T = 25^\circ\text{C}$ ; therefore, one must calculate the new volume using Eq. (1.1)

$$V_2/V_1 = (P_1/P_2)(T_2/T_1)$$

Normally, a constant pressure is assumed between conditions 1 and 2, such that

$$\begin{aligned} V_2 &= V_1(T_2/T_1) \\ &= 22.4(273 + 25)/273 \\ &= 24.5\text{ liter} \end{aligned}$$

In turn, there are  $10^{-3}\text{ m}^3/\text{liter}$  and the mass of the moles of product = molecular weight (MW), g/mole.

Combining these conversions:

$$\begin{aligned} 1\text{ ppm} &= (10^{-6}/24.5)[(\text{moles per mole air})/(\text{liters per mole air})][\text{MW}/10^{-3}][\text{g}/\text{mole}]/[\text{m}^3/\text{liter}] \\ &= (10^{-3}/24.5)(\text{MW})[(10^6)(\mu\text{g}/\text{g})] \\ &= 40.8[\text{MW}][\text{this term has the units of } \mu\text{g}/\text{m}^3] \end{aligned}$$

$$1\text{ ppm} = 40.8[\text{MW}], \quad \mu\text{g}/\text{m}^3 \quad (1.4)$$

**EXAMPLE 2:** units of ppm and  $\mu\text{g}/\text{m}^3$  for  $\text{SO}_2$ 

Apply Eq. (1.4)

$$\begin{aligned} 1\text{ ppm SO}_2 &= 40.8(64) \\ &= 2611\ \mu\text{g}/\text{m}^3 \end{aligned}$$

### 3.3 Determination of Excess Air

Another type of calculation often necessary involves combustion equipment stack gas samples obtained by Orsat analysis. Before outlining the fundamental basis of corrections here, it would be well to note several aspects of the problem. The stack sampling is directed to determine the pollutants emitted by equipment and compared with standards. The raw gas leaving a combustion device contains certain levels of pollutants, which can be made to appear smaller if the total gas quantity is increased by adding nonpollutant gas to the stream. For example, consider the ideal combustion of carbon monoxide with air (EPA-80/02, p. 5-4).

Here, the percentage of  $\text{CO}_2$  in the flue gas is

$$\begin{aligned} \% \text{CO}_2 &= (\text{mole of CO}_2) / (\text{mole of CO}_2 + \text{mole of N}_2) \\ &= 1 / (1 + 1.88) \\ &= 34.8\% \text{ by volume} \end{aligned}$$

Suppose the same mole of CO were burned with 100% excess air? The combustion reaction now is given by

Now the total moles of product is given by

$$\begin{aligned} 1 \text{ mole CO}_2 + 0.5 \text{ mole O}_2 + 3.76 \text{ mole N}_2 &= 5.26 \text{ moles} \\ \% \text{CO}_2 &= 1 / 5.26 = 19.0\% \text{ by volume} \end{aligned}$$

Here the volume fraction of  $\text{CO}_2$  was reduced by adding more air—in effect a dilution of the products by additional air. The original 2.88 moles of flue gas also could have been diluted through the addition of steam, a practice which is fundamentally possible since flue gas temperatures are normally higher than dew point temperatures. Suppose one added two moles of steam to the flue gas of Eq. (1.5):

Now there are 4.88 moles of product and the  $\text{CO}_2$  percentage would be

$$\begin{aligned} \% \text{CO}_2 &= 1 / 4.88 \\ &= 20.5\% \text{ by volume} \end{aligned}$$

Clearly, the volume fraction of any gas present in the flue gas can be reduced by dilution, either by adding air or steam. It is for this reason that combustion equipment emission standards are written with a specified amount of excess air and based on dry flue gas. Flue gases which indicate combustion occurred with excess air different from 50% require correction of observed concentration to that which would have been realized with 50% excess air.

Stack gas measurements are usually made with the Orsat apparatus, an absorption device with separate chambers to remove  $\text{CO}_2$ , CO, and  $\text{O}_2$  from the flue gas in a manner permitting measurement of percentage of each present on a volume basis. The device is designed so that a dry basis measurement is realized. Excess air can be determined from the Orsat readings by computation as follows:

Consider the complete combustion of carbon with air:

Here the product contains only  $\text{CO}_2 + \text{N}_2$ . With excess air, the reaction becomes

where  $e$  is the number of moles of excess  $\text{O}_2$  in the excess air. By definition, the percent of excess air is

$$\%A_e = [(A_a - A_t)/A_t](100) \quad (1.10)$$

where  $A_a$  = moles of actual air used in the combustion process

$A_t$  = moles of theoretical air (stoichiometric air) used at 100% of stoichiometric combustion

$A_e$  = excess air

The theoretical air is  $\text{O}_2 + 3.76\text{N}_2$  from Eq. (1.8) with the actual air  $(1 + e)\text{O}_2 + (1 + e)3.76\text{N}_2$  as given by Eq. (1.9). Combining Eqs. (1.8), (1.9) and (1.10):

$$\%A_e = [(e\text{O}_2 + e3.76\text{N}_2)/(\text{O}_2 + 3.76\text{N}_2)]100\% \quad (1.11)$$

Equation (1.11) requires knowledge of the excess oxygen  $e$  in order to compute the excess air. Actually, the Orsat analysis contains the information to accomplish the same result based on knowledge of the product composition alone.

Note that oxygen can only appear in the product if excess air is present, assuming complete combustion. Noting product with a subscript  $p$ :

where  $\text{O}_{2p} = e\text{O}_2$ , the excess air required

$\text{N}_{2p} = (1 + e)3.76\text{N}_2$ , the nitrogen which was part of the total air supplied

$e$  = moles of excess air

Now the nitrogen present in the product came from the combustion air (unless fuel contained significant nitrogen). Therefore, the actual  $\text{O}_2$  supplied can be determined by computing the moles  $\text{O}_2$  which were associated with  $\text{N}_{2p}$ . In air, 1 mole of  $\text{O}_2$  is associated with 3.76 moles of  $\text{N}_2$  (by volume); therefore, for  $\text{N}_{2p}$  moles of nitrogen, the oxygen supplied is given by

$$\text{O}_2 \text{ supplied} = \text{N}_{2p}/3.76 = 0.264\text{N}_{2p} \quad (1.13)$$

$$\text{The theoretical } \text{O}_2 \text{ is } 0.264\text{N}_{2p} - \text{O}_{2p} \quad (1.14)$$

From Eq. (1.10)

$$\begin{aligned} \%A_e &= [(A_a - A_t)/A_t](100) \\ &= \{[0.264\text{N}_{2p} - (0.264\text{N}_{2p} - \text{O}_{2p})]/(0.264\text{N}_{2p} - \text{O}_{2p})\}100\% \\ &= [\text{O}_{2p}/(0.264\text{N}_{2p} - \text{O}_{2p})](100) \end{aligned} \quad (1.15)$$

If the combustion produced both  $\text{CO}$  and  $\text{CO}_2$  (case of incomplete combustion), the  $\text{O}_{2p}$  measured must be reduced by the amount of oxygen which would have combined with  $\text{CO}$  to form  $\text{CO}_2$ .

Then:

$$\%A_e = \{[\text{O}_{2p} - 0.5\text{CO}_p]/[0.264\text{N}_{2p} - (\text{O}_{2p} - 0.5\text{CO}_p)]\}100\% \quad (1.16)$$

In each case, the quantity introduced is the percentage of each constituent as measured by the Orsat analyzer.

**EXAMPLE:** combustion air analysis by Orsat method

Find the percent excess air by using the following Orsat analysis data:

$$\text{CO}_2 = 10\%$$

$$\text{O}_2 = 4\%$$

$$\text{CO} = 1\%$$

By difference:

$$\begin{aligned} \text{N}_2 &= 100 - (10 + 4 + 1) \\ &= 85\% \end{aligned}$$

Find % $A_e$  from Eq. (1.16):

$$\begin{aligned} \%A_e &= \{[4 - 0.5(1)]/[0.264(85) - (4 - 0.5(1))]\}100\% \\ &= 18.5\% \end{aligned}$$

One caution must be mentioned regarding the  $\text{CO}_2$  measurement as determined by an Orsat analyzer. The chemical, caustic potash, employed to absorb  $\text{CO}_2$  also absorbs  $\text{SO}_2$ . Therefore,  $\text{SO}_2$  must be measured separately from  $\text{CO}_2$  and the percentage  $\text{SO}_2$  determined must be subtracted from the observed  $\text{CO}_2$  reading. Also, the cuprous chloride solution used to absorb CO also absorbs  $\text{O}_2$ ; therefore, a sample which is not correctly analyzed could erroneously indicate  $\text{O}_2$  for CO.

### 3.4 Excess Air Correction

Correction of concentrations where excess air is different from 50% is accomplished by adjusting the gas volume to that which would have been present if 50% excess air had been used. Equation (1.16) and correction factors for 50% excess air, 12%  $\text{CO}_2$ , and 6%  $\text{O}_2$  are presented (EPA-80/02, p. 5-20) below:

*Determination of excess air*

$$\%A_e = \{[0.264\text{N}_{2p} - (0.264\text{N}_{2p} - \text{O}_{2p})]/(0.264\text{N}_{2p} - \text{O}_{2p})\}100\% \quad (1.17)$$

*Factors for correction to 50% excess air*

$$F_{50v} = 1 - [1.5\text{O}_{2p} - 0.133\text{N}_{2p} - 0.75\text{CO}_p]/0.21 \quad (1.18)$$

$$C_{50v} = C_{vs}/F_{50v} \quad (1.19)$$

$$F_{50m} = 1 - (29/M_e)[1.5\text{O}_{2p} - 0.133\text{N}_{2p} - 0.75\text{CO}_p]/0.21 \quad (1.20)$$

$$C_{50m} = C_{ms}/F_{50m} \quad (1.21)$$

*Factor for correction to 12%  $\text{CO}_2$*

$$F_{12v} = \text{CO}_{2p}/0.12 \quad (1.22)$$

$$C_{12v} = C_{vs}/F_{12v} \quad (1.23)$$

$$F_{12m} = 1 - (29/M_e)[1.5\text{O}_{2p} - \text{CO}_{2p}/0.12] \quad (1.24)$$

$$C_{12m} = C_{ms}/F_{12m} \quad (1.25)$$

Factor for correction to 6% O<sub>2</sub>

$$F_{6v} = (0.21 - O_{2p})/0.15 \quad (1.26)$$

$$C_{6v} = C_{vs}/F_{6v} \quad (1.27)$$

$$F_{6m} = 1 - (29/M_c)[(1.5O_{2p} - 0.06)/0.15] \quad (1.28)$$

$$C_{6m} = C_{ms}/F_{6m} \quad (1.29)$$

*Note:* If CO is present in the product gas, the value  $(O_{2p} - 0.5CO_p)$  must be substituted for  $O_{2p}$  in Eqs (1.26) and (1.28).

**EXAMPLE:** excess air correction

**Given conditions**

power plant steam generator data

stack gas temperature = 756°R

pressure = 28.49 in. Hg

wet gas flow =  $Q_o = 367,000$  acfm, 6.25% moisture by volume

apparent molecular weight of gas is 29.29

Orsat analysis is CO<sub>2</sub> = 10.7%; O<sub>2</sub> = 8.2%; CO = 0

pollutant mass rate (PMR) is 103 lb/min

With these data, find the following:

- (A) Pollutant mass rate, tons/day
- (B) Mass and volume basis concentration at the standards:  $T_S = 530$  R;  $P_S = 29.92$  inches Hg;  $\rho_s = 0.0732$  lb/ft<sup>3</sup>
- (C) Percent excess air in effluent
- (D) Concentrations found in B corrected to 50% EA
- (E) Concentrations corrected to 12% CO<sub>2</sub>
- (F) Concentrations corrected to 6% O<sub>2</sub>

*Solution:*

(A) Pollutant mass rate (PMR), tons/day:

$$\text{PMR} = (103 \text{ lb/min})(60 \text{ min/h})(24 \text{ h/day})(\text{ton}/2000 \text{ lb}) = 74.2 \text{ ton/day}$$

(B) Concentration-mass and volume basis

Dry volume at the observed condition,  $V_o \text{ dry} = 367,000(1 - 0.0625) = 344,062$  acfm

$$\begin{aligned} \text{Concentration by volume at the observed condition, } C_{vo} &= \text{PMR}/V_o \\ &= 103/344,062 \end{aligned}$$

Using Eq. (1.3), concentration by volume at the standard condition

$$\begin{aligned} C_{vs} &= (103/344,062)(29.92/28.49)(756/530) \\ &= 4.48 \times 10^{-4} \text{ lb/dscf or } 3.14 \text{ grain/dscf} \end{aligned}$$

Concentration by mass at the standard condition

$$\begin{aligned} C_{ms} &= (C_{vs} \text{ lb/ft}^3)(\text{ft}^3/0.0732 \text{ lb})(1000/1000) \\ &= (6.12 \text{ lb})/(1000 \text{ lb}) \end{aligned}$$

(C) % Excess air in effluent using Eq. (1.17) is

$$\begin{aligned} \%A_e &= \{[O_{2p} - 0.5CO_{p}]/[0.264N_{2p} - (O_{2p} - 0.5CO_{p})]\}100\% \\ &= (8.2 - 0)(100)/[(0.264)(81.1) - 8.2] \\ &= 62.1\% \end{aligned}$$

(D) Concentration corrected to 50% EA is accomplished using Eqs. (1.18) and (1.19) for the volume basis, and Eqs. (1.20) and (1.21) for the mass basis concentrations

$$\begin{aligned} F_{50v} &= 1 - [1.5O_{2p} - 0.133N_{2p} - 0.75CO_{p}]/0.21 \\ &= 1 - [1.5(0.082) - 0.133(0.811)]/0.21 \\ &= 0.928 \end{aligned}$$

Concentration by volume corrected to 50% excess air

$$\begin{aligned} C_{50v} &= C_{vs}/F_{50v} \\ &= 3.14/0.928 \\ &= 3.38 \text{ grain/scf} \\ F_{50m} &= 1 - (29/M_e)[1.5O_{2p} - 0.133N_{2p} - 0.75CO_{p}]/0.21 \\ &= 0.930 \end{aligned}$$

Concentration by mass corrected to 50% excess air

$$\begin{aligned} C_{50m} &= C_{ms}/F_{50m} \\ &= 6.12/0.930 \\ &= 6.56 \text{ lb}/1000 \text{ lb dry} \end{aligned}$$

(E) Correction to 12% CO<sub>2</sub> is accomplished with Eqs. (1.22) and (1.23)

$$\begin{aligned} F_{12v} &= CO_{2p}/0.12 \\ C_{12v} &= C_{vs}/F_{12v} \\ &= C_{vs}(0.12)/CO_{2p} \\ &= 3.14[0.12/0.107] \\ &= 3.52 \text{ grain/dscf} \end{aligned}$$

(F) Correction for 6% O<sub>2</sub> is

$$\begin{aligned}
 F_{6v} &= (0.21 - O_{2p})/0.15 \\
 &= (0.21 - 0.082)/0.15 \\
 &= 0.85
 \end{aligned}$$

$$\begin{aligned}
 C_{6v} &= C_{vs}/F_{6v} \\
 &= 3.14/0.85 \\
 &= 3.69 \text{ grain/dscf}
 \end{aligned}$$

This example clearly illustrates how one applies corrections for temperature, pressure, and excess air. The emissions in this sample were expressed as concentrations given by Orsat.

### 3.5 Process Rate Factor

Process rates are normally based on either energy or material input to a process, and the next example illustrates application of a process rate standard applied to a combustion source. Figure 1.5 is a process rate standard for particulates taken from the State of Virginia air quality control regulations (EPA-80/02, p. 5-10).

#### EXAMPLE

Determine whether this plant meets the standard imposed by the Virginia code.

#### Given conditions

pollutant mass rate (PMR)<sub>particulate</sub> = 1800 g/s

fuel: coal @ 23 tons/hour, high heating value (HHV) = 12,500 Btu/lb

proposed abatement uses an electrostatic precipitator with 99% rated collection efficiency

*Solution:*

(A) Find the process energy rate, *H*

$$\begin{aligned}
 H &= (\text{mass of coal})(\text{energy value per unit mass}) \\
 &= (23 \text{ ton/h})(12,500 \text{ Btu/lb})(2000 \text{ lb/ton}) \\
 &= 575 \times 10^6 \text{ Btu/h}
 \end{aligned}$$

(B) Find the allowable emission rate from Fig. 1.5.

From graph at  $H = 575 \times 10^6 \text{ Btu/h}$

$$E = 0.19 \text{ lb}/10^6 \text{ Btu}$$

or calculate from the equation in the graph

$$\begin{aligned}
 E &= 0.8425(575)^{-0.2314} \\
 &= 0.194 \text{ lb}/10^6 \text{ Btu}
 \end{aligned}$$

(C) Now find the actual particulate emission rate

$$\begin{aligned}
 E_{\text{actual}} &= [(1800 \text{ g/s})(\text{lb}/454 \text{ g})(3600 \text{ s/h})(1 - 0.99)]/(575 \times 10^6 \text{ Btu/h}) \\
 &= 0.25 \text{ lb}/10^6 \text{ Btu}
 \end{aligned}$$

$0.25 > 0.19$ ; therefore, this unit does not conform to the Virginia regulations.

### 3.6 Use of Emission Factor

US EPA publication AP-42 is a compilation of emission factors which have been gathered from various references. These factors, while quite valuable when calculations of gross inventory for a large number of sources are involved, are not necessarily valid for a specific single source (EPA-80/02, p. 5-14).

While more precise emission information is needed in order to pinpoint actual emissions, factors such as those presented in AP-42 can be used to form estimates of the control required.

The next example (using Table 1.3) indicates that the particulate loading a spreader stoker might produce (in lb/ton of coal) is thirteen times the coal ash weight percentage (EPA-80/02, p. 5-27). This factor tells us that a large number of spreader stoker fired units operating without control would produce, on the average, 13 lb of particulates for each 1 percent of ash in the coal burned. Any given unit might produce this amount at some operating capacity but not at all operating levels. At light loads, for example, gas flows are reduced compared to design capacity, and particulate entrainment is reduced because of lower gas velocity.

The emission factors are essentially process emission rate values expressed in terms of mass fired (lb/ton). These values are convertible to pollutant mass rate, PMR, by knowing the firing rate in lb/h.

#### EXAMPLE 1: emission factor

If one burns 6 tons/h of coal with  $A = 10\%$  (i.e., % ash = 10) and a heating value HHV of 12,500 Btu/lb in a spreader stoker fired boiler, the uncontrolled emission rate is (EPA-80/02, p. 5-14):

From Table 1.3, the particulate emissions are 13A

$$\begin{aligned}
 E &= (13 \text{ lb/ton})(10) \\
 &= 130 \text{ lb/ton}
 \end{aligned}$$

and the pollutant mass rate (PMR) is

**TABLE 1.3** Emission Factors for Bituminous Coal Combustion without Control Equipment Emission Factor Rating *A*

	Particulates <sup>b</sup>		Sulfur oxides <sup>c</sup>		Carbon monoxide		Hydrocarbons <sup>d</sup>		Nitrogen oxides		Aldehydes	
	lb/ton coal burned	kg/MT coal burned	lb/ton coal burned	kg/MT coal burned	lb/ton coal burned	kg/MT coal burned	lb/ton coal burned	kg/MT coal burned	lb/ton coal burned	kg/MT coal burned	lb/ton coal burned	kg/MT coal burned
Furnace size, 10 <sup>6</sup> Btu/hr heat input <sup>a</sup>												
Greater than 100 <sup>e</sup> (utility and large industrial boilers)												
Pulverized general	16A	8A	38S	19S	1	0.5	0.3	0.15	18	9	0.005	0.0025
Pulverized wet bottom	13A <sup>f</sup>	6.5A	38S	19S	1	0.5	0.3	0.15	30	15	0.005	0.0025
Pulverized dry bottom	17A	8.5A	38S	19S	1	0.5	0.3	0.15	18	9	0.005	0.0025
Cyclone	2A	1A	38S	19S	1	0.5	0.3	0.15	55	27.5	0.005	0.0025
10 to 100 <sup>g</sup> (large commercial and general industrial boilers)												
Spreader stoker <sup>h</sup>	13A <sup>i</sup>	6.5A	38S	19S	2	1	1	0.5	15	7.5	0.005	0.0025
Less than 10 <sup>j</sup> (commercial and domestic furnaces)												
Under feed stoker	2A	1A	38S	19S	10	5	3	1.5	6	3	0.005	0.0025
Hand-fired units	20	10	38S	19S	90	45	20	10	3	1.5	0.005	0.0025

<sup>a</sup> 1 Btu/h = 0.252 kcal/h.

<sup>b</sup> The letter A on all units other than hand-fired equipment indicates that the weight percentage of ash in the coal should be multiplied by the value given. Example: If the factor is 16 and the ash content is 10 percent, the particulate emissions before the control equipment would be 10 times 16, or 160 pounds of particulate per ton of coal (10 × 8, or 80 kg of particulates per MT of coal).

<sup>c</sup> S equals the sulfur content (see footnote *b* above).

<sup>d</sup> expressed as methane.

<sup>e</sup> References 1 and 3 through 7 in (EPA-80/02, p. 5-28).

<sup>f</sup> Without fly-ash reinjection.

<sup>g</sup> References 1, 4, and 7 through 9 in (EPA-80/02, p. 5-28).

<sup>h</sup> For all other stokers use 5A for particulate emission factor.

<sup>i</sup> Without fly-ash reinjection. With fly-ash reinjection use 20 A. This value is not an emission factor but represents loading reaching the control equipment.

<sup>j</sup> References 7, 9, and 10 in (EPA-80/02, p. 5-28).

$$\begin{aligned} \text{PMR} &= (130 \text{ lb/ton})(6 \text{ ton/h}) \\ &= 780 \text{ lb/h} \end{aligned}$$

Conversion of the emission rate from lb/ton to lb per million Btu is as follows:

$$\begin{aligned} \text{HHV} &= 12,500 \text{ Btu/lb} \\ &= (12,500 \text{ Btu/lb})(2000 \text{ lb/ton}) \\ &= 25 \times 10^6 \text{ Btu/ton} \end{aligned}$$

Therefore,

$$\begin{aligned} E &= (130 \text{ lb/ton})(1/25 \times 10^6 \text{ Btu/ton}) \\ &= 5.2 \text{ lb}/10^6 \text{ Btu} \end{aligned}$$

The degree of control required for a source performance standard of 0.1 lb/10<sup>6</sup> Btu would be determined as follows:

$$\begin{aligned}
 \eta &= (\text{collected}/\text{input})100\% \\
 &= [(\text{input} - \text{allowable})/(\text{input})]100\% \\
 &= [(5.2 - 0.1)/5.2]100\% \\
 &= 98.1\%
 \end{aligned}$$

This would be an estimate only. More precise emission data for a specific unit would be desirable.

The  $\text{SO}_2$  factor is more nearly representative of an actual case since the sulfur in the fuel is measurable. The factor 38S in Table 1.3 assumes 4% of the sulfur in the fuel does not appear as  $\text{SO}_2$ . This difference is greater if the system has a high percentage of unburned fuel in the ash. Where unburned combustible in the ash is a specified value, the  $\text{SO}_2$  reduction is calculable, again provided the sulfur appearing as  $\text{SO}_3$  can be predicted. The 38S emission factor is a valid first approximation of the uncontrolled  $\text{SO}_2$  to be expected. Using the coal in Example 1 above with 1.3% sulfur, the following can be seen.

**EXAMPLE 2:** emission factor

Compute  $\text{SO}_2$  emission per  $10^6$  Btu for the coal in Example 1.

$$\begin{aligned}
 E(\text{SO}_2) &= 38(1.3) = 49.4 \text{ lb/ton} \\
 (\text{PMR}) &= (49.4 \text{ lb/ton})(1/25 \times 10^6 \text{ Btu/ton}) \\
 &= 1.98 \text{ lb}/10^6 \text{ Btu}
 \end{aligned}$$

If one assumes that the new source performance standard for  $\text{SO}_2$  is  $1.2 \text{ lb}/10^6$  Btu, this would require a

$$(1.98 - 1.2)/1.98 = 39.3\%$$

reduction of  $\text{SO}_2$  in the flue gas.

Similar calculations of uncontrolled emissions are possible using factors for hydrocarbons and  $\text{NO}_x$ .

## 4 GASEOUS EMISSION CONTROL TECHNIQUES

---

Gaseous pollutants are emitted from a variety of processes. Table 1.4 lists typical gaseous pollutants and their sources (EPA-81/12, p. 1-4).

The main techniques used to control gaseous emissions are

- absorption
- adsorption
- incineration
- condensation

The applicability of a given technique depends on the physical and chemical properties of the pollutant and the exhaust stream. More than one technique may be capable of controlling emissions from a given source. For example, vapors generated from loading gasoline into tank trucks at large bulk terminals are controlled by using any of these four techniques. Most often, however, one control technique is used more frequently than others for a given source-pollutant combination. For example, absorption is commonly used to remove  $\text{SO}_2$  from boiler flue gas.

**TABLE 1.4** Typical Gaseous Pollutants and Their Sources

Key element	Pollutant	Source
S	SO <sub>2</sub>	Boiler flue gas
	SO <sub>3</sub> H <sub>2</sub> SO <sub>4</sub> vapor	Sulfuric acid manufacturing Sulfuric acid manufacturing, pickling operations
	H <sub>2</sub> S	Natural gas processing, pulp and paper mills, sewage treatment
N	R-SH (mercaptans)	Petroleum refining, pulp and paper mills
	NO, NO <sub>2</sub>	Nitric acid manufacturing, boiler flue gas
	HNO <sub>3</sub> vapors	Nitric acid manufacturing, pickling operations
	NH <sub>3</sub>	Ammonia manufacturing
C	Other N compounds (i.e. amines, pyridines)	Sewage, rendering, solvent processes
	Inorganic CO	Incomplete combustion
	Organics: volatile organic compounds (VOC)	
	VOC hydrocarbons	Solvent uses, gasoline marketing, petrochemical plants
	• paraffins	
	• olefins	
	• aromatics	
	VOC oxygenated hydrocarbons	Surface-coating operations, petroleum processing, plastics manufacturing
	• aldehydes	
	• ketones	
• alcohols		
• phenols		
VOC chlorinated solvents		
Halogen—F	HF	Dry cleaning, degreasing Phosphate fertilizer plant, aluminum plant
	SiF <sub>4</sub>	Ceramics, fertilizer plant
Halogen—Cl	HCl	HCl manufacturing, PVC combustion
	Cl <sub>2</sub>	Chlorine manufacturing

#### 4.1 Absorption for Gaseous Emission Control

Absorption is a mass transfer operation in which a gas is dissolved in a liquid. It is the transfer of a gaseous component from the gas phase to a liquid phase. In air pollution control, absorption involves the removal of objectionable gaseous contaminants from a process stream by dissolving them in a liquid; i.e., a contaminant (pollutant) exhaust stream contacts a liquid, and the contaminant diffuses from the gas phase into the liquid phase. The absorption rate is enhanced by high diffusion rates of the contaminant in both the liquid and gas phase, high solubility of the contaminant, large liquid–gas contact area, and good mixing between liquid and gas phases (turbulence) (EPA-81/12, p. 4-1).

Some common terms used when discussing the absorption process are:

- *absorbent*: the liquid, usually water mixed with neutralizing agents, into which the contaminant is absorbed
- *absorbate or solute*: the gaseous contaminant being absorbed, such as SO<sub>2</sub>, H<sub>2</sub>S, etc
- *carrier gas*: the inert portion of the gas stream, usually flue gas, from which the contaminant is to be removed
- *interface*: the area where the gas phase and the absorbent contact each other

- *solubility*: the capability of a gas to be dissolved in a liquid

Absorption is a mass transfer operation. The mass transfer can be compared to heat transfer in that both occur because a system is trying to reach equilibrium conditions. For example, in heat transfer, if a hot slab of metal is placed on top of a cold slab, heat will be transferred from the hot slab to the cold slab until both are at the same temperature (equilibrium). In heat transfer, the process continues as long as a temperature differential or gradient exists. In absorption, mass instead of heat is transferred, and instead of occurring due to a temperature difference, absorption occurs as a result of a concentration difference. Absorption continues as long as a concentration differential exists between the absorbent and the gas from which the contaminant is being removed. In absorption, equilibrium is not as easily defined as in heat transfer, since the concentration difference depends on the solubility of the solute.

Absorption devices used to remove gaseous contaminants are referred to as *absorbers* or *wet scrubbers*. Wet scrubbers are also used to remove particulate matter from gas streams. Wet scrubbers usually cannot be operated to optimize simultaneous removal of both gases and particulate matter. In designing absorbers for gaseous emissions, optimum mass transfer can be accomplished by

- providing a large interfacial contact area
- providing good mixing between gas and liquid phases
- allowing sufficient residence or contact time between the phases
- ensuring a high degree of solubility of the contaminant in the absorbent

***Mechanism of absorption.*** To remove a gaseous contaminant by absorption, the contaminant-laden exhaust stream must be passed through (contacted with) a liquid with the following steps (EPA-81/12, p. 4-2):

- Step 1: The solute diffuses from the bulk area of the gas phase to the gas–liquid interface
- Step 2: The solute transfers across the interface to the liquid phase
- Step 3: The solute diffuses into the bulk area of the liquid, making room for additional gas molecules to be absorbed

Figure 1.6 illustrates the steps involved in the absorption process. The purpose of analyzing these three steps is to determine which variables control the process. The most efficient system can be designed by knowing these variables. It is assumed that once the solute arrives at the interface area, transfer across it occurs instantaneously. This second step in the absorption mechanism is extremely rapid; therefore, it does not need to be considered when deriving absorption efficiency equations. The rate of mass transfer (absorption) is dependent upon the diffusion rate in either the gas phase or the liquid phase.

Two terms used to describe the mass transfer rate are gas-phase controlled absorption and liquid-phase controlled absorption. Each mechanism depends on the rate of diffusion in both phases and upon the solubility of the pollutant in the liquid.

The diffusion rate of a gaseous pollutant molecule through a gas is always faster than its diffusion rate through a liquid because gas molecules in a gas are further apart than liquid molecules in a liquid. The pollutant molecule will move faster through the gas phase than through the liquid phase since, in a gas, obstructions such as other molecules are farther apart than in a liquid. However, the mass transfer rate depends primarily upon the solubility of the pollutant in the liquid.

Consider two gaseous pollutants A and B that are approximately equal in size. Assume that A is not very soluble in the liquid while B is very soluble in the liquid. Assume also that both A and B will move through the gas phase at the same rate. The rates at which the pollutants will be absorbed in the liquid phase are different because B is very soluble while A is not. A is absorbed very slowly and B is absorbed very quickly.

FIGURE 1.6 Gas collection by absorption (EPA-81/12, p. 4-2).

The transfer rate of A (slowly absorbed) is greatly affected by its absorption and diffusion in the liquid phase and is therefore referred to as liquid-phase controlled. The transfer rate of B (quickly absorbed) is also greatly affected by its rate of movement through the liquid phase but is absorbed so rapidly that it doesn't influence the overall transfer rate. The mass transfer rate for B depends only on how fast it diffuses through the gas phase towards the gas-liquid interface and is referred to as gas-phase controlled.

The gas-phase controlled systems absorb pollutants more readily than do the liquid-phase controlled systems. Thus, absorption systems used in the field of air pollution control are usually designed to be gas-phase controlled.

The previously mentioned three-step mechanism of absorption occurs on two levels: a micro or molecular level and a macro or bulk level. Molecular diffusion of individual molecules occurs due to a concentration difference because all systems try to achieve an equilibrium state. Molecules migrate from areas of high concentrations to areas of low concentrations. Macro or bulk diffusion occurs as a mass of liquid or gas moves to or from the interface. In an absorber, bulk diffusion is accomplished by turbulent mixing of the gas and liquid phases. To be efficient, an absorber must provide both turbulent mixing of the gas and liquid phases and sufficient residence time to allow pollutant molecules to be absorbed.

**Solubility.** A very important factor affecting the amount of a contaminant that can be absorbed is the solubility of the contaminant. Solubility is a function of both the temperature and to a lesser extent the pressure of the system. As temperature increases, the amount of gas that can be absorbed by a liquid decreases. From the ideal gas law: as temperature increases, the volume of a gas also increases; therefore, at the higher temperature less gas is absorbed due to the increased volume it occupies. Pressure affects the solubility of a gas in the opposite manner. By increasing the pressure of a system the amount of gas absorbed generally increases (EPA-81/12, p. 4-3).

Under certain conditions, Henry's law may also be used to express equilibrium solubility of gas-liquid systems. Henry's law states that for dilute solutions, where the components do not interact, the resulting partial pressure ( $p$ ) of a component A in equilibrium with other components in a solution can be expressed as

$$p = Hx_A$$

where  $p$  = equilibrium partial pressure of component A over a solution  
 $x_A$  = mole fraction or concentration of A in liquid phase, g-mole/cm<sup>3</sup>  
 $H$  = Henry's law constant (atm-cm<sup>3</sup>)/(g-mole) of pure A at the same temperature and pressure as the solution

This equation is the equation of a straight line, where the slope ( $m$ ) is equal to  $H$ . Henry's law can be used to predict solubility only when the equilibrium line is straight. Equilibrium lines are usually straight when the solute concentrations are very dilute. In air pollution control applications this is usually the case. For example, an exhaust stream that contains a 1000 ppm SO<sub>2</sub> concentration corresponds to a mole fraction of SO<sub>2</sub> in the gas phase of only 0.001.

Another restriction on using Henry's law is that it does not hold true for gases that react or dissociate upon dissolution. If this happens, the gas no longer exists as a simple molecule. For example, scrubbing HF or HCl gases with water causes both compounds to dissociate in solution. In these cases, the equilibrium lines are curved rather than straight. Data on systems that exhibit curved equilibrium lines must be obtained from experiments.

The units of Henry's law constants are atm/(mole fraction). The smaller the constant, the more soluble the gas. The following example illustrates how to develop an equilibrium diagram from solubility data.

**EXAMPLE 1:** Henry's law

Given the data shown in Table 1.5 for the solubility of SO<sub>2</sub> in pure water at 303K (30°C) and 101.3 kPa (760 mm Hg), plot the equilibrium diagram and determine if Henry's law applies (EPA-81/12, p. 4-7).

*Solution:*

1. The data must first be converted to mole fraction units.

The mole fraction in the gas phase  $y$  is obtained by dividing the partial pressure of SO<sub>2</sub> by the total pressure of the system:

$$y = p/P = 6 \text{ kPa}/(101.3 \text{ kPa}) = 0.06$$

The mole fraction in the liquid phase  $x$  is obtained by dividing the moles of SO<sub>2</sub> by the total moles of liquid (basis = 100g of H<sub>2</sub>O):

**TABLE 1.5** Solubility of SO<sub>2</sub> in Pure Water

Equilibrium data	
$C$ (g of SO <sub>2</sub> per 100 g/H <sub>2</sub> O)	$p$ (partial pressure of SO <sub>2</sub> )
0.5	6 kPa (42 mmHg)
1.0	11.6 kPa (85 mmHg)
1.5	18.3 kPa (129 mmHg)
2.0	24.3 kPa (176 mmHg)
2.5	30.0 kPa (224 mmHg)
3.0	36.4 kPa (273 mmHg)

$$x = (\text{moles SO}_2 \text{ in solution})/(\text{moles SO}_2 \text{ in solution} + \text{moles of H}_2\text{O})$$

$$\begin{aligned} \text{moles of SO}_2 \text{ in solution} &= (\text{concentration of SO}_2)/(\text{64 g of SO}_2 \text{ per mole}) \\ &= 0.5/64 \\ &= 0.0078 \end{aligned}$$

$$\begin{aligned} \text{moles of H}_2\text{O} &= (100 \text{ g of H}_2\text{O})/(18 \text{ g H}_2\text{O per mole}) = 5.55 \\ x &= 0.0078/(0.0078 + 5.55) \\ &= 0.0014 \end{aligned}$$

2. Table 1.6 is completed. The data from Table 1.6 is plotted in Fig. 1.7. Henry's law applies in the given concentration range with Henry's law constant equal to 42.7 mole fraction SO<sub>2</sub> in air/mole fraction SO<sub>2</sub> in water.

**TABLE 1.6** Solubility Data for SO<sub>2</sub>

$C = (\text{g of SO}_2)/(\text{100 g H}_2\text{O})$	$p$ (kPa)	$y = p/101.3$	$x = (C/64)/(C/64 + 5.55)$
0.5	6	0.06	0.0014
1.0	11.6	0.115	0.0028
1.5	18.3	0.18	0.0042
2.0	24.3	0.239	0.0056
2.5	30	0.298	0.007
3.0	36.4	0.359	0.0084

**FIGURE 1.7** Equilibrium diagram for SO<sub>2</sub>-H<sub>2</sub>O system (*EPA-81/12, p. 4-8*).

**Material balance.** In designing or reviewing the design of an absorption control system, the first task is to determine the flow rates and composition of each stream entering the system. From the law of conservation of mass, the material entering a process must either accumulate or exit. In other words, 'what comes in must go out'. A material balance is used to help determine flow rates and compositions of individual streams. Figure 1.8 illustrates a typical countercurrent flow absorber in which a material balance is drawn. The solute is used as the 'material' in the material balance (EPA-81/12, p. 4-14).

For material balance, the following equation can be obtained:

$$Y_1 - Y_2 = (L_m/G_m)(X_1 - X_2)$$

- where
- $Y_1$  = inlet solute concentration
  - $Y_2$  = outlet solute concentration
  - $X_2$  = inlet composition of scrubbing liquid
  - $X_1$  = outlet composition of scrubbing liquid
  - $L_m$  = liquid flow rate, g-mole/h
  - $G_m$  = gas flow rate, g-mole/h

FIGURE 1.8 Operating line for a countercurrent flow absorber (EPA-81/12, p. 4-17).

The above equation is the equation of a straight line. When this line is plotted on an equilibrium diagram it is referred to as an *operating line* (Fig. 1.8). This line defines operating conditions within the absorber: what is going in and what is coming out. The slope of the operating line is the liquid mass flow rate divided by the gas mass flow rate, which is the liquid-to-gas ratio or ( $L_m/G_m$ ). The liquid-to-gas ratio is used extensively when describing or comparing absorption systems.

**EXAMPLE 2:** Henry's law

Using the data and results from Example 1, compute the minimum liquid rate of pure water required to remove 90% of the  $\text{SO}_2$  from a gas stream of  $84.9 \text{ m}^3/\text{min}$  (3000 acfm) containing 3%  $\text{SO}_2$  by volume. The temperature is 293 K and the pressure is 101.3 kPa (EPA-81/12, p. 4-20).

**Given conditions**

Inlet gas solute concentration ( $Y_1$ ) = 0.03

Minimum acceptable standards (outlet solute concentration) ( $Y_2$ ) = 0.003

Composition of the liquid into the absorber ( $X_2$ ) = 0

Gas flow rate ( $Q$ ) =  $84.9 \text{ m}^3/\text{min}$

Outlet liquid concentration ( $X_1$ ) = ?

Liquid flow rate ( $L$ ) = ?

*Solution:*

1. First, sketch and label a drawing of the system (Fig. 1.9).

$$Y_1 = 3\% \text{ by volume} = 0.03$$

$$Y_2 = 90\% \text{ reduction from } Y_1 \text{ or only } 10\% \text{ of } Y_1; \text{ therefore}$$

$$Y_2 = (0.10)(0.03) = 0.003$$

2. At the minimum liquid rate,  $Y_1$  and  $X_1$  will be in equilibrium; the liquid will be saturated with  $\text{SO}_2$ .

At equilibrium:  $Y_1 = H'X_1$

From Fig. 1.7,

**FIGURE 1.9** Material balance for absorber (EPA-81/12, p. 4-20).

$$H' = 42.7 \text{ (mole fraction SO}_2 \text{ in air)/(mole fraction SO}_2 \text{ in water)}$$

$$0.03 = 42.7X_1$$

$$X_1 = 0.000703 \text{ mole fraction}$$

3. The minimum liquid-to-gas ratio is

$$Y_1 - Y_2 = (L_m/G_m)(X_1 - X_2)$$

$$(L_m/G_m) = (Y_1 - Y_2)/(X_1 - X_2)$$

$$= (0.03 - 0.003)/(0.000703 - 0)$$

$$= 38.4 \text{ (g mole water)/(g mole of air)}$$

4. Compute the minimum required liquid flow rate:

First, convert  $\text{m}^3$  of air to g moles.

At  $0^\circ\text{C}$  (or 273 K) and 101.3 kPa, there are  $0.0224 \text{ m}^3/\text{g mole}$  of an ideal gas.

At  $20^\circ\text{C}$  (293 K):  $0.0224(293/273) = 0.024 \text{ m}^3/\text{g mole}$

$$G_m = 84.9 \text{ (m}^3/\text{min)(g-mole air/0.024 m}^3)$$

$$= 3538 \text{ g-mole air/min}$$

$$L_m/G_m = 38.4 \text{ (g-mole water)/(g-mole of air) at minimum conditions}$$

$$L_m = 38.4(3538)$$

$$= 136.0 \text{ kg-mole water min}$$

In mass units:

$$L = 136 \text{ kg-mole/min (18 kg/kg mole)}$$

$$= 2448 \text{ kg/min}$$

5. Figure 1.10 illustrates the graphical solution to this problem.

The slope of the minimum operating line  $\times 1.5$  = the slope of the actual operating line (line AC).

$$38.4 \times 1.5 = 57.6$$

**Sizing packed column diameter of an absorber.** The main parameter that affects the size of a packed column is the gas velocity at which liquid droplets become entrained in the exiting gas stream. Consider a packed column operating at set gas and liquid flow rates. By decreasing the diameter of the column, the gas flow rate (m/s or ft/s) through the column will increase. If the gas flow rate through the column is gradually increased (by using smaller and smaller diameter columns) a point will be reached where the liquid flowing down over the packing begins to be held in the void spaces between the packing. This gas-to-liquid flow ratio is termed the *loading point*. The pressure drop over the column begins to increase and the degree of mixing between the phases decreases. A further increase in gas velocity will cause the liquid to completely fill the void spaces in the packing. The liquid forms a layer over the top of the packing and no more liquid can flow down through the tower. The pressure drop increases substantially and mixing between the phases is minimal. This condition is referred to as *flooding* and the gas velocity at which it occurs is the *flooding velocity*. Using an extremely large diameter tower would eliminate this problem. However, as the diameter increases the cost of the tower increases (EPA-81/12, p. 4-22).

Normal practice is to size a packed column diameter to operate at a certain percent of the flooding velocity. A typical operating range for the gas velocity through the columns is 50–75 percent of the flooding velocity. It is assumed that by operating in this range the gas velocity will also be below the loading point.

A common and relatively simple procedure to estimate the flooding velocity (thus setting a minimum column diameter) is to use a generalized flooding and pressure drop correlation. One version of the flooding and pressure drop relationship in a packed tower is shown in Fig. 1.11. This correlation is based on the physical properties of the gas and liquid streams and tower packing characteristics. The procedure to determine the tower diameter is

1. Calculate the value of the abscissa.

$$(L/G)(\rho_g/\rho_l)^{0.5} \tag{1.30}$$

where

$L$  and  $G$  = mass flow rates: any consistent set of units may be used as long as the abscissa is dimensionless

$\rho_g$  = density of the gas stream

$\rho_l$  = density of the absorbing liquid

2. From the point calculated in Eq. (1.30) proceed up the graph to the flooding line and read the ordinate  $\epsilon$ .

FIGURE 1.11 Generalized flooding and pressure drop correlation (EPA-81/12, p. 4-23).

3. Rearrange the equation of the ordinate and solve for  $G'$ .

$$G' = \{[(\varepsilon)(\rho_g)(\rho_l)(g_c)]/[F\phi(\mu_1)^{0.2}]\}^{0.5} \tag{1.31}$$

where

$G'$  = mass flow rate of gas per unit cross-sectional area of column at flooding, g/s-m<sup>2</sup> (lb/s-ft<sup>2</sup>)

$\varepsilon$  = ordinate value in Fig. 1.11

$\rho_g$  = density of the gas stream, kg/m<sup>3</sup> (lb/ft<sup>3</sup>)

$\rho_l$  = density of the absorbing liquid, kg/m<sup>3</sup> (lb/ft<sup>3</sup>)

$g_c$  = gravitational constant = 9.82 m/s<sup>2</sup> (32.2 ft/s<sup>2</sup>)

$F$  = packing factor

$\phi$  = ratio of specific gravity of the scrubbing liquid to that of water

$\mu_1$  = viscosity of liquid (for water = 0.8 centipoise = 0.0008 Pa-s) [use Pa-s in this equation]

4.  $G'$  at operating conditions is a fraction of  $G'$  at flooding:

$$G'_{\text{operating}} = f G'_{\text{flooding}} \tag{1.32}$$

5. The cross-sectional area of column A is calculated from

$$A = G/G'_{\text{operating}} \quad (1.33)$$

6. The diameter of the column is obtained from

$$d = (4A/\pi)^{0.5} \quad (1.34)$$

**EXAMPLE 3:** column sizing

For the scrubber in Example 2, determine the column diameter if the operating liquid rate is 1.5 times the minimum. The gas velocity should be no greater than 75% of the flooding velocity and the packing material is 2-inch ceramic Intalox saddles.

*Solution:*

From Example 2:

$$G_m = 3538 \text{ g-mole/min}$$

$$L_m = 2448 \text{ kg/min}$$

Convert gas molar flow to a mass flow, assuming molecular weight of the gas to be 29 kg/mole.

$$G = 3.538 \text{ (kg-mole/min)}(29)(\text{kg/mole}) = 102.6 \text{ kg/min}$$

Adjusting the liquid flow to 1.5 times the minimum:

$$L = 1.5(2448) = 3672 \text{ kg/min}$$

The densities of water and air at 20°C are:

$$\rho_l = 1000 \text{ kg/m}^3$$

$$\rho_g = 1.17 \text{ kg/m}^3$$

1. Compute the abscissa from Eq. (1.30).

$$(L/G)(\rho_g/\rho_l)^{0.5} = (3672/102.6)(1.17/1000)^{0.5} = 1.22$$

2. From Fig. 1.11, proceed up to the flooding line from 1.22. The ordinate  $\varepsilon$  is 0.019.

3. From Eq. (1.31), calculate  $G'$ :

$$G' = \{[(\varepsilon)(\rho_g)(\rho_l)(g_c)]/[F\phi(\mu_1)^{0.2}]\}^{0.5}$$

where

$G'$  = mass flow rate of gas per unit cross-sectional area of column at flooding,  
g/s-m<sup>2</sup> (lb/s-ft<sup>2</sup>)

$\varepsilon$  = ordinate value in Fig. 1.11

$\rho_g$  = density of the gas stream, kg/m<sup>3</sup> (lb/ft<sup>3</sup>)

$\rho_l$  = density of the absorbing liquid, kg/m<sup>3</sup> (lb/ft<sup>3</sup>)

$g_c$  = gravitational constant = 9.82 m/s<sup>2</sup> (32.2 ft/s<sup>2</sup>)

$F$  = packing factor. For this example, the factor is assumed to be 40 ft<sup>2</sup>/ft<sup>3</sup> or 131 m<sup>2</sup>/m<sup>3</sup> for 2-inch Intalox saddles

$\phi$  = ratio of specific gravity of the scrubbing liquid to that of water

$\mu_1$  = viscosity of liquid (for water = 0.8 centipoise = 0.0008 Pa-s)

For water,  $\phi = 1.0$  and  $\mu_1 = 0.0008$  Pa-s

For 2-inch Intalox saddles,  $F = 40 \text{ ft}^2/\text{ft}^3$  or  $131 \text{ m}^2/\text{m}^3$ .

$$G' = \{(0.019)(1.17)(1000)(9.82)/[(1)(131)(0.0008)^{0.2}]\}^{0.5}$$

$$= 2.63 \text{ kg/m}^2\text{-s at flooding}$$

4. The superficial gas velocity at operating is obtained from Eq. (1.32).

$$G'_{\text{operating}} = f G'_{\text{flooding}} = 0.75 \times 2.63 = 1.97 \text{ kg/(m}^2\text{-s)}$$

5. From Eq. (1.33), the cross-sectional area of the tower is

$$A = G/G'_{\text{operating}}$$

$$= (102.6 \text{ kg/min})(\text{min}/60 \text{ s})/(1.97 \text{ kg/m}^2\text{-s})$$

$$= 0.87 \text{ m}^2$$

6. From Eq. (1.34), the diameter of the tower is

$$d = (4A/\pi)^{0.5}$$

$$= [(4)(0.87 \text{ m}^2)]^{0.5}$$

$$= 1.05 \text{ m or at least 1 m (3.5 ft)}$$

Figure 1.11 may also be used to estimate the pressure drop of the tower once  $G'_{\text{operating}}$  is set. This is done by plugging  $G'$  back into the equation to compute  $\varepsilon$

$$\varepsilon = [(G')^2 F \phi (\mu_1)^{0.2}]/[(\rho_g)(\rho_l)(g_c)]$$

$$= (1.97)^2 (1)(131)(0.0008)^{0.2}/[(1.17)(1000)(9.82)]$$

$$= 0.0106$$

The abscissa remains unchanged and equals 1.22. The pressure drop through the column is the point at which these two lines cross. From Fig. 1.11

$$\Delta p = (0.0416 \text{ meter of H}_2\text{O})/(\text{meter of packing})(0.5 \text{ inches of H}_2\text{O})/$$

$$(\text{foot of packing})$$

**Sizing the packed column height of an absorber.** The height of a packed column refers to the depth of packing material needed to accomplish the required removal efficiency. The more difficult the separation, the larger the packing height required. For example, a much larger packing height would be required to remove  $\text{SO}_2$  than to remove  $\text{Cl}_2$  from an exhaust stream using water as the absorbent. This is because  $\text{Cl}_2$  is more soluble in water than  $\text{SO}_2$ . Determining the proper height of packing is important since it affects both the rate and efficiency of absorption (EPA-81/12, p. 4-26).

The height of a packed column can be expressed as

$$Z = \text{HTU} \times \text{NTU} \quad (1.35)$$

where  $Z$  = height of packed column

HTU = height of a transfer unit

NTU = number of transfer units

The concept of a transfer unit comes from the operation of plate columns. Discrete stages (plates) of separation occur in plate columns. These stages can be visualized as a transfer unit with the number and height of each giving the total tower height. Although a packed column operates as one continuous separation process, in design terminology it is treated as if it were broken into discrete sections (height of a transfer unit). The number and the height of a transfer unit are based on either the gas or liquid phase. Equation (1.35) now becomes

$$Z = N_{OG}H_{OG} = N_{OL}H_{OL} \quad (1.36)$$

where  $Z$  = height of packing, m

$N_{OG}$  = number of transfer units based on overall gas film coefficient

$H_{OG}$  = height of a transfer unit based on overall gas film coefficient, m

$N_{OL}$  = number of transfer units based on overall liquid film coefficient

$H_{OL}$  = height of a transfer unit based on overall liquid film coefficient, m

Values for the height of a transfer unit used in designing absorption systems are usually obtained from experimental data. To ensure greatest accuracy, vendors of absorption equipment normally perform pilot plant studies to determine the height of a transfer unit.

When no experimental data are available or if only a preliminary estimate of absorber efficiency is needed, there are generalized correlations available to predict the height of a transfer unit. The correlations for predicting the  $H_{OG}$ , or the  $H_{OL}$ , are empirical in nature and are a function of

Type of packing

Liquid and gas flow rates

Concentration and solubility of the contaminant

Liquid properties

System temperature

For most applications, the height of a transfer unit ranges between 0.3 and 1.2 m (1 and 4 ft). As a rough estimate, 0.6 m (2.0 ft) can be used.

The number of transfer units, NTU, can be obtained experimentally or calculated from a variety of methods. For the case where the solute concentration is very low and the equilibrium line is straight, the following equation can be used to determine the number of transfer units ( $N_{OG}$ ) based on the gas phase resistance.

$$N_{OG} = \ln[(Y_1 - mX_2)/(Y_2 - mX_2)(1 - mG_m/L_m) + mG_m/L_m]/(1 - mG_m/L_m) \quad (1.37)$$

where  $N_{OG}$  = transfer units

$Y_1$  = mole fraction of solute in entering gas

$X_2$  = mole fraction of solute entering the column

$Y_2$  = mole fraction of solute in exiting gas

$m$  = slope of equilibrium line

$G_m$  = molar flow rate of gas, kg-mole/h

$L_m$  = molar flow rate of liquid, kg-mole/h

Equation (1.37) may be solved directly or graphically by using the Colburn diagram which is presented in Fig. 1.12. The Colburn diagram is a plot of the  $N_{OG}$  versus  $\ln[Y_1 - mX_2/(Y_2 - mX_2)]$  at various values of  $mG_m/L_m$ . The term  $mG_m/L_m$  is referred to as the *absorption factor*. Figure 1.12 is used by first computing the value of  $\ln[Y_1 - mX_2/(Y_2 - mX_2)]$ , reading up the graph to the line corresponding to  $(mG_m/L_m)$ , and then reading across to obtain the  $N_{OG}$ .

Equation (1.37) can be further simplified for situations where a chemical reaction occurs or if the solute is extremely soluble. In these cases the solute exhibits almost no partial pressure

FIGURE 1.12 Colburn diagram (EPA-84/03, p. 104; EPA-81/12, p. 4-30).

and therefore the slope of the equilibrium line approaches zero ( $m = 0$ ). For either of these cases, the equation is reduced to

$$N_{OG} = \ln(Y_1/Y_2) \quad (1.38)$$

This means that the number of transfer units only depends on the inlet and outlet concentration of the solute (contaminant). For example, if the conditions of Eq. (1.38) are met, to achieve 90% removal of any pollutant requires 2.3 transfer units. The equation applies only when the equilibrium line is straight and approaches zero (for very soluble or reactive gases). Example 4 illustrates a procedure to calculate the packed column height.

**EXAMPLE 4:** column sizing

From pilot plant studies of the absorption system in Example 2, it was determined that the  $H_{OG}$  for the  $\text{SO}_2$ -water system is 0.829 m (2.72 ft). Calculate the total height of packing required to achieve 90% removal. The following data were taken from the previous examples:

**Given conditions**

$$H_{OG} = 0.829 \text{ m}$$

$$m = 42.7 \text{ (kg-mole SO}_2 \text{ in air)/(kg-mole SO}_2 \text{ in water)}$$

$$G_m = 3.5 \text{ kg-mole/min}$$

$$L_m = 3672 \text{ (kg/min)(kg-mole)/18 kg} = 204 \text{ kg-mole/min}$$

$$X_2 = 0 \text{ (no recycle liquid)}$$

$$Y_1 = 0.03$$

$$Y_2 = 0.003$$

*Solution:*

1. Compute the  $N_{OG}$  from Eq. (1.37)

$$N_{OG} = \ln[(Y_1 - mX_2)/(Y_2 - mX_2)(1 - mG_m/L_m) + mG_m/L_m]/(1 - mG_m/L_m)$$

where  $N_{OG}$  = transfer units

$Y_1$  = mole fraction of solute in entering gas

$X_2$  = mole fraction of solute entering the column

$Y_2$  = mole fraction of solute in exiting gas

$m$  = slope of equilibrium line

$G_m$  = molar flow rate of gas, kg-mole/h

$L_m$  = molar flow rate of liquid, kg-mole/h

$$\begin{aligned} N_{OG} &= \ln[(Y_1 - mX_2)/(Y_2 - mX_2)(1 - mG_m/L_m) + mG_m/L_m]/(1 - mG_m/L_m) \\ &= \ln\{(0.03/0.003)[1 - 42.7(3.5)/204] + 42.7(3.5)/204\}/[1 - 42.7(3.5)/204] \\ &= 4.58 \end{aligned}$$

2. Calculate the total packing height.

$$\begin{aligned} Z &= H_{OG}(N_{OG}) \\ &= 0.829 \times 4.58 \\ &= 3.79 \text{ m of packing height} \end{aligned}$$

**Sizing the plate tower.** In a plate tower the scrubbing liquid enters at the top of the tower, passes over the top plate, and then down over each lower plate until the liquid reaches the bottom. Absorption occurs as the gas, which enters at the bottom, passes up through the plate and contacts the liquid. In a plate tower, absorption occurs in a stepwise or stage process. The operation of plate towers is discussed in greater detail in EPA-81/12, p. 4-32.

The minimum diameter of a single-pass plate tower is determined by using the gas velocity through the tower. If the gas velocity is too fast, liquid droplets are entrained, causing a condition known as priming. Priming occurs when the gas velocity through the tower is so fast that it causes liquid on one tray to foam and then rise to the tray above. Priming reduces absorber efficiency by inhibiting gas and liquid contact. For the purpose of determining tower diameter, priming in a plate tower is analogous to the flooding point in a packed tower. It determines the minimum acceptable diameter. The actual diameter should be larger.

The smallest allowable diameter for a plate tower is expressed by

$$d = \Psi[Q(\rho_g)^{0.5}]^{0.5} \quad (1.39)$$

where  $d$  = plate tower diameter  
 $\Psi$  = empirical correlation,  $\text{m}^{0.25}(\text{h})^{0.25}/(\text{kg})^{0.25}$   
 $Q$  = volumetric gas flow,  $\text{m}^3/\text{h}$   
 $\rho_g$  = gas density,  $\text{kg}/\text{m}^3$

The term  $\Psi$  is an empirical correlation and is a function of both the tray spacing and the densities of the gas and liquid streams. Values for  $\Psi$  shown in Table 1.7 are for a tray spacing of 61 cm (24 in) and a liquid specific gravity of 1.05. If the specific gravity of a liquid varies significantly from 1.05, the values for  $\Psi$  in the table cannot be used.

Depending on operating conditions, trays are spaced at a minimum distance between plates to allow the gas and liquid phases to separate before reaching the plate above. Trays should be spaced to allow for easy maintenance and cleaning. Trays are normally spaced 45 to 70 cm (18 to 28 in) apart. In using the information in Table 1.7 for a tray spacing different from 61 cm, a correction factor must be used. Figure 1.13 is used to determine the correction factor which is multiplied by the estimated diameter. Example 5 illustrates how to estimate the minimum diameter of a plate tower.

**TABLE 1.7** Empirical Constants for Eq. (1.39)

Tray	Metric $\Psi^*$	Engineering $\Psi^\dagger$
Bubble cap	0.0162	0.1386
Sieve	0.014	0.1198
Valve	0.0125	0.1069

\* Metric  $\Psi$  is expressed in  $\text{m}^{0.25}\text{hr}^{0.5}/\text{kg}^{0.25}$ , for use with  $Q$  expressed in  $\text{m}^3/\text{h}$ , and  $\rho_g$  expressed in  $\text{kg}/\text{m}^3$ .

† Engineering  $\Psi$  is expressed in  $\text{ft}^{0.25}\text{min}^{0.5}/\text{lb}^{0.25}$ , for use with  $Q$  expressed in  $\text{cfm}$ , and  $\rho_g$  expressed in  $\text{lb}/\text{ft}^3$ .

**EXAMPLE 5:** plate tower diameter

For the condition described in Example 2, determine the minimum acceptable diameter if the scrubber is a bubble cap tray tower. The trays are spaced 0.53 m (21 in) apart (EPA-81/12, p. 4-34).

*Solution:*

From Example 2 and Example 3, the following information is obtained:

$$\text{Gas flow rate} = Q = 84.9 \text{ m}^3/\text{min}$$

$$\text{Density} = \rho_g = 1.17 \text{ kg}/\text{m}^3$$

From Table 1.7 for a bubble cap tray:

$$\Psi = 0.0162 \text{ m}^{0.25}(\text{h})^{0.25}/(\text{kg})^{0.25}$$

Before Eq. (1.39) can be used,  $Q$  must be converted to  $\text{m}^3/\text{h}$ .

$$\begin{aligned} Q &= 84.9(\text{m}^3/\text{min})(60)(\text{min}/\text{h}) \\ &= 5094 \text{ m}^3/\text{h} \end{aligned}$$

Substituting these values into Eq. (1.39) for a minimum  $d$ :

$$d = \Psi[Q(\rho_g)^{0.5}]^{0.5}$$

FIGURE 1.13 Tray spacing correction factor (EPA-81/12, p. 4-33).

where  $d$  = plate tower diameter  
 $\Psi$  = empirical correlation,  $m^{0.25}(h)^{0.25}/(kg)^{0.25}$   
 $Q$  = volumetric gas flow,  $m^3/h$   
 $\rho_g$  = gas density,  $kg/m^3$

$$d = \Psi[Q(\rho_g)^{0.5}]^{0.5}$$

$$= (0.0162)[5094(1.17)^{0.5}]^{0.5} = 1.2 \text{ m}$$

Correct this diameter for a tray spacing of 0.53 m. From Fig. 1.13 read the correction factor as 1.05. Therefore, the minimum diameter is

$$d = 1.2(1.05) = 1.26 \text{ m (4.13 ft)}$$

*Note:* this estimated diameter is a minimum acceptable diameter based on actual conditions. In practice, a larger diameter based on maintenance or economic considerations is usually chosen.

**Number of theoretical plates or trays.** There are several methods used to determine the number of ideal plates or trays that are required for a given removal efficiency. These methods, however, can become quite complicated. One method used is a graphical technique (EPA-81/12, p. 4-34).

The number of ideal plates is obtained by drawing ‘steps’ on an operating diagram. This procedure is illustrated in Fig. 1.14. This method can be rather time-consuming and inaccuracies can result at both ends of the graph. The following is a simplified method of estimating the number of plates. It can only be used if both the equilibrium and operating lines for the system are straight. This is a valid assumption for most air pollution control systems.

$$N_p = \ln[(Y_1 - mX_2)/(Y_2 - mX_2)(1 - mG_m/L_m) + mG_m/L_m] / \ln(L_m/mG_m) \quad (1.40)$$

- where  $N_p$  = number of theoretical plates
- $Y_1$  = mole fraction of solute in entering gas
- $X_2$  = mole fraction of solute entering the column
- $Y_2$  = mole fraction of solute in exiting gas
- $m$  = slope of equilibrium line
- $G_m$  = molar flow rate of gas, kg-mole/h
- $L_m$  = molar flow rate of liquid, kg-mole/h

Equation (1.40) is used to predict the *number of theoretical plates* ( $N_p$ ) required to achieve a given removal efficiency. The operating conditions for a theoretical plate assume that the gas and liquid stream leaving the plate are in equilibrium with each other. This ideal condition is never achieved in practice. A larger number of actual trays are required to compensate for this decreased tray efficiency.

Three types of efficiencies are used to describe absorption efficiency for a plate tower:

- An overall efficiency, which is concerned with the entire column
- Murphree efficiency, which is applicable with a single plate
- Local efficiency, which pertains to a specific location on a plate

FIGURE 1.14 Graphic determination of the number of theoretical plates (EPA-81/12, p. 4-35).

The simplest of the tray efficiency concepts, the overall efficiency, is the ratio of the number of theoretical plates to the number of actual plates. Since overall tray efficiency is an oversimplification of the process, reliable values are difficult to obtain. For a rough estimate, overall tray efficiencies for absorbers operating with low-viscosity liquid normally fall in a 65–80% range. Example 6 shows a procedure to calculate the number of theoretical plates.

**EXAMPLE 6:** number of theoretical plates

Calculate the number of theoretical plates required for the scrubber in Example 5, using the same conditions as in Example 4. Estimate the total height of the column if the trays are spaced at 0.53 m intervals and assume an overall tray efficiency of 70%.

*Solution:*

From Example 5 and the previous examples the following data are obtained:

Slope of equilibrium line,  $m = 42.7$  (kg-mole  $\text{SO}_2$  in air)/(kg-mole  $\text{SO}_2$  in water)

$G_m = 3.5$  kg-mole/min

$L_m = 3672$  (kg/min)(kg-mole)/18 kg = 204 kg-mole/min

$X_2 = 0$  (no recycle liquid)

$Y_1 = 0.03$

$Y_2 = 0.003$

The number of theoretical plates from Eq. (1.40) is

$$N_p = \ln[(Y_1 - mX_2)/(Y_2 - mX_2)(1 - mG_m/L_m) + mG_m/L_m] / \ln(L_m/mG_m)$$

where  $N_p$  = number of theoretical plates  
 $Y_1$  = mole fraction of solute in entering gas  
 $X_2$  = mole fraction of solute entering the column  
 $Y_2$  = mole fraction of solute in exiting gas  
 $m$  = slope of equilibrium line  
 $G_m$  = molar flow rate of gas, kg-mole/h  
 $L_m$  = molar flow rate of liquid, kg-mole/h

$$\begin{aligned} N_p &= \ln[Y_1 - mX_2]/(Y_2 - mX_2)(1 - mG_m/L_m) + mG_m/L_m / \ln(L_m/mG_m) \\ &= \ln[(0.03 - 0)/(0.003 - 0)[1 - 42.7(3.5)/204] + 42.7(3.5)/204] / \ln[204/(42.7)(3.5)] \\ &= 3.94 \text{ theoretical plates} \end{aligned}$$

Assuming that the overall plate efficiency is 70%,

$$\begin{aligned} \text{Actual number of plates} &= 3.94/0.7 \\ &= 5.6 \text{ or } 6 \text{ plates} \end{aligned}$$

The height of the tower is given by

$$Z = N_p (\text{tray spacing}) + \text{top height}$$

The top height is the distance over the top plate which allows the gas-vapor mixture to separate. This distance is usually the same as the tray spacing.

$$\begin{aligned} Z &= 6 \text{ plates } (0.53 \text{ m}) + 0.53 \text{ m} \\ &= 3.71 \text{ m} \end{aligned}$$

*Note:* this height is approximately the same as that predicted for the packed tower in Example 4. This seems logical since both the packed and plate towers are efficient gas absorption devices. However, due to the many assumptions, no concrete generalization can be made.

**Factors affecting absorption performance.** The physical and chemical characteristics of the exhaust gas stream play an important role in both the selection and proper operation of an absorption system. Factors affecting the absorption performance include:

1. **Absorbent:** selection of the proper absorbing liquid (absorbent) is based on the efficiency required and the liquid cost. Water is the usual choice because many gaseous contaminants are soluble in it, it is readily available, and relatively inexpensive. The following properties must also be kept in mind when selecting a liquid:
  - **Gas solubility:** high solubility increases the absorption rate and minimizes the quantity of liquid needed. The solubility of the gaseous contaminant is the first characteristic to evaluate. If the gaseous contaminant is very soluble, then high removal efficiencies can be achieved by almost any absorption device. For a relatively insoluble contaminant only certain systems may be able to achieve the required removal efficiency. In some cases a chemical reagent may have to be added to the absorbing liquid to increase the solubility of the contaminant. These reagents may increase the physical solubility of the contaminant (i.e. sodium citrate added to absorb  $\text{SO}_2$ ) or can chemically react with the contaminant (i.e. lime scrubbing of  $\text{SO}_2$ ). If a precipitate is formed by a chemical reaction when a reagent is used, plugging or corrosion problems may arise.
  - **Volatility:** low volatility of the liquid will reduce the amount of vapor that is lost in the exiting gas stream.
  - **Viscosity:** low viscosity promotes rapid absorption rates, improves flooding characteristics, and lowers the pressure drop.
  - **Chemical stability:** the absorbent should not degrade but remain effective throughout its useful lifetime.
  - **Flammability:** if at all possible, the liquid should be nonflammable, non-corrosive, non-toxic, and inexpensive.
2. **Temperature:** the temperature of the exhaust stream is another important characteristic which affects absorption. The solubility of a gas decreases with an increase in operating temperature. As the temperature increases, so does the kinetic energy of the gas molecules in solution. At these higher states of energy the gas molecules will come out of solution. This loss of solubility at higher temperatures necessitates that some gas streams be cooled before effective absorption occurs. For example, in certain flue gas desulfurization (FGD) systems the exhaust gases from the boiler must be cooled from  $150^\circ\text{C}$  ( $300^\circ\text{F}$ ) to approximately  $50^\circ\text{C}$  ( $125^\circ\text{F}$ ) to achieve the desired  $\text{SO}_2$  removal efficiency. This is accomplished by adding inlet sprays or adjusting the liquid flow rate to the absorber. The temperature of the exhaust stream also affects the size of the absorption system. Decreasing the temperature decreases the volume of gases which must be handled. This decreases the size of the absorption system.
3. **Construction materials:** an important factor in the successful operation of any absorber is to initially select the proper construction materials. Quenching hot gases to their saturation temperatures forms corrosive acids. Depending on the substances present in the exhaust stream, sulfuric, hydrochloric, or hydrofluoric acids may be formed. The presence of these acids can cause severe corrosion problems unless special materials of construction are used.

**Absorption equipment.** Absorption equipment includes two major categories:

Wet absorption scrubber (or wet scrubber)

Dry absorption scrubber (or dry scrubber)

The description of the absorption equipment is provided in Chapter 3.3.

## 4.2 Adsorption for Gaseous Emission Control

During adsorption, one or more gaseous components are removed from an effluent gas stream by adhering to the surface of a solid. The gas molecules being removed are referred to as the *adsorbate*, while the solid doing the adsorbing is called the *adsorbent*. Adsorbents are highly porous particles. Adsorption occurs on the internal surfaces of the particles (EPA-81/12, p. 5-1).

The attractive forces which hold the gas to the surface of the solid are the same that cause vapors to condense (van der Waals' forces). All gas–solid interfaces exhibit this attraction, some more than others. Adsorption systems use materials that are highly attracted to each other to separate these gases from the non-adsorbing components of a gas stream. For air pollution control purposes, adsorption is not a final control process. The contaminant gas is merely stored on the surface of the adsorbent. After it becomes saturated with adsorbate, the adsorbent must either be disposed of and replaced, or the vapors must be desorbed. Desorbed vapors are highly concentrated and may be recovered more easily and more economically than before the adsorption step.

Traditionally, adsorption has been used for air purification and solvent recovery. Air purification processes are those in which the contaminant is present in trace quantities (less than 1.0 ppm) but is highly odorous or toxic. Systems used for air purification are small thin bed adsorbers. When the bed becomes saturated with contaminant, it is taken out and replaced. Solvent recovery processes require much larger systems and are usually designed to control organic emissions whose concentrations are greater than 1000 ppm. This has been the point where the recovery value of the solvent could justify the expense of the large adsorption–desorption system. Currently, adsorption is used as a method of recovering valuable organic vapors from flue gases at all concentration levels. This is due to present regulations limiting volatile organic emissions and the higher costs of solvents.

**Mechanism of adsorption.** Adsorption occurs by a series of three steps (EPA-81/12, p. 5-2):

- Step 1: The contaminant diffuses from the major body of the air stream to the external surface of the adsorbent particle.
- Step 2: The contaminant molecule migrates from the relatively small area of the external surface (a few  $\text{m}^2/\text{g}$ ) to the pores within each adsorbent particle. The bulk of adsorption occurs in these pores because the majority of available surface area is there (hundreds of  $\text{m}^2/\text{g}$ ).
- Step 3: The contaminant molecule adheres to the surface in the pore.

Figure 1.15 illustrates this overall diffusion and adsorption process. The purpose of analyzing the mechanism of adsorption is to determine which step controls the overall process. By analyzing each step, adsorber performance can be predicted from physical data. The actual adsorption of a molecule, step 3, proceeds relatively quickly compared to steps 1 or 2. Therefore, step 3 can be ignored when developing design equations. Steps 1 and 2 are both diffusional processes. They involve the transport of the adsorbate through a carrier gas phase to an adsorption site.

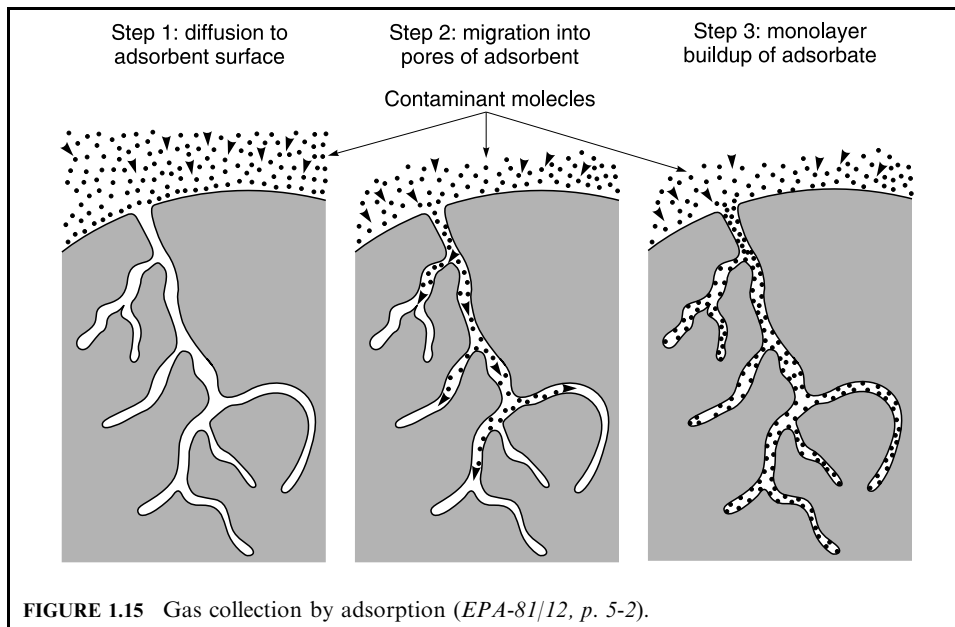

FIGURE 1.15 Gas collection by adsorption (EPA-81/12, p. 5-2).

**Adsorption forces—physical and chemical.** The adsorption process is classified as either *physical* or *chemical*. The basic difference between physical and chemical adsorption is the manner in which the gas molecule is bonded to the adsorbent. In physical adsorption, the gas molecule is bonded to the solid surface by weak forces of intermolecular cohesion. The chemical nature of the adsorbed gas remains unchanged; therefore, physical adsorption is a readily reversible process. In chemical adsorption a much stronger bond is formed between the gas molecule and adsorbent. A sharing or exchange of electrons takes place—as happens in a chemical bond. Chemical adsorption is not easily reversible.

**Physical adsorption:** The forces active in physical adsorption are electrostatic in nature. These forces are present in all states of matter: gas, liquid, and solid. They are the same forces of attraction which cause gases to condense and real gases to deviate from ideal behavior. This electrostatic force can be measured by the constant  $a$  in van der Waals' equation describing non-ideal gas behavior. Physical adsorption is sometimes also referred to as *van der Waals' adsorption*. The electrostatic effect which produces the van der Waals' forces depends on the polarity of both the gas and solid molecules. Molecules in any state are either polar or nonpolar depending on their chemical structure. *Polar substances* are those which exhibit a separation of positive and negative charges within the compound. This separation of positive and negative charges is referred to as a *permanent dipole*. Water is a prime example of a polar substance. Nonpolar substances have both their positive and negative charges in one center so they have no permanent dipole. Most organic compounds, because of their symmetry, are nonpolar.

**Chemical adsorption:** Chemical adsorption or chemisorption results from the chemical interaction between the gas and the solid. The gas is held to the surface of the adsorbent by the formation of a chemical bond. Adsorbents used in chemisorption can be either pure substances or chemicals deposited on an inert carrier material. One example is using pure iron oxide chips to adsorb  $H_2S$  gases. Another example is using activated carbon which has been impregnated with sulfur to remove mercury vapors.

All adsorption processes are exothermic, whether adsorption occurs from chemical or physical forces. In adsorption, molecules are transferred from the gas to the surface of a solid. The fast-moving gas molecules lose their kinetic energy of motion to the adsorbent in the form of heat.

**Adsorption equilibrium relationship.** Most available data on adsorption systems are determined at equilibrium conditions. Adsorption equilibrium is the set of conditions at which the number of molecules arriving on the surface of the adsorbent equals the number of molecules that are leaving. The adsorbent bed is said to be “saturated with vapors” and can remove no more vapors from the exhaust stream. Equilibrium determines the maximum amount of vapor that may be adsorbed at a given set of operating conditions. Although a number of variables affect adsorption, the two most important in determining equilibrium for a given system are temperature and pressure. Three types of equilibrium graphs are used to describe adsorption systems:

- Isotherm at constant temperature
- Isostere at constant amount of vapors adsorbed
- Isobar at constant pressure

*Isotherm:* The most common and useful adsorption equilibrium data is the adsorption isotherm. The isotherm is a plot of the adsorbent capacity versus the partial pressure of the adsorbate at a constant temperature. Adsorbent capacity is usually given in weight percent expressed as gram of adsorbate per 100 grams of adsorbent. Figure 1.16 is a typical example of an adsorption isotherm for carbon tetrachloride on activated carbon. Graphs of this type are used to estimate the size of adsorption systems as illustrated in Example 1 to follow.

*Isostere:* Two additional adsorption equilibrium relationships are the isostere and the isobar. The isostere is a plot of the  $\ln(p)$  versus  $1/T$  at a constant amount of vapor adsorbed. Adsorption isostere lines are usually straight for most adsorbate–adsorbent systems. Figure 1.17 is an adsorption isostere graph for the adsorption of  $H_2S$  gas onto molecular sieves. The isostere is important in that the slope of the isostere corresponds to the heat of adsorption.

*Isobar:* The isobar is a plot of the amount of vapors adsorbed versus temperature at a constant pressure. Figure 1.18 shows an isobar line for the adsorption of benzene vapors on activated carbon. Note that the amount adsorbed decreases with increasing temperature, which is always the case for physical adsorption.

Since these three relationships were developed at equilibrium conditions, they depend on each other. By determining one, such as the isotherm, the other two relationships can be determined for a given system. In the design of a pollution control system, the adsorption isotherm is by far the most commonly used equilibrium relationship.

**EXAMPLE 1:** adsorption

A dry cleaning process exhausts a 15,000 scfm air stream containing 680 ppm carbon tetrachloride. Using Fig. 1.16 and assuming the exhaust stream is at approximately 140°F and 14.7 psia, determine the saturation capacity of the carbon (EPA-81/12, p. 5-8).

*Solution:*

In the gas phase, the mole fraction  $Y$  is equal to the percent by volume:

$$\begin{aligned}
 Y &= \% \text{volume} = 680 \text{ ppm} \\
 &= 680 / (10^6) \\
 &= 0.00068
 \end{aligned}$$

Obtain the partial pressure:

$$\begin{aligned}
 p &= YP \\
 &= (0.00068)(14.7 \text{ psia}) \\
 &= 0.01 \text{ psia}
 \end{aligned}$$

From Fig. 1.16, at a partial pressure of 0.01 psia and a temperature of 140°F, the carbon capacity is read as 30%. This means that at saturation, 30 lb of vapor are removed per 100 lb of carbon in the adsorber (30 kg/100 kg).

**EXAMPLE 2:** adsorption

Assume the same conditions as stated above in Example 1. Estimate the amount of carbon that would be required if the adsorber were to operate on a 4-hour cycle. The molecular weight of  $\text{CCl}_4$  is 154 lb/lb-mole (EPA-81/12, p. 5-18).

*Solution:*

From Example 1 we know that the carbon used will remove 30 lb of vapor for every 100 lb of carbon at saturation conditions.

First compute the flow rate of  $\text{CCl}_4$ :

$$Q(\text{CCl}_4) = 15,000 \text{ scfm} \times 0.00068 = 10.2 \text{ scfm } \text{CCl}_4$$

Converting to pounds per hour:

$$10.2 \text{ (ft}^3/\text{min)} \times (\text{lb-mole})/(359 \text{ ft}^3) \times (154 \text{ lb})/(\text{lb-mole}) \times (60 \text{ min})/\text{h} = 262.5 \text{ lb-CCl}_4/\text{h}$$

The amount of carbon (at saturation) required (assuming that the working charge is twice the saturation capacity):

$$2(3500) = 7000 \text{ lb (3182 kg) carbon per 4-hour cycle per adsorber}$$

*Note:* This gives only a rough estimate of the amount of carbon needed.

**Adsorbent materials.** Adsorbents are characterized by their chemical nature, extent of their surface area, pore size distribution, and particle size. In physical adsorption, the most important characteristic in distinguishing between adsorbents is their surface polarity. The surface polarity determines the type of vapors a particular adsorbent will have the greatest affinity for (EPA-81/12, p. 5-12).

Several materials are used effectively as adsorbing agents. The most common adsorbents used industrially are

- activated carbon
- silica gel
- molecular sieves
- activated alumina (aluminum oxide)

Of the above adsorbents, activated carbon is the primary nonpolar adsorbent. It is possible to manufacture other adsorbing material having nonpolar surfaces. Since their surface area is much less than that of activated carbon, they are not used commercially. Polar adsorbents will preferentially adsorb any water vapor that may be present in a gas stream. Since moisture is present in most polluted gas streams, the use of polar adsorbents is severely limited for an air pollution system.

*Activated carbon:* Activated carbon can be produced from a variety of feedstocks such as wood, coal, coconut, nutshells, and petroleum-based products. The activation process takes place in two steps.

- First, the feedstock is carbonized. Carbonization involves heating (usually in the absence of air) the material to a temperature high enough ( $600^\circ\text{C}$ ) to drive off all volatile material. Thus, carbon is essentially all that is left. To increase the surface area, the carbon is then activated by using steam, air, or carbon dioxide at higher temperatures. These gases attack the carbon and increase the pore structure. The temperature involved, the amount of oxygen present, and the type of feedstock, all greatly affect the adsorption qualities of the carbon.
- Because of its nonpolar surface, activated carbon is used to control emission of organic solvents, odors, toxic gases, and gasoline vapors. Carbons used in gas phase adsorption systems are manufactured in granular form, usually between  $4 \times 6$  to  $4 \times 20$  mesh in size. Bulk density of the packed bed can range from  $0.08$  to  $0.5 \text{ g/cm}^3$  ( $5$  to  $30 \text{ lb/ft}^3$ ) depending on the internal porosity of the carbon. Surface area of the carbon can range from  $600$  to  $1600 \text{ m}^2/\text{g}$  ( $2.9 \times 10^6$  to  $7.8 \times 10^6 \text{ ft}^2/\text{lb}$ ).

*Silica gel:* Silica gels are made from sodium silicate. Sodium silicate is mixed with sulfuric acid, resulting in a jelly-like precipitant from where the gel name comes. The precipitant is then dried and roasted. Depending on the processes used in manufacturing the gel, different grades varying in activity can be produced. Silica gels have surface areas of approximately  $750 \text{ m}^2/\text{g}$  ( $3.7 \times 10^6 \text{ ft}^2/\text{lb}$ ). Silica gels are used primarily to remove moisture from exhaust streams, but are ineffective at temperatures above  $260^\circ\text{C}$  ( $500^\circ\text{F}$ ).

*Molecular sieves:* Unlike the other adsorbents, which are amorphous (not crystalline) in nature, molecular sieves have a crystalline structure. The pores are, therefore, uniform in diameter. Molecular sieves can be used to capture or separate gases on the basis of molecular size and shape. An example of this are refining processes which sometimes use molecular sieves to separate straight-chained paraffins from branched and cyclic compounds. However, the main use of molecular sieves is in the removal of moisture from exhaust streams. The surface area of molecular sieves range from  $600$  to  $700 \text{ m}^2/\text{g}$  ( $2.9 \times 10^6$  to  $3.4 \times 10^6 \text{ ft}^2/\text{lb}$ ).

*Aluminum oxide (activated alumina):* Aluminum oxides are manufactured by thermally activating alumina or bauxite. This is accomplished by heating the alumina in an inert atmosphere to produce a porous aluminum oxide pellet. Aluminum oxides are not commonly used in air pollution applications. They are primarily used for the drying of gases, especially under high pressures, and as support material in catalytic reactions. A prime example is the impregnating of the alumina with platinum or palladium for use in catalytic incineration. Activated alumina's surface areas can range from  $200$  to  $300 \text{ m}^2/\text{g}$  ( $0.98 \times 10^6$  to  $1.5 \times 10^6 \text{ ft}^2/\text{lb}$ ).

**Factors affecting adsorption performance.** A number of factors or system variables influence the performance of an adsorption system. These variables and their effects on the adsorption process are discussed in turn (EPA-81/12, p. 5-18).

- Temperature
- Pressure
- Gas velocity
- Bed depth
- Humidity
- Contaminants

*Temperature:* For physical adsorption processes, the capacity of an adsorbent decreases as the temperature of the system increases. As the temperature increases the vapor pressure of the adsorbate increases, raising the energy level of the adsorbed molecules. Adsorbed molecules now have sufficient energy to overcome the van der Waals' attraction and migrate back to the gas phase. Molecules already in the gas phase tend to stay there due to their high vapor pressure. As a general rule, adsorber temperatures are kept below  $55^\circ\text{C}$  ( $130^\circ\text{F}$ ) to ensure adequate bed capacities. Temperatures above this limit can be avoided by cooling the exhaust stream that is to be treated.

*Pressure:* Adsorption capacity increases with an increase in the partial pressure of the vapor. The partial pressure of a vapor is proportional to the total pressure of the system. Any increase in pressure will increase the adsorption capacity of a system. The increase in capacity occurs because of a decrease in the mean free path of vapors at higher pressures: simply, the molecules are packed more tightly together. More molecules have a chance to hit the available adsorption sites, increasing the number of molecules adsorbed.

*Gas velocity:* The contact or residence time between the contaminant stream and adsorbent is determined by the gas velocity through the adsorber. The residence time directly affects capture efficiency. The slower the contaminant stream flows through the adsorbent bed, the greater the probability of a contaminant molecule hitting an available site. Once a molecule has been captured it will stay on the surface until the physical conditions of the system are changed. To achieve  $90\% +$  capture efficiency, most carbon adsorption stems are designed for

a maximum gas flow velocity of 30 m/min (100 ft/min) through the adsorber. A lower limit of at least 6 m/min (20 ft/min) is maintained to avoid flow distribution problems, such as channeling.

*Bed depth:* Providing a sufficient depth of adsorbent is very important in achieving efficient gas removal. If the adsorber bed depth is shorter than the required mass transfer zone, breakthrough will immediately occur rendering the system ineffective. Computing the length of the mass transfer zone (MTZ) is very difficult since it depends upon six factors:

- adsorbent particle size
- gas velocity
- adsorbate concentration
- fluid properties of the gas stream
- temperature
- pressure

The relationship between breakthrough capacity and MTZ is

$$C_B = [0.5C_s(\text{MTZ}) + C_s(D - \text{MTZ})]/D$$

where  $C_B$  = breakthrough capacity  
 $C_s$  = saturation capacity  
 MTZ = mass transfer zone length  
 $D$  = adsorption bed depth

The above equation is used mainly as a check to ensure that the proposed bed depth is longer than the MTZ. Actual bed depths are usually many times longer than the length of the MTZ. The additional bed depth allows for adequate cycle times.

The total amount of adsorbent required is usually determined from the adsorption isotherm, as illustrated in Example 2. Once this has been set, the bed depth can then be estimated by knowing the tower diameter and density of the adsorbent. Example 3 illustrates how this is done. Generally, the adsorbent bed is sized to the maximum length allowed by the pressure drop across the bed.

*Humidity:* As stated previously, activated carbon will preferentially adsorb nonpolar hydrocarbons over polar water vapor. The water vapor molecules in the exhaust stream exhibit strong attractions for each other rather than the adsorbent. At high relative humidity, over 50%, the number of water molecules increases such that they begin to compete with the hydrocarbon molecules for active adsorption sites. This reduces the capacity and the efficiency of the adsorption system. Exhaust streams with humidity greater than 50% may require installation of additional equipment to remove some of the moisture. Coolers to remove the water are one solution. Dilution air with significantly less moisture in it than the process stream has also been used. Also, the contaminant stream may be heated to reduce the humidity as long as the increase in temperature does not greatly affect adsorption efficiency.

*Contaminants:* In addition to humidity, particulate matter, entrained liquid droplets, and organic compounds that have high boiling points can also reduce adsorber efficiency if present in the air stream. Any micron-sized particle of dust or lint which is not filtered can cover the surface of the adsorbent. This greatly reduces the surface area of the adsorbent available to the gas molecule for adsorption. Covering of active adsorption sites by an inert material is referred to as *blinding or deactivation*. To avoid this situation almost all industrial adsorption systems are equipped with some type of particulate removal device.

Entrained liquid droplets can also cause operational problems. Liquid droplets that are non-adsorbing act the same as particulate matter. The liquid covers the surface, blinding the bed. If the liquid is the same as the adsorbate, high heats of adsorption occur. This is especially a problem in activated carbon systems where liquid organic droplets carried over from the

process can cause bed fires from the heat released. Some type of entrainment separator may be required when liquid droplets are present.

**Adsorption equipment.** Adsorption control systems are summarized in Table 1.8.

*Non-regenerable adsorption system.* Non-regenerable systems are normally used to control exhaust streams with low pollutant concentrations, below 1.0 ppm. Generally these pollutants are highly odorous or to some degree toxic. When these systems reach the breakthrough point the bed is taken off-stream and replaced with a fresh bed. The used carbon can then be sent back to the manufacturer for reactivation (EPA-81/12, p. 5-26).

Non-regenerable adsorption systems are manufactured in a variety of configurations. Bed areas are sized to control the gas flow through them at between 6.0 and 18 m/min (20 and 60 ft/min). They usually consist of thin adsorbent bed depth, ranging in thickness from 1.25 to 10.0 cm (0.5 to 4.0 in). These thin beds have a low pressure drop, normally below 62 Pa (0.25 in H<sub>2</sub>O), dependent on the bed thickness, gas velocity, and particle size of the adsorbent. Service time for these units can range from 6 months for heavy odor concentrations to up to 2 years for trace concentrations or intermittent operations. They are used mainly as air-purification devices for small air flows in offices, laboratory exhausts, and other small exhaust streams (EPA-81/12, p. 5-26).

The shapes of these thin bed adsorbers are

- Flat adsorber
- Pleated adsorber
- Cylindrical adsorber
- Canister adsorber

The granules of activated carbon are retained by porous support materials, usually perforated sheet metals. An adsorber system usually consists of a number of retainers or panels placed in one frame.

*Flat adsorber:* Figure 1.19 shows a nine-cell thin bed adsorber. The panels are similar to home air filters except that instead of containing steel wool they contain activated carbon as the filter. Flat panel beds are sized to handle higher exhaust flow rates, approximately 9.4 m<sup>3</sup>/s (20,000 cfm).

*Pleated cell adsorber:* Figure 1.20 illustrates a pleated cell adsorber. The pleated cell is one continuous retainer of activated carbon, rather than individual panels. Panel and pleated beds are dimensionally about the same size, normally 0.6 m<sup>2</sup> (2.5 ft × 2.5 ft) with the carbon depth ranging from 0.2 to 0.6 m (8 in to 2 ft). Pleated beds are limited to flow rates of approximately 4.7 m<sup>3</sup>/s (10,000 cfm).

*Cylindrical adsorber:* Figure 1.21 illustrates a cylindrical adsorber. It is usually a small unit designed to handle low flow rates of approximately 0.12 m<sup>3</sup>/s (250 cfm). Cylindrical adsorbers

**TABLE 1.8** Gaseous Adsorption Control Systems

Adsorption process	Control equipment
1. Non-regenerable adsorption system	1.1 Flat adsorber
	1.2 Cylindrical adsorber
	1.3 Pleated adsorber
	1.4 Canister adsorber
2. Regenerable adsorption system	2.1 Fixed bed adsorber
	2.2 Moving bed adsorber
	2.3 Fluidized bed adsorber

FIGURE 1.19 Non-regenerable flat adsorber (EPA-81/12, p. 5-27).

are made of the same materials as the panel and pleated adsorbers except their shape is round rather than square.

*Canister absorber:* Figure 1.22 illustrates a canister absorber. The unit that can be used is essentially just a 55-gallon drum. The bottom of the drum is filled with gravel to support a bed of activated carbon weighing approximately 150 kg (330 lb). These units are used to treat small flow rates (0.5 m<sup>3</sup>/s or 100 cfm) from laboratory hoods, chemical storage tank vents, and chemical reactors.

*Regenerable adsorption system.* Regenerable systems are used for higher pollutant concentrations, such as in solvent recovery operations. Once the bed reaches the breakthrough

FIGURE 1.20 Non-regenerable pleated thin adsorber (EPA-81/12, p. 5-28).

FIGURE 1.21 Non-regenerable cylindrical adsorber (EPA-81/12, p. 5-28).

point in a regenerable system, the pollutant vapors are directed to a second bed while the first has the vapors desorbed (EPA-81/12, p. 5-26).

A large regenerable adsorption system can be categorized as

- Fixed bed system
- Moving bed system
- Fluidized bed system

The name refers to the manner in which the vapor stream and adsorbent are brought into contact. The choice of a particular system depends on the pollutants to be controlled and the recovery requirements. The most common adsorption system for controlling air pollutants is the fixed carbon bed. These systems are used to control a variety of organic vapors and are

FIGURE 1.22 Non-regenerable canister adsorber (EPA-81/12, p. 5-29).

usually regenerated by direct steaming of the bed. The organic compounds may be recovered by condensing the exhaust from the regeneration step and separating out the water and solvent.

Figure 1.23 shows a typical three fixed bed regenerable adsorber. Fixed bed adsorption systems generally involve multiple beds. One or more beds treat the process exhaust while the other beds are either being regenerated or cooled. The solvent-laden air stream is first pre-treated to remove any solid or liquid particles that could blind the carbon bed and decrease its efficiency. The solvent-laden air stream then usually passes down through the fixed carbon bed. Upward flow through the bed is usually avoided (unless flow rates are low ( $< 500$  cfm) to eliminate the risk of entraining carbon particles in the exhaust stream).

After a predetermined length of time, referred to as the *cycle time*, the solvent-laden air stream is directed to the second adsorber by a series of valves. Steam is then injected into the first bed to remove the adsorbed vapors. The steam and desorbed vapors are then usually sent to a recovery system. If the solvents are immiscible in water, they can be separated by condensing the exhaust and decanting off the solvent. If the solvents are miscible in water, distillation may be required. Before the first adsorber is returned to service, cooling and drying of the carbon should be provided. This will ensure against immediate breakthrough occurring from the 'hot, wet' carbon bed. This can be accomplished by venting the solvent-laden air stream through the hot, wet adsorber, then to the on-line adsorber to maintain a high removal efficiency.

Regenerable fixed carbon beds are usually between 0.3 and 1.2 m (1 and 4 ft) thick. The maximum adsorbent depth of 1.2 m is based on pressure drop considerations. Superficial gas velocities through the adsorber range from 6.0 to 30.0 m/min (20 to 100 ft/min) with 30.0 m/min being a maximum permissible flow rate. Pressure drops normally range from 750 to 3730 Pa (3 to 15 in  $H_2O$ ) depending on the gas velocity, bed depth and carbon particle size.

FIGURE 1.23 Regenerable three fixed bed adsorber (EPA-81/12, p. 5-30).

**EXAMPLE 3:** sizing adsorber

A solvent degreaser is designed to recover toluene from a 3.78 m<sup>3</sup>/s (8000 acfm) air stream at 25°C (77°F) and atmospheric pressure. The company is planning to use a two-bed carbon adsorption system with a cycle time of 4 hours. The maximum concentration of toluene is kept below 50% of the lower explosive limit (LEL) for safety purposes. Using Fig. 1.24, the adsorption isotherm for toluene, and the additional operational data, estimate (EPA-81/12, p. 5-38):

1. The amount of carbon required for a 4-hour cycle
2. Square feet of surface area required based on a 0.508 m/s (100 fpm) maximum velocity
3. Depth of the carbon bed

**Given conditions**

- LEL for toluene = 1.2%
- molecular weight of toluene = 92.1 kg/kg-mol
- carbon density = 480 kg/m<sup>3</sup> (30 lb/ft<sup>3</sup>)

*Solution:*

1. To compute amount of carbon required, first, calculate the toluene flow rate.

$$(3.78 \text{ m}^3/\text{s})(50\%)(1.2\%) = 0.023 \text{ m}^3/\text{s toluene}$$

To determine the saturation capacity of the carbon, calculate the partial pressure of toluene at the adsorption conditions.

$$\begin{aligned} p &= YP \\ &= (0.023/3.78)(14.7 \text{ psia}) \\ &= 0.089 \text{ psia} \end{aligned}$$

FIGURE 1.24 Adsorption isotherm for toluene (EPA-81/05, p. 18-9).

At 0.089 psia and 77°F, from Fig. 1.24 the saturation capacity of the carbon is 40% or 40 kg toluene per 100 kg of carbon.

The flow rate of toluene is

$$\begin{aligned} & (0.023 \text{ m}^3/\text{s}) \times (\text{kg-mol}/22.4 \text{ m}^3) \times (273 \text{ K}/350 \text{ K}) \times (92.1 \text{ kg/kg-mol}) \\ & = 0.074 \text{ kg/s of toluene} \end{aligned}$$

The amount of carbon at saturation for a 4-hour cycle is:

$$\begin{aligned} & (0.074 \text{ kg/s toluene}) \times (100 \text{ kg carbon}/40 \text{ kg toluene}) \times (3600 \text{ s/h}) \times (4 \text{ h}) \\ & = 2664 \text{ kg of carbon} \end{aligned}$$

The working charge of carbon can be estimated by doubling the saturation capacity. Therefore,

$$\begin{aligned} \text{working charge} & = (2)(2664 \text{ kg of carbon}) \\ & = 5328 \text{ kg of carbon} \end{aligned}$$

2. The square feet of superficial surface area is the surface area set by the maximum velocity of 0.508 m/s (100 fpm) through the adsorber.

The required surface area is

$$\begin{aligned} A & = Q/(\text{maximum velocity}) \\ & = (3.78 \text{ m}^3/\text{s})/(0.508 \text{ m/s}) \\ & = 7.44 \text{ m}^2 \end{aligned}$$

For a horizontal flow adsorber this would correspond to a vessel approximately 2 m (6.6 ft) in width and 4 m (13.1 ft) in length to give 8.0 m<sup>2</sup> (87 ft<sup>2</sup>) surface area. This would supply more than the required area.

The flow rate is too high to be handled by a single vertical flow adsorber. An alternative would be to use three vessels, two adsorbing while one is being regenerated. Each vessel then must be sized to handle 1.89 m<sup>3</sup>/s (4000 acfm). The area required for a limiting velocity of 0.508 m/s is

$$\begin{aligned} \text{Area to handle half flow } A & = (1.89 \text{ m}^3/\text{s})/(0.508 \text{ m/s}) \\ & = 3.72 \text{ m}^2 \end{aligned}$$

This cross-sectional area corresponds to a vessel diameter of

$$\begin{aligned} d & = (4A/\pi)^{0.5} \\ & = [4(3.72)/\pi]^{0.5} \\ & = 2.18 \text{ m (7 ft)} \end{aligned}$$

3. The volume that the carbon would occupy in the horizontal bed system is

$$\begin{aligned} \text{Volume of carbon} & = \text{weight/density} \\ & = 5328 \text{ kg} \times (\text{m}^3/480 \text{ kg}) \\ & = 11.1 \text{ m}^3 \end{aligned}$$

*Note:* for the three-bed vertical system, the volume of each bed would be half this or 5.55 m<sup>3</sup>.

4. The depth of carbon for the horizontal bed is given by

$$\begin{aligned}\text{Depth of carbon} &= (\text{volume of carbon})/(\text{cross-sectional area of adsorber}) \\ &= (11.1 \text{ m}^3)/(7.44 \text{ m}^2) \\ &= 1.49 \text{ m}\end{aligned}$$

*Note:* the depth for the three-bed vertical system is the same, since both the volume and area are halved.

The above solution is based on a number of adsorber design maximum and minimum rules of thumb. It is intended as a guide to illustrate how to 'red flag' any parameters which may be greatly exceeded.

**EXAMPLE 4:** adsorption working capacity

You are to calculate the working capacity of an adsorption bed given the saturation (equilibrium) capacity, mass transfer zone, and heel (EPA-84/09, p. 110).

**Given conditions**

depth of adsorption bed = 3 ft

saturation capacity = 39%

MTZ = 4 in

heel = 2.5% = amount remaining on the adsorbent following regeneration

*Solution:*

1. Calculate the breakthrough capacity.

The breakthrough capacity is the capacity when traces of the contaminant first begin to appear in the exit gas stream from an adsorption bed.

$$C_B = [0.5C_s(\text{MTZ}) + C_s(D - \text{MTZ})]/D$$

where  $C_B$  = breakthrough capacity

$C_s$  = saturation capacity

MTZ = mass transfer zone length

$D$  = adsorption bed depth

Breakthrough capacity,

$$\begin{aligned}C_B &= [0.5C_s(\text{MTZ}) + C_s(D - \text{MTZ})]/D \\ &= [(0.5)(0.39)(4) + (0.39)(36 - 4)]/36 \\ &= 0.368 \\ &= 36.8\%\end{aligned}$$

2. Calculate the working capacity.

The working capacity is lower than the saturation capacity or the breakthrough capacity. It results from unrecoverable solvent in the carbon and occasionally from a lower packing factor than laboratory specifications.

$$\text{Working capacity} = (\text{breakthrough capacity}) - (\text{heel}) - (\text{packing factor})$$

Neglect the packing factor for this calculation.

$$\text{Working capacity} = 36.8 - 2.5 = 34.3\%$$

**EXAMPLE 5:** adsorption–degreaser ventilation clean up

You are asked to determine the required height of adsorbent for an adsorber which treats a degreaser ventilation stream contaminated with trichloroethylene (TCE) given the following operating and design data (EPA-84/09, p. 112).

**Given conditions**

volumetric flow rate of contaminated air stream = 10,000 scfm

standard conditions = 60°F, 1 atm

operating temperature = 70°F

operating pressure = 20 psia

adsorbent = activated carbon

bulk density of activated carbon = 36 lb/ft<sup>3</sup>

working capacity of activated carbon = 28 lb TCE/100 lb carbon

inlet concentration of TCE = 2000 ppm (by volume)

molecular weight of TCE = 131.5

the adsorption column cycle is set at 4 hours in the adsorption mode, 2 hours in heating and desorbing, 1 hour in cooling, and 1 hour in stand-by

the adsorber recovers 99.5% by weight of TCE

a horizontal unit with a width of 6 ft and length of 15 ft is used.

*Solution:*

1. What is the volume of activated carbon required to treat the contaminated gas stream?

Since the dimensions of the adsorber are known, you only need the volume of activated carbon to calculate the height of adsorbent (activated carbon).

1.a. What is the mass of TCE to be adsorbed during a 4 hour period?

1.a.1. Calculate the actual volumetric flow rate of contaminated gas stream in acfh?

$$Q_a/Q_s = T_a/T_s$$

where  $Q_a$  = actual volumetric flow rate

$Q_s$  = standard volumetric flow rate

$T_a$  = actual operating temperature in °R or K

$T_s$  = standard operating temperature in °R or K

$$\begin{aligned} Q_a &= Q_s(T_a/T_s)(P_s/P_a) \\ &= 10,000[(70 + 460)/(60 + 460)][(14.7)/(20)] \\ &= 7491 \text{ acfm} \\ &= 4.5 \times 10^5 \text{ acfh} \end{aligned}$$

1.a.2. Calculate the volumetric flow rate of TCE in acfh?

$$Q_{\text{TCE}} = (y_{\text{TCE}})(Q_a)$$

where  $Q_{\text{TCE}}$  = volumetric flow rate of TCE

$y_{\text{TCE}}$  = inlet concentration of TCE

$Q_a$  = actual volumetric flow rate

$$\begin{aligned} Q_{\text{TCE}} &= (y_{\text{TCE}})(Q_a) \\ &= (2000 \times 10^{-6})(4.5 \times 10^5) \\ &= 900 \text{ acfh} \end{aligned}$$

1.a.3. Calculate the mass flow rate of TCE  $m_r$ , in lb/hour?

From the ideal gas equation,

$$\rho = PM/R_u T$$

$$m_r = Q\rho = Q(PM/R_u T)$$

where  $\rho$  = density  
 $P$  = pressure  
 $M$  = molecular weight  
 $R_u$  = universal gas constant = 10.73 (psia-ft<sup>3</sup>)/(lb-mole-°R)  
 $T$  = absolute temperature  
 $Q$  = volumetric flow rate (ft<sup>3</sup>/h)  
 $m_r$  = mass flow rate (lb/h)

$$m_r = Q\rho = Q(PM/R_u T)$$

$$= (900)(20)(131.5)/(10.73)(70 + 460)$$

$$= 416.2 \text{ lb/h}$$

1.a.4. Calculate the mass of TCE to be adsorbed during the 4 hour period?

$$\text{TCE adsorbed} = m_r(0.995)(4)$$

$$= (416.2)(0.995)(4)$$

$$= 1656.6 \text{ lb}$$

1.b. What is the volume of activated carbon required in ft<sup>3</sup>?

$$\text{Activated carbon required} = (\text{TCE to be adsorbed})/[(\text{bulk density})(\text{ads cap. of carbon})]$$

$$= (\text{TCE to be adsorbed})/$$

$$[(28 \text{ lb TCE})/(100 \text{ lb carbon})(\text{bulk density})]$$

$$= (1656.6)(100/28)/(36)$$

$$= 164 \text{ ft}^3$$

2. What is the height of adsorbent in ft?

$$\text{Height actual of adsorbent} = (\text{actual carbon volume})/(\text{cross-sectional area})$$

$$= (164)/(6)(15)$$

$$= 1.83 \text{ ft}$$

**EXAMPLE 6:** adsorption—plan review

The permit to construct a solvent recovery plant which recovers acetone from a contaminated air stream with three adsorbers has been applied for (Fig. 1.25) and you are asked to review the plans for the adsorption system. In reviewing these plans you should check the time to run each adsorber to breakthrough and the amount of steam required to regenerate the adsorbent (EPA-84/09, p. 114).

Information given in the permit application

1. Volumetric flow rate of contaminated air stream = 30,000 acfm at 1 atm
2. Temperature of contaminated air stream = 20°C
3. Molecular weight of acetone = 58

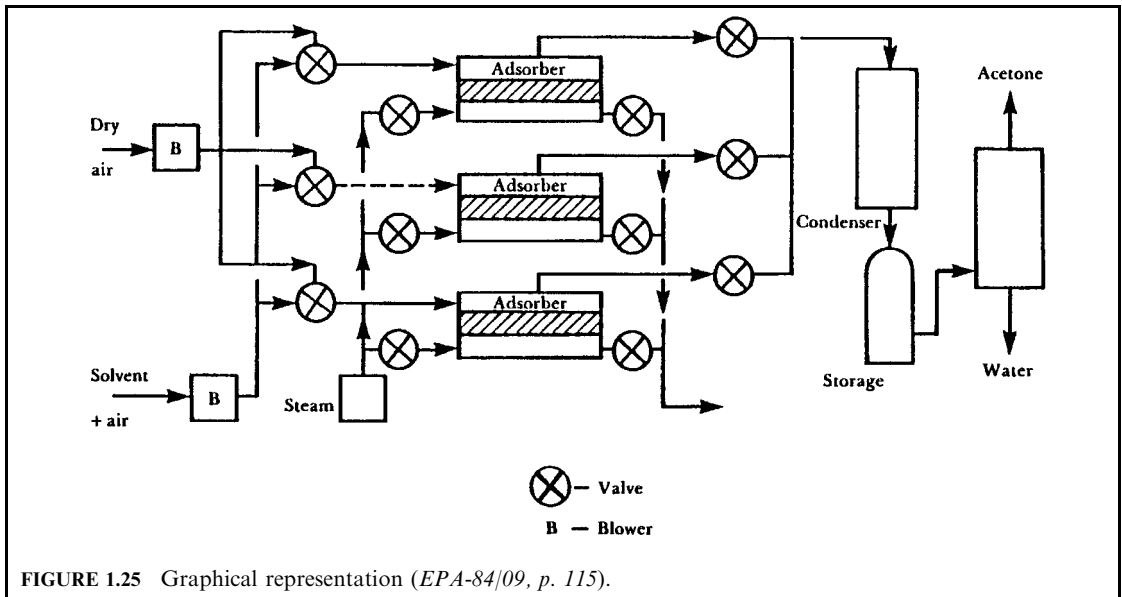

FIGURE 1.25 Graphical representation (EPA-84/09, p. 115).

4. Composition of acetone in air stream = 0.15 mole%
5. Carbon type; charge per adsorber = B, 4 × 6 mesh; 15,000 lb
6. Heel = 2 wt %
7. Packing factor (capacity correction due to different packing) = 3 wt %
8. Adsorber dimensions = 10 ft by 24 ft
9. Adsorption bed depth = 1.96 ft
10. Vapor pressure of acetone at 20°C = 170 mmHg
11. MTZ length = 2 inches
12. Figure 1.26 (% relative saturation)
13. Figure 1.27 (steam requirement)
14. Two of the three adsorbers are in the adsorption phase at all times. The plant operates 24 hours a day and 365 days a year. Plant steam is available at 5 psig.

*Solution:*

1. What is the adsorption time per adsorber bed?
- 1.a. What is the working capacity of the activated carbon (carbon B)?

The working capacity of the carbon is lower than the saturation capacity or the break-through capacity and results from unrecoverable solvent in the carbon and from a lower packing factor than laboratory specifications. Based on experience, the unrecoverable solvent, or heel, is 2 wt % and the lower capacity due to the lower packing factor is estimated to be 3 wt %.

- 1.a.1. Calculate the relative saturation of acetone in the air stream.

$$\text{Percent relative saturation} = \frac{(\text{partial pressure of acetone in air})}{(\text{vapor pressure of acetone at } 20^{\circ}\text{C})}$$

FIGURE 1.26 Saturation capacity vs. relative saturation (EPA-84/09, p. 116).

The partial pressure of acetone in air is equal to the product of acetone mole fraction and atmospheric pressure.

$$\begin{aligned}
 \text{Percent relative saturation} &= \frac{(\text{mole fraction})(\text{air pressure})}{(\text{vapor pressure of acetone at } 20^{\circ}\text{C})}(100) \\
 &= \frac{(0.0015)(760)}{(170)}(100) \\
 &= 0.67\%
 \end{aligned}$$

1.a.2. Determine the saturation capacity of carbon B and  $C_s$  for acetone from Fig. 1.26 using the percent relative saturation calculated above.

From Fig. 1.26, saturation capacity = 23 wt %

1.a.3. Calculate the breakthrough capacity in wt %.

$$C_B = [0.5C_s(\text{MTZ}) + C_s(D - \text{MTZ})]/D$$

- where  $C_B$  = breakthrough capacity  
 $C_s$  = saturation capacity  
 MTZ = mass transfer zone length  
 $D$  = adsorption bed depth

The breakthrough capacity is the capacity when traces of acetone begin to appear in the exit gas stream.

$$\begin{aligned} \text{Breakthrough capacity} &= [(0.5)(0.23)(2/12) + (0.23)(1.96 - (2/12))]/1.96 \\ &= 0.22 \\ &= 22 \text{ wt \%} \end{aligned}$$

1.a.4. Calculate the working capacity of the carbon B in wt %.

$$\begin{aligned} \text{Working capacity} &= (\text{breakthrough capacity}) - \text{heel} - (\text{packing factor}) \\ &= 22 - 2 - 3 \\ &= 17 \text{ wt \%} \end{aligned}$$

1.b. Calculate the mass flow rate of acetone  $m_f$ .

1.b.1. Calculate the volumetric flow rate of acetone,  $Q$ , in acfm.

$$\begin{aligned} Q &= (\text{mole fraction of acetone})(\text{volumetric flow rate of air}) \\ &= (0.0015)(30,000) \\ &= 45 \text{ acfm} \end{aligned}$$

1.b.2. Calculate the mass flow rate,  $m_r$ , in lb/min.

From the ideal gas equation,

$$\rho = PM/R_u T$$

$$m_r = Q\rho = Q(PM/R_u T)$$

where  $\rho$  = density  
 $P$  = pressure  
 $M$  = molecular weight  
 $R_u$  = universal gas constant = 0.73 (atm-ft<sup>3</sup>)/(lb-mole-°R)  
 $T$  = absolute temperature  
 $Q$  = volumetric flow rate (ft<sup>3</sup>/h)  
 $m_r$  = mass flow rate (lb/h)

$$m_r = Q(PM/R_u T)$$

$$= (45)(1)(58)/(0.73)(68 + 460)$$

$$= 6.77 \text{ lb/min}$$

1.c. Calculate the adsorption time in minutes for each adsorption bed (time for breakthrough).

$$\text{Adsorption time} = (\text{carbon charge})(\text{working capacity})/[0.5(\text{mass flow rate, } m_r)]$$

*Note:* two adsorbers are on stream with each cleaning one-half of the total gas stream.

$$\text{Adsorption time} = (\text{carbon charge})(\text{working capacity})/(0.5m_r)$$

$$= (15,000)(0.17)/(0.5)(6.77)$$

$$= 753 \text{ min}$$

or

$$= 12 \text{ h } 33 \text{ min}$$

1.d. Calculate the regeneration time in hours to complete the total cycle.

The regeneration time should be less than one-half of the time for breakthrough.

$$\text{Regeneration time} = 6 \text{ h } 16.5 \text{ min}$$

2. What is the amount of steam required?

2.a. Determine the steam requirement for carbon B in lb steam/lb solvent removed using the working capacity calculated above and Fig. 1.27.

This is commonly referred to as the steam-to-solvent ratio.

From Fig. 1.27,

$$\text{Steam requirement} = 2.4 \text{ lb steam/lb solvent removed}$$

2.b. Calculate the lbs of steam required for each adsorber during regeneration.

$$\text{Mass of steam} = (\text{steam requirement})(\text{working capacity})(\text{carbon charge})$$

$$= (2.4)(0.17)(15,000)$$

$$= 6120 \text{ lb steam}$$

**EXAMPLE 7:** rotogravure printing adsorber

A printing company must reduce the amount of toluene they emit from their printing operation. The company comes in with some preliminary information on installing a carbon adsorption system. You are given the following information (EPA-81/05, p. 18-5):

- air flow is 20,000 cfm
- they operate at 25% of LEL for toluene in the exit air
- LEL for toluene is 1.2%
- toluene MW is 92.1 lb/lb mole
- carbon density is 30 lb/ft<sup>3</sup>
- working charge (or working capacity) is 30% of saturation capacity
- regeneration is just under 1 hour
- temperature is 77°F
- maximum velocity through adsorber is 100 fpm
- refer to Fig. 1.24.

Determine the minimum size of adsorber that you would approve:

1. Diameter of the adsorber
2. Square feet of carbon face area
3. Depth of bed

*Solution:*

(*Note:* all amounts are based on 1 hour because desorption takes only 1 hour)

1. Amount of carbon needed.

First, calculate amount of toluene emitted per hour.

$$\begin{aligned} (20,000 \text{ cfm})(25\%)(1.2\%) &= 60 \text{ cfm of toluene} \\ (60 \text{ scf}) \times (\text{lb mole}) / (359 \text{ scf}) \times (492^\circ\text{R} / 537^\circ\text{R}) \times (92.1 \text{ lb/lb mole}) \times (60 \text{ min/h}) \\ &= 846 \text{ lb/h} \end{aligned}$$

In order to compute saturation capacity from Fig. 1.24, we need the partial pressure of toluene.

$$\begin{aligned} p &= (60 \text{ cfm} / 20,000 \text{ cfm})(14.7 \text{ psia}) \\ &= 0.044 \text{ psia} \end{aligned}$$

saturation capacity = 38% from Fig 1.24

working capacity is 30% of saturation

$$\begin{aligned} \text{w.c.} &= (38\%)(30\%) \\ &= 11.4\% \text{ or } 11.4 \text{ lb toluene per } 100 \text{ lb carbon} \end{aligned}$$

Amount of carbon needed for 1-hour cycle =

$$\begin{aligned} (846 \text{ lb toluene}) / (\text{h}) \times (100 \text{ lb carbon} / 11.4 \text{ lb toluene}) \times (1 \text{ h}) \\ = 7421 \text{ lb carbon} \end{aligned}$$

Amount of carbon = 7421 lb

2. Volume occupied by the carbon.

$$(7421 \text{ lb carbon}) \times (\text{ft}^3 / 30 \text{ lb}) = 247 \text{ ft}^3$$

3. Cross-sectional area of bed.

$$\begin{aligned} & 20,000 \text{ (scf/m)} \times (\text{m}/100 \text{ ft}) \\ & = 200 \text{ ft}^2 \end{aligned}$$

based on 100 fpm limiting

*Note:* this requirement could be met by a horizontal flow bed 10 ft wide and 20 ft long.

4. Depth of carbon bed.

$$\begin{aligned} D &= (\text{volume of carbon})/(\text{cross-sectional area}) \\ &= 247 \text{ ft}^3/(200 \text{ ft}^2) \\ &= 1.24 \text{ ft} \end{aligned}$$

Depth of carbon bed = 1.24 ft

*Note:* these calculations are based on minimum acceptable design conditions using only two beds. In practical situations, we may opt for three-bed systems, each handling only 10,000 cfm. This will decrease the size (cost) of each individual unit and allow for more carbon length to ensure against breakthrough.

### 4.3 Incineration for Gaseous Emission Control

The process of incineration is most often used to control the emissions of volatile organic compounds from process industries. At a sufficiently high temperature and adequate residence time, any organic vapor can be incinerated (oxidized) to produce energy and incineration gases which may include carbon dioxide and water. Solid waste can also be treated by the incineration process. Figure 1.28 shows the concept of incineration. Incinerators are capable of

FIGURE 1.28 Waste (gas and solid) treatment by incineration (EPA-89/03).

achieving very high removal efficiencies. They consist of burners, which ignite the fuel and organic vapors and a chamber, which provides appropriate residence time for the oxidation process. Due to the high cost and decreasing supply of fuels, incineration systems are designed to include some type of heat recovery. If heat recovery can be used, incineration can be a very effective control technique. For example, pollutant emissions from paint bake ovens can be reduced by 99.9 + % using incineration while heat recovered from the incinerator flue gases can be fed back to the oven. Incineration can also be used for serious emission problems that require high destruction efficiencies, such as odor problems or the emission of toxic gases (EPA-81/12, p. 3-1).

There are, however, some problems that may occur when using incineration to control gaseous pollutants. Incomplete incineration of many organic compounds results in the formation of aldehydes and organic acids which may create an additional pollution problem. Oxidizing organic compounds containing sulfur or halogens produce unwanted pollutants such as sulfur dioxide, hydrochloric acid, hydrofluoric acid or phosgene. If present, these pollutants would require a scrubber to remove them prior to release into the atmosphere.

Incineration is a chemical process resulting from the rapid combination of oxygen with various elements or chemical compounds, a process which releases heat. Incineration is also referred to as oxidation. Most fuels used for combustion are composed essentially of carbon and hydrogen, but can include other elements such as sulfur. Simplified reactions for the oxidation of carbon and hydrogen are given as (EPA-81/12, p. 3-1)

Equations (1.41) and (1.42) show that the final major products of combustion from the burning of an organic fuel are carbon dioxide and water vapor. Although combustion seems to be a very simple process that is well understood, in reality it is not. The exact manner in which a fuel is oxidized does not occur exactly as given in the above equations, but rather in a series of complex, free-radical chain reactions. The precise set of reactions by which combustion occurs is termed the mechanism of combustion. By analyzing the mechanism of combustion, the rate at which the reaction proceeds and the variables affecting the rate can be predicted. For most combustion devices, the rate of reaction proceeds extremely fast. Maintaining efficient and complete combustion is somewhat of an art rather than a science, as anyone who has built a campfire can attest to. Therefore, this chapter focuses on the factors which influence the completeness of combustion, rather than analyzing the mechanisms involved.

To achieve complete combustion once the air (oxygen) and fuel have been brought into contact, the following conditions must be provided: a temperature high enough to ignite the air and fuel mixture; turbulent mixing of the air and fuel; and sufficient residence time for the reaction to occur. These three conditions are referred to as the three T's of combustion: time, temperature, and turbulence. They govern the speed and completeness of reaction. They are not independent variables since changing one affects the other two.

**EXAMPLE:** combustion air requirements

You are requested to calculate the amount of air required to completely combust a given volumetric flow rate of a particular type of natural gas and also determine the volumetric flow rate of combustion products (EPA-84/09, p. 90).

**Given conditions**

The composition of this particular "natural gas" is shown in Table 1.9

Volumetric flow rate of natural gas = 1.0 scfm

*Solution:*

1. Write the balanced chemical equations for complete combustion.

Combustion with 100% of theoretical (stoichiometric) air insures that no oxygen will remain in the flue gas with complete combustion. Remember that the combustion products are  $\text{CO}_2$ ,  $\text{H}_2\text{O}$ , and inert  $\text{N}_2$  (from both the air and this particular natural gas).

2. Determine the scfm of  $\text{O}_2$  required from the above balanced chemical equations.

A chemically balanced equation tells us, in terms of moles (or volume), the ratios among reactants and products. From the mole fraction information given in Table 1.9,

$$\text{scfm of O}_2 = 1.62 + 0.35 + 0.2 = 2.17 \text{ scfm}$$

3. Calculate scfm of air required.

Air components:  $0.21\text{O}_2 + 0.79\text{N}_2 = 1$  air (by volume or by moles)

1 mole  $\text{O}_2$  + 3.76 moles  $\text{N}_2$  = 4.76 moles of air

1 lb  $\text{O}_2$  + 3.31 lb  $\text{N}_2$  = 4.31 lb of air

$$\begin{aligned} \text{scfm of air} &= (\text{scfm of O}_2)(1.0 \text{ scfm of air}/0.21 \text{ scfm of O}_2) \\ &= 2.17(1/0.21) \\ &= 10.33 \text{ scfm} \end{aligned}$$

4. Calculate total scfm of  $\text{N}_2$  in the flue gas.

Remember that the flue gas nitrogen is the sum of the  $\text{N}_2$  in the natural gas and the  $\text{N}_2$  in air accompanying the required  $\text{O}_2$  for combustion.

$$\begin{aligned} \text{scfm of N}_2 &= 0.05 + (\text{scfm of air})(0.79 \text{ scfm of N}_2/1.0 \text{ scfm of air}) \\ &= 0.05 + (10.33)(0.79) \\ &= 8.21 \text{ scfm} \end{aligned}$$

5. Calculate scfm of  $\text{CO}_2$  and  $\text{H}_2\text{O}$  in the flue gas.

**TABLE 1.9** Composition of Natural Gas

Component		Mole fraction
Nitrogen	$\text{N}_2$	0.05
Methane	$\text{CH}_4$	0.81
Ethane	$\text{C}_2\text{H}_6$	0.1
Propane	$\text{C}_3\text{H}_8$	0.04

$$\text{CO}_2 = 0.81 + 0.2 + 0.12 = 1.13 \text{ scfm}$$

$$\text{H}_2\text{O} = 1.62 + 0.3 + 0.16 = 2.08 \text{ scfm}$$

6. Calculate the total scfm of flue gas.

The total products of combustion (flue gas) include  $\text{CO}_2$ ,  $\text{H}_2\text{O}$ , and  $\text{N}_2$ .

$$\begin{aligned} \text{Total scfm of combustion products} &= 1.13 + 2.08 + 8.21 \\ &= 11.42 \text{ scfm} \end{aligned}$$

**Factors affecting incineration for emission control.** Factors affecting combustion for emission control include:

- Temperature
- Time
- Turbulence
- Oxygen requirement
- Combustion limit
- Flame combustion
- Heat

*Temperature:* The rate at which a combustible compound is oxidized is greatly affected by temperature. The higher the temperature, the faster the oxidation reaction will proceed. The chemical reactions involved in the combination of a fuel and oxygen can occur even at room temperature, but very slowly. For this reason, a pile of oily rags can be a fire hazard. Small amounts of heat are liberated by the slow oxidation of the oils. This in turn raises the temperature of the rags and increases the oxidation rate, liberating more heat. Eventually a fully engulfed fire can break out (EPA-81/12, p. 3-2).

For combustion processes, ignition is accomplished by adding heat to speed up the oxidation process. Heat is needed to combust any mixture of air and fuel until the ignition temperature mixture is reached. By gradually heating a mixture of fuel and air, the rate of reaction and energy released will gradually increase until the reaction no longer depends on the outside heat source. More heat is being generated than is lost to the surroundings. The ignition temperature must be reached or exceeded to ensure combustion. Ignition depends on:

1. Concentration of combustibles in the waste stream
2. Inlet temperature of the waste stream
3. Rate of heat lost from combustion chamber
4. Residence time and flow pattern of the waste stream
5. Combustion chamber geometry and materials of construction

Most incinerators operate at higher temperature than the ignition temperature which is a minimum temperature. Thermal destruction of most organic compounds occurs between 590 and 650°C (1100 and 1200°F). However, most incinerators are operated at 700 to 820°C (1300 to 1500°F) to convert CO to  $\text{CO}_2$ , which occurs only at these higher temperatures.

*Time:* Time and temperature affect combustion in much the same manner as temperature and pressure affect the volume of a gas. When one variable is increased, the other may be decreased with the same end result. With a higher temperature, a shorter residence time can achieve the same degree of oxidation. The reverse is also true—a higher residence time allows the use of a lower temperature. In describing incinerator operation, these two terms are always mentioned together. One has little meaning without specifying the other.

The choice between higher temperature or longer residence time is based on economic considerations. Increasing residence time involves using a larger combustion chamber resulting in a higher capital cost. Raising the operating temperature increases fuel usage which also adds to the operating costs. Fuel costs are the major operating expense for most incinerators. Within certain limits, lowering the temperature and adding volume to increase residence time can be a cost-effective alternative method of operation.

The residence time of gases in the combustion chamber may be calculated from

$$t = V/Q \quad (1.43)$$

where:  $t$  = residence time, seconds  
 $V$  = chamber volume,  $m^3$   
 $Q$  = gas volumetric flow rate at combustion conditions,  $m^3/s$ .

$Q$  is the total flow of hot gases in the combustion chamber. Adjustments to the flow rate must include any outside air added for combustion. Example 1 below shows the determination of residence time from the volumetric flow rate of gases.

*Turbulence:* Proper mixing is important in combustion processes for two reasons. First, for complete combustion to occur, every particle of fuel must come into contact with air (oxygen). If not, unreacted fuel will be exhausted from the stack. Second, not all of the fuel or waste gas stream is able to be in direct contact with the burner flame. In most incinerators a portion of the waste stream bypasses the flame and is mixed at some point downstream of the burner with the hot products of combustion. If the two streams are not completely mixed, a portion of the waste stream will not react at the required temperature and incomplete combustion will occur.

A number of methods are available to improve mixing the air and combustion streams. Some of these include the use of refractory baffles, swirl-fired burners, and baffle plates. These devices are discussed in more detail in the equipment section of this book. The problem of obtaining complete mixing is not easily solved. Unless properly designed, many of these mixing devices may create dead spots and reduce operating temperatures. Merely inserting obstructions to increase turbulence is not always the answer. According to one study of afterburner systems, the process of mixing the flame and the fume streams to obtain a uniform temperature for decomposition of pollutants is the most difficult part in the design of the afterburner (EPA-73).

*Oxygen requirement:* Oxygen is necessary for combustion to occur. To achieve complete combustion of a compound, a sufficient supply of oxygen must be present to convert all of the carbon to  $CO_2$ . This quantity of oxygen is referred to as the stoichiometric or theoretical amount. The stoichiometric amount of oxygen is determined from a balanced chemical equation summarizing the oxidation reactions. For example, from Eq. (1.44), 1 mole of methane requires 2 moles of oxygen for complete combustion (EPA-81/12, p. 3-4):

If an insufficient amount of oxygen is supplied, the mixture is referred to as rich. There is not enough oxygen to combine with all the fuel so that incomplete combustion occurs. This condition results in black smoke being exhausted. If more than the stoichiometric amount of oxygen is supplied, the mixture is referred to as lean. The added oxygen (i.e., the amount over stoichiometric) plays no part in the oxidation reaction and passes through the incinerator.

Oxygen for combustion processes is supplied by using air. Since air is essentially 79% nitrogen and 21% oxygen, a larger volume of air is required than if pure oxygen were used. To balance Eq. (1.44) 9.53 moles of air would be required to completely combust the 1 mole of methane.

In industrial applications, more than the stoichiometric amount of air is used to ensure complete combustion. This extra volume is referred to as excess air. If ideal mixing were achievable, no excess air would be necessary. However, most combustion devices are not

capable of achieving ideal mixing of the fuel and air streams. The amount of excess air is held to a minimum in order to reduce heat losses. Excess air takes no part in the reaction but does absorb some of the heat produced. To raise the excess air to the combustion temperature, additional fuel must be used to make up for this loss of heat.

*Combustion limit:* Not all mixtures of fuel and air are able to support combustion. The flammable or explosive limits for a mixture are the maximum and minimum concentrations of fuel in air that will support combustion. The *upper explosive limit (UEL)* is defined as the concentration of fuel which produces a non-burning mixture due to a lack of oxygen. The *lower explosive limit (LEL)* is defined as the concentration of fuel below which combustion will not be self-sustaining.

*Flame combustion:* When mixing fuel and air, two different mechanisms of combustion can occur. A *luminous (yellow) flame* results when air and fuel flowing through separate ports are ignited at the burner nozzle. The yellow flame results from thermal cracking of the fuel. Cracking occurs when hydrocarbons are intensely heated before they have a chance to combine with oxygen. The cracking releases both hydrogen and carbon, which diffuse into the flame to form  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . The carbon particles give the flame the yellow appearance. If incomplete combustion occurs from flame temperature cooling or if there is insufficient oxygen, soot and black smoke will form (EPA-81/12, p. 3-7).

Blue flame combustion occurs when the fuel and air are premixed in front of the burner nozzle. This produces a short, intense, blue flame. The reason for the different flame is that the fuel-air mixture is gradually heated. The hydrocarbon molecules are slowly oxidized, going from aldehydes and ketones to  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . No cracking occurs and no carbon particles are formed. Incomplete combustion results in the release of the intermediate, partially oxidized compounds. Blue haze and odors are emitted from the stack.

*Heat:* A main area of concern in vapor incineration deals with the amount of fuel required to raise the temperature of the waste stream to the temperature required for complete oxidation. The first step in computing the heat required is to perform a heat balance around the oxidation system.

From the law of conservation of energy:

$$\text{Heat in} = \text{heat out} + \text{heat lost} \quad (1.45)$$

Heat is a relative term which is compared at a reference temperature. The heat content of a substance is arbitrarily taken as zero at a specified reference temperature. In the gas industry (natural gas), the reference temperature is normally  $16^\circ\text{C}$  ( $60^\circ\text{F}$ ). Thus, the heat content can be computed from Eq. (1.45):

$$H = C_p(T - T_0) \quad (1.46)$$

where  $H$  = enthalpy, J/kg or Btu/lb  
 $C_p$  = specific heat at temperature  $T$ , J/kg- $^\circ\text{C}$  or Btu/lb- $^\circ\text{F}$   
 $T$  = temperature of the substance,  $^\circ\text{C}$  or  $^\circ\text{F}$   
 $T_0$  = reference temperature,  $^\circ\text{C}$  or  $^\circ\text{F}$

Subtracting the heat going in from the heat leaving the system gives the heat which must be supplied by the fuel. This is referred to as a *change in enthalpy or heat content*. Using Eq. (1.46), the enthalpy going in ( $T_1$ ) is subtracted from the enthalpy leaving ( $T_2$ ), giving

$$q = m\Delta H = mC_p(T_2 - T_1) \quad (1.47)$$

where  $q$  = heat rate, Btu/h  
 $m$  = mass flow rate, lb/h  
 $\Delta H$  = enthalpy change  
 $C_p$  = specific heat, J/kg- $^\circ\text{C}$  or Btu/lb- $^\circ\text{F}$   
 $T_2$  = exit temperature of the substance,  $^\circ\text{C}$  or  $^\circ\text{F}$   
 $T_1$  = initial temperature,  $^\circ\text{C}$  or  $^\circ\text{F}$

**EXAMPLE 1:** oxidizer (solution in the metric system)

Emissions from a paint baking oven are controlled by a thermal oxidizer. The unit has a diameter of 1.5 m (5 ft) and is 3.5 m (11.5 ft) long. The exhaust from the oven is  $3.8 \text{ m}^3/\text{s}$  (8050 scfm). The oxidizer uses  $0.14 \text{ m}^3/\text{s}$  (300 scfm) of natural gas and operates at a temperature of  $760^\circ\text{C}$  ( $1400^\circ\text{F}$ ). If all the oxygen necessary for combustion is supplied from the process stream (no outside air added), what is the residence time of the gases in the chamber (EPA-81/12, p. 3-7)?

*Solution:*

To solve the problem one can use the approximation that  $11.5 \text{ m}^3$  of combustion products are formed for every  $1.0 \text{ m}^3$  of natural gas burned at standard conditions ( $16^\circ\text{C}$  and  $101.3 \text{ kPa}$ ). Also,  $10.33 \text{ m}^3$  of theoretical air is required to combust  $1 \text{ m}^3$  of natural gas at standard conditions.

1. Determine the volume of combustion products from burning the natural gas.

$$(0.14 \text{ m}^3/\text{s}) \times (11.5 \text{ m}^3 \text{ of product}) / (1.0 \text{ m}^3 \text{ of gas}) = 1.61 \text{ m}^3/\text{s}$$

2. Determine the air required for combustion.

$$(0.14 \text{ m}^3/\text{s}) \times (10.33 \text{ m}^3 \text{ of air}) / (1 \text{ m}^3 \text{ of gas}) = 1.45 \text{ m}^3/\text{s}$$

3. Sum up the volumes.

flow from paint bake oven = 3.8

products from combustion = 1.61

minus the air from exhaust used on combustion =  $-1.45$

total volume =  $3.8 + 1.61 - 1.45 = 3.96 \text{ m}^3/\text{s}$

4. Convert the  $\text{m}^3/\text{s}$  calculated under the standard conditions to actual conditions.

$$(3.96 \text{ m}^3/\text{s}) \times (273^\circ\text{C} + 760^\circ\text{C}) / (273^\circ\text{C}) = 14.98 \text{ m}^3/\text{s}$$

5. Determine the chamber volume  $V$ .

$$\begin{aligned} V &= \pi r^2 L \\ &= 3.14(0.75 \text{ m})^2(3.5 \text{ m}) \\ &= 6.18 \text{ m}^3 \end{aligned}$$

6. The residence time from Eq. 1.43 is

$$t = V/Q$$

where  $t$  = residence time

$V$  = chamber volume

$Q$  = gas volumetric flow rate at combustion conditions,  $\text{m}^3/\text{s}$ .

$$\begin{aligned} t &= V/Q \\ &= (6.18 \text{ m}^3) / (14.98 \text{ m}^3/\text{s}) \\ &= 0.41 \text{ s} \end{aligned}$$

**EXAMPLE 2:** oxidizer (solution in the British system)

Emissions from a paint baking oven are controlled by a thermal oxidizer. The unit has a diameter of 5 ft and is 11.5 ft long. The exhaust from the oven is  $134 \text{ ft}^3/\text{s}$ . The oxidizer uses

4.94 ft<sup>3</sup>/s of natural gas and operates at a temperature of 1400°F. If all the oxygen necessary for combustion is supplied from the process stream (no outside air added), what is the residence time of the gases in the chamber?

**Given conditions**

- reactor diameter  $D = 5$  ft
- reactor length  $L = 11.5$  ft
- initial flue gas flow rate = 134 ft<sup>3</sup>/s
- natural gas used = 4.94 ft<sup>3</sup>/s
- combustion temperature  $T = 1400^\circ\text{F}$

*Solution:*

General assumptions (or rules of thumb):

- 1 m<sup>3</sup> of natural gas burned produces 11.5 m<sup>3</sup> of combustion products under standard conditions,  $T = 16^\circ\text{C}$  and  $P = 1$  atm.
- 1 m<sup>3</sup> of natural gas requires 10.33 m<sup>3</sup> of theoretical air for complete combustion.

Because 1 m<sup>3</sup> = 35.31 ft<sup>3</sup>, these two general assumptions become:

- 35.31 ft<sup>3</sup> of natural gas burned produces 406.07 ft<sup>3</sup> of combustion products.
- 35.31 ft<sup>3</sup> of natural gas requires 364.75 ft<sup>3</sup> of theoretical air for complete combustion.

1. Determine the volume  $Q$  of combustion products.

Because 35.31 ft<sup>3</sup> of natural gas burned produces 406.07 ft<sup>3</sup> of combustion products, 4.94 ft<sup>3</sup>/s of natural gas will produce the combustion products  $Q$  as follows:

$$\begin{aligned} Q &= 4.94(406.07)/35.31 \\ &= 56.81 \text{ ft}^3/\text{s} \end{aligned}$$

2. Determine the air required for combustion.

$$\begin{aligned} \text{Air} &= 4.94(364.75)/35.31 \\ &= 51.03 \text{ ft}^3/\text{s} \end{aligned}$$

3. Sum up the volume  $Q_1$  at the standard condition at  $T_1 = 60^\circ\text{F}$ .

$$\begin{aligned} Q_1 &= \text{flow from paint bake oven (134 ft}^3/\text{s)} + \text{products of combustion (56.81 ft}^3/\text{s)} \\ &\quad - \text{the air from exhaust used in combustion (51.03 ft}^3/\text{s)**} \\ &= 139.78 \text{ ft}^3/\text{s} \end{aligned}$$

\*\*All the oxygen necessary for combustion products is supplied from the process stream (no outside air added).

4. Calculate actual flue gas flow rate  $Q_2$  at  $T_2 = 1400^\circ\text{F}$ .

$$\begin{aligned} Q_2 &= Q_1(T_2/T_1)(P_1/P_2) \\ &= 139.78(460 + 1400)/(460 + 60) \\ &= 500 \text{ acfs} \end{aligned}$$

5. Calculate the chamber volume.

$$\begin{aligned} V &= (\pi)(\text{diameter}/2)^2(\text{length}) \\ &= \pi(2.5)^2(11.5) \\ &= 226 \text{ ft}^3 \end{aligned}$$

6. Calculate residence time  $t$ .

$$\begin{aligned} \text{residence time} &= (\text{chamber volume})/(\text{gas volumetric flow rate at combustion condition}) \\ t &= V/Q_2 \\ &= 226/500 \\ &= 0.45 \text{ s} \end{aligned}$$

**EXAMPLE 3:** heat load

Assume that the exhaust from a meat smokehouse contains obnoxious odors and fumes. The company plans to incinerate the 5000 acfm exhaust stream at the initial temperature of 90°F. The gross heating value of natural gas is 1059 Btu/scf and assume no heat losses. Determine what quantity of natural gas is required to raise the waste gas stream from a temperature of 90°F to the required temperature of 1200°F (EPA-81/12, p. 3-14).

**Given conditions**

- standard condition (state 1),  $T_1 = 60^\circ\text{F}$
- exhaust gas flow rate  $V_2 = 5000$  acfm at temperature  $T = 90^\circ\text{F}$
- exhaust gas initial temperature  $T_2 = 90^\circ\text{F}$
- natural gas gross heating value = 1059 Btu/scf (standard cubic foot)
- combustion temperature  $T_3 = 1200^\circ\text{F}$

*Solution:*

1. Correct the actual waste gas volume ( $V_a$ ) to standard condition volume. The correction equation is

$$\begin{aligned} V_1/T_1 &= V_2/T_2 \\ V_1 &= V_2(T_1/T_2) \\ V_1 &= (5000)(460 + 60)/(460 + 90) \\ &= 4727 \text{ scfm (standard cubic feet per minute)} \\ &= 283,620 \text{ scfh (standard cubic feet per hour)} \end{aligned}$$

2. Convert the volumetric flow rate to a mass flow rate by multiplying by the density.

$$\begin{aligned} \text{Mass flow rate} &= (\text{volume rate}) \times (\text{density}) \\ \text{Standard volume of an ideal gas at } 60^\circ\text{F} &= 379.64 \text{ ft}^3/(\text{lb-mole}) \end{aligned}$$

Assume that the waste gas molecular weight is the same as air: 29 lb/(lb-mole)

$$\begin{aligned} \text{Density} &= (\text{molecular weight})/\text{volume} \\ &= 29/379.64 \\ &= 0.076388 \text{ lb/ft}^3 \end{aligned}$$

$$\begin{aligned}\text{Mass flow rate} &= 4727(0.076388) \\ &= 361 \text{ lb/min}\end{aligned}$$

3. Calculate the heat rate by using the ideal gas equation.

$$\begin{aligned}Q &= mC_p(T_3 - T_2) \\ &= 361(0.26)(1200 - 90) \\ &= 104,185 \text{ Btu/min}\end{aligned}$$

4. Determine the heating value of natural gas (for the present, ignoring the distinction between “gross” and “available” heating value which will be treated in the next Example).

For natural gas, 1 scf contains 1059 Btu (given)

5. Determine the natural gas quantity,  $W$ .

$$\begin{aligned}W &= 104,185/1059 \\ &= 98 \text{ scfm}\end{aligned}$$

**Incineration equipment.** Equipment used to control waste gases by incineration can be divided into four categories:

- Direct combustor or flare
- Thermal oxidizer or incinerator or afterburner
- Catalytic oxidizer
- Process boiler

Although these devices are physically similar, the parameters under which they operate are markedly different. Choosing the proper device depends on many factors, including concentration of combustibles in the gas stream, process flow rate, control requirements, presence of contaminants in the waste stream, and an economic evaluation.

A direct combustor or flare is a device in which air and all the combustible waste gases react at the burner. Complete combustion must occur instantaneously because there is no holdup chamber. Therefore, the flame temperature is the most important variable in flaring waste gases. In contrast, in thermal oxidation or incineration, the combustible waste gases pass over or around or through a burner flame into a holdup chamber where oxidation of the waste gases is completed. Catalytic oxidation is very similar to thermal oxidation. The main difference is that after passing through the flame area, the gases pass over a catalyst bed which promotes oxidation at a lower temperature than does thermal oxidation (EPA-81/12, p. 3-15).

*Direct combustor or flare:* Direct combustors or flares are used for the disposal of intermittent or emergency emissions of combustible gases from industrial sources. Safety and health hazards at or near the plant can be eliminated by using flares to prevent the direct venting of these emissions. Flares have been used mainly at oil refineries and chemical plants which handle large volumes of combustible gases.

Flares are simply burners that have been designed to handle varying rates of fuel while burning smokelessly. In general, flares can be classified as elevated flares and ground-level flares.

The reason for elevating a flare (Fig. 1.29) is to eliminate any potential fire hazard at ground level. Ground-level flares must be completely enclosed to conceal the flame. Either type of flare must be capable of operating over a wide range of flow rates in order to handle all plant emergencies. The range of waste gas flows within which a flare can operate and still burn efficiently is referred to as the *turndown ratio*. Flares are expected to handle turndown ratios of 1000:1, while most industrial boilers seldom handle more than a 10:1 turndown ratio. For

FIGURE 1.29 Flare tip (elevated flare) (EPA-81/12, p. 3-17).

example, a flare should be capable of maintaining complete combustion for waste gas flow rates ranging from 20,000 m<sup>3</sup>/h to 20 m<sup>3</sup>/h.

*Incinerator (afterburner):* Thermal oxidizers or organic vapor incinerators refer to any device that uses a flame (temperature) combined with a chamber (time and turbulence) to convert combustible materials to carbon dioxide and water. An incinerator usually consists of a refractory-lined chamber that is equipped with one or more sets of burners. A typical incinerator is depicted in Fig. 1.30. The contaminant-laden stream is passed through the burners, where it is heated above its ignition temperature. The hot gases then pass through one or more combustion chambers, where they are held for a certain length of time to ensure complete combustion. Depending on the particular needs of the system, additional fuel and/or excess air can be added through the burners. Also, since the flue gases are discharged at elevated temperatures, a system to recover the heat may be included.

FIGURE 1.30 Thermal incinerator (EPA-81/12, p. 3-19).

With the rising costs of fuel and solvents, heat-recovery devices are becoming an integral part of many incineration systems (EPA-81/12, p. 3-19).

**EXAMPLE 1:** combustion: thermal afterburner design

As an air pollution control engineer, you have been requested to evaluate the gross heating value of a natural gas of a given composition. You are also to determine the available heat of the natural gas at a given temperature, the rate of auxiliary fuel (natural gas) required to heat a known amount of contaminated air to a given temperature, the dimensions of an afterburner treating the contaminated air stream, and the residence time (EPA-84/09, p. 92).

**Given conditions**

natural gas composition (mole or volume fraction) as shown in Table 1.10

linear gas velocity = 20 ft/s

length-to-diameter ratio of the afterburner = 2.0

temperature of dry natural gas = 60°F

volumetric flow rate of contaminated air  $Q = 5000$  scfm (60°F, 1 atm)

it is required to heat the contaminated air from 200°F to 1200°F

**TABLE 1.10** Composition of Natural Gas

Component		Mole fraction
Nitrogen	N <sub>2</sub>	0.0515
Methane	CH <sub>4</sub>	0.8111
Ethane	C <sub>2</sub> H <sub>6</sub>	0.0967
Propane	C <sub>3</sub> H <sub>8</sub>	0.0351
<i>n</i> -Butane	C <sub>4</sub> H <sub>10</sub>	0.0056
Total		1

*Solution:*

1. Determine the gross heating value of the natural gas.

From Table 1.11, the gross heating value of the natural gas is

$$\begin{aligned} HV_G &= \sum n_i HV_{Gi} \\ &= (0.0515)(0) + (0.8111)(1013) + (0.0967)(1792) + (0.0351)(2590) + (0.0056)(3370) \\ &= 1105 \text{ Btu/scf of natural gas} \end{aligned}$$

2. What is the available heat of this natural gas at 1200°F?

The available heat ( $HA_t$ ) at any temperature is the gross heating value ( $HV_G$ ) minus the amount of heat required to take products of combustion to that temperature ( $\Sigma\Delta H$ ).

2.a. Write the balanced chemical combustion equations for each of the four components of this natural gas. Use 1 scf of natural gas as a basis.

For 1 mole of each species:

**TABLE 1.11** Heat of Combustion at 25°C (77°F)

Substance		lb/ft <sup>3</sup>	ft <sup>3</sup> /lb	Btu/ft <sup>3</sup>		Btu/lb	
				Gross (high)	Net (low)	Gross (high)	Net (low)
Nitrogen	N <sub>2</sub>	0.0744	13.443				
Methane	CH <sub>4</sub>	0.0424	23.565	1013	913	23,879	21,520
Ethane	C <sub>2</sub> H <sub>6</sub>	0.0803	12.455	1792	1641	22,320	20,432
Propane	C <sub>3</sub> H <sub>8</sub>	0.1196	8.365	2590	2385	21,661	19,944
<i>n</i> -Butane	C <sub>4</sub> H <sub>10</sub>	0.1582	6.321	3370	3113	21,308	19,680

Source: EPA-84/09, p. 37.

For one mole of the natural gas in question:

2.b. Determine the number of standard cubic feet for each of the following components of combustion.

For O<sub>2</sub>:  $1.622 + 0.3385 + 0.1755 + 0.0364 = 2.172$  scf/scf of natural gas

For CO<sub>2</sub>:  $0.8111 + 0.1934 + 0.1053 + 0.0224 = 1.132$  scf/scf of natural gas

For H<sub>2</sub>O:  $1.6222 + 0.2901 + 0.1404 + 0.028 = 2.081$  scf/scf of natural gas

For N<sub>2</sub>:  $0.0515 + (79/21)(2.172) = 8.222$  scf/scf of natural gas

The calculation for N<sub>2</sub> assumes that the natural gas is burned with air (21% O<sub>2</sub> and 79% N<sub>2</sub>), the total amount of nitrogen in the products of combustion is the sum of N<sub>2</sub> in the natural gas (0.0515 scf) and that amount accompanied by the required O<sub>2</sub> ( $79/21 \times$  scf of O<sub>2</sub>).

2.c. How many cubic feet of products are there per scf of natural gas burned, assuming that a stoichiometric (theoretical) quantity of air (21% O<sub>2</sub> + 79% N<sub>2</sub>) is used?

Total cubic feet of products per scf of natural gas are the sum of the scfs of the product species.

$$\text{Total cubic feet of combustion products} = 1.132 + 2.081 + 8.222 = 11.435 \text{ scf of products/scf of natural gas}$$

2.d. Determine the amount of heat required to take the products of combustion from 60°F to 1200°F.

The enthalpies of combustion gases are given in Table 1.12 and the latent heat of vaporization of water ( $\Delta H$ ) at 60°F is 1060 Btu/lb. The changes in enthalpy in Btu/scf of natural gas can be calculated by multiplying the change in enthalpy in Btu/lb-mole by scf of gas/scf of natural gas and divided by 379 scf/lb-mole.

2.d.1. From Table 1.12, the following values of enthalpies at 60°F and 1200°F are obtained.

**TABLE 1.12** Enthalpies of Combustion Gases (Btu/lb-mole)

°F	Air			
	N <sub>2</sub>	MW 28.97	CO <sub>2</sub>	H <sub>2</sub> O
32	0	0	0	0
60	194.9	194.6	243.1	224.2
77	312.2	312.7	392.2	360.5
100	473.3	472.7	597.9	545.3
200	1170	1170	1527	1353
300	1868	1870	2509	2171
400	2570	2576	3537	3001
500	3277	3289	4607	3842
600	3991	4010	5714	4700
700	4713	4740	6855	5572
800	5443	5479	8026	6460
900	6182	6227	9224	7364
1000	6929	6984	10,447	8284
1200	8452	8524	12,960	10,176
1500	10,799	10,895	16,860	13,140
2000	14,840	14,970	23,630	18,380
2500	19,020	19,170	30,620	23,950
3000	23,280	23,460	37,750	29,780

Source: EPA-84/09, p. 93.

$$\begin{aligned} \text{For CO}_2: \Delta H &= H \text{ at } 1200^\circ\text{F} - H \text{ at } 60^\circ\text{F} = 12,960 - 243.1 = 12,716.9 \text{ Btu/lb-mole} \\ &= (12,716.9)(1.132)/(379) \\ &= 38.0 \text{ Btu/scf of natural gas} \end{aligned}$$

This calculation uses the fact that there are 379 scf per lb mole of any ideal gas, and there are 1.132 scf of CO<sub>2</sub>/scf of natural gas. Similarly, for N<sub>2</sub>:

$$\Delta H = (8452 - 194.9)(8.222)/(379) = 179.1 \text{ Btu/scf of natural gas}$$

for H<sub>2</sub>O(g):

$$\Delta H = (10,176 - 224.2)(2.081)/(379) = 54.6 \text{ Btu/scf of natural gas}$$

Since the water present in the combustion product is vapor, the latent heat of vaporization should be included in the heat balance calculation.

$$\begin{aligned} \Delta H \text{ for water latent heat} &= (1060 \text{ Btu/lb})(18)\text{lb/lb-mole} \\ &\quad \times (2.081 \text{ scf of H}_2\text{O/scf of natural gas})/(379 \text{ scf/lb mole}) \\ &= 104.8 \text{ Btu/scf of natural gas} \end{aligned}$$

2.d.2. Calculate the heat needed.

$$\begin{aligned} \Sigma\Delta H &= \Delta H \text{ for CO}_2 + \Delta H \text{ for N}_2 + \Delta H \text{ for H}_2\text{O} + \Delta H \text{ for water latent heat} \\ &= 38.0 + 179.1 + 54.6 + 104.8 \\ &= 376.5 \text{ Btu/scf of natural gas} \end{aligned}$$

2.e. Calculate the available heat of natural gas at 1200°F in Btu/scf of natural gas.

$$\begin{aligned}
 HA &= HV_G - \Sigma \Delta H \\
 &= 1105 - 376.5 \\
 &= 728.5 \text{ Btu/scf of natural gas}
 \end{aligned}$$

3. Calculate the rate of auxiliary fuel required to heat 5000 scfm of contaminated air from 200°F to 1200°F.

To calculate the rate of natural gas required, you need both the enthalpy change of air and the available heat.

3.a. Determine the enthalpy change of air going from 200°F to 1200°F.  
From Table 1.12,

$$\Delta H \text{ for air} = H \text{ at } 1200^\circ\text{F} - H \text{ at } 200^\circ\text{F} = 8524 - 1170 = 7354 \text{ Btu/lb-mole}$$

3.b. Calculate the heat rate  $q$  required to heat 5000 scfm of the contaminated air from 200°F to 1200°F in Btu/min.

$$\begin{aligned}
 q &= (5000 \text{ scfm})(7354 \text{ Btu/lb-mole})/(379 \text{ scf/lb-mole}) \\
 &= 97,018 \text{ Btu/min}
 \end{aligned}$$

3.c. Calculate the rate of natural gas required to heat 5000 scfm of air from 200°F to 1200°F in scfm.

$$\begin{aligned}
 \text{Rate of natural gas required} &= q/HA \\
 &= 97,018/728.5 \\
 &= 133.2 \text{ scfm}
 \end{aligned}$$

4. What are the dimensions of an afterburner treating 5000 scfm of contaminated air stream? To determine the dimensions of the afterburner, you need the total flue gas flow rate at 1200°F. The total flue gas flow rate is the sum of the contaminated gas stream and the flow rate of the combustion products. The volumetric flow rate of the products of combustion is obtained by multiplying the total cubic feet of products per scf of natural gas (previously determined) by the natural gas rate (also previously determined).

4.a. What is the total flue gas flow rate?

4.a.1. Calculate the volumetric flow rate of products of combustion in scfm.

$$\begin{aligned}
 Q \text{ of combustion products} &= (11.435 \text{ scf of products/scf of natural gas}) \\
 &\quad \times (133.2 \text{ scfm of natural gas}) \\
 &= 1523 \text{ scfm}
 \end{aligned}$$

4.a.2. Calculate the total flue gas flow rate in scfm.

This includes both the products of combustion (flue) and the process gas stream.

$$\begin{aligned}
 \text{Total flue gas flow rate} &= 5000 + 1523 \\
 &= 6523 \text{ scfm}
 \end{aligned}$$

4.a.3. Determine the total flue gas flow rate at 1200°F in acfm.

$$\begin{aligned}
 \text{Actual total flue gas flow rate} &= 6523 (1200 + 460)/(60 + 460) \\
 &= 20,823 \text{ acfm} \\
 &= 347 \text{ acfs}
 \end{aligned}$$

4.b. Determine the diameter of the afterburner in ft.

$$S = \pi D^2/4 = Q/v$$

where  $S$  = cross-sectional area of the afterburner  
 $D$  = diameter of the afterburner  
 $Q$  = total flue gas flow rate  
 $v$  = linear gas velocity

$$\begin{aligned} D &= (4Q/v\pi)^{1/2} \\ &= [(4)(347)/(20)(\pi)]^{1/2} \\ &= 4.7 \text{ ft} \end{aligned}$$

4.c. Determine the length of the afterburner in ft.

Since the length-to-diameter ratio is 2.0,

$$\begin{aligned} L &= (2.0)(4.7) \\ &= 9.4 \text{ ft} \end{aligned}$$

4.d. Determine the residence time for the gases in the afterburner in seconds.

$$\text{Residence time} = \text{length}/v$$

Typical residence times in an afterburner are in the 0.1–0.5 second range.

$$\begin{aligned} t &= L/v \\ &= (9.4)/(20) \\ &= 0.47 \text{ s} \end{aligned}$$

**EXAMPLE 2:** combustion: plan review of a direct-flame afterburner

You must review plans for a permit to construct a direct flame afterburner serving a lithographer. Review is for the purpose of judging whether the proposed system, when operating as it is designed to operate, will meet emission standards. The permit application provides operating and design data. Agency experience has established design criteria which, if met in an operating system, typically ensure compliance with standards (EPA-84/09, p. 96).

**Given conditions: operating and design data from permit application**

application = lithography

effluent exhaust volumetric flow rate = 7000 scfm

exhaust temperature = 300°F

hydrocarbons in effluent air to afterburner (assume hydrocarbons to be toluene) = 30 lb/h

afterburner entry temperature of effluent from preheater = 738°F

afterburner exit temperature = 1400°F

afterburner heat loss = 10%

afterburner dimensions = 4.2 ft in diameter, 14 ft in length

**Agency design criteria**

afterburner temperature = 1300–1500°F

residence time = 0.3–0.5 s

afterburner velocity = 20–40 ft/s

**Standard data**

- gross heating value of natural gas = 1059 Btu/scf of natural gas  
 combustion products per cubic ft of natural gas burned = 11.5 scf  
 available heat of natural gas at 1400°F = 600 Btu/scf of natural gas  
 molecular weight of toluene = 92  
 specific heat of effluent gases at 738°F (above 0°F) = 7.12 Btu/lb-mole-°F  
 specific heat of effluent gases at 1400°F (above 0°F) = 7.38 Btu/lb-mole-°F  
 volume of air required to combust natural gas = 10.33 scf air/scf natural gas

*Solution:*

1. Does this application meet any of the agency design criteria?

The afterburner exit temperature is 1400°F, which is already within agency criteria. Therefore, you need be concerned only with whether, under the conditions given, the residence time and the afterburner velocity will be within agency design criteria.

2. Determine the fuel requirement for the afterburner.

2.a. Calculate the total heat load (heating rate) required to raise 7000 scfm of the effluent stream from 738°F to 1400°F (in Btu/min).

First, calculate the molar flow rate of the effluent.

$$n = (7000 \text{ scfm}) / (379 \text{ scf/lb-mole}) = 18.47 \text{ lb-mole/min}$$

The given conditions shows that the combustion gas at different temperature ranges has different specific heat values. The heat load can now be calculated:

$$\begin{aligned} q &= n[C_{p2}(T_2 - T_0) - C_{p1}(T_1 - T_0)] \\ &= 18.47[(7.38)(1400 - 0) - (7.12)(738 - 0)] \\ &= 93,772 \text{ Btu/min} \end{aligned}$$

2.b. Calculate the actual heat load required, accounting for a 10% heat loss, in Btu/min.

$$\begin{aligned} \text{Actual heat load} &= q + 10\%(q) \\ &= (1.1)(93,772) \\ &= 103,149 \text{ Btu/min} \end{aligned}$$

2.c. Calculate the rate of natural gas required to supply the actual heat required to heat 7000 scfm of effluent from 738°F to 1400°F in scfm.

$$\begin{aligned} \text{Rate of natural gas} &= (\text{actual heat}) / (\text{available heat}) \\ &= (103,149) / (600) \\ &= 171.9 \text{ scfm} \end{aligned}$$

3. What is the total volumetric flow rate through the afterburner  $Q_t$ ?

Once you determine the volumetric flow rate, you can calculate the afterburner velocity and residence time, since the dimensions of the afterburner are given. The total volumetric flow rate is the sum of the process effluent from the lithographer plus the combustion products of the natural gas.

3.a. Calculate the volumetric flow rate of the combustion products of the natural gas,  $Q_1$ , in scfm.

To calculate the volumetric flow rate of combustion products of the natural gas, you use the amount of natural gas just calculated:

$$\begin{aligned}
 Q_1 &= (\text{rate of natural gas})(11.5 \text{ scf of combustion products/scf of natural gas}) \\
 &= (171.9)(11.5) \\
 &= 1976 \text{ scfm}
 \end{aligned}$$

3.b. What is the volumetric flow rate of the effluent stream from the lithographer in scfm?

$$\text{Volumetric flow rate of the effluent} = 7000 \text{ scfm}$$

3.c. Calculate the volumetric flow rate of air required to combust the natural gas, %, in scfm.

$$\begin{aligned}
 Q_2 &= (\text{rate of natural gas})(10.33 \text{ scf of air/scf of natural gas}) \\
 &= 1776 \text{ scfm}
 \end{aligned}$$

3.d. Calculate the total volumetric flow rate through the afterburner,  $Q_t$ , in scfm.

$$\begin{aligned}
 Q_t &= 7000 + Q_1 \\
 &= 7000 + 1976 \\
 &= 8976 \text{ scfm}
 \end{aligned}$$

*Note:* Combustion air for the natural gas is already in the “11.5” figure.

3.e. Calculate  $Q_t$  in acfm.

$$\begin{aligned}
 Q_t &= (8976)(1400 + 460)/(60 + 460) \\
 &= 32,106 \text{ acfm}
 \end{aligned}$$

4. Does the afterburner velocity meet the criteria?

To calculate the afterburner velocity you need the cross-sectional area of the afterburner and actual volumetric flow rate through the afterburner.

4.a. Calculate the cross-sectional area of the afterburner  $S$  in  $\text{ft}^2$ .

$$\begin{aligned}
 S &= \pi D^2/4 \\
 &= (\pi)(4.2)^2/4 \\
 &= 13.85 \text{ ft}^2
 \end{aligned}$$

4.b. Calculate the afterburner velocity  $v$  in ft/s.

$$\begin{aligned}
 v &= Q_t/S \\
 &= (32,106)/(13.85) \\
 &= 2317 \text{ ft/min} \\
 &= 38.6 \text{ ft/s}
 \end{aligned}$$

4.c. Is the afterburner velocity within agency criteria?

Yes.

5. Does the residence time meet agency criteria?

5.a. Calculate the residence time  $t$  in s.

$$t = L/v$$

where  $L$  = afterburner length

$v$  = velocity

$$\begin{aligned}
 t &= L/v \\
 &= 14/38.6 \\
 &= 0.363 \text{ s}
 \end{aligned}$$

5.b. Is the residence time within agency criteria?

Yes.

*Note:* The above calculations have assumed combustion of the natural gas to take place with primary air; i.e. air supplied external to the process effluent. In addition, the energy released and volume of gases formed by the combustion of the pollutant (toluene) have been neglected. This is common practice in combustion calculations. If secondary air (from process effluent) is employed for combustion of the natural gas, a trial-and-error calculation is required for a rigorous solution to this problem.

*Catalytic oxidizer:* A catalyst is a substance which causes or speeds a chemical reaction without itself undergoing a change. In catalytic incineration, a waste gas is passed through a layer of catalyst known as the catalyst bed. The catalyst causes the oxidation reaction to proceed at a faster rate and lower temperature than is possible in thermal oxidation. Catalytic incinerators operating in a 370–480°C (700–900°F) range can achieve the same efficiency as a thermal incinerator operating between 700 and 820°C (1300 and 1500°F). This can result in 40–60% fuel savings.

Catalytic reactions can be classified as either *homogeneous* or *heterogeneous*. Homogeneous reactions occur throughout the bulk of the catalyst, while heterogeneous reactions occur only on the surface of the catalytic material. In air pollution control applications, all reactions are heterogeneous. The oxidation reaction of the organic vapors occurs only on the surface of the catalyst. It should be noted that catalytic reactions produce the same end products (CO<sub>2</sub> and H<sub>2</sub>O) and liberate the same heat of combustion as does thermal incineration.

A heterogeneous catalytic reaction proceeds through a series of five basic steps:

1. Organic compounds in the waste gas must first diffuse from the bulk of the vapor to the surface of the catalyst.
2. Organic compounds then adsorb onto the surface of the catalyst.
3. Organic compounds then react (oxidize).
4. New compounds then desorb after reacting.
5. New compounds then diffuse and mix back into the bulk of the exhaust air stream.

The most effective and commonly used catalysts for oxidation reactions come from the noble metals group. Platinum either alone or in combination with other noble metals is by far the most commonly used. Desirable characteristics of platinum are that it gives a high oxidation activity at low temperatures, is stable at high temperatures, and is chemically inert. Palladium is another noble metal which exhibits these properties and is sometimes used in catalytic incinerators.

Since catalytic oxidation is a surface reaction, the noble metal is coated onto the surface of a cheaper support material. The support material can be made of a ceramic or a metal such as alumina, silica-alumina or nickel-chromium. The support material is arranged in a matrix shape to provide high geometric surface area, low pressure drop, uniform flow of the waste gas through the catalyst bed, and a structurally stable surface. Structures which provide these characteristics are pellets, a honeycomb matrix, or a mesh matrix.

A schematic of a catalytic incinerator is shown in Fig. 1.31. Catalytic incinerators consist of a preheat section (burner area), where part of the waste gas is raised to operating temperature. The burners are the same as those used for thermal incineration. The remaining portion of the waste gas is mixed with the hot products of combustion before passing over the catalyst bed. This ensures a homogenous waste gas and a uniform-temperature mixture as it passes over the bed. After passing over the bed, the hot flue gases may be sent to a heat recovery system.

*Process boiler:* An alternative to installing a thermal or catalytic incinerator would be to combust the waste gases in an existing plant or process boiler. This would avoid the capital cost of new equipment and may help to reduce present fuel consumption. Process and plant boilers are normally designed to operate in excess of 980°C (1800°F) with a flue gas residence time of 0.5 to 3.0 seconds. These conditions exceed those recommended for thermal incinerators. However, a number of additional conditions must be satisfied before waste gases can be properly disposed of in this manner.

The following criteria must be considered before a process boiler can be used as an incinerator:

1. The waste gases must be almost completely combustible. If solid particles are present in the waste gases, or formed by incomplete combustion, they can foul heat exchanger surfaces in the boiler, thus reducing boiler efficiency. Particulate matter may also cause boiler emissions to exceed applicable emission regulations. The costs of increased maintenance of the boiler and/or control of particulate matter may well exceed the purchase price of an incinerator.
2. The waste gas should, preferably, constitute only a small fraction of the air requirements of the boiler. If the volume of the waste gas is large, special attention must be paid to the oxygen balance, mixing, and continuation of the air flow in the boiler when the process is shut down.
3. The oxygen concentration of the contaminated gas stream should be close to that of air to avoid incomplete combustion. Incomplete combustion produces tars that coat heat exchanger surfaces, reducing boiler efficiency.
4. The boiler must operate at all times when incineration is required.
5. The waste gas must be free of compounds, such as halogenated hydrocarbons, that accelerate corrosion of the boiler.
6. Baffling may be required in the combustion chamber to ensure adequate mixing and combustion of the waste gas.
7. If the boiler-firing rate varies greatly, it may be necessary to install a small auxiliary boiler that will operate under steady load conditions.

To date, not many industries have been successful in using plant or process boilers as incinerators. Petroleum refineries, which have numerous waste gas streams and process boilers, are one of the few industries which have been able to incinerate waste gases in process boilers.

#### 4.4 Condensation for Gaseous Emission Control

Condensation is the process of reducing a gas or vapor to a liquid. Any gas can be reduced to a liquid by lowering its temperature and/or increasing its pressure. The most common approach is to reduce the temperature of the gas stream, since increasing the pressure of a gas is very costly (EPA-81/12, p. 6-1).

Condensers are simple, relatively inexpensive devices that normally use water or air to cool and condense a vapor stream. Since these devices are usually not capable of reaching low temperatures (below 80°F), high removal efficiencies of most gaseous pollutants are not obtained unless the vapors will condense at high temperatures. Condensers are typically used as pretreatment devices. They are used ahead of incinerators, absorbers, or adsorbers to reduce the total gas volume to be treated by more expensive control equipment. Used in this manner, they help reduce the overall cost of the control system.

**Condensation basics.** When a hot vapor stream contacts a cooler surface, heat is transferred from the hot gases to the cooler surface. As the temperature of the vapor stream is cooled, the average kinetic energy of the gas molecules is reduced. Also, the volume that these vapors occupy is reduced. Ultimately the gas molecules are slowed down and crowded together so closely that the attractive forces (van de Waals' forces) between the molecules cause them to condense to a liquid.

The two conditions which aid condensation are low temperatures, so that the kinetic energy of the gas molecules are low, and high pressures so that the molecules are brought close together.

The actual conditions at which a particular gas molecule will condense depends on its physical and chemical properties. Condensation occurs when the partial pressure of the pollutant in the gas stream equals its vapor pressure as a pure substance at operating conditions.

Condensation of a gas can occur in three ways:

1. At a given temperature, the system pressure is increased (compressing the gas volume) until the partial pressure of the gas equals its vapor pressure.
2. At a fixed pressure, the gas is cooled until the partial pressure equals its vapor pressure.
3. By using a combination of compression and cooling of the gas until its partial pressure equals its vapor pressure.

These processes are illustrated in Fig. 1.32, a typical vapor pressure diagram for a pure substance. In Fig. 1.32, point I is the initial temperature and pressure of a gas. The dotted lines indicate the paths a quantity of gas would follow to reach the vapor pressure curve. Points on the vapor pressure curve are also referred to as dew points. The *dew point* is defined as the condition at which gas is ready to condense into the first drop of liquid.

Also in Fig. 1.32, the critical point is plotted. Each substance has a critical temperature and critical pressure. The critical temperature is important in that it is the maximum temperature above which the gas will not condense, no matter how great a pressure is applied. The pressure required to liquefy a gas at its critical temperature is the critical pressure.

Once the gas conditions (temperature, pressure, and volume) equal those on the vapor pressure line, liquid begins to condense. From this point on, the gas-liquid mixture follows the vapor pressure line. If the mixture is cooled continuously, the partial pressure of the remaining gas will always equal the vapor pressure. This is important since even though the contaminated gas is being condensed, it still has a certain partial pressure indicating that uncontrolled

FIGURE 1.32 Typical vapor pressure diagram (EPA-81/12, p. 6-2).

vapors are being emitted from the condenser. For most practical applications, the vapor-liquid equilibrium restricts the use of condensers as primary air pollution control devices. Unless very low temperatures or high pressures are attained, condensers are generally not capable of reducing the pollutant concentration to within acceptable emission limits.

Practically, temperature is the only process variable which governs the effectiveness of a condenser. In industrial applications, increasing the system pressure is very costly and therefore rarely used for condensation. At the operating pressure of the system, the outlet temperature from the condenser determines the maximum removal efficiency. Therefore, condensers cannot be used in the same manner as other gaseous pollutant control devices. For example, condensers cannot be used in series, like adsorbers or absorbers, to further reduce outlet concentration unless the outlet temperature of the second condenser is lower than the previous one. Increasing gas residence time or decreasing flow rates in the condenser does not add to the theoretically achievable efficiency as these operations do in incinerators, adsorbers, and absorbers.

**Condensation equipment—condenser.** Condensers fall into two basic categories (EPA-81/12, p. 6-3):

- Contact condenser
- Surface condenser

*Contact condenser:* In a contact condenser (Fig. 1.33) the coolant and vapor stream are physically mixed. They leave the condenser as a single exhaust stream. Contact condensers

FIGURE 1.33 Direct contact condenser (*EPA-81/12, p. 6-4*).

are simple devices such as spray towers, steam or water jet ejectors, and barometric condensers. These devices bring the coolant, usually water, into direct contact with the vapors. The liquid stream leaving the condenser contains the coolant plus the condensed vapors. If the vapor is soluble in the coolant then absorption also occurs. Absorption increases the amount of contaminant that can be removed at the given conditions.

Condensers reduce the temperature (heat content) of a hot vapor stream by contacting it with a cooler liquid or air stream. Heat is being transferred from a hot to a colder fluid; thus, the process is termed a heat transfer or heat exchange operation. Condensers are designed using the same basic principles and empirical relationships used for heat exchangers.

Simplified heat balance calculations are used to estimate the important parameters. The following equations are not intended to be used as a design method, but only as rough estimates for evaluation purposes.

The first step in analyzing any heat transfer process is to set up a heat balance relationship. For a condensation system, the heat balance can be expressed as

Heat in = Heat out

(Heat required to reduce vapors to the dew point) + (heat required to condense vapors)  
= (heat needed to be removed by the coolant)

This heat balance is written in equation form as

$$q = mC_p(T_{G1} - T_{\text{dew point}}) + mH_V = LC_p(T_{L2} - T_{L1}) \quad (1.48)$$

where  $q$  = heat transfer rate, Btu/h  
 $m$  = mass flow rate of vapor, lb/h  
 $C_p$  = average specific heat of a gas or liquid, Btu/lb-°F  
 $T$  = temperature of the streams; G for gas and L for liquid coolant  
 $H_v$  = heat of condensation or vaporization, Btu/lb  
 $L$  = mass flow rate of liquid coolant, lb/h

In Eq. (1.48) the mass flow rate  $m$  and inlet temperature  $T_{G1}$  of the vapor stream are set by the process exhaust stream. The temperature of the coolant entering the condenser  $T_{L1}$  is also set. The average specific heats  $C_p$  of both streams, the heat of condensation  $H_v$ , and the dew point temperature can be obtained from chemistry handbooks. Therefore, only the amount of coolant  $L$  and its outlet temperature are left to be determined. If either one of these terms are set by process restrictions (i.e. only  $x$  pounds an hour of coolant are available or the outlet temperature of coolant must be below a set temperature), then the other term can be solved for directly.

Equation (1.48) is applicable for direct contact condensers and should be used only to obtain rough estimates. The equation has a number of limitations:

1. The specific heat  $C_p$  of a substance is dependent on temperature, and the temperature throughout the condenser is constantly changing.
2. The dew point of a substance is dependent on its concentration in the gas phase, and since the mass flow rate is constantly changing (vapors being condensed) the dew point temperature is constantly changing.
3. No provision is made for cooling the vapors below their dew point. An additional term would have to be added to the left side of the equation to account for this amount of cooling.

*Surface condenser:* In a surface condenser (Fig. 1.34), the coolant is separated from the vapors by tubular heat transfer surfaces. The coolant and condensed vapors leave the device by separate exits. Surface condensers are commonly called shell-and-tube heat exchangers. The temperature of the coolant is increased, so these devices also act as heaters (EPA-81/12, p. 6-3).

FIGURE 1.34 Surface condenser (EPA-81/12, p. 6-6).

A surface condenser consists of a circular or oval cylindrical shell into which the vapor stream flows. Inside the shell are numerous small tubes through which the coolant flows. Vapors contact the cool surface of the tubes, condense, and are collected, while noncondensed vapors are sent for further treatment.

In a surface condenser or heat exchanger, heat is transferred from the vapor stream to the coolant through a heat exchange surface. The rate of heat transfer depends upon three factors:

- Total cooling surface available
- Resistance to heat transfer
- Mean temperature difference between condensing vapor and coolant.

This can be expressed mathematically by

$$q = UA\Delta T_m \quad (1.49)$$

where  $q$  = heat transfer rate, Btu/h  
 $U$  = overall heat transfer coefficient Btu/°F-ft<sup>2</sup>-h  
 $\Delta T_m$  = mean temperature difference, °F

The overall heat transfer coefficient  $U$  is a measure of the total resistance heat experiences while being transferred from a hot body to a cold body. In a shell-and-tube condenser cold water flows through the tubes, causing vapor to condense on the outside surface of the tube wall. Heat is transferred from the vapor to the coolant. The ideal situation for heat transfer would be where heat is transferred from the vapor to the coolant without any heat loss (heat resistance). However, in an engineering application, every time heat moves through a different medium, it encounters a different and additional heat resistance. These heat resistances are throughout the condensate; through any scale or dirt on the outside of the tube (fouling); through the tube itself; and through the film on the inside of the tube (fouling). Each of these resistances are individual heat transfer coefficients and must be added together to obtain an overall heat transfer coefficient.

A number of correlations exist to determine the individual heat transfer coefficient. These correlations are usually presented in terms of dimensionless numbers, such as the Reynolds' number. These correlations consider variables including geometry of the condenser, gas and liquid density and viscosity, and the mechanism of heat transfer (convection, conduction, and radiation). Calculation of individual heat transfer coefficients require numerous data from the system. An estimate of an overall heat transfer coefficient can be used for preliminary calculations. Table 1.13 lists some typical values for overall heat transfer coefficients. Table 1.13 should be used only for preliminary estimating purposes.

**TABLE 1.13** Heat Transfer Coefficients in Tubular Heat Exchangers

Condensing vapor (shell side)	Cooling liquid (tube side)	$U$ (Btu/°F-ft <sup>2</sup> -h)
Alcohol vapor	Water	100–200
High-boiling hydrocarbons (vacuum)	Water	20–50
Low-boiling hydrocarbons	Water	80–200
Organic solvents	Water	100–200
Organic solvents with high percentage of non-condensables present	Water or brine	20–60
Naphtha	Water	50–75
Stabilizer reflux vapors	Water	80–120
Sulfur dioxide	Water	150–200
Tall oil derivatives, vegetable oil vapors	Water	20–50
Steam	Feedwater	400–1000

*Note:* For a water–water (liquid–liquid) heat exchanger (no phase change), the values for  $U$  range between 200 and 250.

In a surface heat exchanger the temperature difference between the hot vapor and the coolant usually varies throughout the length of the exchanger. Therefore, a mean temperature difference ( $\Delta T_m$ ) must be used. For the special cases where the flow of both streams is completely co-current, the flow of both streams is completely countercurrent, or the temperature of one of the fluids remains constant (as is the case in condensing a pure liquid), the log mean temperature difference can be used. The temperature profiles for these three conditions are illustrated in Fig. 1.35. The log mean temperature for countercurrent flow can be expressed as

$$\Delta T_m = \Delta T_{lm} = (\Delta T_1 - \Delta T_2) / \ln(\Delta T_1 / \Delta T_2) \tag{1.50}$$

where  $\Delta T_{lm}$  = log mean temperature.

The value calculated from Eq. (1.50) is used for single-pass heat exchangers or condensers. For multiple-pass exchangers a correction factor to the log mean temperature must be included. However, for the special case of isothermal condensation (no change in temperature) of a single-component vapor,  $T_{G1} = T_{G2}$  and is equal to the dew point temperature. No correction factor is needed.

In order to size a condenser, Eq. (1.49) must be rearranged to solve for the surface area:

$$A = q/U\Delta T_{lm} \quad (1.51)$$

where  $A$  = surface area of a shell-and-tube condenser, ft<sup>2</sup>  
 $q$  = heat transfer rate, Btu/lb  
 $U$  = overall heat transfer coefficient, Btu/°F-ft<sup>2</sup>-h  
 $\Delta T_{lm}$  = log mean temperature difference, °F

For the exact determination of the surface area,  $U$  in Eq. (1.51) should be calculated from the individual resistances (coefficients). For a rough estimate, the values in Table 1.13 can be used.

Equation (1.51) is strictly valid only for isothermal condensation of a single component. This implies that the pollutant is a pure vapor stream comprised only of one specific hydrocarbon such as benzene, not a mixture of hydrocarbons. Nearly all air pollution applications involve multicomponents, since air and any other gas are two components. This complicates the design procedure for a condenser.

For preliminary rough estimates of condenser size, the procedure in Example 1 (which follows) for single-component condensation can be used for condensing multicomponents. In choosing a heat transfer coefficient, the smallest value should be used to allow as much over-design as possible.

*Comparison of contact and surface condensers:* Since in contact condensers, coolant is merely sprayed on the vapors, these systems are simpler in design, less expensive, and more flexible in application than surface condensers. However, contact condensers require more coolant, and due to direct mixing, produce 10 to 20 times the amount of wastewater (condensate) than surface condensers. Since the wastewater from a contact condenser is contaminated with vapors, it cannot be reused, which poses a water disposal problem. If the condensed vapors have a recovery value, surface condensers are usually used since the condensate can be recovered directly.

#### EXAMPLE 1: condenser

In a rendering plant, tallow is obtained by removing the moisture from animal matter in a cooker. Exhaust gases from the cookers contain essentially steam; however, the entrained vapors are highly odorous and must be controlled. Condensers are normally used to remove most of the moisture prior to incineration, scrubbing, or carbon adsorption (EPA-81/12, p. 6-15).

The exhaust flow rate from the continuous rendering cooker is 20,000 acfm at 250°F. The exhaust gases are 95% moisture, with the remaining portion consisting of air and obnoxious organic vapors. The exhaust stream is sent first to a shell-and-tube condenser to remove the moisture and then to a carbon adsorption unit. If the coolant water enters at 60°F and leaves at 120°F, estimate the required surface area of the condenser. The condenser is a horizontal, countercurrent flow system with the bottom few tubes flooded to provide subcooling.

*Solution:*

1. First, compute the pounds of steam condensed per minute.

$$(20,000 \text{ acfm}) \times (0.95) = 19,000 \text{ acfm steam}$$

From the ideal gas law:

$$\begin{aligned}
 PV &= nRT \\
 n &= PV/RT \\
 &= (1 \text{ atm})(19,000 \text{ acfm})/[(0.73 \text{ atm}\cdot\text{ft}^3/\text{lb}\cdot\text{mole}\cdot^\circ\text{R})(250 + 460)^\circ\text{R}] \\
 &= 36.66 \text{ lb}\cdot\text{mole}/\text{min} \\
 m &= (36.66 \text{ lb}\cdot\text{mole}/\text{min})(18 \text{ lb}/\text{lb}\cdot\text{mole}) \\
 &= 660 \text{ lb}/\text{min of steam to be condensed}
 \end{aligned}$$

2. Solve the heat balance to determine  $q$  for cooling the superheated steam and condensing only.

$$\begin{aligned}
 q &= (\text{heat needed to cool steam to condensation temperature}) + (\text{heat of condensation}) \\
 &= mC_p\Delta T + mH_v
 \end{aligned}$$

The average specific heat ( $C_p$ ) of steam at 250°F is roughly 0.45 Btu/lb-°F. The heat of vaporization of steam at 212°F = 970.3 Btu/lb. Substituting into the equation:

$$\begin{aligned}
 q &= (660 \text{ lb}/\text{min})(0.45 \text{ Btu}/\text{lb}\cdot^\circ\text{F})(250 - 212^\circ\text{F}) + (660 \text{ lb}/\text{min})(970.3 \text{ Btu}/\text{lb}) \\
 &= 11,286 \text{ Btu}/\text{min} + 640,398 \text{ Btu}/\text{min} \\
 &= 651,700 \text{ Btu}/\text{min}
 \end{aligned}$$

3. Now using Eq. (1.51) to estimate the surface area for this part of the condenser.

$$A = q/U\Delta T_{lm}$$

where  $A$  = surface area of a shell-and-tube condenser, ft<sup>2</sup>  
 $q$  = heat transfer rate, Btu/lb  
 $U$  = overall heat transfer coefficient, Btu/°F-ft<sup>2</sup>-h  
 $\Delta T_{lm}$  = log mean temperature difference, °F

For a countercurrent condenser, the log mean temperature is given by

$$\Delta T_{lm} = [(T_{G1} - T_{L2}) - (T_{G2} - T_{L1})]/\ln[(T_{G1} - T_{L2})/(T_{G1} - T_{L1})]$$

where  $\Delta T_{lm}$  = log mean temperature difference  
 $T_{G1}$  = gas entering temperature  
 $T_{L2}$  = coolant leaving temperature  
 $T_{G2}$  = gas leaving temperature  
 $T_{L1}$  = coolant entering temperature

Remember that the desuperheater-condenser section is designed using the saturation temperature to calculate the log mean temperature difference.

gas entering temperature  $T_{G1} = 212^\circ\text{F}$   
 coolant leaving temperature  $T_{L2} = 120^\circ\text{F}$   
 gas leaving temperature  $T_{G2} = 212^\circ\text{F}$   
 coolant entering temperature  $T_{L1} = 60^\circ\text{F}$

$$\begin{aligned}
 \Delta T_{lm} &= [(212 - 120) - (212 - 60)]/\ln[(212 - 120)/(212 - 60)] \\
 &= 119.5^\circ\text{F}
 \end{aligned}$$

The overall heat transfer coefficient  $U$  is assumed to be 100 Btu/°F-ft<sup>2</sup>-h.

Substituting the appropriate values into Eq. (1.51):

$$A = [(651,700 \text{ Btu/min})(60 \text{ min/h})]/[(100 \text{ Btu/}^\circ\text{F-ft}^2\text{-h})(119.5^\circ\text{F})]$$

$$= 3272 \text{ ft}^2$$

4. To estimate the total size of the condenser, we may need to allow for subcooling of the condensed water ( $212^\circ\text{--}160^\circ\text{F}$ ).  $160^\circ\text{F}$  is a safe margin.

Re-figuring the heat balance for cooling the water:

$$q = UA\Delta T_m$$

where  $q$  = heat transfer rate, Btu/h  
 $U$  = overall heat transfer coefficient Btu/ $^\circ\text{F-ft}^2\text{-h}$   
 $\Delta T_m$  = mean temperature difference,  $^\circ\text{F}$   
 $m$  = 660 lb/min (assuming all the steam is condensed)  
 $C_p$  for water = 1 Btu/lb- $^\circ\text{F}$

$$q = (660 \text{ lb/min})(1 \text{ Btu/lb-}^\circ\text{F})(212 - 160)^\circ\text{F}$$

$$= 34,320 \text{ Btu/min}$$

The new log mean temperature can be calculate from

gas entering temperature  $T_{G1} = 212^\circ\text{F}$   
 coolant leaving temperature  $T_{L2} = 120^\circ\text{F}$   
 gas leaving temperature,  $T_{G2} = 160^\circ\text{F}$   
 coolant entering temperature  $T_{L1} = 60^\circ\text{F}$

$$\Delta T_{1m} = [(212 - 120) - (160 - 60)]/\ln[(212 - 120)/(160 - 60)]$$

$$= 96^\circ\text{F}$$

$$A = q/UA\Delta T_{1m}$$

where  $A$  = surface area of a shell-and-tube condenser,  $\text{ft}^2$   
 $q$  = heat transfer rate, Btu/lb  
 $U$  = overall heat transfer coefficient, Btu/ $^\circ\text{F-ft}^2\text{-h}$   
 $\Delta T_m$  = mean temperature difference,  $^\circ\text{F}$

For cooling water with a water coolant,  $U$  is assumed to be 200 Btu/ $^\circ\text{F-ft}^2\text{-h}$ .

$$A = (34,320 \text{ Btu/min})/[(200 \text{ Btu/}^\circ\text{F-ft}^2\text{-h})(96^\circ\text{F})]$$

$$= 1.79 \text{ ft}^2 \text{ or } 2 \text{ ft}^2$$

5. The total area needed is

$$A = 3272 + 2$$

$$= 3274 \text{ ft}^2$$

As illustrated by this example, the area for subcooling is usually very small compared with the area required for condensing.

**EXAMPLE 2:** contact condenser

In an oil refinery, a stream of light hydrocarbons is to be condensed by a direct contact condenser. The light hydrocarbon stream is essentially benzene. From Perry's *Chemical*

*Engineer's Handbook* (Perry-73) you found that for benzene: the boiling point is 175°F, the latent heat of vaporization ( $H_v$ ) is 160 Btu/lb, and the specific heat ( $C_p$ ) is 0.45 Btu/lb-°F. Water is used as the coolant at 60°F and  $C_p = 1.0$  (EPA-81/05, p. 19-1).

*Questions*

- (a) For a benzene mass flow rate ( $m$ ) of 10,000 lb/h, how much coolant ( $w$ ) is required if the condensate temperature ( $T_c$ ) can be no higher than 100°F.  
 (b) How much benzene is lost in the water if the solubility of benzene at 100°F is 0.05 lb/100 lb water.

*Solution:*

1. To calculate the amount of water, we must set up a heat balance:

Heat input = heat output

Heat required to condense vapors

+ heat required to cool vapors to outlet temperatures = heat supplied by water

$$mH_v + mC_p(T_{IN} - T_c) = wC_p(T_c - T_{IN})$$

$$(10,000 \text{ lb/h}) \times (160 \text{ Btu/lb}) + (10,000 \text{ lb/h}) \times (0.45 \text{ Btu/lb-}^\circ\text{F})$$

$$\times (175 - 100^\circ\text{F}) = w(1.0 \text{ Btu/lb-}^\circ\text{F}) \times (100 - 60)$$

$$160 \times 10^4 \text{ Btu/h} + 33.8 \times 10^4 \text{ Btu/h} = w(40 \text{ Btu/lb})$$

$$w = 48,450 \text{ lb/h} = 97 \text{ gal/min} \quad (8.34 \text{ lb} = 1 \text{ gal H}_2\text{O})$$

Amount of coolant  $w$  required = 97 gal/min

2. Benzene lost in water

$$\begin{aligned} \text{benzene lost} &= [(0.05 \text{ lb benzene}) / (100 \text{ lb-water})] \times (48,450 \text{ lb-water/h}) \\ &= 24 \text{ lb/h} \end{aligned}$$

**EXAMPLE 3:** surface condenser

A surface condenser is used to condense the hydrocarbon vapors for the same conditions as in Example 2 above (EPA-81/05, p. 19-1), except that the gas outlet temperature is to be 130°F. The overall heat transfer coefficient  $U$  from Perry's *Chemical Engineer's Handbook* (Perry-73) is 110 Btu/°F-ft<sup>2</sup>-h.

*Question*

What is the surface of the tubes required for the surface condenser?

*Solution:*

To calculate the surface area of tubes, use the equation

$$q = UA\Delta T_m$$

where  $q$  = heat transfer rate, Btu/h

$U$  = overall heat transfer coefficient, Btu/°F-ft<sup>2</sup>-h

$\Delta T_m$  = log mean temperature difference, °F

1. We must first calculate the mean temperature change

$$\Delta T_{lm} = [(T_{G1} - T_{L2}) - (T_{G2} - T_{L1})] / \ln[(T_{G1} - T_{L2}) / (T_{G1} - T_{L1})]$$

where  $\Delta T_{lm}$  = log mean temperature difference

$T_{G1}$  = gas entering temperature

$T_{L2}$  = coolant leaving temperature

$T_{G2}$  = gas leaving temperature

$T_{L1}$  = coolant entering temperature

$$\begin{aligned}\Delta T_{\text{lm}} &= [(T_{G1} - T_{L2}) - (T_{G2} - T_{L1})] / \ln[(T_{G1} - T_{L2}) / (T_{G1} - T_{L1})] \\ &= [(175 - 60) - (130 - 100)] / \ln[(175 - 60) / (130 - 100)] \\ &= 63.3^\circ\text{F}\end{aligned}$$

2. The heat required is

$q$  = heat required to condense vapors + heat required to subcool

$$q = mH_v + mC_p(T_{G1} - T_{G2})$$

$$q = (10,000 \text{ lb/h}) \times (160 \text{ Btu/lb}) + (10,000 \text{ lb/h}) \times (0.45 \text{ Btu/lb}\cdot^\circ\text{F}) \times (175 - 130^\circ\text{F})$$

$$q = 160 \times 10^4 \text{ Btu/h} + 20.25 \times 10^4 \text{ Btu/h}$$

$$= 180.25 \times 10^4 \text{ Btu/h}$$

3. Surface area

$$A = q / U \Delta T_{\text{lm}}$$

where  $A$  = surface area of a shell-and-tube condenser,  $\text{ft}^2$

$q$  = heat transfer rate,  $\text{Btu/h}$

$U$  = overall heat transfer coefficient,  $\text{Btu}/^\circ\text{F}\cdot\text{ft}^2\cdot\text{h}$

$\Delta T_{\text{lm}}$  = log mean temperature difference,  $^\circ\text{F}$

$$\begin{aligned}A &= (180.25 \times 10^4 \text{ Btu/h}) / [(110 \text{ Btu}/^\circ\text{F}\cdot\text{ft}^2\cdot\text{h})(63.3^\circ\text{F})] \\ &= 263 \text{ ft}^2\end{aligned}$$

## 4.5 $\text{NO}_x$ Emission Control

Approximately one-half of the total nitrogen oxide emissions come from motor vehicles. The other half comes from fossil fuel combustion by utility and industrial boilers, other industrial furnaces and processes, and waste incinerators. Nitrogen oxide emissions that come from fossil fuel combustion result mainly from operating conditions in combustion chambers of furnaces and incinerators. The amount of nitrogen in the combustion air and the amount of nitrogen in the fuel are the two major components that form the nitrogen oxides during combustion or incineration (EPA-81/12, p. 7-1).

**Formation of nitrogen oxide.** When fossil fuels are burned with air in a boiler or a furnace, some of the oxygen ( $\text{O}_2$ ) and nitrogen ( $\text{N}_2$ ) present combine to form nitrogen oxides ( $\text{NO}_x$ ). Most of the oxides form according to the following reaction:

Once the NO forms, the rate of decomposition is very slow and NO does not dissociate back into  $\text{N}_2$  and  $\text{O}_2$  in any appreciable amounts. The NO formed can react with more oxygen to form  $\text{NO}_2$ .

In large combustion furnaces, the majority of  $\text{NO}_x$  formed, approximately 95%, is in the form of NO. The main factors involved in  $\text{NO}_x$  formation include:

- Flame temperature
- Length of time combustion gases are maintained at that temperature

- Amount of excess air present in the flame

Flame temperature in a utility boiler furnace is approximately 1650°C (3000°F). At this high temperature, NO is formed in great abundance (sometimes greater than 1000 ppm). The residence time usually available in combustion equipment is too short for an appreciable fraction (usually less than 5%) of the NO to be oxidized to NO<sub>2</sub>. The bulk of the NO<sub>2</sub> is formed in the atmosphere after release from the stack rather than in the confines of the combustion furnace. In this chapter, NO<sub>x</sub> refers to the total NO and NO<sub>2</sub> being emitted from major combustion sources.

In small residential heating units, furnace temperatures are usually less than 1090°C (2000°F). These relatively low-temperature operating units produce an exhaust gas containing low NO<sub>x</sub> emissions; usually less than 10 ppm.

**Thermal NO<sub>x</sub> and fuel NO<sub>x</sub>.** Nitrogen oxide emissions are formed by two chemical processes occurring during combustion: the thermal NO<sub>x</sub> process and the fuel NO<sub>x</sub> process.

**Thermal NO<sub>x</sub>:** Thermal NO<sub>x</sub> results from intense heat during combustion, causing a fraction of the nitrogen content of the combustion air to be oxidized. Its rate of formation is highly sensitive to the flame temperature and to a lesser extent to the local concentration of oxygen at the flame. Virtually all thermal NO<sub>x</sub> is formed in the region of the flame which is at the highest temperature. In theory, the formation of thermal NO<sub>x</sub> can be reduced in four ways:

- Reduce the nitrogen level (of air) at peak temperature
- Reduce the oxygen level at peak temperature
- Reduce the peak flame temperature
- Reduce the time of exposure at peak temperature

Since the concentration of nitrogen in air–fuel mixtures is relatively fixed, this tactic is not really applicable. Therefore, thermal NO<sub>x</sub> is reduced in field practice by reducing oxygen levels, peak flame temperatures, and residence time in the NO<sub>x</sub>-producing section of the furnace. This is accomplished by various combustion modification techniques, such as the use of low excess air, staged combustion, reduced air preheat, or flue gas recirculation.

**Fuel NO<sub>x</sub>:** Fuel NO<sub>x</sub> occurs as the nitrogen contained in the fuel is oxidized. Therefore, it is dependent on the nitrogen content of the fuel. In fuels such as coal and heavy oil that are relatively high in nitrogen content, approximately 20 to 60% of the fuel-bound nitrogen is oxidized. Its rate of formation is strongly affected by the local oxygen concentration present in the flame and also by the mixing rate of the fuel and air. Thus, like thermal NO<sub>x</sub>, fuel NO<sub>x</sub> is dominated by the local combustion conditions. One way to reduce fuel NO<sub>x</sub> emissions is to reduce the nitrogen content in the fuel. This is not always possible and therefore combustion modification techniques are generally used to reduce NO<sub>x</sub> emissions. These include:

- Use of low excess air firing
- Optimum burner designs
- Two-stage combustion or high air preheat (secondary air preheat).

**NO<sub>x</sub> emission control techniques.** The control techniques for nitrogen oxide emissions are summarized in Table 1.14.

**Fuel denitrogenation.** One control technology for reducing NO<sub>x</sub> emissions is to remove the nitrogen contained in the fuel. Amounts of nitrogen vary in a fossil fuel. Coal, shale, and residual fuel oil contain a larger amount of nitrogen than either distillate oil or natural gas. The nitrogen in the fuel can be emitted as NO<sub>x</sub> when the fossil fuel is burned in the furnace.

Nitrogen is removed from coal, shale, or heavy fuel oil by liquefying the fuels and mixing with hydrogen gas. The mixture is heated and a catalyst is used to cause the nitrogen in the fuel and the hydrogen to unite. This reaction produces two products: ammonia and a cleaner fuel.

**TABLE 1.14** Techniques for the Control of Nitrogen Oxide Emissions

1. Fuel denitrogenation (before burning)		
2. Combustion modification (during burning)	2.1. Low excess air	
	2.2. Staged combustion	
	2.3. Flue gas recirculation	
	2.4. Low NO <sub>x</sub> burner	
	2.5. Other techniques	2.5.1. Reduced air preheater
		2.5.2. Load reduction
		2.5.3. Steam and water injection
		2.5.4. Catalytic combustion
3. Flue gas treatment (after burning)	3.1. Exxon thermal DeNO <sub>x</sub>	
	3.2. Selective catalytic reduction (SCR)	
	3.3. Shell UOP	
	3.4. Wet simultaneous NO <sub>x</sub> and SO <sub>2</sub> reduction	

Researchers are developing better catalysts and finding ways to reduce the deposition of carbon on the catalyst surface. Carbon deposits reduce the effectiveness of the catalyst life. This technology can reduce the nitrogen content in both natural fuels and synthetic liquid or gaseous fuel (made from shale and coal). This could become an increasingly important technology with the development and use of synthetic fuels in the future.

*Combustion modification.* Combustion conditions in the combustion chamber can be modified to reduce NO<sub>x</sub> formation. Techniques of combustion modifications to reduce the formation of nitrogen oxides include:

- Low excess air
- Staged combustion
- Flue gas recirculation
- Low NO<sub>x</sub> burner
- Other techniques

*Low excess air:* In a combustion system, a certain amount of excess air is required to ensure complete combustion of the fuel. The more efficient the burners are for air and fuel mixing, the less amount of excess air is required for complete combustion. The minimum amount of excess air is limited by the production of smoke and unburned fuel leaving the furnace.

The level of excess air in an industrial or utility boiler usually ranges from 5% to as high as 50 or 100%. However, most large boilers today operate with excess air less than 5%. Small residential heating furnaces, because of their unsophisticated design, usually operate with approximately 80 to 100% excess air. Gas turbines operate at very high excess air conditions, 300 to 400%. Most of this excess air is added as secondary air at lower temperatures, resulting in low NO<sub>x</sub> emissions (EPA-81/12, p. 7-7).

NO<sub>x</sub> emissions are reduced from many combustion furnaces by low excess air firing. The local flame zone concentration of oxygen is reduced, thus reducing both thermal and fuel NO. This method is easy to implement and actually increases the efficiency of the furnace slightly. However, there are problems with this combustion modification. Low excess air firing can produce smoke and high CO emissions. Also, fouling and slagging of boiler tube surfaces can occur if various coal and residual oils are burned.

NO<sub>x</sub> reductions averaging between 16 and 20% are achieved on gas- and oil-fired utility boilers when the excess air is reduced to a level between 2 and 7%. NO<sub>x</sub> reductions averaging

around 20% can be achieved on coal-fired utility boilers if the excess air is reduced to the 20% level or lower. For most utility boiler applications, operating at low excess air conditions is considered a routine procedure.

*Staged combustion:* During staged combustion, air and fuel mixtures are combusted in two separate zones. In one zone, the fuel is fired with less than a stoichiometric amount of air. This creates a fuel-rich local zone in the regions of the primary flame. The second zone is an air-rich zone where the remainder of the combustion air is introduced to complete the combustion of the fuel. The heat in the primary flame zone is not as intense as with normal firing because combustion is incomplete. The air mixed with the fuel is sub-stoichiometric in the  $\text{NO}_x$ -forming region of the flame, thus creating a low  $\text{NO}_x$  condition. This modification is also referred to as “off-stoichiometric” combustion (EPA-81/12, p. 7-8).

Staged combustion reduces  $\text{NO}_x$  emissions by a combination of several factors:

- A lack of available oxygen for  $\text{NO}_x$  formation in the fuel-rich stage is due to off-stoichiometric firing.
- The flame temperature may be lower in the first stage than with single-stage combustion.
- The peak temperature in the second stage (air rich) is lower.

Staged combustion is an effective technique for controlling both thermal and fuel  $\text{NO}_x$  due to its ability to control the mixing of fuel with combustion air. The  $\text{NO}_x$  reduction effectiveness depends on good burner operation to prevent convective boiler tube fouling, unburned hydrocarbon emissions, and poor ignition characteristics which occasionally occur at an excessively fuel-rich boiler operation. Fire-side boiler tube corrosion may occur when burning some coals or heavy oils under staged combustion conditions.

In staged combustion the flame is long, yellow, and slightly smokey as opposed to the short and intense flame observed on normal firing. Fuel combustion (second stage) also extends further into the furnace, sometimes causing excessive temperatures in the convective and superheater sections of the boiler.

Staged combustion is accomplished by using modifications to the boiler such as over fire air (OFA) port and burners out of service (BOOS).

*Over fire air port:* Over fire air ports are separate ports located above the burner. The burners are operated fuel rich with the remainder of the combustion air coming in through the over fire air ports. These are sometimes referred to as  $\text{NO}_x$  ports. In some boilers, a number of the burners are operated fuel rich, others air rich in a staggered configuration. This is called *biased firing*. In the case where some burners are operated on air only, this modification is called *burners out of service*.

On existing boilers, a steam load reduction will result in burners out of service if the active fuel burners do not have the capacity to supply fuel for a full load. Most utility boilers installed since 1971 have been designed with over fire air ports so that all fuel burners are active during the staged combustion operation. Using staged combustion modifications on oil- and gas-fired boilers reduces  $\text{NO}_x$  emissions by approximately 30 to 40%. Modifying existing coal boilers has reduced  $\text{NO}_x$  emissions 30 to 50%.

Staged combustion can also be accomplished by careful control of air and fuel mixing in the burner.

*Flue gas recirculation:* Flue gas recirculation (FGR) has been used to reduce thermal  $\text{NO}_x$  emissions from large oil- and gas-fired boilers. A portion (10 to 30%) of the flue gas exhaust is recycled back into the main combustion chamber by removing it from the stack breeching and mixing it with the secondary air windbox. In order for FGR to be effective in reducing  $\text{NO}_x$  emissions, the gas must enter directly into the combustion zone. This recirculated gas lowers the flame temperature and dilutes the oxygen content of the combustion air, thus lowering thermal  $\text{NO}_x$  emissions (EPA-81/12, p. 7-10).

Some operational problems can occur using flue gas recirculation. Possible flame instability, loss of heat exchanger efficiency and, for small package boilers, condensation on internal heat transfer surfaces, limit the usefulness of gas recirculation.

Flue gas recirculation requires greater capital expenditures than low excess air and staged combustion modifications. High temperature fans (forced or induced draft), ducts, and large space are required for recirculating the gas. However, the costs can be reasonable if the boiler is already equipped with gas recirculation for steam temperature control.

$\text{NO}_x$  reduction of approximately 40 to 50% is possible with recirculation of 20 to 30% of the exhaust gas in gas- and oil-fired boilers. Since FGR is used to reduce thermal  $\text{NO}_x$ , it is not effective for reducing  $\text{NO}_x$  emissions generated from burning a high nitrogen content fuel such as coal. At high rates of recirculation (greater or equal to 30%) the flame can become unstable, thus increasing carbon monoxide and hydrocarbon emissions.

This combustion modification technique (FGR) should not be confused with flue gas recirculation used by utilities to control boiler tube (superheat) temperature. In this utility practice, flue gas is taken from the stack breeching and mixed into the hopper bottom section of the boiler that is located below the combustion chamber. Since flue gas is not recirculated into the main combustion chamber, this utility practice is not useful in reducing  $\text{NO}_x$  emissions.

*Low  $\text{NO}_x$  burner:* Low  $\text{NO}_x$  burners have been developed by several manufacturers to reduce  $\text{NO}_x$  emissions. Burners control mixing of fuel and air in a pattern to keep flame temperature low and to dissipate the heat quickly. Some burners are designed to control the flame shape to minimize the reaction of nitrogen and oxygen at peak flame temperatures. Other designs have fuel-rich and air-rich regions to reduce flame temperature and oxygen availability.

*Other combustion modification techniques:* Other combustion modifications can also reduce  $\text{NO}_x$  emissions from combustion sources. These include: reduced air preheater, load reduction, steam and water injection, and catalytic combustion. Reduced air preheat and load reduction are used sparingly in large boilers because of the energy penalty involved and the relatively low emission reduction occurring. Steam and water injection are used mainly for  $\text{NO}_x$  emission reduction in gas turbines and internal combustion engines. Steam or water is injected into the combustion area to lower the peak flame temperature and thus reduce thermal  $\text{NO}_x$  emissions. In catalytic combustion, a catalyst is used to achieve oxidation of the fuel rather than using high flame temperatures. These systems have been used in gas turbines to reduce  $\text{NO}_x$  emissions well below 10 ppm (EPA-81/12).

*Flue gas treatment.* Nitrogen oxide emissions can be reduced by treating the flue gas after it leaves the combustion zone. Flue gas treatment processes include:

- Exxon Thermal  $\text{DeNO}_x$
- Selective catalytic reduction (SCR)
- Shell UOP
- Wet simultaneous  $\text{NO}_x$  and  $\text{SO}_x$  reduction.

*Exxon Thermal  $\text{DeNO}_x$  process:* Thermal  $\text{DeNO}_x$  is a process that uses ammonia injection to reduce  $\text{NO}_x$  emissions. The process was developed by Exxon Research and Engineering Co. Ammonia is injected into the post-combustion zone of the boiler (EPA-81/12, p. 7-13).

The ammonia reacts with  $\text{NO}_x$  (which is 95% NO) to reduce the oxides to molecular nitrogen and water:

The above reaction is extremely temperature dependent. In a boiler, this reaction successfully takes place at approximately  $950^\circ\text{C}$  ( $1740^\circ\text{F}$ ). At higher temperatures (above  $1090^\circ\text{C}$ ) the ammonia is oxidized, forming additional  $\text{NO}_x$ . At lower temperatures (below  $850^\circ\text{C}$ ) the ammonia passes through the boiler unreacted.

*Selective catalytic reduction:* Selective catalytic reduction (SCR) is a dry process used to reduce  $\text{NO}_x$  emissions from fossil-fuel-fired boilers. This process is based on the preferential reaction of  $\text{NH}_3$  with  $\text{NO}_x$  rather than with  $\text{SO}_2$  in the flue gas. The reactions are expressed as

The first equation represents the predominant reaction occurring, since 95% of  $\text{NO}_x$  emissions in combustion flue gas are in the form of NO.

This process involves injecting  $\text{NH}_3$  into the flue gas and passing this mixture through a catalytic reactor.  $\text{NO}_x$  emissions are reduced to harmless molecular nitrogen ( $\text{N}_2$ ) and water vapor ( $\text{H}_2\text{O}$ ). Ammonia is injected on an  $\text{NH}_3$ :NO mole ratio of 1:1, attaining a 90%  $\text{NO}_x$  emission reduction with less than 20 ppm  $\text{NH}_3$  leaving the reactor.

*Shell UOP process:* The Shell UOP is a dry process that simultaneously removes both  $\text{NO}_x$  and  $\text{SO}_x$  emissions. This process can also be designed to remove either compound separately. The process uses a copper oxide (CuO) catalyst supported on alumina. These catalysts are located in two or more parallel passage reactors (EPA-81/12, p. 7-20).

Flue gas containing both  $\text{NO}_x$  and  $\text{SO}_x$  is introduced into the reactor where the  $\text{SO}_x$  reacts with copper oxide to form copper sulfate ( $\text{CuSO}_4$ ). At the same time ammonia is being injected; this reacts with the  $\text{NO}_x$ . The copper sulfate, and to a less extent the copper oxide, act as catalysts for the  $\text{NO}_x$ - $\text{NH}_3$  reaction.

The following reactions occur in the reactor ( $\text{SO}_2$  and  $\text{NO}_x$  reduction):

When the reactor catalyst is saturated with  $\text{CuSO}_4$ , the flue gas is redirected to a fresh reactor and the spent catalyst is regenerated. Hydrogen is used to regenerate the catalyst by reducing the  $\text{CuSO}_4$  to copper and producing a concentrated  $\text{SO}_2$  gas stream. The  $\text{SO}_2$  gas is then used to produce sulfuric acid or elemental sulfur for commercial sale. The copper in the reactor is oxidized to CuO and the process is ready to be put on line again. The reactions that take place in the reactor during catalyst regeneration are

The Shell UOP process can be operated as a  $\text{NO}_x$  emission reduction process by eliminating the regeneration cycle. The process can be operated as an  $\text{SO}_x$  emission reduction process by eliminating the ammonia injection.

*Wet  $\text{NO}_x$  and  $\text{SO}_x$  process:* Wet processes use absorbers to reduce both  $\text{SO}_x$  and  $\text{NO}_x$  emissions simultaneously. These will not be discussed in detail.

#### 4.6. $\text{SO}_x$ Emission Control

Flue gas desulfurization (FGD) is the generic name of air pollution control technologies that are used to reduce the emissions of sulfur dioxide ( $\text{SO}_2$ )—a major acid rain precursor (EPA-79/11). Fossil fuels, especially coal, usually contain up to 7% of sulfur. Through the combustion process, almost all of the sulfur in the fuel is oxidized into gaseous  $\text{SO}_2$ . After the  $\text{SO}_2$  is emitted into the atmosphere, it is further oxidized and incorporated into rain, fog, and snow as sulfuric acid. The ‘acid rain’ or ‘acid precipitation’ can result in damages to aquatic ecosystems, soil systems, vegetation and man-made objects (Chang-98/07).

The techniques to reduce the sulfur oxide emissions from fossil fuel combustion sources can be grouped into Table 1.15 (EPA-84/03, p. 8-1; EPA-81/12, p. 8-1).

**Fuel desulfurization.** Fuel desulfurization removes or reduces the sulfur content of coal before it is burned. Coal contains sulfur in two forms:

- Mineral sulfur in the form of inorganic pyrite: mineral sulfur can be removed by physical coal cleaning.
- Organic sulfur which is chemically bound to the coal: organic sulfur requires chemical cleaning.

One of the most straightforward ways to reduce SO<sub>2</sub> emissions from combustion sources is by burning fuel containing less sulfur. This might involve using low sulfur coal, low sulfur fuel oil, or natural gas instead of a high sulfur coal. The use of low sulfur coal (usually supplied from the western United States) can reduce SO<sub>2</sub> emissions. In some cases, low sulfur coal has been used to meet state and federal air pollution regulations. Low sulfur coal generally contains less than 1% sulfur; high sulfur coal contains between 3 and 5% sulfur. Low sulfur coal is more expensive and less available (in the eastern United States) than high sulfur coal. However, the sulfur content can be reduced by a process called fuel desulfurization which includes two major processes (EPA-81/12, p. 8-4):

- Physical coal cleaning
- Chemical coal cleaning

*Physical coal cleaning:* Physical coal cleaning is important, because it can reduce the ash and sulfur content of coal and hence the potential SO<sub>2</sub> emissions which result from coal combustion. Physical coal cleaning depends on the differences in density of both coal and the impurities. Coal is crushed, washed, and then separated by settling processes using cyclones, air classifiers or magnetic separators. Approximately 40 to 90% of the pyritic sulfur content can be removed by physical coal cleaning (EPA-80/08). Its effectiveness depends on the size of pyritic sulfur particles and the amount of pyritic sulfur contained in the coal.

*Chemical coal cleaning:* Chemical coal cleaning methods that reduce the organic-bound sulfur include two technologies: (1) microwave desulfurization and (2) hydrothermal desulfurization.

- *Microwave desulfurization:* In microwave desulfurization, coal is crushed, then heated for 30 to 60 seconds by exposure to microwaves. Mineral sulfur selectively absorbs this radiation forming hydrogen sulfide gas (H<sub>2</sub>S). The H<sub>2</sub>S is usually reduced to elemental sulfur by the Claus process. Another microwave process adds calcium hydroxide [Ca(OH)<sub>2</sub>] to crushed coal. The organic sulfur converts to calcium sulfite (CaSO<sub>3</sub>) when exposed to this radiation. The coal is washed with water to remove the CaSO<sub>3</sub> and other impurities. As much as 70% of the sulfur can be removed by the microwave process (EPA-80/08).
- *Hydrothermal desulfurization:* In hydrothermal desulfurization, coal is crushed and mixed with a solution of sodium and calcium hydroxides [NaOH and Ca(OH)<sub>2</sub>]. When this mixture is heated to 275°C in a pressurized vessel, most of the pyritic sulfur and 20 to 50% of the organic sulfur is converted to sodium and calcium sulfites (Na<sub>2</sub>SO<sub>3</sub> and CaSO<sub>3</sub>) (EPA-80/08). The coal is rinsed to remove the sulfites and the water is processed to recycle the sodium and calcium hydroxides. This process is an expensive but effective method for removing sulfur from coal.

**Combustion of coal and limestone mixture.** Sulfur oxides can be removed by burning coal and limestone mixtures in a boiler. Two promising burning technologies under development are (EPA-81/12, p. 8-5):

- Fluidized bed combustion
- Limestone coal pellets as fuel

**TABLE 1.15** Techniques for the Control of Sulfur Oxide Emissions

		5.1.2. Regenerable	5.1.2.1. Wellman-Lord process 5.1.2.2. Magnesium oxide process 5.1.2.3. Citrate process
	5.2. Dry scrubbing process		

*Fluidized bed combustion process:* In the fluidized bed combustion process, a grid supports a bed of coal and limestone (or dolomite) in the firebox of the boiler. Combustion air is forced upward through the grid suspending the coal and limestone bed in a fluid-like motion. Natural gas is used to ignite the pulverized coal. Once the coal is ignited, the gas is turned off. The sulfur in the coal is oxidized to  $\text{SO}_2$  and subsequently combined with the limestone to form calcium sulfate ( $\text{CaSO}_4$ ). The  $\text{CaSO}_4$  and flyash particulate matter are usually collected in a baghouse or electrostatic precipitator (ESP).

*Limestone coal pellets as fuel:* Another way to reduce  $\text{SO}_2$  emissions from combustion processes is by burning pellets made of limestone and coal. Pellets are made by pulverizing coal and limestone and adding a binder forming small, cylindrical pellets which are about half the size of a charcoal briquette. These consist of approximately two-thirds coal, and one-third limestone. As the pellet burns, the calcium in the limestone absorbs the  $\text{SO}_2$  generated by coal combustion and forms calcium sulfate. Calcium sulfate emissions are subsequently collected in a baghouse or electrostatic precipitator.

**Coal gas gasification.** Over 70 different processes have been developed for producing a combustible gas from coal. Three basic steps are common to all coal gasification processes:

1. Coal pretreatment
2. Gasification

### 3. Gas cleaning.

*Coal pretreatment:* Coal pretreatment involves coal pulverizing and washing.

*Gasification:* The pulverized coal is gasified in a reactor with limited oxygen. Gasification produces either a low, medium, or high Btu gas by applying heat and pressure or by using a catalyst to break down the components of coal (EPA-80/08). The gas produced contains carbon monoxide (CO), hydrogen (H<sub>2</sub>), carbon dioxide (CO<sub>2</sub>), water (H<sub>2</sub>O), methane (CH<sub>4</sub>), and contaminants such as hydrogen sulfide and char. Low and medium Btu gas contains more CO and H than high Btu gas, which contains a higher C content. Methane gas produces more heat when burned. The sulfur in the coal is converted to H<sub>2</sub>S during gasification.

*Gas cleaning:* H<sub>2</sub>S is removed during the gas cleaning step generally by a scrubbing process. Hydrogen sulfide is converted to elemental sulfur by partial oxidation and catalytic conversion (EPA-80/08). The synthetic gas produced is sulfur-free and can be burned without releasing harmful pollutants.

*Coal liquefaction.* *Coal liquefaction* is a process for changing coal into synthetic oil, and is similar to coal gasification. Two basic approaches for liquefaction are used: using a gasifier to convert coal to carbon monoxide, hydrogen, and methane, followed by condensation to convert the gases to oils; using a solvent or slurry to liquefy pulverized coal and then processing this liquid into a heavy fuel oil. Some processes produce both a synthetic gas and a synthetic oil.

Hydrogen is used to convert sulfur in the coal to hydrogen sulfide gas. Hydrogen sulfide is partially oxidized to form elemental sulfur and water. More than 85% of the sulfur is removed from coal by liquefaction (EPA-80/08).

**Flue gas desulfurization (FGD).** FGD refers to the removal of SO<sub>2</sub> from the process exhaust stream. FGD scrubbing processes can either be wet or dry and can be further grouped into:

- Wet nonregenerable scrubbing processes
- Wet regenerable scrubbing processes
- Dry scrubbing processes

FGD systems can be operated wet or dry. In wet scrubbing systems, liquid absorbs SO<sub>2</sub> in the exhaust stream. The scrubbing liquid contains an alkali reagent to enhance SO<sub>2</sub> absorption. More than a dozen different reagents have been used, with lime and limestone being the most popular for utility boilers, and sodium-based reagents the most popular for industrial boilers. Sodium-based solutions (sometimes referred to as clear solutions) provide better SO<sub>2</sub> solubility and less scaling problems than lime or limestone. However, sodium reagents are much more expensive. Wet FGD scrubbers can further be classified as nonregenerable or regenerable. Nonregenerable processes, sometimes called *throwaway processes*, produce a sludge waste that must be disposed of properly. Most regenerable processes produce a product that may be sold to partially offset the cost of operating the FGD system. Regenerated products include elemental sulfur and sulfuric acid. The throwaway processes are simpler and presently more economical than those used to recover and sell products. As a result, 95% of the FGD processes utilized are nonregenerable, or throwaway (EPA-84/03, p. 8-3).

Most FGD systems employ two stages: one for fly ash removal and the other for SO<sub>2</sub> removal. Attempts have been made to remove both the fly ash and SO<sub>2</sub> in one scrubbing vessel; however, these systems experienced severe maintenance problems and low simultaneous removal efficiencies. The flue gas normally passes first through a fly ash removal device, either an electrostatic precipitator or a wet scrubber, and then into the SO<sub>2</sub> absorber.

Many different types of absorbers have been used in FGD systems, including spray towers, venturists, plate towers, and mobile packed beds. Because of scale buildup, plugging, or erosion,

which affect FGD dependability and absorber efficiency, the trend is to use simple scrubbers such as spray towers instead of more complicated ones. The configuration of the tower may be vertical or horizontal, and flue gas can flow co-currently, counter-currently, or cross-currently to the liquid. The chief drawback of spray towers is that they have a higher liquid-to-gas ratio requirement (for equivalent SO<sub>2</sub> removal) than other absorber designs.

FGD is the most popular technology used for controlling sulfur oxide emissions from combustion sources. The majority of FGD systems have been applied to combustion sources such as utility and some industrial coal-fired boilers. FGD systems are also used to reduce SO<sub>2</sub> emissions from some industrial plants such as smelters, acid plants, refineries, and pulp and paper mills. FGD scrubbing processes can either be wet or dry and can be grouped as shown in Table 1.16.

*Wet nonregenerable FGD scrubber.* Wet nonregenerable FGD processes, also known as wet throwaway FGD processes, generate non-salable (sludge or waste) products. The sludge must be disposed of properly in a pond or landfill. The most common nonregenerable processes used on utility boilers include:

- Lime scrubber
- Limestone scrubber
- Double-alkali scrubber
- Sodium-based throwaway scrubber

**LIME SCRUBBER:** A lime scrubber is a wet nonregenerable FGD process. It uses an alkaline slurry made by adding lime (CaO), usually 90% pure, to water. The alkaline slurry is sprayed in the absorber and reacts with the SO<sub>2</sub> in the flue gas. Insoluble calcium sulfite (CaSO<sub>3</sub>) and calcium sulfate (CaSO<sub>4</sub>) salts are formed in the chemical reaction that occurs in the scrubber and are removed as sludge. The sludge produced can be stabilized to produce an inert landfill material or can be stored in sludge ponds (EPA-84/03, p. 8-6; EPA-81/12, p. 8-7).

*Process chemistry*

A number of reactions take place in the absorber. Before the calcium can react with the SO<sub>2</sub>, both must be broken down into their respective ions.

*SO<sub>2</sub> dissociation:* SO<sub>2</sub> is absorbed in the water to form sulfite (SO<sub>3</sub>)<sup>-</sup> and sulfate (SO<sub>4</sub>)<sup>-</sup> ions.

**TABLE 1.16** Flue Gas Desulfurization (FGD) Techniques

Wet scrubbing process	Throwaway (nonregenerable) process	Lime scrubber Limestone scrubber Double-alkali scrubber Sodium-based throwaway scrubber
	Regenerable process	Wellman-Lord scrubber Magnesium oxide scrubber Citrate scrubber
Dry scrubbing process		

*Lime CaO dissolution:* This is accomplished by slaking (dissolving) the lime in water to produce a calcium slurry of CaO and H<sub>2</sub>O or calcium hydroxide [Ca(OH)<sub>2</sub>] and then spraying the slurry into the flue gas to dissolve the SO<sub>2</sub>. The calcium hydroxide–water mixture is a solution containing calcium ions (Ca<sup>2+</sup>) and hydroxide ions (OH<sup>-</sup>).

Now that the SO<sub>2</sub> and lime are broken into their ions, namely, (SO<sub>3</sub>)<sup>2-</sup> and Ca<sup>2+</sup>, the following reaction occurs:

Combining all reactions above, the basic reactions occurring are

From the above relationships and assuming that the lime is 90% pure, it will take 1.1 moles of lime to remove 1 mole of SO<sub>2</sub> gas.

#### *System description*

The equipment necessary for SO<sub>2</sub> emission reduction is used in four operations:

- *Scrubbing or absorption:* accomplished with scrubbers, holding tanks, liquid-spray nozzles, and circulation pumps.
- *Lime handling and slurry preparation:* Accomplished with lime unloading and storage equipment, lime processing and slurry preparation equipment.
- *Sludge processing:* accomplished with sludge clarifiers for dewatering, sludge pumps and handling equipment, and sludge solidifying equipment.
- *Flue gas handling:* accomplished with inlet and outlet ductwork, dampers, fans, and stack gas reheaters.

Figure 1.36 is a schematic of a typical lime FGD system. Flue gas from the boiler first passes through a particulate emission removal device then into the absorber where the SO<sub>2</sub> is removed. The gas then passes through the entrainment separator to a reheater and is finally exhausted out of the stack. Individual FGD systems vary considerably, depending on the FGD vendor and the plant layout. ESPs or scrubbers can be used for particle removal with the various absorbers used for SO<sub>2</sub> removal.

A slurry of spent scrubbing liquid and sludge from the absorber then goes to a recirculation tank. From this tank, a fixed amount of the slurry is bled off to process the sludge, and, at the same time, an equal amount of fresh lime is added to the recirculation tank. Sludge is sent to a clarifier, where a large portion of water is removed from the sludge and sent to a holding tank. Makeup water is added to the process-water holding tank, and this liquid is returned to the recirculation tank. The partially dewatered sludge from the clarifier is sent to a vacuum filter, where most of the water is removed (and sent to the process-water holding tank) and the sludge is sent to a lined settling pond.

**LIMESTONE SCRUBBER:** A limestone scrubber is very similar to a lime scrubber. It is a wet nonregenerable process. Limestone scrubbing uses an alkaline slurry from limestone (CaCO<sub>3</sub>) in an absorber to react with SO<sub>2</sub> in the flue gas. Calcium sulfite (CaSO<sub>3</sub>) and calcium sulfate (CaSO<sub>4</sub>) salts are formed in the reaction and are removed as sludge. Two major equipment differences between lime and limestone scrubbing are (EPA-84/03, p. 8-11; EPA-81/12, p. 8-11) lime's use of feed preparation equipment and limestone's use of higher liquid-to-gas

FIGURE 1.36 Process flow for a lime or limestone FGD process (EPA-84/03, p. 8-7).

ratios (because limestone is less reactive than lime). Even with these differences, the processes are so similar that an FGD system can be set up to use either lime or limestone in the scrubbing liquid.

The basic chemical reactions occurring in the limestone process are very similar to those in the lime-scrubbing process. Limestone ( $\text{CaCO}_3$ ) is slaked with water to form aqueous  $\text{CaCO}_3$  and is sprayed into the absorber. Sulfite and sulfate ions are produced as the  $\text{SO}_2$  gas contacts the water. These ions combine with calcium ions to produce calcium sulfite and calcium sulfate sludge. The basic reactions are

The only difference is in the dissolution reaction that generates the calcium ion. When limestone is mixed with water, the following reaction occurs:

The equipment necessary for  $\text{SO}_2$  absorption is the same as that for lime scrubbing, except in the slurry preparation. The limestone feed (rock) is reduced in size by crushing it in a ball mill. Limestone is then sent to a size classifier. Pieces larger than 200 mesh are sent back to the ball mill for recrushing. Limestone is mixed with water in a slurry supply tank; it is generally a little cheaper than lime, making it more popular for use in large FGD systems.

**DOUBLE-ALKALI SCRUBBER:** Dual- or double-alkali scrubbing is a wet nonregenerable or throwaway FGD process that uses a sodium-based alkali solution to remove  $\text{SO}_2$  from combustion exhaust gas. Although the double-alkali process regenerates the scrubbing reagent, it is classified as throwaway since it does not produce a salable product and generates solids that must be disposed of in a landfill (EPA-84/03, p. 8-15; EPA-81/12, p. 8-15).

The sodium alkali solution absorbs  $\text{SO}_2$  and the spent absorbing liquor is regenerated with lime or limestone. Calcium sulfites and sulfates are precipitated and discarded as sludge. The regenerated sodium scrubbing solution is returned to the absorber loop. The double-alkali

process has reduced plugging and scaling problems in the absorber because sodium scrubbing compounds are very soluble. Double-alkali systems are capable of 95% SO<sub>2</sub> reduction.

Particulate matter is removed prior to SO<sub>2</sub> scrubbing by an electrostatic precipitator or a venturi scrubber. This is done to prevent fly ash erosion of the absorber internals and to prevent any appreciable oxidation of the sodium solution in the absorber due to catalytic elements in the fly ash.

*Process chemistry*

The sodium alkali solution is usually a mixture of three components: sodium carbonate (Na<sub>2</sub>CO<sub>3</sub>), also called soda ash; sodium sulfite (Na<sub>2</sub>SO<sub>3</sub>); and sodium hydroxide (NaOH), also called caustic soda.

The SO<sub>2</sub> reacts with the alkaline components to primarily form two salts: sodium sulfite (Na<sub>2</sub>SO<sub>3</sub>) and sodium bisulfite (NaHSO<sub>3</sub>) as indicated in the following main absorption reactions:

In addition to the above reactions, any SO<sub>3</sub> present will react with alkaline components to produce sodium sulfate. For example,

Throughout the system, some sodium sulfite is oxidized to sulfate by

After reaction in the absorber, spent scrubbing liquor is bled to a reactor tank for regeneration. Sodium bisulfite and sodium sulfate are inactive salts and do not absorb any SO<sub>2</sub>. Actually, it is the hydroxide ion (OH<sup>-</sup>), sulfite ion (SO<sub>3</sub>)<sup>2-</sup> and carbonate ion (CO<sub>3</sub>)<sup>2-</sup> that absorb SO<sub>2</sub> gas.

Sodium bisulfite and sodium sulfate are reacted with lime or limestone to produce a calcium sludge and a regenerated sodium solution. The solution is the mixture of sodium sulfite (Na<sub>2</sub>SO<sub>3</sub>) and sodium hydroxide (NaOH).

At the present time, lime regeneration is the only regeneration process that has been used on commercial double-alkali installations.

*Process description*

The double-alkali process uses two loops: absorption and regeneration.

*Absorption loop:* In the absorption loop the sodium solution contacts the flue gas in the absorber to remove  $\text{SO}_2$ , as shown in Eqs. (1.52)–(1.56). The main products of the absorption loop are two salts: sodium sulfite ( $\text{Na}_2\text{SO}_3$ ) and sodium bisulfite ( $\text{NaHSO}_3$ ).

*Regeneration loop:* The products from the absorption loop are mixed with lime ( $\text{CaO}$ ) or limestone ( $\text{CaCO}_3$ ) to produce a calcium sludge and a regenerated sodium solution as shown in Eqs. (1.59)–(1.61). In this example, the regenerated sodium solution is a mixture of sodium sulfite ( $\text{Na}_2\text{SO}_3$ ) and sodium hydroxide ( $\text{NaOH}$ ). The third component of the sodium solution, sodium carbonate ( $\text{Na}_2\text{CO}_3$ ) (also called soda ash), is not regenerated and therefore new soda ash is needed for the system. This need is indicated at the mixing tank shown in Fig. 1.37.

As shown in Fig. 1.37 the scrubbing liquor from the bottom of the absorber is used mixed with regenerated solution and sprayed in at the top of the absorber. A bleed stream from the recirculating liquid is sent to the reactor tank in the regeneration loop. The bleed stream is mixed with a lime slurry in a reactor tank, where insoluble calcium salts are formed and the absorbent is regenerated. The sludge from the reactor is then sent to a clarifier, or thickener, where the calcium sludge is drawn off the bottom, filtered, and washed with water. From the filter, the sodium solution is recycled to the thickener, and the sludge is discarded. From the thickener, the regenerated sodium solution is sent to a holding tank, where the sodium compounds and makeup water are added.

Some sodium sulfate solution is unreacted in the regeneration step. Additional sodium is added to the regenerated solution in the form of soda ash or caustic soda. This regenerated absorbent is now ready to be used again.

**SODIUM-BASED SCRUBBER:** A sodium-based scrubber is a wet nonregenerable (throwaway or once-through) FGD process. It is the overwhelming choice for FGD systems installed on industrial boilers. This system uses a clear liquid absorbent of either sodium carbonate ( $\text{Na}_2\text{CO}_3$ ), sodium hydroxide ( $\text{NaOH}$ ), or sodium bicarbonate ( $\text{NaHCO}_3$ ).

Advantages of the sodium-based systems include:

FIGURE 1.37 Typical process flow for a double-alkali system (EPA-84/03, p. 8-17).

- Sodium alkali is the most efficient of the commercial reagents in removing  $\text{SO}_2$  and the chemistry is relatively simple.
- They are soluble systems—as opposed to slurry systems—making for scale-free operation and fewer components.
- Such systems can handle the wider variations in flue gas composition resulting from the burning of many different fuels by industry.
- The systems are often smaller, and operating costs are a small percentage of total plant costs.
- In some cases, these plants have a waste caustic stream or soda ash available for use as the absorbent.

Disadvantages of the sodium-based systems include:

- The process consumes a premium chemical ( $\text{NaOH}$  or  $\text{Na}_2\text{CO}_3$ ) that is much more costly per pound than calcium-based reagents.
- The liquid wastes contain highly soluble sodium salt compounds. Therefore, the huge quantities of liquid wastes generated by large utilities would have to be sent to ponds to allow the water to evaporate.

The process chemistry is very similar to that of the double-alkali process, except the absorbent is not regenerated.

Figure 1.38 illustrates a basic sodium-based throwaway FGD system. Exhaust gas from the boiler may first pass through an ESP or baghouse to remove particulate matter. Sodium chemicals are mixed with water and sprayed into the absorber. The solution reacts with the

FIGURE 1.38 Sodium-based throwaway FGD system (*EPA-84/03, p. 8-21*).

SO<sub>2</sub> in the flue gas to form sodium sulfite, sodium bisulfite, and a very small amount of sodium sulfate. A bleed stream is taken from the scrubbing liquor recirculation stream at a rate equal to the amount of SO<sub>2</sub> that is being absorbed. The bleed stream is sent to a neutralization tank and aeration tower before being sent to a lined disposal pond.

Some coal-fired units use ESPs or baghouses to remove fly ash before the gas enters the scrubber. In these cases, the absorber can be a plate tower or spray tower that provides good scrubbing efficiency at low pressure drops. For simultaneous SO<sub>2</sub> and fly ash removal, venturi scrubbers can be used. In fact, many of the industrial sodium-based throwaway systems are venturi scrubbers originally designed to remove particulate matter. These units were slightly modified to inject a sodium-based scrubbing liquor. Although removal of both particles and SO<sub>2</sub> in one vessel can be economically attractive, the problems of high pressure drops and using a scrubbing medium to remove fly ash must be considered. However, in cases where the particle concentration is low, such as from oil-fired units, simultaneous particulate and SO<sub>2</sub> emission reduction can be effective.

*Wet regenerable scrubbing process.* Wet regenerable FGD processes remove SO<sub>2</sub> from the flue gas and generate salable products. Regenerable products include elemental sulfur, sulfuric acid, or, in the case of lime or limestone scrubbing, gypsum (used for wallboard). Regenerable processes do not produce a sludge, thereby eliminating the sludge disposal problem. Most regenerable processes also:

- Have the potential for consistently obtaining a high SO<sub>2</sub> removal efficiency, usually exceeding 90%.
- Utilize the scrubbing reagent more efficiently than nonregenerable processes
- Use scrubbing liquors that do not cause scaling and plugging problems in the scrubber.

The major drawback of using these processes is that these systems are usually more complicated in design and are more expensive to install and operate.

Regenerable processes include:

- Wellman–Lord scrubber
- Magnesium oxide scrubber
- Citrate scrubber

**WELLMAN–LORD SCRUBBER:** A Wellman–Lord scrubber is the heart of a wet regenerable FGD process. It is a process used to reduce SO<sub>2</sub> emissions from utility and industrial boilers and produces a usable or salable product. This process is sometimes referred to as the Wellman–Lord/Allied Chemical process: Allied Chemical referring to the regeneration step (EPA-84/03, p. 8-26; EPA-81/12, p. 8-18).

*Process chemistry*

In the Wellman–Lord scrubber, the SO<sub>2</sub> is absorbed by an aqueous sodium sulfite solution which forms a sodium bisulfite solution according to the following equation:

Some oxidation occurs in the absorber to form sodium sulfate, which is unreactive with SO<sub>2</sub> gas.

The formation of sodium sulfate depletes the supply of sodium sulfite available for scrubbing. This can be made up by adding sodium carbonate to the scrubbing slurry to combine with sodium bisulfite according to the following chemical reaction:

The absorbent is then regenerated by evaporating the water from the bisulfite solution.

The concentrated  $\text{SO}_2$  produced in the regeneration step is then sent to the Allied process for conversion to elemental sulfur or sulfuric acid.

*Process description*

Figure 1.39 shows a typical process flow of a Wellman–Lord system. The process equipment includes an electrostatic precipitator for removing particulate matter; a venturi scrubber for cooling flue gas and removing  $\text{SO}_2$  and chlorides; an  $\text{SO}_2$  absorber; an evaporator-crystallizer for regenerating the absorbent; and the Allied Chemical process for reducing concentrated  $\text{SO}_2$  gas into elemental sulfur or sulfuric acid. The absorber is a plate tower.  $\text{SO}_2$  gas is scrubbed with a sodium sulfite solution at each plate. A mist eliminator removes entrained liquid droplets from gas exiting the absorber. There is a direct-fired natural gas reheating system in the absorber stack to reheat cleaned gas for good dispersion of the steam plume.

The solution (sodium bisulfite), collected at the bottom of the absorber, overflows into an absorber surge tank. This solution is pumped through a filter to remove any collected particulate matter. A small side-stream is sent to a purge treatment system, where sodium sulfate is removed. The solution is then pumped to the evaporator for regeneration of the sodium sulfite solution.

The evaporator is a forced-circulation vacuum evaporator. Solution is recirculated in the evaporator, where low-pressure steam evaporates water from the sodium bisulfite solution. When sufficient water is removed, sodium sulfite crystals form and precipitate. Concentrated  $\text{SO}_2$  gas (95% by volume) is removed by the steam. The sodium sulfite crystals form a slurry that is withdrawn continuously and sent to a dissolving tank, where condensate from the evaporator is used to dissolve the sodium sulfite crystals into a solution. This solution is pumped back into the top stage of the absorber. The water vapor is removed from the evaporator's overhead  $\text{SO}_2/\text{H}_2\text{O}$  vapors by water-cooled condensers.

**MAGNESIUM OXIDE SCRUBBER:** A magnesium oxide scrubber is a regenerable FGD process used to remove SO<sub>2</sub> from combustion exhaust gas. Magnesium oxide (MgO) slurry absorbs SO<sub>2</sub> and forms magnesium sulfite. Magnesium sulfite solids are separated by centrifugation and dried to remove moisture. The mixture is calcined to regenerate magnesium oxide and produce concentrated SO<sub>2</sub> gas for production of sulfuric acid or elemental sulfur (EPA-81/12, p. 8-21).

Particulate matter is removed from boiler exhaust by a precipitator or wet scrubber prior to entering the absorber. Magnesium oxide slurry is sprayed and absorbs SO<sub>2</sub> according to the following simplified reactions:

The aqueous slurry used for scrubbing contains the hydrated crystals of MgO, MgSO<sub>3</sub>, and MgSO<sub>4</sub>. A continuous side-stream of this recycled slurry is sent to a centrifuge where partial dewatering produces a moist cake. The liquor removed from the crystals is returned to the main slurry stream. The moist cake is dried at 350 to 450°F in a direct contact or rotary bed dryer. The dried cake is then sent to a calciner, where coke is burned at very high temperatures (1250 to 1340°F) to regenerate magnesium oxide crystals according to the following reactions:

*Cake dryer*

*MgO regeneration in calciner*

**CITRATE SCRUBBER:** A citrate scrubber is a wet regenerable FGD process that was developed by the US Bureau of Mines. The citrate process uses sodium citrate and citric acid as buffering agents to attain a higher solubility of the SO<sub>2</sub> in an aqueous absorbent solution. The chemistry of this process is very complex. The absorption of SO<sub>2</sub> is pH-dependent, increasing with higher pH. SO<sub>2</sub> forms H<sub>2</sub>SO<sub>3</sub> when absorbed by water, resulting in decreasing pH values. This creates a more acidic solution that inhibits additional absorption of SO<sub>2</sub> gas. By using a buffering agent to prevent a pH drop, a substantially higher amount of SO<sub>2</sub> can be absorbed (EPA-81/12, p. 8-22).

One commercial installation of this process was on a 60 MW industrial boiler at St. Joe Minerals in Monaca, Pennsylvania. Particulate matter is removed from the flue gas by an electrostatic precipitator. Chlorides and sulfuric acid mist are removed from the flue gas by a small venturi scrubber before entering the packed tower. SO<sub>2</sub> is absorbed by a solution of sodium citrate, citric acid, and sodium thiosulfate to produce sodium sulfite. SO<sub>2</sub> removal efficiency is approximately 90%. The solution (containing absorbed SO<sub>2</sub>) is reacted with hydrogen sulfide gas (H<sub>2</sub>S) in a closed vessel to precipitate elemental sulfur and regenerate citrate solution. The elemental sulfur precipitate is concentrated by air flotation into a sulfur

slurry which is separated from the regenerated solution. Sulfur slurry is heated to form liquid sulfur and the solution is decanted. Hydrogen sulfide gas (used in regeneration) is obtained either as a by-product of petroleum refining or produced onsite by reacting recovered sulfur with natural gas and steam.

The citrate process has some drawbacks. It is expensive compared with lime and limestone scrubbing. Production of  $H_2S$  from methane and sulfur can be a problem whenever natural gas is not available. Since the size of the absorption, regeneration, and flotation equipment is large, boiler retrofitting is sometimes difficult.

#### *Dry $SO_2$ scrubber*

Dry scrubbing processes use a dry spray to absorb  $SO_2$  gas and form dry particles. These particles are collected in a baghouse or electrostatic precipitator. In dry FGD, the flue gas containing  $SO_2$  is contacted with an alkaline material to produce a dry waste product for disposal.

This technology includes (EPA-81/12, p. 8-23; EPA-89/03, p. 4-14; EPA-92/01, p. 95):

- Injection of an alkaline slurry in a spray dryer with collection of dry particles in a baghouse or electrostatic precipitator (ESP).
- Dry injection of alkaline material into the flue gas stream with collection of dry particles in a baghouse or ESP.
- Addition of alkaline material to the fuel prior to combustion.

The dry FGD has two major types: spray dryer system and dry injection system.

**SPRAY DRYER WITH A BAGHOUSE OR ESP:** Spray dryers are vessels where hot flue gases are contacted with a finely atomized wet alkaline spray. The high temperatures of the flue gas, 250 to 400°F, evaporate the moisture from the wet alkaline sprays, leaving a dry powdered product. The dry product is collected in a baghouse or ESP (EPA-81/12, p. 8-24).

Flue gas enters the top of the spray dryer and is swirled by a fixed vane ring to cause intimate contact with the slurry spray. The slurry is atomized into extremely fine droplets by rotary atomizers. The turbulent mixing of the flue gas with the fine droplets results in rapid  $SO_2$  absorption and evaporation of the moisture. A small portion of the hot flue gas is added to the spray dryer discharge duct to maintain the temperature of the gas above the dew point. Reheat prevents condensation and corrosion in the duct. Reheat also prevents bags in the baghouse from becoming plugged or caked with moist particles.

Sodium carbonate solutions and lime slurries are the most common absorbents used. A sodium carbonate solution will generally achieve a higher level of  $SO_2$  removal than lime slurries. When sodium carbonate is used,  $SO_2$  removal efficiencies are approximately 75 to 90%, lime removal efficiencies are 70 to 85%. However, vendors of dry scrubbing systems claim that their units are capable of achieving 90%  $SO_2$  reduction using a lime slurry in a spray dryer. Lime is very popular for two reasons:

- Lime is less expensive than sodium carbonate
- Sodium carbonate and  $SO_2$  form sodium sulfite and sodium sulfate which are very soluble causing leaching problems when landfilled.

Some of the evaporated alkaline spray will fall into the bottom of the spray dryer and be recycled. The majority of the spray reacts with  $SO_2$  in the flue gas to form powdered sulfates and sulfites. The particles, along with fly ash in the flue gas, are then collected in a baghouse or electrostatic precipitator. Baghouses have an advantage because unreacted alkaline material collected on the bags can react with any remaining  $SO_2$  in the flue gas.

The major differences between wet absorption  $SO_2$  scrubbers and spray dryer systems is in the scrubbing method and the amount of moisture during the scrubbing action. In a wet scrubber, flue gas is saturated with liquid sprays (usually alkaline).  $SO_2$  is absorbed by the water and also reacts with the chemical. Absorption increases as temperature decreases. Flue

gas is cooled and saturated with the scrubbing liquid to remove  $\text{SO}_2$ . At optimum operating temperatures efficiency is usually  $> 90\%$ .

**DRY INJECTION:** In dry injection systems, a dry alkaline material is injected into a flue gas stream. This is accomplished by pneumatically injecting the dry sorbent into a flue gas duct, or by precoating or continuously feeding sorbent onto a fabric filter surface. Most dry injection systems use pneumatic injection of dry alkaline material in the boiler furnace area or in the duct that precedes the ESP or baghouse. Sodium-based sorbents are used more frequently than lime. Many dry injection systems have used nahcolite, a naturally occurring mineral which is 80% sodium bicarbonate found in large reserves in Colorado. Sodium carbonate (soda ash) is also used but is not as reactive as sodium bicarbonate. The major problem of using nahcolite is that it is not presently being mined on a commercial scale (EPA-81/12, p. 8-27).

**$\text{SO}_2$  control calculations.** This section was authored by Dr John Chang. Dr Chang is an Engineer with the US Environmental Protection Agency in Research Triangle Park, North Carolina.

**$\text{SO}_2$  CONTROL REQUIREMENTS:** Government standards requiring control of  $\text{SO}_2$  emissions are of two types. Ambient air quality standards established by the federal government define the maximum or average permissible level of  $\text{SO}_2$  concentration at ground level (40CFR50). The federal government also established emission standards for new and existing combustion sources to avoid any degradation of air quality. For example, the 1979 New Source Performance Standards (NSPS) included  $\text{SO}_2$  emission regulations for coal-fired electric utility steam generating units for which construction was commenced after September 18, 1978 (40CFR60). The standards require a minimum of 70% removal when  $\text{SO}_2$  emissions are less than 0.6 lb/million Btu heat input. In addition, no gases containing in excess of 1.2 lb/million Btu heat input and 10% of the potential combustion concentration (90% reduction) shall be discharged to the atmosphere (Chang-98/07).

Though it may appear that there are two options in the NSPS for new coal-fired power plants, only one of these sets of requirements applies for a given coal (Molburg-80/02). The new standard can conveniently be regarded as a coal-specific standard. For a coal of specified sulfur content and heating value, the standard determines a unique maximum allowable emission rate and a unique minimum reduction of potential emission.

**EXAMPLE 1:**  $\text{SO}_2$  standards

Consider a 3% sulfur coal with a heating value of 12,000 Btu/lb. Determine the  $\text{SO}_2$  removal requirement based on the NSPS.

1. Determine the  $\text{SO}_2$  emission without control.

Upon combustion, all the sulfur in the coal is oxidized by air and forms sulfur dioxide:

One mole of sulfur generates 1 mole of  $\text{SO}_2$ . Since the molecular weight of  $\text{SO}_2$  (64) is twice that of S (32), each lb of S generates 2 lb of  $\text{SO}_2$ . For one million Btu heat input, the amount of coal and  $\text{SO}_2$  generated are estimated as

$$\begin{aligned} \text{Coal needed} &= 1,000,000/12,000 \\ &= 83.33 \text{ lb/million Btu} \end{aligned}$$

$$\begin{aligned} \text{The } \text{SO}_2 \text{ generated} &= 3\% \times 83.33 \times 2 \\ &= 5 \text{ lb/million Btu} \end{aligned}$$

2. Determine the NSPS  $\text{SO}_2$  removal requirement

First, let us determine the  $\text{SO}_2$  emissions with the two removal requirements.

$$\begin{aligned}\text{SO}_2 \text{ emission with 70\% removal} &= 5 \times (100 - 70\%) \\ &= 1.5 \text{ lb/million Btu}\end{aligned}$$

$$\begin{aligned}\text{SO}_2 \text{ emission with 90\% removal} &= 5 \times (100 - 90\%) \\ &= 0.5 \text{ lb/million Btu}\end{aligned}$$

The  $\text{SO}_2$  emission with 70% removal exceeds 1.2 lb/million Btu, which means greater than 70% removal is required. On the other hand, the  $\text{SO}_2$  emission with 90% removal is less than 0.6 lb/million Btu, which means less than 90% removal is required for this particular coal to meet the NSPS (the standards require a minimum of 70% removal when  $\text{SO}_2$  emissions are less than 0.6 lb/million Btu heat input).

$$\begin{aligned}\text{SO}_2 \text{ removal requirement based on NSPS} &= (1 - 0.6/5) \times 100\% \\ &= 88\%\end{aligned}$$

With 88% removal, the  $\text{SO}_2$  emission meets all the NSPS.

**EXAMPLE 2:**  $\text{SO}_2$  standards

Consider three different types of coal: 0.25% sulfur with 9000 Btu/lb heating value, 0.5% sulfur with 9500 Btu/lb heating value, and 4.5% sulfur with 10,500 Btu/lb heating value. Determine the NSPS  $\text{SO}_2$  removal requirement for each coal.

1. Coal with 0.25% sulfur and 9000 Btu/lb heating value

The amount of coal needed and  $\text{SO}_2$  generated for one million Btu heat input is

$$\begin{aligned}\text{Coal needed} &= 1,000,000/9000 \\ &= 111.11 \text{ lb/million Btu}\end{aligned}$$

$$\begin{aligned}\text{SO}_2 \text{ generated} &= 0.25\% \times 111.11 \times 2 \\ &= 0.55 \text{ lb/million Btu}\end{aligned}$$

The  $\text{SO}_2$  generated is less than 0.6 lb/million Btu and therefore 70%  $\text{SO}_2$  removal is required based on the NSPS.

2. Coal with 0.5% sulfur and 9500 Btu/lb heating value

$$\begin{aligned}\text{SO}_2 \text{ generated} &= 0.5\% \times (1,000,000/9500) \times 2 \\ &= 1.05 \text{ lb/million Btu}\end{aligned}$$

$$\begin{aligned}\text{SO}_2 \text{ emission with 70\% removal} &= 1.05 \times (100 - 70\%) \\ &= 0.315 \text{ lb/million Btu}\end{aligned}$$

The  $\text{SO}_2$  emission with 70% removal is less than 0.6 lb/million Btu; therefore, 70% removal is the NSPS requirement.

3. Coal with 4.5% sulfur and 10,500 Btu/lb heating value

$$\begin{aligned}\text{SO}_2 \text{ generated} &= 4.5\% \times (1,000,000/10,500) \times 2 \\ &= 8.57 \text{ lb/million Btu}\end{aligned}$$

$$\begin{aligned}\text{SO}_2 \text{ emission with 70\% removal} &= 8.57 \times (100 - 70\%) \\ &= 2.57 \text{ lb/million Btu}\end{aligned}$$

The  $\text{SO}_2$  emission with 70% removal exceeds 0.6 lb/million Btu, which means greater than 70% removal is required.

$$\begin{aligned}\text{SO}_2 \text{ emission with 90\% removal} &= 8.57 \times (100 - 90\%) \\ &= 0.857 \text{ lb/million Btu}\end{aligned}$$

The  $\text{SO}_2$  emission with 90% removal is greater than 0.6 lb/million Btu but less than 1.2 lb/million Btu. Therefore, the NSPS requirement of this particular coal is 90%  $\text{SO}_2$  removal.

**LIMESTONE FLUE GAS DESULFURIZATION PROCESS:** The primary source of  $\text{SO}_2$  emissions in the United States is fuel combustion in utility and industrial boilers, usually coal-fired. An example of such a source are given in Table 1.17.

Note that the flue gas contains not only  $\text{SO}_2$  but also  $\text{O}_2$ ,  $\text{CO}_2$ , HCl, and fly ash, which complicate the application of FGD technologies. Combustion gas from the boiler is usually not cooled below about  $150^\circ\text{C}$  because of the condensation of sulfuric acid, which corrodes any of the more economical materials of construction for heat exchangers.

The limestone wet scrubbing process is the most widely used FGD technology in the United States (and the world) for utility and industrial boiler  $\text{SO}_2$  emission control (EPA-81/08). This process is based on the chemistry of acid–base titration, buffer capacity, and neutralization (Chang-82/03). The basic idea is to use alkaline water as a medium to absorb the acid gas, water-soluble  $\text{SO}_2$ , from a flue gas. The acidified water is neutralized by the alkali,  $\text{CaCO}_3$  and  $\text{MgCO}_3$ , derived from finely ground limestone. Since HCl is very water soluble, almost all the HCl in the flue gas is also absorbed by the scrubbing liquor and eventually neutralized by the limestone.

In brief, the FGD process involves:

- Flue gas from the boiler enters the scrubber, where it is contacted by a recirculating slurry containing the fine ground limestone.
- The cleaned gas leaves the scrubber and flows into the atmosphere via a stack. While passing through the scrubber the gas is cooled and saturated with water vapor.
- During the absorption process, some of the suspended limestone particles in the recirculating slurry dissolve to react with the absorbed  $\text{SO}_2$  and precipitate calcium sulfite and sulfate as solid waste. The slurry from the scrubber drains to a hold tank where reactions go to completion. Makeup limestone is added to the tank and part of the slurry recycles back to the scrubber. Typically the continuously recycled scrubbing liquor may contain from 5 to 15% suspended solids, consisting of fresh alkali, reacted waste products, and fly ash.
- The workhorse of the whole system is the scrubber which provides intimate gas/liquid contacting to facilitate  $\text{SO}_2$  absorption. To promote maximum gas–liquid surface area and liquor holdup a number of devices are used. Common methods include stages of moving

**TABLE 1.17**  $\text{SO}_2$  Emission Source

Flue gas feature	Quantity
Flue gas flow rate, 1000 acfm	970
Flue gas temperature, $^\circ\text{F}$	290
$\text{SO}_2$ concentration, ppm	3000
HCl concentration, ppm	95
$\text{CO}_2$ concentration, mol %	12
$\text{H}_2\text{O}$ concentration, mol %	8.5
Fly ash, g/scf	0.1
$\text{O}_2$ concentration, mol %	4.5
$\text{N}_2$ concentration, mol %	74.7

spheres supported on grids, towers with staged spray headers, towers with closely spaced rods or grids, and perforated trays. Fixed packings are generally not used in slurry service because of a tendency to plug or to scale.

- To remove the solid waste products from the system, a bleed stream is withdrawn from the recycle loop and routed to the solids dewatering equipment. The bleed is routed to a clarifier (also called a thickener or settling tank). The suspended solids settle to the bottom of the tank, and clear liquor is drawn off the top and returned to the scrubber loop. At the bottom of the clarifier, the solids may be concentrated to 20 to 40 %. This underflow then goes to a filter for further thickening, where the separated liquor is also returned to the scrubber loop. The filter cake, consisting of 60% or more solids, is discharged to a waste disposal area.
- Intentional oxidation of the absorbed  $\text{SO}_2$  can be conducted by sparging air into the hold tank or a separated oxidation tank. The purposes are to produce marketable gypsum (EPA-78/10) for a solid waste product which occupies less volume and is more suitable for landfill disposal (EPA-79/11). Intentional oxidation also reduces the costs of solids dewatering. Without intentional oxidation the solid product, mostly calcium sulfite, precipitates in the scrubber system as small, thin platelets or rosettes less than 5 microns in the largest dimension. On the other hand, gypsum crystallizes as blocky, large crystals up to 50 microns in size (Chang-86/11). As a result, sulfite sludges and filter cakes retain more water and are also more thixotropic. Without intentional oxidation, the oxygen in flue gas usually can cause 20 to 30% oxidation of the absorbed  $\text{SO}_2$ . The solid waste product from the final dewatering device contains 30 to 60% interstitial water. With greater than 95% oxidation by intentional air sparging, the water content of the final solid product can be reduced to less than 10%.

**EXAMPLE 3:**  $\text{SO}_2$  control

Consider a wet limestone scrubber for controlling  $\text{SO}_2$  emissions with the flue gas features listed in Table 1.17. Determine how much limestone is required per year. The limestone supplier reported that analytical data showed that the limestone contains 94.5 wt %  $\text{CaCO}_3$ , 1.5 wt %  $\text{MgCO}_3$  and 4.0 wt % of inert material. The actual limestone consumption rate is usually 110% of the theoretical requirement.

1. Determine the overall reaction balance between  $\text{SO}_2$ ,  $\text{HCl}$ ,  $\text{CaCO}_3$ , and  $\text{MgCO}_3$

The equation shows that 1 mole of  $\text{SO}_2$  requires 1 mole of  $\text{CaCO}_3$  and 0.5 mole of  $\text{H}_2\text{O}$  or 1 mole of  $\text{MgCO}_3$ . The equation also shows that one mole of  $\text{HCl}$  requires 0.5 mole of  $\text{CaCO}_3$  or  $\text{MgCO}_3$ .

2. Determine the amount of  $\text{SO}_2$  and  $\text{HCl}$  at the scrubber inlet

Assume that the flue gas pressure is about 1 atm and the ideal gas law can be applied to the scrubber inlet flue gas:

$$\begin{aligned} V/n &= RT/P \\ &= 0.73(290 + 460)/1 \\ &= 547.5 \text{ acf/lb-mol} \end{aligned}$$

$$\begin{aligned}\text{The scrubber inlet flue gas flow rate} &= 970,000 \times 60/547.5 \\ &= 106,301 \text{ lb-mol/h}\end{aligned}$$

$$\begin{aligned}\text{The total amount of SO}_2 \text{ at the scrubber inlet} &= 3000 \times 106,301/1,000,000 \\ &= 318.9 \text{ lb-mol/h}\end{aligned}$$

$$\begin{aligned}\text{The total amount of HCl at the scrubber inlet} &= 95 \times 106,301/1,000,000 \\ &= 10.1 \text{ lb-mol/h}\end{aligned}$$

### 3. Determine the SO<sub>2</sub> and HCl removal requirement

Under current NSPS regulation, the scrubber system must remove 90% of the inlet SO<sub>2</sub> for this high sulfur coal case.

$$\begin{aligned}\text{The amount of SO}_2 \text{ to be removed by the scrubber system} &= 318.9 \times 90\% \\ &= 287.01 \text{ lb-mol/h}\end{aligned}$$

Due to the high solubility, all of the HCl from the flue gas is removed.

### 4. Calculate the amount of limestone required

The theoretical limestone requirement depends on the amount of SO<sub>2</sub> and HCl to be removed. Since 1 mole of SO<sub>2</sub> requires 1 mole of alkalinity (as CaCO<sub>3</sub> and MgCO<sub>3</sub>), and 1 mole of HCl requires 0.5 mole alkalinity:

$$\begin{aligned}\text{The theoretical alkalinity requirement} &= 287.01 + 0.5 \times 10.1 \\ &= 292.06 \text{ lb-mol/h}\end{aligned}$$

$$\begin{aligned}\text{The actual alkalinity consumption rate} &= 292.06 \times 110\% \\ &= 321.27 \text{ lb-mol/h}\end{aligned}$$

The limestone supplied contains 94.5 wt % CaCO<sub>3</sub> (molecular weight 100.09) and 1.5 wt % MgCO<sub>3</sub> (molecular weight 84).

$$\begin{aligned}\text{The alkalinity in each 100 lb of limestone} &= 100 \times 94.5\%/100 + 100 \times 1.5\%/84 \\ &= 0.962 \text{ lb-mol}\end{aligned}$$

$$\begin{aligned}\text{The total amount of limestone consumed} &= (321.27/0.962) \times 100 \\ &= 33,396.05 \text{ lb/h}\end{aligned}$$

### EXAMPLE 4: SO<sub>2</sub> control

Assume that the scrubber exit flue gas is adiabatically saturated with water. Determine the water required to humidify the flue gas in the scrubber and the flue gas composition at the scrubber exit.

#### 1. Humidity of the scrubber inlet flue gas

The definition of humidity is the mass of water vapor associated with unit mass of dry gas (Bennett-82/01). For the scrubber inlet flue gas, 8.5 mol % of it is water and 91.5% is dry gas.

$$\begin{aligned}\text{The mass of water in each mole of flue gas} &= 18 \times 0.085 \\ &= 1.53 \text{ lb}\end{aligned}$$

The average molecular weight of the dry gas can be estimated from the composition data given in Table 1.17.

Average molecular weight of dry gas

$$= (28 \times 0.747 + 32 \times 0.045 + 44 \times 0.12 + 64 \times 0.00300 + 36.5 \times 0.000095) / 0.915095 \\ = 30.42$$

The mass of dry gas in each mole of flue gas =  $30.42 \times 0.915$

$$= 27.83$$

Thus, the humidity of the flue gas at  $290^\circ\text{F}$  =  $1.53/27.83$

$$= 0.055 \text{ lb of water per lb of dry gas}$$

## 2. Temperature and humidity of the wet flue gas at the scrubber exit

Use of a psychrometric chart (which can be found from any thermodynamic text book) permits rapid estimation of the humidity and temperature of the wet flue gas leaving a scrubber.

When unsaturated hot flue gas is introduced into a scrubber, water evaporates into the flue gas immediately to humidify the flue gas until it is saturated with water vapor. Due to the short residence time (usually only a few seconds) and insignificant pressure change of the flue gas inside the scrubber, the humidification process can be considered as under adiabatic conditions (heat loss through scrubber wall is negligible) at constant pressure. As the flue gas is humidified heat is transferred from the flue gas to the water for evaporation, causing the flue gas temperature to decrease following an adiabatic cooling line in the psychrometric chart. But the wet-bulb temperature (dew point) remains constant throughout the period of vaporization because of the adiabatic conditions.

When evaporation continues until the flue gas is 100% saturated with water vapor, the final temperature of the gas will be the same as its initial wet-bulb temperature. For air–water vapor mixtures, the wet-bulb temperature and adiabatic cooling lines are practically the same.

As the vaporization takes place, the humidity of the gas is increased and the dry-bulb temperature must correspondingly decrease along the wet-bulb temperature line (adiabatic cooling line). For use with the psychrometric chart, the humidity of the inlet flue gas must be corrected for air. The average molecular weight of air is 29 (actually 28.97); therefore,

The mass of dry air in each mole of gas =  $29 \times 0.915$

$$= 26.54$$

Equivalent humidity of air =  $1.53/26.54$

$$= 0.0576 \text{ lb of H}_2\text{O/lb of dry air}$$

From the psychrometric chart, point A corresponds to humidity 0.0576 lb H<sub>2</sub>O/lb dry air at  $290^\circ\text{F}$ . Point B is the intersection of the adiabatic cooling line with the 100% saturation line, which is 0.10 lb H<sub>2</sub>O/lb dry air at  $127^\circ\text{F}$ . This air–water system humidity has to be corrected to obtain the flue gas humidity.

The value for saturation humidity of flue gas =  $0.10 \times 28.97/30.42$

$$= 0.0952 \text{ lb H}_2\text{O/lb dry gas at } 127^\circ\text{F}$$

*Note:* It was assumed the molecular weight of the scrubber outlet dry flue gas is the same as that at the scrubber inlet. This approximation is acceptable because the difference is usually within 1%.

## 3. The amount of water required to saturate the flue gas

The amount of water required to saturate the flue gas can be estimated by the difference between the inlet and outlet of the scrubber.

$$\begin{aligned}\text{The amount of water vapor in the inlet gas} &= 0.085 \times 18 \times 106,031 \\ &= 162,227.43 \text{ lb/h}\end{aligned}$$

$$\begin{aligned}\text{The amount of water vapor in the outlet gas} &= 0.0952 \times 106,031 \times 0.915 \times 30.42 \\ &= 280,963.63 \text{ lb/h}\end{aligned}$$

$$\begin{aligned}\text{Water required for humidification} &= 280,963.63 - 162,227.43 \\ &= 118,736.2 \text{ lb/h or } 237.5 \text{ gpm}\end{aligned}$$

#### 4. Flue gas composition at the scrubber exit

To calculate the flue gas composition at the scrubber outlet, the  $\text{CO}_2$  flow rate needs to be estimated. Chemical reaction balance showed that 1 mole of  $\text{CO}_2$  is produced for each mole of  $\text{SO}_2$  removed. Therefore

$$\begin{aligned}\text{CO}_2 \text{ in the scrubber outlet flue gas} &= 287.01 + 106,031 \times 0.12 \\ &= 13,010.7 \text{ lb-mol/h}\end{aligned}$$

The composition of the cleaned flue gas leaving the scrubber is summarized in Table 1.18 (remember that the  $\text{N}_2$  and the  $\text{O}_2$  remain unchanged from the inlet).

#### EXAMPLE 5: $\text{SO}_2$ control

Assume that 20% of the  $\text{CaSO}_3$  formed was oxidized to  $\text{CaSO}_4$  in the scrubber and precipitated as  $\text{CaSO}_3 \cdot \text{CaSO}_4 \cdot 0.5\text{H}_2\text{O}$  solid solution crystal. The waste sludge from the dewatering device contains 60% solids. Determine the waste sludge composition, its production rate, and the total water consumption rate.

##### 1. Solids from the excess limestone supplied

The overall effect of the scrubbing system is that 90% of the incoming  $\text{SO}_2$  is removed from the flue gas and transferred to the effluent sludge. The moles of  $\text{SO}_2$  removed from the flue gas equal the moles of sulfur in the sludge. The  $\text{HCl}$  is assumed to be removed as  $\text{MgCl}_2$  and  $\text{CaCl}_2$ . The remainder of the  $\text{MgCO}_3$  reacts with  $\text{SO}_2$  to form  $\text{MgSO}_3$ . Some of the  $\text{MgSO}_3$  may oxidize to  $\text{MgSO}_4$  but for the sake of simplicity the formation of  $\text{MgSO}_4$  is neglected here.

**TABLE 1.18** Composition of Cleaned Flue Gas Leaving the Scrubber

Flue gas	Flow rate, lb-mol/h	Composition, mol %
$\text{N}_2$	79,406.8	70.37
$\text{O}_2$	4,783.5	4.24
$\text{CO}_2$	13,010.7	11.53
$\text{SO}_2$	31.9	0.028
$\text{H}_2\text{O}$	15,609.1	13.832
Total	112,842.0	100

$$\begin{aligned}\text{Excess limestone supplied} &= 33,396.05 \times 0.1/1.1 \\ &= 3036.0 \text{ lb/h}\end{aligned}$$

$$\begin{aligned}\text{Excess CaCO}_3 \text{ supplied} &= 3036.0 \times 94.5\% \\ &= 2869.0 \text{ lb/h}\end{aligned}$$

$$\begin{aligned}\text{Excess MgCO}_3 \text{ supplied} &= 3036.0 \times 1.5\% \\ &= 45.54 \text{ lb/h}\end{aligned}$$

$$\begin{aligned}\text{Inert supplied} &= 33,396.05 \times 4\% \\ &= 1335.84 \text{ lb/h}\end{aligned}$$

$$\begin{aligned}\text{Total solids from the excess limestone supplied} &= 2869.0 + 45.54 + 1335.84 \\ &= 4250.38 \text{ lb/h}\end{aligned}$$

## 2. Solids from the crystals formed

The  $\text{SO}_2$  removed in the scrubber either reacts with  $\text{CaCO}_3$  to precipitate as solids or associates with  $\text{MgCO}_3$  and remains in the scrubbing liquor.

$$\begin{aligned}\text{Percent of SO}_2 \text{ precipitated} &= 287.01 \times (94.5/100)/0.962 \\ &= 281.94 \text{ lb-mol/h}\end{aligned}$$

Each mole of solid solution crystal contains 2 moles of sulfur. Therefore, when 20% of the  $\text{CaSO}_3$  is oxidized to  $\text{CaSO}_4$ , actually 60% of the sulfur removed is precipitated as  $\text{CaSO}_3 \cdot 0.5\text{H}_2\text{O}$ .

$$\begin{aligned}\text{The amount of sulfur in the CaSO}_3 \cdot 0.5\text{H}_2\text{O} &= 281.94 \times 60\% \\ &= 169.16 \text{ lb-mol/h}\end{aligned}$$

$$\begin{aligned}\text{The CaSO}_3 \cdot 0.5\text{H}_2\text{O} \text{ formed by the precipitation reaction} &= 169.16 \times 129 \\ &= 21,821.64 \text{ lb/h}\end{aligned}$$

$$\begin{aligned}\text{The number of moles of CaSO}_3 \cdot \text{CaSO}_4 \cdot 0.5\text{H}_2\text{O} \text{ formed} &= 281.94 \times 0.2 \\ &= 56.39 \text{ lb-mol/h}\end{aligned}$$

$$\begin{aligned}\text{The CaSO}_3 \cdot \text{CaSO}_4 \cdot 0.5\text{H}_2\text{O} \text{ formed by the precipitation reaction} &= 56.39 \times 265 \\ &= 14,943.35 \text{ lb/h}\end{aligned}$$

## 3. Total waste sludge production rate

The total solids production rate is the sum of excess  $\text{CaCO}_3$ , excess  $\text{MgCO}_3$ , inert,  $\text{CaSO}_3 \cdot 0.5\text{H}_2\text{O}$  and  $\text{CaSO}_3 \cdot \text{CaSO}_4 \cdot 0.5\text{H}_2\text{O}$ .

$$\begin{aligned}\text{The total solids production rate} &= 2869.0 + 45.54 + 1335.84 + 21,821.64 + 14,943.35 \\ &= 41,015.37 \text{ lb/h}\end{aligned}$$

$$\begin{aligned}\text{The waste sludge production rate} &= 41,015.37/0.6 \\ &= 68,358.95 \text{ lb/h}\end{aligned}$$

## 4. Waste sludge composition

The waste sludge composition is shown in Table 1.19.

**TABLE 1.19** Waste Sludge Composition

Material	Mass flow rate, lb/h	Composition, wt %
CaCO <sub>3</sub>	2,869.0	4.6
MgCO <sub>3</sub>	45.54	0.073
CaSO <sub>3</sub> · 0.5H <sub>2</sub> O	21,821.64	31.56
CaSO <sub>3</sub> · CaSO <sub>4</sub> · 0.5H <sub>2</sub> O	14,943.35	21.61
Inert	1,335.84	2.157
Water	27,343.58	40
Total	68,358.95	100

## 5. Total water consumption rate

The total water consumption rate includes the water required for humidification and the water associated with the solid crystals and contained in the waste sludge. There is 0.5 lb-mole of H<sub>2</sub>O associated with each lb-mole of CaSO<sub>3</sub> · 0.5H<sub>2</sub>O and CaSO<sub>3</sub> · CaSO<sub>4</sub> · 0.5H<sub>2</sub>O solid crystals.

$$\begin{aligned} \text{The water associated with the solid crystals} &= 18 \times 0.5 \times (169.16 + 56.39) \\ &= 2029.95 \end{aligned}$$

$$\begin{aligned} \text{The total water consumption rate} &= 118,736.2 + 27,652.9 + 2029.95 \\ &= 148,419.05 \text{ lb/h} \end{aligned}$$

## 6. Distribution of water consumption

As shown in Table 1.20, the majority of the water consumed in the scrubber system was for the humidification of the flue gas.

**EXAMPLE 6:** SO<sub>2</sub> control

Assume all the chlorides leave the scrubber system with the interstitial water of the dewatered sludge. Determine the steady-state chloride concentration in the scrubbing liquor.

## 1. The amount of chloride removed in the scrubber

It is assumed that 100% of the HCl in the flue gas is absorbed by the scrubbing liquor in the scrubber.

$$\begin{aligned} \text{The amount of chloride removed in the scrubber} &= 35.5 \times 10.1 \\ &= 358.55 \text{ lb/h} \end{aligned}$$

## 2. The steady-state chloride concentration in the scrubbing liquor

At steady state, there is no accumulation of chloride in the scrubber system and the mass balance equation requires that

$$\text{Chloride removed in the scrubber} = \text{Chloride leaving the scrubber system}$$

**TABLE 1.20** Distribution of Water Consumption

	Consumption rate, lb/h	Distribution, %
Flue gas humidification	118,736.2	80.17
Waste sludge interstitial water	27,343.58	18.46
Solid crystal	2,029.95	1.37
Total	148,109.73	100

When the steady-state chloride concentration in the scrubbing liquor is  $C_{Cl}$  and all the chlorides leave the scrubber system with the interstitial water of the dewatered sludge, the chloride balance equation becomes

$$\begin{aligned}\text{Chloride leaving the scrubber system} &= C_{Cl} \times \text{water leaving with the sludge} \\ C_{Cl} &= 358.55/27,343.58 \\ &= 0.013 \text{ or } 1.3\% (13,000 \text{ ppm})\end{aligned}$$

**EXAMPLE 7:**  $\text{SO}_2$  control

Assume that air is injected to the scrubber hold tank to oxidize 95% of the  $\text{SO}_2$  removed to form sulfate ions  $(\text{SO}_4)^{2-}$  and precipitate as gypsum ( $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ ). The waste sludge from the dewatering device contains 90% solids. Determine the theoretical air consumption rate, the waste sludge production rate, the water consumption rate, and the steady-state chloride concentration.

*Solution:*

1. Determine overall reaction balance with oxidation

The equations show that each mole of  $\text{SO}_2$  requires 0.5 mole of  $\text{O}_2$  for oxidation and each mole of gypsum needs 2 moles of water.

2. Theoretical air consumption rate

$$\begin{aligned}\text{Theoretical oxygen consumption rate} &= 0.5 \times 281.94 \times 0.95 \\ &= 133.92 \text{ lb-mol/h} \\ \text{Theoretical air consumption rate} &= 133.92/0.21 \\ &= 637.71 \text{ lb-mol/h or } 18493.59 \text{ lb/h}\end{aligned}$$

3. Solids from precipitation reactions

When 95% of the  $\text{SO}_2$  removed is oxidized by air to form gypsum,

$$\begin{aligned}\text{CaSO}_4 \cdot 2\text{H}_2\text{O} \text{ production rate} &= 172 \times 281.94 \times 0.95 \\ &= 267.84 \text{ lb-mol/h or } 46,069 \text{ lb/h} \\ \text{CaSO}_3 \cdot 0.5\text{H}_2\text{O} \text{ production rate} &= 129 \times 281.94 \times (1 - 0.95) \\ &= 14.1 \text{ lb-mol/h or } 1818.51 \text{ lb/h}\end{aligned}$$

4. Total waste sludge production rate

The total solids production rate is the sum of excess  $\text{CaCO}_3$ , excess  $\text{MgCO}_3$ , inert,  $\text{CaSO}_3 \cdot 0.5\text{H}_2\text{O}$  and  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ .

$$\begin{aligned}\text{Total solids production rate} &= 2869.0 + 45.54 + 1335.84 + 1818.51 + 46,069 \\ &= 52,137.89 \text{ lb/h}\end{aligned}$$

$$\begin{aligned}\text{The waste sludge production rate} &= 52,137.89/0.9 \\ &= 57,930.99 \text{ lb/h}\end{aligned}$$

5. Waste sludge composition

The waste sludge composition is shown in Table 1.21.

## 6. Total water consumption rate

The total water consumption rate includes the water required for humidification and the water associated with the solid crystals and contained in the waste sludge. There is 0.5 lb-moles of  $\text{H}_2\text{O}$  associated with each lb-mole of  $\text{CaSO}_3 \cdot 0.5\text{H}_2\text{O}$  and 2 lb-mole of  $\text{H}_2\text{O}$  with each lb-mole of  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  solids.

$$\begin{aligned}\text{The water associated with the solids} &= 18 \times 0.5 \times 14.1 + 18 \times 2 \times 267.84 \\ &= 9769.14\end{aligned}$$

$$\begin{aligned}\text{The total water consumption rate} &= 118,736.2 + 5793.10 + 9769.14 \\ &= 134,298.44 \text{ lb/h}\end{aligned}$$

## 7. The steady-state chloride concentration in the scrubbing liquor

Chloride leaving the scrubber system =  $C_{\text{Cl}}$  × water leaving with the sludge

$$\begin{aligned}C_{\text{Cl}} &= 358.55/5793.10 \\ &= 0.012 \text{ or } 6.2\% \text{ (62,000 ppm)}\end{aligned}$$

**TABLE 1.21** Waste Sludge Composition

Component	Mass flow rate, lb/h	Composition, wt %
$\text{CaCO}_3$	2,869.0	4.952
$\text{MgCO}_3$	45.54	0.079
$\text{CaSO}_3 \cdot 0.5\text{H}_2\text{O}$	1,818.51	3.139
$\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$	46,069	79.524
Inert	1,335.84	2.306
Water	5,793.10	10
Total	57,930.99	100

## 5. MANAGEMENT OF INCINERATION RESIDUES

### 5.1 Solid Residue

**Quantities/characteristics.** Ash produced from incineration is primarily inorganic and can be classified into the categories of fly ash and bottom ash. Fly ash is entrained in exhaust gases leaving the incinerator and is usually captured in air pollution control equipment. Bottom ash is that portion that remains in the combustion chamber after incineration and is normally associated with inerts (OME-88/12, p. 6-50).

Ash composition varies greatly and depends on the composition of the waste being incinerated. In municipal refuse incineration, solid materials not susceptible to oxidation (e.g. ceramic or glass) constitute most of the ash; however, depending on the type of incinerator and its efficiency, the ash might also contain unburned waste feed.

The relative proportion of fly ash to bottom ash depends on the waste composition and on the incinerator design and operation. When liquid or gaseous wastes are incinerated, no bottom ash and relatively little fly ash result. However, more ash is produced by liquids derived from complex chemical processes containing inerts or from blending procedures that produce inerts.

When other solid wastes are incinerated, both bottom ash and fly ash can also result. The bottom ash from the incineration of sewage sludge is approximately from 15 to 20% of the

total mass feed. Refuse incineration can produce ash in varying amounts depending on the waste material burned, but ash content normally ranges from 5 to 25% of the total mass feed.

**Wet and dry residue.** Ash can be removed by either wet or dry methods. Fly ash, along with other gaseous pollutants, should be removed by an air pollution control system. If a wet system is used, fly ash and gases will form a sludge if allowed to concentrate in the scrubber. Normally, however, scrubber blowdown will control the solids so that sludges do not form. Again, the composition of the scrubber wastewater stream depends directly on the wastes being incinerated. Blowdown is usually mixed with other liquid and undergoes further treatment and disposal.

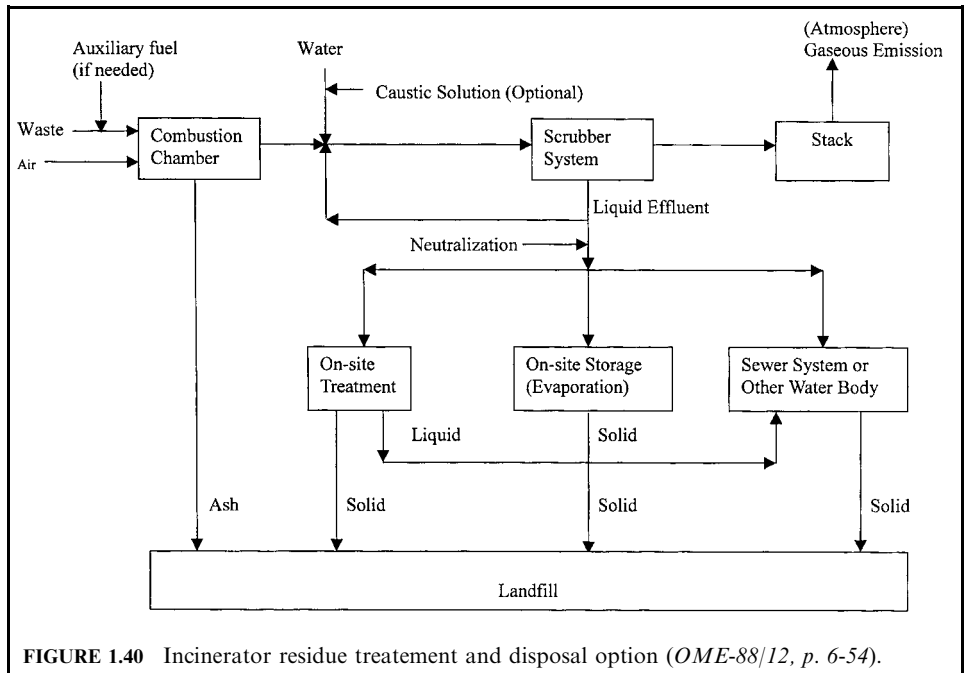

If a baghouse or an electrostatic precipitator removes fly ash, a dry solid residue results.

**Incineration residue handling.** Bottom ash is discharged continuously or periodically. In a continuous system, the ash discharges into a dry ash bin or wet well. From this point, it is transferred to a container or truck, usually by means of drag conveyors. Lighter ash is collected at the outlet of the incinerator and is normally directed into a closed system.

Fly ash collected in a wet scrubber leaves the system with the scrubber blowdown and is further treated in a liquid waste treatment system.

Figure 1.40 (OME-88/12, p. 6-54) is a schematic of a solid waste incineration process including bottom ash collection and a fly ash scrubbing system.

Incineration operations may generate sludge from water/wastewater treatment and ash sludge if a wet ash removal system is employed. Sludges are normally dewatered to reduce the volume before landfilling. Sludge dewatering is usually accomplished by gravity.

## 5.2 Liquid Residue

Gaseous pollutants and particulates resulting from incineration can be captured by one of the following wet methods: (1) water in a quench tower, (2) water in a scrubber, or (3) alkaline liquid in a scrubber. The wet bottom quench tower, used mainly to lower the flue gas temperature, also functions as a scrubber by removing a small amount of particulate and gaseous pollutants from the incinerator exhaust. Water scrubbers are used for capturing the majority of gaseous pollutants in the combustion gas prior to atmospheric discharge. An alkaline scrubber is used to further reduce gaseous components that were not removed in the quench tower or water scrubber.

A water quench tower is used when a waste heat recovery system is not part of the incinerator design package. In addition to lowering the flue gas temperature, it operates like a single-pass scrubber. The quench tower effluent characteristics are highly variable, depending on incinerator operation, waste material being incinerated, quench tower feed rates, and scrubbing efficiency of the tower.

A wet scrubber with water as a medium is normally used downstream of the waste heat recovery system or water quench tower. Water scrubber effluents are quite different from quench tower effluents. Normally, scrubbers are recirculated systems with blowdown that controls the amount of total dissolved solids (TDS). The blowdown rate is variable, depending on the water feed rate and on the amount of acidic gases in the incinerated waste stream. Generally, blowdown occurs when the TDS content reaches approximately 3%. Water scrubber effluents are usually acidic in nature and may contain trace quantities of incinerated waste constituents and/or organics. Acidic effluents may be further processed for acid recovery or may be treated as a liquid waste. As a waste liquid, the stream may or may not be neutralized prior to mixing with other waste streams.

Alkaline (caustic) scrubbers are often used in conjunction with quench towers and/or water scrubbers. This type of scrubber would be used to remove acidic gases and other residual combustion products not captured in the water scrubbers. Alkaline scrubbers are usually recirculated systems with blowdown. Scrubber effluents are generally alkaline, since the scrubbing medium is used in excess to ensure that all noxious substances in the exhaust gas are removed prior to being discharged to the atmosphere. Alkaline scrubber effluents may or may not be neutralized prior to mixing with other liquid waste streams.

Other wastewater sources include waste heat recovery boiler blowdown, raw water treatment wastewaters, cooling tower blowdown, sludge dewatering liquid wastes, site runoff, and drainage from waste storage areas. All of these wastewaters are typically rich in suspended and dissolved solids and are of similar chemical makeup. Some streams may contain hazardous compounds and/or organics. Depending on the overall wastewater treatment program, it may be desirable to (1) separate some streams from the total combination of streams in order to treat them separately prior to disposal or (2) combine them with other wastewater streams.

## **6 ACCESSORY EQUIPMENT FOR AIR POLLUTION CONTROL**

---

### 6.1 Duct

Ducts, or ductwork, transport exhaust gas to and from the scrubber. Ducts are carefully designed to keep pressure losses at a minimum. In general, this requires sizing the duct properly and minimizing the number of bends, expansions, and contractions. Sizing the duct to suit the exhaust stream velocity will generally reduce the amount of dust that settles in the ductwork. Bends, expansions, and contractions cause pressure loss in the system and, consequently, increase operating costs (EPA-84/03, p. 7-3; EPA-81/12, p. 9-14).

Abrasion and corrosion are common problems of ductwork. Abrasion is generally more severe on ductwork leading into the scrubber, while corrosion affects ductwork leaving the scrubber. Using proper construction materials or linings greatly reduces corrosion or abrasion. For example, ductwork can be lined partially or fully with brick (especially at elbows) to prevent erosion due to abrasion. For ductwork exiting the scrubber, special alloys resistant to acid attack should be used. Also, ductwork can be insulated to prevent acids in the flue gas from condensing.

In describing air flow through a system, a number of pressure terms are used. The three most important are

- Static pressure
- Velocity pressure
- Total pressure

Air flowing in a pipe is acted on by static and velocity pressure, which when added together give the total pressure (Fig. 1.41).

Any gas within a confined enclosure will have a static pressure, whether or not the gas is in motion. *Static pressure*  $p_s$  acts in all directions and is independent of the velocity of the gas. Therefore, static pressure is measured at right angles to the direction of air flow to avoid influence from the air velocity. In duct design, the friction losses in a pipe can sometimes be measured by the difference in static pressure (no change in direction or velocity). Therefore, the static pressure is sometimes called the *frictional or resistance pressure*. Static pressure can be positive or negative, compared with the local atmosphere.

The velocity pressure  $p_v$  is the pressure created by a fluid traveling at a specific velocity. Velocity pressure acts only in the direction of flow; therefore, it is always positive. The velocity pressure is obtained by measuring the total pressure and subtracting out the static pressure. There is a basic relationship between the velocity of a gas and the velocity pressure. For an air stream with a density of  $0.075 \text{ lb/ft}^3$  (standard conditions) the air velocity can be computed from the velocity pressure by applying Bernoulli's equation:

$$v = (85.486 \text{ ft/s})[T_s \Delta p / (M_s P_s)]^{0.5}$$

- where
- $v$  = gas velocity, ft/s
  - $T_s$  = temperature of the stack, °R
  - $\Delta p$  = velocity pressure, in.  $\text{H}_2\text{O}$
  - $M_s$  = molecular weight of the stack gas, lb/lb-mol
  - $P_s$  = absolute pressure of the stack, in. Hg

FIGURE 1.41 Duct pressure terms (EPA-81/12, p. 9-14).

*Note:* In stack sampling, the velocity pressure is symbolized by  $\Delta p$ , while in industrial ventilation it is  $p_v$ .

The sum of the static and the velocity pressures at a given point in the duct is the total pressure  $P_T$ . Total pressure is measured in the direction of the flow. Therefore, the total pressure is sometimes referred to as the impact or dynamic pressure. The total pressure should not be confused with the absolute pressure. The absolute pressure is the sum of the atmospheric pressure plus the pressure of the system. The system pressure can be either positive or negative.

Pressure losses from air flowing in a pipe are due to friction and turbulence. Static or friction pressure losses are caused by air abrading or rubbing against the sides of the duct. Turbulent losses are due to rapid changes in direction or velocity. A change in duct cross-sectional area will change the velocity of the gas in the duct. The sum of the friction and turbulent losses over a specific length of pipe is termed the *pressure drop*. The pressure drop of a system is determined by measuring the difference in total pressure at two points in the system.

The friction and dynamic losses can be further subdivided into five categories. These losses are:

- *Inertial losses:* Energy required to accelerate a volume of air from rest. Inertia losses are essentially the same as the velocity pressure.
- *Orifice losses:* Pressure losses at a hood or duct entrance due to turbulence. Orifice losses are dependent on the shape of the opening and are measured by the entry coefficient  $C_e$ .
- *Straight duct friction losses:* Pressure losses due to air rubbing along the sides of the duct.
- *Elbow and branch entry losses:* Pressure losses due to change in the streamlines of an air stream moving through an elbow or entering a branched connection.
- *Contraction and expansion losses:* For gradual contractions in the cross-sectional area of a duct, the pressure losses are small. Abrupt contractions are rare in well-designed exhaust systems except for outlets from chambers. For duct expansions, abrupt enlargements result in a greater pressure loss.

## 6.2 Fan

**Fan type.** Fans transport exhaust gas through ducts to and from the scrubber, while pumps transport liquids through pipes (EPA-84/03, p. 7-2; EPA-81/12, p. 9-25).

In controlling air pollution, it is necessary to move the contaminants from their point of generation to the control device. Air and gas moving devices using rotary motion are normally termed *fans*. Fans are classified as *axial* or *centrifugal*, depending on the direction of air flow through the impeller. Two other terms used to describe air movers are *blowers* or *compressors*.

Distinguishing between air movers and fans is somewhat arbitrary and is based on the static pressure they are capable of producing. The term 'fan' is generally used to describe air movers with pressure rises up to about 2 psig. The term 'blower' refers to a centrifugal fan or positive displacement compressor operating with static pressures in the 2–15 psig range. For pressures higher than 15 psig, the term 'compressor' is used. Unlike fans, some blowers and compressors operate by piston movement (positive displacement) rather than rotation (EPA-81/12, p. 9-25).

*Axial fan:* In axial flow fans, air moves directly forward through the axis of rotation of the fan blades. A home window or room fan is an example of an axial flow fan. For industrial use, axial fans are best suited for moving large volumes of clean air with low static pressures.

*Centrifugal fan:* In centrifugal fans, the air is introduced into the center of a revolving wheel or rotor and exits at right angles to the rotation of the blades. Centrifugal fans are more widely used than axial fans, since they can handle dirtier air streams with higher system resistances.

Fans used in wet scrubbing systems are usually centrifugal. In centrifugal fans, exhaust gas is introduced into the center of a revolving wheel, or rotor, and exits at a right angle ( $90^\circ$ ) to the rotation of the blades (Fig. 1.42). Centrifugal fans are classified by the type and shape of blades used in the fan. They include:

- Forward-curved fan
- Backward-curved fan
- Radial fan
- Airfoil fan

*Forward-curved fan:* Forward-curved fans use blades that are curved toward the direction of the wheel rotation. The blades are small and spaced closer together than are the blades in other centrifugal fans. These fans are not usually used if the flue gas contains dust or sticky materials. They have been used for heating, ventilating, and air-conditioning applications in industrial plants.

*Backward-curved fan:* Backward-curved fans use blades that are curved away from the direction of wheel rotation. The blades will clog when the fan is used to move flue gas containing dust and sticky fumes. They may be used on the clean-air discharge of air pollution control devices or to provide clean combustion air for boilers.

*Radial fan:* Radial fans use straight blades that are attached to the wheel of the rotor. These fans are built for high mechanical strength and can be easily repaired. Fan blades may be constructed of alloys or coated steel to help prevent deterioration when handling abrasive and corrosive exhaust gas. Radial fans are used most frequently for air pollution control applications; however, backward-curved fans are also used on wet scrubbing systems.

*Airfoil fan:* Airfoil fans use thick teardrop-shaped blades that are curved away from the wheel rotation. Airfoil fans can clog when handling dust or sticky materials.

Fans used for wet scrubbing systems can be located before or after the scrubber. When located before the scrubber, they are referred to as *forced draft*, *positive pressure*, or *dirty-side fans*. These fans normally move dry air, but can move moist air depending on process conditions. They are subject to abrasion and solids buildup when dust concentration is high. Abrasion on the fan can be reduced by using special wear-resistant alloys, by using replaceable liners on the wheel, or by reducing fan speed (using a large fan that moves slower). The solids buildup can sometimes be controlled by using a spray wash to periodically clean the wheel. If dirty-side fans are used, a cyclone or knockout chamber can reduce dust concentration.

Fans located after the scrubber are always operated wet and are called *induced draft*, *negative pressure*, or *clean-side fans*. These fans are subject to corrosion and solids buildup from mist escaping from the entrainment separator. Corrosion problems can result when the exhaust gas contains acid-forming or soluble electrolytic compounds, especially if the temperature of the gas stream falls below the dew point of these compounds. Corrosion can be reduced by using proper construction materials and careful pH control in the scrubbing system. Solids buildup can occur when the mist escaping from the entrainment separator contains dissolved or settleable solids. As the mist enters the fan, evaporation occurs and some solids deposit on the wheel. Keeping entrainment separators operating efficiently or using clean water sprays on the fan blades will help reduce solids buildup problems.

**Fan power.** In specifying the proper size fan, it is desirable to know the horsepower requirement for the system. Two terms are used when describing horsepower: *air horsepower (AHP)* and *brake horsepower (BHP)*. Air horsepower is the power output of a fan if the fan were 100% efficient. Since no fan is 100% efficient, the more important term is the brake horse-

FIGURE 1.42 Centrifugal fan (EPA-84/03, p. 7-2).

power. Brake horsepower equals the air horsepower times the efficiency of the fan. Knowing the efficiency of the fan, brake horsepower can be calculated from

$$\text{BHP} = QP_T / (6356E)$$

where    BHP = brake horsepower  
            $Q$  = air flow, cfm  
            $P_T$  = total pressure of the system, in. H<sub>2</sub>O  
            $E$  = mechanical efficiency of the fan, %

**Fan laws.** Fan laws are used to predict how a change in one of the performance variables (size, speed, air density, volume, system pressure, power, efficiency and sound level) affects the others. Fan laws are based on the premise that if two fans are geometrically similar (homologous), their performance curves have the same shape. Therefore, if the two fans operate at the same point of rating, their efficiencies are equal and the ratio of all other variables are interrelated.

The fan laws can be written in as many as 10 different ways, depending on which variables change. The following relationships are some of the more useful of the fan laws.

For a change in fan speed (rpm<sub>1</sub> → rpm<sub>2</sub>):

- the flow rate ( $Q$ ) varies directly with the fan speed ratio  
 $Q_1/Q_2 = \text{rpm}_1/\text{rpm}_2$
- the power ( $P$ ) varies with the cube of the fan speed ratio  
 $P_1/P_2 = (\text{rpm}_1/\text{rpm}_2)^3$
- the static pressure ( $p_s$ ) varies with the square of the fan speed ratio

$$p_{s1}/p_{s2} = (\text{rpm}_1/\text{rpm}_2)^2$$

For a change in fan size (wheel diameter  $d_{w1} \rightarrow d_{w2}$ ):

- the flow rate ( $Q$ ) varies with the cube of the wheel diameter

$$Q_1/Q_2 = (d_{w1}/d_{w2})^3$$

- the power ( $P$ ) varies with the fifth power of the wheel diameter

$$P_1/P_2 = (d_{w1}/d_{w2})^5$$

- the horsepower changes with the fifth power of the fan wheel diameter and the cube of the fan speed

$$P_1/P_2 = (d_1/d_2)^5 (\text{rpm}_1/\text{rpm}_2)^3$$

- the static pressure ( $p_s$ ) varies with the square of the wheel diameter

$$p_{s1}/p_{s2} = (d_{w1}/d_{w2})^2$$

For a change in gas density ( $\rho_1 - \rho_2$ )

- the flow rate is constant

$$\rho_1/\rho_2 = Q$$

- the power varies directly with the density ratio

$$P_1/P_2 = \rho_1/\rho_2$$

- the static pressure ( $p_s$ ) varies with the density ratio

$$p_{s1}/p_{s2} = \rho_1/\rho_2$$

The fan laws can be used to construct performance curves or to determine new operating conditions as process variables change. It is important to note that these fan laws are based on the restriction that the fan at the new conditions will operate at the same point of rating (mechanical efficiency). Therefore, the complete set of operating conditions should be calculated for any change.

**EXAMPLE 1:** fan laws

A fan operating at a speed of 1474 rpm delivers 10,200 cfm at 4 in. static pressure and requires 8.85 brake horsepower (BHP).

What will be the new operating conditions if the fan is speeded up to 2000 rpm?

*Solution:*

The new flow is:  $Q_1/Q_2 = \text{rpm}_1/\text{rpm}_2$

$$\begin{aligned} Q_2 &= (10,200 \text{ cfm})[(2000\text{rpm})/(1474 \text{ rpm})] \\ &= 13,840 \text{ cfm} \end{aligned}$$

The new static pressure of the system is:

$$\begin{aligned} p_{s1}/p_{s2} &= (\text{rpm}_1/\text{rpm}_2)^2 \\ p_{s2} &= (4 \text{ in.})(2000/1474)^2 \\ &= 7.4 \text{ in.} \end{aligned}$$

The horsepower required is:

$$\begin{aligned} P_1/P_2 &= (\text{rpm}_1/\text{rpm}_2)^3 \\ P_2 &= 8.85 \text{ hp } (2000/1474)^3 \\ &= 22.1 \text{ hp} \end{aligned}$$

Note the drastic increase in horsepower for increasing the fan speed.

**EXAMPLE 2:** fan laws

The exhaust system for a rotary dryer is designed to deliver 12,000 cfm of air at 600°F and 4 in. H<sub>2</sub>O static pressure. Fan speed is 630 rpm and requires 13 horsepower. If the dryer has been down for repairs, compute the horsepower required to pull the same amount of air at ambient conditions.

**Given conditions**

density of air at 70°F = 0.075 lb/ft<sup>3</sup>

density of air at 600°F = 0.0375 lb/ft<sup>3</sup>

*Solution:*

The horsepower is:

$$\begin{aligned} P_1/P_2 &= \rho_1/\rho_2 \\ P_2 &= 13 \text{ hp } (0.075/0.0375) \\ &= 26 \text{ hp} \end{aligned}$$

*Note:* this would require a motor twice the size as needed for normal operation. An alternative would be to install dampers until the system reaches operating temperature.

**EXAMPLE 3:** fan (effect of fan wheel and speed)

You are requested to determine the power requirement of fan "B" which is from the same homologous series as fan "A." The speed (rpm), blade diameter (*D*), capacity (acfm), and the power (bhp) of fan "A" are given. Fan "B" delivers a gas having the same density as fan "A." (EPA-84/09, p. 120).

**Given conditions**

Fan "A"

Speed = 1622 rpm

Blade diameter = 46 in.

Gas delivered = 15,120 acfm

Power (brake) = 45.9 bhp

Fan "B"

Speed = 1590 rpm

Blade diameter = 50 in.

*Solution:*

1. Calculate the power requirement of fan "B"

There are many fan laws. One that relates horsepower with fan wheel (diameter) and speed (rpm) is given below

$$P_B/P_A = (d_B/d_A)^5(N_B/N_A)^3$$

where  $P_A, P_B$  = horsepower of fan "A" and "B"  
 $d_A, d_B$  = blade diameter of fan "A" and "B"  
 $N_A, N_B$  = speed (rpm) of fan "A" and "B"

Remember that the brake horsepower represents the power the user pays for.

$$\begin{aligned} P_B/P_A &= (d_B/d_A)^5(N_B/N_A)^3 \\ &= (50/46)^5(1590/1622)^3 \\ &= 1.429 \end{aligned}$$

$$P_B = (1.429)(45.9) \\ = 65.6 \text{ bhp}$$

**EXAMPLE 4:** fan (brake horsepower requirement)

You are requested to calculate the horsepower required for a fan treating a gas stream through a packed tower. The pressure drop across the packing, pressure loss for the duct work, elbows, valves, etc., and overall fan-motor efficiency are given (EPA-84/09, p. 121).

**Given conditions**

Volumetric flow rate of gas stream = 6000 acfm

Pressure drop across the packing = 6.0 in. H<sub>2</sub>O

Pressure loss for the duct work, elbows, valves, etc., and expansion/contraction = 4.0 in. H<sub>2</sub>O

Overall fan-motor efficiency = 63%

*Solution:*

1. Calculate the total pressure drop in inches of H<sub>2</sub>O

The total pressure drop is the sum of the pressure drop across the packing and pressure loss due to the duct work, elbows, valves, expansion/contraction, etc.

$$\text{Total pressure drop} = 6.0 + 4.0 \\ = 10.0 \text{ in. H}_2\text{O}$$

2. Calculate the brake horsepower (bhp) required to treat the gas stream in bhp.

The brake horsepower represents the power the user pays for, i.e. it is the power to operate the fan. The term gas or air horsepower is used to describe the power delivered to the gas.

$$\text{Brake horsepower} = (Q)(\Delta p)(1.573 \times 10^{-4})/\eta_f$$

where  $Q$  = volumetric flow rate of gas stream, acfm

$\Delta p$  = pressure drop, in. H<sub>2</sub>O

$\eta_f$  = fan efficiency, usually in the 0.5–0.65 range

$$\text{Brake horsepower} = (6000)(10.0)(1.573 \times 10^{-4})/(0.63) \\ = 15 \text{ bhp}$$

**6.3 Hood**

Control of many air pollutants begins at their point of capture, the hood. The overall control efficiency that can be achieved is a function of the capture efficiency of the hood. For example, if a poorly designed hood captures only 70% of the emissions generated, then the overall efficiency of the system can never be greater than 70% even if the downstream control device is 100% efficient. Any pollutant can be captured effectively with an appropriately sized hood and a fan with enough power to supply the suction. Hoods are traditionally designed, however, to achieve the maximum pollutant capture efficiency with a minimum of air flow and power consumption (EPA-81/12, p. 9-1).

Hoods are generally classified according to their shape and the manner in which they capture the contaminant. Hoods are referred to as the enclosure and non-enclosure types.

Some common hood shapes are shown in Fig. 1.43; they include slot, plain opening, booth, and canopy.

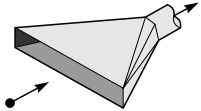

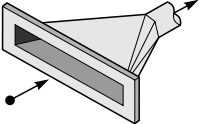

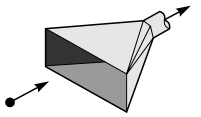

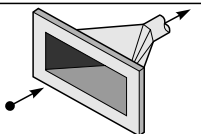

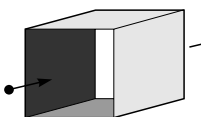

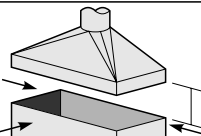

Hood	Description	Entry coefficient ( $C_e$ )
	Slot	0.60
	Flanged slot	0.82
	Plain opening	0.72
	Flanged opening	0.82
	Booth	0.82
	Canopy	0.82

FIGURE 1.43 Hoods and their entry coefficients (*EPA-81/12, p. 9-1*).

The air volume or suction required for a hood depends on hood shape, hood type, hood size, required capture velocity, distance of the hood from the source of pollutants, and temperature of the contaminant exhaust stream. Due to the numerous variables, equations for predicting the required exhaust volume are based on empirical data for a particular type of hood.

When air flows into a hood or duct, pressure losses occur, which result in a decreased flow rate. These losses are due to turbulence and are dependent on the shape of the hood or duct. The coefficient of entry  $C_e$  indicates the extent of these losses. For example, in a theoretically perfect hood with no turbulence loss,  $C_e = 1.0$ . Figure 1.43 lists the entry coefficients for some typical hoods. The coefficient of entry is used to determine the actual flow rate and pressure after the air enters the hood (*EPA-81/12, p. 9-14*).

**Enclosure hood.** Enclosure hoods may totally or only partially enclose the source of emissions. The term 'enclosure' is somewhat of a misnomer since some of these hoods can be located close to the point of emissions so that capture occurs before dispersion of the contaminant can

take place. For example in many paint-spraying operations, a booth is used to capture the emissions generated. Occasionally, the painting is done inside the booth or it may be done a few feet in front of the booth. Both of these operations would be an example of an enclosure hood (EPA-81/12, p. 9-1).

For any totally enclosed hood or for emissions generated inside a booth, the air flow into the hood can be computed by

$$Q = vA \quad (1.62)$$

where  $Q$  = air flow (into hood face), cfm

$v$  = air velocity required to capture the pollutant, fpm  
 $A$  = total open area of the hood, ft<sup>2</sup>

The capture velocity is the velocity necessary (at any point) to overcome opposing air currents and to capture the air contaminants.

**Non-enclosure hood.** Non-enclosure hoods refer to hoods that are usually placed around the perimeter of the contaminant generating source. The most common non-enclosure hood used to capture gaseous emissions is the lip or rim exhaust located on open surface tanks.

For a free-standing or unbounded hood where air flows into a plain, circular duct or a rectangular hood, Eq. (1.62) can be modified to account for the distance a source is from the hood:

$$Q = v_x(10x^2 + A) \quad (1.63)$$

where  $Q$  = air flow (into hood face), cfm

$v_x$  = air velocity required for capture at some distance ( $x$ ) from hood opening, fpm  
 $x$  = distance of contaminant source from the center of the hood face, ft  
 $A$  = area of hood face, ft<sup>2</sup>

Equation (1.63) shows the rapid increase in air volume required for capture (due to decrease in velocity) as the source gets farther from the hood. The volume increases in relation to the distance squared. It is applied to a free-standing or unobstructed hood. For a square or rectangular hood that is bounded on one side by a flat surface (the floor or wall), Eq. (1.63) then becomes

$$Q = v_x(10x^2 + A)/2 \quad (1.64)$$

**EXAMPLE:** non-enclosure hood

Determine the total volume of air entering a paint spray booth that is 10 ft wide and 7 ft high. Some objects are painted outside the booth but never at a distance of more than 3 ft. Room air currents are kept low (EPA-81/12, p. 9-6).

*Solution:*

The paint spray booth would be a plain opening bounded on one side by a flat surface (the floor). Therefore, Eq. (1.64) applies.

$$\begin{aligned} Q &= v_x(10x^2 + A)/2 \\ &= 100[10(3^2) + 2(7)(10)]/2 \\ &= 11,500 \text{ cfm} \end{aligned}$$

An important point to note is that, in order to capture the pollutant, the velocity at 3 ft from the hood face must be at least 100 fpm. If painting was done farther away from the hood face,

the velocity still must be the same. The volume of air would then greatly increase. For example, if painting is done at 5 ft instead of 3 ft from the hood, then this raises the required air volume pulled into the system to 19,500 cfm.

A common way of expressing control volume is based on the square feet of hood opening. For example, assuming that the hood dimensions are the same as the paint booth, we have

$$\begin{aligned} Q/A &= (11,500 \text{ cfm})/[(7 \text{ ft})(10 \text{ ft})] \\ &= 164.3 \text{ cfm of air per square foot of hood opening} \end{aligned}$$

**Non-enclosure lip hood.** One of the most common types of non-enclosure hoods for controlling vapors from open surface tanks is the lip hood pictured in Fig. 1.44 (these hoods are sometimes called *slot hoods*). These hoods are rarely used with hot gases. The lips are designed for a velocity of approximately 200 fpm through the lip face at the required ventilation rate (EPA-73).

For a tank with two parallel lip hoods, the ventilation rate required and the lip width may be estimated from Fig. 1.45. If a lip hood is used on only one side of a tank and the opposite side of the tank is bounded by a vertical wall, Fig. 1.45 can be used to estimate the ventilation rate. The procedure used below is to double the tank width and read a ventilation rate from Fig. 1.45. The actual ventilation rate is estimated as one-half the value read from the graph. The following example illustrates the use of Fig. 1.45.

FIGURE 1.44 Open top tank degreaser with lip exhausts (EPA-81/12, p. 9-12).

FIGURE 1.45 Minimum ventilation rates for lip exhaust hoods (EPA-81/12, p. 9-13).

**EXAMPLE:** non-enclosure lip hood

A degreasing tank 6 ft long and 4 ft wide (width) is controlled by using parallel lip hoods along each of the 6 ft lengths. Determine the total exhaust rate required and the width of the lips (EPA-81/12, p. 9-13).

*Solution:*

From Fig. 1.45 and the given tank width, 4 ft (48 in.), the ventilation rate can be read as 860 cfm per ft of tank length. The exhaust volume is

$$Q = Q_v l_T$$

where  $Q$  = exhaust volume, cfm  
 $Q_v$  = minimum ventilation rate per ft of tank length, cfm/ft  
 $l_T$  = tank length, ft

Then

$$Q = (860 \text{ cfm/ft})(6 \text{ ft})$$

$$Q = 5160 \text{ cfm}$$

Also, from Fig. 1.45, the lip width is approximately 2.6 inches.

**6.4 Pipe**

Pipes transport liquid to and from the scrubber. As with ducts, pipes are susceptible to abrasion, corrosion, and plugging. A wide variety of materials can be used to make pipes to reduce these problems (EPA-84/03, p. 7-4).

## 6.5 Pump

A wide variety of pumps are used to transport both the scrubbing liquid and the sludge. The proper choice of a pump depends on flow rate, pressure, temperature, and material being pumped. Electric-motor-driven centrifugal pumps are the pumps most frequently used in wet scrubbing systems. The rotating impeller produces a reduction in pressure at the eye (center) of the impeller, causing liquid to flow into the impeller from the suction pipe. The liquid is then forced outward along the blades and discharged (EPA-84/03, p. 7-3).

As with fans, abrasion and corrosion are the major maintenance problems associated with pumps in scrubbing systems. The impeller housing, and seals are subject to potential corrosion and abrasion problems. Abrasion is caused by solids buildup in the scrubbing liquid. Bleeding this liquid and removing the solids before recycling it back through the pump (or scrubber) will reduce pump wear. Most vendors suggest that the solids content be less than 15%. Special alloys or rubber linings can also be used to help reduce abrasion and corrosion.

## 7 MONITORING EQUIPMENT

---

Having adequate equipment is imperative when monitoring the performance of a scrubber. Instrumentation on a wet scrubber can provide three distinct services:

- Obtaining operational information by recording daily data to help detect any problems or misoperation that may occur.
- Providing operating input for other devices to automatically operate some parts of the system.
- Providing for safety by sounding alarms and/or releasing interlocks to protect both the operators and equipment.

A monitoring system must be properly installed and maintained to provide reliable data. Monitors should be installed, operated, and calibrated according to the manufacturer's instructions. This is essential in obtaining reliable information. Because every scrubbing system is unique, the instrumentation and variables measured will vary from source to source. Table 1.22 lists monitors that are typically used in wet scrubbing systems.

For any of these monitors, high and/or low settings can be chosen so that if the set value is exceeded, an alarm sounds, a bypass is opened, or an emergency system is activated. For example, sources scrubbing hot gases normally have a high-temperature alarm and/or an interlock system to automatically introduce emergency water or to bypass the scrubber if the high-temperature setting is exceeded.

**TABLE 1.22** Monitoring Equipment for Wet Scrubbing Systems

Monitor	Measurements
Thermometer or thermocouple	Measures inlet and outlet temperatures of gas to and from scrubber. Measures inlet and outlet temperatures of liquid to and from scrubber
Flowmeter	Measures liquid flow rate to scrubber. Measures the amount of recycled liquid and bleed stream. Measures flow rate of fresh makeup liquid to scrubber
Manometer	Measures pressure drop (inlet and outlet static pressure) across fan, scrubber vessel, and entrainment separator
pH meter	Measures pH level in chemical feed stream, scrubbing liquid, recycle liquor, and bleed stream
Ammeter	Monitors the current of the fans and pumps

## 8 RECORD KEEPING

---

Keeping good records of instrument readings and operating practices is important because it (EPA-89/03):

- Helps an operator detect problems and develop corrective actions
- Provides proof that an operator is properly operating and maintaining equipment
- Allows an operator to prepare accurate annual (or more frequent) reports that may be required by state regulations

Certain types of records are commonly required by state regulations or operating permits. Most of them are listed below and involve recording the levels indicated on automatic monitoring devices periodically or require recording the parameters continuously. Example record-keeping items are provided below.

Incinerator record keeping includes:

- Temperature of incinerator chamber(s)
- Oxygen concentration of exhaust gas
- Temperature at inlet and/or outlet of control device
- Continuous emission monitoring records (carbon monoxide or opacity)
- Weight of waste charged to incinerator

Air pollution control equipment record keeping includes:

- Scrubber: (1) pressure drop and (2) liquid flow rate
- Fabric filter: pressure drop

## **1 INTRODUCTION**

---

Particle or particulate matter is defined as any finely divided solid or liquid material, other than uncombined water, emitted to the ambient air as measured by applicable reference methods, or an equivalent or alternative method, or by a test method specified in 40CFR50.

## **2 BASICS OF PARTICULATE EMISSION CONTROL**

---

### **2.1 Collection Forces**

The basic collection forces which govern the control of particulate emissions include the following mechanisms:

- Collection by gravity
- Collection by centrifugal force

- Collection by impaction, interception, and diffusion
- Collection by electrostatic force

Particle collection can occur from an individual effect or a combined effect of the mechanisms mentioned above. In addition, particles can agglomerate or grow in size by cooling, increasing humidity, or from electrostatic effects. Agglomerated particles thus have a larger aerodynamic diameter and can be collected more easily by impaction, interception, or gravitational forces.

*Collection by gravity:* All particulate emission control devices collect particles by mechanisms involving an applied force, the simplest being gravity. Large particles moving slowly enough in a gas stream can be overcome by gravity and be collected. Such a phenomenon is shown in Fig. 2.1. Gravity is responsible for particle collection in the simplest devices, such as settling chambers.

*Collection by centrifugal force:* Centrifugal force is another collection mechanism used for particle capture. The shape or curvature of the collector causes the gas stream to rotate in a spiral motion. Larger particles move toward the outside of the wall by virtue of their momentum. Such a phenomenon is shown in Fig. 2.2. The particles lose kinetic energy there and are separated from the gas stream. Particles are then overcome by gravitational force and are collected. Centrifugal and gravitational forces are both responsible for particle collection in a cyclone.

*Collection by impaction, interception, and diffusion:* In both fabric filters and wet collectors, three separate forces are responsible for particle collection: impaction, direct interception, and diffusion. In a fabric filter, the target object for particle capture is a stationary fiber. In a wet collector, the target object is a water droplet that is introduced into the gas stream, generally through a nozzle.

Consider the case of an individual fiber in a fabric filter. Impaction occurs when the particle is so large that it cannot follow the gas streamlines around the stationary fiber and impacts on the fiber, as shown in Fig. 2.3. Direct interception is a special case of the impaction mechanism. The center of a particle may follow the streamlines formed around the fibers. A collision will occur if the distance between the particle center and the collection surface is less than the particle radius, as shown in Fig. 2.4. Particles below  $0.1 \mu\text{m}$  (micrometer) in aerodynamic diameter undergo Brownian motion, randomly moving or diffusing throughout the gas volume ( $1 \mu\text{m} = 1 \text{ micron} = 10^{-6} \text{ m}$ ). The mechanism of diffusion is responsible for the collection of particles that are so small that they become affected by collisions of molecules in the gas stream. The randomly moving particles then move or diffuse through the gas to impact on the fiber and are collected as shown in Fig. 2.5.

*Collection by electrostatic force:* The other primary particle collection mechanism involves electrostatic forces. The particles can be naturally charged, or, as in most cases involving electrostatic attraction, be charged by subjecting the particle to a strong electric field. The charged particles migrate to an oppositely charged collection surface, as shown in Fig. 2.6. This is the collection mechanism responsible for particle capture in both electrostatic

FIGURE 2.1 Particle collection by gravity (EPA-81/10, p. 1-3).

FIGURE 2.2 Particle collection by centrifugal force (*EPA-81/10, p. 1-3*).

FIGURE 2.3 Particle collection by impaction (*EPA-84/03, p. 1-4*).

FIGURE 2.4 Particle collection by interception (*EPA-81/10, p. 1-4*).

FIGURE 2.5 Particle collection by diffusion (*EPA-84/03, p. 1-5*).

precipitators (ESPs) and charged droplet scrubbers. In an ESP, particle collection occurs due to electrostatic forces only. In a charged droplet scrubber, particle removal occurs by the combined effects of impaction, direct interception, diffusion, and electrostatic attraction. Particles are charged in these scrubbers to enhance both diffusion and direct interception.

## 2.2 Particle Dynamics

Collection of solid or liquid particles in an air pollution control device is based upon the movement of a particle in the gas (fluid) stream. For a particle to be captured, the particle must be subjected to external forces large enough to separate it from the gas stream. Forces acting on a particle include three major forces and other forces. They are (*EPA-81/10, p. 3-1*):

- Gravitational force
- Buoyant force
- Drag force
- Other forces, including magnetic, inertial, electrostatic, and thermal forces

The consequence of acting forces on a particle results in the terminal velocity for a particle to settle. The terminal velocity (also known as the settling velocity) is a constant value of velocity reached when all forces (gravity, drag, buoyancy, etc.) acting on a body are balanced. The sum of all the forces is then equal to zero (no acceleration). To solve for an unknown particle settling velocity, the flow regime of particle motion must be determined. Once the flow regime has been determined, the settling velocity of a particle can be calculated.

The flow regime can be determined by the following equation (*EPA-81/10, p. 3-10*):

$$K = d_p(g\rho_p\rho_a/\mu^2)^{0.33}$$

where  $K$  = a dimensionless constant which determines the range of the fluid-particle dynamic laws

- $d_p$  = particle diameter, cm or ft
- $g$  = gravity force,  $\text{cm/s}^2$  or  $\text{ft/s}^2$
- $\rho_p$  = particle density,  $\text{g/cm}^3$  or  $\text{lb/ft}^3$
- $\rho_a$  = fluid (gas) density,  $\text{g/cm}^3$  or  $\text{lb/ft}^3$
- $\mu$  = fluid (gas) viscosity,  $\text{g/cm-s}$  or  $\text{lb/ft-s}$

The  $K$  values corresponding to different flow regimes appear below (*EPA-81/10, p. 3-10*):

- Laminar regime (also known as Stokes' law range):  $K < 3.3$
- Transition regime (also known as intermediate law range):  $3.3 < K < 43.6$
- Turbulent regime (also known as Newton's law range):  $K > 43.6$

The  $K$  value determines the appropriate range of the fluid-particle dynamic laws which apply. For a laminar regime (Stokes' law range), the terminal velocity is (EPA-81/10, p3-10):

$$v = g\rho_p(d_p)^2/(18\mu)$$

For a transition regime (intermediate law range), the terminal velocity is (EPA-81/10, p. 3-10):

$$v = 0.153g^{0.71}(d_p)^{1.14}(\rho_p)^{0.71}/[\mu^{0.43}(\rho_a)^{0.29}]$$

For a turbulent regime (Newton's law range), the terminal velocity is (EPA-81/10, p. 3-10):

$$v = 1.74(gd_p\rho_p/\rho_a)^{0.5}$$

When particles approach sizes comparable with the mean free path of the fluid molecules, the medium can no longer be regarded as continuous, since particles can fall between the molecules at a faster rate than predicted by aerodynamic theory. To allow for this slip, Cunningham's correction factor is introduced into Stoke's law (EPA-84/09, p. 58):

$$v = g\rho_p(d_p)^2C_f/(18\mu)$$

where  $C_f$  = Cunningham correction factor =  $1 + (2A\lambda/d_p)$   
 $A = 1.257 + 0.40e^{-1.10d_p/2\lambda}$   
 $\lambda$  = free path of the fluid molecules ( $6.53 \times 10^{-6}$  cm for ambient air)

**EXAMPLE 1:** particle terminal velocity. Calculate the settling velocity of a particle moving in a gas stream. Assume the following information (EPA-81/10, p. 3-11):

**Given conditions**

$d_p$  = particle diameter = 45  $\mu\text{m}$  (45 microns)  
 $g$  = gravity force = 980  $\text{cm/s}^2$   
 $\rho_p$  = particle density = 0.899  $\text{g/cm}^3$   
 $\rho_a$  = fluid (gas) density = 0.012  $\text{g/cm}^3$   
 $\mu$  = fluid (gas) viscosity =  $1.82 \times 10^{-4}$   $\text{g/cm-s}$   
 $C_f$  = 1.0 (if applicable)

*Solution:*

1. Calculate the  $K$  parameter to determine the proper flow regime.

$$\begin{aligned} K &= d_p(g\rho_p\rho_a/\mu^2)^{0.33} \\ &= 45 \times 10^{-4}[980(0.899)(0.012)/(1.82 \times 10^{-4})^2]^{0.33} \\ &= 3.07 \end{aligned}$$

Therefore, the flow regime is laminar.

2. The settling velocity is calculated using the laminar regime equation

$$\begin{aligned} v &= g\rho_p(d_p)^2C_f/18\mu \\ &= 980(0.899)(45 \times 10^{-4})^2(1)/[18(1.82 \times 10^{-4})] \\ &= 5.38 \text{ cm/s} \end{aligned}$$

**EXAMPLE 2:** particle terminal velocity. Three different-sized fly ash particles settle through air. The question is to calculate the particle terminal velocity and determine how far each will fall in 30 seconds. Assume the particles are spherical (EPA-84/09, p. 57).

**Given conditions**

Fly ash particle diameters = 0.4, 40, 400 microns ( $\mu\text{m}$ )

Air temperature and pressure = 238°F, 1 atm

Specific gravity of fly ash = 2.31

Check how the Cunningham correction factor affects the terminal settling velocity for the 0.4 micron particle. The Cunningham correction factor is usually applied to particles equal to or smaller than 1 micron.

*Solution:*

1. Determine the value for  $K$  for each fly ash particle size settling in air.

1.1. Calculate the particle density using the specific gravity given.

$$\begin{aligned}\rho_p &= \text{particle density} = (\text{specific gravity of fly ash}) (\text{density of water}) \\ &= 2.31(62.4) \\ &= 144.14 \text{ lb/ft}^3\end{aligned}$$

1.2. Calculate the density of air.

$$\begin{aligned}\rho &= \text{air density} = PM/RT \\ &= (1)(29)/(0.7302)(238 + 460) = 0.0569 \text{ lb/ft}^3 \\ \mu &= \text{air viscosity} = 0.021 \text{ cp} = 1.41 \times 10^{-5} \text{ lb/ft-s (EPA-84/09, p. 167)}\end{aligned}$$

1.3. Determine the flow regime ( $K$ ).

$$K = d_p (g \rho_p \rho_a / \mu^2)^{0.33}$$

For  $d_p = 0.4$  micron

$$K = [(0.4)/(25,400)(12)][(32.2)(144.14)(0.0569)/(1.41 \times 10^{-5})^2]^{0.33} = 0.0144$$

where

$$1 \text{ ft} = 25,400(12) \mu\text{m (EPA-84/09, p. 183)}$$

For  $d_p = 40$  microns

$$K = [(40)/(25,400)(12)][(32.2)(144.14)(0.0569)/(1.41 \times 10^{-5})^2]^{0.33} = 1.44$$

For  $d_p = 400$  microns

$$K = [(400)/(25,400)(12)][(32.2)(144.14)(0.0569)/(1.41 \times 10^{-5})^2]^{0.33} = 14.4$$

2. Select appropriate law.

The numerical value of  $K$  determines the appropriate law.

$K < 3.3$ ; Stokes' law range

$3.3 < K < 43.6$ ; intermediate law range

$43.6 < K < 2360$ ; Newton's law range

For  $d_p = 0.4$  micron, the flow regime is laminar (EPA-81/10, p. 3-10)

For  $d_p = 40$  microns, the flow regime is also laminar

For  $d_p = 400$  microns, the flow regime is the transition regime

3. Calculate terminal velocity.

For  $d_p = 0.4$  micron

$$\begin{aligned} v &= g\rho_p(d_p)^2/18\mu \\ &= (32.2)[(0.4)/(25,400)(12)]^2(144.14)/(18)(1.41 \times 10^{-5}) \\ &= 3.15 \times 10^{-5} \text{ ft/s} \end{aligned}$$

For  $d_p = 40$  microns

$$\begin{aligned} v &= g\rho_p(d_p)^2/18\mu \\ &= (32.2)[(40)/(25,400)(12)]^2(144.14)/(18)(1.41 \times 10^{-5}) \\ &= 0.315 \text{ ft/s} \end{aligned}$$

For  $d_p = 400$  microns, use the transition regime equation

$$\begin{aligned} v &= 0.153g^{0.71}(d_p)^{1.14}(\rho_p)^{0.71}/(\mu^{0.43}\rho^{0.29}) \\ &= 0.153(32.2)^{0.71}[(400)/(25,400)(12)]^{1.14}(144.14)^{0.71}/[(1.41 \times 10^{-5})^{0.43}(0.0569)^{0.29}] \\ &= 8.90 \text{ ft/s} \end{aligned}$$

4. Calculate distance.

For  $d_p = 40$  microns, distance = (time)(velocity)

$$\text{Distance} = 30(0.315) = 9.45 \text{ ft}$$

For  $d_p = 400$  microns, distance = (time)(velocity)

$$\text{Distance} = 30(8.90) = 267 \text{ ft}$$

For  $d_p = 0.4$  micron without Cunningham correction factor, distance = (time)(velocity)

$$\text{Distance} = 30(3.15 \times 10^{-5}) = 94.5 \times 10^{-5} \text{ ft}$$

For  $d_p = 0.4$  micron with Cunningham correction factor, the velocity term needs to be corrected. The Cunningham correction factor ( $C_f$ ) can be found in Appendix A. The data given in the example are

Particle diameter = 0.4 micron

air temperature = 238°F

For use of the data in Appendix A, use particle diameter = 0.5 micron and temperature = 212°F to find the  $C_f$  value. Therefore,  $C_f$  is approximately equal to 1.446.

$$\text{The corrected velocity} = vC_f = 3.15 \times 10^{-5}(1.446) = 4.55 \times 10^{-5} \text{ ft/s}$$

$$\text{Distance} = 30(4.55 \times 10^{-5}) = 1.365 \times 10^{-3} \text{ ft}$$

**EXAMPLE 3:** fluid particle dynamics—stack application. Determine the minimum distance downstream from a cement dust emitting source that will be free of cement deposit. The source is equipped with a cyclone (EPA-84/09, p. 59).

**Given conditions**

particle size range of cement dust = 2.5–50.0 microns

specific gravity of the cement dust = 1.96

wind speed = 3.0 miles/h

the cyclone is located 150 ft above ground level. Assume ambient conditions are at 60°F and 1 atm. Neglect meteorological aspects.

$\mu$  = air viscosity at 60°F =  $1.22 \times 10^{-5}$  lb/ft-s (EPA-84/09, p. 167)

$\mu\text{m}$  (micrometer or micron) =  $3.048 \times 10^5$  ft (EPA-84/09, p. 183)

Note:  $1 \mu\text{m} = 1 \text{ micron} = 10^{-6} \text{ m}$ .

*Solution:*

1. Determine the particle size that should be considered for this question.

A particle diameter of 2.5 microns is used to calculate the minimum distance downstream free of dust since the smallest particle will travel the greatest horizontal distance.

2. Determine the value of  $K$  for the appropriate size of the dust.

This calculation is similar to that presented in the previous problem.

- 2.1. Calculate the particle density ( $\rho_p$ ) using the specific gravity given.

$$\begin{aligned}\rho_p &= (\text{specific gravity of fly ash})(\text{density of water}) \\ &= 1.96(62.4) \\ &= 122.3 \text{ lb/ft}^3\end{aligned}$$

- 2.2. Calculate the air density ( $\rho$ ).

Rewrite the ideal gas equation,  $PV = nR_u T = (m/M)R_u T$

$$\begin{aligned}\rho &= (\text{mass})/(\text{volume}) \\ &= PM/R_u T \\ &= (1)(29)/[0.73(60 + 460)] = 0.0764 \text{ lb/ft}^3\end{aligned}$$

- 2.3. Determine the flow regime ( $K$ ).

$$K = d_p (g\rho_p\rho_a/\mu^2)^{0.33}$$

For  $d_p = 2.5$  microns

$$K = [(2.5)/(25,400)(12)][(32.2)(122.3)(0.0764)/(1.22 \times 10^{-5})^2]^{0.33} = 0.104$$

where  $1 \text{ ft} = 25,400(12) \mu\text{m} = 304,800 \mu\text{m}$  (EPA-84/09, p. 183)

3. Determine which fluid-particle dynamic law applies for the above value of  $K$ .

Compare the  $K$  value of 0.104 with the following range:

$K < 3.3$ ; Stokes' law range

$3.3 < K < 43.6$ ; intermediate law range

$43.6 < K < 2360.0$ ; Newton's law range

The flow is in the Stokes' law range, therefore it is laminar.

4. Calculate the terminal settling velocity in ft/s.

For Stokes' law range, the velocity is

$$\begin{aligned} v &= g\rho_p(d_p)^2/18\mu \\ &= (32.2)(2.5)/(25,400)(12)]^2(122.3)/(18)(1.22 \times 10^{-5}) \\ &= 1.21 \times 10^{-3} \text{ ft/s} \end{aligned}$$

5. Calculate the time for descent (settling).

$$\begin{aligned} t &= (\text{outlet height})/(\text{terminal velocity}) \\ &= 150/1.21 \times 10^{-3} \\ &= 1.24 \times 10^5 \text{ s} = 34.4 \text{ h} \end{aligned}$$

6. Calculate the horizontal distance travelled.

$$\begin{aligned} \text{distance} &= (\text{time for descent})(\text{wind speed}) \\ &= (1.24 \times 10^5)(3.0/3600) \\ &= 103.3 \text{ miles} \end{aligned}$$

## 2.3 Particle Sizing Devices

Particle sizing data is a very important consideration in the design of particulate control equipment. Appropriate design is directly dependent on good particle size data. An ideal particle measuring device should have the following features:

- Measure the exact size of each particle
- Report data instantaneously without averaging data over some specified time interval
- Determine the complete composition of each particle, including shape, density, chemical nature, etc.

It is an extremely difficult task to produce such an instrument. Current devices incorporate only one or two of these ideal functions. Several methods are used to obtain particle size data from industrial sources. They include:

- Microscopy
- Optical counter
- Electrical aerosol analyzer
- Bahco micro-particle classifier
- Impactor

**Microscopy.** The microscope is an instrument in common use for particle size analysis. It measures the geometric diameter of each individual particle. The determination of particle size analysis is carried out by measuring the size of a number of particles. Particles are sized as they are traversed past the eyepiece micrometer. Each particle, presented in a fixed area of the eyepiece, is sized and tallied into one of a number of size classes. The number of particles sized may range from 100 to several thousand depending on the accuracy desired. This method can be time consuming and extremely tedious.

The particles are collected by deposition on a glass slide or on a filter by using an EPA Method 5 sampling train, and the glass slide or filter is analyzed subsequently by a microscope in a laboratory. The analysis of size distribution of particles collected in the field and trans-

ported to the laboratory must be viewed with great caution. It is difficult to collect a representative sample in the first place, and it is almost impossible to maintain the original size distribution under laboratory conditions. For example, laboratory measurements cannot determine whether some of the particles existed in the process stream as agglomerates of smaller particles. In spite of the limitations of the microscopic method, this method is useful in the determination of some properties of interest.

The optical microscope can measure particles from about  $0.5\ \mu\text{m}$  to about  $100\ \mu\text{m}$  in diameter. Electron microscopes can measure particles with diameters as small as  $0.001\ \mu\text{m}$ , which is useful for examining extremely minute particles.

**Optical counter.** Optical particle counters work on the principle of light scattering. Each particle in a continuously flowing sample stream is passed through a small illuminated viewing chamber. Light scattered by the particle is sensed by a photodetector during the time the particle is in the viewing chamber. The intensity of the scattered light is a function of particle size, shape, and index of refraction. Optical counters give reliable particle size information if only one particle is in the viewing chamber at a single time. The simultaneous presence of more than one particle can be interpreted by the photodetector as a large-sized particle. This error can be avoided by maintaining sample dilutions less than 300 particles per cubic centimeter.

Optical particle counters have not been widely used for particle sizing because they cannot be directly applied to the stack exhaust gas stream. The sample must be extracted, cooled, and diluted before entering the counter. This procedure must be done with extreme care to avoid introducing serious errors in the sample. The major advantage of the counter is its capability of observing emission (particle) fluctuations on an instantaneous level. One can size particles as small as  $0.3\ \mu\text{m}$  with the optical counter.

A disadvantage of the optical counter is the dependence of the calibration instrument upon the index of refraction and shape of the particle. Errors in counting can also occur from the presence of high concentrations of very small particles which are sensitive to the light wavelength used.

**Electrical aerosol analyzer.** An electrical aerosol analyzer (EAA) is an aerosol size distribution measuring device. The EAA uses an electric field (which is set at an intensity dependent upon the size and mass of the particle) to measure the mobility of a charged aerosol. The analyzer operates by first placing a unipolar charge on the aerosol being measured, and measuring the resulting mobility distribution of the charged particles by means of a mobility analyzer.

The EAA has been used for source analysis by pulling a sample from the stack into the chamber and introducing the gas stream into the analyzer. The instrument requires that enough particles pass through the chamber so that a charge can be detected. The concentration range for most efficient operation of the EAA is from 1 to  $1000\ \mu\text{g}/\text{m}^3$ . Since stack gas concentrations usually exceed  $1000\ \mu\text{g}/\text{m}^3$ , sample dilution with clean air is required. No information on the chemical composition of the particles is possible since the particles are not collected. The major advantage of the EAA is that the instrument can measure particles from  $0.003$  to  $1.0\ \mu\text{m}$  in diameter.

**Bahco micro-particle classifier.** A Bahco is a versatile particle classifier used for measuring powders, dust, and other finely divided solid materials. The Bahco's working range is approximately  $1$  to  $60\ \mu\text{m}$ . The Bahco uses a combination of elutriation and centrifugation to separate particles in an air stream. Particles can be collected onto a filter by using an EPA Method 5 sampling train. The collected particles are subsequently analyzed in the laboratory.

A weighed sample, usually 5 grams, is introduced into a spiral-shaped air current to separate the particle fractions. The larger particles overcome the viscous forces of the fluid and migrate to the wall of the chamber, while the smaller particles remain suspended. After the two size fractions are separated, one of them is reintroduced into the device and is fractionated further. A different spin speed is used to give a slightly different centrifugal force. This is

repeated as many times as desired to give an adequate size distribution. The measurements are grouped into discrete size ranges (i.e. 40–60  $\mu\text{m}$ , 20–40  $\mu\text{m}$ , etc.).

The Bahco provides information on the aerodynamic size of particles. This data can be translated into settling velocity information useful in the design of emission control devices. Several hours are required to complete the fractionation analysis. Once the particles have been fractionated into the discrete range, a chemical analysis can be done on the collected particles.

**Impactor.** An impactor is a sampling device that employs the principle of impaction (impingement) to collect successively smaller sizes of particles. It is commonly used to determine the particle size distribution of exhaust streams from industrial sources. It can be directly attached to an EPA Method 5 sampling train and easily inserted into the stack of an industrial source.

Typical impactors consist of a series of stacked stages and collection surfaces. Depending on the calibration requirements, each stage contains from one to as many as 400 precisely drilled jet orifices, identical in diameter in each stage but decreasing in diameter in each succeeding stage. Adhesive, electrostatic, and van der Waals' forces hold the particles to each other and to the collection surfaces. Moreover, the particles are not blown off the collecting plate by the jets of air because the jets follow laminar flow paths so that no turbulent areas exist. This results in complete dead air spaces over and around the samples.

Particles are collected on preweighed individual stages, usually filters made of glass fiber or thin metal foil. Once the sample is complete, the collection filters are weighed again, yielding particle size distribution data for the various collection stages. Occasionally, there are some dusts that are very difficult to collect, and require grease on the collection filter for adequate particle capture. Once the particles have been fractionated into discrete ranges, a chemical analysis can be performed on the collected particles.

The effective range for measuring the aerodynamic diameter is generally between 0.3 and 20  $\mu\text{m}$ . Some vendors have claimed size fractionation as small as 0.02  $\mu\text{m}$  with the use of 20 or more stages. Impactors are one of the most useful devices for determining particle size. This is because of the impactor's compact arrangement, mechanical stability, and its ability to draw a sample directly from a stack. In addition, the impactor measures the aerodynamic diameter of particles, which describes the movement of the particles in a gas stream. Particle movement information is extremely useful in designing air pollution control equipment, especially mechanical collectors which depend on aerodynamic drag forces for particle collection.

## 2.4 Particle Size Presentation

There are various ways to analyze or reduce the data generated from a particle sizing device. The most common methods of expressing particle size data include (EPA-81/10, p. 4-12):

- Frequency distribution curve (histograms)
- Cumulative distribution curve
- Log normal distribution

All forms of graphical presentation employ one axis to represent particle size and the other axis to represent particle amount. The particle amount can be expressed by either the mass of particles or the number of particles.

*Frequency distribution curve:* This curve is usually plotted on regular coordinate (linear) paper. The curve describes the amount of material (particles) falling within each size range. When gas-borne particles produced in industrial operations are measured, the data have a tendency to show a preferential particle size. A plot of percent mass versus particle size on a linear scale gives a curve with a peak at the preferential size. An example of such a curve is shown in Fig. 2.7

Figure 2.7 shows a normal probability distribution that is symmetrical about the preferential size. This curve is encountered for dusts consisting of large particles. This curve may be

found for particles such as fumes formed by vapor phase reaction and condensation or for tar and acid mists. For very fine particles, the curve will be off-center or skewed about the preferential size. If a particle size distribution shows two peaks, the curve simply shows that the data have two preferential sizes instead of one.

The normal probability of the distribution can also be plotted on a log scale. The representation of the distribution can be seen in Fig. 2.8. The percent mass (concentration) is plotted on a linear scale as the  $y$ -axis. The particle size  $d_p$  is plotted on a log scale as the  $x$ -axis. If the curve takes on a bell-shape, the distribution appears normal.

*Cumulative distribution:* Particle size data can also be plotted as a cumulative plot. Particle size of each size range is plotted on the ordinate ( $y$ -axis). The cumulative percent by weight (frequency) is plotted on the abscissa ( $x$ -axis). The cumulative percent by weight can be given as cumulative percent less than stated particle size or cumulative percent larger than a stated particle size. The cumulative percent by weight can be plotted on either a linear percentage or a probability percentage scale. The particle size range (ordinate) is usually a logarithmic scale (*EPA-81/10*, p. 4-15). If the particle size  $d_p$  of each size range is plotted versus the cumulative percent larger than  $d_p$  (linear scale) one could get a distribution curve as shown in Fig. 2.9. In Fig. 2.9, the distribution approaches the 0% and 100% values asymptotically. It is evident that the cumulative distribution in this figure is not a straight line for the entire range of particle size in the sample. The majority of the size ranges occur toward the 0% size and the 100% size.

More frequently, the cumulative distribution is plotted on special coordinate paper called *log probability paper*. The particle size of each size range is plotted on the logarithmic ordinate. The percent by weight larger than  $d_p$  is plotted on the probability scale as the abscissa (Fig. 2.10). This allows one to expand the cumulative distribution axis near 0% and near 100%. The cumulative distribution plot in Fig. 2.10 is identical to that in Fig. 2.9, except that the percentage scale is expanded near 0% and 100%. It should be noted that one can just as easily plot percent mass less than on the abscissa.

*Log-normal distribution:* When measuring dusts from industrial sources, the graph of the particle size distribution often displays the logarithmic variation of the normal distribution. If the distribution follows the log-normal relationship, then the plot will result in a straight line. The linearity of the relationship allows one to describe the distribution statistically with a minimum of individual observations. The distribution is completely specified by two parameters (EPA-81/10, p. 4-16):

- *Geometric mean:* The geometric mean value of log-normal distribution can be read directly from a plot (Fig. 2.11). The geometric mean size is the 50% size on the plot.
- *Geometric standard deviation:* The geometric standard deviation is a good measure of the dispersion or spread of a distribution. The geometric standard deviation is the root-mean square deviation about the mean value. Its derivation and application in significance testing and setting of confidence levels can be found in most statistics textbooks. The geometric standard deviation is identical for specifying the size distribution of a log-normal distribution, whether by particle number, surface, mass, or any other quantity of the form  $k(d_p)^n$  where  $k$  is a parameter common to all particles and  $d_p$  is the diameter. Plots of cumulative distribution on log-probability paper are then parallel straight lines for number, mass, or surface which leads to a greater simplification and easy graphical technique. The geometric standard deviation can be read directly from a plot such as that shown in Fig. 2.11. For a log-normal distribution (that plots  $d_p$  maximum versus percent mass larger than  $d_p$ ), the geometric standard deviation ( $\sigma_{gm}$ ) is given by

$$\sigma_{gm} = (50\% \text{ size}) / (84.13\% \text{ size}); \text{ or}$$

$$\sigma_{gm} = (15.87\% \text{ size}) / (50\% \text{ size})$$

FIGURE 2.11 Geometric mean and standard deviation from a log normal distribution plot.

**TABLE 2.1** Typical Particle Size Data

Size range $d_p$ , $\mu\text{m}$	Concentration ( $\mu\text{g}/\text{m}^3$ )	Concentration/ $\Delta d_p$	Concentration/ $\Delta \log d_p$
1–2	0.8	$0.8/(2.0 - 1.0) = 0.8$	$0.8/[\log 2 - \log 1] = 2.66$
2–4	12.2	6.1	40.53
4–6	25	12.5	142
6–10	56	14	252.3
10–20	76	7.6	253.2
20–40	27	1.35	89.7
> 40	3	0.075	10

**EXAMPLE 1:** typical particle size data reduction. Consider the data listed in Table 2.1 (EPA-81/10, p. 4-19). Suppose we were asked to determine if the distribution was log normal, and if so, determine the geometric mean diameter ( $d_p$ ) and the geometric standard deviation ( $d_{gm}$ ). How would one approach this problem?

First we could plot the mass concentration (concentration/ $\Delta d_p$ ) versus particle diameter  $d_p$  on a linear scale (Fig. 2.12). The data appear to be skewed and would therefore lead one to believe that the distribution could be log normal.

**FIGURE 2.12** Mass concentration versus particle diameter on a linear scale (EPA-81/10, p. 4-20).

We can now plot mass concentration  $(\text{concentration})/\Delta \log d_p$  on a log scale (Fig. 2.13). The particle size  $d_p$  ( $x$ -axis) is plotted on a log scale. The area under the smooth curve between two different values of  $d_p$  represents the total particle mass concentration between the two values of  $d_p$ . If the  $y$ -axis is not 'concentration divided by  $\Delta \log d_p$ ' then the distribution shape will be partly determined by the size ranges of the sampling device (i.e. impactor stages) rather than the true particle distribution shape.

This plot yields an appropriately shaped bell curve that appears to indicate that this is a log-normal distribution. However, it is extremely important to plot the data on log-probability paper to see if a straight line results. If the distribution plots a straight line on log-probability paper, then the distribution is log normal.

First we must calculate the percent in each size range and then the cumulative percent larger than  $d_p$  maximum (Table 2.2).

The plot (Fig. 2.14) on log-probability paper yields a straight line. Therefore the distribution is log normal. To determine the geometric mean diameter one can read the 50% size from Fig. 2.14.

$$d_{gm} = 10.5 \text{ micrometers}$$

**TABLE 2.2** Cumulative Particle Size Data

Size range $d_p, \mu\text{m}$	Concentration	Percent weight in size range	Cumulative percent larger than $d_p$ -max
0-2	0.8	0.4	99.6
2-4	12.2	6.1	93.5
4-6	25	12.5	81
6-10	56	28	53
10-20	76	38	15
20-40	27	13.5	1.5
> 40	3	1.5	—
Total	200		

FIGURE 2.14 Log probability distribution.

The geometric standard deviation is

$$\begin{aligned} \sigma_{gm} &= (50\% \text{ size}) / (84.13\% \text{ size}) \\ &= 10.5 / 5.5 \\ &= 1.9 \end{aligned}$$

**EXAMPLE 2:** log-normal distribution. Determine if a particle size distribution is log normal, based on the data given in Table 2.3 (EPA-84/09, p. 49).

*Solution:*

1. Generate a cumulative distribution curve.

Cumulative distribution plots are generated by plotting particle diameter versus cumulative percent. For log-normal distributions, plots of particle diameter versus either percent less than stated size (% LTSS) or percent greater than stated size (% GTSS) produce straight lines on log-probability (normal) coordinates.

1.1. Complete Table 2.4 (given below), calculating the percent of the total mass and the cumulative percent GTSS for each particle size range.

The cumulative percent, based on % GTSS, is the total percent of the mass of particles greater than the upper size for the range in question.

1.2. Plot the cumulative distribution curve on a blank log-probability graph paper as shown in Fig. 2.15.

The cumulative distribution points are plotted using the upper-size particle diameter of each range versus cumulative % GTSS.

2. Is the distribution log normal?

Since a straight line is obtained on log-normal coordinates, the particle size distribution is log normal or a linear (straight line) relationship on log-normal coordinates.

**EXAMPLE 3:** Andersen 2000 sampler data analysis. Given Andersen 2000 sampler data, plot a cumulative distribution curve on log-probability paper and determine the mean particle diameter and geometric standard deviation (EPA-84/09, p. 52).

**Given conditions**

volumetric flow rate  $Q = 0.5$  cfm

 †Column (4): 100 – cumulative % of column (3); e.g. 100–10 = 90; 100–10–13 = 77.

Fig. 2.16 gives aerodynamic diameter versus flow rate through an Andersen sampler for an impaction efficiency of 95%.

Andersen 2000 sampler data (Table 2.5)

*Solution:*

1. Generate a cumulative distribution curve.

1.1. Complete Table 2.6 (given below) by calculating the net weight, % of total weight, and cumulative percent for each plate. Use % LTSS.

1.2. Determine the 95% aerodynamic diameter at  $Q = 0.5$  cfm for each plate from Fig. 2.16. These values are listed in Table 2.7.

The aerodynamic diameter of a particle is defined as the diameter of a sphere having the same resistance to motion as the particle. The 95% aerodynamic diameter assigned to each plate may be thought of as that particle size that will not pass through the sampler opening.

Back-up filter	0.2081	0.21156	0.00346	34.22	34.22
Total	141.34266	141.35277	0.01011	100.00	

Notes for Tables 2.6A and 2.6B

\*Column (4) = column (3) – column (2), i.e. net weight = final weight – tare weight.

†Column (5) = ((column (4))/total) (100); where total = 0.01011 g.

‡Column (6) = 100% – cumulative %; e.g. for plate 1, 100% – 14.24% = 85.76%; for plate 2, 85.76% – 5.54% = 80.22%. As indicated in the previous example, cumulative distribution plots are generated by plotting particle diameter versus cumulative percent. For log-normal distributions, % LTSS are usually plotted on the probability normal coordinates. Cumulative % represents the percent less than stated size (% LTSS) associated with each plate. Thus, the calculated cumulative percent is that quantity of particles, in percent, captured by the appropriate plate and all other captured smaller particles.

1.3. Plot the cumulative distribution curve on a blank log-probability sheet as shown in Fig. 2.17.

The cumulative distribution curve is plotted as diameter versus cumulative percent less than stated size (% LTSS).

2. From the cumulative distribution curve, determine the mean particle diameter in microns ( $\mu\text{m}$ ).

Since the mean particle diameter is the particle diameter corresponding to a cumulative percent of 50%, read off the particle diameter at a cumulative percent of 50% from Fig. 2.17.

$$\text{Mean particle diameter} = Y_{50} = 1.2 \text{ microns}$$

3. Determine the geometric standard deviation  $\sigma_{gm}$ , if the distribution is approximately log normal.

Geometric standard deviation is defined as (EPA-81/10, p. 4-19):

$$\sigma_{gm} = (50\% \text{ size}) / (84.13\% \text{ size})$$

$$\sigma_{gm} = (15.87\% \text{ size}) / (50\% \text{ size})$$

3.1. The distribution approaches log-normal behavior. Read off the particle diameter at 84.13 cumulative% from Fig. 2.17, the particle diameter at 84.13 cumulative%.

**TABLE 2.7** Aerodynamic Diameters for Plate Numbers

Plate No. (stage No.)	95% aerodynamic diameter, $\mu\text{m}$
0	20
1	13
2	8.5
3	5.7
4	3.7
5	1.8
6	1.2
7	0.78

$$Y_{84.13} = 17.0 \text{ microns}$$

3.2. For a log-normal distribution:

$$\begin{aligned}\sigma_{\text{gm}} &= Y_{50}/Y_{84.13} \\ &= 1.2/17.0 = 0.071\end{aligned}$$

### 3 FACTORS AFFECTING THE SELECTION OF PARTICULATE CONTROL EQUIPMENT

---

Many factors influence the choice of a control device used to reduce particulate emissions. The composition of the particles in terms of concentration, size, and chemical and physical characteristics must be considered. If emitted material can be used in the process, dry collection should be used. If the pollutant has little economic value, collection should be accomplished and the pollutant disposed of safely and economically. The industrial process and potential control devices must both be carefully reviewed. The conversion of an air pollution problem into a water pollution problem can create a more difficult disposal problem. It is necessary to consider many factors (EPA-81/10, p. 1-5), which are illustrated below.

#### 3.1 Particle Concentration or Grain Loading

One selection factor to be considered is the concentration or grain loading of particulate pollutants in the process exhaust stream. Pollutant concentration is typically expressed in terms of pounds per cubic foot ( $\text{lb}/\text{ft}^3$ ), grains per cubic foot ( $\text{gr}/\text{ft}^3$ ), and grams per cubic meter ( $\text{g}/\text{m}^3$ ). Both the level and fluctuation of grain loading are very important. Some control devices are not affected by high levels or great fluctuations in particle concentration such as in fabric filters. Others, such as electrostatic precipitators, do not function effectively with a large fluctuating concentration level. Another related problem can occur when the exhaust gas velocity changes rapidly. Some control devices are designated to operate at a specific exhaust gas velocity; large changes can drastically affect the collection efficiency of the unit.

#### 3.2 Particle Characteristics

Particle characteristics such as size, shape, and density must also be considered. Particle size is usually expressed in terms of aerodynamic diameter. The *aerodynamic diameter* describes how the particle moves in a gas stream. The larger particles ( $> 60 \mu\text{m}$  aerodynamic diameter) can be collected in simple devices such as settling or baffle chambers. Particles greater than  $5 \mu\text{m}$  can be collected in cyclones or multicyclones. Smaller particles ( $< 5 \mu\text{m}$ ) must be collected in more sophisticated devices, such as scrubbers, baghouses, or electrostatic precipitators. Particle size thus plays a large role in the collection efficiency of a specific control device.

#### 3.3 Chemical and Physical Properties

Chemical and physical properties of particulate emissions greatly affect the selection of control devices. Electrical properties of the particle can be both a hindrance and an aid to collection. Static electricity can create solid buildup in both inertial and baghouse collectors. Cakes can form on the bag filters, as a result of the static electric forces, and can be difficult to dislodge.

In an electrostatic precipitator, on the other hand, the collection of particulate matter depends on the ability of the precipitator to charge the particle. Particles passing through

an electric field are charged and, consequently, migrate to an oppositely charged collection plate. Although there are many factors that govern the ease of charging the particles, the primary factor governing adequate particle collection is particle dust resistivity (a term that describes the resistance of the collected dust layer to the flow of electric current).

If the particles in the gas stream are explosive, electrostatic precipitators cannot be used. Fabric filters might be used, but only if no static electric effects exist in the baghouse. The logical choice of control would be a scrubber in which water is used as the scrubbing liquid. The water has a dampening effect on the explosive dust.

### 3.4 Hygroscopicity

Hygroscopicity is the tendency of a material to absorb water. It is a physical characteristic of some particles which causes changes in the crystal structure as water is added. Some particles such as sodium sulfate can absorb up to 12 moles of water per mole of anhydrous salt in high humidity conditions. Other particles from processes such as alfalfa dehydration and pelleting, and cotton ginning, are hygroscopic to varying degrees. The hygroscopic nature of the particle affects the performance of mechanical collectors by causing dust deposits to build up on their internal surfaces. This may cause internal plugging or unpredictable dust cake discharges into collection hoppers at various times. Hygroscopic particles also affect the choice of cleaning in a baghouse in that they form cakes on the bags that are difficult to remove.

### 3.5 Particle Toxicity

Particle toxicity influences the location of the control device and the air moving system (fan). Highly toxic materials require the use of a negative pressure system, so that leaks can be contained within the collector. A positive pressure system could cause fugitive emissions, creating an occupational health and safety problem. In a negative pressure system, the fan is located downstream of the air pollution control devices. The volume of gas to be handled may increase slightly by air leakage into the collector, but little or no contaminant leakage from the collector should occur.

### 3.6 Carrier Gas Stream

The behavior of the carrier gas stream is also important in the design phases of air pollution control systems. Gas stream temperature affects a number of variables in the design stages of the control device. The size and thus the cost of the unit depends on the temperature of the exhaust gas stream being treated. The volume of gas to be cleaned would be larger at high temperatures than that at correspondingly lower gas temperatures. Reducing the temperature reduces the volume of exhaust gas to be handled; however, this could create some additional problems. The gas stream temperature must be maintained above the dew point of the gas to prevent water and acid from condensing in the collector. Water and acid mists could cause corrosion and complete deterioration of the structural material of the collector.

High gas stream temperatures can also cause equipment failure to components of a fabric filtration system. At exhaust gas temperatures greater than 300°C most fabric materials deteriorate. Gas temperature can also affect conditions such as particle resistivity. By changing the temperature of the exhaust stream in an electrostatic precipitator, one can also change the resistivity of the particles, and thus the collection efficiency of the unit.

### 3.7 Efficiency/Cost Trade-off

In air pollution work, the control equipment should be designed to meet emission limitations at minimum cost with maximum reliability. The basic trade-offs involve decisions between collection efficiency, pressure drop, installation cost, and operating costs. Of these, the principal one is the trade-off between collection efficiency and pressure drop (which can be translated into power requirements) across the control device.

Collection efficiency (by weight) can be defined by the following formula:

$$\text{Collection efficiency} = [(\text{inlet loading} - \text{outlet loading}) / (\text{inlet loading})] \times 100$$

Emission limits are usually set by existing air pollution regulations. The control to be achieved is dependent on the allowed outlet concentration and the quantity of emissions generated from the process.

Equipment should be operated at the pressure drop specified by the design. Pressure drop describes the pressure loss between the inlet and outlet sections of the control device. Collectors with large pressure drops would require larger fans (and greater power requirements) to either push or pull the exhaust gas through the system. An increase in pressure drop means that there is a larger pressure loss in the system. Some control devices such as venturi scrubbers are designed to operate at high pressure drops (as great as 60 in. H<sub>2</sub>O; 14.9 kPa). On the other hand, electrostatic precipitators are designed to operate at much lower pressure drops (usually less than 10 in. H<sub>2</sub>O; 2.49 kPa) for similar collection efficiencies. It may be advantageous, however, to choose the scrubber as the control device in some cases, especially if the dust to be collected is explosive.

Other conditions such as space limitations for installation may affect the ultimate decision for control equipment. Scrubbers generally require less installation space than either baghouses or electrostatic precipitators. There are, of course, water disposal problems with wet collectors that could sway the choice toward some other type of control. Installed cost and operating costs vary for each type of collector. For a given process, electrostatic precipitators may be more expensive to install than baghouses. However, baghouses may be more expensive to operate and maintain on an annual basis. The cost trade-offs must be examined carefully in making the final choice in control equipment.

## 4 PARTICULATE EMISSION CONTROL EQUIPMENT

---

### 4.1 Gravity Settling Chamber

Gravity settling chambers have long been used by industry for removing solids or liquid particulate matter from gaseous streams. The technology has the advantages of simple construction, low initial cost and maintenance, low pressure losses, and simple disposal of collected materials.

The technology was one of the first devices used to control particulate emissions. It is an expansion chamber in which particle velocity is reduced, thus allowing the particle to settle out under the action of gravity. One primary feature of this device is that the external force causing separation of particles from the gas stream is provided free by nature. This chamber's use in industry, however, is generally limited to the removal of larger sized particles, 40–60 μm in diameter (EPA-81/10, p. 5-1).

**Gravity settler type.** There are basically three types of gravity settlers (EPA-81/10, p. 5-1):

- Simple expansion chamber
- Multiple-tray settling chamber
- Baffle chamber

*Simple expansion chamber:* A typical horizontal flow (simple expansion) gravity settling chamber is presented in Fig. 2.18. The unit is constructed in the form of a long horizontal box with an inlet, outlet, and dust collection hoppers. These units depend on gravity for collection of the particles. The particle-laden gas stream enters the unit at the gas inlet. The gas stream then enters the expansion section of the duct. Expansion of the gas stream causes the gas velocity to be reduced. All particles in the gas stream are subject to the force of gravity. However, at reduced gas velocities (in the range of 0.305 to 3.05 m/s) the larger particles can be overcome by gravity and fall into the dust hoppers. Theoretically, a settling chamber of infinite length could collect even the very small particles ( $< 10 \mu\text{m}$ ).

The collection hoppers located at the bottom of the settler are usually designed with positive seal valves and must be emptied as dust buildup occurs. Dust buildup will vary depending on the concentration levels of particulate matter in the gas streams, especially for heavy concentrations of particles greater than  $60 \mu\text{m}$  in diameter.

*Multiple-tray settling chamber:* The multiple-tray settling chamber, also known as the Howard settling chamber, is shown in Fig. 2.19. Several horizontal collection plates are introduced to shorten the settling path of the particle and to improve the collection efficiency of small particles (as small as  $15 \mu\text{m}$  in diameter). Each shelf or tray in the unit can collect dust that settles out by gravitational force. Since the vertical distance that a particle must fall to be captured is less than the distance in a horizontal settling unit, the overall collection efficiency of the Howard settling chamber can be greater than the horizontal chamber. The gas must be uniformly distributed as it passes through each tray throughout the chamber. Uniform distribution is usually achieved by the use of gradual transition, guide vane, distributor screens, and perforated plates. The particles will settle on the individual trays, which must be cleaned periodically. The vertical distance between trays may be as little as 1 inch, making cleaning much more difficult than with the horizontal settling chamber. Other disadvantages include the tendency of trays to warp during high-temperature operation and the inability of the unit to handle dust concentrations exceeding approximately  $1 \text{ grain/ft}^3$  ( $2.29 \text{ g/m}^3$ ). For these reasons, the Howard settling chamber is not used very frequently for particulate emission control.

*Baffle chamber:* A variation of the gravity settling chamber is a baffle chamber, sometimes referred to as an inertial separator. These units have baffles within the chamber to enhance particle separation and collection. This arises by changing the direction of the gas velocity and imparting a downward motion to the particle. This induced motion is superimposed on the motion due to gravity. Thus, particle collection is accomplished by gravity and an inertial or momentum effect. Particles as small as 20 to  $40 \mu\text{m}$  can be collected. An example of this device

FIGURE 2.18 Horizontal flow settling chamber (EPA-81/10, p. 5-2).

is shown in Fig. 2.20. These units are more compact and require less space than gravity settling chambers. The pressure drops are slightly higher, ranging from 0.1 to 1.0 in. of  $\text{H}_2\text{O}$  (0.25 to 2.5 cm  $\text{H}_2\text{O}$ ).

**Design parameter.** Understanding the principles governing particle collection in a gravity settler begins by examining the behavior of a single spherical particle in the chamber, as shown in Fig. 2.21. The bulk flow air velocity profile in this case is assumed to be uniform throughout the chamber. The particle flows with the same velocity as the gas stream, and the horizontal velocity is given as  $v_x$ . The particle also has a vertical velocity,  $v_y$ . The term  $v_y$  is also called the terminal settling velocity  $v_t$ . The length, width, and height of the chamber are  $L$ ,  $B$ , and  $H$ , respectively (*EPA-81/10*, p. 5-4).

Suppose a particle enters the chamber at a height  $h_p$ . The particle must fall this distance ( $h_p$ ) before it travels the length of the chamber if the particle is to be collected. In other words, the

FIGURE 2.21 Settling chamber dimensions (EPA-81/10, p. 5-4).

particle will settle if the time required for the particle to settle is less than the time that the particle resides in the chamber.

The theoretical collection efficiency of the settling chamber is given by the expression:

$$\eta = (v_y L) / (v_x H) \tag{2.1}$$

- where  $\eta$  = fractional efficiency of particle size  $d_p$  (one size)
- $v_y$  = vertical settling velocity
- $v_x$  = horizontal gas velocity
- $L$  = chamber length
- $H$  = chamber height (greatest distance a particle must fall to be collected)

The settling velocity can be calculated from Stokes' law, as previously discussed. As a rule of thumb, Stokes' law applies when the particle size  $d_p$  is less than 100  $\mu\text{m}$  in size. The settling velocity is

$$v_t = [g(d_p)^2(\rho_p - \rho_a)] / (18\mu) \tag{2.2}$$

- where  $v_t$  = settling velocity in Stokes' law range, m/s (ft/s)
- $g$  = acceleration due to gravity, 9.8 m/s<sup>2</sup> (32.1 ft/s<sup>2</sup>)
- $d_p$  = diameter of the particle,  $\mu\text{m}$
- $\rho_p$  = particle density, kg/m<sup>3</sup> (lb/ft<sup>3</sup>)
- $\rho_a$  = gas density (usually air), kg/m<sup>3</sup> (lb/ft<sup>3</sup>)
- $\mu$  = gas viscosity, Pa-sec (lb/ft-s)
- Pa = N/m<sup>2</sup>
- N = kg-m/s<sup>2</sup>

Thus, Eq. (2.2) can be rearranged to determine the minimum particle size that can be collected in the unit with 100% efficiency. The minimum particle size  $d_p^*$  (in  $\mu\text{m}$ ) is given as

$$(d_p)^* = \{v_t(18\mu) / [g(\rho_p - \rho_a)]\}^{0.5} \tag{2.3}$$

The density of the particle  $\rho_p$  is usually much greater than the density of gas  $\rho_a$ . Therefore, the quantity  $\rho_p - \rho_a$  reduces to  $\rho_p$ . The velocity can be written as

$$v = Q / BL$$

- where  $Q$  = volumetric flow rate
- $B$  = chamber width
- $L$  = chamber length

Equation (2.3) is reduced to

$$(d_p)^* = \{(18\mu Q)/[g\rho_p BL]\}^{0.5} \quad (2.4)$$

The efficiency equation can also be expressed as

$$\eta = [(g\rho_p BLN_c)/(18\mu Q)](d_p)^2 \quad (2.5)$$

where  $N_c$  = number of parallel chambers: 1, for simple settling chamber and  $N$  trays +1, for a Howard settling chamber.

In Eq. (2.5),  $\rho_p$  (particle density) was assumed to be much greater than  $\rho_a$  (gas density); hence  $\rho_p - \rho_a = \rho_p$ . The term in the brackets in Eq. (2.5) is often multiplied by a dimensionless empirical factor to correlate theoretical efficiencies with experimental data. If no information is available, it is suggested that 0.5 be used. Thus, Eq. (2.5) can be written as

$$\eta = 0.5[(g\rho_p BLN_c)/(18\mu Q)](d_p)^2 \quad (2.6)$$

Equations (2.1) and (2.5) give the theoretical collection efficiencies of a settling chamber for a single-sized particle. Since the gas stream entering a unit consists of a distribution of particles of various sizes, a fractional efficiency curve must be used to determine the overall collection efficiency.

The overall efficiency can be calculated using

$$\eta_{TOT} = \sum \eta_i w_i \quad (2.7)$$

where  $\eta_{TOT}$  = overall collection efficiency

$\eta_i$  = fractional efficiency of specific size particle

$w_i$  = weight fraction of specific size particle

Equations (2.1) and (2.2) were developed with the assumption that gas flow through the settling chamber is laminar. This assumption is usually incorrect. The gas flow is usually turbulent. The equation for determining efficiency when the flow is turbulent is

$$\eta = \exp[-(Lv_y/Hv_x)] \quad (2.8)$$

One must be careful when using Eqs. (2.1)–(2.6). For example, Eq. (2.4) is used to find the minimum particle size collected with 100% efficiency. This equation assumes that Stokes' law describes particle settling. However, Stokes' law does not work for particles greater than 100  $\mu\text{m}$ ; in some cases, it gives results that are gravely in error.

**Process variables.** The process design variables for a settling chamber consist of length ( $L$ ), width ( $B$ ), and height ( $H$ ). The parameters are usually chosen by a chamber manufacturer to remove all particles above a specified size. The chamber design must provide conditions for sufficient particle residence time to capture the desired particle size range. This can be accomplished by keeping the velocity of the exhaust gas through the chamber as low as possible. If the velocity is too high dust re-entrainment will occur. However, the design velocity must not be so low as to cause the design of the chamber volume to be exorbitant. Consequently, the units are designed for a gas velocity in the range from 1 to 10 ft/s (0.305 to 3.05 m/s). Errors in estimating settling velocity from equations such as Eq. (2.2) can occur due to agglomeration and electrostatic effects. Therefore, in actual practice, the terminal settling velocities used for design purposes are based upon experience and tests under normal process conditions (EPA-81/10, p. 5-7).

In settling chamber designs, the velocity at which the gas moves through the chamber is usually called the *throughput velocity*. The velocity at which settled materials (particles) become re-entrained is called the *pickup velocity*. In order to avoid re-entrainment of collected

dust, the throughput velocity must not exceed the pickup velocity. Experimental data or equipment supplier data such as that presented in Table 2.8 should be used to estimate the pickup velocity. As can be seen from this table, the pickup velocity can exceed 10 ft/s. If no data for determining the pickup velocity is available, the pickup velocity should be assumed to be 10 ft/s. In this case, the velocity of gas through the settling chamber (throughput velocity) must be less than 10 ft/s.

**TABLE 2.8** Pickup Velocities of Various Materials

Material	Density (g/cm <sup>3</sup> )	Median size (μm)	Pickup velocity (ft/s)
Aluminum chips	2.72	335	14.2
Asbestos	2.20	261	17.0
Nonferrous foundry dust	3.02	117	18.8
Lead oxide	8.26	14.7	25.0
Limestone	2.78	71	21.0
Starch	1.27	64	5.8
Steel shot	6.85	96	15.2
Wood chips	1.18	1370	13.0
Wood sawdust	–	1400	22.3

In terms of overall design considerations for gravity settlers, advantages include:

- low cost of construction and operation
- few maintenance problems
- relatively low operating pressure drops in the range of approximately 0.2–0.5 in. (0.51–1.27 cm) of water
- temperature and pressure limitations imposed only by the materials of construction used
- dry disposal of solid particulates

The disadvantages include:

- large space requirements
- relatively low overall collection efficiency (typically ranging from 20 to 60%)

In general, most gravity settlers are precleaners removing the relatively large particles (greater than 60 μm) before the gas stream enters a more efficient particulate control device such as a multicyclone, baghouse, electrostatic precipitator, or scrubber.

**EXAMPLE 1:** gravity settler—minimum particle size. A hydrochloric acid mist in air at 25°C is to be collected in a gravity settler. You are requested to calculate the smallest mist droplet (spherical in shape) that will be entirely collected by the settler. Assume the acid concentration to be uniform through the inlet cross-section of the unit and Stokes' law applies (EPA-84/09, p. 61).

**Given conditions**

dimensions of gravity settler = 30 ft wide, 20 ft high, 50 ft long

actual volumetric flow rate of acid gas in air = 50 ft<sup>3</sup>/s

specific gravity of acid = 1.6

viscosity of air = 0.0185 cp =  $1.243 \times 10^{-5}$  lb/ft-s

density of air = 0.076 lb/ft<sup>3</sup>

*Solution:*

1. Calculate the density of the acid mist using the specific gravity given.

$$\begin{aligned}\rho_p &= \text{particle density} = (\text{specific gravity of fly ash})(\text{density of water}) \\ &= 1.6(62.4) = 99.84 \text{ lb/ft}^3\end{aligned}$$

2. Calculate the minimum particle diameter both in feet and microns ( $\mu\text{m}$ ) assuming Stokes' law applies.

For Stokes' law range:

$$\text{Minimum } d_p = (18\mu Q/g\rho_p BL)^{0.5}$$

where  $\mu$  = gas (fluid) viscosity  
 $Q$  = volumetric flow rate  
 $g$  = gravity force  
 $\rho_p$  = particle or mist density  
 $B$  = width of settler  
 $L$  = length of settler

Note that the above equation can be derived by substituting the terminal velocity for Stokes' law into the gravity settler equation  $v = Q/BL$ .

$$\begin{aligned}\text{Minimum } d_p &= [(18)(1.243 \times 10^{-5})(50)/(32.2)(99.84)(30)(50)]^{0.5} \\ &= 4.82 \times 10^{-5} \text{ ft} \\ &= (4.82 \times 10^{-5} \text{ ft})(3.048 \times 10^5 \mu\text{m/ft}) \\ &= 14.7 \mu\text{m}\end{aligned}$$

**EXAMPLE 2:** gravity settler—traveling grate stoker. A settling chamber is installed in a small heat plant which uses a traveling grate stoker. You are requested to determine the overall collection efficiency of the settling chamber given the operating conditions, chamber dimensions, and particle size distribution data (EPA-84/09, p. 62).

**Given conditions**

chamber width = 10.8 ft

chamber height = 2.46 ft

chamber length = 15.0 ft

volumetric flow rate of contaminated air stream = 70.6 scfs

flue gas temperature = 446°F

flue gas pressure = 1 atm

particle concentration = 0.23 grains/scf

particle specific gravity = 2.65

standard conditions = 32°F, 1 atm

particle size distribution data of the inlet dust from the traveling grate stoker are shown in Table 2.9.

**TABLE 2.9** Particle Size Distribution Data

Particle size range, $\mu\text{m}$	Average particle diameter, $\mu\text{m}$	Inlet	
		grains/scf	wt %
0–20	10	0.0062	2.7
20–30	25	0.0159	6.9
30–40	35	0.0216	9.4
40–50	45	0.0242	10.5
50–60	55	0.0242	10.5
60–70	65	0.0218	9.5
70–80	75	0.0161	7
80–94	85	0.0218	9.5
94	94	0.0782	34
Total		0.23	100

Assume that the actual terminal settling velocity is one-half of the Stokes' law velocity.

*Solution:*

1. Plot the size efficiency curve for the settling chamber.

You need the size efficiency curve to calculate the outlet concentration for each particle size (range). These outlet concentrations are then used to calculate the overall collection efficiency of the settling chamber. The collection efficiency for a settling chamber can be expressed in terms of the terminal settling velocity, volumetric flow rate of contaminated stream, and chamber dimensions:

$$\eta = vBL/Q = [g\rho_p(d_p)^2/18\mu](BL/Q)$$

- where  $\eta$  = fractional collection efficiency  
 $v$  = terminal settling velocity  
 $B$  = chamber width  
 $L$  = chamber length  
 $Q$  = volumetric flow rate of the stream

1.a. Express the collection efficiency in terms of the particle diameter  $d_p$ .

1.a.1. Replace the terminal settling velocity in the above equation with Stokes' law.

Since the actual terminal settling velocity is assumed to be one-half of the Stokes' law velocity (according to the problem statement), the velocity equation becomes

$$v = g(d_p)^2\rho_p/36\mu$$

$$\eta = [g\rho_p(d_p)^2/36\mu](BL/Q)$$

1.a.2. Determine the viscosity of the air in lb/ft-s.

$$\text{Viscosity of air at } 446^\circ\text{F} = 1.75 \times 10^{-5} \text{ lb}_f/\text{ft-s}$$

1.a.3. Determine the particle density in lb/ft<sup>3</sup>

$$\rho_p = 2.65(62.4) = 165.4 \text{ lb}/\text{ft}^3$$

1.a.4. Determine the actual flow rate in acfs.

In order to calculate the collection efficiency of the system at the operating conditions, the standard volumetric flow rate of contaminated air of 70.6 scfs is converted to actual volumetric flow of 130 acfs.

$$\begin{aligned} Q_a &= Q_s(T_a/T_s) \\ &= 70.6(446 + 460)/(32 + 460) \\ &= 130 \text{ acfs} \end{aligned}$$

1.a.5. Express the collection efficiency in terms of  $d_p$ , with  $d_p$  in ft. Also express the collection efficiency in terms of  $d_p$ , with  $d_p$  in microns.

Use the equation developed in 1.a.1. above, substitute values for  $\rho_p$ ,  $g$ ,  $B$ ,  $L$ ,  $\mu$ , and  $Q$  in consistent units. Use the conversion factor for ft to microns. To convert  $d_p$  from ft<sup>2</sup> to  $\mu^2$ ,  $d_p$  is divided by (304,800)<sup>2</sup>.

$$\begin{aligned} \eta &= [g\rho_p(d_p)^2/36\mu](BL/Q) \\ &= (32.2)(165.4)(10.8)(15)(d_p)^2/[(36)(1.75 \times 10^{-5})(130)(304,800)^2] \\ &= 1.134 \times 10^{-4}(d_p)^2 \end{aligned}$$

where  $d_p$  is in  $\mu\text{m}$  (microns).

1.b. Calculate the collection efficiency for each particle size.

For a particle diameter of 10 microns:

$$\eta = (1.134 \times 10^{-4})(d_p)^2 = (1.134 \times 10^{-4})(10)^2 = 1.1 \times 10^{-2} = 1.1\%$$

Table 2.10 provides the collection efficiency for each particle size.

1.c. The size efficiency curve for the settling chamber is shown in Fig. 2.22.

2. Read off the collection efficiency of each particle size from Fig. 2.22.

3. Calculate the overall collection efficiency (Table 2.11)

$$\begin{aligned} \eta &= \Sigma w_i \eta_i \\ &= (0.027)(1.1) + (0.069)(7.1) + (0.094)(14.0) + (0.105)(23.0) + (0.105)(34.0) \\ &\quad + (0.095)(48.0) + (0.070)(64.0) + (0.095)(83.0) + (0.340)(100.0) \\ &= 59.0\% \end{aligned}$$

**TABLE 2.10** Collection Efficiency for Each Particle Size

## 4.2 Cyclone

Cyclones provide a relatively low-cost method of removing particulate matter from exhaust gas streams. Cyclones are somewhat more complicated in design than simple gravity settling systems and their removal efficiency is accordingly much better than that of settling chambers. However, cyclones are not as efficient as baghouses and electrostatic precipitators, but are often installed as precleaners before these more effective devices (EPA-81/10, p. 6-1).

**FIGURE 2.22** Size efficiency curve for settling chamber (EPA-84/09, p. 136).

Cyclones come in many sizes and shapes and have no moving parts. From the 1- and 2-cm diameter source sampling cyclones used for particle size analysis to the large 5-m diameter cyclone separators used after wet scrubbers, the basic separation principle remains the same. Particles enter the device with the flowing gas, as shown in Fig. 2.23; the gas stream is forced to turn, but the larger particles have too much momentum and cannot turn with the gas. These larger particles impact and fall down the cyclone wall, then are collected in a hopper. The gas stream actually turns a number of times in a helical pattern, much like the funnel of a tornado. The repeated turnings provide many opportunities for particles to break through the streamlines, thus hitting the cyclone wall.

The range of particle sizes collected in a cyclone is dependent upon the overall diameter and relative dimensions of the device. Various refinements, such as the use of skimmers, turning vanes, and water sprays, can in some cases improve efficiency. Stacking cyclones in series or in parallel can provide further alternatives for improving overall collection efficiency.

**Cyclone type.** Three types of cyclones are shown in Fig. 2.24. Figure 2.24a shows a typical tangential entry cyclone arrangement. These cyclones have a distinctive and easily recognized form and can be found in almost any industrial area of a town or a city at lumber companies, feed mills, cement plants, power plants, smelters, and at many other processing industrial sites. Since top inlet type cyclones are so widely used, most of this chapter will be devoted to their operational characteristics.

In axial entry cyclones (Fig. 2.24b), the gas inlet is parallel to the axis of the cyclone body. The exhaust process gases enter from the top and are directed into a vortex pattern by the vanes attached to the central tube. Axial entry cyclones are commonly used in multicyclone configurations.

The large cyclonic type separator, shown in Fig. 2.24c, is often used after wet scrubbers to collect particulate matter entrained in water droplets. The gas enters tangentially at the bottom of the drum, forming a vortex. The large water droplets are forced against the walls and are removed from the gas stream.

FIGURE 2.23 Particle collection mechanism (EPA-81/10, p. 6-1).

**Cyclone design factors.** The common cyclone has four major design areas:

- Inlet
- Cyclone body
- Dust discharge system
- Outlet

Each part of the cyclone is important to its overall effectiveness.

*Inlet:* The inlet directs gas into the cyclone body and is important in forming the vortex. In the cylindrical section, the particulate matter is forced to the wall. The gas spirals down to the cone section, where the body is tapered to give the gas enough rotational velocity to keep the dust against the wall. The particulate matter is collected in the hopper or vortex arrestor, and is continuously or periodically removed. The gas vortex changes from the downward to the upward direction at the bottom of the cone.

A tube extends from the top of the cyclone into the cylinder of the body. This tube extension is sometimes called a *vortex finder*. The ascending vortex enters the tube extension and then exits. A helical exhaust duct or a drum may be placed on the exit tube to straighten the gas flow before it flows through further ductwork. The length and width of the inlet are important, since the smaller the inlet, the greater the inlet velocity becomes. A greater inlet velocity gives greater efficiency but also increases the pressure drop.

*Cyclone body and cone:* The removal efficiency of a cyclone for a given size particle is very dependent upon the cyclone dimensions. The particle drop at a given volumetric flow rate is most affected by the diameter. The overall length determines the number of turns of the vortex. The greater the number of turns, the greater the efficiency.

The cone primarily serves as a mechanism to remove particulate matter down the walls to the hopper, and to provide greater tangential velocities near the bottom for removal of smaller particles. The vortex formed in a cyclone is, however, eccentric. Just as a tornado moves at an angle to the ground, the cyclone's main vortex can deviate from the vertical axis. For this reason, it has been found that the bottom of the cone should have a diameter of at least 1/4 of the cylinder diameter; otherwise, the outer vortex could touch the cone wall and entrain already separated particulate matter into the ascending vortex.

Even if optimum dimensions are selected, problems can occur within the cyclone which can reduce the efficiency. Rough walls will slow down the gas, decreasing the velocity of the vortex, thus causing small particles to be lost. Particles can bounce off the walls into the inner vortex and also be lost. Secondary flow patterns or eddies can form in the annular region at the inlet. The recirculation and turbulence here can prevent all particles from entering the vortex and instead be drawn into the outlet tube. The lower pressure in the inner vortex caused by its faster velocity can cause particles to drift in from the main vortex. These problems limit the efficiency of a cyclone.

*Dust discharge system (hopper):* The vortex will extend into the discharge bin if the bin is immediately below the cone and nothing is added at the bottom of the cone to arrest the vortex. Since the static pressure in the vortex core is slightly negative, dust can be re-entrained from the hopper into the inner vortex. Also, if leaks exist in the bin, dust can be sucked back up into the cyclone.

*Cyclone gas outlet:* The exit tube is an important consideration in the design of any cyclone. Its length must extend beyond the inlet so that the eddies created in the annulus between the tube and the walls do not mix particles up and into the exit tube.

**Factors affecting cyclone performance.** The factors that affect cyclone performance include:

- Centrifugal force
- Cut diameter
- Pressure drop
- Collection efficiency
- Summary of performance characteristics

*Centrifugal force:* Objects moving in circular paths tend to move away from the center of their motion. The object moves outward as if a force were pushing it out. This force is known as the *centrifugal force*. The whirling motion of the gas in a cyclone causes particulate matter

in the gas to feel this force and move out to the walls. An expression for this phenomenon is as follows:

$$F = [\rho_p(d_p)^3(v_p)^2]/r \quad (2.9)$$

where  $F$  = centrifugal force  
 $\rho_p$  = particles density, lb/ft<sup>3</sup> (kg/m<sup>3</sup>)  
 $d_p$  = particle diameter, ft ( $\mu\text{m}$ )  
 $v_p$  = particle tangential velocity, ft/s (m/s)  
 $r$  = radius of the circular path, ft (m)

$F$  is the force that the particulate matter views as acting on it. This expression explains several of the cyclone characteristics. For example,  $\rho_p(d_p)^3$  is merely proportional to the mass of the particle. The larger the mass, the greater the force. The tendency to move toward the walls is consequently increased and larger particles are more easily collected. The reason all of the particles do not move to the wall is because of the drag resistance of the air. The buffeting molecules in the gas resist the outward motion and act like an opposing force. Particles move to the wall when the centrifugal force is greater than the opposing drag force.

Note also from Eq. (2.9) that as  $r$  (the radius of the circular path) decreases, the force again increases. This is why smaller cyclones are more efficient for the collection of smaller-sized particles than are large cyclones.

These types of considerations, in conjunction with considerations of cyclone geometry and vortex formation, have led to the development of numerous performance equations. There are three important parameters which can be used to characterize cyclone performance. These are cut diameter  $[d_p]_{\text{cut}}$ , pressure drop  $\Delta p$ , and overall collection efficiency  $\eta$ .

*Cut diameter:* The cut diameter is defined as the size (diameter) of particles collected with 50% efficiency. It is a convenient way of defining efficiency for a control device since it gives an idea of the effectiveness for a particle size range. A frequently used expression for cut diameter is given below:

$$[d_p]_{\text{cut}} = \{9 \mu B / [2\pi n_t v_i (\rho_p - \rho_g)]\}^{0.5} \quad (2.10)$$

where  $[d_p]_{\text{cut}}$  = cut diameter, ft ( $\mu\text{m}$ , microns)  
 $\mu$  = viscosity, lb/s-ft (Pa-s) (or kg/s-m)  
 $B$  = inlet width, ft (m)  
 $n_t$  = effective number of turns (5 to 10 for common cyclones)  
 $v_i$  = inlet gas velocity, ft/s (m/s)  
 $\rho_p$  = particle density, lb/ft<sup>3</sup> (kg/m<sup>3</sup>)  
 $\rho_g$  = gas density, lb/ft<sup>3</sup> (kg/m<sup>3</sup>)

The cut diameter,  $[d_p]_{\text{cut}}$ , is a characteristic of the control device and should not be confused with the geometric mean particle diameter  $d_{\text{gm}}$  of the size distribution.

The expression for the cut diameter (Eq. 2.10) has been found to agree within  $4 \mu\text{m}$  for some experimental data. However, other experimental work has shown limitations to its application. A high-efficiency cyclone will have a cut diameter of typically  $5\text{--}10 \mu\text{m}$ . Equation (2.10) is typical of most of those devised for determining the cut or critical diameter. Note that an increase in the number of turns, inlet velocity, or the particle density will decrease the cut size as one would expect. A decrease in viscosity will decrease the drag force opposing the centrifugal force and therefore also reduce the cut size (i.e. smaller-size particles will be collected).

*Pressure drop,  $\Delta p$ :* The pressure drop across a cyclone is an important parameter to the purchaser of such equipment. Increased pressure drop means greater costs for power to move exhaust gas through the control device. With cyclones, an increase in pressure drop usually means that there will be an improvement in collection efficiency (one exception to this is the use of pressure recovery devices attached to the exit tube; these reduce the pressure drop but

do not adversely affect collection efficiency). For these reasons, there have been many attempts to predict pressure drops from design variables. The idea is that having such an equation, one could work backwards and optimize the design of new cyclones.

*Collection efficiency:* A number of formulations have been developed for determining the fractional cyclone efficiency  $\eta_i$  for a given size particle. *Fractional efficiency* is defined as the fraction of particles of a given size collected in the cyclone, compared to those of that size going into the cyclone.

*Summary of performance characteristics:* Efficiency, pressure drop, and costs are intimately related in cyclones, as they are with most other particulate control equipment. Many factors affect efficiency and pressure drop. A number of factors can be taken into account in the theoretical formulation; others cannot. A thorough evaluation of cyclone design will depend on previous experience or empirical information derived from experiments on similar cyclones. A summary of changes in performance characteristics is provided in Table 2.12.

**Cyclone arrangement.** It is apparent from the above discussion that small cyclones are more efficient than large cyclones. Small cyclones, however, have a higher pressure drop and are limited with respect to volumetric flow rates. Smaller cyclones can be arranged either in series or in parallel to substantially increase efficiency at lower pressure drops. These gains are somewhat offset, however, by increased maintenance problems. Multicyclone arrangements tend to plug more easily. When common hoppers are used in such arrangements, different flows through cyclones can lead to re-entrainment problems.

**EXAMPLE 1:** Cyclone—cut diameter and overall collection efficiency. You are requested to determine the cut size diameter and overall collection efficiency of a cyclone given the particle size distribution of a dust from a cement kiln (EPA-84/09, p. 66).

#### Given conditions

gas viscosity  $\mu = 0.02 \text{ cp} = 0.02 (6.72 \times 10^{-4}) \text{ lb/ft-s}$

specific gravity of the particle = 2.9

inlet gas velocity to cyclone = 50 ft/s

effective number of turns within cyclone = 5

cyclone diameter = 10 ft

cyclone inlet width = 2.5 ft

particle size distribution data is shown in Table 2.13.

**TABLE 2.12** Changes in Performance Characteristics

Cyclone and process design changes*	Pressure drop	Efficiency	Cost
Increase cyclone size $D$	Decreases	Decreases	Increases
Lengthen cylinder $L$	Decreases slightly	Decreases	Increases
Lengthen cone $Z$	Decreases slightly	Increases	Increases
Increase exit tube diameter $E$	Decreases	Decreases	Increases
Increase inlet area (maintaining velocity)	Increases	Decreases	Decreases
Increase velocity	Increases	Increases	Operating costs higher
Increase temperature (maintaining velocity)	Decreases	Decreases	No change
Increase dust concentration	Decrease for large increases	Increases	No change
Increase particle size and/or density	No change	Increases	No change

Solution:

1. Calculate the cut diameter  $[d_p]_{\text{cut}}$ .

The cut diameter is the particle diameter collected at 50% efficiency. For cyclones:

$$[d_p]_{\text{cut}} = [9\mu B_c / 2\pi n_t v_i (\rho_p - \rho)]^{0.5}$$

where  $\mu$  = gas viscosity, lb/ft-s  
 $B_c$  = cyclone inlet width, ft

$$\begin{aligned}n_t &= \text{number of turns} \\v_i &= \text{inlet gas velocity, ft/s} \\ \rho_p &= \text{particle density, lb/ft}^3 \\ \rho &= \text{gas density, lb/ft}^3\end{aligned}$$

1.a. Determine the value of  $\rho_p - \rho$ .

Since the particle density is much greater than the gas density,  $\rho_p - \rho$  can be assumed to be  $\rho_p$ .

$$\rho_p - \rho = \rho_p = 2.9(62.4) = 180.96 \text{ lb/ft}^3$$

1.b. Calculate the cut diameter using the equation given.

$$\begin{aligned}[d_p]_{\text{cut}} &= [(9)(0.02)(6.72 \times 10^{-4})(2.5)/(2\pi)5(50)(180.96)]^{0.5} \\ &= 3.26 \times 10^{-5} \text{ ft} \\ &= 9.94 \mu\text{m}\end{aligned}$$

2. Complete size efficiency table (Table 2.14) using Lapple's method.

Lapple's method provides the collection efficiency as a function of the ratio of particle diameter to cut diameter. Use the equation

$$\eta = 1 - (1.0)/[1.0 + (d_p/[d_p]_{\text{cut}})^2]$$

3. Determine overall collection efficiency.

$$\begin{aligned}\Sigma w_i \eta_i (\%) &= 0 + 4 + 7.5 + 16 + 14.4 + 9.3 + 5.7 + 2.94 + 7 \\ &= 66.84\%\end{aligned}$$

**TABLE 2.14** Size Efficiency Table

$d_p, \mu\text{m}$	$w_i$	$d_p/[d_p]_{\text{cut}}$	$\eta_i, \%$	$w_i \eta_i, \%$
1	0.03	0.1	0	0
5	0.2	0.5	20	4
10	0.15	1	50	7.5
20	0.2	2	80	16
30	0.16	3	90	14.4
40	0.1	4	93	9.3
50	0.06	5	95	5.7
60	0.03	6	98	2.94
> 60	0.07	—	100	7

**EXAMPLE 2:** cyclone—plan review. As an air pollution control officer you have been asked to evaluate a permit application to operate a cyclone as the only device on the ABC Stoneworks plant's gravel drier (EPA-84/09, p. 68).

**Given conditions—design and operating data from permit application**

average particle diameter = 7.5 microns ( $\mu\text{m}$ )

total inlet loading to cyclone = 0.5 grains/ft<sup>3</sup>

cyclone diameter = 2.0 ft  
 inlet velocity = 50 ft/s  
 specific gravity of the particle = 2.75  
 number of turns = 4.5 turns  
 operating temperature = 70°F  
 viscosity of air at operating temperature =  $1.21 \times 10^{-5}$  lb/ft-s  
 the cyclone is a conventional one.

**Air Pollution Control Agency criteria**

maximum total outlet loading = 0.1 grains/ft<sup>3</sup>  
 cyclone efficiency as a function of particle size ratio is provided in Fig. 2.26 (Lapple's curve).

*Solution:*

1. Determine the collection efficiency of the cyclone.

Utilize Lapple's method which provides collection efficiency values from a graph relating efficiency to the ratio of average particle diameter to the cut diameter. The cut diameter is the particle diameter collected at 50% efficiency (see Fig. 2.26).

1.a. Calculate the cut diameter

The equation for determining cut size diameter is

$$[d_p]_{cut} = [9\mu B_c / 2\pi n_t v_i (\rho_p - \rho)]^{0.5}$$

where  $\mu$  = gas viscosity, lb/ft-s  
 $B_c$  = cyclone inlet width, ft  
 $n_t$  = number of turns  
 $v_i$  = inlet gas velocity, ft/s  
 $\rho_p$  = particle density, lb/ft<sup>3</sup>  
 $\rho$  = gas density, lb/ft<sup>3</sup>

1.a.1. Determine the inlet width of the cyclone,  $B_c$ .

The permit application has established this cyclone as conventional. The inlet width of a conventional cyclone is 1/4 the cyclone diameter.

$$B_c = \text{cyclone diameter}/4 = 2.0/4 = 0.5 \text{ ft}$$

1.a.2. Determine the value of  $\rho_p - \rho$ .

Since the particle density is much greater than the gas density,  $\rho_p - \rho$  can be assumed to be  $\rho_p$ .

$$\rho_p - \rho = \rho_p = 2.75(62.4) = 171.6 \text{ lb/ft}^3$$

1.a.3. Calculate the cut diameter using the equation given.

$$\begin{aligned} [d_p]_{\text{cut}} &= [9\mu B_c / 2\pi n_t v_i (\rho_p - \rho)]^{0.5} \\ &= [(9)(1.21 \times 10^{-5})(0.5) / (2\pi)4.5(50)(171.6)]^{0.5} \\ &= 1.5 \times 10^{-5} \text{ ft} \\ &= 4.57 \text{ microns} \end{aligned}$$

1.b. Calculate the ratio of average particle diameter to the cut diameter.

$$d_p / [d_p]_{\text{cut}} = 7.5 / 4.57 = 1.64$$

1.c. Determine the collection efficiency utilizing Lapple's curve (see Fig. 2.26).

$$\eta = 72\%$$

2. Calculate the required collection efficiency for the approval of the permit.

$$\begin{aligned} \eta &= [(\text{inlet loading} - \text{outlet loading}) / (\text{inlet loading})](100) \\ &= [(0.5 - 0.1) / (0.5)](100) \\ &= 80\% \end{aligned}$$

3. Would you approve the permit?

Since the collection efficiency of the cyclone is lower than the collection efficiency required by the agency, the permit should not be approved.

### 4.3 Electrostatic Precipitator (ESP)

An electrostatic precipitator (ESP) is an effective device for controlling particle emissions from cement kiln, pulp and paper plants, acid plants, sintering operations, and other industrial sources. The method is extensively used where dust emissions are less than 10–20  $\mu\text{m}$  in size with a predominant portion in the submicron range (EPA-81/10, p. 7-1).

In general, an electrostatic precipitator is comprised of four essential components, as shown in Fig. 2.27. The essential components are

FIGURE 2.27 Typical plate and wire single-stage ESP (EPA-81/10, p. 7-1).

- discharge electrodes
- collection electrodes
- rappers
- hoppers

The discharge electrode is normally a wire where a corona discharge occurs. This electrode is used to ionize the gas (which charges the particles) and create an electric field. The collection electrode consists of either a tube or flat plate which is oppositely charged (relative to the discharge electrode) and is the surface where the charged particles are collected. The rapper is a device used to impart a vibration or shock to dislodge the deposited dust on the electrodes. Rappers are used to remove dust accumulated on both the collection electrodes and discharge electrodes. Hoppers are located at the bottom of the precipitator and are used to collect and store the dust removed by the rapping process.

**ESP type.** The types of electrostatic precipitators include (EPA-81/10, p. 7-2):

- Low voltage two-stage precipitators
- High voltage single-stage precipitators
  - Tubular high voltage single-stage precipitators;
  - Plate high voltage single-stage precipitators

*Low voltage two-stage ESPs:* Low voltage two-stage precipitators are limited almost exclusively to the collection of liquid aerosols discharged from sources such as meat smokehouses, pipe-coating machines, asphalt paper saturators, and high-speed grinding machines. The precipitators were originally designed for air purification in conjunction with air conditioning systems (they are also referred to as electronic air filters). Two-stage ESPs have been used primarily for the control of finely divided liquid particles. Controlling solid or sticky materials is usually difficult, and the collector becomes ineffective for dust loadings greater than 0.4

grains per standard cubic foot ( $0.916 \text{ g/m}^3$ ). Therefore, two-stage precipitators have limited use for particulate emission control.

*High voltage single-stage precipitators:* The high voltage single-stage precipitator is the more popular type and has been used successfully to collect both solid and liquid particulate matter in industrial facilities such as smelters, steel furnaces, cement kilns, municipal incinerators, and utility boilers. There are two major types of high voltage single-stage ESP configuration. Particles are both charged and collected in a single stage.

- *Tubular precipitators:* Tubular precipitators consist of cylindrical collection electrodes with discharge electrodes located in the center of the cylinders. Dirty gas flows into the cylinder, where precipitation occurs. The negatively charged particles migrate to and are collected on grounded collecting tubes. The collected dust or liquid is removed by washing the tubes with water sprays located directly above the tubes. These precipitators are generally referred to as water-washed ESPs. Tubular precipitators are generally used for collecting mists or fogs. Tube diameters typically vary from 0.5 to 1 ft (0.15 to 0.31 m), with length usually ranging from 6 to 15 ft (1.85 to 4.6 m).
- *Plate precipitators:* Plate electrostatic precipitators are used more often than tubular ESPs in industrial applications. High voltage is used to subject the particles in the gas stream to an intense electric field. Dirty gas flows into a chamber consisting of a series of discharge electrodes (wires) spaced along the center line of adjacent plates, as shown in Fig. 2.28. Charged particles migrate to and are collected at oppositely charged collection plates. Collected particles are usually removed by rapping (dry precipitator) or by a liquid film (wet precipitator). Particles fall by force of gravity into hoppers, where they are stored prior to removal and final disposal.

*Collection efficiency.* ESP collection efficiency can be expressed by the following two equations (EPA-81/10, p. 7-9):

- Migration velocity equation
- Deutsch–Anderson equation

FIGURE 2.28 Gas flow through a wire and plate precipitator (EPA-81/10, p. 7-4).

*Migration velocity:* Once the particle is charged, it migrates toward the grounded collection electrode. An indicator of particle movement toward the collection electrode is denoted by the symbol  $w$  and is called the *particle migration velocity* or *drift velocity*. The migration velocity parameter represents the collectability of the particle within the confines of a specific collector. The migration velocity can be expressed in terms of

$$w = d_p E_o E_p / (4\pi\mu) \quad (2.11)$$

where  $w$  = migration velocity  
 $d_p$  = diameter of the particle,  $\mu\text{m}$   
 $E_o$  = strength of field in which particles are charged, volts per meter (represented by peak voltage)  
 $E_p$  = strength of field in which particles are collected, volts per meter (normally the field close to the collecting plates)  
 $\mu$  = viscosity of gas, Pa-s

Migration velocity is quite sensitive to the voltage, since the electric field appears twice in Eq. (2.11). Therefore, the precipitator must be designed using the maximum electric field for maximum collection efficiency. The migration velocity is also dependent on particle size; larger particles are collected more easily than smaller ones.

Particle migration velocity can also be determined by the following equation:

$$w = qE_p / (4\pi\mu r) \quad (2.12)$$

where  $w$  = migration velocity  
 $q$  = particle charge (charges)  
 $E_p$  = strength of field in which particles are collected, volts per meter (normally the field close to the collecting plates)  
 $\mu$  = viscosity of gas, Pa-s  
 $r$  = radius of the particle,  $\mu\text{m}$

*Deutsch-Anderson equation:* This equation has been used to determine the collection efficiency of the precipitator under ideal conditions. The simplest form of the equation is

$$\eta = 1 - \exp(-wA/Q) \quad (2.13)$$

where  $\eta$  = fractional collection efficiency  
 $A$  = collection surface area of the plates  
 $Q$  = gas volumetric flow rate  
 $w$  = drift velocity

This equation has been used extensively for many years for theoretical collection efficiency calculations. Unfortunately, while the equation is scientifically valid, there are a number of operating parameters that can cause the results to be in error by a factor of two or more. The Deutsch-Anderson equation neglects three significant process variables.

1. It completely ignores the fact that dust re-entrainment may occur during the rapping process.
2. It assumes that the particle size and, consequently, the migration velocity is uniform for all particles in the gas stream.
3. It assumes that the gas flow rate is uniform everywhere across the precipitator and that particle sneakage through the hopper section does not occur.

Therefore, this equation should be used only for making preliminary estimates of precipitation collection efficiency.

**Design parameters.** Many parameters must be taken into consideration in the design and specification of electrostatic precipitators. The typical design parameters include (EPA-81/10, p. 7-11):

- Resistivity
- Specific collection area
- Aspect ratio
- Gas flow distribution
- Electrical sectionalization

*Resistivity:* Particle resistivity is a condition of the particle in the gas stream that can alter the actual collection efficiency of an ESP design. Resistivity is a term that describes the resistance of the collected dust layer to the flow of electrical current. By definition, *resistivity* is the electrical resistance of a dust sample 1.0 cm<sup>2</sup> in cross-sectional area, 1.0 cm thick; it is recorded in units of ohm-cm. It can also be described as the resistance to charge transfer by the dust. Dust resistivity values can be classified roughly into three groups:

- between 10<sup>4</sup> and 10<sup>7</sup> ohm-cm (low resistivity)
- between 10<sup>7</sup> and 10<sup>10</sup> ohm-cm (normal resistivity)
- above 10<sup>10</sup> ohm-cm (high resistivity)

*Specific collection area (SCA):* The specific collection area is defined as the ratio of collection surface area to the gas flow rate into the collector. The importance of this term is that it represents the  $A/Q$  relationship in the Deutsch–Anderson equation.

$$\begin{aligned} \text{SCA} &= (\text{Total collection surface, ft}^2)/[\text{flow rate (1000 acfm)}] \\ &= \text{m}^2/(1000 \text{ m}^3/\text{h}) \text{ in metric units} \end{aligned}$$

Increases in the SCA of a precipitator design will in most cases increase the collection efficiency of the precipitator. Most conservative designs call for an SCA of 350 to 400 ft<sup>2</sup> per 1000 acfm (19 and 22 m<sup>2</sup> per 1000 m<sup>3</sup>/h) to achieve 99.5% particle removal. The general range of SCA is between 200 and 800 ft<sup>2</sup> per 1000 acfm (11 and 45 m<sup>2</sup> per 1000 m<sup>3</sup>/h), depending on precipitator design conditions and desired collection efficiency.

*Aspect ratio:* The aspect ratio is the ratio of the total length to height of collector surface. The aspect ratio can be calculated by

$$\text{AR} = (\text{effective length})/(\text{effective height})$$

Having a precipitator chamber many times larger in length than in height would be ideal. However, space limitations and cost could be prohibitive. The aspect ratio for ESPs can range from 0.5 to 2.0. For 99.5% collection efficiency, the precipitator design should have an aspect ratio of greater than 1.0.

*Gas flow distribution:* Gas flow through the ESP chamber should be slow and evenly distributed throughout the unit. The gas velocities in the duct ahead of the ESP are generally between 20 and 80 ft/s (6 and 24 m/s). The gas velocity into the ESP must be reduced for adequate particle collection. This is achieved by using an expansion inlet plenum.

The inlet plenum contains diffuser-perforated plate openings to evenly distribute the gas flow throughout the precipitator. Typical gas velocities in the ESP chamber range from 2 to 8 ft/s (0.6 to 2.4 m/s). With aspect ratios of 1.5, the optimum gas velocity is generally between 5 and 6 ft/s (1.5 and 1.8 m/s).

*Electrical sectionalization:* Precipitator performance is dependent on the number of individual sections or fields installed. The maximum voltage at which a given field can be maintained depends on the properties of the gas and dust being collected. These parameters may vary

from one point to another in the unit. To keep each section of the precipitator working at high efficiency, a high degree of sectionalization is recommended. Multiple fields or stages are used to provide electrical sectionalization. Each field has separate power supplies and controls to adjust for varying gas conditions in the unit.

In general, precipitators have voltage control devices that automatically limit precipitator power input. A well-designed automatic control system keeps the voltage level at approximately the value needed for optimum particle charging by the discharge electrodes.

The voltage control devices operate in the following manner: increases in voltage cause a greater spark rate between the discharge and collection electrodes. Occurrence of a spark counteracts high ESP performance, since it causes an immediate, short-term collapse of the precipitator field. Consequently, less useful power is applied to capture particles. There is, however, an optimal sparking rate where the gains in particle charging are just offset by corona current losses from sparkover.

Measurements on commercial precipitators have determined that the optimal sparking rate is between 50 and 150 sparks per minute per electrical section. The objective in power control is to maintain corona power input at this optimal sparking rate. This can be accomplished by momentarily reducing precipitator power whenever excessive sparking occurs.

The need for separate fields arises mainly because power input requirements differ at various locations in a precipitator. The particulate matter concentration is generally high at the inlet sections of the precipitator. High dust concentrations tend to suppress corona current. Therefore, a great deal of power is needed to generate corona discharge for optimal particle charging at the inlet.

In the downstream fields of a precipitator, the dust loading is usually lighter. Consequently, corona current flows freer in downstream fields. Particle charging will more likely be limited by excessive sparking in downstream fields than in the inlet fields. The power to the outlet sections must still be high in order to collect small particles, particularly if they exhibit high resistivity.

If the precipitator had only one power set, the excessive sparking would limit the power input to the entire precipitator. This would result in a reduction of overall collection efficiency.

**Review of ESP design plan.** The first step in reviewing design plans for air pollution permits is to read the vendor literature and specifications of the precipitator design. The design specifications should include at least (EPA-81/10, p. 7-26):

- Exhaust gas flow rate and temperature
- Inlet dust concentration
- Specific collection area (SCA)
- Gas velocity in the precipitator
- Distance between the plates
- Aspect ratio
- Number and size of transformer-rectifier (T-R) sets
- Number of fields
- Design migration velocity
- Corona power/1000 m<sup>3</sup>/min
- Corona current/ft<sup>2</sup> plate area
- Design collection efficiency
- Outlet dust concentration

The next step is to review the outlet concentration from the ESP. The concentration must meet the grain-loading requirements of air pollution regulations. The design reviewer can determine if the calculated outlet values, using the Deutsch-Anderson equation, are within the regulation

limits. In addition, requiring the source to perform a source test to verify the designed collection efficiency of the ESP would be extremely useful.

**EXAMPLE 1:** electrostatic precipitator—process change. A horizontal parallel-plate electrostatic precipitator consists of a single duct 24 ft high and 20 ft deep with an 11 inch plate-to-plate spacing. Given a collection efficiency at a gas flow rate of 4200 acfm, you are required to determine the bulk velocity of the gas, outlet loading, and drift velocity of this electrostatic precipitator. You are also requested to calculate a revised collection efficiency if the flow rate and the plate spacing are changed (EPA-84/09, p. 71).

**Given conditions**

- inlet loading = 2.82 grains/ft<sup>3</sup>
- collection efficiency at 4200 acfm = 88.2%
- increased (new) flow rate = 5400 acfm
- new plate spacing = 9 in.

*Solution:*

1. Calculate the bulk flow (throughput) velocity  $v$ .  
The equation for calculating throughput velocity is

$$V = Q/S$$

- where  $Q$  = gas volumetric flow rate  
 $S$  = cross-sectional area through which the gas passes

$$\begin{aligned} V &= Q/S \\ &= (4200)/[(11/12)(24)] \\ &= 191 \text{ ft/min} \\ &= 3.2 \text{ ft/s} \end{aligned}$$

2. Calculate outlet loading  
Remember that

$$\eta \text{ (fractional)} = (\text{inlet loading} - \text{outlet loading})/(\text{inlet loading})$$

Therefore

$$\begin{aligned} \text{Outlet loading} &= (\text{inlet loading})(1 - \eta) \\ &= (2.82)(1 - 0.882) \\ &= 0.333 \text{ grains/ft}^3 \end{aligned}$$

3. Calculate the drift velocity.

The drift velocity is the velocity at which the particle migrates toward the collection electrode within the electrostatic precipitator.

The Deutsch-Anderson equation describing the collection efficiency of an electrostatic precipitator is

$$\eta = 1 - \exp(-wA/Q)$$

- where  $\eta$  = fractional collection efficiency  
 $A$  = collection surface area of the plates  
 $Q$  = gas volumetric flow rate  
 $w$  = drift velocity

- 3.a. Calculate the collection surface area  $A$ .  
Remember that the particles will be collected on both sides of the plate.

$$A = (2)(24)(20) = 960 \text{ ft}^2$$

- 3.b. Calculate the drift velocity  $w$ .

Since the collection efficiency, gas flow rate, and collection surface area are now known, the drift velocity can easily be found from the Deutsch–Anderson equation:

$$\begin{aligned}\eta &= 1 - \exp(-wA/Q) \\ 0.882 &= 1 - \exp[-(960)(w)/(4200)]\end{aligned}$$

Solving for  $w$

$$w = 9.36 \text{ ft/min}$$

4. Calculate the revised collection efficiency when the gas volumetric flow rate is increased to 5400 acfm.

Assume the drift velocity remains the same.

$$\begin{aligned}\eta &= 1 - \exp(-wA/Q) \\ &= 1 - \exp[-(960)(9.36)/(5400)] \\ &= 0.812 \\ &= 81.2\%\end{aligned}$$

5. Does the collection efficiency change with changed plate spacing?

No. Note that the Deutsch–Anderson equation does not contain a plate-spacing term.

**EXAMPLE 2:** electrostatic precipitator—collection efficiency. You have been requested to calculate the collection efficiency of an electrostatic precipitator containing three ducts with plates of a given size, assuming a uniform distribution of particles. Also, determine the collection efficiency if one duct is fed 50% of the gas and the other passages 25% each (EPA-84/09, p. 73).

**Given conditions**

volumetric flow rate of contaminated gas = 4000 acfm  
operating temperature and pressure = 200°C and 1 atm  
drift velocity = 0.40 ft/s  
size of the plate = 12 ft long and 12 ft high  
plate-to-plate spacing = 8 in.

*Solution:*

1. What is the collection efficiency of the electrostatic precipitator with a uniform volumetric flow rate to each duct?

The Deutsch–Anderson equation describing the collection efficiency of an electrostatic precipitator is

$$\eta = 1 - \exp(-wA/Q)$$

where  $\eta$  = fractional collection efficiency  
 $A$  = collection surface area of the plates

$Q$  = gas volumetric flow rate

$w$  = drift velocity

- 1.a. Calculate the collection surface area per duct,  $A$ .  
Considering both sides of the plate,

$$A = (2)(12)(12) = 288 \text{ ft}^2$$

- 1.b. Calculate the collection efficiency of the electrostatic precipitator using the Deutsch-Anderson equation.

The volumetric flow rate ( $Q$ ) through a passage is one-third of the total volumetric flow rate,

$$\begin{aligned} Q &= (4000)/(3)(60) \\ &= 22.22 \text{ acfs} \\ \eta &= 1 - \exp(-wA/Q) \\ &= 1 - \exp[-(288)(0.4)/(22.22)] \\ &= 0.9944 \\ &= 99.44\% \end{aligned}$$

2. What is the collection efficiency of the electrostatic precipitator if one duct is fed 50% of gas and the others 25% each. The collection surface area per duct remains the same.

- 2.a. What is the collection efficiency of the duct with 50% of gas,  $\eta_1$ ?

- 2.a.1. Calculate the volumetric flow rate of gas through the duct in acfs.

$$Q = (4000)/(2)(60) = 33.33 \text{ acfs}$$

- 2.a.2. Calculate the collection efficiency of the duct with 50% of gas.

$$\begin{aligned} \eta_1 &= 1 - \exp[-(288)(0.4)/(33.33)] \\ &= 0.9684 \\ &= 96.84\% \end{aligned}$$

- 2.b. What is the collection efficiency ( $\eta_2$ ) of the ducts with 25% of gas flow in each?

- 2.b.1. Calculate the volumetric flow rate of gas through the duct in acfs.

$$Q = (4000)/(4)(60) = 16.67 \text{ acfs}$$

- 2.b.2. Calculate the collection efficiency ( $\eta_2$ ) of the duct with 25% of gas.

$$\begin{aligned} \eta_2 &= 1 - \exp[-(288)(0.4)/(16.67)] \\ &= 0.9990 \\ &= 99.90\% \end{aligned}$$

- 2.c. Calculate the new overall collection efficiency.

The key equation becomes:

$$\begin{aligned} \eta_t &= (0.5)(\eta_1) + (2)(0.25)(\eta_2) \\ &= (0.5)(96.84) + (2)(0.25)(99.90) \\ &= 98.37\% \end{aligned}$$

**EXAMPLE 3:** electrostatic precipitator—plan review. Fractional efficiency curves describing the performance of a specific model of an electrostatic precipitator have been compiled by a vendor. Although you do not possess these curves, the cut diameter is known. The vendor claims that this particular model will perform with a given efficiency under your operating condition. You are asked to verify this claim and to make certain that the effluent loading does not exceed the standard set by EPA (EPA-84/09, p. 75).

**Given conditions**

- plate-to-plate spacing = 10 in.
- cut diameter = 0.9 μm (microns)
- collection efficiency claimed by the vendor = 98%
- inlet loading = 14 grains/ft<sup>3</sup>
- EPA standard for the outlet loading = 0.2 grains/ft<sup>3</sup> (maximum)

The particle size distribution is given in Table 2.15. A Deutsch–Anderson type of equation describing the collection efficiency of an electrostatic precipitator is

$$\eta = 1 - \exp(-Kd_p)$$

- where  $\eta$  = fractional collection efficiency  
 $K$  = empirical constant  
 $d_p$  = particle diameter

**TABLE 2.15** Particle Size Distribution

Weight range	Average particle size $d_p$ , μm
0–20%	3.5
20–40%	8
40–60%	13
60–80%	19
80–100%	45

*Solution:*

1. Is the overall efficiency of the electrostatic precipitator equal to or greater than 98%? Since the weight fractions are given, collection efficiencies of each particle size are needed to calculate the overall collection efficiency.

1.a. Determine the value of  $K$  by using the given cut diameter.

Remember that the cut diameter is the particle diameter collected at 50% efficiency. Since the cut diameter is known, you can solve the Deutsch–Anderson type equation directly for  $K$ .

$$\eta = 1 - \exp(-Kd_p)$$

$$0.5 = 1 - \exp[-K(0.9)]$$

Solving for  $K$ ,

$$K = 0.77$$

1.b. Calculate the collection efficiency using the Deutsch–Anderson equation. Use the Deutsch–Anderson equation to calculate the collection efficiency. For  $d_p = 3.5$

$$\begin{aligned}\eta &= 1 - \exp[(-0.77)(3.5)] \\ &= 0.9325\end{aligned}$$

Table 2.16 shows the collection efficiency for each particle size.

**TABLE 2.16** Collection Efficiency for Each Particle Size

Weight fraction $w_i$	Average particle size $d_p$ , $\mu\text{m}$	$\eta_i$
0.2	3.5	0.9325
0.2	8	0.9979
0.2	13	0.9999
0.2	19	0.9999
0.2	45	0.9999

1.c. Calculate the overall collection efficiency.

$$\begin{aligned}\eta &= \sum w_i \eta_i \\ &= (0.2)(0.9325) + (0.2)(0.9979) + (0.2)(0.9999) + (0.2)(0.9999) + (0.2)(0.9999) \\ &= 0.9861 \\ &= 98.61\%\end{aligned}$$

where  $\eta$  = overall collection efficiency  
 $w_i$  = weight fraction of  $i$ th particle size  
 $\eta_i$  = collection efficiency of  $i$ th particle size

1.d. Is the overall collection efficiency greater than 98%?  
 Yes

2. Does the outlet loading meet EPA's standard?

2.a. Calculate the outlet loading in grains/ft<sup>3</sup>.

$$\text{Outlet loading} = (1.0 - \eta)(\text{inlet loading})$$

where  $\eta$  is the fractional efficiency for the above equation.

$$\begin{aligned}\text{Outlet loading} &= (1.0 - 0.9861)(14) \\ &= 0.195 \text{ grains/ft}^3\end{aligned}$$

2.b. Is the outlet loading less than 0.2 grains/ft<sup>3</sup>.  
 Yes

3. Is the vendor's claim verified?  
 Yes.

#### 4.4 Fabric Filtration

Fabric filtration is one of the most common techniques used to collect particulate matter (EPA-81/10, p. 8-1).

**Filter type.** There are two basic types of filters:

- Disposable filters
- Nondisposable filters

*Disposable filters:* Disposable filters are similar to those used in a home heating or air conditioning system. Disposable filters can be constructed as mats or as deep beds (12 in. or more). Mat filters are usually made using fiber glass mats with a thin metal plate on the outside of the filter used for structural reinforcement. Depth filters are generally constructed using fiber glass fibers, glass fiber paper, or some other inert material such as fine grade steel to form a deep mesh. The filters are very efficient (99.97%) for the collection of  $0.3\ \mu\text{m}$  and larger particles but must be replaced when they become loaded with particulate matter (when the pressure drop across the filter becomes excessive). Depth filters are widely useful for the collection of toxic dust materials.

*Nondisposable filters:* Nondisposable fabric filters consist of some type of fabric material (nylon, wool, or others) that is commonly used to clean dirty exhaust gas streams from industrial processes. The particles are retained on the fabric material, while the cleaned gas passes through the material. The collected particles are then removed from the filter by a cleaning mechanism: by shaking or using blasts of air. The removed particles are stored in a collection hopper until they are disposed of or are reused in the process.

**Collection mechanisms.** Particles are collected on a filter by a combination of the mechanisms described earlier. The most important here are

- Impaction
- Direct interception
- Diffusion
- Others

*Impaction:* In collection by impaction, the particles in the gas stream have too much inertia to follow the gas streamlines around the fiber and are impacted on the fiber surface.

*Direct interception:* In the case of direct interception, the particles have less inertia and barely follow the gas streamlines around the fiber. If the distance between the center of the particle and the outside of the fiber is less than the particle radius, the particle will graze or hit the fiber and be 'intercepted.'

Impaction and direct interception mechanisms account for 99% of the collection of particles greater than  $1\ \mu\text{m}$  aerodynamic diameter in fabric filter systems.

*Diffusion:* The third collection mechanism is that of diffusion. In diffusion, small particles are affected by collisions on a molecular level. Particles less than  $0.1\ \mu\text{m}$  aerodynamic diameter have individual or random motion. The particles do not necessarily follow the gas streamlines, but move randomly throughout the fluid. This is known as Brownian motion. The particles may have a different velocity than the fluid and at some point could come in contact with the fiber and be collected.

*Others:* Other collection mechanisms such as gravitational settling, agglomeration, and electrostatic attraction may contribute slightly to particle collection. Particles can agglomerate or grow in size and then be more easily collected by the fibers. Some particles have a small electrostatic charge and can be attracted to a material of opposite charge. Electrostatic charges could, on the other hand, have a bad effect if the charges of the particles and fiber are the same. Electrostatic charges can be particularly useful for the capture of particles in the sub-micron range. The use of a selected fiber material or a specially coated material may enhance particle capture. Different materials will develop electrostatic charges of varying degree and sign.

#### 4.5 Baghouse

Nondisposable fabric filter systems were developed for industrial application as were baghouse systems (EPA-81/10, p. 8-4).

The particle collection surface is composed of the filtering material and usually some type of support structure. Most US baghouse designs employ long cylindrical tubes that contain felted fabric or woven cloth as the filtering medium. The cloth can be supported at the top and bottom of the bag by metal rings or by a cage that completely supports the entire bag, as shown in Fig. 2.29.

Baghouses are usually constructed using many cylindrical bags that hang vertically in the baghouse. The number of bags can vary from a few hundred to a thousand or more depending on the size of the baghouse. When dust layers have built up to a sufficient thickness, the bag is cleaned, causing the dust particles to fall into a collection hopper. Bag cleaning can be done by a number of methods. Particles are stored in the hopper and are usually removed by a pneumatic or screw conveyer. The baghouse is enclosed by sheet metal to contain the collected dust and to protect the bags from atmospheric environmental conditions.

Dirty gas is either pushed or pulled through the baghouse by a fan. When the dust-laden gas is pushed through the baghouse, the collector is called a *positive-pressure baghouse*. When the fan is on the downstream side of the baghouse, the dirty gas is pulled through the baghouse and the collector is called a *negative-pressure baghouse*. The structure of the negative-pressure baghouse must be reinforced because of the suction on the baghouse shell. Vendors can construct positive-pressure baghouses with weaker support structure since the positive pressure will counterbalance the atmospheric pressure on the baghouse shell. Limitations, however, do exist since the fan is located on the dirty side of the system. Premature deterioration of fan blades and bearings can occur in this configuration.

**Baghouse filtration type.** There are two filtration designs used in baghouses: interior filtration and exterior filtration.

*Interior filtration:* In interior filtration, particles are collected on the inside of the bag. The dust-laden gas enters either through the top or bottom of the collector and is directed inside the bag by diffuser vanes and a cell plate. The cell plate is a thin metal sheet surrounding the bag openings. The cell plate separates the clean gas section from the baghouse inlet. The particles are filtered by the bag and clean air exits through the outside of the bag.

*Exterior filtration:* In exterior filtration, dust is collected on the outside of the bags. The filtering process goes from the outside of the bag to the inside with clean gas exiting through the inside of the bag. Consequently, some type of bag support is necessary, such as an internal bag cage or rings sewn into the bag fabric.

The dust-laden gas inlet position for both filtration systems often depends on the baghouse model and manufacturer. If the gas enters the top of the unit, a downwash of gas occurs which tends to clean the bags somewhat while the bags are filtering. This usually allows slightly higher gas volumes to be filtered through the baghouse before cleaning is required. If the gas enters the bottom of the unit, the inlet is positioned at the very top part of the dust hopper, as shown in Fig. 2.30. Bottom or hopper inlets are easier to design and manufacture structurally than are the top inlets. However, when using hopper inlets, vendors must carefully design gas flows to avoid dust re-entrainment from the hopper.

FIGURE 2.30 Dust inlet to the baghouse (EPA-81/10, p. 8-10).

**Bag.** Tubular bags vary in both length and diameter, depending on baghouse design and manufacturer. The length ranges from 10 to 40 feet and the diameter is usually between 6 and 18 inches. Bags are usually hung vertically in the baghouse and are attached at the top and bottom by some type of ring, cap, clamp, or clasp (EPA-81/10, p. 8-11).

Baghouses are constructed as single units or compartmental units. The single unit is generally used on all processes that are not in continuous operation, such as grinding and paint-spraying processes. Compartmental units consist of more than one baghouse compartment and are used in continuous operating processes with large exhaust volumes, such as electric melt steel furnaces and industrial boilers. In both cases, the bags are housed in a shell made of a rigid metal material. Occasionally, it is necessary to include insulation with the shell when treating high-temperature flue gas. This is done to prevent moisture or acid mist from condensing in the unit, causing corrosion and rapid deterioration of the baghouse.

**Hopper.** Hoppers are used to store the collected dust before it is disposed in a landfill or reused in the process. They are designed usually with a 60° slope to allow dust to flow freely from the top of the hopper to the bottom discharge opening. Some manufacturers add devices to the hopper to promote easy and quick discharge. These devices include strike plates, poke holes, vibrators, and rappers. Strike plates are simply pieces of flat steel which are bolted or welded to the center of the hopper wall. If dust becomes stuck in the hopper, rapping the strike plate several times with a mallet will free this material. Hopper designs also usually include access doors or ports. Access ports provide for easier cleaning, inspection, and maintenance of the hopper.

Some type of discharge device is necessary for emptying the hopper. Discharge devices can be manual or automatic. The simplest manual discharge device is the slide gate, a plate held in place by a frame and sealed with gaskets. When the hopper needs to be emptied, the plate is removed and the material discharges. Other manual discharge devices include hinged doors or drawers. The collector must be shut down before opening any manual discharge device. Thus, manual discharge devices are used on baghouses that operate on a periodic basis.

Automatic continuous discharge devices are installed on baghouses that are used in continuous operation: devices include trickle valves, rotary air lock valves, screw conveyors and pneumatic conveyers. Trickle valve discharge devices are shown in Fig. 2.31. As dust collects in the hopper, the weight of the dust pushes down on the counterweight of the top flap and dust discharges downward. The top flap then closes, the bottom flap opens, and the material falls out. This type of valve is available in gravity-operated and motorized versions.

Rotary airlock valves (Fig. 2.32) are used on medium or large-sized baghouses. The valve is designed with a paddle wheel which is shaft-mounted and driven by a motor. The rotary valve is similar to a revolving door: the paddles or blades form an airtight seal with the housing; the motor slowly moves the blades to allow the dust to discharge from the hopper.

Other automatic dust discharge devices include screw and pneumatic conveyers. Screw conveyers employ a revolving screw feeder located at the bottom of the hopper to remove the dust from the bin. Pneumatic conveyers use compressed air to blow dust from the hopper.

**Fabric filter material.** Types of fabric filter materials include:

- Woven material
- Felted material

Woven and felted materials are used to make bag filters. Woven filters are made of yarn with a definite repeated pattern. Felted filters are composed of randomly placed fibers compressed into a mat and attached to some loosely woven backing material. Woven filters are used with low-energy cleaning methods, such as shaking and reverse air. Felted fabrics are usually used with higher-energy cleaning systems, such as pulse jet cleaning.

*Woven filters:* Woven filters are made of yarn with a definite repeated pattern and are used with low-energy cleaning methods, such as shaking and reverse air. Woven filters have open spaces around the fibers. The type of weave used depends on the design and the actual intended application of the woven filter. The simple woven weave is the plain weave. The yarn is woven over and under to form a checkerboard pattern. This weave is not frequently used. Other weaves include the twill and sateen (satin). In the twill weave, yarn is woven over two and under one but in one direction only (Fig. 2.33). This weave is tighter and more durable than the simple weave. Sateen weave goes one over and four under in both directions. Sateen weaves are very tight and allow the use of very fine yarns. Different weaving patterns

FIGURE 2.32 Rotary airlock discharge device (EPA-81/10, p. 8-14).

increase or decrease the open spaces between the fibers, which affects both fabric strength and permeability. Fabric permeability affects the amount of air passing through the filter at a specified pressure drop. A tight weave, for instance, has low permeability and is better for the capture of small particles at the cost of increased pressure drop. The true filtering surface for the woven filter is not the bag itself, but the dust layer or filter cake. The bag simply provides the surface for capture of larger particles. Particles are collected by impaction or interception and the open areas in the weave are closed. This process is referred to as sieving (Fig. 2.34). Some particles escape through the filter until the cake is formed. Once the cake builds up, effective filtering will occur until the bag becomes plugged and cleaning is required. At this point the pressure drop will be exceedingly high and filtering will no longer be cost-effective. The effective filtering time will vary from approximately 15–20 minutes to as long as a number of hours, depending on the concentration of particulate matter in the gas stream.

*Felted filters:* Felted filters are made by needle punching fibers onto a woven backing called a scrim. The fibers are randomly placed as opposed to the definite repeated pattern of the woven filter. The felts are attached to the scrim by chemical, heat, resin, and stitch-bonding methods. To collect fine particles, the felted filters depend to a lesser degree on the initial dust deposits than do woven filters. The felted filters are generally two to three times thicker than

woven filters. Each individual randomly-oriented fiber acts as a target for particle capture by impaction and interception. Small particles can be collected on the outer surface of the filter (Fig. 2.35). Felted filters are usually used in pulse jet baghouses. A pulse jet baghouse generally filters more air per cloth area (higher air-to-cloth ratio) than a shaker or reverse air unit. Felted bags should not be used in high-humidity situations, especially if the particles are hygroscopic. Clogging and blinding could result in such situations.

**Fiber.** The fibers used for fabric filters vary, depending on the industrial application to be controlled. Some filters are made from natural fibers such as cotton or wool. These fibers are relatively inexpensive but have temperature limitations ( $< 100^{\circ}\text{C}$ ) and only average abrasion resistance. Synthetic fibers such as nylon, Orlon, and polyester have slightly higher temperature limitations and chemical resistance. Synthetic fibers are more expensive than natural fibers. Nomex<sup>®</sup> is a registered trademark of fibers made by DuPont. DuPont makes the fibers, not filter fabrics or bags. Nomex<sup>®</sup> is widely used, because of its relatively high temperature resistance and its resistance to abrasion. Other fibers such as Teflon<sup>®</sup> and Fiber glass<sup>®</sup> can be used in very high temperature situations (230 to  $260^{\circ}\text{C}$ ). Both materials have good resistance to acid attack, but are generally more expensive than other fibers.

Fabrics are usually pretreated to improve their mechanical and dimensional stability. They can be treated with silicone to give them better cake-release properties. Natural fabrics (wool and cotton) are usually preshrunk to eliminate bag shrinkage during operation. Both synthetic and natural fabrics usually undergo processes such as heat setting, flame retardation, and napping; these processes increase fabric life, improve dimensional stability and permeability, and ease the work of bag cleaning.

**Bag failure mechanism.** There are three failure mechanisms that shorten the operating life of a bag. The mechanisms are related to abrasion, thermal durability, and chemical attack. The chief design variable is the upper temperature limit of the fabric. The process exhaust temperature will determine which fabric material should be used for dust collection. Exhaust gas cooling may be feasible, but one must be careful to keep the exhaust gas hot enough to prevent moisture or acid from condensing on the bags.

FIGURE 2.35 Felted fabric filter (EPA-81/10, p. 8-18).

Another problem frequently encountered in baghouse operation is that of abrasion. Bag abrasion can result from bags rubbing against each other or from the type of bag cleaning employed in the baghouse. For instance, in a shaker baghouse, vigorous shaking may cause premature bag deterioration, particularly at the points where the bags are attached. In pulse jet units, the continual, slight motion of the bags against the supporting cages can also seriously affect bag life. As a result, a 25% per year bag replacement rate is usually encountered. This is the single biggest maintenance problem associated with baghouses.

Bag failure can also occur by chemical attack to the fabric. Changes in dust composition and exhaust gas temperatures from industrial processes can greatly affect the bag material. If the exhaust gas stream is lowered to its dew point or a new chemical species is created, the design of the baghouse (fabric choice) may be completely inadequate. Proper fabric selection and good process operating practices can help eliminate bag deterioration caused by chemical attack.

**Gas conditioning.** Occasionally, it is necessary to cool the process gas stream before the gas goes to the baghouse. Since there is an upper temperature limit on the fabrics used for bags, gas cooling is sometimes necessary to preserve bag life. This can be accomplished by a number of cooling methods.

Dilution of the exhaust gas stream by air is the easiest and cheapest method, especially at very high temperature. However, air dilution requires the use of a larger baghouse to handle the increased volume of air. Other problems can arise due to the difficulty of controlling the intake of ambient moisture and other contaminants from the dilution air intake.

Radiation cooling can also be used to lower the process exhaust gas temperature. Radiation cooling involves the use of long uninsulated ducts that allow the gas stream to cool as heat radiates from the duct walls. Ducts can be designed in U-shapes to allow more duct surface area to be exposed for radiation cooling. Radiation cooling would not normally be very effective to cool gas temperatures below 300°C. This would require substantial surface area, lengthy duct runs, and increased fan horsepower. Precise temperature control is difficult to maintain and there is a possibility of the ducts becoming plugged due to particle sedimentation.

Evaporative cooling is also used to reduce exhaust gas stream temperature. Evaporative cooling is accomplished by injecting fine water droplets into the gas stream. The water droplets absorb heat from the gas stream as they evaporate. Spray nozzles are located in a quench chamber or somewhere in the duct preceding the baghouse. Evaporative cooling gives a great amount of controlled cooling at a relatively low installation cost. Temperature control can be flexible and accurate. However, this cooling method increases the exhaust volume to the baghouse. The biggest problem with evaporative cooling is keeping the gas temperature above the dewpoint of the gas (SO<sub>2</sub>, NO<sub>2</sub>, HCl, etc.); otherwise, gases may condense on the bags causing rapid bag deterioration. In addition, all moisture injected into the gas must be evaporated to prevent corrosion of metal parts, and blinding or plugging of caked dust on the bags.

### **Bag cleaning**

*Cleaning sequences.* Three basic sequences are used for bag cleaning:

- Intermittent cleaning
- Periodic cleaning
- Continuous cleaning

*Intermittent cleaning:* Intermittent cleaning is done on a demand basis. In intermittently cleaned baghouses, an entire compartment (or baghouse) is bypassed and the bags are cleaned either row by row or simultaneously. Intermittent baghouses are used for batch processes that can be shut down for bag cleaning.

*Periodic cleaning:* Periodic cleaning is performed on a timed or scheduled basis. Periodically cleaned baghouses consist of a number of compartments or sections. One compartment at a time is removed from service and cleaned on a regular rotation basis. The dirty gas stream is diverted from the compartment being cleaned to the other compartments in the baghouse, so it is not necessary to shut down the process.

*Continuous cleaning:* Continuously cleaned baghouses are fully automatic and can constantly remain on-line for filtering. The filtering process is momentarily interrupted by a blast of compressed air that cleans the bag; this is called pulse jet cleaning. In continuous cleaning, there is always a row of bags which are being cleaned somewhere in the baghouse. The advantage of continuous cleaning is that it is not necessary to take the baghouse out of service. Large continuous cleaning baghouses are built with compartments to help prevent total baghouse shutdown for bag maintenance and failures to the compressed air cleaning system or hopper conveyers. This allows the baghouse operator to take one compartment off-line to perform necessary maintenance.

*Types of bag cleaning.* A number of cleaning mechanisms are used to remove caked particles from bags. The three most common are

- Shaking
- Reverse air
- Pulse jet

*Shaking:* Shaking can be done manually, but is usually performed mechanically in an industrial-scale baghouse. It is a low-energy process that gently shakes the bags to remove deposited particles. The shaking motion and speed depends upon the vendors' design and the composition of dust deposited onto the bag. The shaking motion can be either in a horizontal or vertical direction. The tops of the bags in shaker baghouses are sealed or closed and supported by some type of hook or clasp. Bags are open at the bottom and attached to a cell plate. The cell plate is shaken as a unit, causing the bag to ripple and releasing the dust (Fig. 2.36). In a few systems, shaking is accomplished by sonic vibration (Fig. 2.36). A sound generator is used

to produce a low-frequency sound that causes the bags to vibrate. The noise level produced by the generator is barely discernible outside the baghouse.

*Reverse air:* Reverse air, the simplest cleaning mechanism, is accomplished by stopping the flow of dirty gas into the compartment and backwashing the compartment with a low-pressure flow of air. Dust is removed by merely allowing the bags to collapse, thus causing the dust cake to break and fall into the hopper. The cleaning action is very gentle and allows the use of less abrasion-resistant fabrics such as Fiberglass<sup>®</sup> (Fig. 2.37).

Reverse air cleaning baghouses are usually compartmentalized to permit a section to be off-line for cleaning. Dust can be collected on either the inside or outside of the bag. If collected on the outside, some type of support is needed to prevent bag collapse during the filtering process. Bags can be supported by small steel rings sewn to the inside of the bag.

Reverse air cleaning baghouses generally have very low air-to-cloth (A/C) ratios. Air-to-cloth ratios describe how much dirty gas passes through a given surface area of filter in a given time. A high air-to-cloth ratio means a large volume of air passes through the fabric area. A low air-to-cloth ratio means a small volume of air passes through the fabric. The A/C ratios are usually expressed in units of (ft<sup>3</sup>/min)/ft<sup>2</sup> of cloth [(cm<sup>3</sup>/s)/cm<sup>2</sup> of cloth]. The A/C ratio can be used interchangeably with a term called filtration velocity. The units for filtration velocity are ft/min (cm/s). When using the A/C ratios for comparison purposes one should use the units (ft<sup>3</sup>/min)/ft<sup>2</sup> or (cm<sup>3</sup>/s)/cm<sup>2</sup>. Likewise, when using filtration velocities one should use the units ft/min or cm/s.

For reverse air baghouses, the filtering velocity (filtration velocity) range is usually between 1 and 3 ft/min (0.51 and 1.52 cm/s). For shaker baghouses, the filtering velocity range is between 2 and 6 ft/min (1.02 and 3.05 cm/s). More cloth is generally needed for a given flow rate in a reverse air baghouse than in a shaker baghouse. Hence, reverse air baghouses tend to be larger in size.

Occasionally, baghouse cleaning is accomplished by two methods in combination. Many baghouses have been designed with both reverse air and gentle shaking to remove the dust cake from the bag.

*Pulse jet:* The third bag cleaning mechanism most commonly used is the pulse jet or pressure jet cleaning (Fig. 2.38). The pulse jet cleaning mechanism uses a high pressure jet

FIGURE 2.37 Reverse air cleaning (EPA-81/10, p. 8-23).

FIGURE 2.38 Pulse jet cleaning (*EPA-81/10, p. 8-25*).

of air to remove the dust from the bag. Bags in the baghouse compartment are supported internally by rings or cages. Bags are held firmly in place at the top by clasps and have an enclosed bottom. Dust-laden gas is filtered through the bag, depositing dust on the outside surface of the bag.

The dust cake is removed from the bag by a blast of compressed air injected into the top of the bag tube. The blast of high-pressure air stops the normal flow of air through the filter. The air blast develops into a standing wave that causes the bag to expand as the bubble travels down the bag tube. As the bag flexes, the cake fractures and deposited particles are discharged from the bag. The air bubble travels down and back up the tube in approximately 0.5 seconds.

The blast of compressed air must be strong enough to travel the length of the bag and shatter or crack the dust cake. Pulse jet units use air supplies from a common header above each bag. In most baghouse designs, a venturi sealed at the top of each bag is used to create a large enough pulse to travel down and up the bag. This occurs in approximately 0.3 to 0.5 s. The pressures involved are commonly between 60 and 100 psig (414 kPa and 689 kPa).

Most pulse jet baghouses use bag tubes that are 4 to 6 in. (10.2 to 15.2 cm) in diameter. The length of the bag is usually around 10 to 12 ft (3.05 to 3.66 m), but can be as long as 25 ft (7.6 m). The shaker and reverse air baghouses use larger bags than the pulse jet units. The bags in these units are 6 to 18 in. (15.2 to 45.7 cm) in diameter and up to 40 ft (12.2 m) in length.

Pulse jet baghouses are designed with filtering velocities between 5 to 15 ft/min (2.5 to 7.5 cm/s); therefore, these units usually use felted fabrics as bag material. Felted material holds up very well under the high filtering rate and vigorous pulse jet cleaning. Pulse jet cleaning methods have the advantage of having no moving parts within the compartment. In addition, pulse jet units can clean bags on a continuous basis without isolating a compartment from service. The duration of the cleaning time is short (< 1.0 s) when compared to the time length between cleaning intervals (approximately 20 minutes to several hours). The major disadvantage of high-pressure cleaning methods is that the bags are subjected to more mechanical stress. Fabric with higher dimensional stability and high tensile strength are required for these units.

**Baghouse design variables.** Baghouses are designed by considering a number of variables:

- Pressure drop
- Filter drag
- Air-to-cloth ratio
- Collection efficiency
- Gas conditioning

*Pressure drop:* Pressure drop, a very important baghouse design variable, describes the resistance to air flow across the baghouse. Pressure drop is usually expressed in millimeters of mercury (mmHg) or inches of water (in. H<sub>2</sub>O). It can be related to the size of the fan that would be necessary to either push or pull the exhaust gas through the baghouse. A baghouse with a high pressure drop would need a larger fan and more energy to move the exhaust gas through the baghouse.

*Filter drag:* Filter drag is the filter resistance across the fabric dust layer. It is a function of the quantity of dust accumulated on the filter. As previously mentioned, the true filtering surface is not the bag itself, but the dust layer. Dust bridges the pores or openings in the weave, increasing the drag rapidly. The filter drag increases exponentially up to a constant rate of increase. Following cleaning by shaking, there is a period of cake repair and initial cake buildup. Effective filtration takes place while the filter drag increases at a constant rate. When the total pressure drop reaches a value set by the system design, bag cleaning is initiated. At this point, the pressure drop decreases (almost vertically on the performance curve) to the initial point. Cake repair begins when the cleaning cycle stops and the cycle repeats.

*Filtration velocity and air-to-cloth ratio:* As previously mentioned, the terms filtration velocity and air-to-cloth ratio can be used interchangeably. The formula used to express filtration velocity is

$$v_f = Q/A_c$$

where  $v_f$  = filtration velocity, ft/min (cm/s)  
 $Q$  = volumetric air flow rate, ft<sup>3</sup>/min (cm<sup>3</sup>/s)  
 $A_c$  = area of cloth filter, ft<sup>2</sup> (cm<sup>2</sup>)

Air-to-cloth ratio is defined as the ratio of gas filtered in cubic feet per minute to the area of filtering media in square feet. Typical units used to express the A/C ratio are

$$(\text{ft}^3/\text{min})/\text{ft}^2 \text{ or } (\text{cm}^3/\text{s})/\text{cm}^2$$

These A/C ratio units essentially reduce to velocity units.

The A/C ratio (filtration velocity) varies for various baghouse designs. Shaker and reverse air baghouses generally have small A/C ratios (shaker units < 3 : 1 (cm<sup>3</sup>/s)/cm<sup>2</sup> and reverse air units < 1.5 : 1 (cm<sup>3</sup>/s)/cm<sup>2</sup>). On the other hand, pulse jet units usually operate at A/C ratios between 2.5 and 10 : 1 (cm<sup>3</sup>/s)/cm<sup>2</sup>. For a given flow rate, pulse jet units can be smaller in size (fewer bags) than the shaker and reverse air baghouse.

The A/C ratio (filtering velocity) is a very important factor used in the design and operation of a baghouse. Improper ratios can cause the baghouse to be in violation of air pollution regulations. Operating at an A/C ratio that is too high may lead to a number of problems. Very high ratios can cause compaction of dust on the bag, resulting in excessive pressure drops. In addition, breakdown of the dust cake could also occur, which in turn results in reduced collection efficiency. The major problem of a baghouse using a very low A/C ratio is that the baghouse will be larger in size.

During a permit review for baghouse installations the reviewer should check the A/C ratio. Typical A/C ratios for shakers, reverse air and pulse jet baghouses are listed in Table 2.17.

**TABLE 2.17** Typical Air-to-Cloth Ratios

Baghouse cleaning method	Air-to-cloth ranges	
	(cm <sup>3</sup> /s)/cm <sup>2</sup>	(ft <sup>3</sup> /min)/ft <sup>2</sup>
Shaking	1–3	2–6
Reverse air	0.5–1.5	1–3
Pulse jet	2.5–7.5	5–15

*Note:* Air-to-cloth ratios are occasionally given as 2.0:1 instead of 2.0 (cm<sup>3</sup>/s)/cm<sup>2</sup>

Baghouses should be operated within a reasonable design A/C ratio range. For example, assume a permit was submitted indicating the use of a reverse air cleaning baghouse using woven Fiberglass<sup>®</sup> bags for reducing particulate emissions from a small foundry furnace. If the information supplied indicated that the baghouse would operate with an A/C ratio of 6 (cm<sup>3</sup>/s)/cm<sup>2</sup> of fabric material, one should question this information. Reverse air units should be operated with a much lower A/C ratio. The fabric would probably not be able to withstand the stress from such high filtering rates and could cause premature bag deterioration. Too high an A/C ratio results in excessive pressure drops, reduced collection efficiency, blinding, and rapid wear. In this case a better design might include reducing the A/C ratio within the acceptable range, thus adding more bags. Another alternative would be to use a pulse jet baghouse with the original design A/C ratio of 6 (cm<sup>3</sup>/s)/cm<sup>2</sup> and use felted bags made of Nomex<sup>®</sup> fibers. Either alternative would be more acceptable than the original permit submission.

*Collection efficiency:* Extremely small particles can be efficiently collected in a baghouse. Baghouse units designed with collection efficiencies of 99.99% are common. Exhaust air from a baghouse can even be recirculated back into the plant for heating purposes, as long as the particles collected are not toxic.

Baghouses are not normally designed with the use of fractional efficiency curves as are some of the other particulate emission control devices. Vendors design and size the units strictly on experience. The baghouse units are designed to meet particulate emission outlet loading and opacity regulations. There is no one formula that can determine the collection efficiency of a specific baghouse. Some theoretical formulas for determining collection efficiency have been suggested, but these formulas contain numerous (three to four) experimentally determined coefficients in the equations. Therefore, these efficiency equations give at best only an estimate of baghouse performance.

*Summary of design criteria.* The principal design criterion is the gas flow rate to the baghouse, measured in cubic meters (cubic feet) per minute. The gas volume to be treated is set by the process exhaust, but the filtration velocity or A/C ratio is determined by the baghouse vendor's design. The A/C ratio depends on a number of variables. A thorough review of baghouse design plans should consider the following factors.

1. Type, shape, and density of the dust; average and maximum concentrations; chemical properties such as abrasiveness, explosiveness, electrostatic charge, and agglomerating tendencies.
2. Gas flow rate: average and maximum flow rate, temperature, moisture content, chemical properties such as dew point, corrosiveness, and combustibility.
3. Fabric construction: woven or felt filters, filter thickness, fiber size, fiber density, filter treatments such as napping, resin and heat setting, and special coatings.
4. Fiber type: natural, synthetic, etc.

5. Cleaning methods: low-energy methods, which are shaker and reverse air cleaning; or a high-energy method, which is pulse jet cleaning.
6. Cleaning time: ratio of filtering time to cleaning time is the measure of the percent of time the filters are performing; this should be at least 10 : 1 or greater.
7. Cleaning and filtering stress: amount of flexing and creasing of the fabric; reverse air is the gentlest, shaking and pulse jet have the most vigorous stress on the fabric.
8. Bag spacing: bags must be properly spaced to eliminate rubbing against each other; bags must be accessible for inspection and maintenance service.
9. Compartment design: allowance for proper cleaning of bags; design should include an extra compartment to allow for reserve capacity and off-line cleaning, and inspection and maintenance of broken bags.
10. Space and cost requirements: baghouses require a good deal of installation space; initial costs, and operating and maintenance costs can be high.
11. Emission requirements: efficiency in terms of opacity and grain-loading regulations.
12. Proper A/C ratio: reverse air lowest, shakers next, pulse jet baghouses allow the highest A/C ratio.

**EXAMPLE 1:** baghouse—simple cloth size check. Baghouse sizing is done by the manufacturer. A simple check or estimate of the amount of baghouse cloth needed for a given process flow rate can be computed by using the A/C ratio equation (EPA-81/10, p. 8-34):

$$v_f = Q/A_c \text{ or } A_c = Q/v_f$$

where  $v_f$  = filtration velocity, ft/min (cm/s)  
 $Q$  = volumetric air flow rate, ft<sup>3</sup>/min (cm<sup>3</sup>/s)  
 $A_c$  = area of cloth filter, ft<sup>2</sup> (cm<sup>2</sup>)

For example, if the process gas exhaust rate is given as  $4.72 \times 10^6$  cm<sup>3</sup>/s (10,000 ft<sup>3</sup>/min) and the filtration velocity is 4 cm/s (A/C is 4:1 (cm<sup>3</sup>/s)/cm<sup>2</sup>), the cloth area would be

$$\begin{aligned} A_c &= 4.72 \times 10^6 / 4 \\ &= 118 \text{ m}^2 \text{ (cloth required)} \end{aligned}$$

To determine the number of bags required in the baghouse, one would simply use the formula:

$$A_b = \pi dh$$

where  $A_b$  = area of bag, m (ft)  
 $d$  = bag diameter, m (ft)  
 $h$  = bag height, m (ft)

If the bag diameter is 0.203 m (8 in.) and the bag height is 3.66 m (12 ft), the area of each bag is

$$\begin{aligned} A_b &= 3.14(0.203)(3.66) \\ &= 2.33 \text{ m}^2 \end{aligned}$$

The calculated number of bags in the baghouse is

$$\begin{aligned} \text{Number of bags} &= 118/2.33 \\ &= 51 \text{ bags} \end{aligned}$$

**EXAMPLE 2:** baghouse—bag selection. It is proposed to install a pulse-jet fabric filter system to clean an air stream containing particulate pollutants. You are asked to select the most appropriate filter bag considering the performance and cost (EPA-84/09, p. 84).

**Given conditions**

- Volumetric flow rate of polluted air stream = 10,000 scfm (60°F, 1 atm)
- Operating temperature = 250°F
- Concentration of pollutants = 4 grains/ft<sup>3</sup>
- Average air-to-cloth ratio = 2.5 cfm/ft<sup>2</sup> cloth
- Collection efficiency requirement = 99%

Information given by filter bag manufacturers is listed in Table 2.18. *Note:* No bag has an advantage from the standpoint of durability under the operating conditions for which the bag is to be designed.

**TABLE 2.18** Filter Bag Properties

Property	Filter bag			
	A	B	C	D
Tensile strength	excellent	above average	fair	excellent
Recommended maximum temperature, °F	260	275	260	220
Resistance factor	0.9	1	0.5	0.9
Cost per bag, \$	26.00	38.00	10.00	20.00
Standard size	8 in. × 16 ft	10 in. × 16 ft	1 ft × 16 ft	1 ft × 20 ft

*Solution:*

1. Eliminate from consideration bags which, on the basis of given characteristics, are unsatisfactory.

Considering operating temperature and bag tensile strength required for a pulse jet system:

- Bag D is eliminated since its recommended maximum temperature (220°F) is below the operating temperature of 250°F.
- Bag C is also eliminated since a pulse jet fabric filter system requires the tensile strength of the bag to be at least above average.

2. Determine comparative costs of the remaining bags.

Total cost for each bag type is the number of bags × cost per bag. No one type of bag is more durable than the other.

2.a. Establish the cost per bag.

From the information given by filter bag manufacturers (Table 2.18), the cost per bag is \$26.00 for A bag and \$38.00 for B bag.

2.b. Determine number of bags, *N*, for each type.

The number of bags required, *N*, is the total filtering area required divided by the filtering area per bag.

2.b.1. Calculate the total filtering area *A<sub>t</sub>*.

2.b.1.a. Convert given flow rate to acfm, *Q<sub>a</sub>*.

$$Q_a = (10,000)(250 + 460)/(60 + 460) = 13,654 \text{ acfm}$$

2.b.1.b. Establish filtering velocity  $v_f$ .

This is given. The A/C ratio, expressed in  $\text{cfm}/\text{ft}^2$ , is the same as the filtering velocity which is given above as  $2.5 \text{ cfm}/\text{ft}^2$  cloth. From the information given in Table 2.18, the filtering velocity is:

$$\begin{aligned}v_f &= 2.5 \text{ cfm}/\text{ft}^2 \\ &= 2.5 \text{ ft}/\text{min}\end{aligned}$$

2.b.1.c. Calculate the total filtering cloth area  $A_c$  from the acfm and filtering velocity determined above.

$$A_c = Q_a/v_f = 13,654/2.5 = 5461.6 \text{ ft}^2$$

2.b.2. Calculate the filtering area per bag.

Bags are assumed to be cylindrical; the bag area is  $A = \pi Dh$ , where  $D$  = bag diameter and  $h$  = bag length.

$$\text{For bag A: } A = \pi Dh = \pi(8/12)(16) = 33.5 \text{ ft}^2$$

$$\text{For bag B: } A = \pi Dh = \pi(10/12)(16) = 41.9 \text{ ft}^2$$

2.b.3. Determine the number of bags required,  $N$ .

$$N = (\text{filtering cloth area of each bag } A_c)/(\text{bag area } A)$$

$$\text{For bag A: } N = A_c/A = 5461.6/33.5 = 163$$

$$\text{For bag B: } N = 5461.6/41.9 = 130$$

2.c. Determine the total cost for each bag.

$$\text{For bag A: total cost} = (N)(\text{cost per bag}) = (163)(26.00) = \$4238$$

$$\text{For bag B: total cost} = (130)(38.00) = \$4940$$

3. Select the most appropriate filter bag considering the performance and cost.

Since the total cost for bag A is less than bag B, select bag A.

**EXAMPLE 3:** baghouse cleaning frequency. You are requested to determine the number of filtering bags required and cleaning frequency for a plant equipped with a fabric filter system. Operating and design data are given below (EPA-84/09, p. 86).

#### Given conditions

volumetric flow rate of the gas stream = 50,000 acfm

dust concentration = 5.0 grains/ $\text{ft}^3$

efficiency of the fabric filter system = 98.0%

filtration velocity = 10 ft/min

diameter of filtering bag = 1.0 ft

length of filtering bag = 15 ft

the system is designed to begin cleaning when the pressure drop reaches 8.0 inches of water.

the pressure drop is given by  $\Delta p = 0.2v_f + 5c(v_f)^2 t$ , where

$\Delta p$  = pressure drop, in.  $\text{H}_2\text{O}$

$v_f$  = filtration velocity, ft/min

$c$  = dust concentration,  $\text{lb}/\text{ft}^3$

$t$  = time since the bags were cleaned, min

*Solution:*

1. What are the number of bags  $N$  needed?

To calculate  $N$ , you need the total required surface area of the bags and the surface area of each bag.

1.a. Calculate the total required surface area of the bags  $A_c$  in  $\text{ft}^2$

$$A_c = Q/v_f$$

where  $A_c$  = total surface area of the bags  
 $Q$  = volumetric flow rate  
 $v_f$  = filtering velocity

$$\begin{aligned} A_c &= Q/v_f \\ &= 50,000/10 \\ &= 5000 \text{ ft}^2 \end{aligned}$$

1.b. Calculate the surface area of each bag  $A$ , in  $\text{ft}^2$

$$A = \pi Dh$$

where  $A$  = surface area of a bag  
 $D$  = diameter of the bag  
 $h$  = length of the bag

$$\begin{aligned} A &= \pi Dh \\ &= \pi(1.0)(15) \\ &= 47.12 \text{ ft}^2 \end{aligned}$$

1.c. Calculate the number of bags  $N$  required.

$$\begin{aligned} N &= A_c/A \\ &= 5000/47.12 \\ &= 106 \end{aligned}$$

2. Calculate the required frequency of cleaning.

$$\Delta p = 0.2v_f + 5c(v_f)^2 t$$

Since  $\Delta p$  is given as 8.0 in.  $\text{H}_2\text{O}$ , the time since the bags were cleaned is calculated by solving the above equation.

Since  $5.0 \text{ grains/ft}^3 = 0.0007143 \text{ lb/ft}^3$  and  $\Delta p = 0.2v_f + 5c(v_f)^2 t$

$$8.0 = (0.2)(10) + (5)(0.0007143)(10)^2 t$$

Solving for  $t$ ,

$$t = 16.8 \text{ min}$$

**EXAMPLE 4:** baghouse—bag failure. An installed baghouse is presently treating a contaminated gas stream. Suddenly some of the bags are broken. You are now requested to estimate the new outlet loading of this baghouse system (EPA-84/09, p. 88).

**Given conditions**

operation conditions of the system = 60°F, 1 atm

inlet loading = 4.0 grains/acf

outlet loading before bag failure = 0.02 grains/acf

volumetric flow rate of contaminated gas = 50,000 acfm

number of compartments = 6

number of bags per compartment = 100

bag diameter = 6 inches

pressure drop across the system = 6 in. H<sub>2</sub>O

number of broken bags = 2 bags

assume that all the contaminated gas emitted through the broken bags is the same as that passing through the tube sheet thimble.

*Solution:*

1. Calculate the collection efficiency and penetration before the bag failure(s).

Collection efficiency is a measure of degree of performance of a control device; it specifically refers to degree of removal of pollutants. *Loading* refers to the concentration of pollutants, usually in grains of pollutants per cubic feet of contaminated gas streams. Mathematically, the collection efficiency is defined as

$$\eta = [(\text{inlet loading} - \text{outlet loading})/(\text{inlet loading})](100)$$

From the above equation, the collected amount of pollutants by a control unit is the product of collection efficiency  $\eta$  and inlet loading. The amount discharged to the atmosphere is given by the inlet loading minus the amount collected.

Another term used to describe the performance or collection efficiency of control devices is penetration  $P_t$ . It is given by (EPA-84/09, p. 3.3):

$$P_t = 1 - \eta/100 \quad (\text{fractional basis})$$

$$P_t = 100 - \eta \quad (\text{percent basis})$$

The effect of bag failure on baghouse efficiency is described by the following equation:

$$P_t^* = P_t + P_{tc}$$

$$P_{tc} = 0.582(\Delta p)^{0.5}/\phi$$

$$\phi = Q/(LD^2(T + 460)^{0.5})$$

where  $P_t^*$  = penetration after bag failure  
 $P_t$  = penetration before bag failure  
 $P_{tc}$  = penetration correction term, contribution of broken bags to  $P_t^*$   
 $\Delta p$  = pressure drop, in. H<sub>2</sub>O  
 $\phi$  = dimensionless parameter  
 $Q$  = volumetric flow rate of contaminated gas, acfm  
 $L$  = number of broken bags  
 $D$  = bag diameter, inches  
 $T$  = temperature, °F

Collection efficiency  $\eta$  is

$$\begin{aligned}\eta &= (\text{inlet loading} - \text{outlet loading})/(\text{inlet loading}) \\ &= (4.0 - 0.02)/(4.0) \\ &= 0.995 \\ &= 99.5\%\end{aligned}$$

Penetration is:

$$\begin{aligned}P_t &= 1.0 - \eta \\ &= 0.005\end{aligned}$$

2. Calculate the bag failure parameter  $\phi$ . It is a dimensionless number

$$\begin{aligned}\phi &= Q/(LD^2(T + 460)^{0.5}) \\ &= 50,000/(2)(6)^2(60 + 460)^{0.5} \\ &= 30.45\end{aligned}$$

3. Calculate the penetration correction  $P_{tc}$ .

This is to determine penetration due to bag failure.

$$\begin{aligned}P_{tc} &= 0.582(\Delta p)^{0.5}/\phi \\ &= (0.582)(6)^{0.5}/30.45 \\ &= 0.0468\end{aligned}$$

4. Calculate the penetration and efficiency after the two bag failures.

Use the results of steps 1 and 3 to calculate  $P_t^*$

$$\begin{aligned}P_t^* &= P_t + P_{tc} \\ &= 0.005 + 0.0468 \\ &= 0.0518\end{aligned}$$

$$\begin{aligned}\eta^* &= 1 - 0.0518 \\ &= 0.948\end{aligned}$$

5. Calculate the new outlet loading after the bag failures.

Relate inlet loading and new outlet loading to the revised efficiency or penetration.

$$\begin{aligned}\text{New outlet loading} &= (\text{inlet loading})P_t^* \\ &= (4.0)(0.0518) \\ &= 0.207 \text{ grains/acf}\end{aligned}$$

6. What other system and/or operating variables will affect the new outlet loading (or what other variables will affect penetration after bag failures)? Discuss qualitatively.  
Note that

$$P_t^* = P_t + P_{tc}$$

$$P_{tc} = 0.582(\Delta p)^{0.5}/\phi$$

$$\phi = Q/(LD^2(T + 460)^{0.5})$$

$$P_t^* = P_t + 0.582(\Delta p)^{0.5}(LD^2(T + 460)^{0.5})/Q$$

Decreasing either the operating temperature and/or pressure drop will decrease  $P_t^*$  (and therefore lower the new outlet loading) assuming  $L$ ,  $D$ , and  $Q$  remain the same. Note that increasing  $Q$  will also decrease  $P_t^*$ , since the fraction of gas emitted through the broken bags is reduced.

## 5 PARTICULATE CONCENTRATION CALCULATION

---

**EXAMPLE 1:** particulate concentration. An analysis of a stack sample indicated that the concentration of particulates from a coal-burning boiler is 2.5 grains per cubic foot. Determine:

1. What is the concentration in the units of  $\text{lb}/\text{ft}^3$ ,  $\text{g}/\text{m}^3$ , and  $\mu\text{g}/\text{m}^3$ ?
2. If  $350 \text{ ft}^3$  of flue gas are produced for every pound of coal burned, and if all ash in coal becomes particulate in flue gas, what is the maximum ash content in the coal?
3. If the air standard is  $75 \mu\text{g}/\text{m}^3$ , calculate the dilution factor.
4. Calculate the particulate collection efficiency, if the air standard is to be met.

### Given conditions

particulate concentration,  $P_c = 2.5 \text{ grains}/\text{ft}^3$   
 flue gas volume produced per pound coal burned,  $V = 350 \text{ ft}^3/\text{lb}$   
 air standard level on particulate  $P_s = 75 \mu\text{g}/\text{m}^3$   
 $1 \text{ lb} = 7000 \text{ grains}$   
 $1 \text{ lb} = 454 \text{ grams}$   
 $1 \text{ ft}^3 = 0.0283 \text{ m}^3$

*Solution for question (1):*

- 1.1 Convert the particulate concentration  $P_c$  from  $\text{grains}/\text{ft}^3$  to  $\text{lb}/\text{ft}^3$ .

$$P_c = 2.5/7000$$

$$= 0.000357 \text{ (lb-particulate)}/\text{ft}^3$$

- 1.2. Convert the particulate concentration  $P_c$  from  $\text{lb}/\text{ft}^3$  to  $\text{g}/\text{m}^3$ .

$$P_c = 0.000357(454)/(0.0283)$$

$$= 5.73 \text{ (g-particulate)}/\text{m}^3$$

1.3. Convert the particulate concentration  $P_c$  from  $\text{g}/\text{m}^3$  to  $\mu\text{g}/\text{m}^3$ .

$$\begin{aligned} P_c &= 5.73(1000000) \\ &= 5.73 \times 10^6 (\mu\text{g-particulate})/\text{m}^3 \end{aligned}$$

*Solution for question (2):*

2.1. Calculate the particulate loading  $P_{10}$  in flue gas.

Because it is assumed that all ash becomes particulates in the flue gas, the particulate loading in the flue gas can be calculated from  $P_c$  in step 1.1, by multiplying by the flue gas volume rate.

$$\begin{aligned} P_{10} &= (\text{particulate concentration}) \times (\text{flue gas volume per pound of coal burned}) \\ &= 0.000357(350) \\ &= 0.12495 (\text{lb-particulate}/\text{lb-coal}) \\ &= 12.50\% \end{aligned}$$

2.2. Determine the ash content in coal.

The ash content in coal is equal to the particulate loading in step 2.1; that is, 12.50%.

*Solution for question (3):*

Dilution factor (DF) means the amount of additional air that is needed to dilute the flue gas so that the particulate concentration can meet the air standard requirement. To maintain the consistency of the units in this calculation, the  $P_c$  value in step 1.3 is used for this calculation.

$$\begin{aligned} \text{DF} &= (\text{particulate loading})/(\text{air standard}) \\ &= (5.73 \times 10^6)/75 \\ &= 7.64 \times 10^4 \end{aligned}$$

*Solution for question (4):*

1. Write the collection efficiency equation  $C_e$ .

$$C_e = (1 - P_s/P_c)$$

where  $P_s$  = air standard level provided in given conditions  
 $P_c$  = particulate concentration from step 1.3

2. Calculate the collection efficiency.

$$\begin{aligned} C_e &= (1 - 75/5.73 \times 10^6) \\ &= 0.999987 \\ &= 99.9987\% \end{aligned}$$

**EXAMPLE 2:** particulate concentration. (1) A boiler is burning 8% coal. If  $250 \text{ ft}^3$  of flue gas are produced for every pound of coal burned, what is the maximum effluent particulate loading in grains/ $\text{ft}^3$ ? (2) If the  $250 \text{ ft}^3$  of flue gas contains 12% oxygen, correct the particulate concentration to the standards requirement of 7% oxygen concentration.

**Given conditions**

- coal ash content = 8%  
 flue gas volume produced per pound coal burned,  $V = 250 \text{ ft}^3/\text{lb}$   
 flue gas oxygen concentration,  $\text{O}_2 = 12\%$   
 flue gas standards oxygen concentration, std  $\text{O}_2 = 7\%$   
 1 lb = 7000 grains

*Solution for question (1):*

1.1. Calculate particulate amount produced.

Assume that all 8% of ash becomes particulates in the flue gas. For 1 lb of coal burned, the amount of particulates emitted is 0.08 lb.

1.2. Calculate the maximum particulate loading  $P_c$ .

$$\begin{aligned} P_c &= 0.08/250 \\ &= 0.00032 \text{ lb/ft}^3 \\ &= 2.24 \text{ grains/ft}^3 \end{aligned}$$

*Solution for question (2):*

2.1. Write the correction equation below from 40CFR264.343.

$$P_c = P_m \times (21 - \text{std O}_2)/(21 - Y)$$

- where  $P_c$  = corrected particulate concentration  
 $P_m$  = measured particulate concentration (at 12%  $\text{O}_2$  for this case)  
 $Y$  = %  $\text{O}_2$  in discharge, dry basis  
 std  $\text{O}_2$  = 7% for this case

2.2. Calculate the corrected particulate concentration

$$\begin{aligned} P_c &= 2.24(21 - 7)/(21 - 12) \\ &= 3.48 \text{ grains/ft}^3 \end{aligned}$$

## 6 PARTICULATE EMISSION CONTROL COST

---

### 6.1 Breakeven Operation

**EXAMPLE 1:** control costs. A plant emits 50,000 acfm of gas containing a dust loading of 2.0 grains/ft<sup>3</sup>. A particulate control device is employed for particle capture and the dust captured from the unit is worth \$0.01/lb of dust. You are requested to determine at what collection efficiency is the cost of power equal to the value of the recovered material. Also determine the pressure drop in inches of  $\text{H}_2\text{O}$  at this condition (EPA-84/09, p. 122).

**Given conditions**

- Overall fan efficiency = 55%  
 Electric power cost = \$0.06/kW-h

For this control device, assume that the collection efficiency is related to the system pressure drop  $\Delta p$  through the following equation.

$$\eta = \Delta p / (\Delta p + 5.0)$$

where  $\Delta p$  = pressure drop,  $\text{lb}_f/\text{ft}^2$   
 $\eta$  = fractional collection efficiency

*Solution:*

- Express the value of the dust collected in terms of collection efficiency  $\eta$ .

$$\text{Amount of dust collected} = (Q)(\text{inlet loading})(\eta)$$

Remember there are 7000 grains per pound.

$$\begin{aligned} \text{The value of dust collected} &= 50,000(\text{ft}^3/\text{min})^2(\text{grains}/\text{ft}^3)(1/7000)(\text{lb}/\text{grain}) \times 0.01(\$/\text{lb})\eta \\ &= 0.143\eta \text{ \$/min} \end{aligned}$$

- Express the value of the dust collected in terms of pressure drop  $\Delta p$ .  
Remember that  $\eta = \Delta p / (\Delta p + 5.0)$

$$\text{The value of dust collected} = 0.143[\Delta p / (\Delta p + 5.0)] \text{ \$/min}$$

- Express the cost of power in terms of pressure drop  $\Delta p$ .

$$\text{bhp} = Q\Delta p / \eta' = \text{brake horsepower}$$

where  $\eta'$  = fan efficiency  
 $\Delta p$  = pressure drop,  $\text{lb}_f/\text{ft}^2$   
 $Q$  = volumetric flow rate

$$\begin{aligned} \text{Cost of power} &= \Delta p(\text{lb}_f/\text{ft}^2)(50,000)[(\text{ft}^3/\text{min})(1/44,200)(\text{kW}\cdot\text{min}/\text{ft}\cdot\text{lb}_f)(1/0.55) \\ &\quad \times (0.06)(\$/\text{kW}\cdot\text{h})(1/60)(\text{h}/\text{min})] \\ &= 0.002\Delta p \text{ \$/min} \end{aligned}$$

- Set the cost of power equal to the value of dust collected and solve for  $\Delta p$  in  $\text{lb}_f/\text{ft}^2$ . This represents breakeven operation. Then, convert this pressure drop to in.  $\text{H}_2\text{O}$ .  
To convert from  $\text{lb}_f/\text{ft}^2$  to in.  $\text{H}_2\text{O}$ , divide by 5.2.

$$(0.143)\Delta p / (\Delta p + 5) = 0.002\Delta p$$

Solving for  $\Delta p$

$$\Delta p = 66.5 \text{ lb}_f/\text{ft}^2 = 12.8 \text{ in. H}_2\text{O}$$

- Calculate the collection efficiency using the value of  $\Delta p$  calculated above.  
Use the equation for  $\eta$  in Solution (2):

$$\eta = 66.5 / (66.5 + 5) = 0.93 = 93.0\%$$

## 6.2 Annualized Installed, Operation, and Maintenance Costs

**EXAMPLE 2:** control costs. You are requested to determine capital, operating, and maintenance costs on an annualized basis for a textile dye and finishing plant (with two coal-fired

stoker boilers) where a baghouse is employed for particulate control. Operating, design, and economics factors are given (EPA-84/09, p. 123).

**Given conditions**

exhaust volumetric flow from two boilers = 70,000 acfm

overall fan efficiency = 60%

operating time = 6240 h/year

surface area of each bag = 12.0 ft<sup>2</sup>

bag type = Teflon<sup>®</sup> felt

air-to-cloth ratio = 5.81 acfm/ft<sup>2</sup>

total pressure drop across the system = 17.16 lb<sub>f</sub>/ft<sup>2</sup>

cost of each bag = \$75.00

installed capital costs = \$2.536/acfm

cost of electrical energy = \$0.03/kW-h

yearly maintenance cost = \$5000 plus yearly cost to replace 25% of the bags

salvage value = 0

interest rate ( $i$ ) = 8%

lifetime of baghouse ( $m$ ) = 15 yr

annual installed capital cost (AICC) = (installed capital cost)  $\{i(1+i)^m / [(1+i)^m - 1]\}$

*Solution:*

1. What is the annual maintenance cost?
  - 1.a. Calculate the number of bags  $N$ .

$$N = Q / (\text{air-to-cloth ratio})(A)$$

where  $Q$  = total exhaust volumetric flow rate  
 $A$  = surface area of a bag

$$\begin{aligned} N &= Q / (\text{air-to-cloth ratio})(A) \\ &= (70,000) / (5.81)(12) \\ &= 1004 \text{ bags} \end{aligned}$$

- 1.b. Calculate the annual maintenance cost in dollars/year.

$$\begin{aligned} \text{Annual maintenance cost} &= \$5000/\text{year} + \text{cost of replacing 25\% of the bags each year} \\ &= \$5000 + (0.25)(1004)(75.00) \\ &= \$23,825/\text{year} \end{aligned}$$

2. What is the annualized installed cost (AICC)?

- 2.a. Calculate the installed capital cost in dollars.

$$\begin{aligned} \text{Installed capital cost} &= (Q)(\$2.536/\text{acfm}) \\ &= (70,000)(2.536) \\ &= \$177,520 \end{aligned}$$

2.b. Calculate the AICC using the equation given above.

$$\begin{aligned} \text{AICC} &= (\text{installed capital cost})\{i(1+i)^m / [(1+i)^m - 1]\} \\ &= (177,520)\{0.08(1+0.08)^{15} / [(1+0.08)^{15} - 1]\} \\ &= \$20,740/\text{year} \end{aligned}$$

3. Calculate the operating cost in dollars per year.

$$\text{Operating cost} = Q\Delta p(\text{operating time})(0.03/\text{kW}\cdot\text{h}/E)$$

Since 1 ft-lb/s = 0.0013558 kW,

$$\begin{aligned} \text{Operating cost} &= (70,000/60)(17.16)(6240)(0.03)(0.0013558)/0.6 \\ &= \$8470/\text{year} \end{aligned}$$

4. Calculate the total annualized cost in dollars per year.

$$\begin{aligned} \text{Total annualized cost} &= (\text{maintenance cost}) + \text{AICC} + (\text{operating cost}) \\ &= 23,825 + 20,740 + 8470 \\ &= \$53,035/\text{year} \end{aligned}$$

### 1 INTRODUCTION

---

Generally speaking, absorption equipment includes two major categories:

- Wet absorption scrubbers (or wet scrubbers)
- Dry absorption scrubbers (or dry scrubbers)

*Wet scrubbers:* As the name implies, wet scrubbers (also known as wet collectors) are devices which use a liquid for the removal of source emissions from effluent gas streams (EPA-84/03, p. 1-1; EPA-81/10, p. 9-1). These air pollution control devices can remove both particulate matter and gaseous pollutants.

The dirty exhaust stream is brought into contact with the liquid by spraying it into the liquid; by forcing it through a pool of liquid; or by some other contact method. The advantages or disadvantages of using a wet scrubber instead of some other control device depend on the pollutant (gas or particle) to be controlled. The types of wet scrubber equipment are shown in Table 3.1.

*Particulate matter removal:* When wet scrubbers are used for removing particles, the particles are captured by and incorporated into liquid droplets. The droplet must then be

**TABLE 3.1** Types of Wet Scrubbers

	3.4. Mechanically aided scrubber	

separated from the clean exhaust stream. Wet collectors, baghouses, or electrostatic precipitators (ESPs) can be used when collecting small particles at a high efficiency (> 95%) is necessary. When only large particles are to be removed, either a low-energy scrubber or a cyclone can be used. Choosing the ‘best’ collection system depends on many factors (EPA-84/03, p. 1-1).

*Gaseous removal:* When wet scrubbers are used for removing gases, the gases are dissolved or absorbed by the liquid. For gaseous pollutant removal, the choice of the control device depends mainly on the type of gaseous pollutant to be controlled. In choosing a system to control organic vapors, the choice of control is among wet scrubbers, adsorbers, thermal oxidizers (incinerators), or condensers; to control most inorganic gases (HCl, H<sub>2</sub>S, HF, and SO<sub>2</sub>), a wet scrubber is usually the primary control device (EPA-84/03, p. 1-2).

If the exhaust stream contains both particles and gases, wet scrubbers are generally the only air pollution control device used to remove both pollutants. One exception is using a baghouse or an ESP with a spray dryer in a dry SO<sub>2</sub> scrubbing system.

Wet scrubbers can achieve high removal efficiencies for either particles or gases and, in some instances, can achieve a high removal efficiency for both pollutants in the same system. However, in many cases, the best operating conditions for particle collection are the poorest for gas removal. In general, obtaining high simultaneous gas and particle removal efficiencies requires that one of them be easily collected (i.e., that the gases are very soluble in the liquid or that the particles are large and readily captured). Wet scrubbers have been used in a variety of industries such as acid plants, fertilizer plants, steel mills, asphalt plants, and large power plants.

The advantages and disadvantages of using a wet scrubber to remove particulate and gaseous emissions are summarized below:

#### *Advantages*

- *Small space requirement:* Scrubbers reduce the temperature and sometimes can reduce the volume of the unsaturated exhaust stream. Therefore, vessel sizes, including fans and ducts

downstream, are smaller than those of other control devices. Smaller sizes result in lower capital costs and more flexibility in the site location of the scrubber.

- *No secondary dust sources:* Once particles are collected, they cannot escape from hoppers or during transport.
- *Handle high-temperature, high-humidity gas streams:* No temperature limit or condensation problems can occur as in baghouses or ESPs.
- *Minimal fire and explosion hazard:* Various dry dusts are flammable. Using water eliminates the possibility of explosions.
- *Ability to collect both gases and particles.*

#### *Disadvantages*

- *Corrosion problems:* Water and dissolved pollutants can form highly corrosive acidic solutions. Proper construction materials are very important. Also, wet-dry interface areas can result in corrosion.
- *High power requirement:* High collection efficiencies for particles are attainable only at high pressure drops, resulting in high operating costs.
- *Water disposal problems:* Settling ponds or sludge clarifiers may be needed to meet wastewater regulations.
- *Difficult product recovery:* Dewatering and drying of scrubber sludge make recovery of any dust for reuse very expensive and difficult.
- *Meteorological problems:* The saturated exhaust gases can produce a wet, visible steam plume. Fog and precipitation from the plume may cause local meteorological problems.

## **2 WET ABSORPTION FOR PARTICULATE EMISSION CONTROL**

---

### **2.1 Collection Mechanism and Efficiency**

Wet absorption processes use wet scrubbers to capture relatively small dust particles with large liquid droplets. Droplets are produced by injecting liquid at high pressure through specially designed nozzles, by aspirating the particle-laden gas stream through a liquid pool, or by submerging a whirling rotor in a liquid pool. These droplets collect particles by using one or more of several collection mechanisms. These mechanisms are summarized in Table 3.2 (EPA-84/03, p. 1-4; EPA-81/10, p. 9-5).

Each of these effects can be characterized by a mathematical expression called the separation number. The *separation numbers* are dimensionless groups of parameters—the higher the value of the separation number, the more effective the mechanism. From these basic expressions, theories have been derived to describe scrubber performance (EPA-81/10, p. 9-5)

The design of a scrubber involves many factors including space restriction, pollutant collection efficiency, pressure drop (gas-side), particle size, exhaust gas flow rate, liquid-to-gas ratio, and many construction details such as using corrosion-resistant materials, baffles, nozzles, venturi throats, water sprays, packing, plates, orifices, entrainment separators, inlets, and outlets. These have been discussed in detail in earlier chapters. Officers who review scrubber design plans for air pollution control agencies should consider these factors during the review process (EPA-84/03, p. 9-1).

Because all scrubbers can be used to collect both particulate and gaseous pollutants, the choice of the most appropriate type can sometimes be difficult. Therefore this chapter will point out those scrubber design features that are important when choosing a scrubber to remove particulate and gaseous pollutants, and will also look at a few equations that can be used to estimate pressure drop and collection efficiency.

**TABLE 3.2** Particle Collection Mechanisms for Wet Scrubbing Systems

Mechanism*	Explanation
Impaction	Particles too large to follow gas streamlines around a droplet collide with it.
Diffusion	Very tiny particles move randomly, colliding with droplets because they are confined in a limited space.
Direct interception	An extension of the impaction mechanism. The center of a particle follows the streamlines around the droplet, but a collision occurs if the distance between the particle and droplet is less than the radius of the particle.
Electrostatic attraction	Particles and droplets become oppositely charged and attract each other.
Condensation	When hot gas cools rapidly, particles in the gas stream can act as condensation nuclei and, as a result, become larger.
Centrifugal force	The shape or curvature of a collector causes the gas stream to rotate in a spiral motion, throwing larger particles toward the wall.
Gravity	Large particles moving slowly enough will fall from the gas stream and be collected.

\*Impaction, direct interception, and diffusion are the three primary collection mechanisms.

Venturi scrubbers are the most popular scrubbers used to remove particulate matter. Other scrubbers used include cyclonic, orifice, mechanically aided, and spray towers. Typical gaseous pressure drops and L/G ratios for these devices are given in Table 3.3.

Wet scrubbers remove particles from an exhaust stream by contacting the particles with liquid, usually water. A number of factors affect particle removal efficiency including:

- particle-size distribution
- liquid flow rate
- exhaust gas flow rate
- method of contacting
- pressure drop across the scrubber

As with gaseous pollutant removal (absorption), efficient particle removal requires contact between the exhaust stream (containing particles) and the scrubbing liquid. However, particle removal occurs instantaneously upon contact with the liquid, whereas efficient absorption requires a long contact time. Therefore, efficient particle removal requires high relative velocities (gas versus liquid velocity).

**TABLE 3.3** Ranges of Pressure Drops and Liquid-to-Gas (L/G) Ratios for Various Wet Scrubbers

Scrubber	Pressure drop, $\Delta p$		Liquid-to-gas ratio*	
	kPa	in. H <sub>2</sub> O	L/m <sup>3</sup>	gal/1000 ft <sup>3</sup>
Venturi	1.5–25.0	6.0–100.0	0.4–5.0	3.0–40.0
Spray tower	0.12–0.75	0.5–3.0	0.7–2.7	5.0–20.0
Cyclonic spray	0.4–4.0	1.5–10.0	0.3–1.3	2.0–10.0
Moving bed (good for removing particulate and gaseous pollutants)	0.5–6.0	2.0–24.0	0.4–8.0	3.0–60.0
Orifice (self-induced spray)	0.5–4.0	2.0–10.0	0.07–0.7	0.5–5.0
Mechanically aided (fan)	1.0–2.0	4.0–8.0	0.07–0.5	0.5–4.0

\*Higher L/G reflects those used for gas absorption.

A number of theories have been developed from basic particle movement principles to explain the action of wet scrubbing systems. Many of these start from firm scientific concepts, but yield only qualitative results when predicting collection efficiencies or pressure drops.

Collection efficiency is frequently expressed in terms of penetration. Penetration is defined as the fraction of particles (in the exhaust stream) that passes through the scrubber uncollected. Penetration is the opposite of the fraction of particles collected, and is expressed as (EPA-84/03, p. 9-3):

$$P_t = 1 - \eta$$

where  $P_t$  = penetration  
 $\eta$  = collection efficiency (expressed as a fraction)

Wet scrubbers usually have an efficiency curve that fits the relationship of:

$$\eta = 1 - e^{-f(\text{system})}$$

where  $\eta$  = collection efficiency  
 $e$  = exponential function  
 $f(\text{system})$  = some function of the scrubbing system variables

By substituting for efficiency, penetration can be expressed as

$$\begin{aligned} P_t &= 1 - \eta \\ &= 1 - [1 - e^{-f(\text{system})}] \\ &= e^{-f(\text{system})} \end{aligned}$$

In testing the design of a specific scrubber, the vendor can measure operating variables and the collection efficiency of the unit. These data can then be used to evaluate the efficiency of the system. An equation for the scrubbing system variables,  $f(\text{system})$ , can be developed for that particular design.

**Impaction.** In a wet scrubbing system, dust particles will tend to follow the streamlines of the exhaust stream. However, when liquid droplets are introduced into the exhaust stream, particles cannot always follow these streamlines as they diverge around the droplet (Fig. 3.1). The

FIGURE 3.1 Particle collection by impaction (EPA-84/03, p. 1-4).

particle's mass causes it to break away from the streamlines and impact on the droplet. Impaction is the predominant collection mechanism for scrubbers having gas stream velocities greater than 0.3 m/s (1 ft/s). Most scrubbers do operate with gas stream velocities well above 0.3 m/s. Therefore, at these velocities, particles having diameters greater than  $1.0\ \mu\text{m}$  are collected by this mechanism (EPA-84/03, p. 1-4).

As the velocity of the particles in the exhaust stream increases relative to the liquid droplet's velocity, impaction increases. Impaction also increases as the size of the liquid droplet decreases. This is because there will be more droplets (for the same amount of liquid) within the vessel; consequently, this increases the likelihood that the particles will impact on the droplets.

The separation number for impaction is obtained by balancing the force of the moving particle against the resistance of the gas stream to its motion. The separation number for impaction is known as the impaction parameter  $\psi$  and is expressed by (EPA-81/10, p. 9-5)

$$\psi = C_f \rho_p v (d_p)^2 / 18 d_d \mu \tag{3.1}$$

- where  $\rho_p$  = particle density
- $v$  = gas velocity at venturi throat, ft/s
- $d_p$  = particle diameter, ft
- $d_d$  = droplet diameter, ft
- $\mu$  = gas viscosity, lb/ft-s
- $C_f$  = Cunningham correction factor

The collection efficiency associated with this impaction effect is expressed as (EPA-81/10, p. 9-7):

$$\eta_{\text{impaction}} = f(\psi)$$

**Interception.** The center of a particle follows the streamlines around the droplet, but a collision occurs if the distance between the particle and droplet is less than the radius of the particle (Fig. 3.2).

The separation number, which characterizes this effect, is the ratio of the particle diameter to the droplet diameter and is expressed as (EPA-81/10, p. 9-8)

$$d_p / d_d$$

- where  $d_p$  = particle diameter, ft
- $d_d$  = droplet diameter, ft

FIGURE 3.2 Particle collection by interception (EPA-81/10, p. 9-8).

The collection efficiency associated with this interception effect is a function of  $d_p$  and  $d_d$  or

$$\eta_{\text{interception}} = f(d_p/d_d)$$

**Diffusion.** Very small particles (less than  $0.1 \mu\text{m}$  in diameter) experience random (Brownian) movement in an exhaust stream. These particles are so tiny that they are bumped by gas molecules as they move in the exhaust stream. This bumping, or bombardment, causes them to first move one way and then another in a random manner, or diffuse, through the gas. This irregular motion can cause the particles to collide with a droplet and be collected (Fig. 3.3). Because of this, in certain scrubbers, the removal efficiency of particles smaller than  $0.1 \mu\text{m}$  can actually increase.

The rate of diffusion depends on relative velocity, particle diameter, and liquid droplet diameter. As with impaction, collection increases with an increase in relative velocity (liquid- or gas-pressure input) and a decrease in liquid droplet size. However, collection by diffusion increases as particle size decreases. This mechanism enables certain scrubbers to effectively remove the very tiny particles. In the particle size range of approximately  $0.1$  to  $1.0 \mu\text{m}$ , neither of these two dominates. Particles in this size range are not collected as efficiently as are either larger particles collected by impaction or smaller particles collected by diffusion (EPA-84/03, p. 1-5).

The Brownian diffusion process leading to particle capture is most often described by a parameter called the Péclet number  $Pe$  (EPA-81/10, p. 9-8):

$$Pe = 3\pi\mu v d_p d_d / (C_f k_B T)$$

- where
- $Pe$  = Péclet number
  - $\mu$  = gas viscosity
  - $v$  = gas stream velocity
  - $d_p$  = particle diameter
  - $d_d$  = liquid droplet diameter
  - $C_f$  = Cunningham correction factor
  - $k_B$  = Boltzmann's constant
  - $T$  = temperature of gas stream

The above equation shows that, as the temperature increases,  $Pe$  decreases. An increase in temperature means that gas molecules will move around faster than at lower temperatures.

FIGURE 3.3 Particle collection by diffusion (EPA-84/03, p. 1-5).

This will lead to increased bombardment of the small particles, increased random motion, and increased collection efficiency by this mechanism. Expressions for collection efficiency by the diffusion process are generally in the form:

$$\eta_{\text{diffusion}} = f(1/\text{Pe})$$

This equation shows that as the Péclet number decreases, collection efficiency by diffusion increases.

## 2.2 Combined Efficiency

When attempting to collect 100 particles using a collection mechanism having 80% efficiency, 80 particles would be collected and 20 would escape. If another mechanism with 60% efficiency was used to collect the remaining 20 particles, 8 would escape this time. Ninety-two particles would therefore be collected, giving a total efficiency of  $92/100 = 0.92$  or 92%. This can be expressed as (EPA-81/10, p. 9-9):

$$\begin{aligned} 100 - \{[100 - 100(0.80)] - [100 - 100(0.80)]0.60\} \\ = 100 - \{[100 - 100(0.80)](1 - 0.60)\} \\ = 100 - 100\{(1 - 0.8)(1 - 0.6)\} \\ = 100 - 8 \\ = 92 \end{aligned}$$

Generalizing in terms of the number of mechanisms which may be involved in wet collection devices, the combined efficiency can be expressed as

$$\eta_{\text{combined}} = 1 - (1 - \eta_{\text{impaction}})(1 - \eta_{\text{interception}})(1 - \eta_{\text{diffusion}})$$

Depending on flow conditions (laminar, turbulent, etc.), other combinations of these parameters have been used to provide expressions for the efficiency of wet collectors. The number of variables are so great and the interaction between varying size distributions of both particulate matter and liquid droplets is so complex, that this type of theoretical approach is difficult to apply in practice.

This academic approach, although useful in understanding basic phenomena, is commonly sidestepped for more empirical approaches. Correction factors obtained from actual operating systems or pilot plant data are used to correct for complex interactions. A newer concept expressing efficiency in terms of power expended has led to several empirical techniques for evaluating scrubber performance. The subsequent sections of this chapter will describe some of these empirical methods.

## 2.3 Collection Efficiency Models for Venturi Scrubber

Several models have been used for the calculation of venturi collection efficiency. These models include (EPA-84/03, p. 9-1; EPA-81/10, p. 9-1):

- Johnstone equation
- Infinite throat model
- Cut power method
- Contact power theory
- Pressure drop

**Johnstone equation.** Johnstone in 1951 developed an expression for the calculation of venturi scrubber efficiency by considering only the predominant mechanism of inertial impaction (EPA-81/10, p. 9-11).

The Johnstone equation is given as

$$\eta = 1 - \exp[-k(Q_L/Q_G)\sqrt{\psi}]$$

where  $\eta$  = fractional collection efficiency  
 $k$  = correlation coefficient whose value depends on the system geometry and operating conditions, typically 0.1–0.2, 1000 acf/gal  
 $Q_L/Q_G$  = liquid-to-gas ratio, gal/1000 acf  
 $\psi = C_f \rho_p v(d_p)^5 / 18 d_d \mu$  = inertial impaction parameter  
 $\rho_p$  = particle density  
 $v$  = gas velocity at venturi throat, ft/s  
 $d_p$  = particle diameter, ft  
 $d_d$  = droplet diameter, ft  
 $\mu$  = gas viscosity, lb/ft-s  
 $C_f$  = Cunningham correction factor

**Infinite throat model.** One method used to predict particle collection efficiency in a venturi scrubber is called the infinite throat model (EPA-77). The equations presented in the infinite throat model assume that all particles are captured by the liquid in the throat section of the venturi.

The equations listed in the model can be used to predict the penetration ( $P_t$ ) for one particle size (diameter) or for the overall penetration ( $P_t^*$ ). The equations are provided below (EPA-84/03, p. 9-4):

$$\ln P_t(d_p) = -B \{ [4K_{po} + 4.2 - 5.02(K_{po})^{0.5} (1 + 0.7/K_{po}) \tan^{-1}(K_{po}/0.7)^{0.5}] / (K_{po} + 0.7) \} \quad (3.2)$$

where  $P_t(d_p)$  = penetration for one particle size  
 $B$  = parameter characterizing the liquid-to-gas ratio, dimensionless  
 $K_{po}$  = inertial parameter at throat entrance, dimensionless

*Note:* Equation (3.2) was developed assuming that the venturi has an infinite-sized throat length ( $l$ ). This is valid only when  $l$  is greater than 2.0.

$$l = (3l_\tau C_D \rho_g) / (2d_d \rho_l)$$

where  $l$  = throat length parameter, dimensionless  
 $l_\tau$  = venturi throat length, cm  
 $C_D$  = drag coefficient for the liquid at the throat entrance, dimensionless  
 $\rho_g$  = gas density, g/cm<sup>3</sup>  
 $\rho_l$  = liquid density, g/cm<sup>3</sup>  
 $d_d$  = droplet diameter, cm

The Nukiyama and Tanasawa equation

$$d_d = 50/v_{gr} + 91.8(L/G)^{1.5} \quad (3.3)$$

where  $d_d$  = droplet diameter, cm  
 $v_{gr}$  = gas velocity in the throat, cm/s  
 $L/G$  = liquid-to-gas ratio, dimensionless

$$B = (L/G)\rho_l / (\rho_g C_D) \quad (3.4)$$

where  $B$  = parameter characterizing liquid-to-gas ratio, dimensionless  
 $L/G$  = liquid-to-gas ratio, dimensionless  
 $\rho_g$  = gas density, g/cm<sup>3</sup>  
 $\rho_l$  = liquid density, g/cm<sup>3</sup>  
 $C_D$  = drag coefficient for the liquid at the throat entrance, dimensionless

$$K_{po} = (d_p)^2 v_{g\tau} / (9\mu_g d_d) \quad (3.5)$$

where  $K_{po}$  = inertial parameter at throat entrance, dimensionless  
 $d_p$  = particle aerodynamic resistance diameter, cm  
 $v_{g\tau}$  = gas velocity in the throat, cm/s  
 $\mu_g$  = gas viscosity, g/s-cm  
 $d_d$  = droplet diameter, cm

$$K_{pg} = (d_{pg})^2 v_{g\tau} / (9\mu_g d_d) \quad (3.6)$$

where  $K_{pg}$  = inertial parameter for mass-median diameter, dimensionless  
 $d_{pg}$  = particle aerodynamic geometric mean diameter, cm  
 $v_{g\tau}$  = gas velocity in the throat, cm/s  
 $\mu_g$  = gas viscosity, g/s-cm  
 $d_d$  = droplet diameter, cm

$$C_D = 0.22 + (24/N_{Reo})[1 + 0.15(N_{Reo})^{0.6}] \quad (3.7)$$

where  $C_D$  = drag coefficient for the liquid at the throat entrance, dimensionless  
 $N_{Reo}$  = Reynolds' number for the liquid droplet at the throat inlet, dimensionless

$$N_{Reo} = v_{g\tau} d_d / v_g \quad (3.8)$$

where  $N_{Reo}$  = Reynolds' number for the liquid droplet at the throat inlet, dimensionless  
 $v_{g\tau}$  = gas velocity in the throat, cm/s  
 $d_d$  = droplet diameter, cm  
 $v_g$  = gas kinematic viscosity, cm<sup>2</sup>/s

$$d_{pg} = d_{ps}(C_f \times \rho_p)^{0.5} \quad (3.9)$$

where  $d_{pg}$  = particle aerodynamic geometric mean diameter,  $\mu\text{mA}$  [where A [=] (g/cm<sup>3</sup>)<sup>0.5</sup>, where [=] means "has the units of"]  
 $d_{ps}$  = particle physical, or Stokes' diameter,  $\mu\text{m}$   
 $C_f$  = Cunningham slip correction factor, dimensionless  
 $\rho_p$  = particle density, g/cm<sup>3</sup>

$$C_f = 1 + [(6.21 \times 10^{-4})T] / d_{ps} \quad (3.10)$$

where  $C_f$  = Cunningham slip correction factor, dimensionless  
 $T$  = absolute temperature, K  
 $d_{ps}$  = particle physical, or Stokes' diameter,  $\mu\text{m}$

The following example illustrates how to use the infinite throat model to predict the performance of a venturi scrubber. When using the equations given in the model, make sure that the units for each equation are consistent.

**EXAMPLE:** infinite throat model for venturi collection efficiency calculation. Cheeps Disposal Inc. is planning to install a hazardous-waste incinerator that will burn both liquid and solid waste materials. The exhaust gas from the incinerator will pass through a quench spray and then into a venturi scrubber. Caustic will be added to the scrubbing liquor to remove any HCl

from the flue gas and to control the pH of the scrubbing liquor. The uncontrolled particulate emissions leaving the incinerator are estimated to be 1100 kg/h (maximum average). The local air pollution regulation states that particulate emissions must not exceed 10 kg/h. Using the following data, estimate the overall collection efficiency of the required scrubbing system (EPA-84/03, p. 9-8).

**Given conditions**

- mass-median particle size (physical)  $d_{ps} = 9.0 \mu\text{m}$
- geometric standard deviation  $\sigma_{gm} = 2.5$
- particle density  $\rho_p = 1.9 \text{ g/cm}^3$
- gas viscosity  $\mu_g = 2.0 \times 10^{-4} \text{ g/cm-s}$
- gas kinematic viscosity  $\nu_g = 0.2 \text{ cm}^2/\text{s}$
- gas density  $\rho_g = 1.0 \text{ kg/m}^3$
- gas flow rate  $Q_G = 15 \text{ m}^3/\text{s}$
- gas velocity in venturi throat  $v_{gr} = 9000 \text{ cm/s}$
- gas temperature (in venturi)  $T_g = 80^\circ\text{C}$
- water temperature  $T_l = 30^\circ\text{C}$
- liquid density  $\rho_l = 1000 \text{ kg/m}^3$
- liquid flow rate  $Q_L = 0.014 \text{ m}^3/\text{s}$
- liquid-to-gas ratio  $L/G = 0.0009 \text{ L/m}^3$

*Solution:*

1. Calculate the Cunningham slip correction factor.

The mass-median particle size (physical)  $d_{ps}$  is  $9.0 \mu\text{m}$ . Since the particle aerodynamic geometric mean diameter  $d_{pg}$  is not known, you must use Eq. (3.9) to calculate  $d_{pg}$ , and Eq. (3.10) to calculate the Cunningham slip correction factor  $C_f$ .

From Eq. (3.10)

$$\begin{aligned} C_f &= 1 + [(6.21 \times 10^{-4})T]/d_{ps} \\ &= 1 + [(6.21 \times 10^{-4})(273 + 80)]/9 \\ &= 1.024 \end{aligned}$$

From Eq. (3.9)

$$\begin{aligned} d_{pg} &= d_{ps}(C_f \times \rho_p)^{0.5} \\ &= 9 \mu\text{m}(1.024 \times 1.9 \text{ g/cm}^3)^{0.5} \\ &= 12.6 \mu\text{m} \\ &= 12.6 \times 10^{-4} \text{ cm} \end{aligned}$$

where  $A[=](\text{g/cm}^3)^{0.5}$ .

*Note:* This step would not have been required if the particle diameter had been given as the aerodynamic geometric mean diameter  $d_{pg}$  and expressed in units of  $\mu\text{m}$ .

2. Calculate the droplet diameter  $d_d$  from Eq. (3.3) (Nukiyama and Tanasawa equation).

From Eq. (3.3)

$$d_d = 50/v_{gr} + 91.8(L/G)^{1.5}$$

where  $d_d$  = droplet diameter, cm  
 $v_{gr}$  = gas velocity in the throat, cm/s  
 $L/G$  = liquid-to-gas ratio, dimensionless

$$\begin{aligned}d_d &= 50/(9000 \text{ cm/s}) + 91.8(0.0009)^{1.5} \\ &= 0.0080 \text{ cm}\end{aligned}$$

3. Calculate the inertial parameter for the mass-median diameter  $K_{pg}$ , using Eq. (3.6).  
 From Eq. (3.6)

$$K_{pg} = (d_{pg})^2 v_{gr} / (9\mu_g d_d)$$

where  $K_{pg}$  = inertial parameter for mass-median diameter, dimensionless  
 $d_{pg}$  = particle aerodynamic geometric mean diameter, cmA  
 $v_{gr}$  = gas velocity in the throat, cm/s  
 $\mu_g$  = gas viscosity, g/s-cm  
 $d_d$  = droplet diameter, cm

$$\begin{aligned}K_{pg} &= (12.6 \times 10^{-4} \text{ cm})^2 (9000 \text{ cm/s}) / \{ [9(2.0 \times 10^{-4} \text{ (g/cm-s)})(0.008 \text{ cm})] \} \\ &= 992\end{aligned}$$

4. Calculate the Reynolds' number  $N_{Reo}$ , using Eq. (3.8).  
 From Eq. (3.8)

$$N_{Reo} = v_{gr} d_d / \nu_g$$

where  $N_{Reo}$  = Reynolds' number for the liquid droplet at the throat inlet, dimensionless  
 $v_{gr}$  = gas velocity in the throat, cm/s  
 $d_d$  = droplet diameter, cm  
 $\nu_g$  = gas kinematic viscosity, cm<sup>2</sup>/s

$$\begin{aligned}N_{Reo} &= v_{gr} d_d / \nu_g \\ &= (9000 \text{ cm/s})(0.008 \text{ cm}) / (0.2 \text{ cm}^2/\text{s}) \\ &= 360\end{aligned}$$

5. Calculate the drag coefficient for the liquid at the throat entrance  $C_D$  using Eq. (3.7).  
 From Eq. (3.7)

$$C_D = 0.22 + (24/N_{Reo})[1 + 0.15(N_{Reo})^{0.6}]$$

where  $C_D$  = drag coefficient for the liquid at the throat entrance, dimensionless  
 $N_{Reo}$  = Reynolds' number for the liquid droplet at the throat inlet, dimensionless

$$\begin{aligned}C_D &= 0.22 + (24/N_{Reo})[1 + 0.15(N_{Reo})^{0.6}] \\ &= 0.22 + (24/360)[(1 + 0.15(360)^{0.6})] \\ &= 0.628\end{aligned}$$

6. Now calculate the parameter characterizing the liquid-to-gas ratio  $B$ , using Eq. (3.4).  
 From Eq. (3.4)

$$B = (L/G)\rho_l / (\rho_g C_D)$$

where  $B$  = parameter characterizing liquid-to-gas ratio, dimensionless  
 $L/G$  = liquid-to-gas ratio, dimensionless

$\rho_g$  = gas density, g/cm<sup>3</sup>  
 $\rho_l$  = liquid density, g/cm<sup>3</sup>  
 $C_D$  = drag coefficient for the liquid at the throat entrance, dimensionless

$$\begin{aligned}
 B &= (L/G)\rho_l/(\rho_g C_D) \\
 &= (0.0009)(1000 \text{ kg/m}^3)/(1.0 \text{ kg/m}^3)(0.628) \\
 &= 1.43
 \end{aligned}$$

7. The geometric standard deviation  $\sigma_{gm}$  is 2.5. The overall penetration  $P_t$  can be found from Fig. 3.4.

$$\sigma_{gm} = 2.5$$

$$B = 1.43$$

$$K_{pg} = 992$$

Read  $P_t^* = 0.008$  from Fig. 3.4

FIGURE 3.4 Overall penetration,  $P_t^*$ , for  $\sigma_{gm} = 2.5$ .

8. The collection efficiency can be calculated using the equation

$$\begin{aligned}\eta &= 1 - P_t^* \\ &= 1 - 0.008 \\ &= 0.992 \\ &= 99.2\%\end{aligned}$$

9. Compare with regulatory standards

The local regulations state that the particulate emissions cannot exceed 10 kg/h. The required collection efficiency can be calculated by using

$$\eta_{\text{required}} = (\text{dust}_{\text{in}} - \text{dust}_{\text{out}}) / \text{dust}_{\text{in}}$$

where  $\text{dust}_{\text{in}}$  = dust concentration leading into the venturi  
 $\text{dust}_{\text{out}}$  = dust concentration leaving the venturi

$$\begin{aligned}\eta_{\text{required}} &= (1100 \text{ kg/h} - 10 \text{ kg/h}) / 1100 \text{ kg/h} \\ &= 0.991\end{aligned}$$

The estimated efficiency of the venturi scrubber is slightly higher than the required efficiency.

**Cut power method.** One empirical correlation that has been used to predict the collection efficiency of a scrubber is the cut power method. In this method, penetration is a function of the cut diameter of the particles to be collected by the scrubber. The cut diameter is the diameter of the particles that are collected by the scrubber with at least 50% efficiency. Since scrubbers have limits to the size of particles they can collect, knowledge of the cut diameter is useful in evaluating the scrubbing system (EPA-84/03, p. 9-11).

In the cut power method, penetration is a function of the particle diameter and is given as

$$P_t = \exp[-A_{\text{cut}} d_p (B_{\text{cut}})] \quad (3.11)$$

where  $P_t$  = penetration  
 $A_{\text{cut}}$  = parameter characterizing the particle size distribution  
 $B_{\text{cut}}$  = empirically determined constant, depending on the scrubber design  
 $d_p$  = aerodynamic diameter of the particle

Penetration, calculated by Eq. (3.11), is given for only one particle size ( $d_p$ ). To obtain the overall penetration, the equation can be integrated over the log-normal particle size distribution. By mathematically integrating  $P_t$  over a log-normal distribution of particles and by varying the geometric standard deviation  $\sigma_{\text{gm}}$  and the geometric mean particle diameter  $d_{\text{pg}}$ , the overall penetration  $P_t^*$  can be obtained.

**EXAMPLE 1:** cut power method. Given similar conditions used in the example in the infinite throat model section, estimate the cut diameter for a venturi scrubber. The data below are approximate (EPA-84/03, p. 9-12).

geometric standard deviation  $\sigma_{\text{gm}} = 2.5$   
particle aerodynamic geometric mean diameter  $d_{\text{pg}} = 12.6 \mu\text{mA}$   
required efficiency  $\eta = 99.1\%$  or 0.991

*Solution:*

1. For an efficiency of 99.1%, the overall penetration can be calculated from

$$\begin{aligned} P_t^* &= 1 - \eta \\ &= 1 - 0.991 \\ &= 0.009 \end{aligned}$$

2. The overall penetration is 0.009, and the geometric standard deviation is 2.5. Use the figures on EPA-84/03, p. 9-12 to read  $(d_p)_{\text{cut}}/d_{\text{pg}}$ .

$$\begin{aligned} P_t^* &= 0.009 \\ \sigma_{\text{gm}} &= 2.5 \\ (d_p)_{\text{cut}}/d_{\text{pg}} &= 0.09 \end{aligned}$$

3. The cut diameter  $(d_p)_{\text{cut}}$  is calculated from

$$\begin{aligned} (d_p)_{\text{cut}}/d_{\text{pg}} &= 0.09 \\ (d_p)_{\text{cut}} &= (0.09)d_{\text{pg}} \\ (d_p)_{\text{cut}} &= 0.09(12.6 \mu\text{mA}) = 1.134 \mu\text{mA} \end{aligned}$$

**EXAMPLE 2:** cut diameter. A particle size analysis indicated that (EPA-81/10, p. 9-14)

$$\begin{aligned} d_{\text{gm}} \text{ (geometric mean particle diameter)} &= 12 \mu\text{m} \\ \sigma_{\text{gm}} \text{ (standard deviation of the distribution)} &= 3.0 \\ \eta \text{ (wet collector efficiency)} &= 99\% \end{aligned}$$

If a collection efficiency of 99% is required to meet emission standards, what would the cut diameter of the scrubber have to be?

*Solution:*

1. Write the penetration ( $P_t$ ) equation

$$\begin{aligned} P_t^* &= 1 - \eta \\ &= 1 - 0.99 \\ &= 0.01 \end{aligned}$$

Use the figures on EPA-84/03, p. 9-12 to read  $(d_p)_{\text{cut}}/d_{\text{gm}}$ , for  $P_t^* = 0.01$  and  $\sigma_{\text{gm}} = 3.0$ ;  $[d_p]_{\text{cut}}/d_{\text{gm}}$  equals 0.063. Since  $d_{\text{gm}} = 12 \mu\text{m}$ , then the scrubber must be able to collect particles of size  $0.063 \times 12 = 0.76 \mu\text{m}$  with at least 50% efficiency to achieve an overall scrubber efficiency of 99%.

**Contact power theory.** Theoretical approaches based on the dynamic interactions between particles and water droplets are limited in applicability, since actual scrubber systems are very complex. For example, the Johnstone and cut power methods assume that the water droplets are uniformly distributed over the cross-section of the scrubber. The actual turbulence and eddies existing in the contact zone are not considered (EPA-81/10, p. 9-15).

A more general theory which avoids the details of how particles and droplets hit each other, is the contact power theory. This theory indicates that collection efficiency is a function of how much power is used, and not the details of design. This has a number of implications in the evaluation and selection of wet collectors. Once it is realized that a certain amount of power (or pressure loss) is needed for a required collection efficiency, the claims about specially

located nozzles, baffles, etc., can be evaluated more objectively. The choice between two different scrubbers with the same power requirements may depend primarily on ease of maintenance (EPA-81/10, p. 9-16; EPA-84/03, p. 9-13).

The total pressure loss is expressed in terms of the power expended to inject the liquid into the scrubber plus the power needed to move the process gas through the system (EPA-84/03, p. 9-13):

$$\begin{aligned} P_T &= P_G + P_L \\ P_G &= 0.157\Delta p \\ P_L &= 0.583p_L(Q_L/Q_G) \end{aligned} \quad (3.12)$$

where  $P_T$  = total contacting power (total pressure loss), kWh/100 m<sup>3</sup> (hp/1000 acfm)  
 $P_G$  = power input from gas stream, kWh/100 m<sup>3</sup> (hp/1000 acfm)  
 $P_L$  = contacting power from liquid injection, kWh/100 m<sup>3</sup> (hp/1000 acfm)

*Note:* The total pressure loss  $P_T$  should not be confused with penetration  $P_t$ , which is defined in the previous section.

The power expended in moving the gas through the system  $P_G$  is expressed in terms of the scrubber pressure drop:

$$P_G = 2.724 \times 10^{-4} \Delta p, \text{ kWh/1000 m}^3 \text{ (metric units)} \quad (3.13)$$

or

$$P_G = 0.1575\Delta p, \text{ hp/1000 acfm (British/US Customary units)}$$

where  $\Delta p$  = pressure drop, kPa (in. H<sub>2</sub>O)

The power expended in the liquid stream  $P_L$  is expressed as

$$P_L = 0.28p_L(Q_L/Q_G), \text{ kWh/1000 m}^3 \text{ (metric units)} \quad (3.14)$$

or

$$P_L = 0.583p_L(Q_L/Q_G), \text{ hp/1000 acfm (British/US customary units)}$$

where  $p_L$  = liquid inlet pressure, 100 kPa (lb/in<sup>2</sup>)  
 $Q_L$  = liquid feed rate, m<sup>3</sup>/h (gal/min)  
 $Q_G$  = gas flow rate, m<sup>3</sup>/h (ft<sup>3</sup>/min)

The constants given in the expressions for  $P_G$  and  $P_L$  incorporate conversion factors to put the terms on a consistent basis. The total power can therefore be expressed as

$$\begin{aligned} P_T &= P_G + P_L \\ &= 2.724 \times 10^{-4} \Delta p + 0.28p_L(Q_L/Q_G), \text{ kWh/1000 m}^3 \text{ (metric units)} \end{aligned} \quad (3.15)$$

or

$$P_T = 0.1575\Delta p + 0.583p_L(Q_L/Q_G), \text{ hp/1000 acfm (British/US customary units)}$$

The problem now is to correlate this with scrubber efficiency.

An equation given in Sec. 2.1 shows that efficiency is an exponential function of the system variables for most types of collectors:

$$\eta = 1 - \exp[-f(\text{system})] \quad (3.16)$$

where  $f(\text{system})$  is defined as

$$f(\text{system}) = N_t = \alpha(P_T)^\beta \quad (3.17)$$

where  $N_t$  = number of transfer units

$P_T$  = total contacting power

$\alpha$  and  $\beta$  = empirical constants that are determined from experiment and depend on the characteristics of the particles

The efficiency then becomes

$$\eta = 1 - \exp[-\alpha(P_T)^\beta] \quad (3.18)$$

The values of  $\alpha$  and  $\beta$  which can be used in either the metric or British units can be found from the table in EPA-84/03, p. 9-15.

The scrubber collection efficiency is also expressed as the number of transfer units (EPA-81/10, p. 9-17):

$$N_t = \alpha(P_T)^\beta = \ln[1/(1 - \eta)] \quad (3.19)$$

where  $N_t$  = number of transfer units

$\eta$  = fractional collection efficiency

$\alpha, \beta$  = characteristic parameters for the type of particulates being collected

The contact power theory cannot predict efficiency from a given particle size distribution as can the cut power and Johnstone theories. The contact power theory gives a relationship which is independent of the size of the scrubber. With this observation, a small pilot scrubber could first be used to determine the pressure drop needed for the required collection efficiency. The full-scale scrubber design could then be scaled up from the pilot information. As an example, consider the following problem.

**EXAMPLE:** contact power theory. A wet scrubber is to be used to control particulate emissions from a foundry cupola. Stack test results reveal that the particulate emissions must be reduced by 85% to meet emission standards. If a 100 acfm pilot unit is operated with a water flow rate of 0.5 gal/min at a water pressure of 80 psi, what pressure drop ( $\Delta p$ ) would be needed across a 10,000 acfm scrubber unit (EPA-84/03, p. 9-15; EPA-81/10, p. 9-18)?

*Solution:*

1. From the table in EPA-84/03, p. 9-15, read the  $\alpha$  and  $\beta$  parameters for foundry cupola dust.

$$\alpha = 1.35$$

$$\beta = 0.621$$

2. Calculate the number of transfer units  $N_t$  using Eq. (3.16).

$$\eta = 1 - \exp(-N_t)$$

$$N_t = \ln[1/(1 - \eta)]$$

$$= \ln[1/(1 - 0.85)]$$

$$= 1.896$$

3. Calculate the total contacting power  $P_T$  using Eq. (3.17).

$$\begin{aligned} N_t &= \alpha(P_T)^\beta \\ 1.896 &= 1.35(P_T)^{0.621} \\ 1.404 &= (P_T)^{0.621} \\ \ln 1.404 &= 0.621(\ln P_T) \\ 0.3393 &= 0.621(\ln P_T) \\ 0.5464 &= \ln P_T \\ P_T &= 1.73 \text{ hp}/1000 \text{ acfm} \end{aligned}$$

4. Calculate the pressure drop  $\Delta p$  using Eq. (3.15)

$$\begin{aligned} P_T &= 0.1575\Delta p + 0.583p_L(Q_L/Q_G) \\ 1.73 &= 0.1575\Delta p + 0.583(80)(0.5/100) \\ \Delta p &= 9.5 \text{ in. H}_2\text{O} \end{aligned}$$

**Pressure drop.** As discussed earlier, a number of factors affect particle capture in a scrubber. One of the most important, especially for the contact power theory, is pressure drop. Pressure drop is the difference in pressure between the inlet and the outlet of the scrubber. The pressure drop represents the energy expended in the scrubbing process. From the contact power theory, the higher the pressure drop, the more efficient the scrubber. However, the higher the pressure drop, the higher the operating costs. Most scrubbing systems operate at pressure drops just high enough to ensure adequate collection of particles (EPA-84/03, p. 9-17).

The following factors affect the pressure drop in a scrubber:

- scrubber design and geometry
- gas velocity
- liquid-to-gas ratio

As with calculating collection efficiency, no one equation can predict the pressure drop for all scrubbing systems.

Many theoretical and empirical relationships are available for estimating the pressure drop across a scrubber. Generally, the most accurate are those developed by scrubber manufacturers for their particular scrubbing systems. Due to the lack of validated models, it is recommended that users consult the vendor's literature to estimate pressure drop for the particular scrubbing device of concern.

One expression was developed for venturis and is as follows:

$$\Delta p = 8.24 \times 10^{-4}(v_{g\tau})^2(L/G) \quad (\text{metric units}) \quad (3.20)$$

or

$$\Delta p = 4.0 \times 10^{-5}(v_{g\tau})^2(L/G) \quad (\text{British units}) \quad (3.21)$$

where  $\Delta p$  = pressure drop, cm H<sub>2</sub>O (in. H<sub>2</sub>O)  
 $v_{g\tau}$  = velocity of gas in the venturi throat, cm/s (ft/s)  
 $L/G$  = liquid-to-gas ratio, dimensionless [actually in L/m<sup>3</sup> (gal/1000 ft<sup>3</sup>)]

Using Eq. (3.20) for the conditions given in the example in the infinite throat model section, we obtain

$$\begin{aligned}v_{gr} &= 9000 \text{ cm/s} \\L/G &= 0.0009 \text{ L/m}^3 \\ \Delta p &= 8.24 \times 10^{-4} (9000)^2 (0.0009) \\ &= 60 \text{ cm H}_2\text{O}\end{aligned}$$

### 3 WET ABSORPTION FOR GASEOUS EMISSION CONTROL

Similar to the wet absorption process for particulate emission control, absorption devices used to remove gaseous contaminants are referred to as *absorbers* or *wet scrubbers*. The process of dissolving gaseous pollutants in a liquid is referred to as *absorption*. Absorption is a mass transfer operation. Mass transfer can be compared to heat transfer in that both occur because a system is trying to reach equilibrium conditions. For example, in heat transfer, if a hot slab of metal is placed on top of a cold slab, heat energy will be transferred from the hot slab to the cold slab until both are at the same temperature (equilibrium). In absorption, mass instead of heat is transferred as a result of a concentration difference, rather than a heat energy difference. Absorption continues as long as a concentration differential exists between the liquid and the gas from which the contaminant is being removed. In absorption, equilibrium depends on the solubility of the pollutant in the liquid (EPA-84/03, p. 1-7).

To remove a gaseous pollutant by absorption, the exhaust stream must be passed through (brought into contact with) a liquid (Fig. 3.5). The process involves three steps.

- In the first step, the gaseous pollutant diffuses from the bulk area of the gas phase to the gas-liquid interface.
- In the second step, the gas moves (transfers) across the interface to the liquid phase. This step occurs extremely rapidly once the gas molecules (pollutants) arrive at the interface area.
- In the third step, the gas diffuses into the bulk area of the liquid, thus making room for additional gas molecules to be absorbed. The rate of absorption (mass transfer of the

FIGURE 3.5 Gas collection by absorption (EPA-84/03, p. 1-7).

pollutant from the gas phase to the liquid phase) depends on the diffusion rates of the pollutant in the gas phase (first step) and in the liquid phase (third step).

To enhance gas diffusion and, therefore, absorption, the steps include:

- Providing a large interfacial contact area between the gas and liquid phases.
- Providing good mixing of the gas and liquid phases (turbulence).
- Allowing sufficient residence, or contact, time between the phases for absorption to occur.

Two of these three gas-collection mechanisms—large contact area and good mixing—are also important for particle collection. The third factor, sufficient residence time, works in direct opposition to efficient particle collection. To increase residence time, the relative velocity of the gas and liquid streams must be reduced. Therefore, achieving a high removal efficiency for both gaseous and particulate pollutants at the same time in the same scrubber is extremely difficult unless the gaseous pollutant is very soluble in the liquid.

As previously mentioned, a very important factor affecting the amount of a pollutant that can be absorbed is its solubility. Solubility governs the amount of liquid (liquid-to-gas ratio) required and the necessary contact time. More soluble gases require less liquid. Also, more soluble gases will be absorbed faster. Solubility is a function of both the temperature and, to a lesser extent, the pressure of the system. As temperature increases, the amount of gas that can be absorbed by a liquid decreases. From the ideal gas law: as temperature increases, the volume of a gas also increases; therefore, at a higher temperature, gas volume increases and less gas is absorbed. For this reason, some absorption systems use inlet quench sprays to cool the incoming exhaust stream, thereby increasing absorption efficiency. Pressure affects the solubility of a gas in the opposite manner. When the pressure of a system is increased, the amount of gas absorbed generally increases.

#### **4 WET SCRUBBERS FOR PARTICULATE AND GASEOUS EMISSION CONTROL**

---

Although many unique wet collector systems are available, commercially designed wet collectors use only a few basic components. Some of these components are (EPA-84/03, p. 2-1; EPA-81/10, p. 9-22):

- Spray nozzles
- Venturi constrictions
- Impingement surfaces
  - Plates
  - Baffles
  - Bubble caps
  - Packing
- Cyclonic openings
- Spray-inducing orifices
- Mechanically-driven rotors

The many possible combinations of these basic pieces of hardware has led to the development of numerous types of wet collectors. This is an advantage for the process engineer, who can specify a system in terms of size, cost, and collection efficiency. However, the profusion of devices can also be a disadvantage, especially when confronted with advertisements for such equipment. In this competitive market, the various claims and counterclaims can be confusing.

Scrubbers can be categorized in terms of:

- Power requirements for bringing the pollutant gas stream into contact with the liquid
- Pressure drop

*Power requirement:* Although wet collection systems may vary greatly in complexity, most of them follow a general rule: collection efficiency increases with increased power input. Power is defined as energy applied per unit time. Energy from the gas stream, energy from the liquid stream, or energy from a mechanically-driven rotor is used to bring gas stream particles into contact with the scrubbing liquor. The total energy applied per unit time is the *contacting power*. Scrubbers can be categorized in terms of how this power is applied to the system. The categories are given in Table 3.4.

*Pressure drop:* Scrubbers can also be classed by gas-phase pressure drop. Pressure drop, or gas-side pressure drop, refers to the pressure difference that occurs as the exhaust gas is pushed or pulled through the scrubber, disregarding the pressure that would be used for pumping or spraying the liquid into the scrubber. Pressure drop and gas-side pressure drop are used interchangeably. There are three categories of pressure drops:

- Low-energy scrubbers, having a pressure drop of less than 5 in. (12.7 cm) of water
- Medium-energy scrubbers, having pressure drops between 5 and 15 in. (12.7 to 38.1 cm) of water
- High-energy scrubbers, having a pressure drop greater than 15 in. (38.1 cm) of water

**TABLE 3.4** Categories of Scrubbers and Energy Input

Wet collector type	Scrubbers using energy from
Gas-phase contacting scrubbers	Gas stream
Liquid-phase contacting scrubbers	Liquid stream
Liquid-phase/gas-phase contacting scrubbers	Gas and liquid streams
Mechanically-aided scrubbers	Mechanically-driven rotor

#### 4.1 Gas-Phase Contacting Scrubber

Scrubbers using the process gas stream to provide the energy for particle-liquid contact are known as *gas-phase contacting scrubbers*. By moving the gas across or through a liquid surface, the liquid is sheared to form small droplets. Particulate matter in the gas stream impacts on the larger droplets, which in turn are collected by cyclonic action or other means. A number of methods are used to develop this shearing action in a scrubber. The gas can be forced through cascades of liquid falling over flat plates. Holes can be punched in the plates and the gas can aspirate the water flowing over the plate, or the gas can be forced through constricted passages wetted with liquid such as in orifice and venturi scrubbers. Three collectors which work primarily by this action are

- Venturi scrubber
- Plate tower
- Orifice scrubber

*Venturi scrubber.* A venturi scrubber is designed to effectively use the energy from the exhaust stream to atomize the scrubbing liquid. Venturi devices have been used for over

100 years to measure fluid flow (venturi tubes derived their name from G. B. Venturi, an Italian physicist). In 1949, Johnstone and other researchers found that they could effectively use the venturi configuration to remove particles from an exhaust stream. Figure 3.6 illustrates a venturi configuration (EPA-84/09, p. 3-2; EPA-81/12, p. 4-42; EPA-81/10, p. 9-29).

A venturi scrubber consists of a converging section, a throat section, and a diverging section. The exhaust stream enters the converging section and, as the area decreases the gas velocity increases. The venturi is designed to force gas in and out of a constriction. Since the volumetric flow rate of gas  $Q$  must be the same throughout the system, the velocity of the gas must increase at the throat of the venturi.

$$Q_{\text{entrance}} = Q_{\text{throat}}$$

$$V_{\text{entrance}}A_{\text{entrance}} = V_{\text{throat}}A_{\text{throat}}$$

where  $A$  = area and  $V$  = velocity.

The above equation shows that the velocity at the throat must increase in order to make up for the decrease in area in the throat. Velocities at such a constriction can range from 200 to 800 ft/s (61 to 244 m/s). Now, if water is introduced into the throat, the gas forced to move at high velocity will shear the water into droplets. Particles in the gas stream then impact onto the droplets produced. Moving a large volume of gas through a small constriction gives a high velocity flow, but also a large pressure drop across the system. Collection efficiency for small particles increases with increased velocities (and corresponding increased pressure drops) since the water is sheared into more and smaller droplets than at lower velocities. The large number

FIGURE 3.6 Venturi with a wetted throat (EPA-81/12, p. 4-42).

of small droplets combined with the turbulence in the throat section provides numerous impaction targets for particle collection (EPA-81/10, p. 9-30).

Particle and gas removal occur in the throat section as the exhaust stream mixes with the fog of tiny liquid droplets. The exhaust stream then exits through the diverging section, where it is forced to slow down. Venturis can be used to collect both particulate and gaseous pollutants, but they are more effective in removing particles than in removing gaseous pollutants.

Liquid can be injected at the converging section or at the throat. Figure 3.6 also shows liquid injected at the converging section; thus, the liquid coats the venturi throat. This venturi is very effective for handling hot, dry exhaust gas that contains dust. The dust would have a tendency to cake on or abrade a dry throat. These venturis are sometimes referred to as having a wetted approach.

Figure 3.7 shows liquid injected at the venturi throat. Since it is sprayed at or just before the throat, it does not actually coat the throat surface. These throats are susceptible to solids buildup when the throat is dry. They are also susceptible to abrasion by dust particles. These venturis are best used when the exhaust stream is cool and moist. In this venturi, the relative particle-to-liquid velocity is the highest of any of the venturis; therefore, the smallest particles can be collected efficiently. These venturis are referred to as having a *non-wetted approach*.

Manufacturers have developed other modifications to the basic venturi design to maintain scrubber efficiency by changing the pressure drop for varying exhaust gas rates. Certain types of orifices that create more turbulence than a true venturi were found to be equally efficient for a given unit of energy consumed. Results of these findings led to the development of the annular-orifice, or adjustable throat, venturi scrubber (Fig. 3.8). The throat area is varied by moving a plunger, or adjustable disk, up or down in the throat, decreasing or increasing the

FIGURE 3.7 Venturi with throat sprays (EPA-84/03, p. 3-3).

FIGURE 3.8 Adjustable throat venturi with movable plunger (EPA-84/03, p. 3-5).

annular opening. Gas flows through the annular opening and atomizes liquid that is sprayed onto the plunger or swirled in from the top.

Venturis with round throats (Figs. 3.6 and 3.7) can handle exhaust flows as large as 68,000  $\text{m}^3/\text{h}$  (40,000 cfm). At exhaust flow rates greater than this, achieving uniform liquid distribution is difficult, unless additional weirs or baffles are used. To handle large exhaust flows, scrubbers designed with long, narrow, rectangular throats have been used. Figure 3.9 shows an adjustable throat rectangular venturi. In this scrubber, the throat area is varied by using a movable plate. A water-wash spray is used to continually wash collected material from the plate.

All venturi scrubbers require an entrainment separator because the high velocity of gas through the scrubber will have a tendency to exhaust the droplets. Cyclonic, mesh-pad, and blade separators are all used. Cyclonic separators, the most popular, are connected to the venturi vessel by a flooded elbow (Fig. 3.9). The liquid reduces abrasion of the elbow as the exhaust gas passes at high velocities from the venturi to the separator.

*Particle collection.* Venturis are the most commonly used scrubber for particle collection and are capable of achieving the highest particle collection efficiency of any wet scrubbing system. As the exhaust stream enters the throat, its velocity increases greatly, atomizing and turbulently mixing with any liquid present. The atomized liquid provides an enormous number of tiny droplets for the dust particles to impact on. These liquid droplets incorporating the particles must then be removed from the scrubber exhaust stream, generally by cyclonic separators.

Particle removal efficiency increases with increasing pressure drop (resulting in high gas velocity and turbulence). Venturis can be operated with pressure drops ranging from 12 to 250

**FIGURE 3.9** Adjustable rectangular throat venturi with movable plate and cyclonic separator (EPA-81/10, p. 9-34).

cm (5 to 100 in.) of water. Most venturis normally operate with pressure drops in the range of 50 to 150 cm (20 to 60 in.) of water. At these pressure drops, the gas velocity in the throat section is usually between 30 and 120 m/s (100 and 400 ft/s), or approximately 270 mph at the high end. These high pressure drops result in high operating costs.

The liquid-injection rate, or liquid-to-gas ratio (L/G), also affects particle collection. The liquid-injection rate depends on the temperature (evaporation losses) of the incoming exhaust stream and the particle concentration. Most venturi systems operate with an L/G ratio of 0.4 to 1.3 L/m<sup>3</sup> (3 to 10 gal/1000 ft<sup>3</sup>). L/G ratios less than 0.4 L/m<sup>3</sup> (3 gal/1000 ft<sup>3</sup>) are usually not sufficient to cover the throat, and adding more than 1.3 L/m<sup>3</sup> (10 gal/1000 ft<sup>3</sup>) does not usually significantly improve particle collection efficiency.

*Gas collection.* Venturi scrubbers can be used for removing gaseous pollutants; however, they are not used when removal of gaseous pollutants is the only concern. The high exhaust gas velocities in a venturi result in a very short contact time between the liquid and gas phases. This short contact time limits gas absorption. However, venturi scrubbers are very useful for simultaneous gaseous and particulate pollutant removal, especially when:

- Scaling could be a problem.
- A high concentration of dust is in the exhaust stream.
- The dust is sticky or has a tendency to plug openings.
- The gaseous contaminant is very soluble or chemically reactive with the liquid.

To maximize absorption of gases, venturis operate at a set of conditions different from those used to collect particles. Lower gas velocities and higher liquid-to-gas ratios are necessary for

efficient absorption. These L/G values should be approximately 2.7 to 5.3 L/m<sup>3</sup> (20 to 40 gal/1000 ft<sup>3</sup>). At high liquid-to-gas ratios, the gas velocity in the venturi throat is reduced (for a given pressure drop). The reduction in gas velocity allows for a longer contact time between phases.

In practice, a venturi scrubber for particle collection is usually connected with an absorber for acid gas scrubbing. Figure 3.10 shows the schematic of a venturi particle scrubber and an acid gas packed bed absorber.

**Venturi scrubber/acid gas absorber.** The system configurations for venturi particulate scrubbers and acid gas absorbers are illustrated schematically in Fig. 3.10. The basic configurations, with modifications, are used by other vendors as well. As illustrated, hot flue gas from the incinerator or waste heat boiler is directed to the venturi scrubber, which both quenches the hot gas and removes particulate matter. The venturi scrubber also provides partial collection of acid gases and other condensable flue gas constituents. Particulate collection occurs through a variety of fundamental mechanisms, but the predominant phenomenon is inertial impaction of particulate matter with water droplets sprayed into the venturi inlet. High collection efficiency of submicron particulate requires that the flue gas and particulate be accelerated to high velocity in the venturi throat region. The basic venturi configuration is used to minimize pressure loss associated with flow acceleration, but a venturi pressure drop on the order of 30 in. w.c. (7.5 kPa) is required to achieve 0.03 gr/dscf (0.07 g/dscm) particulate matter control and an even higher pressure drop is needed to achieve a 0.015 gr/dscf (0.03 g/dscm) limit (EPA-92/01, p. 77).

Acid gases such as HCl and SO<sub>2</sub> are only partially absorbed by the water spray in the venturi scrubber. High-level acid gas control is achieved in a counterflow acid gas absorber

FIGURE 3.10 Venturi particle scrubber with acid gas packed bed (EPA-89/03).

downstream of the venturi. As shown in Fig. 3.10, collection of acid gas tends to drop the pH of the scrubber liquor and thus an alkaline buffering reagent is provided for pH control. Either lime or sodium hydroxide may be used for this purpose with NaOH being the typical selection since it can be purchased and stored as a liquid. Common neutralization chemical reactions for sodium hydroxide and absorbed acid gases include

For lime-based systems, the neutralization reactions include

The rate of buffer reagent addition is controlled to maintain the scrubber liquor pH between 6.5 and 7.0. This is essentially stoichiometric for the above reactions. For sodium-based buffering, the resultant salts are water soluble and in many areas, scrubber blowdown can be discharged directly to the facility sewer system. This blowdown will, however, also contain insoluble material, including particulate matter captured in the venturi scrubber.

Since particulate matter is captured in the venturi by impaction with water droplets, any liquid escaping from the absorption tower contributes particulate to the facility exhaust. For this reason, one or more stages of mist elimination are included at the top of the absorption tower.

The total pressure drop across the absorption tower is typically small [4 to 6 in. w.c. (1.0–1.5 kPa)] in comparison with the pressure drop across the venturi scrubber. The total head loss across the air pollution control equipment plus that of the incinerator is provided by the induced draft fan. Flue gases enter the fan saturated but become unsaturated by the fan's pressure increase before exiting through the stack.

**EXAMPLE 1:** scrubber design of a venturi scrubber. You are required to calculate the throat area of a venturi scrubber to operate at a specified collection efficiency (EPA-84/09, p. 77).

#### Given conditions

volumetric flow rate of process gas stream = 11,040 acfm (at 68°F)

density of dust = 187 lb/ft<sup>3</sup>

liquid-to-gas ratio = 2 gal/1000 ft<sup>3</sup>

average particle size = 3.2 microns or  $\mu\text{m}$  ( $1.05 \times 10^{-5}$  ft)

water droplet size = 48 microns ( $1.575 \times 10^{-4}$  ft)

scrubber coefficient  $k = 0.14$

required collection efficiency = 98%

viscosity of gas =  $1.23 \times 10^{-5}$  lb/ft-s

Cunningham correction factor = 1.0

*Solution:*

1. Calculate the inertial impaction parameter,  $\psi$ , from Johnstone's equation.

Johnstone's equation describes the collection efficiency of a venturi scrubber (EPA-81/10, p. 9-11).

$$\eta = 1 - \exp[-k(Q_L/Q_G)\sqrt{\psi}]$$

where  $\eta$  = fractional collection efficiency  
 $k$  = correlation coefficient whose value depends on the system geometry and operating conditions, typically 0.1–0.2, 1000 acf/gal

$Q_L/Q_G$  = liquid-to-gas ratio, gal/1000 acf

$\psi = C_f \rho_p v (d_p)^2 / 18 d_d \mu$  = inertial impaction parameter

$\rho_p$  = particle density

$v$  = gas velocity at venturi throat, ft/s

$d_p$  = particle diameter, ft

$d_d$  = droplet diameter, ft

$\mu$  = gas viscosity, lb/ft-s

$C_f$  = Cunningham correction factor

2. From the calculated value of  $\psi$  (inertial impaction parameter) above, back calculate the gas velocity at the venturi throat  $v$ .

2.a. Calculate  $\psi$ .

$$\eta = 1 - \exp[-k(Q_L/Q_G)\sqrt{\psi}]$$

$$0.98 = 1 - \exp[-0.14(2)\sqrt{\psi}]$$

Solving for  $\psi$

$$\psi = 195.2$$

2.b. Calculate  $v$ .

$$\psi = C_f \rho_p v (d_p)^2 / 18 d_d \mu$$

$$v = 18 \psi d_d \mu / C_f \rho_p (d_p)^2$$

$$= (18)(195.2)(1.575 \times 10^{-4})(1.23 \times 10^{-5}) / (1)(187)(1.05 \times 10^{-5})^2$$

$$= 330.2 \text{ ft/s}$$

3. Calculate the throat area  $S$ , using gas velocity at the venturi throat  $v$ .

$$S = (\text{volumetric flowrate}) / (\text{velocity})$$

$$= 11,040 / (60)(330.2)$$

$$= 0.557 \text{ ft}^2$$

**EXAMPLE 2:** scrubber overall collection efficiency. You are requested to calculate the overall collection efficiency of a venturi scrubber which cleans a fly ash-laden gas stream, given the liquid-to-gas ratio, throat velocity, and particle size distribution (EPA-84/09, p. 79).

**Given conditions**

liquid-to-gas ratio = 8.5 gal/1000 ft<sup>3</sup>

throat velocity = 227 ft/s

particle density of fly ash = 43.7 lb/ft<sup>3</sup>

gas viscosity =  $1.5 \times 10^{-5}$  lb/ft-s

The particle size distribution data are given in Table 3.5.

Use Johnstone’s equation, with a  $k$  value of 0.2, to calculate the collection efficiency. Neglect the Cunningham correction factor effect.

**TABLE 3.5** Particle Size Distribution Data

$d_p$ , microns	Weight, %
< 0.1	0.01
0.1–0.5	0.21
0.5–1.0	0.78
1.0–5.0	13
5.0–10.0	16
10.0–15.0	12
15.0–20.0	8
> 20.0	50

*Solution:*

1. What are the parameters used in Johnstone’s equation?

Johnstone’s equation is

$$\eta = 1 - \exp[-k(Q_L/Q_G)\sqrt{\psi}]$$

- where
- $\eta$  = fractional collection efficiency
  - $k$  = correlation coefficient whose value depends on the system geometry and operating conditions, typically 0.1–0.2, 1000 acf/gal
  - $Q_L/Q_G$  = liquid-to-gas ratio, gal/1000 acf
  - $\psi = C_f \rho_p v (d_p)^2 / 18 d_d \mu$  = inertial impaction parameter
  - $\rho_p$  = particle density
  - $v$  = gas velocity at venturi throat, ft/s
  - $d_p$  = particle diameter, ft
  - $d_d$  = droplet diameter, ft
  - $\mu$  = gas viscosity, lb/ft-s
  - $C_f$  = Cunningham correction factor

1.a. Calculate the average droplet diameter in ft.

The average droplet diameter may be calculated using the equation:

$$d_d = (16,400/v) + 1.45(Q_L/Q_G)^{1.5}$$

where  $d_d$  = droplet diameter, microns

$$\begin{aligned} d_d &= (16,400/272) + 1.45(8.5)^{1.5} \\ &= 96.23 \text{ microns} \\ &= 3.156 \times 10^{-4} \text{ ft} \end{aligned}$$

1.b. Express the inertial impaction parameter in terms of  $d_p$  (ft).

$$\begin{aligned} \psi &= C_f \rho_p v (d_p)^2 / 18 d_d \mu \\ &= (1)(43.7)(272)(d_p)^2 / 18(3.156 \times 10^{-4})(1.5 \times 10^{-5}) \\ &= 1.3945 \times 10^{11} (d_p)^2 \end{aligned}$$

1.c. Express the fractional collection efficiency  $\eta_i$ , in terms of  $d_{pi}$  ( $d_p$  in ft).

$$\begin{aligned} \eta &= 1 - \exp[-k(Q_L/Q_G)\sqrt{\psi}] \\ \eta_i &= 1 - \exp[-(0.2)(8.5)(1.3945 \times 10^{11}(d_{pi})^2)^{0.5}] \\ &= 1 - \exp[-6.348 \times 10^5 d_{pi}] \end{aligned}$$

2. Calculate the collection efficiency for each particle size appearing in Table 3.5. For  $d_p = 0.05$  micron ( $1.64 \times 10^{-7}$  ft), for example:

$$\begin{aligned} \eta_i &= 1 - \exp[-6.348 \times 10^5 d_{pi}] \\ &= 1 - \exp[-6.348 \times 10^5 (1.64 \times 10^{-7})] \\ &= 0.0989 \\ w_i \eta_i &= 0.01(0.0989) = 9.89 \times 10^{-4} \end{aligned}$$

Table 3.6 shows the results of the above calculations for each particle size.

3. Calculate the overall collection efficiency.

$$\begin{aligned} \eta &= \sum w_i \eta_i \\ &= 9.89 \times 10^{-4} + 0.0975 + 0.6325 + 12.980 + 16.00 + 12.00 + 8.00 + 50.00 \\ &= 99.71\% \end{aligned}$$

**TABLE 3.6** Particle Size Data

$d_p$ , ft*	$w_i$ , %	$\eta_i$	$w_i \eta_i$ , %
$1.64 \times 10^{-7}$	0.01	0.0989	$9.89 \times 10^{-4}$
$9.84 \times 10^{-7}$	0.21	0.4645	0.0975
$2.62 \times 10^{-6}$	0.78	0.8109	0.6325
$9.84 \times 10^{-6}$	13	0.9981	12.98
$2.62 \times 10^{-5}$	16	1	16
$4.27 \times 10^{-5}$	12	1	12
$5.91 \times 10^{-5}$	8	1	8
$6.56 \times 10^{-5}$	50	1	50

\*The average particle diameter has been rounded to the nearest significant figure.

**EXAMPLE 3:** scrubber plan review. A vendor proposes to use a spray tower on a lime kiln operation to reduce the discharge of solids to the atmosphere. The inlet loading is to be reduced in order to meet state regulations. The vendor's design calls for a certain water pressure drop and gas pressure drop across the tower. You are requested to determine whether this spray tower will meet state regulations. If the spray tower does not meet state regulations, propose a set of operating conditions that will meet the regulations (EPA-84/09, p. 81).

**Given conditions**

- gas flow rate = 10,000 acfm
- water rate = 50 gal/min
- inlet loading = 5.0 grains/ft<sup>3</sup>
- maximum gas pressure drop across the unit = 15 in. H<sub>2</sub>O
- maximum water pressure drop across the unit = 100 psi
- water pressure drop = 80 psi
- gas pressure drop across the tower = 5.0 in. H<sub>2</sub>O

The state regulations require a maximum outlet loading of 0.05 grains/ft<sup>3</sup>. Assume that the contact power theory applies (EPA-81/10, p. 9-15).

*Solution:*

1. Calculate the collection efficiency based on the design data given by the vendor.

The contact power theory is an empirical approach relating particulate collection efficiency and pressure drop in wet scrubber systems. It assumes that particulate collection efficiency is a sole function of the total pressure loss for the unit.

$$\begin{aligned}
 P_T &= P_G + P_L \\
 P_G &= 0.157 \Delta p \\
 P_L &= 0.583 p_L (Q_L / Q_G)
 \end{aligned}$$

- where
- $P_T$  = total pressure loss, hp/1000 acfm
  - $P_G$  = contacting power based on gas stream energy input, hp/1000 acfm
  - $\Delta p$  = pressure drop across the scrubber, in. H<sub>2</sub>O
  - $P_L$  = contacting power based on liquid stream energy input, hp/1000 acfm
  - $p_L$  = liquid inlet pressure, psi
  - $Q_L$  = liquid feed rate, gal/min
  - $Q_G$  = gas flow rate, ft<sup>3</sup>/min

The scrubber collection efficiency is also expressed as the number of transfer units.

$$N_t = \alpha (P_T)^\beta = \ln[1/(1 - \eta)]$$

- where
- $N_t$  = number of transfer units
  - $\eta$  = fractional collection efficiency
  - $\alpha, \beta$  = characteristic parameters for the type of particulates being collected.

- 1.a. Calculate the total pressure loss  $P_T$

To calculate the total pressure loss, you need the contacting power for both the gas stream energy input and liquid stream energy input.

- 1.a.1. Calculate the contacting power based on the gas stream energy input  $P_G$  in hp/1000 acfm.

Since the pressure drop across the scrubber is given by the vendor, you can calculate  $P_G$ ,

$$\begin{aligned}
 P_G &= 0.157 \Delta p \\
 &= (0.157)(5.0) \\
 &= 0.785 \text{ hp/1000 acfm}
 \end{aligned}$$

- 1.a.2. Calculate the contacting power based on the liquid stream energy input  $P_L$ , in hp/1000 acfm.

Since the liquid inlet pressure and liquid-to-gas ratio are given, you can calculate  $P_L$

$$\begin{aligned} P_L &= 0.583p_L(Q_L/Q_G) \\ &= 0.583(80)(50/10,000) \\ &= 0.233 \text{ hp}/1000 \text{ acfm} \end{aligned}$$

1.a.3. Calculate the total pressure loss  $P_T$ , in hp/1000 acfm.

$$\begin{aligned} P_T &= P_G + P_L \\ &= 0.785 + 0.233 \\ &= 1.018 \text{ hp}/1000 \text{ acfm} \end{aligned}$$

1.b. Calculate the number of transfer units  $N_t$ .

$$N_t = \alpha(P_T)^\beta$$

The values of  $\alpha$  and  $\beta$  for a lime kiln operation are 1.47 and 1.05, respectively. These coefficients have been previously obtained from field test data. Therefore,

$$\begin{aligned} N_t &= \alpha(P_T)^\beta \\ &= (1.47)(1.018)^{1.05} \\ &= 1.50 \end{aligned}$$

1.c. Calculate the collection efficiency based on the design data given by the vendor.

$$\begin{aligned} N_t &= \ln[1/(1 - \eta)] \\ 1.50 &= \ln[1/(1 - \eta)] \end{aligned}$$

Solving for  $\eta$

$$\eta = 0.777 = 77.7\%$$

2. Calculate collection efficiency required by state regulations.

Since the inlet loading is known and the outlet loading is set by the regulations, the collection efficiency can be calculated readily.

$$\begin{aligned} \text{Collection efficiency} &= [( \text{inlet loading} - \text{outlet loading} ) / ( \text{inlet loading} )](100) \\ &= [(5.0 - 0.05) / (5.0)](100) \\ &= 99.0\% \end{aligned}$$

3. Does the spray tower meet the regulations?

No. The collection efficiency based on the design data given by the vendor should be higher than the collection efficiency required by the state regulations.

4. Assuming the spray tower does not meet the regulations, propose a set of operating conditions that will meet the regulations.

Note that the calculational procedure is now reversed.

4.a. Calculate the total pressure loss  $P_T$ , using the collection efficiency required by the regulations in hp/1000 acfm.

4.a.1. Calculate the number of transfer units for the efficiency required by the regulations.

$$\begin{aligned}
 N_t &= \ln[1/(1 - \eta)] \\
 &= \ln[1/(1 - 0.99)] \\
 &= 4.605
 \end{aligned}$$

4.a.2. Calculate the total pressure loss  $P_T$ , in hp/1000 acfm.

$$\begin{aligned}
 N_t &= \alpha(P_T)^\beta \\
 4.605 &= 1.47(P_T)^{1.05}
 \end{aligned}$$

Solving for  $P_T$

$$P_T = 2.96 \text{ hp/1000 acfm}$$

4.b. Calculate the contacting power based on the gas stream energy input  $P_G$ , using a  $\Delta p$  of 15 in.  $H_2O$ .

A pressure drop  $\Delta p$  of 15 in.  $H_2O$  is the maximum value allowed by the design

$$\begin{aligned}
 P_G &= 0.157 \Delta p \\
 &= (0.157)(15) \\
 &= 2.355 \text{ hp/1000 acfm}
 \end{aligned}$$

4.c. Calculate the contacting power based on the liquid stream energy input  $P_L$ .

$$\begin{aligned}
 P_L &= P_T - P_G \\
 &= 2.96 - 2.355 \\
 &= 0.605 \text{ hp/1000 acfm}
 \end{aligned}$$

4.d. Calculate  $Q_L/Q_G$  in gal/acf, using a  $p_L$  of 100 psi.

$$\begin{aligned}
 P_L &= 0.583 p_L (Q_L/Q_G) \\
 Q_L/Q_G &= P_L/0.583 p_L \\
 &= 0.605/(0.583)(100) \\
 &= 0.0104
 \end{aligned}$$

4.e. Determine the new water flow rate  $Q'_L$ , in gal/min.

$$\begin{aligned}
 (Q_L)' &= (Q_L/Q_G)(10,000 \text{ acfm}) \\
 &= 0.0104(10,000 \text{ acfm}) \\
 &= 104 \text{ gal/min}
 \end{aligned}$$

4.f. What are the new set of operating conditions that will meet the regulations?

$$\begin{aligned}
 Q'_L &= 104 \text{ gal/min} \\
 P_T &= 2.96 \text{ hp/1000 acfm}
 \end{aligned}$$

**Plate tower.** A plate tower is a vertical column with one or more plates (trays) mounted horizontally inside. As shown in Fig. 3.11, the exhaust stream enters at the bottom and flows upward, passing through openings in the plates. Liquid enters at the top of the tower, traveling across each plate, and reaches either the next plate below or the bottom of the tower. Pollutant

collection (mass transfer) occurs as the gas stream bubbles up through the openings and into the liquid layer on the plate. The smaller the bubbles and the more numerous they are, the more effective the mass transfer. The formation of smaller and more numerous bubbles promotes better mixing and exposes a larger gas-to-liquid surface area. As the gas disengages from the liquid, a froth is formed atop the liquid. Ideally, the gas and liquid leaving each plate are in equilibrium with each other at the conditions of that particular plate. Each plate acts as a separate absorption stage. The amount of absorption that can occur at one plate or stage is referred to as a *transfer unit*. Plate towers are very effective in removing gaseous pollutants and can be used simultaneously for particle removal. Plate towers may not be appropriate when particle removal is the only consideration (EPA-84/03, p. 3-15; EPA-81/10, p. 9-23; EPA-81/12, p. 4-52).

The function of the plates or trays is to disperse the gas into numerous bubbles, exposing a large surface for mass transfer. Plates, or trays, are designed in a variety of ways. The ones most commonly used for industrial sources are

- Sieve plate
- Impingement plate
- Bubble-cap plate
- Valve plate

The sieve, impingement, and bubble-cap plates do not have moving parts, while the valve plates have liftable caps above the opening in the plate. Plate openings can range from 0.32 to 2.50 cm (0.125 to 1.0 in.) in diameter for the sieve plate. Openings for the other plate designs are generally larger.

*Sieve plate:* Sieve plates contain approximately 6456–32,280 holes per square meter (600–3000 per square foot) of surface. Exhaust gas rises through these small holes and contacts the liquid at the holes. The gas atomizes the liquid, forming a froth with droplets ranging from 10 to 100  $\mu\text{m}$  in diameter. Particle collection efficiency increases as the size of the sieve opening decreases. This is because of an increasing gas velocity and because smaller droplets are formed. Sieve plates with large openings will not become plugged as easily as will other plate designs. Figure 3.12A depicts gas–liquid contact on a sieve plate.

*Impingement plate:* Impingement plates are similar to sieve plates with the addition of an impaction target placed above each hole in the plate (Fig. 3.12B). The gas coming up through the hole forces the liquid on the plate up against the target (impingement surface). This design increases the mixing of the gas and liquid, provides an additional contact zone, and creates more liquid droplets.

*Bubble-cap plate:* In the bubble-cap plate design, the exhaust gas enters each cap through a riser around each hole in the plate and exits from several slots in each cap (Fig. 3.13A). This combination of caps and risers creates a bubbly froth that allows good gas–liquid mixing, regardless of the gas-to-liquid ratio. In addition, the caps provide a longer gas–liquid contact than either sieves or impingement plates, thus increasing absorption efficiency. Plugging and corrosion can be a problem for bubble-cap plates because of this more complex design.

*Valve plate:* In the valve plate design, the exhaust gas passes through small holes in the plate, pushing up against a metal valve that covers each hole. The metal valve moves up and down with the gas flow. The valve is limited in its vertical movement by legs attached to the plate (Fig. 3.13B); therefore, the liftable valve acts as a variable orifice. Caps are available in different weights to provide flexibility for varying exhaust gas flow rates. Floating valves increase gaseous pollutant collection efficiency by providing adequate gas–liquid contact time, regardless of the exhaust gas flow rate. This design is also suited for very small particle collection; however, valves will plug if large particles are in the exhaust stream. Wear and

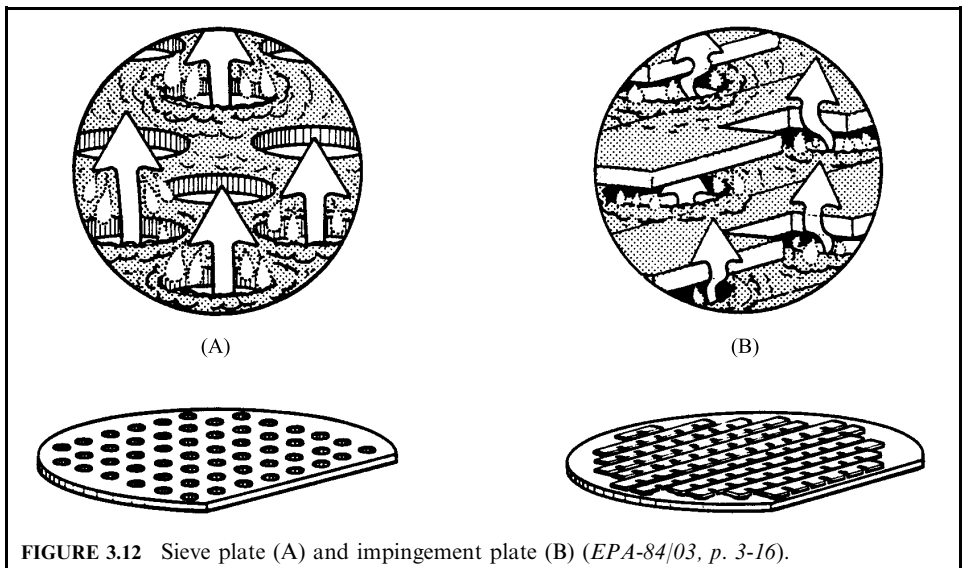

FIGURE 3.12 Sieve plate (A) and impingement plate (B) (EPA-84/03, p. 3-16).

FIGURE 3.13 Bubble-cap plate (A) and valve plate (B) (EPA-84/03, p. 3-17).

corrosion are also a problem for the retaining legs. Valve plates are more expensive than sieve and impingement plates, but less expensive than bubble-cap plates.

Plate towers, like packed towers, can achieve a high removal efficiency even if the gaseous contaminant is relatively insoluble. Therefore, plate towers are used to control emissions from many of the same processes that use packed towers, such as acid plants, fertilizer production plants, the chemical industry and petroleum refineries.

Several advantages and disadvantages must be considered when choosing a plate tower instead of a packed tower for a given control operation. The following list gives some factors used in comparing plate towers with packed towers.

- Plate towers are able to handle particulate matter and other solids better than packed towers. Maintenance openings can be installed so that the plates may be easily cleaned.
- Plate towers are chosen for operations that require a large number of transfer units or that must handle large gas volumes. Packed towers can experience channeling problems if the diameter or height of the tower is too large. Redistribution trays must be installed in large-diameter and tall packed towers to avoid channeling.
- The total weight of a plate tower is less than that of a comparable packed tower.
- Packed towers are much cheaper to construct if corrosive substances are to be handled. Packed towers can be constructed with a fiberglass-reinforced polyester shell, which is generally about half the cost of a carbon steel plate tower.
- Plate towers can handle volume and temperature fluctuations better than packed towers. Expansion or contraction due to temperature changes can crush or melt packing material.

*Particle collection.* Particles are collected in plate towers as the exhaust gas atomizes the liquid flowing over the holes in the plates. The atomized droplets serve as impaction targets for the particles. Plate towers are considered to be medium-energy scrubbers having moderate particle collection efficiencies. Collection efficiency does not significantly increase by increasing the number of plates over two or three. Collection efficiency can be increased by decreasing the hole size and increasing the number of holes per plate. This produces more liquid droplets

of a smaller size and increases the gas velocity through the plate; however, it also increases the pressure drop of the system.

**Gas collection.** Plate towers are very effective for removing gaseous pollutants from an exhaust stream. They can easily achieve greater than 98% removal in many applications. Absorption occurs as the exhaust stream bubbles up through the liquid on the plates and contacts the atomized liquid droplets. This action provides intimate contact between the exhaust gas and liquid streams, allowing the liquid on each plate to absorb the pollutant gas. Each plate acts as a separate absorption stage; therefore, absorption efficiency can be increased by adding plates. Absorption efficiency can also be improved by adding more liquid or by increasing the pressure drop across each plate, which increases the gas-liquid contact.

**Orifice scrubber.** In orifice scrubbers, the exhaust stream from the process is forced through a pool of liquid, usually water. The exhaust stream moves through restricted passages, or orifices, to disperse and atomize the water into droplets. These scrubbers are also called *self-induced spray*, *inertial*, or *submerged orifice scrubbers* (EPA-84/03, p. 3-23; EPA-81/10, p. 9-27).

Several orifice scrubber designs are typically used. In each, the incoming exhaust stream is directed across or through a pool of water. The high exhaust stream velocity, approximately 15.2 m/s (50 ft/s), creates a large number of liquid droplets. Both particles and gaseous pollutants are collected as they are forced through the liquid pool and impact on the droplets. However, these scrubbers are generally used for removing particles. Large particles are collected when they impact on the liquid pool or its surface. Small particles are collected when they impact the droplets. Baffles, or air foils, are added to provide turbulent mixing of the exhaust stream and droplets.

In the self-induced scrubber, the exhaust stream enters through a duct, as shown in Fig. 3.14. The exhaust stream is forced by baffles through a pool of liquid. Particles and gases are collected in the pool and by the droplets. Additional baffles placed in the path of the 'clean'

exhaust stream as it exits the vessel serve as impingement surfaces to remove entrained droplets.

Particulate matter collected in the scrubber forms a sludge that must be disposed of. Sludge disposal involves removing and recycling large amounts of liquid, from 3.5 to 4.0 L/m<sup>3</sup> (25 to 30 gal/1000 acfm). Some designs use a sludge separation and removal system inside the scrubber. The water level inside the scrubber must be maintained during the sludge separation and removal cycle so that the unit can operate efficiently.

*Particle collection.* Large particles in the incoming exhaust stream are collected as they impinge on the surface of the pool. Smaller particles are collected as they impact on the droplets produced by the high-velocity gas skimming over the liquid. Overall particle collection in an orifice scrubber depends on the level of the liquid. The level of the liquid determines the gas velocity (and, thus, the pressure drop) through the orifice. If the liquid level is low, gas velocities decrease because the orifice opening is larger. Lower velocities produce fewer droplets that are larger in size, decreasing particle collection. A turn-down of the system, or reduction in gas volume, will also result in less atomization and produce larger droplets.

*Gas collection.* Orifice scrubbers are rarely used for absorption. However, because orifice scrubbers provide both thorough mixing of the gas and liquid, and large liquid-surface contact areas (many tiny droplets), these devices can be effective for reactive scrubbing or for removing gaseous pollutants that are already very soluble in the liquid. In reactive scrubbing, the gaseous pollutants chemically react with the scrubbing liquid. These reactions occasionally produce scale or sludge that can plug scrubber internals. The relatively large orifice openings will not plug as easily as those in plate towers.

## 4.2. Liquid-Phase Contacting Scrubber

Section 4.1 dealt with scrubbers which primarily use the process gas stream to atomize liquid into collection droplets. Energy can also be applied to a scrubbing system by injecting liquid at high pressure through specially designed nozzles. Nozzles produce droplets which fan out into a scrubber chamber to impact with particulate matter contained in a polluted gas stream. Droplets act as targets for collecting particles and/or absorbing gas in a pollutant exhaust stream. In liquid-phase contacting scrubbers, the liquid-inlet pressure provides the major portion of the energy required for contacting the gas (exhaust stream) and liquid phases (EPA-84/03, p. 4-1).

Two liquid-phase contacting scrubbers are

- Spray tower
- Ejector venturi

Many other scrubber designs also incorporate sprays produced by nozzles, but in those scrubbers, the sprays are used to clean trays or to wet scrubber surfaces and orifices, and not to provide the gas-liquid contact in the system.

*Spray tower.* Spray towers, also known as gravity spray towers, spray chambers, or spray scrubbers, are the simplest devices used for gas absorption. The basic design is simple. A spray tower consists of an empty tower and a set of nozzles to spray liquid. It is similar in operation to spraying water in an open barrel. Typically, the contaminant gas stream enters the bottom of the tower and passes up through the device while liquid is being sprayed at one or more levels by nozzles. The flow of liquid and gas streams in opposite directions is referred to as *countercurrent flow*. Liquid is sprayed into a cylindrical or rectangular chamber using one nozzle or a series of nozzles, as shown in Fig. 3.15. The figure shows a typical countercurrent-flow spray tower. Countercurrent flow exposes the exhaust gas with the lowest pollutant concentration to the freshest scrubbing liquid (EPA-84/03, p. 4-1; EPA-81/10, p. 9-38; EPA-81/12, p. 4-38).

FIGURE 3.15 Countercurrent flow spray tower (EPA-81/12, p. 4-39).

To provide a large liquid surface for contacting the gas, nozzles are arranged to wet the entire cross-section of the tower with fine liquid droplets. Theoretically, the height between levels of nozzles and/or the bottom of the tower determines the residence time. In practice, physical laws limit the removal efficiency of spray towers. After falling short distances, the liquid droplets tend to agglomerate or hit the sides of the tower. Both of these effects reduce the total liquid surface in contact with the gas stream and the residence time. Therefore, spray chambers are limited to applications where the gases are extremely soluble or a high removal efficiency is not required.

The main advantage of spray chambers is that they are completely open; they have no internals except for the spray nozzles. Therefore, they have a very low pressure drop, about 1.25–4 cm (0.5–1.6 in.) of water over the tower. If an entrainment separator is used it will add another 2.5–5 cm (1–2 in.) of water to the total pressure drop. An entrainment separator is used to prevent mist from exhausting out the stack. Spray towers range in size from 42 to 170,000 m<sup>3</sup>/h (25 to 100,000 cfm) with 34,500 m<sup>3</sup>/h (20,000 cfm) as a typical size.

Spray towers are primarily used for gas conditioning—cooling, humidifying, or for the first-stage particulate matter and gas removal. But they can be used effectively for gas absorption if the contaminant to be removed is highly soluble. For example, spray towers are used to remove HCl gas from the tail-gas exhaust in the manufacturing of hydrochloric acid.

No universally acceptable mathematical equation or correlation is presently available for sizing spray towers. Although they are simple devices, variables such as liquid drop size, settling velocity, and residence time vary considerably with height or location in the tower. Tower designs are based on experimental or operational data from similar systems.

However, certain limiting factors must be balanced against each other.

- *Gas velocity*: The gas velocity through the tower must be kept low, around 0.3–1.0 m/s (1–3 ft/s) or excessive liquid entrainment occurs. This implies using a large-diameter tower to keep the gas velocity low. But if the diameter is large, compared with the distance between sprays, back mixing occurs. Back mixing is a condition where the gas changes direction or swirls within the tower and removal efficiency is decreased.
- *Liquid droplet size*: The smaller the liquid droplet size, the greater the rate of absorption, since this increases the surface area available for absorption. However, the liquid droplets must be large enough to not be carried out of the scrubber by the exhaust stream. Therefore, spray towers use nozzles to produce droplets that are usually 500–1000  $\mu\text{m}$  in diameter. High-pressure spray nozzles are used to produce fine liquid droplets. These spray nozzles consume more power in pumping liquid than a packed tower or venturi scrubber for the same liquid rate. The fine openings of the spray nozzles are subject to erosion and plugging problems, especially if scrubbing liquid is recirculated.
- *Liquid-to-gas (L/G) ratio*: Another parameter which characterizes spray tower operation is the liquid-to-gas (L/G) ratio. By increasing the L/G ratio, absorption efficiency can be directly increased.

In addition to a countercurrent-flow configuration, the flow in spray towers can be either a cocurrent or crosscurrent configuration. In cocurrent-flow spray towers, the exhaust gas and liquid flow in the same direction. Because the exhaust gas stream does not ‘push’ against the liquid sprays, these units operate at higher exhaust gas velocities (through the vessels) than do countercurrent-flow spray towers. Consequently, cocurrent-flow spray towers are smaller than countercurrent-flow spray towers (treating the same amount of exhaust flow).

In crosscurrent-flow spray towers, called *horizontal-spray scrubbers*, the exhaust gas and liquid flow in directions perpendicular to each other (Fig. 3.16). In this vessel, the exhaust gas flows horizontally through a number of spray sections. The amount and quality of liquid sprayed in each section can be varied, usually with the cleanest liquid (if recycled liquid is sprayed) in the last of sprays.

*Particle collection.* Spray towers are low-energy scrubbers. Contacting power is much lower than in venturi scrubbers, and the pressure drops across such systems are generally less than 2.5 cm (1 in.) of water. The collection efficiency for small particles is correspondingly

FIGURE 3.16 Crosscurrent flow spray tower (EPA-84/03, p. 4-3).

lower than in more energy-intensive devices. They are adequate for the collection of coarse particles larger than 10–25  $\mu\text{m}$  in diameter, although with increased liquid-inlet nozzle pressures, particles with diameters of 2.0  $\mu\text{m}$  can be collected. Smaller droplets can be formed by higher liquid pressures at the nozzle. The highest collection efficiencies are achieved when small droplets are produced and the difference between the velocity of the droplets and the velocity of the upward-moving particles is high. Small droplets, however, have small settling velocities, so there is an optimum range of droplet sizes for scrubbers that work by this mechanism.

*Gas collection.* Spray towers can be used for gas absorption, but they are not as effective as packed or plate towers. Spray towers can be very effective in removing pollutants if the pollutants are highly soluble or if a chemical reagent is added to the liquid. For example, spray towers are used to remove HCl gas from the tail-gas exhaust in manufacturing hydrochloric acid. In the production of superphosphate used in manufacturing fertilizer,  $\text{SiF}_4$  and HF gases are vented from various points in the processes. Spray towers have been used to remove these highly soluble compounds. Spray towers are also used for odor removal in bone meal and tallow manufacturing industries by scrubbing the exhaust gases with a solution of  $\text{KMnO}_4$ . Because of their ability to handle large exhaust gas volumes in corrosive atmospheres, spray towers are also used in a number of the flue gas desulfurization systems as the first or second stage in the pollutant removal process.

In a spray tower, absorption can be increased by decreasing the size of the liquid droplets and/or increasing the liquid-to-gas (L/G) ratio. However, to accomplish either of these, an increase in both power consumed and operating cost is required. In addition, the physical size of the spray tower will limit the amount of liquid and the size of droplets that can be used.

**EXAMPLE:** spray tower. A steel pickling operation emits 300 ppm HCl (hydrochloric acid) with peak values of 500 ppm 15% of the time. The air flow is a constant 25,000 acfm at 75°F and 1 atm. Only sketchy information was submitted with the scrubber permit application for a spray tower. You are requested to determine if the spray unit is satisfactory (EPA-84/09, p. 100).

#### Given conditions

emission limit = 25 ppm HCl

maximum gas velocity allowed through the tower = 3 ft/s

number of sprays = 6

diameter of the tower = 14 ft

The plans show a countercurrent water spray tower. For a very soluble gas (Henry's law constant approximately zero), the number of transfer units ( $N_{OG}$ ) can be determined by the following equation:

$$N_{OG} = \ln(y_1/y_2)$$

where  $y_1$  = concentration of inlet gas

$y_2$  = concentration of outlet gas

In a spray tower, the number of transfer units  $N_{OG}$  for the first (or top) spray will be about 0.7. Each lower spray will have only about 60% of the  $N_{OG}$  of the spray above it. The final spray, if placed in the inlet duct, has a  $N_{OG}$  of 0.5.

The spray sections of a tower are normally spaced at 3-ft intervals. The inlet duct spray adds no height to the column.

*Solution:*

1. Calculate the gas velocity through the tower.

$$\begin{aligned} V &= Q/S \\ &= Q/(\pi D^2/4) \end{aligned}$$

where  $V$  = velocity  
 $Q$  = actual volumetric gas flow  
 $S$  = cross-sectional area  
 $D$  = diameter of the tower

$$\begin{aligned} V &= Q/(\pi D^2/4) \\ &= 25,000/[\pi(14)^2/4] \\ &= 162.4 \text{ ft/min} \\ &= 2.7 \text{ ft/s} \end{aligned}$$

2. Does the gas velocity meet the requirement?  
 Yes, because the gas velocity is less than 3 ft/s.
3. Calculate the number of overall gas transfer units  $N_{OG}$  required to meet the regulation.  
 Remember that

$$N_{OG} = \ln(y_1/y_2)$$

where  $y_1$  = concentration of inlet gas  
 $y_2$  = concentration of outlet gas

Use the peak value for inlet gas concentration:

$$\begin{aligned} N_{OG} &= \ln(y_1/y_2) \\ &= \ln(500/25) \\ &= 3.0 \end{aligned}$$

4. Determine the total number of transfer units provided by a tower with six spray sections.  
 Remember that each lower spray has only 60% of the efficiency of the section above it.  
 This is due to back-mixing of liquids and gases from adjacent sections.  
 Spray section  $N_{OG}$  values are derived accordingly:

top spray  $N_{OG} = 0.7$  (given)

2nd spray  $N_{OG} = 0.7(0.6) = 0.42$

3rd spray  $N_{OG} = 0.42(0.6) = 0.252$

4th spray  $N_{OG} = 0.252(0.6) = 0.1512$

5th spray  $N_{OG} = 0.1512(0.6) = 0.0907$

Inlet  $N_{OG} = 0.5$  (given)

Total  $N_{OG} = 0.7 + 0.42 + 0.252 + 0.1512 + 0.0907 + 0.5 = 2.114$

*Note* this value is below the required value of 3.0.

5. Calculate the outlet concentration of gas.

$$\begin{aligned}
 N_{OG} &= \ln(y_1/y_2) \\
 y_1/y_2 &= \exp(N_{OG}) \\
 &= \exp(2.114) \\
 &= 8.28 \\
 y_2 &= 500/8.28 \\
 &= 60.4 \text{ ppm}
 \end{aligned}$$

6. Does the spray tower meet the HCl regulation?

Since  $y_2$  is greater than the required emission limit of 25 ppm, the spray unit is not satisfactory.

**Ejector venturi.** The ejector, or jet, venturi scrubber uses a preformed spray, as does the simple spray tower. The difference is that only a single nozzle is used instead of many nozzles. This nozzle operates at higher pressures and higher injection rates than those in most spray chambers. The high pressure spray nozzle (up to 689 kPa or 100 psig) is aimed at the throat section of a venturi constriction. Figure 3.17 illustrates the ejector venturi design. Using high-pressure sprays in this manner serves two purposes (EPA-84/03, p. 4-6; EPA-81/10, p. 9-40; EPA-81/12, p. 4-46):

1. The movement of the liquid creates a suction (vacuum) that pulls the gas stream through the venturi. This eliminates the need for a fan or blower to move the gas stream.
2. The high-pressure sprays, along with the venturi effect, form numerous fine liquid droplets that provide a high degree of turbulence between gas and liquid phases. This limits contact time; therefore, absorption efficiency is usually low.

FIGURE 3.17 Jet or ejector venturi scrubber (EPA-81/12, p. 4-22).

Ejector venturis operate at high liquid-to-gas ratios (around 100 gpm/1000 cfm). The gas-side pressure drop usually ranges between 10–20 cm (4–8 in.) of water. The overall power consumption, however, is much higher, due to liquid pumping requirements. Ejector venturis can be designed for smaller gas flow rates (under 1000 cfm) than most other absorbers are capable of handling.

The ejector venturi is unique among available scrubbing systems since it can move the process gas without the aid of a blower or fan. The liquid spray coming from the nozzle creates a partial vacuum in the side duct of the scrubber. This partial vacuum can be used to move the process gas through the control device as well as through the process system. In the case of explosive or extremely corrosive atmospheres, the elimination of a fan in the system can avoid many potential problems.

The energy for the formation of scrubbing droplets comes from the injected liquid. The high-pressure sprays passing through the venturi throat form numerous fine liquid droplets that provide turbulent mixing between the gas and liquid phases. Very high liquid-injection rates are used to provide the gas-moving capability and higher collection efficiencies. As with other types of venturis, a means of separating entrained liquid from the gas stream must be installed. A liquid sump directs the gas flow to continuing ductwork. Entrainment separators are commonly used to remove remaining small droplets.

*Particle collection.* Venturi scrubbers are the most widely used wet collector for particulate matter removal. Ejector venturis are effective in removing particles larger than  $1.0\ \mu\text{m}$  in diameter. These scrubbers are not used on submicron-sized particles unless the particles are condensable. Particle collection occurs primarily by impaction as the exhaust gas (from the process) travels through the spray.

The turbulence that occurs in the throat area also causes the particles to contact the wet droplets and be collected. Particle collection efficiency increases with an increase in nozzle pressure and/or an increase in the liquid-to-gas ratio. In fact, ejector venturis operate at higher L/G ratios than most other particle scrubbers.

*Gas collection.* Unless a gaseous contaminant is extremely soluble, venturis are seldom used strictly as an absorber. Ejector venturis have a short gas–liquid contact time because the exhaust gas velocities through the vessel are very high. This short contact time limits the absorption efficiency of the system. Although ejector venturis are not used primarily for gas removal, they can be effective if the gas is very soluble or if a very reactive scrubbing reagent is used. In these instances, removal efficiencies of as high as 95% can be achieved.

### 4.3 Wet-Film Scrubber

In wet-film scrubbers, liquid is sprayed or poured over packing material contained between support trays. A liquid film coats the packing through which the exhaust gas stream is forced. Pollutants are collected as they pass through the packing, contacting the liquid film. Therefore, both gas and liquid phases provide energy for the gas–liquid contact. These scrubbers are commonly called packed towers.

A wet-film scrubber uses packing to provide a large contact area between the gas and liquid phases, to provide turbulent mixing of the phases, and to provide sufficient residence time for the exhaust gas to contact the liquid. These conditions are ideal for gas absorption. A large contact area and good mixing are also good for particle collection; however, once collected, the particles tend to accumulate and, thus, plug the packing bed. The exhaust gas is forced to make many changes in direction as it winds through the openings of the packed material. Large particles unable to follow the streamlines hit the packing and are collected in the liquid. As this liquid drains through the packing bed, the collected particles may accumulate, thus plugging the void spaces in the packed bed. Therefore, wet-film scrubbers are not used where particle removal is the only concern. Many other scrubber designs achieve better particle removal for the same power input (operating costs).

**Packed tower (packed column).** The packed column (tower) is the most common scrubber used for gas absorption. Packed columns disperse the scrubbing liquid over packing material which provides a large surface area for continuous gas-liquid contact. Packed towers are classified according to the relative direction of gas-to-liquid flow. Packed towers are typically designated by the flow arrangement used for gas-liquid contact or by the material used as packing for the bed (EPA-84/03, p. 5-1; EPA-81/12, p. 4-47).

The most common flow configuration for packed towers is countercurrent flow. Figure 3.18 shows a packed tower with this arrangement. The exhaust stream being treated enters the bottom of the tower and flows upward over the packing material. Liquid is introduced at the top of the packing by sprays or weirs, and it flows downward over the packing material. As the exhaust stream moves up through the packing, it is forced to make many winding changes in direction, resulting in intimate mixing of both the exhaust gas and liquid streams. This countercurrent-flow arrangement results in the highest theoretically achievable efficiency. The most dilute gas is in contact with the purest absorbing liquor, providing a maximized concentration difference (driving force) for the entire length of the column.

The countercurrent-flow packed tower does not operate effectively if there are large variations in the liquid or gas flow rates. If either the liquid-injection rate or the gas flow rate through the packing bed is too high, a condition called flooding may occur. Flooding is a condition where the liquid is 'held' in the pockets, or void spaces, between the packing and does not drain down through the packing. Flooding can be reduced by reducing the gas velocity through the bed or by reducing the liquid-injection rate.

FIGURE 3.18 Countercurrent flow packed tower (EPA-84/03, p. 5-3).

In another flow arrangement used with packed towers, cocurrent flow, both the exhaust gas and liquid phases enter at the top of the absorber and move downward over the packing material. This allows the absorber to be operated at higher liquid and gas flow rates since flooding is not a problem. The pressure drop is lower than with countercurrent flow since both streams move in the same direction. The major disadvantage is that removal efficiency is very limited due to the decreasing driving force (concentration differential) as the streams travel down through the column. This limits the areas of application for cocurrent absorbers. They are used almost exclusively in situations where limited equipment space is available, since the tower diameter is smaller than for a countercurrent or plate tower of equivalent flow rates. Cocurrent flow is illustrated in Fig. 3.19.

In packed towers using the crossflow arrangement, the exhaust gas stream moves horizontally through the packed bed. The bed is irrigated by the scrubbing liquid flowing down through the packing material. The liquid and exhaust gas flow in directions perpendicular to each other. A typical crossflow packed tower is shown in Fig. 3.20. (Inlet sprays aimed at the face of the bed may also be included. If included, these sprays scrub both the entering gas and the face of the packed bed.) The leading face of the packed bed is slanted in the direction of the oncoming gas stream. This ensures complete wetting of the packing by allowing the liquid at the front face of the packing time to drop to the bottom before being pushed back by the entering gas.

Crossflow absorbers are smaller and have a lower pressure drop than any other packed or plate towers for the same application (removal efficiency and flow rates). In addition, they are better suited than other wet-film scrubbers to handle exhaust streams with high particle concentrations. By adjusting the liquid flow rate, incoming particles can be removed and washed

FIGURE 3.19 Cocurrent flow packed tower (EPA-84/03, p. 5-4).

away in the front half of the bed. This also results in a liquid saving by enabling the crossflow packed tower to use less liquid in the rear sprays.

Another crossflow packed tower is the fiber-bed scrubber. The fiber-bed scrubber has packed beds that are made with fibrous materials such as fiberglass or plastic (Fig. 3.21). Liquid is sprayed onto the fiber beds to provide a wetted surface for pollutant removal and to wash away any collected materials.

*Particle collection.* For particle collection, packing materials are literally packed in a column or in sectional compartments. Liquid is sprayed on the material and allowed to flow through the system. Process exhaust gas is introduced into this system and the particles in the gas stream move through the packing and are collected. Cocurrent flow provides better particle collection than countercurrent flow since higher gas velocities can be used. With higher velocities, smaller particles can be collected than in similar countercurrent scrubbers (*EPA-81/10, p. 9-54*).

The particles impinge upon the liquid film covering the packing and are drained off with the liquid as it flows through the system. Many changes of direction occur as the gas winds through the openings of the packing materials. Larger particles unable to follow the streamlines associated with this flow will consequently hit the packing and be collected.

The packed column or tower can have several problems when not operated under proper conditions. Heavy loadings of particulate matter can plug beds of packing material. Deep beds will provide high pressure drops and higher efficiencies, but can be more susceptible to plugging. However, gas channeling is more likely to occur in thin beds. The gas flows through the path of least resistance and may channel through a certain section of the bed if the bed is not thick enough. In the countercurrent design, if the liquid rates are too high or the gas rates too low, the tower will flood and begin to fill with liquid.

For a crossflow scrubber, the water sprays can be positioned in front of the packing, above the packing, or behind the packing. This configuration has an advantage since particulate matter accumulated on the face of the packing can be washed off by water sprays.

*Gas collection.* For gas absorption, wet-film scrubbers are the most commonly used devices. The wet film covering the packing enhances gas absorption several ways by providing (EPA-84/03, p. 5-2):

- A large surface area for gas–liquid contact.
- Turbulent contact (good mixing) between the two phases.
- Long residence time and repetitive contact.

Because of these features, packed towers are capable of achieving high removal efficiencies for many different gaseous pollutants.

Numerous operating variables affect absorption efficiency. Of primary importance is the solubility of the gaseous pollutants. Pollutants that are readily soluble in the scrubbing liquid can be easily removed under a variety of operating conditions. Some other important operating variables are:

- *Gas velocity:* The rate of exhaust gas from the process determines the scrubber size to be used. The scrubber should be designed so that the gas velocity through it will promote good mixing between the gas and liquid phase. However, the velocity should not be too fast to cause flooding.
- *Liquid-injection rate:* Generally, removal efficiency is increased by an increase in the liquid-injection rate to the vessel. The amount of liquid that can be injected is limited by the dimensions of the scrubber. Increasing liquid-injection rates will also increase the operating costs. The optimum amount of liquid injected is based on the exhaust gas flow rate.
- *Packing size:* Smaller packing sizes offer a larger surface area, thus enhancing absorption. However, smaller packing fits tighter, which decreases the open area between packing, thus increasing the pressure drop across the packing bed.
- *Packing height:* As packing height increases, total surface area and residence time increase, enhancing absorption. However, more packing necessitates a larger absorption system, which increases capital cost.

***Packing material.*** Packing material is the heart of the absorber. It provides the surface over which the scrubbing liquid flows, presenting a large area for mass transfer to occur. Packing material represents the largest material cost of the packed tower. Figure 3.22 shows some of commonly used packing materials which are made in numerous geometric shapes and sizes. These materials were originally made of stoneware, porcelain, or metal; but, presently, a large majority are being made of high-density thermoplastics (polyethylene and polypropylene). A specific packing is described by its trade name and overall size. For example, a column can be packed with 5 cm (2 inch) Raschig rings or 2.5 cm (1 inch) Tellerettes. The overall dimensions

FIGURE 3.22 Common packing materials (EPA-84/03, p. 5-7).

of packing materials normally range from 0.6 to 10 cm (1/4 to 4 inches) (EPA-84/03, p. 5-7; EPA-81/12, p. 4-50).

Packing material may be arranged in an absorber in either of two ways: the packing may be dumped into the column randomly or in certain cases systematically stacked, as bricks are laid atop each other. Randomly packed towers provide a higher surface area,  $\text{m}^2/\text{m}^3$  ( $\text{ft}^2/\text{ft}^3$ ), but also cause a higher pressure drop than stacked packing. In addition to the lower pressure drop, the stacked packing provides better liquid distribution over the entire surface of the packing. The large installation costs required to stack the packing material usually make it impractical unless high flow rates are required.

**EXAMPLE 1:** packed tower review. Pollution Unlimited, Inc., has submitted plans for a packed ammonia scrubber on an air stream containing  $\text{NH}_3$ . The operating and design data are given by Pollution Unlimited, Inc. You remember approving plans for a nearly identical scrubber for Pollution Unlimited, Inc., in 1978. After consulting your old files you find all the conditions were identical except for the gas flow rate. What is your recommendation (EPA-84/09, p. 102)?

#### Given conditions

tower diameter = 3.57 ft

packed height of column = 8 ft

gas and liquid temperature = 75°F

operating pressure = 1.0 atm

ammonia-free liquid flow rate (inlet) = 1000  $\text{lb}/\text{ft}^2\text{-h}$

gas flow rate = 1575 acfm

gas flow rate in the 1978 plan = 1121 acfm  
 inlet NH<sub>3</sub> gas composition = 2.0 mole %  
 outlet NH<sub>3</sub> gas composition = 0.1 mole %  
 air density = 0.0743 lb/ft<sup>3</sup>  
 molecular weight of air = 29  
 Henry's law constant  $m = 0.972$   
 molecular weight of water = 18  
 See Figs. 3.23 (packing A is used) and 3.24  
 emission regulation = 0.1% NH<sub>3</sub>

*Solution*

1. What is the number of overall gas transfer units  $N_{OG}$ ?

The number of overall gas transfer units  $N_{OG}$  is used in calculating packing height requirements. It is a function of the extent of the desired separation and the magnitude of the driving force through the column (the displacement of the operating line from the equilibrium line).

1.a. Calculate the gas molar flow rate  $G_m$  and liquid molar flow rate  $L_m$ , in lb-mole/ft<sup>2</sup>-h.

The values of  $G_m$  and  $L_m$  are needed to use the Colburn chart (Fig. 3.24), which graphically predicts the value of  $N_{OG}$ .

1.a.1. Calculate the cross-sectional area of the tower  $S$ , in ft<sup>2</sup>.

$$S = \pi D^2 / 4$$

FIGURE 3.23  $H_{OG}$  vs. liquid rate for ammonia–water absorption (EPA-84/09, p. 103).

FIGURE 3.24 Colburn chart (EPA-84/09, p. 104).

where  $S$  = cross-sectional area of the tower  
 $D$  = diameter of the tower

$$\begin{aligned}
 S &= \pi D^2 / 4 \\
 &= (\pi)(3.57)^2 / (4) \\
 &= 10.0 \text{ ft}^2
 \end{aligned}$$

1.a.2. Calculate the gas molar flow rate  $G_m$ , in lb-mole/ft<sup>2</sup>-h.

$$G_m = Q\rho / SM$$

where  $G_m$  = gas molar flow rate, lb-mole/ft<sup>2</sup>-h

$Q$  = volumetric flow rate of gas stream  
 $\rho$  = density of air  
 $S$  = cross-sectional area of the tower  
 $M$  = molecular weight of air

$$\begin{aligned}
 G_m &= Q\rho/SM \\
 &= (1575)(0.0743)/(10.0)(29) \\
 &= 0.404 \text{ lb-mole/ft}^2\text{-min} \\
 &= 24.2 \text{ lb-mole/ft}^2\text{-h}
 \end{aligned}$$

1.a.3. Calculate the liquid molar flow rate  $L_m$ , in lb-mole/ft<sup>2</sup>-h.

$$L_m = L/M_L$$

where  $L_m$  = liquid molar flow rate, lb-mole/ft<sup>2</sup>-h  
 $L$  = liquid mass velocity, lb/ft<sup>2</sup>-h  
 $M_L$  = liquid molecular weight

$$\begin{aligned}
 L_m &= L/M_L \\
 &= (1000)/(18) \\
 &= 55.6 \text{ lb mole/ft}^2\text{-h}
 \end{aligned}$$

1.b. Calculate the value of  $mG_m/L_m$ .

where  $m$  = Henry's law constant  
 $G_m$  = gas molar flow rate, lb-mole/ft<sup>2</sup>-h  
 $L_m$  = liquid molar flow rate, lb-mole/ft<sup>2</sup>-h

$$\begin{aligned}
 mG_m/L_m &= (0.972)(24.2/55.6) \\
 &= 0.423
 \end{aligned}$$

1.c. Calculate the value of  $(y_1 - mx_2)/(y_2 - mx_2)$ .

$(y_1 - mx_2)/(y_2 - mx_2)$  is the abscissa of the Colburn chart (Fig. 3.24)

where  $y_1$  = inlet gas mole fraction  
 $y_2$  = outlet gas mole fraction  
 $x_2$  = inlet liquid mole fraction  
 $m$  = Henry's law constant

$$\begin{aligned}
 (y_1 - mx_2)/(y_2 - mx_2) &= [0.02 - (0.972)(0)]/[0.001 - (0.972)(0)] \\
 &= 20.0
 \end{aligned}$$

1.d. Determine the value of  $N_{OG}$  from the Colburn chart (Fig. 3.24).

From the Colburn chart (Fig. 3.24), use the values of  $(y_1 - mx_2)/(y_2 - mx_2)$  and  $mG_m/L_m$  to find the value of  $N_{OG}$ .

$$N_{OG} = 4.3$$

2. What is the height of an overall gas transfer unit  $H_{OG}$ ?

The height of an overall gas transfer unit  $H_{OG}$  is also used in calculating packing height requirements.  $H_{OG}$  values in air pollution are almost always based on experience.  $H_{OG}$  is a strong function of the solvent viscosity and difficulty of separation, increasing with increasing values of both.

2.a. Calculate the gas mass velocity  $G$ , in  $\text{lb}/\text{ft}^2\text{-h}$ .

$$G = \rho Q/S$$

where  $G$  = gas mass velocity,  $\text{lb}/\text{ft}^2\text{-h}$   
 $\rho$  = density of air  
 $S$  = cross-sectional area of the tower

$$\begin{aligned} G &= \rho Q/S \\ &= (1575)(0.0743)/10.0 \\ &= 11.7 \text{ lb}/\text{ft}^2\text{-min} \\ &= 702 \text{ lb}/\text{ft}^2\text{-h} \end{aligned}$$

2.b. Determine the value of  $H_{OG}$  from Fig. 3.23

$$H_{OG} = 2.2 \text{ ft}$$

3. What is the required packed column height  $Z$ , in ft?

$$Z = (N_{OG})(H_{OG})$$

where  $Z$  = height of packing  
 $H_{OG}$  = height of an overall gas transfer unit  
 $N_{OG}$  = number of transfer units

$$\begin{aligned} Z &= (N_{OG})(H_{OG}) \\ &= (4.3)(2.2) \\ &= 9.46 \text{ ft} \end{aligned}$$

4. Compare the packed column height of 8 ft specified by Pollution Unlimited, Inc., to the height calculated above. What is your recommendation?

Disapproval, because the calculated height (9.46 ft) is higher than that (8 ft) proposed by the company.

**EXAMPLE 2:** tower height and diameter. A packed column is designed to absorb ammonia from a gas stream. Given the operating conditions and type of packing below, calculate the height of packing and column diameter (EPA-84/09, p. 106).

**Given conditions**

gas mass flow rate = 5000 lb/h  
 $\text{NH}_3$  concentration in inlet gas stream = 2.0 mole %  
 scrubbing liquid = pure water  
 packing type = 1-inch Raschig rings  
 packing factor,  $F = 160$   
 $H_{OG}$  of the column = 2.5 ft  
 Henry's law constant  $m = 1.20$   
 density of gas (air) =  $0.075 \text{ lb}/\text{ft}^3$   
 density of water =  $62.4 \text{ lb}/\text{ft}^3$   
 viscosity of water = 1.8 cp

Figure 3.25: generalized flooding and pressure drop correction

Figure 3.26: graphical representation of the packed column

The unit operates at 60% of the flooding gas mass velocity, the actual liquid flow rate is 25% more than the minimum, and 90% of ammonia is to be collected based on state regulations.

*Solution:*

1. What is the number of overall gas transfer units  $N_{OG}$ ?

Remember that the height of packing  $Z$  is given by

$$Z = (H_{OG})(N_{OG})$$

where  $Z$  = height of packing

$H_{OG}$  = height of an overall gas transfer unit

$N_{OG}$  = number of transfer units

Since  $H_{OG}$  is given, you only need  $N_{OG}$  to calculate  $Z$ .  $N_{OG}$  is a function of both the liquid and gas flow rates; however, it is usually available for most air pollution applications.

- 1.a. What is the equilibrium outlet liquid composition  $x_1$  and the outlet gas composition  $y_2$  for 90% removal?

Remember that you need the inlet and outlet concentrations (mole fractions) of both streams to use the Colburn chart (Fig. 3.24).

- 1.a.1. Calculate the equilibrium outlet concentration  $x_1^*$  at  $y_1 = 0.02$ .

According to Henry's law,  $x_1^* = y_1/m$ . The equilibrium outlet liquid composition is needed to calculate the minimum  $L_m/G_m$ .

FIGURE 3.25 Generalized flooding and pressure drop correction (EPA-84/09, p. 107).

Here  $x_1^*$  = outlet concentration  
 $y_1$  = inlet gas mole fraction  
 $m$  = Henry's law constant  
 $L_m$  = liquid molar flow rate, lb-mole/ft<sup>2</sup>-h  
 $G_m$  = gas molar flow rate, lb-mole/ft<sup>2</sup>-h

$$\begin{aligned}
 x_1^* &= y_1/m \\
 &= (0.02)/(1.20) \\
 &= 0.0167
 \end{aligned}$$

1.a.2. Calculate  $y_2$  for 90% removal.

Since it is required to remove 90% of NH<sub>3</sub>, there will be 10% of NH<sub>3</sub> remaining in the outlet gas stream; therefore, by material balance:

$$y_2 = (0.1y_1)/[(1 - y_1) + (0.1)y_1]$$

where  $y_1$  = inlet gas mole fraction  
 $y_2$  = outlet gas mole fraction

$$\begin{aligned}
 y_2 &= (0.1y_1)/[(1 - y_1) + (0.1)y_1] \\
 &= (0.1)(0.02)/[(1 - 0.02) + (0.1)(0.02)] \\
 &= 0.00204
 \end{aligned}$$

1.b. Determine the minimum ratio of molar liquid flow rate to molar gas flow rate ( $L_m/G_m$ )<sub>min</sub> by a material balance.

Material balance around the packed column:

$$\begin{aligned}
 G_m(y_1 - y_2) &= L_m(x_1^* - x_2) \\
 (L_m/G_m)_{\min} &= (y_1 - y_2)/(x_1^* - x_2)
 \end{aligned}$$

where  $y_1$  = inlet gas mole fraction  
 $y_2$  = outlet gas mole fraction  
 $x_1^*$  = outlet concentration  
 $x_2$  = inlet liquid mole fraction  
 $L_m$  = liquid molar flow rate, lb mole/ft<sup>2</sup>-h  
 $G_m$  = gas molar flow rate, lb mole/ft<sup>2</sup>-h

$$\begin{aligned}(L_m/G_m)_{\min} &= (y_1 - y_2)/(x_1^* - x_2) \\ &= (0.02 - 0.00204)/(0.0167 - 0) \\ &= 1.08\end{aligned}$$

1.c. Calculate the actual ratio of molar liquid flow rate to molar gas flow rate ( $L_m/G_m$ ). Remember that the actual liquid flow rate is 25% more than the minimum based on the given operating conditions.

$$\begin{aligned}(L_m/G_m) &= 1.25(L_m/G_m)_{\min} \\ &= (1.25)(1.08) \\ &= 1.35\end{aligned}$$

1.d. Calculate the value of  $(y_1 - mx_2)/(y_2 - mx_2)$ .

$(y_1 - mx_2)/(y_2 - mx_2)$  is the abscissa of the Colburn chart (Fig. 3.24).

where  $y_1$  = inlet gas mole fraction  
 $y_2$  = outlet gas mole fraction  
 $x_1$  = outlet liquid mole fraction  
 $x_2$  = inlet liquid mole fraction  
 $m$  = Henry's law constant

$$\begin{aligned}(y_1 - mx_2)/(y_2 - mx_2) &= [(0.02) - (1.2)(0)]/[(0.00204) - (1.2)(0)] \\ &= 9.80\end{aligned}$$

1.e. Calculate the value of  $mG_m/L_m$ .

Here  $m$  = Henry's law constant  
 $G_m$  = gas molar flow rate, lb-mole/ft<sup>2</sup>-h  
 $L_m$  = liquid molar flow rate, lb-mole/ft<sup>2</sup>-h

Even though the individual values of  $G_m$  and  $L_m$  are not known, the ratio of the two has been previously calculated:

$$\begin{aligned}mG_m/L_m &= (1.2)/(1.35) \\ &= 0.889\end{aligned}$$

1.f. Determine number of overall gas transfer units  $N_{OG}$  from the Colburn chart using the values calculated in steps 1.d. and 1.e.

From Colburn's chart (Fig. 3.24)  $N_{OG} = 6.2$

2. Calculate the height of packing  $Z$ .

$$Z = (N_{OG})(H_{OG})$$

where  $Z$  = height of packing

$H_{OG}$  = height of an overall gas transfer unit

$N_{OG}$  = number of transfer units

$$\begin{aligned} Z &= (N_{OG})(H_{OG}) \\ &= (6.2)(2.5) \\ &= 15.5 \text{ ft} \end{aligned}$$

3. What is the diameter of the packed column?

The actual gas mass velocity must be determined. To calculate the diameter of the column, you need the flooding gas mass velocity. Figure 3.25 is used to determine the flooding gas mass velocity. The mass velocity is obtained by dividing the mass flow rate by the cross-sectional area.

3.a. Calculate the flooding gas mass velocity  $G_f$ .

3.a.1. Calculate the abscissa of Fig. 3.25,  $(L/G)(\rho/\rho_L)^{0.5}$

$$(L/G)(\rho/\rho_L)^{0.5} = (L_m/G_m)(18/29)(\rho/\rho_L)^{0.5}$$

where  $18/29$  = ratio of molecular weight of water to air

$L$  = liquid mass velocity, lb/s-ft<sup>2</sup>

$G$  = gas mass velocity, lb/s-ft<sup>2</sup>

$\rho$  = gas density

$\rho_L$  = liquid density

$G_m$  = gas molar flow rate in lb-mole/ft<sup>2</sup>-h

$L_m$  = liquid molar flow rate in lb-mole/ft<sup>2</sup>-h

Note that the  $L$  and  $G$  terms in Fig. 3.25 are based on mass and not moles.

$$\begin{aligned} (L/G)(\rho/\rho_L)^{0.5} &= (1.35)(18/29)(0.075/62.4)^{0.5} \\ &= 0.0291 \end{aligned}$$

3.a.2. Determine the value of the ordinate at the flooding line using the calculated value of the abscissa.

$$\text{Ordinate} = G^2 F \psi (\mu_L)^{0.2} / \rho_L \rho g_c$$

where  $F$  = packing factor = 160 for 1-inch Raschig rings

$\psi$  = ratio, density of water/density of liquid

$g_c$  = 32.2 lb-ft/lb<sub>f</sub>-s<sup>2</sup>

$\mu_L$  = viscosity of liquid, cp

$G$  = gas mass velocity, lb/ft<sup>2</sup>-s

From Fig. 3.25,

$$G^2 F \psi (\mu_L)^{0.2} / \rho_L \rho g_c = 0.19$$

3.a.3. Solve the abscissa for the flooding gas mass velocity  $G_f$ , in lb/ft<sup>2</sup>-s.

The  $G$  value in step 3.a.2 becomes  $G_f$  for this case. Thus,

$$\begin{aligned} G_f &= [0.19(\rho_L \rho g_c) / (F \psi (\mu_L)^{0.2})]^{0.5} \\ &= [(0.19)(62.4)(0.075)(32.2) / (160)(1)(1.8)^{0.2}]^{0.5} \\ &= 0.400 \text{ lb/ft}^2\text{-s} \end{aligned}$$

3.b. Calculate the actual gas mass velocity  $G_{\text{act}}$ , in  $\text{lb}/\text{ft}^2\text{-s}$ .

$$\begin{aligned} G_{\text{act}} &= 0.6G_f \\ &= (0.6)(0.400) \\ &= 0.240 \text{ lb}/\text{ft}^2\text{-s} \\ &= 864 \text{ lb}/\text{ft}^2\text{-h} \end{aligned}$$

3.c. Calculate the diameter of the column in ft.

$$\begin{aligned} S &= (\text{mass flowrate of gas stream})/G_{\text{act}} \\ &= 5000/G_{\text{act}} \end{aligned}$$

$$S = \pi D^2/4$$

$$\begin{aligned} \pi D^2/4 &= 5000/G_{\text{act}} \\ D &= [(4(5000))/(\pi G_{\text{act}})]^{0.5} \\ &= 2.71 \text{ ft} \end{aligned}$$

#### 4.4 Combination of Liquid-Phase and Gas-Phase Contacting Scrubbers

A number of wet-collector designs use energy from both the gas stream and liquid stream to collect pollutants. Many of these combination devices are available commercially. A seemingly unending number of scrubber designs have been developed by changing system geometry and incorporating vanes, nozzles, and baffles. These types of scrubbers include:

- Cyclonic spray scrubber
- Mobile-bed scrubber
- Baffle spray scrubber
- Mechanically-aided scrubber

**Cyclonic spray scrubber.** Cyclonic spray scrubbers use the features of both the dry cyclone and the spray chamber to collect pollutants. Generally, the exhaust gas enters the chamber tangentially, swirls through the chamber and exits. At the same time, liquid is sprayed inside the chamber. As the exhaust gas swirls around the chamber, pollutants are captured when they impact on liquid droplets, are thrown to the walls, and washed down and out (EPA-84/03, p. 6-1; EPA-81/10, p. 9-41).

Cyclonic scrubbers are generally low- to medium-energy devices, with pressure drops of 4 to 25 cm (1.5 to 10 in.) of water. Commercially available designs include:

- Irrigated cyclone scrubber
- Cyclonic spray scrubber

*Irrigated cyclone scrubber:* In the irrigated cyclone (Fig. 3.27), the exhaust gas enters near the top of the scrubber into the water sprays. The exhaust gas is forced to swirl downward, then change directions, and return upward in a tighter spiral. The liquid droplets produced capture the pollutants, are eventually thrown to the side walls, and are withdrawn from the collector. The ‘cleaned’ gas leaves through the top of the chamber.

FIGURE 3.27 Irrigated cyclone scrubber (EPA-84/03, p. 6-2).

*Cyclonic spray scrubber:* The cyclonic spray scrubber (Fig. 3.28) forces the exhaust gas up through the chamber from a bottom tangential entry. Liquid sprayed from nozzles on a center post (manifold) is directed toward the chamber wall and through the swirling exhaust gas. As in the irrigated cyclone, liquid captures the pollutant, is forced to the wall, and washes out. The 'cleaned' gas continues upward, exiting through the straightening vanes at the top of the chamber. Stationary vanes are used inside the cyclonic scrubber chamber for much the same purpose that they are used at the top (to alter the gas flow). But inside, they are designed to start or enhance the cyclonic gas flow.

*Particle collection.* Cyclonic spray scrubbers are more efficient than spray towers, but not as efficient as venturi scrubbers, in removing particles from the exhaust gas stream. Particles larger than  $5\ \mu\text{m}$  are generally collected by impaction with 90% efficiency. The cut diameter ranges between 2 and  $3\ \mu\text{m}$  for these devices. In a simple spray tower, the velocity of the particles in the exhaust gas stream is low: 0.6 to 1.5 m/s (2 to 5 ft/s). By introducing the exhaust gas tangentially into the spray chamber, as does the cyclonic scrubber, exhaust gas velocities (thus, particle velocities) are increased to approximately 60 to 180 m/s (200 to 600 ft/s). The velocity of the liquid spray is approximately the same in both devices. This increased particle-to-liquid relative velocity increases particle collection efficiency for this device over that of the spray chamber. Exhaust gas velocities of 60 to 180 m/s are equivalent to those encountered in a venturi scrubber. However, cyclonic spray scrubbers are not as efficient as venturis because they are not capable of producing the same degree of useful turbulence.

*Gas collection.* High exhaust gas velocities through these devices reduce the gas-liquid contact time, thus reducing absorption efficiency. Cyclonic spray scrubbers are capable of effectively removing some gases; however, they are rarely chosen when gaseous pollutant removal is the only concern.

*Mobile-bed scrubber.* Mobile-bed, also called moving-bed, scrubbers use energy from both liquid sprays and the gas stream to provide contact. Instead of having stationary packing, as in packed towers, they use a bed containing packing that is in constant motion. The gas stream provides the energy to keep the packing in motion while, at the same time, liquid is sprayed

FIGURE 3.28 Cyclonic spray scrubber (EPA-84/03, p. 6-2).

over the packing. Mobile-bed scrubbers can be classified as either *flooded* or *fluidized*, depending on the degree of packing movement. In a flooded-bed scrubber, the packing gently moves and rotates, whereas in a fluidized scrubber, the packing is suspended, or fluidized, within the bed (EPA-84/03, p. 6-5; EPA-81/12, p. 4-55; EPA-81/10, p. 9-45).

Mobile-bed scrubbers were developed to provide the effective mass-transfer (absorption) characteristics of packed and plate towers, without the plugging problems. The wetted packing provides a large area for gas-to-liquid contact, promoting absorption. The movement of the bed cleans off any deposited particles. Therefore, these devices are primarily used when good collection efficiency for both particulate and gaseous pollutants is required.

**Flooded-bed scrubber.** A flooded-bed scrubber (Fig. 3.29) contains a section of mobile packing (spheres) 10–20 cm (4–8 in.) deep. The spheres are usually made of plastic; however, glass or marble spheres have been used. The exhaust gas stream enters from the bottom while liquid is sprayed from the top and/or bottom over the packing. Bottom, or inlet, sprays are usually included to saturate the exhaust gas stream and remove any large particles. The gas velocity is such that it causes the packing materials to rotate and rub against each other. This rotating motion acts as a self-cleaning mechanism in addition to enhancing gas and liquid mixing.

Bubbles formed in the bed create a layer of froth over the bed approximately twice as deep as the bed itself. This turbulent froth layer provides an additional surface for absorbing pollutant gases and collecting fine particles. Because of the high gas velocities, entrainment separators are required to prevent liquid-mist carryover.

**Fluidized-bed scrubber:** A fluidized-bed scrubber is very similar to a flooded-bed scrubber. The difference is in the degree of movement of the packing. In a fluidized-bed scrubber, the exhaust gas velocity (1.8–4.8 m/s, or 6–16 ft/s) is such that it keeps the packing in constant motion between a lower and upper retaining grid. This is shown in Fig. 3.30. The packing is

FIGURE 3.29 Flooded-bed absorber (EPA-84/03, p. 6-5).

FIGURE 3.30 Fluidized-bed absorber (EPA-81/12, p. 4-57).

made of either polypropylene or polyethylene plastic balls that are hollow, resembling ping pong balls. The packed sections are usually 0.3–0.6 m (1–2 ft) thick with a froth zone about 0.6 m (2 ft) thick above the packing. These devices can have one to as many as six fluidized packed sections. When used for gas absorption, they are sometimes referred to as turbulent-contact absorbers (TCA).

**Particle collection.** In a mobile-bed scrubber, particles can be collected in three locations. First, sprays are used to remove coarse particles in the inlet below the bed. Particles are also captured when they impinge on the wetted surface of the packing. Finally, small particles are captured in the froth, or foam, layer above the bed. These devices will generally remove particles as small as 2–3  $\mu\text{m}$  in diameter and have been used extensively when the exhaust stream does not contain a substantial amount of particles in the submicron range. These devices usually contain one bed, unless gas absorption is a consideration. Adding additional beds or more packing does not substantially increase the particle collection efficiency (i.e., any particles not captured by the first stage will probably not be collected in any following stage). The pressure drop in mobile-bed scrubbers ranges from 5 to 15 cm (2 to 6 in.) of water per stage of packing.

**Gas collection.** Mobile-bed scrubbers are capable of achieving high gaseous-pollutant removal efficiencies. Their operation is very similar to the operation of packed towers. Liquid is sprayed over the mobile packing, providing a huge surface for the pollutant gas to contact the liquid. Movement of both the gas around the packing and the constantly sprayed liquid provides excellent mixing and contact time for absorption to occur. Mobile-bed scrubbers provide the same amount of absorption efficiency as do packed or plate towers without the associated plugging problems. Due to high exhaust gas velocities through mobile-bed scrubbers, these units can handle five to six times the amount of exhaust gas handled by packed or plate towers of similar size. However, they are not as efficient as packed or plate towers per unit of energy consumed.

Absorption in mobile-bed scrubbers is enhanced by the same factors that affect packed towers. These factors are increasing the liquid-to-gas ratio, increasing the depth of packing, or increasing the number of stages. Increasing these factors increases the gas and liquid contact and the residence time. However, increasing these factors also increases the capital and/or operating costs of the system. As with any system, these process variables are set to achieve the desired removal efficiency at the minimum cost. For gas absorption, multiple stages are used and the liquid-to-gas ratios are high; for example, mobile-bed scrubbers have been used to remove  $\text{SO}_2$  from boiler flue gas exhausts. Using a lime or limestone slurry, the liquid-injection rates are approximately  $8 \text{ L/m}^3$  ( $60 \text{ gal}/1000 \text{ ft}^3$ ) of flue gas. This is compared with  $0.4 \text{ L/m}^3$  ( $3.0 \text{ gal}/1000 \text{ ft}^3$ ) when these devices are used for particle removal.

**Baffle spray scrubber.** Baffle spray scrubbers are very similar to spray towers in design and operation. However, in addition to using the energy provided by the spray nozzle, baffles are added to allow the gas stream to atomize some liquid as it passes over them. A simple baffle scrubber system is shown in Fig. 3.31. Liquid sprays capture pollutants and also remove collected particles from the baffle. Adding baffles slightly increases the pressure drop of the system (EPA-84/03, p. 6-11; EPA-81/10, p. 9-46).

**Particle collection.** These devices are used much the same as spray towers—to preclean or remove particles larger than  $10 \mu\text{m}$  in diameter. However, they will tend to plug or corrode if particle concentration of the exhaust gas stream is high.

**Gas collection.** Even though these devices are not specifically used for gas collection, they are capable of a small amount of gas absorption because of their large wetted surface.

**Mechanically-aided scrubber.** In addition to using liquid sprays or the exhaust stream, energy can be supplied to a scrubbing system by using a motor. The motor is used to drive a rotor or paddles which, in turn, generate water droplets for gas and particle collection. Systems designed in this manner have an advantage of requiring less space than do other scrubbers, but the overall power requirements tend to be higher than for other scrubbers of equivalent

FIGURE 3.31 Baffle spray scrubber (EPA-84/03, p. 6-11).

efficiency. This point might appear to contradict the contact power principle; however, significant power losses occur in driving the rotor. Power is not expended to provide for gas-liquid contact (EPA-84/03, p. 6-11; EPA-81/10, p. 9-46).

Fewer mechanically-aided scrubber designs are available than are liquid- and gas-phase contacting collector designs. Mechanically-aided scrubbers include *centrifugal fan scrubbers* and *mechanically-induced spray scrubbers*.

*Centrifugal fan scrubber:* A centrifugal fan scrubber can serve as both an air mover and a collection device. Figure 3.32 shows such a system, where water is sprayed onto the fan blades concurrently with the moving exhaust gas. Some gaseous pollutants and particles are initially removed as they pass over the liquid sprays. The liquid droplets then impact on the blades to create smaller droplets for additional collection targets. Collection can also take place on the liquid film that forms on the fan blades. The rotating blades force the liquid (and any particles) off of the blades. The liquid droplets separate from the gas stream because of their centrifugal motion.

Centrifugal fan collectors are the most compact of the wet scrubbers since the fan and collector comprise a combined unit. No internal pressure loss occurs across the scrubber, but a power loss equivalent to a pressure drop of 10.2 to 15.2 cm (4 to 6 in.) of water occurs because the blower efficiency is low.

*Mechanically-induced spray scrubber:* A mechanically-induced spray scrubber consists of a whirling rotor submerged in a pool of liquid. The whirling rotor produces a fine droplet spray. By moving the process gas through the spray, particles and gaseous pollutants can subsequently be collected. Figure 3.33 shows an induced-spray scrubber that uses a vertical-spray rotor.

*Particle collection.* Mechanically-aided scrubbers are capable of high collection efficiencies for particles with diameters of 1  $\mu\text{m}$  or greater. However, achieving these high efficiencies

FIGURE 3.32 Centrifugal fan scrubber (EPA-84/03, p. 6-13).

usually requires a greater energy input than those of other scrubbers operating at similar efficiencies. In mechanically-aided scrubbers, the majority of particle collection occurs in the liquid droplets formed by the rotating blades or rotor.

*Gas collection.* Mechanically-aided scrubbers are generally not used for gas absorption. The contact time between the gas and liquid phases is very short, limiting absorption. For gas removal, several other scrubbing systems provide much better removal per unit of energy consumed.

## 5 DRY ABSORPTION FOR GASEOUS EMISSION CONTROL

Dry absorption devices used to remove gaseous contaminants are referred to as *dry scrubbers*. Dry scrubbers are primarily used to remove acid gases, primarily HCl and SO<sub>2</sub>. The basic procedures of collecting pollutants are as follows. Alkaline sorbent materials are injected into the dirty flue gas. The acid gases begin to react with the alkaline sorbents to produce solid particulate salts that are collected by a particulate control device, usually a fabric filter, that follows the dry scrubber. The unreacted sorbent is also captured on the fabric filter cake, where additional acid gas reacts with the sorbent and is captured. There are two types of dry scrubber systems. They are:

- Spray dryer
- Dry injection

FIGURE 3.33 Mechanically-induced spray scrubber (EPA-84/03, p. 6-14).

The basic operating principle for both the spray dryer and the dry injection process is to mix an adequate supply of alkaline sorbent with the flue gas and allow sufficient contact time for the reaction to occur. On most units, outlet gas stream acid gas monitors provide a direct indication of system performance.

## 5.1 Spray Dryer

**Major components.** Figure 3.34 shows a schematic of a spray dryer system for the absorption of acid gases. A spray dryer is usually connected with a fabric filter which is used to collect the particles as shown. The major components of a dry scrubber system are: (1) lime slaker, if pebble lime is used; (2) sorbent mixing tank; (3) sorbent feed tank; (4) atomizer feed tank; (5) rotary atomizers or air atomizing nozzles; (6) spray dryer/absorber reaction vessel; (7) solids recycle tank; and (8) particulate control device.

**Process description.** This type of scrubber uses the alkaline reagent (pebble lime) as a slurry containing 5–20% by weight solids. This slurry is atomized by either rotary atomizers or air atomizing nozzles in a large absorber vessel having a residence time of 6–20 seconds. The major process steps are:

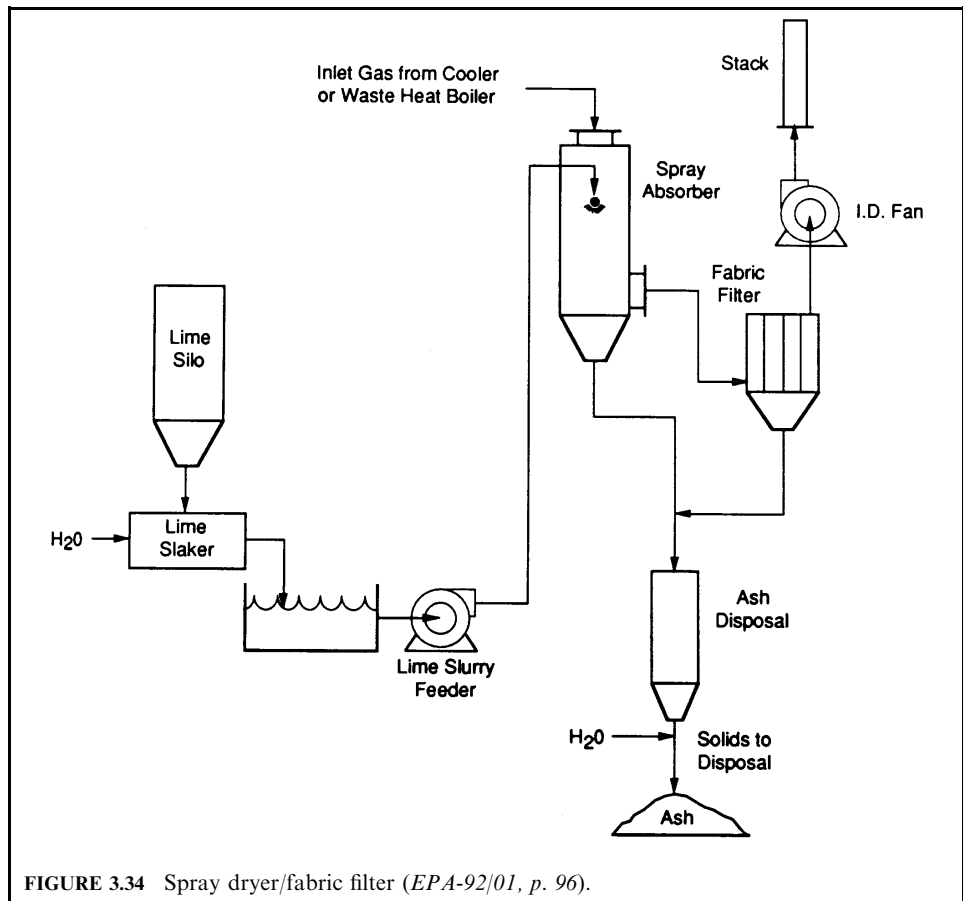

FIGURE 3.34 Spray dryer/fabric filter (EPA-92/01, p. 96).

1. Spray dryers are designed to spray an alkaline slurry of sorbent material into the hot flue gases where the acid gases are absorbed into the slurry droplets and reacted with the alkaline material to form solid particle reaction products.
2. Spray dryer facilities usually use pebble lime ( $\text{CaO}$ ) as the alkaline reagent. The pebble lime is converted to calcium hydroxide [ $\text{Ca}(\text{OH})_2$ ] by the addition of water in the slaker. The calcium hydroxide is mixed with water in the mixing tank to produce a slurry containing 5–20% solids. The slurry is stored in the feed tank and is transferred to the atomizer feed tank immediately prior to use. The atomizers produce small droplets of slurry that are injected into the absorber reaction vessel.
3. The alkaline sorbents in the slurry react with the acid gases, producing  $\text{CaCl}_2$  and  $\text{CaSO}_4$  solid salts.
4. The hot flue gases dry the moisture from the slurry and the reacted and unreacted sorbent either is entrained in the flue gas stream or drops to the bottom of the reaction vessel.
5. The entrained sorbent and reaction products are carried to the particulate control device where they are captured.

6. The sorbent and reaction products that drop to the bottom of the reaction vessel can either be disposed of or retained in the solids recycle tank for recycling back to the mixing tank.

**Dry scrubber operation.** The key operating parameters that are necessary for effective operation of a spray dryer are:

- Sorbent feed
- Slurry sorbent content
- Outlet gas wet and dry bulb temperatures—the wet bulb/dry bulb temperature readings give an indication of the saturation of the gas stream and the potential for evaporation of moisture.

Effective operation of a spray dryer requires adequate sorbent for reacting with the acid gases and prevention of solids buildup. Solids buildup can occur if slurry moisture is not evaporated within the design time period. The liquid slurry feed rate and sorbent content should be balanced with the hot flue gas volume and acid gas content to ensure the desired removal of acid gases and evaporation of all moisture. The recommended operating ranges are:

- Slurry sorbent content—5 to 20% solids by weight.
- Wet bulb/dry bulb outlet gas temperature difference—90 to 180°F (50 to 100°C). The temperature difference is to ensure evaporation of all moisture.

The feed rate of dry sorbent to the makeup water in the sorbent mix tank is adjusted to obtain the desired sorbent content of the slurry. The flow rate of slurry to the atomizer in the reaction vessel is adjusted to change the wet bulb/dry bulb temperature difference. The slurry flow rate is usually monitored by a magnetic flow meter. An increase in slurry flow will reduce the wet bulb/dry bulb temperature difference.

Startup of a spray dryer should follow procedures that prevent condensation in the system and ensure evaporation of all slurry moisture in the scrubber reactor vessel. One method of ensuring evaporation is to use auxiliary fuel firing to bring the exhaust gas temperature up to the normal operating range before injecting the slurry. Another method would be to gradually increase slurry feed at startup to maintain a 90–180°F (50–100°C) wet bulb/dry bulb temperature differential.

Proper shutdown should ensure that:

- No liquid moisture remains or condenses in the spray dryer or fabric filter after shutdown.
- Auxiliary fuel firing should be used to maintain temperatures above saturation until all sorbent is purged from the system.
- The fabric filter should go through a complete cleaning cycle before shutdown to prevent bag blinding and reaction product salt corrosion.

**Spray dryer/fabric filter (SD/FF).** Figure 3.34 provides a schematic diagram of a typical SD/FF system. Lime (CaO) is stored as a dry powder in a silo. Before use, it is slaked and fed into a storage tank. The lime slurry is then pumped into the spray absorber, typically with a rotary atomizer. The heat from the flue gases entering the absorber is sufficient to evaporate the water, leaving a dry powder in the reactor. By controlling the amount of water in the slurry, the temperature of flue gas leaving the spray dryer can be controlled to a desired range between 230 and 320°F (110 and 160°C). Some of the powder drops to the bottom of the spray dryer but the majority passes to the fabric filter. The baghouse provides for excellent particulate matter collection at relatively low pressure loss [6–10 in. w.c. (1.5–2.5 kPa)]. Solid material collected by the fabric filter consists of combustor particulate matter, calcium salts, and unreacted lime. This material may be disposed of as dry solid waste.

Typical systems of fabric filters are designed with air-to-cloth ratios of the order of 3.5–5.0 (ft<sup>3</sup>/s)/ft<sup>2</sup> or 3.5–5.0 ft/s (1.1–1.5 m/s). This implies that baghouse designs with 40 to 180 bags (depending mainly on air flow) are needed for average medical waste incinerators. Bag replacement will likely be required about every 3 years. Replacing all the bags should take less than about 40 hours and can be accomplished over a weekend. United McGill (a baghouse supplier) expects overall system maintenance to be about 40 hours per year.

## 5.2 Dry Injection

**Major components.** Figure 3.35 shows a dry injection system schematic. Similar to a spray dryer, a dry injection scrubber is combined with a fabric filter, which is used to collect the particles in the system. The major components of a dry injection system are: (1) dry sorbent storage tank; (2) blower and pneumatic line for transfer of the sorbent; (3) injector; (4) particulate control device (fabric filter or ESP) for collection of the dry sorbent; (5) expansion/reaction chamber (optional). In some cases, the dry alkaline sorbent is injected directly into an expansion/reaction vessel rather than into the duct.

This type of scrubber uses finely-divided calcium hydroxide for absorption of acid gases. The reagent feed has particle sizes which are 90% by weight through 325 mesh screens. The calcium hydroxide is injected countercurrently in the gas stream. The gas stream, containing the entrained calcium hydroxide particles and fly ash, is then fed to the fabric filter. Absorption of acid gases and organic compounds (if present) occurs primarily while the gas stream passes the dust cake on the surface of the filter bags. The calcium hydroxide feed rate for dry injection is three to four times the stoichiometric quantities needed, thus making the system unattractive for very large systems (EPA-89/03).

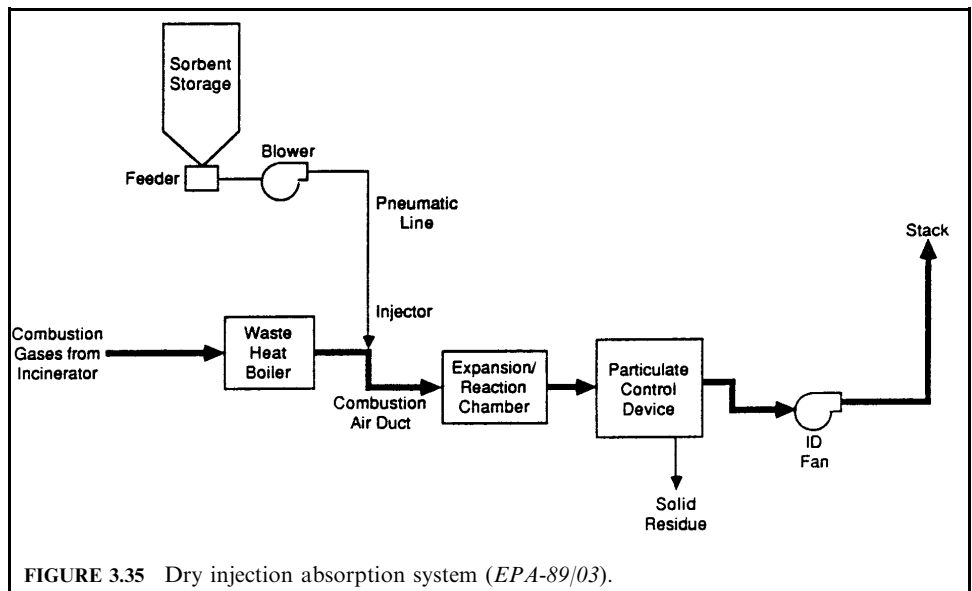

FIGURE 3.35 Dry injection absorption system (EPA-89/03).

**Process description.** The process of dry injection can be described as follows:

1. Dry injection systems are similar to spray dryers, with the exception that the sorbent materials are injected into the flue gases as a dry powder. Since there is no moisture, the reaction rate is slower than with a spray dryer.
2. The dry injection system uses finely-divided alkaline sorbent material, usually calcium hydroxide or sodium bicarbonate, with the approximate consistency of talcum powder.
3. The sorbent is injected into the flue gas duct. The injection creates turbulence that results in mixing of the sorbent with the flue gas.
4. Absorption of the acid gases by the sorbent begins in the flue gas ductwork.
5. An expansion/reaction chamber may be included to increase the residence time of the gases in the system, allowing more time for the reaction to occur.
6. The sorbent and reaction products are carried by the flue gas to the particulate control device, where the solids are collected.
7. If a fabric filter is used as the particulate control device, acid gas removal may be further enhanced by reaction with the sorbent collected in the filter cake.

**Dry injection.** The key operating parameters for a dry injection system are:

- Sorbent injection rate—The sorbent injection rate should provide adequate sorbent for neutralization of the acid gases and is dependent on the acid gas content of the flue gas.
- Particle size of the sorbent—As particle size decreases, the surface area to volume ratio increases, which improves the efficiency of acid gas collection.

The particle size and injection rate of the sorbent should be specified by the process vendor. Generally, the sorbent feed will have a particle size where 90% by weight will pass through a 325 mesh screen. This dust is approximately the consistency of talcum powder.

Operation of a dry injection system is relatively simple. The key operation includes:

- Maintaining the pneumatic transfer line at a constant airflow rate.
- Monitoring outlet acid gas concentration and increasing the sorbent injection rate to achieve the desired acid gas levels.

There are no special startup considerations for dry injection. At startup of the incinerator, the dry sorbent can be injected without any special preparations.

The only special concern for shutdown of a dry injection system is to put the fabric filter through a cleaning cycle after sorbent injection is stopped. This prevents possible blinding from condensation and reaction product salt damage to the fabric filter components.

**Dry injection/fabric filter (DI/FF).** Figure 3.35 is a schematic diagram of a typical DI/FF system. The DI/FF system has several major potential advantages, including:

1. It is able to achieve 0.015 gr/dscf (0.03 g/dscm) or even lower particulate emission limits;
2. It does not have liquid discharge and it should have no visible plume.
3. It is able to effectively capture particles smaller than 1  $\mu\text{m}$ . Submicrometer particles contain high concentrations of volatile metals.

Disadvantages include the fact that reagent costs are two to three times that of a wet control system due to the inefficiency of acid gas capture by dry particles. Further, since continuous HCl monitoring is not readily available, the rate of sorbent injection must be set at a sufficiently high level to reach 90% capture at the maximum expected acid gas level (90% capture is required by some states and is likely to be required by many more). For small-scale systems,

careful modulation of solid sorbent flow is difficult to achieve and would add needlessly to system cost and complexity.

## 6 ACCESSORY EQUIPMENT FOR SCRUBBER

---

Many components comprise a complete scrubbing system. To fully appreciate the operation of a scrubber, it is important to have a basic understanding of the major components of the system. For instance, fans and ducts are required to transport exhaust gas while pumps, nozzles, and pipes transport liquid to and from the scrubbing vessel. Water-recirculation and mist-elimination systems are also necessary. Failure of any of these parts will cause problems for the entire scrubbing system. Major components of a scrubbing system include (EPA-84/03, p. 7-1):

- Entrainment separator (mist separator)
- Nozzle
- Quencher

### 6.1 Entrainment Separator

The basic principle of wet scrubbers is that the pollutants must first be contacted with the liquid; then the liquid droplets must be removed from the exhaust gas stream before it is exhausted to the atmosphere. Gas moving at high velocities that mixes with a liquid will entrain drops of that liquid. Entrainment separators, also called mist eliminators, are used to remove the liquid droplets. Although the major function of an entrainment separator is to prevent liquid carryover, it also performs additional scrubbing and recovers the scrubbing liquor, which saves on operating costs. Entrainment separators are therefore usually an integral part of any wet scrubbing system (EPA-84/03, p. 2-3; EPA-81/12, p. 4-57; EPA-81/10, p. 9-39).

Entrained liquid droplets vary in size depending on how the droplets were formed. Drops that are torn from the body of a liquid are large (10–100  $\mu\text{m}$  in diameter), whereas drops that are formed by a chemical reaction or by condensation are of the order of 5  $\mu\text{m}$  or less in diameter. Numerous types of entrainment separators are capable of removing these droplets. Those most commonly used for air pollution control purposes are:

- Cyclonic separator (centrifugal separator)
- Wire mesh pad separator (plastic pad separator)
- Chevron blade separator
- Impingement blade separator

*Cyclonic separator:* A cyclonic separator is also known as a centrifugal separator. It is a separator in a cylindrical tank with a tangential inlet or turning vanes (Fig. 3.36). The tangential inlet or turning vanes impart a swirling motion to the droplet-laden gas stream. The droplets are thrown outward by centrifugal force to the walls of the cylinder. Here they coalesce and drop down the walls to a central location and are recycled to the absorber. These units are simple in construction, having no moving parts. Therefore, they have few plugging problems. Good separation down to the 10- $\mu\text{m}$  range can be expected. The pressure drop across the cyclone is 10–15 cm (4–6 in.) of water for a 98% removal efficiency of droplets down to the 20–25  $\mu\text{m}$  range. Cyclonic separators are commonly used with venturi scrubbers.

*Wire mesh separator:* Wire mesh or plastic pad separators consist of woven material about 10–15 cm (4–6 in.) thick that fit across the entire diameter of the scrubber (Fig. 3.37). The

mesh allows droplets to impact on the material surface, agglomerate with other droplets and drain off by gravity. The pad is usually slanted (no more than a few degrees) to permit the liquid to drain off. Essentially 100% collection of droplets larger than  $3\ \mu\text{m}$  is obtained with pressure drops of approximately 10–15 cm (4–6 in.) of water (the pressure drop is dependent on depth and compaction of fibers). The disadvantage with mesh pads is that their small passages are subject to plugging.

*Chevron blade separator:* In the chevron blade separator (Fig. 3.38), gas passes between the blades and is forced to travel in a zigzag pattern. The liquid droplets cannot follow the gas streamlines, so they impinge on the blade surfaces, coalesce, and fall back into the scrubber chamber or drain. Special features such as hooks and pockets can be added to the sides of these blades to help improve droplet capture. Chevron grids can be stacked or angled on top of one another to provide a series of separation stages. Pressure drop is approximately 6.4 cm (2.5 in.) of water for capture of droplets as small as  $5\ \mu\text{m}$  in diameter.

*Impingement blade separator:* Impingement blade separators (Fig. 3.39) create a cyclonic motion because they are similar in shape to the common house fan. As the gas passes over the curved blades, they impart a spinning motion that causes the mist droplets to be directed to the vessel walls, where they are collected. Pressure drop ranges from 5 to 15 cm (2 to 6 in.) of water.

Table 3.7 summarizes some operating characteristics of entrainment separators.

**TABLE 3.7** Typical Operational Characteristics of Entrainment Separators

Separator type	Droplet size collected at 99%, $\mu\text{m}$	Max. gas velocity		Pressure drop	
		m/s	ft/s	cm H <sub>2</sub> O	in. H <sub>2</sub> O
Cyclonic	10–25	20	65	10–15	4–6
Wire mesh pad	3	5	15	1.0–15	0.5–6
Chevron blade	35	3	10	6.4	2.5
Impingement blade	20	8	27	5–15	2–6

## 6.2 Nozzle

Three different nozzle designs are used to produce a fine, cone-patterned spray (Fig. 3.40). They are:

- Impingement nozzle
- Solid cone nozzle
- Helical spray nozzle

*Impingement nozzle:* In the impingement nozzle, highly pressurized liquid passes through a hollow tube in the nozzle and strikes a pin or plate at the nozzle tip. A very fine fog of tiny,

uniform-sized droplets approximately 25–400  $\mu\text{m}$  in diameter is produced. Because there are no internal parts in the nozzle, it will not plug as long as particles larger than the opening are filtered out by a strainer. These nozzles are usually made of stainless steel or brass.

*Solid cone nozzle:* In the solid cone nozzle, liquid is forced over an insert to break it up into a cone of fine droplets. Cones can be full, hollow, or square with spray angles from  $15^\circ$  to  $140^\circ$ . These nozzles can be made of stainless steel, brass, alloys, Teflon, and other plastic materials.

*Helical spray nozzle:* The helical spray nozzle has a descending spiral impingement surface that breaks up the sprayed liquid into a cone of tiny droplets. The cones can be full or hollow with spray angles from  $50^\circ$  to  $180^\circ$ . There are no internal parts, which helps reduce nozzle plugging. These nozzles can be made of stainless steel, brass, alloys, Teflon, and other plastic materials.

Different spray nozzles are appropriate for different scrubbing systems. Characteristics of the nozzles and sprays include the following:

- *Droplet size:* In general, scrubbers using sprays to provide gas–liquid contact (such as in spray towers) require tiny, uniform-sized droplets to operate effectively. If the sprays are used merely as a method of introducing liquid into the vessel (such as in packed towers), then droplet size is not as critical.
- *Opening size:* The actual opening in the nozzle will vary depending on the applications and the amount of liquid required. Openings range from 0.32 to 6.4 cm (0.125 to 2.5 in.).
- *Spray pattern:* Nozzles are available that produce sprays in a number of geometric shapes, such as square, fan, hollow cone, and full cone. Full-cone sprays are used to provide complete coverage of the areas sprayed.
- *Operating mechanism:* Droplets can be produced by a number of methods such as impinging the liquid on a solid surface or atomizing the liquid using air.
- *Power consumption:* In general, the finer the liquid droplet, the higher the power consumption.

Nozzle plugging is one of the most common malfunctions in wet scrubbers. Plugged nozzles reduce the gas–liquid contact and can also result in scale buildup on, or heat damage to, the scrubber parts formerly sprayed by the nozzle. Nozzle plugging can be most readily detected by observing the liquid spray pattern; however, if the nozzles are not easily accessible, a decrease in liquid flow is also a telltale sign. Remedies include replacing the nozzle with one that is more open, cleaning the nozzle frequently, filtering the scrubbing liquid, or increasing the bleed rate and makeup water rates.

Another problem that can arise is reduced pressure in the spray header. This can cause a reduction in the spray angle (area covered) and an increase in the size of droplets produced.

### 6.3 Quencher

Occasionally, hot exhaust gas is quenched by water sprays before entering the scrubber. This can be accomplished by spraying liquid into the exhaust gas. Hot gases (those above ambient temperature) are often cooled to near the saturation level by sprays before they enter a scrubber. If not cooled, the hot gas stream can evaporate a large portion of the scrubbing liquor, adversely affecting collection efficiency. Some liquid droplets can evaporate before they have a chance to contact pollutants in the exhaust stream, and others can evaporate after contact, causing captured particles to become re-entrained. In some cases, quenching can actually save money. Cooling the gases reduces the temperature and, therefore, the volume of gases, permitting the use of less expensive materials of construction and a smaller scrubber vessel and fan (EPA-84/03, p. 7-5).

Quenchers are designed using the same principles as scrubbers. Increasing the gas-liquid contact in them increases their operation efficiency. Small liquid droplets cool the exhaust stream quicker than large droplets because they evaporate more easily. Therefore, less liquid is required. However, in most scrubbing systems, approximately 1.5 to 2.5 times the theoretical evaporation demand is required to ensure proper cooling. Evaporation also depends on time. It does not occur instantaneously. Therefore, the quencher should be sized to allow for an adequate exhaust stream residence time.

The cleanest water available should be used for presaturating. Quenching with recirculated scrubber liquor can reduce overall scrubber performance, since recycled liquid usually contains a high level of suspended and dissolved solids. As the liquid droplets evaporate, these solids become re-entrained in the exhaust gas stream. To help reduce this problem, makeup water can be added directly to the quench system rather than by adding all makeup water to a common sump.

## 1 GENERAL

---

This chapter presents calculation methods to estimate the risk to human health from air toxics. The assessment of risk is described by several guidance documents published by the United States Environmental Protection Agency (USEPA). The assessment of risk from contaminants released by sources of air toxics is different than typical risk assessments such as those performed at Superfund sites or facilities with hazardous waste treatment, storage, and disposal permits, because the concentration of contaminants in environmental media is estimated through the use of models rather than the collection of environmental samples. This does not preclude the collection of environmental samples, but modeling rather than sample collection is preferred in many instances because it is less costly to implement.

Because of this unique difference, the main component of air toxic risk assessment is modeling the fate and transport of air toxics in the environment. Air toxic risk assessment models describe the movement of air toxics from stacks and fugitive emission sources to the air, soil, sediment, and water. The models then describe the movement of contaminants from water and sediment into fish and from soil into vegetables, grain, and forage and then into farm animals where they are consumed by humans. The ambient air concentration is also modeled for the purpose of assessment of direct inhalation risk of air toxics.

The primary reference that describes the fate and transport of air toxics in the environment is the Protocol for Human Health Risk Assessment at Hazardous Waste Combustion Facilities published as a final guidance by the USEPA in September, 2005. This document is commonly referred to as the HHRAP. Mr. David Weeks was the chief editor of the original draft of this document and Dr. Jesse was one of the significant contributors. Some of the text and examples presented here were originated by the authors, and some of them were edited from or quoted from previously published USEPA documents (described in the References section).

In addition to fate and transport modeling, this section also describes ingestion rates of air toxics, risk for cancer, and noncancer health impacts on humans. The base case for all the calculations presented in this section is presented below:

## 2 EMISSIONS AND SITE CHARACTERIZATION

---

The first step in the air toxics risk assessment process is the characterization of emissions. The characterization includes:

1. Compiling basic facility information.
2. Identifying emission sources.
3. Estimating air toxic emission rates.

## 2.1 Calculation Example Case

Throughout this chapter, an example case will be used to illustrate how the risk assessment calculations are performed. The example calculations will be presented for the chemicals 2,3,7,8 = tetrachlorodibenzodioxin (TCDD), silver and divalent mercury (often referred to as mercuric chloride). The emission rates of these three chemicals are  $1.0 \times 10^{-5}$ ,  $2.0 \times 10^{-5}$ , and  $1.44 \times 10^{-5}$  g/s (speciated from a total mercury emission of  $3 \times 10^{-5}$  g/s), respectively, each from a single stack. A water body with an area of  $1 \times 10^6$  m<sup>2</sup> is located nearby, and a watershed that is  $3 \times 10^6$  m<sup>2</sup> in area surrounds it. A multitiered grid of air modeling receptors was used to collect air parameters. The calculations use parameters specific to the adult resident scenario (Fig. 1.1).

## 2.2 Compiling Basic Facility Information

The basic facility information that is necessary to complete an air toxics risk assessment can be grouped into three components:

- Chemicals used or manufactured at the facility.
- Location of emission sources.
- Mechanism of release to the environment.

**Chemicals used or manufactured.** The chemicals used or manufactured at the facility must be identified because this information is necessary to determine which air toxics will be the focus of the risk assessment. The chemicals may be released as fugitive emissions from manufacturing or waste

treatment processes or as products of incomplete combustion (PICs) from combustion processes. Chemicals that are not used or manufactured at the facility or cannot be generated as PICs from combustion processes do not need to be evaluated in the risk assessment. For example, pesticides should not be evaluated at facilities that do not manufacture pesticides because these chemicals are not part of the manufacturing process and are not known to be formed as PICs from combustion processes.

**Location of emission sources.** The geographic location of emission sources is an important component of the air modeling component of the risk assessment process, especially at large facilities that encompass large geographic areas. The location of emission sources is important because the transport of the air toxics from the release point is characterized by models that require the point of the release as one of the modeling input parameters. The geographic location of emission sources is typically characterized by coordinates, preferably in units of Universal Transverse Mercator (UTM), in meters.

**Mechanism of release.** The mechanism of release to the environment is important because it affects the mass emission rate of air toxics. The emission rate of air toxics from stacks is determined differently from the emission rate of air toxics from fugitive sources like valves and flanges.

In many cases the information needed to complete an air toxic risk assessment can be obtained from state environmental agency emission inventories. In other cases, emission rates must be estimated based on test data or with other common engineering techniques described elsewhere in this text.

## 2.3 Identifying Emission Sources

The sources of air toxic emissions include PICs from combustion devices such as utility boilers, thermal oxidizers, and incinerators. Other sources of air toxic emissions include fugitive emissions from manufacturing processes, wastewater treatment, spills, and transportation.

**Estimating emission rates from stacks.** The emission of air toxics from stacks is typically characterized by testing. These emission tests describe the concentrations of contaminants in the stack gas at dry standard conditions in terms of mass per unit volume (e.g.,  $\mu\text{g}/\text{m}^3$ ). The mass rate of air toxic emissions is calculated as the product of the stack gas concentration and the stack gas flow rate also at dry standard conditions.

$$Q = SGF \times SGC \times CFO_2 / 10^6 \quad (1.1)$$

where

$$\begin{aligned} Q &= \text{COPC (Compounds of potential concern)-specific emission rate (g/s)} \\ SGF &= \text{Stack gas flow rate at dry standard conditions (dscfm/s)} \\ SGC &= \text{COPC stack gas concentration at 7 percent O}_2 \text{ as measured in the stack test} \\ &\quad (\mu\text{g/dscfm}) \\ CFO_2 &= \text{Correction factor for conversion to actual stack gas concentration O}_2 \text{ (unitless)} \\ 1 \times 10^6 &= \text{Unit conversion factor } (\mu\text{g/g}) \end{aligned}$$

It should be noted that the oxygen correction factor is equal to 1.0 if the stack gas concentration is not corrected to 7 percent oxygen for the purpose of evaluating compliance with other regulatory standards.

**Emissions from process upsets.** USEPA typically recommends that stack emissions be adjusted for process upsets when air toxic risk assessments are performed in support of hazardous waste combustion permits. Process upsets can occur during start-ups, shutdowns, and malfunctions of the combustion unit or air pollution control system (APCS). Upset emissions are generally expected to be greater than stack emissions (over short periods of time) because the process upsets results in incomplete destruction of the wastes or other physical or chemical conditions within the system that promote the formation and/or release of hazardous compounds.

To account for the increased emissions associated with process upsets, the stack emission rate derived from stack test data is multiplied by an upset factor. The following types of data may be considered and evaluated to derive upset factors:

- Data for continuous emissions monitoring systems that measure stack carbon monoxide, oxygen, total hydrocarbon (if required), or opacity (if appropriate)
- Data on combustion chamber, APCS, or stack gas temperature
- Frequency and causes of automatic waste feed cutoffs (AWFCO)
- APCS operating variables such as baghouse pressure drop, liquid scrubber flow rate, or electrostatic precipitator voltage
- Stack test collected while the combustion unit was operated under upset conditions

This information can be used to estimate the magnitude of the increase in emissions and the percentage of time on an annual basis that the unit operates at upset conditions. When site specific data are not available upset emissions can be estimated using the California Air Resources Board reference (CARB, 1990).

*Estimating emissions from process upsets.* To represent stack emission rates during process upsets, multiply the emission rate developed from the stack test data by 2.8 for organics and 1.45 for metals. These factors are derived by assuming that emissions during process upsets are 10 times greater than emissions measured during the stack test. Since the unit does not operate under upset conditions continually, the factor must be adjusted to account for only the period of time, on an annual basis, that the units operates under upset conditions:

1. For organic compounds, the facility is assumed to operate as measured during the stack test 80 percent of the year and operate under upset conditions 20 percent of the year:

$$[(0.80)(1) + (0.20)(10) = 2.8].$$

2. For metals, the combustion unit is assumed to operate as measured during the stack test 95 percent of the year and operate under upset conditions the remaining 5 percent of the year:

$$[(0.95)(1)+(0.05)(10) = 1.45].$$

Catastrophic process upsets brought about by complete failure of combustion and APCS resulting from nonroutine events such as explosions, fires, and power failures are considered accidental releases. The emissions associated with these events are estimated using different methods that are beyond the scope of this chapter.

*Quantitative estimation of fugitive emissions from process equipment.* Quantitative estimation of fugitive emissions includes: (1) identifying equipment to be evaluated as fugitive emission source(s); (2) grouping equipment, as appropriate, into a combined source; and (3) estimating compound specific emission rates for each source. Multiple steps are commonly necessary to estimate fugitive emissions.

Step 1. Identifying fugitive emission sources: Equipment types covered under a fugitive emission analysis include the following:

1. Pumps
2. Valves
3. Connectors (flanges, unions, tees, and so on.)
4. Compressors
5. Pressure-relief devices
6. Open-ended lines
7. Product accumulator vessels
8. Sampling connecting systems

## 9. Closed vent systems

## 10. Agitators

Step 2. Estimating fugitive emissions from process equipment: Based on guidelines provided in USEPA (1995e), "Protocol for Equipment Leak Emission Estimates, EPA-453/R-93-017," fugitive emissions for each equipment listed under 40 CFR Part 265, Subpart BB can be estimated by the following four approaches, in order of increasing refinement and data requirements:

1. Average emission factor approach (AEFA), which is the least refined of these methods
2. Screening ranges approach (SRA)
3. USEPA correlation approach (EPACA)
4. Unit-specific correlation approach (USCA)

These four approaches are used to estimate fugitive emission rates of volatile organic compounds (VOCs) from process equipment. Because data on fugitive emissions at a facility is generally limited, the AEFA method will apply in most cases.

*An example calculation using the AEFA method.* Information required for estimating fugitive emission rates using the AEFA method is as follows:

1. Type of waste stream associated with each equipment type
  - Light liquids are those in which the sum of the concentration of individual constituents with a vapor pressure over 0.3 kPa at 20°C is greater than or equal to 20 percent by weight
  - Heavy liquids are all others liquids not meeting the definition of light liquids as specified above
2. Number of each equipment type associated with each waste stream
3. Total VOC weight fraction of each waste stream
4. Weight fraction of each VOC in each waste stream
5. Operational time period of equipment

When this approach is used, equipment can be grouped by waste streams of similar characteristics and VOC composition. Site-specific factors can significantly influence fugitive emission rates of leaks from equipment.

The average emission factors for synthetic organic chemicals manufacturing industry process units, refineries, and natural gas plants are presented in USEPA (1995k). Table 1.1 is an excerpt from this guidance document. These emission factors are most valid for estimating rates of emissions from a grouping of equipment over a long time period.

**TABLE 1.1** Emissions Factors for Fugitive Emissions from Pipelines

Equipment type	Service	Emission factor (kg/hr/source)
Valves	Gas	0.00597
	Light liquid	0.00403
	Heavy liquid	0.00023
Pump seals	Light liquid	0.0199
	Heavy liquid	0.00862
Compressor seals	Gas	0.228
Pressure relief valves	Gas	0.104
Connectors	All	0.00183
Open-ended lines	All	0.0017
Sampling connectors	All	0.0150

*Source:* USEPA (1993e).

The total VOC emissions rate for a specified equipment type can be calculated by multiplying the equipment emission factor by the total VOC weight fraction and the number of each equipment type per waste stream. Speciated fugitive emissions can then be calculated by multiplying the weight fraction of each VOC in the waste stream and the total fugitive emission rate for the waste stream.

*Hazardous air pollutants (HAPs) fugitive emissions—unit leaks.* Examples of fugitive emissions from combustion unit leaks include the following:

- Combustion units that operate under negative pressure may experience temporary positive pressures (“puffing”) that cause fugitive emissions.
- Fugitive emissions resulting from the day-to-day operation of the combustion unit and APCs. These emissions will typically include: (1) leaks that occur due to a positive pressure in the APCs, and (2) routine maintenance activities such as replacement of baghouse collection bags.

*Fugitive particulate emissions.* The combustion of fuels and hazardous waste materials may result in the production of flyash. Fugitive particle emissions may result from the subsequent collection, handling, and disposal of the flyash.

*Quantitative estimation of fugitive particulate emissions.* Steps for the quantitative estimation of RCRA fugitive ash emissions include:

- Determining an empirical emission factor.
- Estimating the flyash generation rate.
- Accounting for air pollution control equipment, if applicable.

As demonstrated in the example calculation below, the fugitive particulate emission rate can be estimated by multiplying the empirical emission factor by the flyash generation rate and the control deficiency of the air pollution control equipment.

*Step 1. Determining an empirical emission factor*

Particle emissions associated with flyash loading and unloading can be estimated using an empirical emission factor of 1.07 lb/ton flyash. Because the combustion of coal and hazardous wastes are similar activities, flyash generated from similar control devices is expected to behave similarly under the same conditions, with respect to fugitive emissions. The emission factor determined during the empirical study (0.107 lb/ton flyash) can be adjusted by a factor (e.g., 10) to account for the fact that the flyash from the combustion of coal (as in the study) was wetted.

*Step 2. Estimating the flyash generation rate*

The flyash generation rate from the APCD (**air pollution control district**) can be obtained from the Permit Application or the equipment manufacturer. Both values should be approximately the same. Since a major portion of ash fed to the combustor is converted to bottom ash, it is likely that this value is a conservatively high estimate of the actual flyash generation rate.

*Step 3. Accounting for air pollution control equipment*

An APCD is used for controlling emissions during exhaust handling operations, such as flyash, an efficiency factor (e.g., 99.5 percent) can be applied to the emission rate.

*Example calculation to estimate the particle fugitive emissions.*

Step 1. Determine the empirical emission factor.

Step 2. Estimate the flyash generation rate. Ash emission rate is calculated by multiplying the empirical emission factor times the estimated flyash generation rate

$$(1.07 \text{ lb/ton}) \times (5000 \text{ tons/yr}) = 5350 \text{ lb/yr}$$

Step 3. Account for the air pollution control equipment removal efficiency:

The product of Steps 1 and 2 is multiplied times one minus the fabric filter efficiency to obtain the final fugitive ash emission rate for use in the risk assessment

$$(5350 \text{ lb/yr}) \times (1 - 0.995) = 26.75 \text{ lb/yr}$$

## 2.4 Identifying Compounds of Potential Concern

Compounds of Potential Concern (COPCs) are those air toxics evaluated throughout the risk assessment. COPCs are volatile organic compounds (VOCs), metals, and PICs. COPCs have typically been identified by USEPA in seven different general categories (US EPA 1994g; 1994i; 1994j; 1994n):

1. Polychlorinated dibenzo(*p*)dioxins (PCDD) and polychlorinated dibenzofurans (PCDF)
2. Polynuclear aromatic hydrocarbons (PAH)
3. Polychlorinated biphenyls (PCB)
4. Nitroaromatics
5. Phthalates
6. Other organics
7. Metals

**Polychlorinated dibenzo(*p*)dioxins and dibenzofurans.** PCDD and PCDF's are routinely evaluated in air toxic risk assessments that are performed on combustion sources because the de novo formation of these air toxics is well supported in the scientific literature. De novo formation occurs when PCDDs and PCDFs form in dry APCSS by reactions between halogens and undestroyed organic material from the furnace and are catalyzed by flyash. PCDDs and PCDFs were first discovered as thermal decomposition products of polychlorinated compounds, including:

1. Herbicide 2,4,5-T
2. Hexachlorophene
3. PCBs
4. Pentachlorophenol
5. Intermediate chemicals used to manufacture these compounds

A review of currently available dioxin data for combustion units reveals that total PCDD/PCDF emission rates vary by more than 28-fold between different facilities, even though they use similar combustion units and APCSS (USEPA 1996b). Site-specific emission data are needed to enable completion of a more refined risk assessment at each combustion unit.

**Polynuclear aromatic hydrocarbons.** The HHRAP states that PAHs are common products of incomplete combustion. However, the authors note that their anecdotal experience is that carcinogenic PAHs are not typically detected at concentrations above the detection limit when common stack test methods are used to quantify emissions from well-operated combustion units. (Noncarcinogenic PAHs such as naphthalene and pyrene, however, are routinely detected.) The carcinogenic PAHs include the following: benzo(a)pyrene (BaP); benzo(a)anthracene; benzo(b)fluoranthene; benzo(k)fluoranthene; chrysene; dibenz(a,h)anthracene; and indeno(1,2,3-cd)pyrene. USEPA considers all of these compounds to be carcinogenic; all except chrysene are known to be animal carcinogens. However, an oral cancer slope factor is only available for one PAH, benzo(a)pyrene. The risk associated with the remaining six carcinogenic PAHs is assessed through the use of relative potency factors that are described in the HHRAP.

**Volatile organic compounds.** USEPA (1990e) reported that volatile organics listed as probable PICs produced by the combustion of hazardous waste include benzene, chloroform, tetrachloroethylene, 1,1,1-trichloroethane, toluene, and methylene chloride. The author's anecdotal experience is

that VOCs are the most common types of PICs detected in combustion stack gas. However, VOCs do not bioaccumulate in the environment and, thus, are not typically a significant concern for air toxic risks through the food chain. The quantities of VOCs emitted from combustion stacks are typically so minor that they rarely drive the outcome of air toxic risk assessments, although each case should be evaluated separately. However, the risk associated with the direct inhalation of VOCs from fugitive and other emission sources is much more problematic and in many cases exceeds the risk from indirect sources (e.g., food chain) for combustion units.

**Metals other than mercury.** Metals are a component of the inorganic air toxics and can include: antimony, arsenic, barium, beryllium, cadmium, chromium, hexavalent chromium, lead, nickel, selenium, silver, thallium, and zinc. Unlike other COPCs, the emission rate of metal air toxics is significantly affected by the feed rate of metals into the combustion unit and the removal efficiency of the air pollution control equipment.

**Mercury.** USEPA commonly recommends that mercury be evaluated as a COPCs in air toxic risk assessment, especially for coal fired units and units that burn waste containing mercury. It is the author's experience that mercury is the most problematic of all the air toxics because of its high bioaccumulation properties and extremely low reference dose. Indeed, even facilities that do not use mercury in their processes may have issues with it at concentrations close to the detection limit in air toxic risk assessments if the facility is located near shallow water bodies that can support recreational fishing. Additionally, air emissions of mercury contribute to local, regional, and global deposition. This fact is important when conducting air toxic risk assessments at specific facilities because not all the mercury emitted by one facility will be deposited in the area immediately around the facility.

The speciation of mercury emissions is thought to depend on the fuel used, flue gas cleaning, and operating temperatures. Total mercury exiting the stack is assumed to consist of elemental and divalent species, with no emissions of methylmercury assumed. The divalent fraction is split between vapor- and particle-bound phases. Much of the divalent mercury is thought to be mercuric chloride ( $\text{HgCl}_2$ ) (USEPA 1997d).

*Phase allocation and speciation of mercury exiting the stack.* Mercury emissions from stacks include both vapor and particle-bound forms; and speciated as both divalent ( $\text{HG}^{2+}$ ) and elemental mercury ( $\text{HG}^0$ ). USEPA recommends a conservative approach that assumes phase allocation of mercury emissions from hazardous waste combustion of 80 percent of the total mercury in the vapor phase and 20 percent of total mercury in the particle-bound phase. This allocation is:

- Consistent with mercury emissions speciation data for hazardous waste combustion sources reported in literature (Peterson et al. 1995).
- Believed to be reasonably conservative, since it results in the highest percentage of total mercury being deposited in proximity to the source, and therefore, indicative of the maximum indirect risk.

The divalent form emitted, either in the vapor phase or particle-bound, are removed faster from the atmosphere than elemental mercury. In addition, vapor phase divalent mercury is thought to be more rapidly and effectively removed by both dry and wet deposition than particle-bound divalent mercury, as a result of the reactivity and water solubility of vapor divalent mercury.

*Vapor phase mercury.* Only a small fraction (assumed to be 1 percent) of vapor-phase elemental mercury either is adsorbed to particulates in the air and is deposited or converted to the divalent form to be deposited. Of the 60 percent vapor phase divalent mercury, about 68 percent is deposited and about 32 percent is transported outside of the United States or is vertically diffused to the free atmosphere to become part of the global cycle (USEPA 1997d).

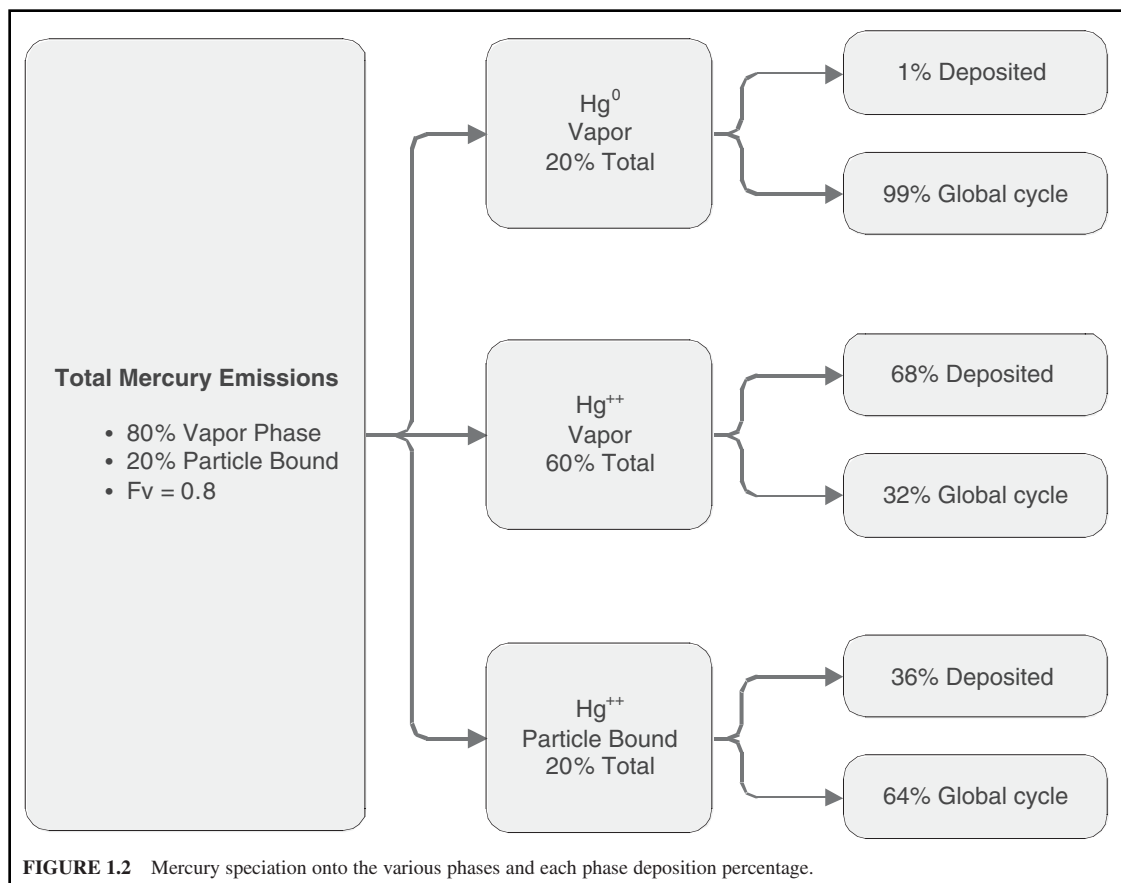

*Particle-bound mercury.* Of the 20 percent of the total mercury that is particle-bound, 99 percent is in the divalent form. (USEPA 1997d) indicates that only 36 percent of the particle-bound divalent mercury is deposited, and the rest is either transported outside of the United States or is vertically diffused to the free atmosphere to become part of the global cycle.

*Deposition and modeling of mercury.* USEPA assumes that deposition to the various environmental media is entirely divalent mercury in either vapor or particle-bound form. Without consideration of the global cycle, mercury speciations will result in 80 percent of the total mercury emitted, being deposited as divalent mercury and the remaining 20 percent being deposited as elemental mercury. Divalent mercury is considered for both the indirect exposure and inhalation pathways. Based on these assumptions, human exposure to (1) elemental mercury occurs only through direct inhalation of the vapor phase elemental form, and (2) divalent mercury occurs through both indirect exposure and direct inhalation of the vapor and particle-bound mercuric chloride.

*Methylation of mercury.* Both watershed erosion and direct atmospheric deposition can be important sources of mercury to a water body (USEPA 1997d). Mercury entering the water body is methylated predominately through biotic processes (USEPA 1997d). In the absence of modeling site-specific water body properties and biotic conditions, Risk assessors assume that 85 percent of total mercury in surface water is assumed to be divalent mercury and the remaining mass as methyl mercury.

*Note:* Methylation can be highly variable between environmental systems. This results in a significant degree of uncertainty implicit in modeling of mercury methylation.

Figure 1.2 below depicts the partitioning of mercury in the various phases, along with the deposition percentages and the portion that the Mercury Report to Congress estimates that escapes to the global cycle.

**FIGURE 1.2** Mercury speciation onto the various phases and each phase deposition percentage.

## 2.5 Particulate Matter

Particulate matter (PM) can be classified as aerosols, fogs, fumes, mists, smogs, or smokes depending on its physical state and origin.  $PM_{10}$  is defined as all condensed material suspended in air that has a mean aerodynamic diameter of 10  $\mu\text{m}$  or less;  $PM_{2.5}$  is the part of  $PM_{10}$  that is 2.5  $\mu\text{m}$  or less in diameter. Because of this wide range of toxicity, PM concentrations cannot be used to estimate the toxicity of emissions. USEPA does not recommend that PM be evaluated as a separate COPC in the risk assessment. However, PM is quite useful as an indicator variable, because it can be measured in real time and is sensitive to changes in operating conditions.

## 3 AIR DISPERSION MODELLING FOR AIR TOXICS

---

Estimation of potential human health risks associated with air toxics releases requires knowledge of atmospheric pollutant concentrations and annual deposition rates at actual and reasonable future exposure scenario locations. Air concentrations and deposition rates are estimated by using air dispersion models (ADMs). Air dispersion models are mathematical constructs that estimate the dispersion of gaseous and particulate emissions from sources of HAPs such as stacks, fugitive, area, mobile, among others.

This section provides brief guidance on the use of the standard USEPA ADMs, which may be used in most risk assessments, AERMOD (American Meteorological Society/EPA regulatory model) and CALPUFF (California Puff model). ADMs require the use of the following information for input into the model, and consideration of output file development:

1. Site-specific characteristics required for air modeling
  - Surrounding terrain
  - Surrounding land use
  - Facility building characteristics
2. Unit emission rate
3. Partitioning of emissions
4. Meteorological data

ADMs also require several preprocessing support computer programs that prepare and organize data for use in the model.

### 3.1 Background on ADMs for Risk Assessment

Two air models in current regulatory use are AERMOD and CALPUFF. These ADMs satisfy the following criteria:

1. Broad regulatory acceptance and experience in evaluating the impacts of air contaminants emitted from various industrial sources (e.g., short and tall stack heights, fugitive emissions from process and storage areas).
2. Can evaluate impacts attributable to a single source, with capability for evaluating multiple sources.
3. Can evaluate compounds emitted as vapor or particulate phase with consideration of deposition and removal processes based on the physical characteristics of the compound.
4. Accept placement of grid nodes at any location within the applicable range of the air model.
5. Can conduct stepwise evaluation of hourly meteorological conditions for multiple years of data producing short-term (acute) and long-term (chronic) averages as outputs.
6. Can evaluate building downwash effects.

The USEPA recommends the AERMOD for distances up to 50 km and CALPUFF for long-range transport (greater than 50 km and less than 200 km), and for the special conditions of very light or calm winds (less than 1 m/s) and areas with strong coastal effects, on a case-by-case basis. CALPUFF may be an important consideration in cases for evaluating chemical transformation of highly reactive contaminants based on long residence times during extended periods of light winds or calm conditions, transport over long distances, recirculation of contaminants due to local wind effects, coastal areas, and in hilly terrain and river valleys.

**Preprocessing programs.** Both AERMOD and CALPUFF require the use of additional computer programs, referred to as *preprocessors*. These programs manipulate available information regarding surrounding buildings and meteorological data into a format that can be used by ADM. Currently, these programs include the following:

- Building Profile Input Program (BPIP) calculates the maximum crosswind widths of buildings, which AERMOD then uses to estimate the effects on air dispersion. This effect on dispersion by surrounding buildings is typically known as building downwash or wake effects. The BPIP User's Guide contains detailed information for preparing the required building dimensions (length, height, and width) and locations for the AERMOD model.
- AERMET (American Meteorological Society/EPA regulatory meteorological processor) prepares meteorological data for use in the AERMOD. AERMET merges hourly measurements of surface parameters (e.g., precipitation, wind speed, and wind direction) with upper air soundings to generate micro-meteorology turbulence parameters, which will be used by AERMOD.

When sufficient site-specific data is available on the location, size and shape of structures in the vicinity of the emissions sources, the BPIP program should be used to prepare the AERMOD input file to consider the effects of building downwash on pollutant transport. The inclusion or omission of nearby structures should be approved by the permitting authority prior to performing the air dispersion modeling.

### 3.2 Site-Specific Information Required to Support Air Modeling

Site-specific information for the facility and surrounding area required to support air dispersion modeling includes:

1. The elevation of the surrounding land surface or terrain
2. Surrounding land uses
3. Characteristics of on-site buildings that may affect the dispersion of COPCs into the surrounding environment.

Often, site-specific information required to support air dispersion modeling can be obtained from review of available maps and other graphical data on the area surrounding the facility. The first step in the air modeling process is a review of available maps and other graphical data on the surrounding area. U.S. Geological Survey (USGS) 7.5-min topographic maps (1:24,000) extending to 10 km from the facility, and USGS 1:250,000 maps extending out to 50 km, should be obtained to identify site location, nearby terrain features, waterbodies and watersheds, ecosystems, nearby residences, and land use. Aerial photographs are frequently available for supplemental depiction of the area. An accurate facility plot plan—showing buildings, stacks, property, and fence lines—is also needed. Facility information including stack and fugitive source locations, building corners, plant property, and fence lines should be provided in Universal Transverse Mercator (UTM) grid coordinates in meters east and north in both USGS reference systems.

**Surrounding terrain information.** Terrain is important to air modeling because air concentrations and deposition rates are greatly influenced by the height of the plume above local ground level. For

air modeling purposes, terrain is referred to as *complex* if the elevation of the surrounding land within the assessment area—typically defined as anywhere within 50 km from the stack—is above the top of the stack evaluated in the air modeling analysis. USEPA recommends that most air modeling include terrain elevations for every receptor grid node. Some exceptions may be those sites characterized by very flat terrain.

In addition to maps which are used to orient and facilitate air modeling decisions, the digital terrain data used to extract receptor grid node elevations should be provided in electronic form. One method of obtaining receptor grid node elevations is using digital terrain data available from the USGS on the Internet at web site <http://www.WebGIS.com>.

**Surrounding land use information.** Land use information in the risk assessment is used for purposes of air dispersion modeling and the identification or selection of exposure scenario locations in the risk assessment. Land use analysis for purposes of selecting exposure scenario locations usually occurs out to a radius of 50 km from the centroid of the stacks to ensure identification of all receptors that may be impacted. However, in most cases, air modeling performed out to a radius of 10 km allows adequate characterization for the evaluation of exposure scenario locations. If a facility with multiple stacks or emission sources is being evaluated, the radius should be extended from the centroid of a polygon drawn from the various stack coordinates.

### 3.3 Use of Unit Emission Rate

In risk assessment studies from air toxics sources the ADM is usually run with a unit emission rate of 1.0 g/s in order to preclude having to run the model for each specific chemical. The unitized concentration and deposition output from the ADM, using a unit emission rate, are adjusted to the COPC-specific air concentrations and deposition rates in the estimating media concentration equations by using COPC-specific emission rates obtained during the stack test. Concentration and deposition are directly proportional to the unit emission rate used in the air dispersion modeling.

### 3.4 Partitioning of Emissions

COPC emissions to the environment occur in either vapor or particle phase. In general, most metals and organic COPCs with very low volatility (refer to fraction of COPC in vapor phase [ $F_v$ ] less than 0.05) are assumed to occur only in the particle phase. Organic COPCs occur as either only vapor phase (refer to  $F_v$  of 1.0) or with a portion of the vapor condensed onto the surface of particulates (e.g., particle-bound). COPCs released only as particulates are modeled with different mass fractions allocated to each particle size than the mass fractions for the organics released in both the vapor and particle-bound phases.

**Vapor phase modeling.** AERMOD output for vapor phase air modeling runs are vapor phase ambient air concentration, dry vapor deposition, and wet vapor deposition at receptor grid nodes based on the unit emission rate. Vapor phase runs do not require a particle size distribution in the AERMOD input file.

**Particle phase modeling (mass weighting).** Particle size is the main determinant of the fate of particles in air flow, whether dry or wet. The key to dry particle deposition rate is the terminal, or falling, velocity of a particle. Particle terminal velocity is calculated mainly from the particle size and particle density. Large particles fall more rapidly than small particles and are deposited closer to the stack. Wet particle deposition also depends on particle size as larger particles are more easily removed, or scavenged, by falling liquid (rain) or frozen (snow or sleet) precipitation.

The diameters of small particulates contained in stack emissions are usually measured in micrometers ( $\mu\text{m}$ ). Unfortunately, few studies have been performed to directly measure particle size distributions from a variety of stationary combustion sources.

*Note:* Actual stack test data will be different from the hypothetical values, because of the use of particle “cut size” for the different cascade impactor filters (or Coulter counter-based distributions) used during actual stack sampling. However, because ADMs require mean particle diameter for each particle size distribution, and the stack test data identifies only the mass (weight) of particles in a range bounded by two specific diameters, stack test data must be converted into a mean particle diameter which approximates the diameter of all the particles within a defined range. Consistent with USEPA 1993h, the mean particle diameter is calculated by using the following equation:

$$D_{Mean} = (0.25 \times (D_1^3 + D_1^2 D_2 + D_1 D_2^2 + D_2^3))^{1/3} \quad (1.2)$$

where

$D_{mean}$  = Mean particle diameter for the particle size category ( $\mu\text{m}$ )

$D_1$  = Lower bound cut of the particle size category ( $\mu\text{m}$ )

$D_2$  = Upper bound cut of the particle size category ( $\mu\text{m}$ )

**Example for mass weighted particulate fraction.** For example, the mean particle diameter of  $5.5 \mu\text{m}$  in Table 1.2 is calculated from a lower bound cut size (assuming a cascade impactor is used to collect the sample) of  $5.0 \mu\text{m}$  to an upper bound cut size of  $6.15 \mu\text{m}$ . In this example, the mean particle diameter is calculated as:

From Table 1.2, the mean particle diameter is  $5.5 \mu\text{m}$ . The mass of particulate from the  $5.0 \mu\text{m}$  stack test data is then assigned to the  $5.5 \mu\text{m}$  mean particle diameter for the purpose of computing the “fraction of total mass.”

Typically, 8 to 10 mean particle diameters are available from stack test results and should be used in the air modeling. A minimum of three particle size categories ( $> 10 \mu\text{m}$ , 2 to  $10 \mu\text{m}$ , and  $< 2 \mu\text{m}$ ) detected during stack testing are required for air modeling. For facilities with stack test results which indicate mass amounts lower than the detectable limit (or the filter weight is less after sampling than before), a single mean particle size diameter of  $1.0 \mu\text{m}$  should be used to represent all mass (e.g., particle diameter of  $1.0 \mu\text{m}$  or a particle mass fraction of 1.0) in the particle and particle-bound model runs.

After calculating the mean particle diameter (Col. 1), the fraction of total mass (Col. 4) per mean particle size diameter must be computed from the stack test results. For each mean particle diameter, the stack test data provides an associated mass of particulate. The fraction of total mass for each mean particle diameter is calculated by dividing the associated mass of particulate for that diameter by the total mass of particulate in the sample. In many cases, the fractions of total mass will not sum to 1.0 due to rounding errors. In these instances, USEPA advocates that the remaining mass fraction be added into the largest mean particle diameter mass fraction to force the total mass to 1.0.

**TABLE 1.2** Hypothetical Particle Size Distribution Data for Example

Mean particle diameter <sup>a</sup> ( $\mu\text{m}$ )	Particle radius ( $\mu\text{m}$ )	Surface area/volume ( $\mu\text{m}^{-1}$ )	Fraction of total mass	Proportion available surface area	Fraction of total surface area
> 15.0	7.50	0.400	0.128	0.0512	0.0149
12.5	6.25	0.480	0.105	0.0504	0.0146
8.1	4.05	0.741	0.104	0.0771	0.0224
5.5	2.75	1.091	0.073	0.0796	0.0231
3.6	1.80	1.667	0.103	0.1717	0.0499

<sup>a</sup>The terms mass and weight are used interchangeably when using stack test data.

*Source:* The geometric mean diameter in a distribution from USEPA (1980a), as presented in USEPA (1993h).

Direct measurements of particle-size distributions at a proposed new facility may be unavailable, so it will be necessary to provide assumed particle distributions for use in the ADM. In such instances, a representative distribution may be used. The unit on which the representative distribution is based should be as similar as practicable to the proposed unit.

After developing the particulate size distribution based on mass, this distribution is used in the ADM to apportion the mass of particle phase COPCs (metals and organics with  $F_v$  values less than 0.05) based on particle size. Col. 4 of Table 1.2 (as developed from actual stack test data) is used in the ADM input file to perform a particulate run with the particle phase COPCs apportioned based on mass weighting.

**Particle-bound modeling (surface area weighting).** A surface area weighting, instead of mass weighting, of the particles is used in separate particle runs of the ADM. Surface area weighting approximates the situation where a semivolatile organic contaminant has been volatilized in the high temperature environment of a combustion system and then condensed to the surface of particles entrained in the combustion gas after it cools in the stack. Thus, the apportionment of emissions by particle diameter becomes a function of the surface area of the particle that is available for chemical adsorption (USEPA 1993h).

**Example calculation of surface weighted particle fraction.** The first step in apportioning COPC emissions by surface area is to calculate the proportion of available surface area of the particles. If particle density is held constant (such as  $1 \text{ g/m}^3$ ), the proportion of available surface area of aerodynamic spherical particles is the ratio of surface area ( $S$ ) to volume ( $V$ ), as follows:

- Assume aerodynamic spherical particles.
- Specific surface area of a spherical particle with a radius,  $r$   $S = 4 \pi r^2$ .
- Volume of a spherical particle with a radius,  $r$   $V = 4/3 \pi r^3$ .
- Ratio of  $S$  to  $V$   $S/V = 4 \pi r^2 / (4/3 \pi r^3) = 3/r$ .

The following uses the particle size distribution in Table 1.2 as an example of apportioning the emission rate of the particle-bound portion of the COPC based on surface area. This procedure can be followed for apportioning actual emissions to the actual particle size distribution measured at the stack. In Table 1.2, a spherical particle having a diameter of  $15 \mu\text{m}$  (Col. 1) has a radius of  $7.5 \mu\text{m}$  (Col. 2). The proportion of available surface area (assuming particle density is constant) is  $0.400(S/V = 3/7.5)$ , which is the value in Col. 3. Col. 4 shows that particles with a mean diameter of  $15 \mu\text{m}$ , constitute 12.8 percent of the total mass. Multiplication of Col. 3 by Col. 4 yields a value of 0.0512 in Col. 5. This value is an approximation of the relative proportion of total surface area, based on the percent of particles that are  $15 \mu\text{m}$  in diameter. The sum of Col. 5 yields the total surface area of all particles in the particle size distribution. In this example, the sum is 3.4423. Col. 6 is the fraction of total surface area represented by the specific particle diameter in the distribution, and is calculated by dividing the relative proportion of surface area (Col. 5) for a specific diameter by the total relative proportion of surface area (3.4423 square micrometers [ $\mu\text{m}^2$ ]). In the example of the  $15\text{-}\mu\text{m}$ -diameter particle, the fraction of total surface area available for adsorption is  $0.0149$  ( $0.0512/3.4423$ ). This procedure is then repeated for all particle sizes in the array.

After developing the particulate size distribution based on surface area, this distribution is used in the ADM to apportion mass of particle-bound COPCs (most organics) based on particle size. Col. 6 of Table 1.2 (as developed from actual stack test data) is used in the ADM input file to perform a particulate run for the particle-bound COPCs apportioned based on surface area weighting.

### 3.5 Meteorological Data

To model air concentration and deposition, ADMs require a variety of meteorological information:

1. Air concentration
  - A. Hourly values
    1. Wind direction (degrees from true north)
    2. Wind speed (m/s)

3. Dry bulb (ambient air) temperature (K)
4. Opaque cloud cover (tenths)
5. Cloud ceiling height (m)
- B. Daily values
  1. Morning mixing height (m)
  2. Afternoon mixing height (m)
2. Deposition
  - A. Dry particle deposition—hourly values for surface pressure (millibars)
  - B. Wet particle deposition—hourly values
    1. Precipitation amount (in)
    2. Precipitation type (liquid or frozen)
  - C. Dry vapor deposition—hourly values for solar radiation ( $W/m^2$ )

Meteorological data are available from several different sources. For most air modeling, five years of data from a representative National Weather Service (NWS) station is recommended. However, in some instances where the closest NWS data is clearly not representative of site specific meteorological conditions, and there is insufficient time to collect 5 years of onsite data, 1 year of onsite meteorological data (consistent with guideline on air quality models (GAQM)) may be used to complete the risk assessment. The permitting authority should approve the representative meteorological data prior to performing air modeling.

**Surface data meteorological data.** Hourly surface data can be obtained from the National Climate Data Center (NCDC) web site at address <http://www.ncdc.noaa.gov/> or <http://WebMET.com> (WebMet). The recommended meteorological data is the SAMSON format. SAMSON data contain all of the required input parameters used by AERMOD and CALPUFF to compute concentration, dry and wet particle deposition, and dry and wet vapor deposition.

Air quality modeling regulations require complete meteorological data for the most recent 5 years. Note that many jurisdictions specify 5-year period for modeling, say from 2001–2006. It is desirable, but not mandatory, that the 5 years are consecutive. The use of less than 5 years of meteorological data should be approved by appropriate authorities. The following subsections describe important characteristics of the surface data.

### 3.6 ADM Input Files

Human health risk assessments are almost always presented to the public. Therefore, air dispersion modeling must specify input regulatory options for particle and particle-bound phase runs, as follows:

- Use stack-tip downwash (except for Schulman-Scire downwash).
- Use buoyancy-induced dispersion (except for Schulman-Scire downwash).
- Do not use final plume rise (except for building downwash).
- Use the calms processing routines.
- Use upper-bound concentration estimates for sources influenced by building downwash from super-squat buildings.
- Use default wind speed profile exponents.
- Use default vertical potential temperature gradients.

USEPA recommends a dry vapor deposition velocity value of 0.5 cm/s for COPCs other than mercury, and 2.9 cm/s for divalent mercury. For each of the three runs for each emission source, 5 years of off-site (e.g., NWS from SAMSON) meteorological data are completed. For sites with meteorological data collected on-site, the appropriate permitting authority should be notified for the data period required for a risk assessment. The averaging times should be specified to compute chronic annual average health risk, and maximum 1-hour average concentrations over the 5-year period.

**Source information.** Additional source characteristics required by the model include the following:

- Source type (point source for stack emissions; area or volume for fugitive emissions)
- Source location (UTM coordinates, m)
- Source base elevation
- Emission rate (1.0 g/s)
- Stack height (m)
- Stack gas temperature (K)
- Stack gas exit velocity (m/s)
- Stack inside diameter (m)
- Building heights and widths (m)
- Particle size distribution (percent)
- Particle density (g/cm<sup>3</sup>)
- Particle and gas scavenging coefficients (unitless)

Source locations should be entered in UTM coordinates. The easterly coordinate is entered to the nearest meter(m); for example, 637524 m UTM-E. The northerly coordinate is entered to the nearest meter; for example, a northerly coordinate of 4,567,789 m UTM-N is entered as 4567789. The base elevation of each stack must be entered in meters. Base elevation may be obtained from a USGS topographic map, facility plot plans or USGS digital data base.

**Particle size distribution.** The ADM requires particle size distribution for determining deposition velocities.

**Particle density.** Particle density is also required for modeling the air concentration and deposition rates of particles. Site-specific measured data on particle density should be determined for all existing sources when possible. For new or undefined sources requiring air modeling, a default value for particle density of 1.0 g/cm<sup>3</sup> may be used. Particles from combustion sources, however, may have densities that are less than 1.0 g/cm<sup>3</sup> (USEPA 1994d), which would reduce the modeled deposition flux.

**Receptor grids.** The receptor grids identify sets or arrays of receptor grid nodes for which the ADM generates estimates of air parameters including air concentration, dry and wet deposition, and total deposition.

The ADM should include an array of receptor grid nodes covering the area within 10 km of the facility with the origin at the centroid of a polygon formed by the locations of the stack emission sources. This receptor grid node array should consist of a Cartesian grid with grid nodes spaced 100 m apart extending from the centroid of the emission sources out to 3 km from the centroid. For the distances from 3 km out to 10 km, the receptor grid node spacing can be increased to 500 m.

Terrain elevations should be specified for all receptor grid nodes. Several methods are available for assigning terrain elevations to grid nodes using digital terrain data. The 1:250,000 scale DEM digital data are available for download at the USGS Internet site <http://edcwww.cr.usgs.gov/pub/data/dem/250> or from WebGIS <http://www.webGIS.com>

This data has horizontal spacing between digital terrain values of approximately 90 m which provides sufficient accuracy for air modeling. In addition to the receptor grid node array evaluated for each facility out to 10 km, other grid node arrays may be considered for evaluation of water bodies and their watersheds located beyond 10 km. Grid node spacing of 500 m between nodes is recommended for grid node arrays positioned at distances greater than 10 km from the emission source. An equally spaced grid node array facilitates subsequent computation of area averages for deposition rates onto the waterbody and its associated watershed.

**Meteorological data.** For air modeling analysis which uses meteorological data from more than one surface station or upper air station (e.g., the upper air station is moved after the third year of the period and assigned a new station ID), the modeler should delete the headers for subsequent years in the combined file.

For sites where the anemometer height is changed during the 5-year period, the modeler should run each year separately to specify the correct anemometer height in the ADM input file, which corresponds to the correct height for that year of meteorological data.

### 3.7 Use of Modeled Output

The plot file is most useful for facilitating post-processing of the air parameter values in the model output. The plot file lists the x and y coordinates and the concentration or deposition rate values for each averaging period in a format that can be easily pulled into a postprocessing program (or spreadsheet).

The ADM output (air concentrations and deposition rates) are provided on a unit emission rate (1.0 g/s) basis and are not COPC-specific.

**Unit rate output versus COPC-specific output.** The relationship between the unit emission rate and the unit air parameter values (air concentrations and deposition rates) is linear. Similarly, the relationship between the COPC-specific emission rate ( $Q$ ) and the COPC-specific air parameter values (air concentrations and deposition rates) would also be linear if the COPC-specific emission rate was used in the air model. The use of a unit emission rate in the air modeling is advocated because a common ratio relationship can be developed between the unit emission rate and the COPC-specific emission rate based on the fact that in the air model, both individual relationships are linear. This ratio relationship can be expressed by the following equation:

$$\text{Air Concentration of Chemical}(i) = (\text{Modeled Air concentration} \times \text{Emission Rate}) \text{ of Chemical}(i)$$

Use of this equation requires that three of the variables be known. The modeled output air concentration (or deposition rate) is provided by the air model, the unit emission is 1.0 g/s, and the COPC-specific emission rate; which is obtained directly from stack or source test data.

**Use of model output in estimating media equations.** The selection of which air-modeled air parameter values, air concentrations, and deposition rates to use in the estimating media concentration equations is based on how the chemical will partition into the vapor, particle, and particle-bound phases. The ADM parameters, coming from the ADM, are presented in Table 1.3.

**TABLE 1.3** Air Parameters from the ADM Output

Air parameter	Description	Units
(Used for most soil-based exposure pathways)		
$C_{yv}$	Unitized yearly average air concentration from vapor phase	$\mu\text{g}\cdot\text{s}/\text{g}\cdot\text{m}^3$
$C_{yp}$	Unitized yearly average air concentration from particle phase	$\mu\text{g}\cdot\text{s}/\text{g}\cdot\text{m}^3$
$D_{ydv}$	Unitized yearly average dry deposition from vapor phase	$\text{s}/\text{m}^2\cdot\text{yr}$
$D_{yvw}$	Unitized yearly average wet deposition from vapor phase	$\text{s}/\text{m}^2\cdot\text{yr}$
$D_{ydp}$	Unitized yearly average dry deposition from particle phase	$\text{s}/\text{m}^2\cdot\text{yr}$
$D_{ywp}$	Unitized yearly average wet deposition from particle phase	$\text{s}/\text{m}^2\cdot\text{yr}$
(Used for fish and drinking water ingestion exposure pathways)		
$C_{yvw}$	Unitized yearly (water body or watershed) average air concentration from vapor phase	$\mu\text{g}\cdot\text{s}/\text{g}\cdot\text{m}^3$
$D_{ytwv}$	Unitized yearly (water body or watershed) average total (wet and dry) deposition from vapor phase	$\text{s}/\text{m}^2\cdot\text{yr}$
$D_{ytwp}$	Unitized yearly (water body or watershed) average total (wet and dry) deposition from particle phase	$\text{s}/\text{m}^2\cdot\text{yr}$
(Used for evaluation of acute risk via direct inhalation exposure pathway)		
$Chv$	Unitized hourly air concentration from vapor phase	$\mu\text{g}\cdot\text{s}/\text{g}\cdot\text{m}^3$
$Chp$	Unitized hourly air concentration from particle phase	$\mu\text{g}\cdot\text{s}/\text{g}\cdot\text{m}^3$
$Chpb$	Unitized hourly air concentration from particle-bound phase	$\mu\text{g}\cdot\text{s}/\text{g}\cdot\text{m}^3$

*Vapor phase COPCs.* ADM output generated from vapor phase air-modeling runs are vapor phase air concentrations (unitized  $C_{yv}$  and unitized  $C_{yvw}$ ), dry-vapor deposition (unitized  $Dydv$ ), and wet-vapor depositions (unitized  $Dyvw$  and unitized  $Dyvwv$ ) for organic COPCs at receptor grid nodes based on the unit emission rate. These values are used in estimating media concentration equations for all COPC organics except the polycyclic aromatic hydrocarbons dibenzo(a,h)anthracene and indeno(1,2,3-cd)pyrene, which have vapor-phase fractions,  $F_v$ , less than 5 percent. The air concentration (unitized  $C_{yv}$ ), dry-vapor deposition (unitized  $Dydv$ ), and wet-vapor deposition (unitized  $Dyvw$ ) from the vapor phase run is also used in the estimating media concentration equations for mercury. Values for these COPCs are selected from the vapor phase run because the mass of the COPC emitted by the combustion unit is assumed to have either all or a portion of its mass in the vapor phase.

*Particle-phase COPCs.* The ADM result output generated from particle phase air-modeling runs are air concentration (unitized  $C_{yp}$ ), dry deposition (unitized  $Dydp$ ), wet deposition (unitized  $Dywp$ ), and combined deposition (unitized  $Dytwp$ ) for inorganics and relatively nonvolatile organic COPCs at receptor grid nodes based on the unit emission rate. These values are used in the estimating media concentration equations for all COPC inorganics (except mercury) and polycyclic aromatic hydrocarbons with fraction of vapor phase,  $F_v$ , less than 0.05 (e.g., dibenzo(a,h)anthracene and indeno(1,2,3-cd)pyrene). Values for inorganic and relatively nonvolatile COPCs are selected from the particle-phase run because the mass of the COPC emitted by the combustion unit is assumed to have all of its mass in the particulate phase, apportioned across the particle size distribution based on mass weighting.

*Particle-bound COPCs.* The ADM result generated from particle-bound air-modeling runs are air concentration (unitized  $C_{yp}$ ), dry deposition (unitized  $Dydp$ ), wet deposition (unitized  $Dywp$ ), and combined deposition (unitized  $Dytwp$ ) for organic COPCs and mercury at receptor grid nodes based on the unit emission rate. These values are used in estimating media concentration equations for all COPC organics and mercury to account for a portion of the vapor condensed onto the surface of particulates. Values for these COPCs are selected from the particle-bound run because the mass of the COPC emitted by the combustion unit is assumed to have a portion of its mass condensed on particulates, apportioned across the particle size distribution based on surface area weighting.

### 3.8 Modeling of Fugitive Emissions

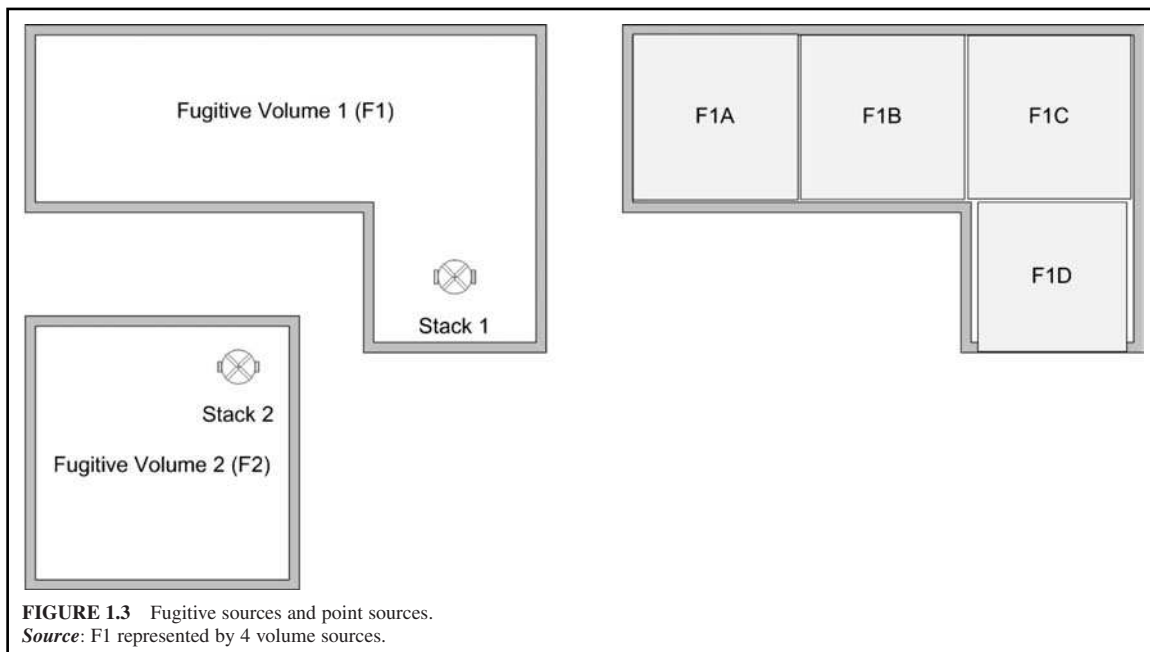

Fugitive source emissions should be modeled using the procedures presented throughout this section for stack source emissions. However, the fugitive emissions should be represented as either “area” or “volume” source types. Fugitive emissions of volatile organics are modeled only in the vapor phase. Fugitive emissions of ash are modeled only in the particle and particle-bound phases, not vapor phase.

Fugitive emissions of volatile organic vapors are associated with processes that include storage vessels, pipes, valves, seals, and flanges. The height of the fugitive source is defined as the top of the vertical extent of the equipment. If the vertical extent of the fugitive source is not known, a default height of ground level (release height of zero) may be input, providing a conservative estimate of potential impacts.

### 3.9 Example ADM for Organic Fugitive Emissions

The following example is for organic fugitive emissions modeled as a volume source type, as presented in Figure 1.3. For a facility which may have two stack emission sources (S1 and S2) and two fugitive emission sources (areas F1, F2); a total of four runs for each year (or 5-year combined file) of meteorological data is required.

One run is required for each of the two stacks, S1 and S2, as point sources. One run is required for each of the two fugitive areas as volume sources (F1 and F2). Since the emissions are fugitive volatile organics, only the vapor phase is modeled. The vertical extent of the pipes, valves, tanks, and flanges

**FIGURE 1.3** Fugitive sources and point sources.  
*Source:* F1 represented by 4 volume sources.

associated with each fugitive emission area is 5 m above plant elevation. To define the sources for input to the ADM, the release height is specified as 2.5 m (half of vertical extent of fugitive emissions). The initial vertical dimension is specified as 2.36 m (vertical extent of 5 m divided by 2.15).

The initial horizontal dimension is the side length of the square fugitive area (footprint) divided by 4.3. If fugitive area F2 has a measured side of 30 m, the initial horizontal dimension is 6.98 (30 m divided by 4.3). For fugitive area F1, the area on the plot plan must be subdivided into 4 volume sources, F1A, F1B, F1C, and F1D. These volume sources are represented on the right side of Fig. 1.3 as squares, which may not precisely match the shape of the original fugitive source F1, as one can see on volume source F1D. The four squares depicted in Fig. 1.3 are input into a single air dispersion modelling run for Fugitive source F1 as four separate volume sources (F1A, F1B, F1C, and F1D). The initial horizontal dimension for each volume source is the side of the square divided by 4.3. It is very important to allocate the unit emissions (1 g/s) for F1 to each source proportionately to its area in relation to the total area. For example, if the F1A area is 25 percent of the total area F1, then the emissions rate of F1A is 0.25 g/s. The summation of each individual emission for F1A + F1B + F1C + F1D must be equal to 1 g/s.

The resulting air parameter values in the plot files may be used directly in the risk assessment equations, the same as if a stack emission were modeled as a single point source. The initial vertical dimension is defined the same as F2, using the vertical extent of 5 m divided by 2.15 and a release height of 2.5 m (half vertical extent). For volume sources, the location is specified by the x and y coordinates of the center of each square area.

### 3.10 Modeling Acute Risk

The acute or short-term effects due to the direct inhalation of vapor phase, particle phase, and particle-bound phase COPCs are generally considered in a risk assessment. From the air modeling perspective, the goal is to compute the highest 1-hour average air concentration for each phase for each source for the entire period of analysis. In most cases, this period is 5 years.

*Note:* The ADM output must include the specification of 1-hour average plot file which contains the highest 1-hour concentration at each receptor grid node for all the hours evaluated. For a single year run, the 1-hour concentration reported in the plot file will be the highest value computed at each x, y grid node location for the total hours in the year (8760, or 8784 for leap years). The appropriate value needed for the acute risk assessment is the highest 1-hour concentration for the 5-year period. Each of the 5 single year values must be reviewed to identify the highest for all 5 years at each receptor grid node. However, if a combined 5-year meteorological file is run, the plot file will already identify the highest value for the 5-year period at each grid node with no additional processing required.

The highest air concentration for the 1-hour averaging period is input as the air parameters, *Chv*, *Chp*, and *Chpb* in the acute risk assessment equations.

## 4 EXPOSURE SCENARIOS

---

The purpose of this section is to provide guidance in the identification of *exposure scenarios* that should be evaluated in the risk assessment, characterization of exposure setting, identification of recommended exposure scenarios, and selection of exposure scenario locations.

An exposure scenario is a combination of *exposure pathways* to which a single “receptor” may be subjected. Human receptors may come into contact with air toxics emitted to the atmosphere from two primary exposure *routes*, either directly via inhalation; or indirectly via subsequent ingestion of water, soil, vegetation, and animals that become contaminated by chemicals through the food chain.

Each exposure pathway consists of four fundamental components: (1) an exposure route; (2) a source and mechanism of COPC release; (3) a retention medium, or a transport mechanism and subsequent retention medium in cases involving media transfer of COPCs; and (4) a point of potential human contact with the contaminated medium, which is referred to as the exposure point and consists of a specific receptor exposed at a specific point. Humans, plants, and animals in the assessment area may take up COPCs directly from the air or indirectly via the media receiving deposition (e.g., soil, vegetation, or water).

The exposure scenarios recommended for risk evaluation are generally conservative in nature. They are intended to allow standardized and reproducible evaluation of risks. Any deviations from these recommendations, such as a deletion or modification of a recommended exposure scenario or scenario location should be well-documented.

### 4.1 Exposure Setting Characterization

The purpose of characterizing the exposure setting is to identify the nonworker related human activities and receptors in the assessment area that may be impacted as a result of exposure to emissions from one or more of a facility’s emission sources.

**Site maps and land use.** Maps are important to define land use to consider in characterizing the exposure setting; and when overlaid with the air dispersion modeling results, will define which recommended exposure scenarios and their locations should be evaluated in the risk assessment.

Maps that support the development of the risk assessment are available from various suppliers. The United State Geological Suvery and WebGIS (<http://www.WebGIS.com>) provide extensive maps free of charge. The main maps used in risk assessment studies are:

*Land Use Land Cover (LULC) Maps:* Exact boundaries of polygon land use area coverages, in areas being considered for evaluation, should be verified using available topographic maps and aerial photographic coverages.

*Topographic Maps:* Topographic maps are readily available in both hard copy and electronic format directly from USGS or numerous other vendors. These maps are commonly at a scale of 1:24,000, and in a file type TIFF format with TIFF World File included for geo-referencing.

*Aerial Photographs:* provide an excellent reference for identifying land use areas and justifying selection of exposure scenario locations.

The risk assessor should focus on land use areas potentially impacted by COPC emissions from facility emission sources being evaluated in the risk assessment.

***Water bodies and their associated watersheds.*** The identification of surface water bodies at locations in the assessment area receiving deposition from emission sources indicates the potential for COPC exposures from ingestion of fish, and possibly drinking water (drinking water is evaluated only if the local population obtains drinking water from surface water sources). In addition, the surface area and exact location with respect to evaluating receptor grid nodes positioned within the water body and watershed should be defined.

The area extent of a watershed is generally defined by topographic highs that result in downslope drainage into the water body. The watershed can be important in determining the overall water body COPC loading, because pervious and impervious areas of the watershed, as well as the soil concentration of COPCs resulting from emissions from facility sources, are also used in the media concentration equations to calculate the water body COPC concentrations resulting from watershed runoff.

For example, if facility emissions impact principally a land area that feeds a specific tributary that drains to a large river system and immediately upstream of a drinking water intake point, the risk assessor should consider evaluating an “effective” watershed area rather than the entire watershed area of the large river system. For such a large river system, the watershed area can be on the order of thousands of square kilometers and can include numerous tributaries draining into the river at points that would not have any net impact on the drinking water intake or on the water body COPC concentration at the exposure point of interest.

Additional water body and watershed required parameters include the following:

- Water body surface area
- Watershed surface area
- Impervious watershed area
- Average surface water volumetric flow rate
- Current velocity of surface water body
- Depth of surface water body column
- Universal soil loss equation (USLE) rainfall/erosivity factor

Water body current velocities and volumetric flow rates should generally be average values on an annual basis. State or local geologic surveys may keep records on water bodies. Volumetric flow rates for smaller streams or lakes can be calculated as the product of the watershed area and one-half of the local average annual surface runoff. Current velocities can be calculated as the volumetric flow rate divided by the cross-sectional area (current velocities are not used in the equations for lakes). Depths of water bodies can sometimes be obtained from state or local sources.

## 4.2 Recommended Exposure Scenarios

USEPA recommends the following exposure scenarios:

- Farmer
- Farmer child
- Adult resident
- Child resident
- Fisher
- Fisher child
- Acute risk

Exposure scenarios are not referred to as subsistence since the actual mass per day amounts of food items evaluated in the recommended exposure pathways are more comparable to reasonable versus subsistence amounts; and therefore, may not preclude ingestion of significant amounts of food items not represented in the exposure pathways of the exposure scenario subject to evaluation. Specific regional exposure setting characteristics may warrant the inclusion of additional recommended exposure pathways when evaluating an exposure scenario for a specific regional exposure setting. For example, the recommended farmer exposure scenario does not automatically include the fish ingestion exposure pathway. However, in some areas of the country, it is common for farms to also have stock ponds which are fished on a regular basis for the farmer's consumption.

USEPA also recommends that infant exposure to PCDDs and PCDFs via the ingestion of their mother's breast milk be evaluated as an additional exposure pathway at all recommended exposure scenario locations.

*Note:* The following exposure scenarios are not very important for air toxics risk assessment:

*Ingestion of ground water:* USEPA (1990e) found that ground water is an insignificant exposure pathway for air toxics emissions risk assessment.

*Inhalation of resuspended dust:* USEPA (1990e) found that inhalation of resuspended dust was insignificant, for air toxics emissions risk assessment.

*Dermal exposure to surface water, soil, or air:* Available data indicate that the contribution of dermal exposure to soils to overall risk is typically small (USEPA 1996g; 1995h). The risk resulting from soil ingestion and dermal contact was 50-fold less than the risk from any other exposure pathway and 300-fold less than the total estimated risk (USEPA 1996g; 1995h).

*Inhalation of COPCs and ingestion of water by animals:* These exposure pathways have not been included in the recommended exposure scenarios because the contribution of these pathways to total risk is anticipated to be negligible in comparison with that of the exposure pathways being evaluated. However, these exposure pathways may need to be evaluated on a case-by-case basis considering site-specific exposure setting characteristics.

**Farmer scenario.** The farmer exposure scenario is evaluated to account for the combination of exposure pathways to which a receptor may be exposed in a farm or ranch exposure setting. The farmer is assumed to be exposed to COPCs emitted from the facility through the following exposure pathways:

- Direct inhalation of vapors and particles
- Incidental ingestion of soil
- Ingestion of drinking water from surface water sources
- Ingestion of homegrown produce
- Ingestion of homegrown beef
- Ingestion of milk from homegrown cows
- Ingestion of homegrown chicken
- Ingestion of eggs from homegrown chickens
- Ingestion of homegrown pork
- Ingestion of breast milk

Figure 1.4 depicts the above pathways.

**Farmer child scenario receptor.** The farmer child exposure scenario is evaluated to account for the combination of exposure pathways to which a receptor may be exposed in a farm or ranch setting.

**Adult resident scenario receptor.** The adult resident exposure scenario is evaluated to account for the combination of exposure pathways to which a receptor may be exposed in an urban or rural (nonfarm)

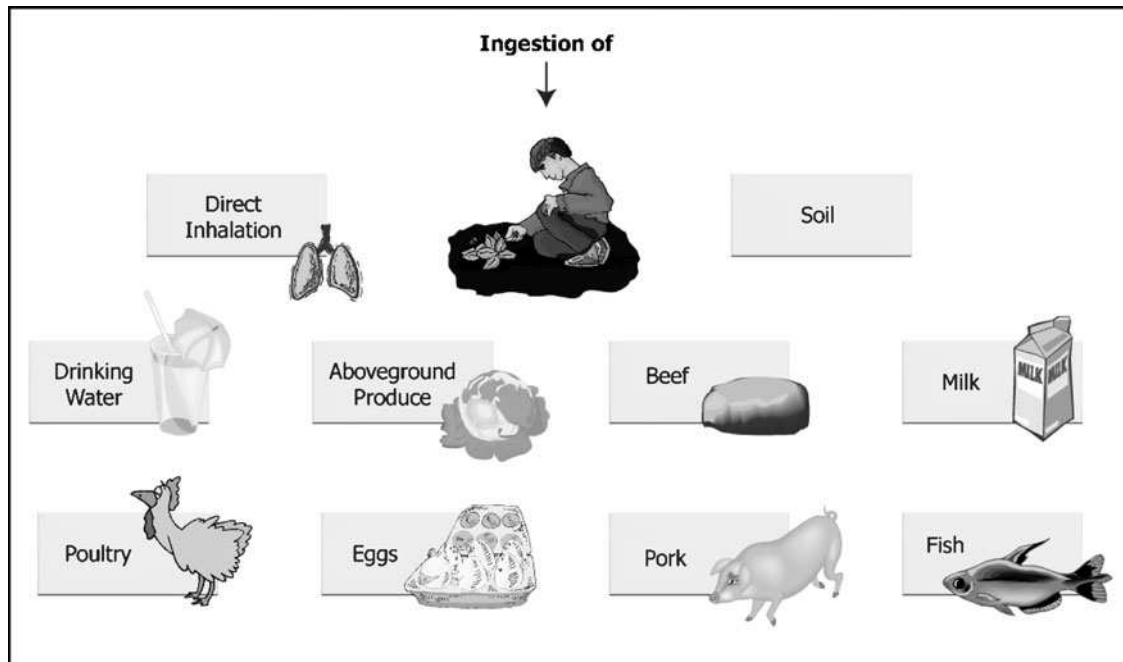

Figure 1.4 Farmer scenario exposure path ways.

setting. The adult resident is assumed to be exposed to COPCs from the emission source through the following exposure pathways:

- Direct inhalation of vapors and particles
- Incidental ingestion of soil
- Ingestion of drinking water from surface water sources
- Ingestion of homegrown produce
- Ingestion of breast milk

**Child resident scenario receptor.** The child resident exposure scenario is evaluated to account for the combination of exposure pathways to which a child receptor may be exposed in an urban or rural (nonfarm) setting. The child resident is assumed to ingest some produce grown by the adult resident (NC DEHNR 1997).

**Fisher scenario receptor.** The Fisher exposure scenario is evaluated to account for the combination of exposure pathways to which a receptor may be exposed in an urban or rural setting where fish is the main component of the receptor diet. The fisher is exposed to COPCs emitted from the facility through the pathways presented in Fig. 1.5, and in the following list:

- Direct inhalation of vapors and particles
- Incidental ingestion of soil
- Ingestion of drinking water from surface water sources, homegrown produce and fish
- Ingestion of breast milk (evaluated separately)

FIGURE 1.5 Fisher exposure pathways.

**Fisher child scenario receptor.** The fisher child exposure scenario is evaluated to account for the combination of exposure pathways to which a receptor may be exposed in an urban or rural setting where fish is the main component of the receptor diet.

**Acute risk scenario.** The acute exposure scenario is evaluated to account for short-term effects of exposure to maximum one-hour concentrations of COPCs in emissions from the facility through direct inhalation of vapors and particles. A receptor may be exposed in an urban or rural setting where human activity or land use supports any of the recommended exposure scenarios, as well as, in commercial and industrial land use areas (excluding workers from the facility under direct evaluation in the risk assessment) not typically evaluated by application of the other recommended exposure scenarios.

### 4.3 Selection of Exposure Scenario Locations

Exposure scenario locations are the receptor grid nodes selected for evaluating one or more of the recommended exposure scenarios. Specific receptor grid nodes are selected as exposure scenario locations based on evaluation of the magnitude of air parameter values estimated by the ADM. Air parameter values specific to the receptor grid node, selected as an exposure scenario location, are then used as inputs to the estimating media concentration equations when evaluating the recommended exposure scenarios. This step is one of the most critical parts of the risk assessment process, ensuring standardization across all facilities evaluated and reproducibility of results. The estimates of risk can vary significantly in direct response to which receptor grid nodes are selected as exposure scenario locations.

The following procedures should be used in the selection of receptor grid nodes as exposure scenario locations, and that selected exposure scenario locations correspond to actual ADM receptor grid node locations defined by UTM coordinates. USEPA recommends exposure scenario(s) at actual receptor grid nodes selected as follows:

Step 1. *Define land use areas to be evaluated* Current and reasonable potential future land use areas, water bodies, and watersheds identified during exposure setting characterization for evaluation in the risk assessment, should be defined and mapped using UTM coordinates in a format (NAD27 or NAD83 UTM) consistent with that used to define locations of facility emission sources and the ADM receptor grid nodes.

Step 2. *Identify receptor grid node(s) within each land use area to be evaluated* For each land use area to be evaluated, identify the receptor grid nodes within that area or on the boundary of that area (defined in Step 1) that represent the location of highest yearly average concentration for each ADM modeled air parameter (e.g., air concentration, dry deposition, wet deposition) for each phase (e.g., vapor, particle, particle-bound); specific to each emission source (e.g., stacks, fugitives) and all emission sources at the facility combined. This results in the selection of one or more receptor grid nodes as one or more exposure scenario locations, within the land use area to be evaluated, that have one or more of the highest modeled unitized:

- vapor phase air concentration
- vapor phase dry- and wet-deposition rate
- particle phase air concentration
- particle phase dry- and wet-deposition rate
- particle-bound phase air concentration
- particle-bound phase dry- and wet-deposition rate

Step 3. *Identify receptor grid nodes for acute risk and site-specific risk considerations* Additional receptor grid nodes within the assessment area may need to be considered as exposure scenario locations for the evaluation of acute risk or site-specific risk considerations (e.g., special subpopulations). In land use areas to be evaluated for acute risk (could potentially include commercial and industrial land use areas), receptor grid nodes with the highest modeled hourly vapor phase air concentration and highest hourly particle phase air concentration specific to each emission source and all emission sources at the facility combined, should be selected as the exposure scenario location(s). For site-specific risk considerations, the closest receptor grid node to the exposure point being evaluated should be considered for the exposure scenario location.

Step 4. *Identify receptor grid nodes for water bodies and watersheds* For recommended exposure scenarios that include evaluation of water bodies and their associated watersheds, the receptor grid nodes within their area should be considered. For water bodies, the risk assessor can select the receptor grid node with the highest modeled air parameter values or average the air parameter values for all receptor grid nodes within the area of the water body. For watersheds, the modeled air parameter values should be averaged for all receptor grid nodes within the area extent or effective area of the watershed (excluding the area of the water body).

## 5 ESTIMATION OF MEDIA CONCENTRATIONS

---

The purpose of this section is to describe the media concentration equations and associated parameters used in evaluation of the recommended exposure scenarios. The origin and development of each of these equations, and description of associated parameters, are presented in most cases.

### 5.1 Calculation of COPC Concentrations in Air for Direct Inhalation

COPC concentrations in air are calculated by summing the vapor phase and particle phase air concentrations of COPCs. Air concentrations used in the evaluation of long-term or chronic exposure, via direct inhalation, should be calculated using unitized yearly air parameter values (Fig. 1.6).

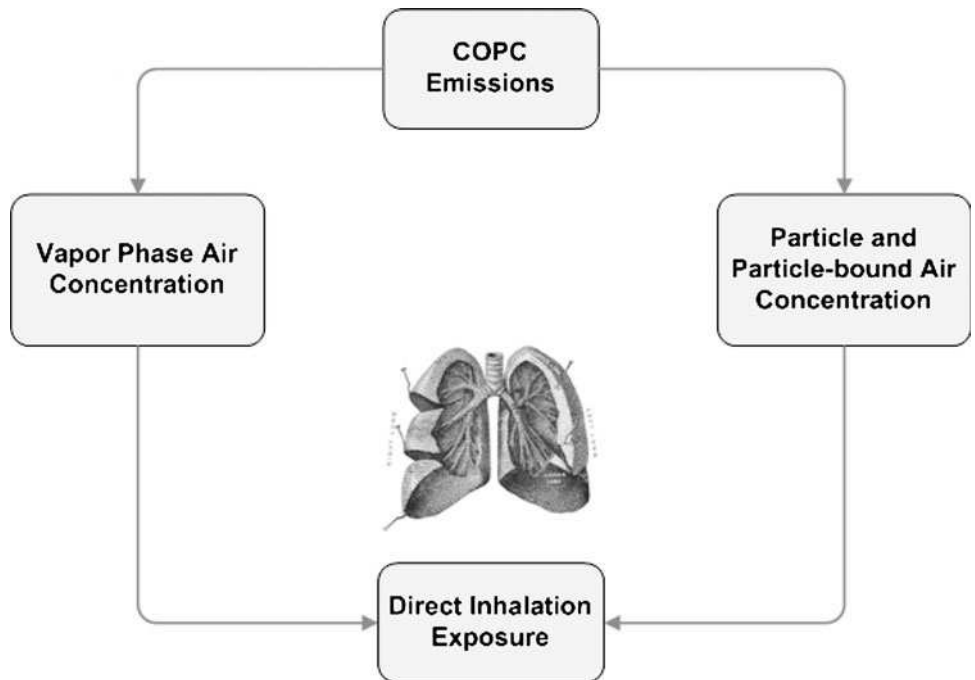

FIGURE 1.6 Direct inhalation exposure pathway.

## 5.2 Calculation of COPC Concentrations in Soil

COPC concentrations in soil are calculated by summing the vapor phase and particle phase deposition of COPCs to the soil. Wet and dry deposition of particles and vapors are considered, with dry deposition of vapors calculated from the vapor air concentration and the dry deposition velocity. The calculation of soil concentration incorporates a term that accounts for loss of COPCs by several mechanisms, including leaching, erosion, runoff, degradation (biotic and abiotic), and volatilization. These loss mechanisms all lower the soil concentration associated with the deposition rate. Figure 1.7 presents the processes described above.

Soil concentrations may require many years to reach steady state. As a result, the equations used to calculate the average soil concentration over the period of deposition were derived by integrating the instantaneous soil concentration equation over the period of deposition. For carcinogenic COPCs, USEPA recommends using two variations of the equation (average soil concentration over exposure duration):

1. One variation to be used if the exposure duration is greater than or equal to the operating lifetime of the emission source or time period of combustion.
2. The other form to be used if the exposure duration is less than the operating lifetime of the emission source or time period of combustion.

For noncarcinogenic COPCs, USEPA recommends the calculation of the highest one-year annual average soil concentration; typically occurring at the end of the operating lifetime of the emission source. Soil conditions such as pH, structure, organic matter content, and moisture content affect the distribution and mobility of COPCs. Loss of COPCs from the soil is modeled by using rates that depend on the physical and chemical characteristics of the soil. These variables and their use are described in the following subsections, along with the recommended equations.

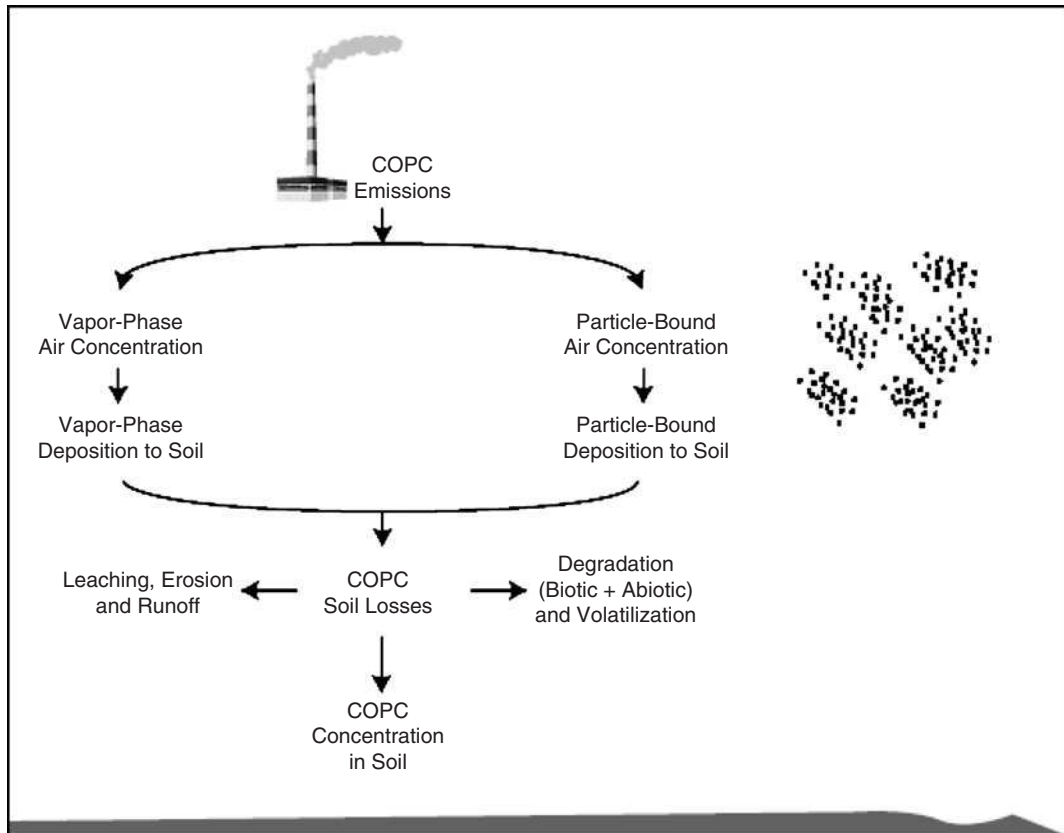

FIGURE 1.7 Chemical of potential concern concentration in soil.

**Calculating cumulative soil concentration.** USEPA recommends the following equations to calculate the cumulative soil concentration ( $C_s$ ).

**Carcinogens:**

For  $T_2 < tD$

$$C_s = \frac{Ds}{ks \cdot (tD - T_1)} \cdot \left[ \left( tD + \frac{\exp(-ks \cdot tD)}{ks} \right) - \left( T_1 + \frac{\exp(-ks \cdot T_1)}{ks} \right) \right] \quad (1.3a)$$

For  $T_1 < tD < T_2$

$$C_s = \frac{\left( \frac{Ds \cdot tD - C_{s,tD}}{ks} \right) + \left( \frac{C_{s,tD}}{ks} \right) \cdot (1 - \exp[-ks \cdot (T_2 - tD)])}{(T_2 - T_1)} \quad (1.3b)$$

**Non-carcinogens:**

$$C_{s,tD} = \frac{Ds \cdot [1 - \exp(-ks \cdot tD)]}{ks} \quad (1.3c)$$

where

- $C_s$  = Average soil concentration over exposure duration (mg COPC/kg soil)  
 $D_s$  = Deposition term (mg COPC/kg soil/year)  
 $T_1$  = Time period at the beginning of combustion (year)  
 $ks$  = COPC soil loss constant due to all processes (year<sup>-1</sup>)  
 $tD$  = Time period over which deposition occurs (time period of combustion) (year)  
 $C_{s,tD}$  = Soil concentration at time  $tD$  (mg/kg)  
 $T_2$  = Length of exposure duration (year)

When an exposure duration that is less than or equal to the operating lifetime of the emission source or hazardous waste combustion unit ( $T_2 < tD$ ), Eq. (1.3a) is recommended; when an exposure duration greater than the operating lifetime of the hazardous waste combustion unit ( $T_1 < tD < T_2$ ), Eq. (1.3b) is recommended. For noncarcinogenic COPCs, Eq. (1.3c) is recommended.

The COPC soil concentration averaged over the exposure duration, represented by  $C_s$ , should be used for carcinogenic compounds, where risk is averaged over the lifetime of an individual. Because the hazard quotient associated with noncarcinogenic COPCs is not averaged over a lifetime of exposure, the highest annual average COPC soil concentration occurring during the exposure duration period should be used for noncarcinogenic COPCs. The highest annual average COPC soil concentration,  $C_{s,tD}$ , will typically occur at the end of the operating life of the emission source or the time period of combustion.

The deposition term in the  $C_s$  equation is expressed in two forms, one for mercury and the other one for all the other chemicals (COPs). The equation for all COPs, except mercury is presented below:

$$D_s = \frac{100 \cdot Q}{Z_s \cdot BD} \cdot [F_v(Dy_{dv} + Dy_{wv}) + (1 - F_v)(Dy_{dp} + Dy_{wp})] \quad (1.4a)$$

The equation for the mercury deposition term, in the cumulative soil concentration is presented as follows:

$$D_s = \frac{100 \cdot 0.48Q_{(\text{Total})}}{Z_s \cdot BD} \cdot [F_{v(\text{Hg}^{2+})}(Dy_{dv} + Dy_{wv}) + (1 - F_{v(\text{Hg}^{2+})})(Dy_{dp} + Dy_{wp})] \quad (1.4b)$$

Use  $0.48Q$  for total mercury and  $F_v = 0.85$  in the mercury modeling equation to calculate  $D_s$ . Apportion the calculated  $D_s$  value into the divalent mercury ( $\text{Hg}^{2+}$ ) and methyl mercury (MHg) forms based on the assumed 98 percent  $\text{Hg}^{2+}$  and 2 percent MHg speciation split in soils. Elemental mercury ( $\text{Hg}^0$ ) occurs in very small amounts in the vapor phase and does not exist in the particle or particle-bound phase. Therefore, assume elemental mercury deposition onto soils is negligible or zero. Evaluate elemental mercury for the direct inhalation pathway only.

$$D_s (\text{Hg}^{2+}) = 0.98 D_s (\text{Mercury})$$

$$D_s (\text{MHG}) = 0.02 D_s (\text{Mercury})$$

$$D_s (\text{Hg}^0) = 0.0$$

Evaluate divalent and methyl mercury as individual COPCs. Calculate  $C_s$  for divalent and methyl mercury using the corresponding fate and transport parameters for mercuric chloride (divalent mercury,  $\text{Hg}^{2+}$ ) and methyl mercury.

**Calculating the COPC soil loss constant.** Organic and inorganic COPCs may be lost from the soil by several processes that may or may not occur simultaneously. The rate at which a COPC is lost from the soil is known as the soil loss constant ( $ks$ ). The constant  $ks$  is determined by using the soil's physical, chemical, and biological characteristics to consider the loss resulting from:

1. leaching,
2. runoff,
3. erosion,

4. biotic and abiotic degradation, and
5. volatilization.

USEPA recommends the following equations to be used to calculate the COPC soil loss constant ( $k_s$ ).

$$k_s = k_{sg} + k_{se} + k_{sr} + k_{sl} + k_{sv} \quad (1.5)$$

where

- $k_s$  = Loss constant due to all processes (year<sup>-1</sup>)
- $k_{sg}$  = Loss constant due to biotic and abiotic degradation (year<sup>-1</sup>)
- $k_{se}$  = Loss constant due to soil erosion (year<sup>-1</sup>)
- $k_{sr}$  = Loss constant due to surface runoff (year<sup>-1</sup>)
- $k_{sl}$  = Loss constant due to leaching (year<sup>-1</sup>)
- $k_{sv}$  = Loss constant due to volatilization (year<sup>-1</sup>)

The use of the soil loss equation assumes that COPC loss can be defined by using first-order reaction kinetics. First-order reaction rates depend on the concentration of one reactant. At low concentrations, a first-order loss constant may be adequate to describe the loss of the COPC from soil (USEPA 1990e).

*COPC loss constant due to biotic and abiotic degradation.* Soil losses resulting from biotic and abiotic degradation ( $k_{sg}$ ) are determined empirically from field studies and are addressed in the literature (USEPA 1990e). USEPA guidance (1994g) had stated that  $k_{sg}$  values for all COPCs other than 2,3,7,8-TCDD should be set equal to zero. However, the final version of the HHRAP provides  $k_{sg}$  values for many COPCs other than PCDD and PCDF.

The rate of biological degradation in soils depends on the concentration and activity of the microbial populations in the soil, the soil conditions, and the COPC concentration. The use of simple rate expressions may be appropriate at low chemical concentrations (e.g., nanogram per kilogram soil) at which a first-order dependence on chemical concentration may be reasonable. The rate of biological degradation is COPC-specific, depending on the complexity of the COPC and the usefulness of the COPC to the microorganisms. These are some of the environmental and COPC-specific factors that may limit the biodegradation of COPCs in the soil:

1. Availability of the COPC
2. Nutrient limitations
3. Toxicity of the COPC
4. Inactivation or nonexistence of enzymes capable of degrading the COPC

Hydrolysis in aqueous systems is characterized by three processes: acid-catalyzed, base-catalyzed, and neutral reactions. The overall rate of hydrolysis is the sum of the first-order rates of these processes. In soil systems, sorption of the COPC can increase, decrease, or not affect the rate of hydrolysis as numerous studies have shown. The total rate of hydrolysis in soil can be predicted by adding the rates in the soil and water phases, which are assumed to be first-order reactions at a fixed pH. Methods for estimating these hydrolysis constants are described by Lyman et al. (1982). The 2005 HHRAP provides  $k_{sg}$  values for COPCs that can be used to calculate  $k_s$ . For example, the  $k_{sg}$  for Pentachlorophenol is identified in the 2005 HHRAP as 1.42 year<sup>-1</sup>.

*COPC loss constant due to soil erosion.* USEPA currently recommends that the constant for the loss of soil resulting from erosion ( $k_{se}$ ) should be set equal to zero based on the theory that contaminated soil erodes onto the specific receptor location where the loss is calculated as well as eroding off it.

$k_{se}$
0.0

*COPC loss constant due to runoff.* USEPA recommends the following equation to calculate the constant for the loss of soil resulting from surface runoff ( $ksr$ ).

$$ksr = \frac{RO}{\theta_{sw} \cdot Z_s} \cdot \left( \frac{1}{1 + (Kd_s \cdot BD/\theta_{sw})} \right) \quad (1.6)$$

where

- $ksr$  = COPC loss constant due to runoff (year<sup>-1</sup>)
- $RO$  = Average annual surface runoff from pervious areas (cm/year)
- $\theta_{sw}$  = Soil volumetric water content (mL water/cm<sup>3</sup> soil)
- $Z_s$  = Soil mixing zone depth (cm)
- $Kd_s$  = Soil-water partition coefficient (mL water/g soil)
- $BD$  = Soil bulk density (g soil/cm<sup>3</sup> soil)

*COPC loss constant due to leaching.* Losses of soil COPCs due to leaching ( $ksl$ ) depend on the amount of water available to generate leachate and soil properties such as bulk density, soil moisture, soil porosity, and soil sorption properties.

USEPA recommends the following equation to calculate the  $ksl$  to account for runoff.

**COPC Loss Constant Due to Leaching ( $ksl$ )**

$$ksl = \frac{P + I - RO - E_v}{\theta_{sw} \cdot Z_s \cdot [1.0 + (BD \cdot K_{ds}/\theta_{sw})]} \quad (1.7)$$

where

- $ksl$  = COPC loss constant due to leaching (year<sup>-1</sup>)
- $P$  = Average annual precipitation (cm/yr)
- $I$  = Average annual irrigation (cm/yr)
- $RO$  = Average annual surface runoff from pervious areas (cm/yr)
- $E_v$  = Average annual evapotranspiration (cm/yr)
- $\theta_{sw}$  = Soil volumetric water content (mL water/cm<sup>3</sup> soil)
- $Z_s$  = Soil mixing zone depth (cm)
- $Kd_s$  = Soil-water partition coefficient (cm<sup>3</sup> water/g soil)
- $BD$  = Soil bulk density (g soil/cm<sup>3</sup> soil)

*COPC loss constant due to volatilization.* Semivolatile and volatile COPCs emitted in high concentrations may become adsorbed to soil particles and exhibit volatilization losses from soil. The loss of a COPC from the soil by volatilization depends on the rate of movement of the COPC to the soil surface, the chemical vapor concentration at the soil surface, and the rate at which vapor is carried away by the atmosphere (Jury 1986).

USEPA recommends the following equation to compute the loss constant due to volatilization.

$$ksv = \left( \frac{3.1536 \times 10^7 \cdot H}{Z_s \cdot Kd_s \cdot R \cdot T_a \cdot BD} \right) \cdot \left( \frac{D_a}{Z_s} \right) \cdot \left[ 1 - \left( \frac{BD}{\rho_{soil}} \right) - \Theta_{sw} \right] \quad (1.8)$$

where

- $ksv$  = COPC loss constant due to volatilization (year<sup>-1</sup>)
- $3.1536 \times 10^7$  = Units conversion factor (s/year)
- $H$  = Henry's law constant (atm · m<sup>3</sup>/mol)
- $Z_s$  = Soil mixing zone depth (cm)
- $Kd_s$  = Soil-water partition coefficient (mL/g)
- $R$  = Universal gas constant (atm · m<sup>3</sup>/mol · K)
- $T_a$  = Ambient air temperature (K) = 298.1 K
- $BD$  = Soil bulk density (g soil/cm<sup>3</sup> soil) = 1.5 g/cm<sup>3</sup>

$$\begin{aligned}
 D_a &= \text{Diffusivity of COPC in air (cm}^2\text{/s)} \\
 \theta_{sw} &= \text{Soil volumetric water content (mL/cm}^3\text{ soil)} = 0.2 \text{ mL/cm}^3 \\
 \rho_{soil} &= \text{Solids particle density (g/cm}^3\text{)} = 2.7 \text{ g/cm}^3
 \end{aligned}$$

**Universal soil loss equation.** USEPA recommends that the USLE be used to calculate the unit soil loss ( $X_e$ ).

**Site-specific parameters for calculating cumulative soil concentration.** Calculating average soil concentration over the exposure duration ( $C_s$ ) requires the use of site-specific parameters including the following:

1. Soil mixing zone depth ( $Z_s$ )
2. Soil bulk density ( $BD$ )
3. Available water ( $P + I - RO - Ev$ )
4. Soil volumetric water content ( $\theta_{sw}$ )

*Soil mixing zone depth.* When exposures to COPCs in soils are modeled, the depth of contaminated soils is important in calculating the appropriate soil concentration. COPCs deposited onto soil surfaces may be moved into lower soil profiles by tilling, whether manually in a garden or mechanically in a large field.

USEPA (1990e) estimated that if the area under consideration is likely to be tilled, soil depth is about 10 to 20 cm depending on local conditions and the equipment used. If soil is not moved, COPCs are assumed to be retained in the shallower, upper soil layer (1 cm).

The assumption made to determine the value of  $Z_s$  may affect the outcome of the risk assessment, because soil concentrations that are based on soil depth are used to calculate exposure via several pathways:

1. Ingestion of plants contaminated by root uptake and by volatilization from soil.
2. Direct ingestion of soil by humans, cattle, swine, or chicken.
3. Surface runoff into water bodies.

For example, in calculations of exposures resulting from uptake through plant roots, the average concentration of COPCs over the depth of the plant root determines plant uptake. However, in calculations of plant uptake resulting from volatilization, only the uppermost soil layer is considered.

USEPA (1990e) recommended that soil mixing depths be selected as in Table 1.4: USEPA recommends the following values for the soil mixing zone depth ( $Z_s$ ) in the 2005 HHRAP.

**TABLE 1.4** USEPA Recommendations for Soil Mixing Depth

Soil depth ( $Z_s$ )	Exposure	Description
1 cm	Direct ingestion of soil.	Human exposure: in gardens, lawns, landscaped areas, parks, and recreational areas. Animal exposure: in pastures, lawns, and parks (untilled soils).
1 cm	Surface water runoff in nonagricultural areas.	These areas are typically assumed to be untilled.
20 cm	Plant uptake for agricultural soils.	The root depth is assumed to equal the tilling depth of 20 cm. In untilled soils, the root zone does not directly reflect tilling depth, although it is assumed that tilling depth is an adequate substitute for root zone depth.
20 cm	Surface water runoff in agricultural areas.	These areas are typically assumed to be tilled.

<p><b>Recommended Values for: Soil Mixing Zone Depth (<math>Z_v</math>)</b></p> <hr/> <p>2 cm—untilled 20 cm—tilled</p>
---

Semivolatile COPCs and volatile COPCs emitted in sufficiently high concentrations may be deposited in particulate form and exhibit volatilization losses from soils. COPCs subject to volatilization losses may be moved to 20 cm by tilling and will not readily volatilized from this depth. The volatilization rate will reflect only the COPC concentration at the soil surface.

*Soil dry bulk density.* Soil dry bulk density (BD) is the ratio of the mass of soil to its total volume. This variable is affected by the soil structure, type, and moisture content (Hillel 1980). USEPA recommends the following value for the *BD*.

<p><b>Recommended Value for: Soil Dry Bulk Density (<i>BD</i>) = 1.50 g/cm<sup>3</sup></b></p>
--

*Available water ( $P + I - RO - E_v$ ).* The average annual volume of water available ( $P + I - RO - E_v$ ) for generating leachate is the mass balance of all water inputs and outputs from the area under consideration. A wide range of values for these site-specific parameters may apply in the various USEPA regions.

The average annual precipitation (*P*), irrigation (*I*), runoff (*RO*), and evapotranspiration (*E<sub>v</sub>*) rates and other climatological data may be obtained from either data recorded on site or from the Station Climatic Summary for a nearby airport. Meteorological variables, such as the evapotranspiration rate (*E<sub>v</sub>*) and the runoff rate (*RO*), may be found in resources such as Geraghty et al (1973).

*Soil volumetric water content.* The soil volumetric water content ( $\theta_{sw}$ ) depends on the available water and the soil structure. A wide range of values for these variables may apply in the various USEPA regions. USEPA recommends a value for  $\theta_{sw}$  of 0.2 mL/cm<sup>3</sup>.

<p><b>Recommended Value for: Soil Volumetric Water Content (<math>\theta_{sw}</math>) = 0.2 ml/cm<sup>3</sup></b></p> <hr/>
---

### 5.3 Calculation of COPC Concentrations in Produce

The concentration of COPCs in plant material is necessary for two reasons:

1. Humans may directly consume vegetables and fruits that are harvested from gardens located in the area impacted by air toxics.
2. Animals (e.g., cattle, chickens) may consume forage, silage, and grain grown in the area impacted by air toxics, and these animals are then consumed by humans.

Indirect exposure resulting from ingestion of produce depends on the total concentration of COPCs in the leafy, fruit, and tuber portions of the plant. Because of general differences in contamination mechanisms, consideration of indirect exposure separates produce into two broad categories, aboveground produce and plant material, and belowground produce. In addition, aboveground produce should be further subdivided into exposed and protected aboveground produce for consideration of contamination as a result of indirect exposure.

### 5.4 Aboveground Produce, Forage, Silage, and Grain

Aboveground exposed produce, animal forage, animal silage, and grain is assumed to be contaminated by three possible mechanisms (Fig. 1.8) :

- Direct deposition of particles: wet and dry deposition of particle-phase COPCs on the leaves and fruits of plants.
- Vapor transfer: uptake of vapor phase COPCs by plants through their foliage.
- Root uptake: root uptake of COPCs available from the soil and their transfer to the aboveground portions of the plant.

FIGURE 1.8 Aboveground produce exposure pathways.

The total COPC concentration in aboveground exposed produce is calculated as a sum of contamination occurring through all three of these mechanisms. However, edible portions of aboveground protected produce, such as peas, corn, melons, and grain are covered by a protective covering; hence, they are protected from contamination through deposition and vapor transfer. Therefore, root uptake of COPCs is the primary mechanism through which aboveground protected vegetation becomes contaminated.

**Belowground produce.** For belowground produce, contamination is assumed to occur only through one mechanism, root uptake of COPCs available from soil. Contamination of belowground produce via direct deposition of particles and vapor transfer are not considered because the root or tuber is protected from contact with contaminants in the vapor phase.

Generally, risks associated with exposure of VOCs via food-chain pathways have not been considered significant, primarily because VOCs are typically low-molecular-weight COPCs that do not persist in the environment and do not bioaccumulate. However, USEPA recommends that all COPCs, including VOCs, be evaluated for each exposure pathway.

**Aboveground vegetation concentrations due to direct deposition.** USEPA recommends that COPC concentrations in aboveground vegetation resulting from wet and dry deposition onto plant surfaces of leafy plants and exposed produce ( $Pd$ ) be calculated as follows:

$$Pd = \frac{1000 \cdot Q \cdot (1 - F_v) \cdot [Dydp + (Fw \cdot Dywp)] \cdot Rp \cdot [1.0 - \exp(-kp \cdot Tp)]}{Yp \cdot kp} \quad (1.9)$$

where

- $Pd$  = Plant (aboveground produce) concentration due to direct (wet and dry) deposition (mg COPC/kg DW)
- 1000 = Units conversion factor (mg/g)
- $Q$  = COPC emission rate (g/s)
- $F_v$  = Fraction of COPC air concentration in vapor phase (unitless)
- $Dydp$  = Unitized yearly average dry deposition from particle phase ( $s/m^2 \cdot yr$ )
- $Fw$  = Fraction of COPC wet deposition that adheres to plant surfaces (unitless)
- $Dywp$  = Unitized yearly wet deposition from particle phase ( $s/m^2 \cdot yr$ )
- $Rp$  = Interception fraction of the edible portion of plant (unitless)
- $kp$  = Plant surface loss coefficient ( $year^{-1}$ )
- $Tp$  = Length of plant exposure to deposition per harvest of the edible portion of the  $i$ th plant group (year)
- $Yp$  = Yield or standing crop biomass of the edible portion of the plant (productivity) (kg DW/m<sup>2</sup>)

*Interception fraction of the edible portion of plant.* As summarized in Baes et al.(1984), experimental studies of pasture grasses identified a correlation between initial interception fraction of the edible portion of plant ( $Rp$ ) values and productivity (standing crop biomass [ $Yp$ ]) (Chamberlain 1970):

$$Rp = 1 - e^{-\gamma Yp} \quad (1.10)$$

where

- $Rp$  = Interception fraction of the edible portion of plant (unitless)
- $\gamma$  = Empirical constant (range as 2.3 to 3.3 for pasture grasses; use the midpoint, 2.88, for pasture grasses.)
- $Yp$  = Standing crop biomass (productivity) (kg DW/m<sup>2</sup> for silage; kg WW/m<sup>2</sup> for exposed produce)

Baes et al. (1984) proposed using the same empirical relationship developed by Chamberlain (1970) for other vegetation classes. Class-specific estimates of the empirical constant ( $\gamma$ ) were developed by forcing an exponential regression equation through several points, including average and

theoretical maximum estimates of  $R_p$  and  $Y_p$  (Baes et al. 1984). Class-specific empirical constants ( $\gamma$ ) that were developed include the following:

- Exposed produce = 0.0324
- Leafy vegetables = 0.0846
- Silage = 0.769

USEPA proposed a default aboveground produce  $R_p$  value of 0.05, which is based on a weighted average class-specific  $R_p$  values. Specifically, class-specific  $R_p$  values were calculated by using the equation developed by Chamberlain (1970) and the following empirical constants:

- Leafy vegetables were assigned the same empirical constant (0.0846) developed by Baes et al. (1984).
- Fruits, fruiting vegetables, and legumes were assigned the empirical constant (0.0324) originally developed by Baes et al. (1984) for exposed produce.

Vegetables and fruits included in each class are as follows:

- Fruits: apple, apricot, berry, cherry, cranberry, grape, peach, pear, plum/prune, and strawberry
- Fruiting vegetables: asparagus, cucumber, eggplant, sweet pepper, and tomato
- Legumes: snap beans
- Leafy vegetables: broccoli, brussel sprouts, cauliflower, celery, lettuce, and spinach

The produce classes have been combined into two groups, exposed fruit and exposed vegetables. The exposed produce empirical constant ( $\gamma$ ) was used to calculate  $R_p$ . Since the exposed vegetable category includes leafy and fruiting vegetables,  $R_p$  was calculated for leafy and fruiting vegetables. The exposed vegetable  $R_p$  was then determined by a weighted average based on productivity ( $Y_p$ ) of leafy and fruiting vegetables, respectively. The relative ingestion rates used to determine an average weighted  $R_p$  value were derived from the intake of homegrown produce discussion presented in the 1997 *Exposure Factors Handbook* (USEPA 1997c). USEPA recommends the use of the weighted average  $R_p$  value of 0.39 as a default  $R_p$  value.

**Interception Fraction of the Edible Portion of Plant ( $R_p$ ) = 0.39**

Unweighted  $R_p$  and ingestion rates used for the weighting were as Table 1.5:

The interception fraction for forage and silage is computed in a manner similar to produce. Substituting the Baes et al. (1984) empirical constant ( $\gamma$ ) value of 2.88 for pasture grass, and the standing crop biomass value of 0.24 kg DW/m<sup>2</sup> the forage  $R_p$  is calculated to be 0.5. the silage  $R_p$  value is calculated to be 0.46.

**Interception Fraction of the Edible Portion of Plant ( $R_p$ )**

---

Forage = 0.5  
Silage = 0.46

**TABLE 1.5** USEPA Recommended Interception Fraction of Edible Portion for Above Ground Produce

Aboveground produce class	$R_p$	Ingestion rate (g DW/kg · d)
Exposed fruits	0.053	0.19
Exposed vegetables	0.982	0.11

The use of the empirical constant midpoint (2.88 for pasture grass) does not significantly affect the  $R_p$  value and the resulting estimate of plant COPC concentration.

*Plant surface loss coefficient.* USEPA (1990e) identified several processes—including wind removal, water removal, and growth dilution—which reduce the amount of contaminant that has deposited on plant surfaces. The term plant surface loss coefficient ( $kp$ ) is a measure of the amount of contaminant that is lost to these physical processes over time. USEPA recommends the following equation:

$$kp = \left( \frac{\ln 2}{t_{1/2}} \right) \cdot 365 \quad (1.11)$$

where

$$\begin{aligned} kp &= \text{Plant surface loss coefficient (year}^{-1}\text{)} \\ t_{1/2} &= \text{Half-life(days)} \\ 365 &= \text{Units conversion factor (d/yr)} \end{aligned}$$

USEPA recommends a  $kp$  value of 18, based on a generic 14-day half-life corresponding to physical processes only.

**Plant Surface Loss Coefficient ( $kp$ ) = 18**

The primary uncertainty associated with this variable is that the calculation of  $kp$  does not consider chemical degradation processes.

*Length of plant exposure to deposition per harvest of edible portion of plant.* USEPA recommends treating length of plant exposure to deposition per harvest of edible portion of plant ( $T_p$ ) as a constant, based on the average period between successive hay harvests. This period was estimated at 60 days (0.164 years) by Belcher and Travis (1989) and represents the length of time that aboveground vegetation (in this case, hay) would be exposed to contaminant deposition before being harvested.  $T_p$  is calculated as follows:

$$T_p = \frac{60 \text{ d}}{365 \text{ d/yr}} = 0.164 \text{ year} \quad (1.12)$$

where

$$\begin{aligned} T_p &= \text{Length of plant exposure to deposition per harvest of the edible portion of plant (year)} \\ 60 &= \text{Average period between successive hay harvests (days)} \\ 365 &= \text{Units conversion factor (d/yr)} \end{aligned}$$

**Length of Plant Exposure to Deposition per Harvest of Edible Portion of Plant ( $T_p$ ) = 0.164 years**

The primary uncertainty associated with the use of this value is that it is based on the growing season for hay rather than aboveground produce. The average period between successive hay harvests (60 days) may not reflect the length of the growing season or the period between successive harvests for aboveground produce at specific sites. To the extent that information documenting the growing season or period between successive harvests for aboveground produce is available, this information may be used to estimate a site-specific  $T_p$  value. Calculated plant concentrations will be affected most if the site-specific value of  $T_p$  is significantly less than 60 days.

For forage and silage,  $T_p$  is treated as a constant, based on the average period between successive hay harvests. This period, which was estimated at 60 days by Belcher and Travis (1989), represents the length of time that aboveground vegetation (in this case, hay) would be exposed to particle

deposition before being harvested. For cattle forage, the risk assessor should consider the average of the period between successive:

1. Hay harvests
2. Grazing

The average period between hay harvests is assumed to be 60 days, and the average period between successive grazing is assumed to be 30 days.  $T_p$  is therefore calculated as follows:

$$T_p = \frac{0.5 \cdot (60 \text{ d} + 30 \text{ d})}{365 \text{ d/yr}} = 0.12 \text{ year} \tag{1.13}$$

<b>Plant Exposure Length to Deposition per Harvest of the Edible Portion of Plant (<math>T_p</math>)</b>
Forage = 0.12 year
Silage = 0.16 year

*Standing crop biomass (productivity).* USEPA (1990e) stated that the best estimate of standing crop biomass ( $Y_p$ ) is productivity, which Baes et al. (1984) and Shor et al. (1982) define as follows:

$$Y_p = \frac{\sum Yh_i}{\sum Ah_i} \tag{1.14}$$

where

- $Yh_i$  = Harvest yield of the  $i$ th crop (kg DW)
- $Ah_i$  = Area planted to the  $i$ th crop (m<sup>2</sup>)

USEPA recommends using this equation and calculate  $Y_p$  value of 1.6 for aboveground produce, based on weighted average  $Yh$  and  $Ah$  values for four aboveground produce classes (fruits, fruiting vegetables, legumes, and leafy vegetables). Vegetables and fruits included in each class are as follows:

- Fruits: apple, apricot, berry, cherry, cranberry, grape, peach, pear, plum/prune, and strawberry
- Fruiting vegetables: asparagus, cucumber, eggplant, sweet pepper, and tomato
- Legumes: snap beans
- Leafy vegetables: broccoli, brussel sprouts, cauliflower, celery, lettuce, and spinach.

For consistency, the produce classes have been combined into two groups: exposed fruit and exposed vegetables. The exposed vegetable  $Y_p$  was determined by summing  $Yh$  values for leafy and fruiting vegetables and dividing by the sum of  $Ah$  values for leafy and fruiting vegetables. USEPA recommends the use of the weighted average  $Y_p$  value of 2.24 as a default  $Y_p$  value based on this value representing the most complete and thorough information available.

<b>Standing Crop Biomass (Productivity) (<math>Y_p</math>) = 2.24</b>
---

Unweighted  $Y_p$  and ingestion rates used for the weighting were as follows:

Aboveground produce class	$Y_p$	Ingestion rate (g DW/kg · d)
Exposed fruits	0.25	0.19
Exposed vegetables	5.66	0.11

The primary uncertainty associated with this variable is that the harvest yield ( $Yh$ ) and area planted ( $Ah$ ) may not reflect site-specific conditions. To the extent to which site-specific

information is available, the magnitude of the uncertainty introduced by the default  $Yp$  value can be estimated.

For forage and silage, USEPA recommends that forage  $Yp$  be calculated as a weighted average of the calculated pasture grass and hay  $Yp$  values. Weightings are assumed to be 0.75 for forage and 0.25 for hay, based on the fraction of a year that cattle are assumed to be pastured and eating grass (9 months/year) or not pastured and fed hay (3 months/year). An unweighted pasture grass  $Yp$  of 0.15 kg DW/m<sup>2</sup> is assumed. An unweighted hay  $Yp$  of 0.5 kg DW/m<sup>2</sup> is adopted by the USEPA. The unweighted pasture grass and hay  $Yp$  values are multiplied by their weighting factors (0.75 and 0.25, respectively), and then added to calculate the weighted forage  $Yp$  of 0.24 kg DW/m<sup>2</sup>.

USEPA recommends that a production-weighted U.S. average  $Yp$  of 0.8 kg DW/m<sup>2</sup> be assumed for silage.

Standing Crop Biomass (Productivity) ( $Yp$ )
Forage = 0.24 kg DW/m <sup>2</sup>
Silage = 0.8 kg DW/m <sup>2</sup>

The primary uncertainty associated with this variable is that the harvest yield ( $Yh$ ) and area planted ( $Ah$ ) may not reflect site-specific conditions. To the extent that site-specific information is available, the magnitude of the uncertainty introduced by the default  $Yp$  value can be estimated. In addition, the weightings assumed in this discussion for the amount of time that cattle are pastured (and foraging) or stabled (and being fed silage) should be adjusted to reflect site-specific conditions, as appropriate.

**Aboveground produce concentration due to air-to-plant transfer.** The methodology used to estimate COPC concentration in exposed and aboveground produce due to air-to-plant transfer ( $Pv$ ) considers limitations of COPCs concentrations to transfer from plant surfaces to the inner portions of the plant. These limitations result from mechanisms responsible for inhibiting the transfer of the lipophilic COPC (e.g., the shape of the produce) and the removal of the COPCs from the edible portion of the produce (e.g., washing, peeling, and cooking).

USEPA recommends the use of Eq. (1.15) to calculate  $Pv$ .

$$Pv = Q \cdot F_v \cdot \frac{C_{yv} \cdot Bv_{ag} \cdot VG_{ag}}{\rho_a} \quad (1.15)$$

where

$Pv$  = Concentration of COPC in the plant resulting from air-to-plant transfer ( $\mu\text{g}$  COPC/g DW)

$Q$  = COPC emission rate (g/s)

$F_v$  = Fraction of COPC air concentration in vapor phase (unitless)

$C_{yv}$  = Unitized yearly average air concentration from vapor phase ( $\mu\text{g} \cdot \text{s/g} \cdot \text{m}^3$ )

$Bv_{ag}$  = COPC air-to-plant biotransfer factor ([mg COPC/g DW plant]/[mg COPC/g air]) (unitless)

$VG_{ag}$  = Empirical correction factor for aboveground produce (unitless)

$\rho_a$  = Density of air ( $\text{g/m}^3$ )

The parameter  $VG_{ag}$  is dependent on lipophilicity of the COPC, and assigned a value of 0.001 for lipophilic COPCs ( $\log K_{ow}$  greater than 4) or a value of 1.0 for COPCs with a  $\log K_{ow}$  less than 4.

**Empirical correction factor for aboveground produce.** USEPA (1994m) recommends an empirical correction factor ( $VG_{ag}$ ) of 0.01 for lipophilic COPCs to reduce estimated vegetable concentrations. The factor of 0.01 is based on a similar correction factor

$$VG_{rootveg} = \frac{M_{skin}}{M_{vegetable}} \quad (1.16)$$

( $VG_{rootveg}$ ) for belowground produce, which is estimated for unspecified vegetables as follows:

where

$$\begin{aligned} VG_{rootveg} &= \text{Correction factor for belowground produce (g/g)} \\ M_{skin} &= \text{Mass of a thin (skin) layer of belowground vegetable (g)} \\ M_{vegetable} &= \text{Mass of the entire vegetable (g)} \end{aligned}$$

If it is assumed that the density of the skin and the whole vegetable are the same, this equation can become a ratio of the volume of the skin to that of the whole vegetable. With this assumption, USEPA (1994m) calculated  $VG_{rootveg}$  values of 0.09 and 0.03 for carrots and potatoes, respectively.

USEPA recommends using a lipophilic COPC ( $\log K_{ow}$  greater than 4)  $VG_{ag}$  value of 0.01 for all aboveground exposed produce. For COPCs with a  $\log K_{ow}$  less than 4, USEPA recommends using a  $VG_{ag}$  value of 1.0, because these COPCs are assumed to pass more easily through the skin of produce.

#### Empirical Correction Factor for Aboveground Produce ( $VG_{ag}$ )

$$\begin{aligned} &0.01 \text{ for COPCs with a } \log K_{ow} \text{ greater than 4} \\ &1.0 \text{ for COPCs with a } \log K_{ow} \text{ less than 4} \end{aligned}$$

Uncertainty may be introduced by the assumption of  $VG_{ag}$  values for leafy vegetables (such as lettuce) and for legumes (such as snap beans). Underestimation may be introduced by assuming a  $VG_{ag}$  value of 0.01 for legumes and leafy vegetables because these species often have a higher ratio of surface area to mass than other bulkier fruits and fruiting vegetables, such as tomatoes.

USEPA recommends the use of  $VG_{ag}$  values of 1.0 for forage and 0.5 for silage. As discussed, the primary uncertainty associated with this variable is the lack of specific information on the proportions of each vegetation type of which silage may consist, leading to the default assumption of 0.5.

#### Empirical Correction Factor for Forage and Silage ( $VG_{ag}$ )

$$\begin{aligned} \text{Forage} &= 1 \\ \text{Silage} &= 0.5 \end{aligned}$$

**Produce concentration due to root uptake.** Root uptake of contaminants from soil may also result in COPC concentrations in aboveground exposed produce, aboveground protected produce, and belowground produce. USEPA recommends the use of the following equations to calculate COPC concentration aboveground and belowground produce due to root uptake ( $Pr$ ).

#### Produce Concentration Due to Root Uptake ( $Pr$ )

**Exposed and protected aboveground produce:**

$$Pr = Cs \cdot Br$$

**Belowground produce:**

$$Pr = \frac{Cs \cdot RCF \cdot VG_{rootveg}}{Kd_s \cdot 1 \text{ kg/L}}$$

where

$$\begin{aligned} Pr &= \text{Concentration of COPC in produce due to root uptake (mg/kg)} \\ Br &= \text{Plant-soil bioconcentration factor for produce (unitless)} \\ VG_{rootveg} &= \text{Empirical correction factor for belowground produce (unitless)} \\ Kd_s &= \text{Soil-water partition coefficient (L/kg)} \end{aligned}$$

$C_s$  = Average soil concentration over exposure duration (mg COPC/kg soil)  
 $RCF$  = Root concentration factor (unitless)

USEPA recommends a  $VG_{rootveg}$  value of 0.01 for lipophilic COPCs ( $\log K_{ow}$  greater than 4) based on root vegetables like carrots and potatoes. For COPCs with a  $\log K_{ow}$  less than 4, USEPA recommends a  $VG_{rootveg}$  value of 1.0.

<p><b>Empirical Correction Factor for Belowground Produce (<math>VG_{rootveg}</math>)</b></p> <hr/> <p>0.01 for COPCs with a <math>\log K_{ow}</math> greater than 4                  1.0 for COPCs with a <math>\log K_{ow}</math> less than 4</p>
---

Similar to comments above regarding soil concentrations, this appears to show produce calculations for several different COPCs. Which ones is not explained.

*Example calculations for the concentration of COPC in produce*

### 5.5 Calculation of COPC Concentrations in Beef and Dairy Products

One of the unique aspects of air toxics risk assessment is the estimation of risk from the consumption of beef, dairy, and other agricultural products. Cattle are assumed to consume forage, silage, and grain that are contaminated with COPCs. The calculations necessary to then estimate the bioaccumulation of COPCs within the cattle related food sources is presented in this section.

**Beef concentration resulting from plant and soil ingestion.** USEPA recommends that COPC concentration in beef tissue ( $A_{beef}$ ) be calculated by using the following equation.

$$A_{beef} = \left( \sum (F_i \cdot Qp_i \cdot P_i) + Qs \cdot Cs \cdot Bs \right) \cdot Ba_{beef} \cdot MF \tag{1.17}$$

where

- $A_{beef}$  = Concentration of COPC in beef (mg COPC/kg FW tissue)
- $F_i$  = Fraction of plant type  $i$  grown on contaminated soil and ingested by the animal (cattle) (unitless)
- $Qp_i$  = Quantity of plant type  $i$  eaten by the animal (cattle) per day (kg DW plant/d)
- $P_i$  = Concentration of COPC in each plant type  $i$  eaten by the animal (cattle) (mg/kg DW)
- $Qs$  = Quantity of soil eaten by the animal (cattle) each day (kg/d)
- $Cs$  = Average soil concentration over exposure duration (mg COPC/kg soil)
- $Bs$  = Soil bioavailability factor (unitless)
- $Ba_{beef}$  = COPC biotransfer factor for beef (d/kg FW tissue)
- $MF$  = Metabolism factor (unitless)

*Fraction of plant type  $i$  grown on contaminated soil and eaten by the animal (cattle).* USEPA recommends that 100 percent of the plant materials eaten by cattle be assumed to have been grown on soil contaminated by the emission sources being evaluated. USEPA recommends a default value of 1.0 for fraction of plant type  $i$  grown on contaminated soil and eaten by the animal (cattle)  $F_i$ .

<b>Fraction of Plant Type <math>i</math> Grown on Contaminated Soil and Eaten by the Animal (Cattle) (<math>F_i</math>)</b>
1.0

*Quantity of plant type  $i$  eaten by the animal (cattle) each day.* The daily quantity of plants eaten by cattle ( $Qp_i$ ) should be estimated (kg DW/day) for each category of plant feed. Forage, silage, and grain feeds should be included in this estimate. Several values of plant consumption rates are summarized in Table 1.6.

USEPA recommends in the 2005 HHRAP the following beef cattle ingestion rates of forage, silage, and grain. These values are based on the total daily intake rate of about 12 kg DW/day.

<b>Quantity of Plant Type <math>i</math> Eaten by Animal (Cattle) Each Day (<math>Qp_i</math>)</b>
Forage = 8.8 kg DW/day Beef; 13.2 kg DW/day Dairy Silage = 2.5 kg DW/day, 4.1 kg DW/day Dairy Grain = 0.47 kg DW/day, 3.0 kg DW/day Dairy

**TABLE 1.6** Plant Consumption Rates from Various Regulatory Guidances

Source	Forage (kg DW/d)	Grain (kg DW/d)	Silage (kg DW/d)	References
NC DEHNR (1997) Subsistence farmer beef cattle	8.8	0.47	2.5	Boone et al. (1981) NAS (1987)
NC DEHNR (1997) Typical farmer beef cattle	3.8	3.8	1.0	Rice (1994)
USEPA (1994) Subsistence farmer beef cattle	8.8	Not reported	Not reported	Boone et al. (1981) NAS (1987)
USEPA (1990e) Subsistence farmer beef cattle	8.8	0.47	2.5	Boone et al. (1981)McKone and Ryan (1989)
Boone et al. (1981)	8.87	1.9	2.5	Boone et al. (1981)

The principal uncertainty associated with  $Qp_i$  is the variability between forage, silage, and grain ingestion rates for cattle.

*Concentration of COPC in plant type i eaten by animal (cattle).* The total COPC concentration in plant type i (forage, silage, and grain) eaten by animal (cattle) ( $P_i$ ) should be calculated by using the following equation

<p><b>Concentration of COPC in Plant Type <i>i</i> Eaten by the Animal (Cattle) (<math>P_i</math>)</b></p> <hr/> $P_i = \sum_i(Pd + Pv + Pr)$
---

where

- $P_i$  = Concentration of COPC in each plant type *i* eaten by the animal (mg COPC/kg DW)
- $Pd$  = Plant concentration due to direct deposition (mg COPC/kg DW)
- $Pv$  = Plant concentration due to air-to-plant transfer (mg COPC/kg DW)
- $Pr$  = Plant concentration due to root uptake (mg COPC/kg DW)

*Quantity of soil eaten by animal (cattle) per day.* Additional cattle contamination occurs through ingestion of soil. USEPA recommends a value of 0.5 kg/d for the quantity of soil ingested by the animal (cattle) ( $Qs$ ).

<p><b>Quantity of Soil Ingested by Animal (Cattle) per Day (<math>Qs</math>)</b></p> <hr/> <p>0.5 kg/d – Beef Cattle 0.4 kg/d – Dairy Cattle</p>
--

*Soil bioavailability factor.* Soil bioavailability factor ( $Bs$ ) is defined as the ratio between bioconcentration (or biotransfer) factors for soil and vegetation for a given COPC. The efficiency of transfer from soil may differ from efficiency or transfer from plant material for some COPCs. If the transfer efficiency is lower for soils, than this ratio would be less than 1.0. If it is equal or greater than that of vegetation, the  $Bs$  value would be equal to or greater than 1.0.

Until more COPC-specific data becomes available for this parameter, USEPA recommends a default value of 1 for  $B_s$ .

Soil Bioavailability Factor ( $B_s$ )
1.0

**Metabolism factor.** The metabolism factor ( $MF$ ) represents the estimated amount of COPC that remains in fat and muscle. USEPA recommends an  $MF$  of 0.01 for bis(2-ethylhexyl)phthalate (BEHP), and 1.0 for all other COPCs. Evidence indicates BEHP is more readily metabolized and excreted by mammalian species than other contaminants. Considering the recommended values for this variable,  $MF$  has no quantitative effect on  $A_{beef}$  (with the exception of BEHP).

$MF$  applies only to mammalian species, including beef cattle, dairy cattle, and pigs. It does not relate to metabolism in produce, chicken, or fish. Use of an  $MF$  does not apply for direct exposures to air, soil, or water, or to ingestion of produce, chicken, or fish.

**COPC concentration in milk due to plant and soil ingestion.** USEPA recommends the following equation to estimate concentrations in beef cattle ( $A_{beef}$ ). Eq. (1.17) can be modified to calculate COPC milk concentrations ( $A_{milk}$ ), as follows:

$$A_{milk} = \left( \sum (F_i \cdot QP_i \cdot P_i) + Q_s \cdot C_s \cdot B_s \right) \cdot Ba_{milk} \cdot MF \quad (1.18)$$

where

- $A_{milk}$  = Concentration of COPC in milk (mg COPC/kg milk)
- $F_i$  = Fraction of plant type  $i$  grown on contaminated soil and ingested by the animal (dairy cattle) (unitless)
- $QP_i$  = Quantity of plant type  $i$  eaten by the animal (dairy cattle) each day (kg DW plant/day)
- $P_i$  = Concentration of COPC in plant type  $i$  eaten by the animal (dairy cattle) (mg/kg DW)
- $Q_s$  = Quantity of soil eaten by the animal (dairy cattle) each day (kg soil/day)
- $C_s$  = Average soil concentration over exposure duration (mg COPC/kg soil)
- $B_s$  = Soil bioavailability factor (unitless)
- $Ba_{milk}$  = COPC biotransfer factor for milk (d/kg WW tissue)
- $MF$  = Metabolism factor (unitless)

## 5.6 Calculation of COPC Concentrations in Pork

COPC concentrations in pork tissue ( $A_{pork}$ ) are estimated on the basis of the amount of COPCs that swine are assumed to consume through their diet; assumed to consist of silage and grain. Additional COPC contamination of pork tissue may occur through the ingestion of soil by swine.

**Concentration of COPC in pork.** USEPA recommends the following equation to calculate COPC concentrations in swine, as follows:

$$A_{pork} = \left( \sum (F_i \cdot QP_i \cdot P_i) + Q_s \cdot C_s \cdot B_s \right) \cdot Ba_{pork} \cdot MF \quad (1.19)$$

where

- $A_{pork}$  = Concentration of COPC in pork (mg COPC/kg FW tissue)
- $F_i$  = Fraction of plant type  $i$  grown on contaminated soil and ingested by the animal (swine)(unitless)
- $QP_i$  = Quantity of plant type  $i$  eaten by the animal (swine) each day (kg DW plant/day)
- $P_i$  = Concentration of COPC in plant type  $i$  eaten by the animal (swine) (mg/kg DW)
- $Q_s$  = Quantity of soil eaten by the animal (swine) (kg/day)
- $C_s$  = Average soil concentration over exposure duration (mg COPC/kg soil)

- $B_s$  = Soil bioavailability factor (unitless)
- $Ba_{pork}$  = COPC biotransfer factor for pork (d/kg FW tissue)
- $MF$  = Metabolism factor (unitless)

*Fraction of plant type i grown on contaminated soil and eaten by the animal (swine).* The calculation of fraction of plant type i grown on contaminated soil and eaten by the animal (swine) ( $F_i$ ) for pork is identical to that for beef cattle.

*Quantity of plant type i eaten by the animal (swine) each day.* The daily quantity of forage, silage, and grain feed consumed by beef cattle is estimated for each category of feed material. Because swine are not grazing animals, they are assumed not to eat forage. The quantity of plant type i eaten by the animal (swine) each day ( $Q_{pi}$ ), consumed by swine should be estimated for each category of plant feed.

USEPA recommends the use of the more conservative ingestion rates:

Quantity of Plant Type <i>i</i> Eaten by Animal (Swine) Each Day ( $Q_{pi}$ )
Grain = 3.3 kg DW/d
Silage = 1.4 kg DW/d

*Concentration of COPC in plant type i eaten by the animal (swine).* The calculation of concentration of COPC in plant type i eaten by the animal (swine) ( $P_i$ ) for pork is identical to that for beef cattle.

*Quantity of soil eaten by the animal (swine) each day.* Additional contamination of swine results from ingestion of soil. The following quantity of soil eaten by the animal (swine) each day ( $Q_s$ ) values, presented in Table 1.7, are recommended by the USEPA:

USEPA recommends in the 2005 HHRAP the following  $Q_s$ :

$Q_s = 0.37$ kg DW/d
----------------------

Uncertainties associated with this variable include the lack of current empirical data to support soil ingestion rates for swine, and the assumption of uniform contamination of soil ingested by swine.

*Average soil concentration over exposure duration.* The calculation of average soil concentration over exposure duration ( $C_s$ ) for pork is the same as for beef cattle.

*Soil bioavailability factor.* The calculation of soil bioavailability factor ( $B_s$ ) for pork is the same as for beef cattle.

*Metabolism factor.* The recommended values for metabolism factor ( $MF$ ) are identical to those recommended for beef cattle.

**TABLE 1.7** Quantity of Soil Eaten by Swine per Day

Guidance	Quantity of soil eaten by swine each day ( $Q_s$ )
USEPA (1990e)	Stated that sufficient data are not available to estimate swine soil ingestion rates.
NC DEHNR (1997)	0.37 kg/d Estimated by assuming a soil intake that is 8 percent of the plant ingestion rate of 4.3 kg DW/d). USEPA (1993h) was cited as the reference for the soil ingestion rate of 8 percent of dry matter intake.

### 5.7 Calculation of COPC Concentrations in Chicken and Eggs

Estimates of the COPC concentrations in chicken and eggs are based on the amount of COPCs that chickens consume through ingestion of grain and soil. The uptake of COPCs via inhalation and via ingestion of water is assumed to be insignificant. Chickens are assumed to be free-range animals that have contact with soil; and therefore, are assumed to consume part of their diet as soil. The remainder of the diet is assumed to consist of grain. Grain ingested by chickens is assumed to have originated from the exposure scenario location; therefore, 100 percent of the grain consumed is assumed to be contaminated.

Grain is considered to be a feed item that is protected from deposition of particles and vapor transfer. As a result, only contamination due to root uptake of COPCs is considered in the calculation of COPC concentration in grain. Figure 1.9 depicts the fate and transport of chemicals, which would affect the concentration of COPC in chicken and eggs.

**Concentration of COPC in chicken and eggs.** USEPA recommends the application of following equation to calculate COPC concentrations in chicken and eggs ( $A_{chicken}$  or  $A_{egg}$ ). COPC concentrations in chicken and eggs should be determined separately.

$$A_{chicken} \text{ or } A_{egg} = \left( \sum [F_i \cdot Qp_i \cdot P_i] + Qs \cdot Cs \cdot Bs \right) \cdot (Ba_{egg} \text{ or } Ba_{chicken}) \quad (1.20)$$

where

- $A_{chicken}$  = Concentration of COPC in chicken (mg COPC/kg FW tissue)
- $A_{egg}$  = Concentration of COPC in eggs (mg COPC/kg FW tissue)
- $F_i$  = Fraction of plant type  $i$  (grain) grown on contaminated soil and ingested by the animal (chicken)(unitless)
- $Qp_i$  = Quantity of plant type  $i$  (grain) eaten by the animal (chicken) each day (kg DW plant/day)
- $P_i$  = Concentration of COPC in plant type  $i$  (grain) eaten by the animal (chicken) (mg/kg DW)
- $Qs$  = Quantity of soil eaten by the animal (chicken) (kg/d)

FIGURE 1.9 Fate and transport in the calculation of COPC concentration in poultry and eggs.

- $C_s$  = Average soil concentration over exposure duration (mg COPC/kg soil)
- $B_s$  = Soil bioavailability factor (unitless)
- $Ba_{chicken}$  = COPC biotransfer factor for chicken (d/kg FW tissue)
- $Ba_{egg}$  = COPC biotransfer factor for eggs (d/kg FW tissue)

*Fraction of plant type i grown on contaminated soil and eaten by the animal (Chicken).* The calculation of fraction of plant type i grown on contaminated soil and eaten by the animal (Chicken) ( $F_i$ ) is identical to that for beef cattle.

*Quantity of plant type i eaten by the animal (chicken) each day.* The daily quantity of forage, silage, and grain feed consumed by beef cattle is estimated for each category of feed material. However, daily ingestion rates for chicken are estimated differently than for beef cattle. Because chickens are not grazing animals, they are assumed not to eat forage (USEPA 1990e). The daily quantity of plant type (i) (kg of DW) consumed by the animal (chicken) ( $Q_{pi}$ ) only should be estimated for grain feed.

USEPA recommends the use of the following ingestion rate:

<p><b>Quantity of Plant Type <math>i</math> Eaten by Animal (Chicken) Each Day (<math>Q_{pi}</math>)</b></p> <hr style="width: 80%; margin: auto;"/> <p>Grain = 0.2 kg DW/d</p>
---

*Concentration of COPC in plant type i eaten by the animal (chicken).* The concentration of COPC in plant type i eaten by the animal (chicken) ( $P_i$ ) is the COPC concentration in grain and should be calculated by using:

<p><b>Concentration of COPC in Plant Type <math>i</math> Eaten by the Animal (Chicken) (<math>P_i</math>)</b></p> <hr style="width: 80%; margin: auto;"/> $P_i = \sum_i (Pr)$
---

where

- $P_i$  = Concentration of COPC in each plant type  $i$  eaten by the animal (mg COPC/kg DW)
- $Pr$  = Plant concentration due to root uptake (mg COPC/kg DW)

*Quantity of soil eaten by the animal (chicken) each day ( $Q_s$ ).* COPC concentration in chickens also results from intake of soil. As discussed earlier, chickens are assumed to consume 10 percent of their total diet as soil. USEPA recommends quantity of soil eaten by the animal (chicken) each day ( $Q_s$ ) as the following

<p><b>Quantity of Soil Eaten by the Animal (Chicken) Each Day (<math>Q_s</math>)</b></p> <hr style="width: 80%; margin: auto;"/> <p>0.022 kg DW/day</p>
---

Uncertainties associated with this variable include the lack of current empirical data to support soil ingestion rates for chicken, and the assumption of uniform contamination of soil ingested by chicken.

*Average soil concentration over exposure duration.* The calculation of average soil concentration over exposure duration ( $C_s$ ) for chicken is the same as for beef cattle.

*Soil bioavailability factor.* The calculation of soil bioavailability factor ( $B_s$ ) for chicken is the same as for beef cattle.

*Example of calculations to estimate COPC concentration in animal products*

### 5.8 COPC Concentrations in Drinking Water and Fish

COPC concentrations in surface water are calculated for all water bodies selected for evaluation in the risk assessment; specifically, evaluation of the drinking water and/or fish ingestion exposure pathways. Mechanisms considered for determination of COPC loading of the water column, as shown in Fig. 1.10, are:

- direct deposition onto the watershed and water body,
- runoff from impervious surfaces within the watershed,

FIGURE 1.10 Processes that occur on the balance of COPC concentration in a waterbody.

- runoff from pervious surfaces within the watershed,
- soil erosion over the total watershed,
- direct diffusion of vapor phase COPCs into the surface water, and
- internal transformation of compounds chemically or biologically.

Other potential mechanisms may require consideration on a case-by-case basis (e.g., tidal influences). However, contributions from other potential mechanisms are assumed to be negligible in comparison with those being evaluated.

The USLE and a sediment delivery ratio are used to estimate the rate of soil erosion from the watershed. Surface water concentration algorithms include a sediment mass balance, in which the amount of sediment assumed to be buried and lost from the water body is equal to the difference between the amount of soil introduced to the water body by erosion and the amount of suspended solids lost in downstream flow. The total water column COPC concentration is the sum of the COPC concentration dissolved in water and the COPC concentration associated with suspended solids. Partitioning between water and sediment varies with the COPC. The total concentration of each COPC is partitioned between the sediment and the water column. To evaluate the COPC loading to a water body from its associated watershed, the COPC concentration in watershed soils should be calculated. The equation for COPC concentration in soil includes a loss term that considers the loss of contaminants from the soil after deposition. These loss mechanisms all lower the soil concentration associated with a specific deposition rate.

**Total COPC load to the water body.** USEPA recommends the following equation to calculate the total COPC load to a water body ( $L_T$ ).

<p><b>Total COPC Load to the Water Body (<math>L_T</math>)</b></p> <hr style="width: 80%; margin: auto;"/> $L_T = L_{DEP} + L_{dif} + L_{RI} + L_R + L_E + L_I$
---

where

- $L_T$  = Total COPC load to the water body (including deposition, runoff, and erosion) (g/yr)
- $L_{DEP}$  = Total (wet and dry) particle phase and vapor phase COPC direct deposition load to water body (g/yr)
- $L_{dif}$  = Vapor phase COPC diffusion load to water body (g/yr)
- $L_{RI}$  = Runoff load from impervious surfaces (g/yr)
- $L_R$  = Runoff load from pervious surfaces (g/yr)
- $L_E$  = Soil erosion load (g/yr)
- $L_I$  = Internal transfer (g/yr)

Due to the limited data and uncertainty associated with the chemical or biological internal transfer,  $L_I$ , of compounds into daughter products, USEPA recommends a default value for this variable of zero.

**Total (wet and dry) particle-phase and vapor-phase COPC direct deposition load to water body.** USEPA recommends the following equation to calculate the load to the water body from the direct deposition of wet and dry particles and vapors onto the surface of the water body ( $L_{DEP}$ ).

$$L_{DEP} = Q \cdot [F_v \cdot D_{ytwv} + (1 - F_v) \cdot D_{ytwp}] \cdot A_w \quad (1.21)$$

where

- $L_{DEP}$  = Total (wet and dry) particle phase and vapor phase COPC direct deposition load to water body (g/yr)
- $Q$  = COPC emission rate (g/s)

- $F_v$  = Fraction of COPC air concentration in vapor phase (unitless)  
 $Dytwv$  = Unitized yearly (water body or watershed) average total (wet and dry) deposition from vapor phase ( $s/m^2 \cdot yr$ )  
 $Dytwp$  = Unitized yearly (water body or watershed) average total (wet and dry) deposition from particle phase ( $s/m^2 \cdot yr$ )  
 $A_w$  = Water body surface area ( $m^2$ )

*Vapor-phase COPC diffusion load to water body.* USEPA recommends using the following equation to calculate the vapor-phase COPC diffusion load to the water body ( $L_{dif}$ ).

$$L_{dif} = \frac{K_v \cdot Q \cdot F_v \cdot C_{yvw} A_w \times 10^{-6}}{R \cdot T_{wk}} \quad (1.22)$$

where

- $L_{dif}$  = Vapor-phase COPC diffusion load to water body (g/yr)  
 $K_v$  = Overall COPC transfer-rate coefficient (m/yr)  
 $Q$  = COPC emission rate (g/s)  
 $F_v$  = Fraction of COPC air concentration in vapor phase (unitless)  
 $C_{yvw}$  = Unitized yearly (water body or watershed) average air concentration from vapor phase ( $\mu g\text{-}s/g\text{-}m^3$ )  
 $A_w$  = Water body surface area ( $m^2$ )  
 $10^{-6}$  = Units conversion factor ( $g/\mu g$ )  
 $H$  = Henry's law constant ( $atm \cdot m^3/mol$ )  
 $R$  = Universal gas constant ( $atm \cdot m^3/mol \cdot K$ )  
 $T_{wk}$  = Water body temperature (K)

*Runoff load from impervious surfaces.* In some watershed soils, a fraction of the total (wet and dry) deposition in the watershed will be to impervious surfaces. This deposition may accumulate and be washed off during rain events. USEPA recommends the use of the following equation to calculate impervious runoff load to a water body ( $L_{RI}$ ).

$$L_{RI} = Q \cdot [ F_v \cdot Dytwv + (1.0 - F_v) \cdot Dytwp ] \cdot A_I \quad (1.23)$$

where

- $L_{RI}$  = Runoff load from impervious surfaces (g/yr)  
 $Q$  = COPC emission rate (g/s)  
 $F_v$  = Fraction of COPC air concentration in vapor phase (unitless)  
 $Dytwv$  = Unitized yearly (water body or watershed) average total (wet and dry) deposition from vapor phase ( $s/m^2 \cdot yr$ )  
 $Dytwp$  = Unitized yearly (water body or watershed) average total (wet and dry) deposition from particle phase ( $s/m^2 \cdot yr$ )  
 $A_I$  = Impervious watershed area receiving COPC deposition ( $m^2$ )

Impervious watershed area receiving COPC deposition ( $A_I$ ) is the portion of the total effective watershed area that is impervious to rainfall (such as roofs, driveways, streets, and parking lots) and drains to the water body.

*Runoff load from pervious surfaces.* USEPA recommends the following equation to calculate the COPC load to the water body from pervious soil surfaces in the watershed ( $L_R$ ).

$$L_R = RO \cdot (A_L - A_I) \cdot \frac{Cs \cdot BD}{\theta_{sw} + Kd_s \cdot BD} \cdot 0.01 \quad (1.24)$$

where

- $L_R$  = Runoff load from pervious surfaces (g/yr)  
 $RO$  = Average annual surface runoff from pervious areas (cm/yr)

- $A_L$  = Total watershed area receiving COPC deposition (m<sup>2</sup>)  
 $A_I$  = Impervious watershed area receiving COPC deposition (m<sup>2</sup>)  
 $C_s$  = Average soil concentration over exposure duration (in watershed soils) (mg COPC/kg soil)  
 $BD$  = Soil bulk density (g soil/cm<sup>3</sup> soil)  
 $\theta_{sw}$  = Soil volumetric water content (mL water/cm<sup>3</sup> soil)  
 $Kd_s$  = Soil-water partition coefficient (cm<sup>3</sup> water/g soil)  
 0.01 = Units conversion factor (kg · cm<sup>2</sup>/mg · m<sup>2</sup>)

**Soil erosion load.** USEPA recommends the use of the following equation to calculate soil erosion load ( $L_E$ ).

$$L_E = X_e \cdot (A_L - A_I) \cdot SD \cdot ER \cdot \frac{C_s \cdot Kd_s \cdot BD}{\theta_{sw} + Kd_s \cdot BD} \cdot 0.001 \quad (1.25)$$

where

- $L_E$  = Soil erosion load (g/yr)  
 $X_e$  = Unit soil loss (kg/m<sup>2</sup> · yr)  
 $A_L$  = Total watershed area (evaluated) receiving COPC deposition (m<sup>2</sup>)  
 $A_I$  = Impervious watershed area receiving COPC deposition (m<sup>2</sup>)  
 $SD$  = Sediment delivery ratio (watershed) (unitless)  
 $ER$  = Soil enrichment ratio (unitless)  
 $C_s$  = Average soil concentration over exposure duration (in watershed soils) (mg COPC/kg soil)  
 $BD$  = Soil bulk density (g soil/cm<sup>3</sup> soil)  
 $\theta_{sw}$  = Soil volumetric water content (mL water/cm<sup>3</sup> soil)  
 $Kd_s$  = Soil-water partition coefficient (mL water/g soil)  
 0.001 = Units conversion factor (k·cm<sup>2</sup>/mg·m<sup>2</sup>)

**Universal soil loss equation.** USEPA recommends that the USLE, be used to calculate the unit soil loss ( $X_e$ ) specific to each watershed.

$$X_e = RF \cdot K \cdot LS \cdot C \cdot PF \cdot \frac{907.18}{4047} \quad (1.26)$$

where

- $X_e$  = Unit soil loss (kg/m<sup>2</sup> · yr)  
 $RF$  = USLE rainfall (or erosivity) factor (year<sup>-1</sup>)  
 $K$  = USLE erodibility factor (ton/acre)  
 $LS$  = USLE length-slope factor (unitless)  
 $C$  = USLE cover management factor (unitless)  
 $PF$  = USLE supporting practice factor (unitless)  
 907.18 = Units conversion factor (kg/ton)  
 4047 = Units conversion factor (m<sup>2</sup>/acre)

The USLE  $RF$  variable, which represents the influence of precipitation on erosion, is derived from data on the frequency and intensity of storms. This value is typically derived on a storm-by-storm basis, but average annual values have been compiled (U.S. Department of Agriculture 1982).

**Sediment delivery ratio.** USEPA recommends the use of the following equation to calculate sediment delivery ratio ( $SD$ ).

$$SD = a \cdot (A_L)^{-b} \quad (1.27)$$

where

- $SD$  = Sediment delivery ratio (watershed) (unitless)  
 $a$  = Empirical intercept coefficient (unitless)

- $b$  = Empirical slope coefficient (unitless)
- $A_L$  = Total watershed area (evaluated) receiving COPC deposition ( $m^2$ )

The  $SD$  for a large land area, a watershed or part of a watershed, can be calculated, on the basis of the area of the watershed. According to Vanoni (1975), sediment delivery ratios vary approximately with the  $-0.125$  power of the drainage area. Therefore, the empirical slope coefficient is assumed to be equal to  $0.125$ .

$A_L$  is the total watershed surface area evaluated that is affected by deposition and drains to the body of water. In assigning values to the watershed surface area affected by deposition, the following may be a consideration:

1. The distance from the emission source.
2. The location of the area affected by deposition fallout with respect to the point at which drinking water is extracted or fishing occurs.
3. The watershed hydrology.

**Total water body COPC concentration.** USEPA recommends the following equation to calculate total water body COPC concentration ( $C_{wtot}$ ). The total water body concentration includes both the water column and the bed sediment.

$$C_{wtot} = \frac{L_T}{Vf_x \cdot f_{wc} + k_{wt} \cdot A_W \cdot (d_{wc} + d_{bs})} \tag{1.28}$$

where

- $C_{wtot}$  = Total water body COPC concentration (including water column and bed sediment) ( $g\ COPC/m^3\ water\ body$ )
- $L_T$  = Total COPC load to the water body (deposition, runoff, and erosion) ( $g/yr$ )
- $Vf_x$  = Average volumetric flow rate through water body ( $m^3/yr$ )
- $f_{wc}$  = Fraction of total water body COPC concentration in the water column (unitless)
- $k_{wt}$  = Overall total water body COPC dissipation rate constant ( $year^{-1}$ )
- $A_W$  = Water body surface area ( $m^2$ )
- $d_{wc}$  = Depth of water column ( $m$ )
- $d_{bs}$  = Depth of upper benthic sediment layer ( $m$ )

USEPA (1993h) recommended values ranging from  $0.01$  to  $0.05$ , with a default value of  $0.03$ , which represents the midpoint of the specified range.

*Fraction of total water body COPC concentration in the water column and benthic sediment.* USEPA recommends the following equation to calculate fraction of total water body COPC concentration in the water column ( $f_{wc}$ ), and the subsequent equation to calculate total water body contaminant concentration in benthic sediment ( $f_{bs}$ ).

**Fraction of Total Water Body COPC Concentration in the Water Column ( $f_{wc}$ ) and Benthic Sediment ( $f_{bs}$ )**

---

$$f_{bs} = 1 - f_{wc}$$

$$f_{wc} = \frac{(1 + Kd_{sw} \cdot TSS \cdot 1 \times 10^{-6}) \cdot d_{wc} / d_z}{(1 + Kd_{sw} \cdot TSS \cdot 1 \times 10^{-6}) \cdot d_{wc} / d_z + (\theta_{bs} + Kd_{bs} \cdot C_{BS}) \cdot d_{bs} / d_z}$$

where

- $f_{wc}$  = Fraction of total water body COPC concentration in the water column (unitless)
- $f_{bs}$  = Fraction of total water body COPC concentration in benthic sediment (unitless)
- $Kd_{sw}$  = Suspended sediments/surface water partition coefficient (L water/kg suspended sediment)

$TSS$  = Total suspended solids concentration (mg/L)  
 $10^{-6}$  = Units conversion factor (kg/mg)  
 $d_z$  = Total water body depth (m)  
 $\theta_{bs}$  = Bed sediment porosity ( $L_{\text{water}}/L_{\text{sediment}}$ )  
 $Kd_{bs}$  = Bed sediment/sediment pore water partition coefficient (L water/kg bottom sediment)  
 $C_{BS}$  = Bed sediment concentration [ $g/cm^3$  (equivalent to kg/L)]  
 $d_{wc}$  = Depth of water column (m)  
 $d_{bs}$  = Depth of upper benthic sediment layer (m)

Average annual values for  $TSS$  are generally expected to be in the range of 2 to 300 mg/L. A calculated  $TSS$  value can be obtained for nonflowing water bodies using:

$$TSS = \frac{X_e \cdot (A_L - A_I) \cdot SD \cdot 1 \times 10^3}{Vf_x + D_{ss} \cdot A_W} \quad (1.29)$$

where

$TSS$  = Total suspended solids concentration (mg/L)  
 $X_e$  = Unit soil loss ( $kg/m^2 \cdot yr$ )  
 $A_L$  = Total watershed area (evaluated) receiving COPC deposition ( $m^2$ )  
 $A_I$  = Impervious watershed area receiving COPC deposition ( $m^2$ )  
 $SD$  = Sediment delivery ratio (watershed) (unitless)  
 $Vf_x$  = Average volumetric flow rate through water body (value should be 0 for quiescent lakes or ponds) ( $m^3/yr$ )  
 $D_{ss}$  = Suspended solids deposition rate (a default value of 1825 for quiescent lakes or ponds) ( $m/yr$ )  
 $A_W$  = Water body surface area ( $m^2$ )

The default value of 1825 m/yr provided for  $D_{ss}$  is characteristic of Stoke's settling velocity for an intermediate (fine to medium) silt.

To evaluate the appropriateness of watershed-specific values used in calculating the unit soil loss ( $X_e$ ), the waterbody specific measured  $TSS$  value should be compared to the calculated  $TSS$  value. If the measured and calculated  $TSS$  values differ significantly, parameter values used in calculating  $X_e$  should be re-evaluated.

Bed sediment porosity ( $\theta_{bs}$ ) can be calculated from the bed sediment concentration by using the following equation (USEPA 1993h):

$$\theta_{bs} = 1 - \frac{C_{BS}}{\rho_s} \quad (1.30)$$

where

$\theta_{bs}$  = Bed sediment porosity ( $L_{\text{water}}/L_{\text{sediment}}$ )  
 $\rho_s$  = Bed sediment density (kg/L)  
 $C_{BS}$  = Bed sediment concentration (kg/L)

USEPA recommends the following default value for  $\theta_{bs}$ :

$$\theta_{bs} = 0.6 L_{\text{water}}/L_{\text{sediment}} \quad (1.31)$$

[assuming  $\rho_s = 2.65$  kg/L (bed sediment density) and  $C_{BS} = 1$  kg/L (bed sediment concentration)]

Concentrations for the bed sediment ( $C_{BS}$ ) and depth of upper benthic sediment layer ( $d_{bs}$ ) range from 0.5 to 1.5 m and 0.01 to 0.05 m, respectively. However, 0.1 kg/L is a reasonable concentration for most applications of the bed sediment ( $C_{BS}$ ), and 0.03 m is the default depth of the upper benthic layer ( $d_{bs}$ ). The default depth of 0.03 m is based on the midpoint of the range presented above.

*Overall total water body COPC dissipation rate constant.* USEPA recommends the following equation to calculate the overall total water body COPC dissipation rate constant ( $k_{wt}$ ) in surface water, resulting from volatilization and benthic burial.

$$k_{wt} = f_{wc} \cdot k_v + f_{bs} \cdot k_b \quad (1.32)$$

where

- $k_{wt}$  = Overall total water body dissipation rate constant (year<sup>-1</sup>)
- $f_{wc}$  = Fraction of total water body COPC concentration in the water column (unitless)
- $k_v$  = Water column volatilization rate constant (year<sup>-1</sup>)
- $f_{bs}$  = Fraction of total water body COPC concentration in benthic sediment (unitless)
- $k_b$  = Benthic burial rate constant (yr<sup>-1</sup>)

*Water column volatilization rate constant.* USEPA recommends the following equation to calculate water column volatilization rate constant ( $k_v$ ).

$$k_v = \frac{K_v}{d_z \cdot (1 + Kd_{sw} \cdot TSS \cdot 1 \times 10^{-6})} \quad (1.33)$$

where

- $k_v$  = Water column volatilization rate constant (yr<sup>-1</sup>)
- $K_v$  = Overall COPC transfer rate coefficient (m/yr)
- $d_z$  = Total water body depth (m)
- $Kd_{sw}$  = Suspended sediments/surface water partition coefficient (L water/kg suspended sediments)
- $TSS$  = Total suspended solids concentration (mg/L)
- $1 \times 10^{-6}$  = Units conversion factor (kg/mg)

*Overall COPC transfer rate coefficient.* Volatile organic chemicals can move between the water column and the overlying air. The overall transfer rate  $K_v$ , or conductivity, is determined by a two-layer resistance model that assumes that two stagnant films are bounded on either side by well-mixed compartments. Concentration differences serve as the driving force for the water layer diffusion. Pressure differences drive the diffusion for the air layer. From balance considerations, the same mass must pass through both films; the two resistances thereby combine in series, so that the conductivity is the reciprocal of the total resistance.

USEPA recommends the following equation to calculate the overall transfer rate coefficient ( $K_v$ ).

**Overall COPC Transfer Rate Coefficient ( $K_v$ )**

---

$$K_v = \left( K_L^{-1} + \left( K_G \cdot \frac{H}{R \cdot T_{wk}} \right)^{-1} \right)^{-1} \cdot \theta^{T_{wk} - 293}$$

where

- $K_v$  = Overall COPC transfer rate coefficient (m/yr)
- $K_L$  = Liquid-phase transfer coefficient (m/yr)
- $K_G$  = Gas-phase transfer coefficient (m/yr)
- $H$  = Henry's law constant (atm · m<sup>3</sup>/mol)
- $R$  = Universal gas constant (atm · m<sup>3</sup>/mol · K)
- $T_{wk}$  = Water body temperature (K)
- $\theta$  = Temperature correction factor (unitless)

The value of the conductivity  $K_v$  depends on the intensity of turbulence in the water body and the overlying atmosphere. As Henry's law constant increases, the conductivity tends to be increasingly influenced by the intensity of turbulence in water. Conversely, as Henry's law constant decreases, the value of the conductivity tends to be increasingly influenced by the intensity of atmospheric turbulence. The liquid and gas phase transfer coefficients,  $K_L$  and  $K_G$ , respectively, vary with the type of water body.

Henry's law constants generally increase with increasing vapor pressure of a COPC and generally decrease with increasing solubility of a COPC. Henry's law constants are compound-specific. The universal ideal gas constant,  $R$ , is  $8.205 \times 10^{-5} \text{ atm} \cdot \text{m}^3/\text{mol} \cdot \text{K}$ , at  $20^\circ\text{C}$ . The temperature correction factor ( $\theta$ ), which is equal to 1.026, is used to adjust for the actual water temperature. Volatilization is assumed to occur much less readily in lakes and reservoirs than in moving water bodies.

*Liquid-phase transfer coefficient.* USEPA recommends the following two equations to calculate liquid phase transfer coefficient ( $K_L$ ).

For flowing streams or rivers:

$$K_L = \sqrt{\frac{(1 \times 10^{-4}) \cdot D_w \cdot u}{d_z}} \cdot 3.1536 \times 10^7 \quad (1.34a)$$

For quiescent lakes or ponds:

$$K_L = (C_d^{0.5} \cdot W) \cdot \left(\frac{\rho_a}{\rho_w}\right) \cdot \frac{k^{0.33}}{\lambda_z} \cdot \left(\frac{\mu_w}{\rho_w \cdot D_w}\right)^{-0.67} \cdot 3.1536 \times 10^7 \quad (1.34b)$$

where

- $K_L$  = Liquid-phase transfer coefficient (m/yr)
- $D_w$  = Diffusivity of COPC in water ( $\text{cm}^2/\text{s}$ )
- $u$  = Current velocity (m/s)
- $1 \times 10^{-4}$  = Units conversion factor ( $\text{m}^2/\text{cm}^2$ )
- $d_z$  = Total water body depth (m)
- $C_d$  = Drag coefficient (unitless)
- $W$  = Average annual wind speed (m/s)
- $\rho_a$  = Density of air ( $\text{g}/\text{cm}^3$ )
- $\rho_w$  = Density of water ( $\text{g}/\text{cm}^3$ )
- $k$  = von Karman's constant (unitless)
- $\lambda_z$  = Dimensionless viscous sublayer thickness (unitless)
- $\mu_w$  = Viscosity of water corresponding to water temperature ( $\text{g}/\text{cm}\cdot\text{s}$ )
- $3.1536 \times 10^7$  = Units conversion factor (s/yr)

For a flowing stream or river, the transfer coefficients are controlled by flow-induced turbulence. For a stagnant system (quiescent lake or pond), the transfer coefficient is controlled by wind-induced turbulence.

USEPA recommends the use of the following default values:

1. Diffusivity of chemical in water ranging ( $D_w$ ) from  $1.0 \times 10^{-5}$  to  $8.5 \times 10^{-2} \text{ cm}^2/\text{s}$
2. Dimensionless viscous sublayer thickness ( $\lambda_z$ ) of 4
3. von Karman's constant ( $k$ ) of 0.4
4. Drag coefficient ( $C_d$ ) of 0.0011
5. Density of air ( $\rho_a$ ) of  $0.0012 \text{ g}/\text{cm}^3$  at standard conditions (temperature =  $20^\circ\text{C}$  or  $293 \text{ K}$ , pressure =  $1 \text{ atm}$  or  $760 \text{ mm}$  of mercury)
6. Density of water ( $\rho_w$ ) of  $1 \text{ g}/\text{cm}^3$ ,
7. Viscosity of water ( $\mu_w$ ) of  $0.0169 \text{ g}/\text{cm}\cdot\text{s}$  corresponding to water temperature

*Gas phase transfer coefficient.* USEPA recommends the following two equations to calculate gas phase transfer coefficient ( $K_G$ ).

**Gas-Phase Transfer Coefficient ( $K_G$ )**

For flowing streams or rivers:

$$K_G = 36500 \text{ m/yr}$$

For quiescent lakes or ponds:

$$K_G = (C_d^{0.5} \cdot W) \cdot \frac{k^{0.33}}{\lambda_z} \cdot \left( \frac{\mu_a}{\rho_a \cdot D_a} \right)^{-0.67} \cdot 3.1536 \times 10^7$$

where

$K_G$  = Gas phase transfer coefficient (m/yr)

$C_d$  = Drag coefficient (unitless)

$W$  = Average annual wind speed (m/s)

$k$  = von Karman's constant (unitless)

$\lambda_z$  = Dimensionless viscous sublayer thickness (unitless)

$\mu_a$  = Viscosity of air corresponding to air temperature (g/cm · s)

$\rho_a$  = Density of air corresponding to water temperature (g/cm<sup>3</sup>)

$D_a$  = Diffusivity of COPC in air (cm<sup>2</sup>/s)

$3.1536 \times 10^7$  = Units conversion factor (s/yr)

USEPA indicated that the rate of transfer of a COPC from the gas phase for a flowing stream or river is assumed to be constant. For a stagnant system (quiescent lake or pond), the transfer coefficients are controlled by wind-induced turbulence. For quiescent lakes or ponds, USEPA recommends that the gas phase transfer coefficient be computed by using the equation presented in O'Connor (1983). USEPA recommends  $1.81 \times 10^{-4}$  g/cm · s for the viscosity of air corresponding to air temperature.

*Benthic burial rate constant.* USEPA recommends the following equation to calculate benthic burial rate ( $k_b$ ).

$$k_b = \left( \frac{X_e \cdot A_L \cdot SD \cdot 1 \times 10^3 - Vf_x \cdot TSS}{A_W \cdot TSS} \right) \cdot \left( \frac{TSS \cdot 1 \times 10^{-6}}{C_{BS} \cdot d_{bs}} \right) \quad (1.35)$$

where

$k_b$  = Benthic burial rate constant (year<sup>-1</sup>)

$X_e$  = Unit soil loss (kg/m<sup>2</sup> · yr)

$A_L$  = Total watershed area (evaluated) receiving deposition (m<sup>2</sup>)

$SD$  = Sediment delivery ratio (watershed) (unitless)

$Vf_x$  = Average volumetric flow rate through water body (m<sup>3</sup>/yr)

$TSS$  = Total suspended solids concentration (mg/L)

$A_W$  = Water body surface area (m<sup>2</sup>)

$C_{BS}$  = Bed sediment concentration (g/cm<sup>3</sup>)

$d_{bs}$  = Depth of upper benthic sediment layer (m)

$1 \times 10^{-6}$  = Units conversion factor (kg/mg)

$1 \times 10^3$  = Units conversion factor (g/kg)

The benthic burial rate constant ( $k_b$ ) can be expressed in terms of the rate of burial ( $Wb$ ):

$$Wb = k_b \cdot d_{bs} \quad (1.36)$$

where

$Wb$  = Rate of burial (m/yr)

$k_b$  = Benthic burial rate constant (year<sup>-1</sup>)

$d_{bs}$  = Depth of upper benthic sediment layer (m)

USEPA recommends the following default value for bed sediment concentration ( $C_{BS}$ ).

$$C_{BS} = 1.0 \text{ kg/L} \quad (1.37)$$

The calculated value for  $k_b$  should range from 0 to 1.0; with low  $k_b$  values expected for water bodies characteristic of no or limited sedimentation (rivers and fast flowing streams), and  $k_b$  values closer to 1.0 expected for water bodies characteristic of higher sedimentation (lakes). For  $k_b$  values calculated as a negative (water bodies with high average annual volumetric flow rates in comparison to watershed area evaluated), a  $k_b$  value of 0 should be assigned for use in calculating the total water body COPC concentration ( $C_{wtot}$ ). If the calculated  $k_b$  value exceeds 1.0, re-evaluation of the parameter values used in calculating  $X_e$  should be conducted.

*Total COPC concentration in water column.* USEPA recommends the following equation to calculate total COPC concentration in water column ( $C_{wctot}$ ).

$$C_{wctot} = f_{wc} \cdot C_{wtot} \cdot \frac{d_{wc} + d_{bs}}{d_{wc}} \quad (1.38)$$

where

- $C_{wctot}$  = Total COPC concentration in water column (mg COPC/L water column)
- $f_{wc}$  = Fraction of total water body COPC concentration in the water column (unitless)
- $C_{wtot}$  = Total water body COPC concentration, including water column and bed sediment (mg COPC/L water body)
- $d_{wc}$  = Depth of water column (m)
- $d_{bs}$  = Depth of upper benthic sediment layer (m)

*Dissolved phase water concentration.* USEPA recommends the following equation to calculate the concentration of COPC dissolved in the water column ( $C_{dw}$ ).

$$C_{dw} = \frac{C_{wctot}}{1 + Kd_{sw} \cdot TSS \cdot 1 \times 10^{-6}} \quad (1.39)$$

where

- $C_{dw}$  = Dissolved phase water concentration (mg COPC/L water)
- $C_{wctot}$  = Total COPC concentration in water column (mg COPC/L water column)
- $Kd_{sw}$  = Suspended sediments/surface water partition coefficient (L water/kg suspended sediment)
- $TSS$  = Total suspended solids concentration (mg/L)
- $1 \times 10^{-6}$  = Units conversion factor (kg/mg)

*COPC Concentration sorbed to bed sediment.* USEPA recommends the following equation to calculate  $C_{sb}$ .

$$C_{sb} = f_{bs} \cdot C_{wtot} \cdot \left( \frac{Kd_{bs}}{\theta_{bs} + Kd_{bs} \cdot C_{BS}} \right) \cdot \left( \frac{d_{wc} + d_{bs}}{d_{bs}} \right) \quad (1.40)$$

where

- $C_{sb}$  = COPC concentration sorbed to bed sediment (mg COPC/kg sediment)
- $f_{bs}$  = Fraction of total water body COPC concentration in benthic sediment (unitless)
- $C_{wtot}$  = Total water body COPC concentration, including water column and bed sediment (mg COPC/L water body)
- $Kd_{bs}$  = Bed sediment/sediment pore water partition coefficient (L COPC/kg water body)
- $\theta_{bs}$  = Bed sediment porosity ( $L_{\text{pore water}}/L_{\text{sediment}}$ )
- $C_{BS}$  = Bed sediment concentration ( $\text{g}/\text{cm}^3$ )
- $d_{wc}$  = Depth of water column (m)
- $d_{bs}$  = Depth of upper benthic sediment layer (m)

*Concentration of COPC in fish.* The COPC concentration in fish ( $C_{fish}$ ) is calculated using either a COPC-specific bio-concentration factor (BCF), a COPC-specific bioaccumulation factor (BAF), or

a COPC-specific biota sediment accumulation factor (*BSAF*). For compounds with a  $\log K_{ow}$  less than 4.0, *BCFs* are used. Compounds with a  $\log K_{ow}$  greater than 4.0 (except for extremely hydrophobic compounds such as dioxins, furans, and PCBs), are assumed to have a high tendency to bioaccumulate, therefore, *BAFs* and *BSAFs* are used to calculate COPC concentrations in fish for dioxins, furans, and PCBs.

*BCF* and *BAF* values are generally based on dissolved water concentrations. Therefore, when *BCF* or *BAF* values are used, the *COPC* concentration in fish is calculated using dissolved water concentrations. *BSAF* values are based on benthic sediment concentrations. Therefore, when *BSAF* values are used, *COPC* concentration in fish is calculated using benthic sediment concentrations. The equations used to calculate fish concentrations are described in the subsequent subsections.

***Fish concentration from bioconcentration factors using dissolved phase water concentration.***

$$C_{fish} = C_{dw} \cdot BCF_{fish} \quad (1.41)$$

where

$$\begin{aligned} C_{fish} &= \text{Concentration of COPC in fish (mg COPC/kg FW tissue)} \\ C_{dw} &= \text{Dissolved-phase water concentration (mg COPC/L)} \\ BCF_{fish} &= \text{Bioconcentration factor for COPC in fish (L/kg)} \end{aligned}$$

***Fish concentration from bioaccumulation factors using dissolved phase water concentration.***

$$C_{fish} = C_{dw} \cdot BAF_{fish} \quad (1.42)$$

where

$$\begin{aligned} C_{fish} &= \text{Concentration of COPC in fish (mg COPC/kg FW tissue)} \\ C_{dw} &= \text{Dissolved phase water concentration (mg COPC/L)} \\ BAF_{fish} &= \text{Bioaccumulation factor for COPC in fish (L/kg FW tissue)} \end{aligned}$$

***Fish concentration from biota-to-sediment accumulation factors using COPC sorbed to bed sediment.***

$$C_{fish} = \frac{C_{sb} \cdot f_{lipid} \cdot BSAF}{OC_{sed}} \quad (1.43)$$

where

$$\begin{aligned} C_{fish} &= \text{Concentration of COPC in fish (mg COPC/kg FW tissue)} \\ C_{sb} &= \text{Concentration of COPC sorbed to bed sediment (mg COPC/kg bed sediment)} \\ f_{lipid} &= \text{Fish lipid content (unitless)} \\ BSAF &= \text{Biota-to-sediment accumulation factor (unitless)} \\ OC_{sed} &= \text{Fraction of organic carbon in bottom sediment (unitless)} \end{aligned}$$

Values for the fraction of organic carbon in bottom sediment ( $OC_{sed}$ ) range from 0.03 to 0.05. These values are based on an assumption of a surface soil OC content of 0.01. USEPA (1993g) recommended a default value of 0.04 for  $OC_{sed}$ , which is the midpoint of the specified range. USEPA also recommends the use of 0.07 as the fish lipid content ( $f_{lipid}$ ).

## 5.9 Use of Site-Specific versus Default Parameter Values

After completing a risk assessment based on the default parameter values recommended in this guidance, risk assessors may choose to investigate the use of site-specific parameter values in order to provide a more representative estimate of site-specific risk. Use of parameter values other than those specified in this guidance should always be clearly described in the risk assessment report and work plan.

## 6 QUANTIFYING EXPOSURE

---

This Section describes the factors to be evaluated in quantifying the exposure received under each of the recommended exposure scenarios. The calculation of COPC-specific exposure rates for each exposure pathway evaluated involves:

1. Estimated COPC media concentrations
2. Consumption rate
3. Receptor body weight
4. Frequency and duration of exposure

This calculation is repeated for each COPC and for each exposure pathway included in an exposure scenario. The following sections describe a general exposure rate calculation and the exposure pathway-specific variables that may affect this calculation. Acute exposure resulting from direct inhalation is also evaluated as a separate issue.

### 6.1 Generic Exposure Rate Equation

Exposure can occur over a period of time. In the calculation of an average exposure per unit of time, the total exposure can be divided by the time period. An average exposure can be expressed in terms of body weight. All exposures quantified in the risk assessment should be:

1. Unitized for time and body weight.
2. Presented in units of milligrams per kilogram of body weight per day.
3. Termed *intakes*.

The generic exposure equation used to calculate chemical intake (USEPA 1989e) is:

$$I = ((C_{gen} \times CR) / BW) \times (EF \times ED / AT) \quad (1.44)$$

where

- $I$  = Intake: the amount of COPC at the exchange boundary (mg/kg · d); for evaluating exposure to noncarcinogenic COPCs, the intake is referred to as average daily dose (*ADD*); for evaluating exposure to carcinogenic compounds, the intake is referred to as lifetime average daily dose (*LADD*)
- $C_{gen}$  = Generic COPC concentration in media of concern (e.g., mg/kg for soil or mg/L for surface water)
- $CR$  = Consumption rate: the amount of contaminated medium consumed per unit of time or event (e.g., kg/d for soil and L/d for water)

$EF$  = Exposure frequency (d/yr)  
 $ED$  = Exposure duration (years)  
 $BW$  = Average body weight of the receptor over the exposure period (kg)  
 $AT$  = Averaging time: the period over which exposure is averaged (days);  
 for carcinogens, the averaging time is 25,550 days, based on a lifetime  
 exposure of 70 years; for noncarcinogens, averaging time equals  $ED$   
 (years) multiplied by 365 d/yr

$(EF \times ED / AT)$  = Temporal adjustment to account for exposure duration and frequency

The exposures calculated in a risk assessment are intended to represent Reasonable Maximum Exposure (RME) conditions as further described in USEPA (1989e). Studies of the compounding of conservatism in probabilistic risk assessments show that setting as few as two factors at RME levels or high end (e.g., near the 90th percentile), while the remaining variables are set at less conservative, typical or “central tendency” values (e.g., near the 50th percentile) resulted in a product of all input variables at an RME level (e.g., 99th percentile value) (Cullen 1994).

USEPA (2005) recommends that the variables set at RME values include (1) the highest air dispersion modeled air parameter values at current and reasonable potential future exposure scenario locations, (2) the exposure frequency, and (3) the exposure duration. Body weight is typically set at average values.

## 6.2 Consumption Rate

*Consumption rate is the amount of contaminated medium consumed per unit of time or event.* Consumption rates for subsistence food types (e.g., beef for the subsistence farmer; fish for the subsistence fisher), is assumed to be 100 percent from the assessment area (e.g., farm, water body) being evaluated. Consumption rates for non-subsistence food types (e.g., home grown garden vegetables) are assumed to be a fraction of the total dietary intake for this food type.

Exposures calculated in a risk assessment are intended to represent RME conditions. Accordingly, the USEPA recommends default values for exposure parameters that will result in estimated RME exposures. However, there are likely to be differences between recommended default, and regional and site-specific exposure parameter values. This may be especially true for the parameter consumption rate (a general term including both intake rate and inhalation rate). The risk assessment performed using recommended default parameter values may be later refined to include supplemental calculations based on regional or site-specific exposure parameter values, provided documentation for these regional or site-specific exposure parameter values is provided. The following subsections describe exposure pathway-specific considerations regarding consumption rate.

***Air exposure pathways.*** Direct inhalation of vapors and particulate emissions from combustion sources is a potential pathway of exposure. Receptors in the assessment area are directly exposed to COPCs in vapor, particulate, and particle-bound phases; as a result of normal respiration. The factors that affect exposure from vapor and particulate inhalation include vapor and particulate COPC concentrations, respiration rate during the period of exposure, and length of exposure.

A single default inhalation rate is provided for use across all adult receptor scenarios. However, if site-specific data is available to show that subsistence farmers and fishers have higher respiration rates due to rigorous physical activities than other receptors, that data may be appropriate. Also, farmers could be assumed to typically spend more time each day in the vicinity of contaminated vapors and particulates, because farms are places of business, and typically their homes. However, any modifications of the respiration rates of receptors should be considered on a site-specific basis, and supported by documentation.

Inhalation of vapors and particulates will be influenced by the relative amount of time that a receptor spends indoors. Although vapors entering buildings and residences as a result of air exchange are likely to remain airborne and, therefore, may be inhaled, particulates entering these same buildings are more likely to settle out and not be inhaled. However, air toxics risk assessments commonly vapor and particulates may both be inhaled throughout the day, both indoors and outdoors.

**Food exposure pathways.** Plants and animals impacted by emission sources may take up emitted COPCs in the air or deposited COPCs in soil. Humans are exposed to COPCs via the food chain when they consume these plants and animals as a food source. Human intake of COPCs is determined on the basis of:

1. The types of foods consumed
2. The amount of food consumed per day
3. The concentration of COPCs in the food
4. The percentage of the diet contaminated by COPCs

Other variables, described below, may also significantly affect the estimation of exposure.

**Types of foods consumed.** The types of foods consumed will affect exposure, because different plants and animal tissues will take up COPCs at different rates. Therefore, COPC concentrations in food are determined, in part, by the type of food, and they vary with the types of food in the diet. Furthermore, the types of foods consumed vary with age, geographical region, and socio-cultural factors.

**Food consumption rate.** The amount of daily food consumption varies with age, sex, body weight, and geographic region, and it also varies within these categories. USEPA recommends in the 2005 HHRAP that food consumption rate information (ingestion rates) be obtained from the 1997 *Exposure Factors Handbook* (USEPA 1997c); specifically, the section regarding home produced food items.

**Percentage of contaminated food.** The percentage of home grown food consumed by the individual will affect exposure because not all of an individual's dietary intake may be contaminated. Receptors, located in a rural or suburban area, which can raise animals and grow food in gardens will have a larger percentage of their food produced locally than people living in the city.

The USEPA HHRAP recommends the following assumptions regarding the percentage of contaminated food:

- With regard to aboveground and belowground produce, it is assumed that 100 percent of the contaminated produce is consumed.
- With regard to beef, milk, pork, chicken, and eggs, it is assumed that 100 percent of these animal tissues consumed by the subsistence farmer and the subsistence farmer child are contaminated. No other receptors are assumed to consume these animal tissues.
- With regard to fish, it is assumed that 100 percent of the fish consumed by the subsistence fisher and subsistence fisher child are contaminated. No other receptors are assumed to consume fish.

**Soil exposure pathways.** Soil ingestion, dermal exposure to soil, and inhalation of resuspended dust are potential soil exposure pathways. For the purpose of RCRA combustion permitting decisions, USEPA recommends that soil ingestion be considered in all risk assessments. However, dermal exposure to soil and inhalation of resuspended dust are currently recommended for evaluation only if site-specific exposure setting characteristics require that these exposure pathways be evaluated. Based on air dispersion modeling and deposition of COPCs, emission concentrations in soil will vary with distance from the source. Potential routes of exposure should be determined by the way in which the soils in the area are used. Soil used for farming or recreation will be involved in pathways of human exposure that differ from those of soil on roadways or in urban areas.

**Soil ingestion.** Children and adults are directly exposed to COPCs in soil when they consume soil that has adhered to their hands. Factors that influence exposure by soil ingestion include soil concentration, the rate of soil ingestion during the time of exposure, and the length of time spent in the vicinity of contaminated soil. Soil ingestion rates in children are based on studies that measure the quantities

of non-absorbable tracer minerals in the feces of young children. Ingestion rates for adults are based on assumptions about exposed surface area and frequency of hand-to-mouth consumption. Indoor dust and outdoor soil may both contribute to the total daily ingestion. Exposure levels are also influenced by the amount of time that the individual spends in the vicinity of soil exposed to deposition of emitted pollutants.

In addition, some young children—referred to as “pica” children—may intentionally eat soil. As discussed in USEPA (1989f), the typical medical and scientific use of the term “pica” refers to the ingestion of non-food items, such as soil, chalk, and crayons. This evaluation should be made on a case-by-case basis based on site-specific exposure setting characterization. Air toxics risk assessments do not typically consider the “pica” child in the assessment process.

***Dermal exposure to soil.*** USEPA does not recommend the use, in the evaluation of recommended exposure scenarios, of the pathway of dermal exposure to COPCs through contact with soil, for air toxic emissions. However, site-specific exposure setting characteristics may require that this exposure pathway be evaluated, therefore, this section discusses dermal soil exposure.

Available data indicate that the contribution of dermal exposure to soils to overall risk is 50-fold less than the risk from any other exposure pathway and 300-fold less than the total estimated risk (USEPA 1996g; 1995h).

***Soil inhalation resulting from dust resuspension.*** USEPA does not recommend the use of soil inhalation exposure pathway of resulting from dust resuspension in the evaluation of air toxic exposure scenarios. However, site-specific exposure setting characteristics may require that this exposure pathway be evaluated; this section discusses exposure to soil resulting from dust re-suspension.

***Water exposure pathways.*** USEPA recommends the use of water exposure pathways resulting from air toxic exposure scenarios. Water exposure pathways can be used to determine COPC concentrations in drinking water obtained from surface water or collected precipitation (e.g., cisterns). Water exposure pathways are also used to determine the COPC concentration in fish. Daily exposures of individuals using these water sources for various purposes—such as fishing and drinking water—can be estimated by using the equations described in this chapter.

Because annual ground-level concentrations of COPCs generally decrease with distance from the source, important factors in determining the water concentration include:

1. The location of the precipitation collection apparatus
2. Surface water body onto which emitted COPCs are deposited
3. The COPC soil concentration (which affects runoff and leachate concentrations)

In addition, the location and size of the watershed will affect the concentration of COPCs suspended in runoff.

***Drinking water exposure from surface water sources.*** For evaluation of a surface water body as a drinking water source, exposure is affected by the concentration of the COPC in the water, the daily amount of water ingested, and the percentage of time that the individual spends in the area serviced by that water supply system. The COPC concentration in a surface water body includes consideration of contribution of COPC loading from the surrounding watershed.

Air toxic risk assessments do not commonly consider the removal of COPCs from drinking water sources by water treatment plants.

***Dermal water exposure.*** Dermal water exposure pathways are not typically considered in air toxics risk assessment. Dermal exposure is affected by (1) the surface area of exposed skin, (2) the COPC concentration in the water, (3) the permeability of the skin to the COPC, and (4) the length of time that the individual is in contact with the water.

***Ingestion of fish.*** Factors that affect human exposure by ingestion of fish from a surface waters affected by sources of air toxics emissions include:

1. Sediment and water COPC concentrations.
2. Types of fish and shellfish consumed.
3. Ingestion rates for the various fish and shellfish groups.
4. Percent of dietary fish caught in the surface water body affected by the combustion unit.

The types of fish consumed will affect exposure, because different types of fish and shellfish take up COPCs at different rates. For example, fatty fish tend to accumulate organic COPCs more readily than lean fish. The amount of fish consumed also affects exposure, because people who eat large amounts of fish will tend to have higher exposures. Fish consumption rates vary greatly, depending on geographic region and social or cultural factors. Because 100 percent of a receptor's dietary fish may not originate from the surface water body near the combustion facility, the percentage of locally caught fish is also a variable for exposure.

### 6.3 Exposure Frequency (EF)

The receptors in each recommended exposure scenario are assumed to be exposed to all of the exposure scenario-specific exposure pathways 350 d/yr (USEPA 1989e; 1991b; 1991d). This assumption is based on the conservative estimate that all receptors spend a minimum of 2 weeks at a location other than the exposure scenario location.

### 6.4 Exposure Duration

Exposure duration (*ED*) is the length of time that a receptor is exposed via a specific exposure pathway. Although a receptor is no longer exposed to COPCs via the direct inhalation exposure pathway after an emission source ceases operation, a receptor is exposed via the indirect exposure pathways for as long as the receptor remains in the assessment area. Therefore, USEPA recommends in the HHRAP using default RME values to estimate exposure duration for specified receptors.

USEPA assumes that receptors could be exposed to the long-term average COPC soil or water concentrations (and the subsequent COPC plant or animal concentrations) after the emission source ceases to operate. For existing facilities, USEPA assumes that this period of time can be represented by default time periods of 30, 60, or 100 years. Thirty (30) years is the most common time period used to evaluate air toxic emission sources. These values are based on the assumptions that the emission source (1) is already in place, (2) will continue to be used for the rest of its useful life (estimated to be 30 years), and (3) may be replaced when it reaches the end of its useful life (estimated to be possibly as long as 60 or 100 years).

Although a combustion unit may remain in the same location for 100 years—and a person may have a lifetime of exposure to emissions from that combustion unit—U.S. Bureau of the Census data (1986) on population mobility indicate that many Americans do not remain in the same area for their 70-year lifetime. An estimate of the number of years that a person is likely to spend in one area, such as the vicinity of a combustion facility, can be derived from information about mobility rate and median time in a residence.

In addition to the number of years at a particular location or residence, the amount of time spent at that location each day directly affects exposure. For example, children that attend day care or adults that work in a different location for part of the day may be exposed to higher or lower COPC levels.

The exposure duration values recommended by USEPA are presented in Table I.6 .

### 6.5 Averaging Time

For non-carcinogenic COPCs, USEPA recommends that a value of exposure duration as years x 365 d/yr be used as the averaging time (*AT*) (USEPA 1989e; 1991d). However, for carcinogenic COPCs—the effects of which may have long latency periods—the age of the receptor (i.e., child, adult, or elderly) influences that COPC exposure pathway, because the exposure duration and, therefore, the quantity of exposure, will vary.

**TABLE 1.6** Exposure Duration Values for the Scenario Receptors

Exposure duration values		
Recommended exposure scenario receptor	Value	Source
Child resident	6 years	USEPA 1990f; 1994r
Adult resident	30 years	USEPA 1990f; 1994r
Subsistence fisher	30 years	USEPA 1990f; 1994r
Subsistence fisher child	6 years	Assumed to be the same as the child resident
Subsistence farmer	40 years	USEPA 1994i; 1994r
Subsistence farmer child	6 years	Assumed to be the same as the child resident

USEPA recommends that carcinogenic exposures for different receptor ages be evaluated separately, because the daily activities of these receptors vary, including:

1. The amounts of food and water consumed.
2. The types of food consumed.
3. The amount of exposed skin surface.

Health-based criteria, such as health advisories for drinking water, are also different for children and adults. As a result, for some exposure pathways, such as soil ingestion, children may have a greater quantifiable exposure and be at greater risk than adults. Some behaviors, such as mouthing of dirty objects or direct ingestion of soil, which could also contribute to exposure, are also much more prevalent in children than adults.

Because quantification of carcinogenic COPC exposure depends on the duration of exposure, the age of the receptor is important. The average human lifespan is generally considered to be 70 years; childhood represents only about 10 percent of the lifespan (6 years) (USEPA 1990e).

## 6.6 Body Weight

USEPA (1990e) defines the body weight of the receptor as either adult weight (70 kg) or child weight (6 years; 15 kg).

## 7 HUMAN HEALTH RISK AND HAZARD CALCULATIONS

Risk characterization must exhibit the core values of transparency, clarity, consistency, and reasonableness. The final step of a risk assessment is the calculation of the upper-bound excess lifetime cancer risks (risk) and noncarcinogenic hazards (hazard) for each of the pathways and receptors. Risks and hazards are then summed for specific receptors, across all applicable exposure pathways, to obtain an estimate of total individual risk and hazard for specific receptors.

Risk from exposure to combustion emissions is the probability that a receptor will develop cancer, based on a unique set of exposure, model, and toxicity assumptions. The slope factor is used in risk assessments to estimate an upper bound lifetime probability of an individual developing cancer as a result of exposure to a particular level of a potential carcinogen. For example, a risk of  $1 \times 10^{-5}$  is interpreted to mean that an individual has no more than, and likely less than, a one in 100,000 chance of developing cancer from the exposure being evaluated.

In contrast, hazard is quantified as the potential for developing non-carcinogenic health effects as a result of exposure to COPCs, averaged over an exposure period. A hazard is not a probability but, rather, a measure (calculated as a ratio) of the magnitude of a receptor's potential exposure relative to a standard exposure level (*RfD* or *RfC*). The standard exposure level is calculated over a similar exposure period and is estimated to pose no appreciable likelihood of adverse health effects to potential receptors, including special populations (USEPA 1989e). Risks and hazards are typically characterized for a single receptor and are referred to as individual risks and hazards (USEPA 1989e; 1994g; NC DEHNR 1997).

### 7.1 Estimation of Individual Risk and Hazard

Individual risk and hazard descriptors are intended to convey information about the potential risks to individuals potentially impacted by air toxic emissions from a source. A well-conducted risk assessment will provide useful impact information, such as:

1. Quantitative and qualitative estimates of risk and hazard associated with exposure to COPCs.
2. Estimates of health effects associated with exposure to lead.
3. Evaluation of infant exposure to 2,3,7,8-TCDD TEQ present in breast milk.
4. Evaluation of acute exposure resulting from direct inhalation.

### 7.2 Quantitative Estimation of Cancer Risk

As described above, for carcinogenic COPCs, risk estimates represent the incremental probability that an individual will develop cancer over a lifetime as a result of a specific exposure to a carcinogenic chemical (USEPA 1989e). These risks are calculated as follows:

$$\text{Cancer Risk} = LADD \times CSF \quad (1.45)$$

where

*LADD* = Lifetime average daily dose (mg/kg-d)

*CSF* = Cancer slope factor (mg/kg-d)

As shown in the above equation as a cancer slope factor, the toxicity of a particular COPC must be available in order to estimate risk. Toxicity values can be obtained from a variety of sources including the following:

1. USEPA's IRIS (USEPA 1996a)
2. California Environmental Protection Agency Toxicity Criteria Database (<http://www.oehha.ca.gov/risk/ChemicalDB/index.asp>)
3. USEPA HEAST (USEPA 1994b)

Within a specific exposure pathway, receptors may be exposed to more than one COPC. The total risk associated with exposure to all COPCs through a single exposure pathway is estimated as follows (USEPA 1989e):

$$\text{Cancer Risk}_T = \sum_i \text{Cancer Risk}_i \quad (1.46)$$

where

$$\begin{aligned} \text{Cancer Risk}_T &= \text{Total cancer risk for a specific exposure pathway} \\ \text{Cancer Risk}_i &= \text{Cancer risk for COPC } i \text{ for a specific exposure pathway} \end{aligned}$$

At particular exposure scenario locations, receptors may be exposed through a number of exposure pathways. Risks from multiple exposure pathways should be summed for a given receptor specific to each recommended exposure scenario. That is, risks should be summed across the receptor-exposure pathway combinations. The total risk posed to a receptor is the sum of total risks from each individual exposure pathway expressed as follows:

$$\text{Total Cancer Risk} = \sum_T \text{Cancer Risk}_T \quad (1.47)$$

where

$$\begin{aligned} \text{Total Cancer Risk} &= \text{Total cancer risk from multiple exposure pathways} \\ \text{Cancer Risk}_T &= \text{Total cancer risk for a specific exposure pathway} \end{aligned}$$

### 7.3 Quantitative Estimation of Potential for Noncancer Effects

Standard risk assessment models assume that non-carcinogenic effects, exhibit a threshold; that is, there is a level of exposure below which no adverse effects will be observed (USEPA 1989e). The potential for noncarcinogenic health effects resulting from exposure to a chemical is generally assessed by:

1. Comparing an exposure estimate to an *RfD* for oral exposures.
2. Comparing an estimated chemical-specific air concentration to the *RfC* for direct inhalation exposures.

An *RfD* is a daily oral intake rate that is estimated to pose no appreciable risk of adverse health effects, even to sensitive populations, over a specific exposure duration. Similarly, an *RfC* is an estimated daily concentration of a chemical in air, the exposure to which over specific exposure duration poses no appreciable risk of adverse health effects, even to sensitive populations (USEPA 1989e).

Chronic *RfDs* and *RfCs* should be used to evaluate all exposure pathways. In the absence of a chronic *RfD*, a sub-chronic *RfD* with an uncertainty factor (3 to 10) can be considered. The comparisons of exposure estimates and COPC-specific air concentrations to *RfD* and *RfC* values, described above, are known as hazard quotients (*HQ*), which are calculated as follows:

$$HQ = ADD / RfD \text{ or } HQ = Ec / RfC \quad (1.48)$$

where

$$\begin{aligned} HQ &= \text{Hazard quotient (unitless)} \\ ADD &= \text{Average daily dose (mg/kg}\cdot\text{d)} \\ EC &= \text{Total COPC air concentration (mg/m}^3\text{)} \\ RfD &= \text{Reference dose (mg/kg}\cdot\text{d)} \\ RfC &= \text{Reference concentration (mg/m}^3\text{)} \end{aligned}$$

In the assessment of noncarcinogenic risk from COPCs, USEPA-derived or reviewed health benchmarks (*RfDs*, *RfCs*) are recommended. However, for numerous COPCs, a complete set of inhalation and oral EPA-derived health benchmarks are not available. It is possible to perform a route-to-route extrapolation when, for example, an oral *RfD* is available but a corresponding *RfC* is not. However, this practice introduces a high level of uncertainty into the risk assessment process and is not recommended in the 2005 HHRAP guidance. However, it may appropriate for some COPCs

of particular interest such as COPCs with relatively greater emission rates than other COPCs. For instance, if the *oral RfD* (mg/kg · d) was available and the *RfC* (mg/m<sup>3</sup>) was not; the *RfC* was calculated by multiplying the *RfD* by an average human inhalation rate of 20 m<sup>3</sup>/d and dividing by the average human body weight of 70 kg.

Because of the degree of uncertainty involved in using toxicity benchmark values calculated, based on route-to-route extrapolation, a qualitative assessment of the toxicity information available for the compound and exposure route should be performed. This will enable the risk assessor to make a well informed decision concerning the validity of values calculated based on route-to-route extrapolation. This qualitative assessment should also be included in the uncertainty section of the risk assessment.

*HQ* values exceeding one significantly increase the level of concern. Because *RfDs* and *RfCs* do not have equal accuracy or precision, and are not based on the same severity of effect, the level of concern does not increase linearly as an *HQ* approaches and exceeds 1 (USEPA 1989e). It should also be noted that background exposures may be an important consideration in setting safe levels. This is because non-cancer effects are generally modeled as thresholds. In specific cases, a permitting authority may elect to adjust the *HQ* downward to account for any exposure that individuals may have from other sources.

As with carcinogenic chemicals in a specific exposure pathway, a receptor may be exposed to multiple chemicals associated with noncarcinogenic health effects. The total noncarcinogenic hazard attributable to exposure to all COPCs through a single exposure pathway is known as a hazard index (*HI*). Consistent with the procedure for addressing carcinogenic risks, the noncarcinogenic hazards from all sources of air toxics emissions should be summed for each receptor. Also, noncarcinogenic hazard from fugitive emissions sources should also be included in the calculation of the *HI* for each receptor. The *HI* is calculated as follows:

$$HI = \sum HQ_i \quad (1.49)$$

where

$$\begin{aligned} HI &= \text{Total hazard for a specific exposure pathway} \\ HQ_i &= \text{Hazard quotient for COPC } i \end{aligned}$$

This summation methodology assumes that the health effects, of the various COPCs to which a receptor is exposed, are additive. Specifically, this methodology is a simplification of the *HI* concept because it does not directly consider the portal of entry associated with each exposure pathway or the often unique toxic endpoints and toxicity mechanisms of the various COPCs.

A receptor may be exposed to COPCs associated with non-carcinogenic health effects through more than one exposure pathway. For the purposes of the risk assessment, it is reasonable to estimate a receptor's total hazard as the sum of the *HI*s for each of the exposure pathways. Specifically, a receptor's total hazard is the sum of hazards from each individual exposure pathway, expressed as follows:

$$\text{Cumulative } HI = \sum HI \quad (1.50)$$

where

$$\begin{aligned} \text{Cumulative } HI &= \text{Total hazard index from multiple exposure pathways} \\ HI &= \text{Total hazard index for a specific exposure pathway} \end{aligned}$$

All total *HI*s exceeding the target hazard level are further evaluated. The total *HI* for an exposure pathway can exceed the target hazard level as a result of the presence of either (1) one or more COPCs with an *HQ* exceeding the target hazard level, or (2) the summation of several COPC-specific *HQ*s that are each less than the target hazard level. In the former case, the presence of at least one COPC-specific hazard greater than the target hazard level is interpreted as indicating the potential for non-carcinogenic health effects. In the latter case, a detailed analysis is required to determine whether the potential for non-carcinogenic health effects is accurately estimated by the total *HI*, because the toxicological effects associated with exposure to multiple chemicals, often through different exposure pathways, may not be additive; therefore, the total *HI* may overestimate the potential

for non-carcinogenic health effects. To address this issue, COPC-specific hazards are summed according to major health effects and target organs or systems (USEPA 1989e). It is especially important to consider any differences related to exposure route; this process is referred to as the segregation of the *HI*.

The highest segregated *HI* resulting from this process is considered. If the segregated *HI* exceeds the target hazard level, there is a potential for non-carcinogenic health effects. However, if the segregated *HI* is less than the target hazard level, the total *HI* of all COPC-specific results likely is too conservative, and noncarcinogenic health effects are not likely to result from exposure to COPCs.

## 7.4 Target Levels

Target levels are risk management based and set by the regulatory authority. Target values are not a discrete indicator of observed adverse effect. If a calculated risk falls within target values, a regulatory authority may, without further investigation, conclude that a proposed action does not present an unacceptable risk. A calculated risk that exceeds these targets, however, would not, in and of itself, indicate that the proposed action is not safe or that it presents an unacceptable risk. Rather, a risk calculation that exceeds a target value triggers further careful consideration of the underlying scientific basis for the calculation.

## 7.5 Acute Exposure Resulting from Direct Inhalation

In addition to long-term chronic effects, short-term or acute effects should be considered from direct inhalation of vapor phase and particle phase COPCs. It is assumed that short-term emissions will not have a significant impact through the indirect exposure pathways (as compared to impacts from long-term emissions). Therefore, acute effects are only evaluated through the short-term (maximum 1 h) inhalation of vapors and particulates exposure pathway of the acute risk scenario.

In addition to the acute effects associated with short term releases of air toxics from stack or fugitive emission sources, other effects may include accidents, fires, or explosions. In these cases, the air dispersion modeling described previously in this chapter will need to be supplemented by other models that are specifically designed to consider these types of scenarios. For example, the rupture of a chlorine tank will result in the release of a dense gas that cannot be modeled with ISCST3, but should be modeled with an appropriate dense gas ADM.

Acute risk assessments uses a hierarchical approach to define the toxicity benchmarks which short term maximum air concentrations are compared. The toxicity benchmarks are called acute inhalation exposure criteria (AIEC). Hierarchical approaches are composed of existing guidelines for acute inhalation exposure, ranked in order of applicability and technical basis, and all being protective of the general public. It should be noted that hierarchical approaches are needed because no single organization or methodology has developed acute criteria values or benchmarks for all COPCs.

**USEPA recommended hierarchal approach.** The approach recommended in the 2005 HHRAP is based on existing acute inhalation values that do not require the use of arbitrary safety factors and are intended to protect the general public from discomfort or mild adverse health effects over 1-hour exposure periods. It includes level 1 acute inhalation exposure guidelines (AEGL-1), level 1 emergency response planning guidelines (ERPG-1), and level 1 acute toxicity exposure levels (ATEL-1); supplemented with DoE TEELs and the SCAPA toxicity-based approach. The hierarchal approach is summarized below:

1. CAL/EPA Acute RELs ([http://www.oehha.ca.gov/air/acute\\_rels/index.html](http://www.oehha.ca.gov/air/acute_rels/index.html))
2. AEGL-1 (<http://www.epa.gov/oppt/aegl/pubs/chemlist.htm>)
3. ERPG-1 (<http://www.bnl.gov/scapa/scapawl.htm>)
4. TEEL-1 ([http://tishq.eh.doe.gov/web/Chem\\_Safety/teel.htm](http://tishq.eh.doe.gov/web/Chem_Safety/teel.htm))
5. AEGL-2 (<http://www.epa.gov/oppt/aegl/pubs/chemlist.htm>)
6. SCAPA Toxicity-based approach (DoE 1997a)

The hierarchy is presented in order of preference from 1 (most preferred) to 5 (least preferred). This preference is based on (1) applicability to a 1-hour exposure duration for protection of the general public (versus only occupational exposure), and (2) level of documentation and associated review.

To characterize the potential for adverse health effects from acute exposure to COPC-specific emissions, the acute air concentration ( $C_{acute}$ ) resulting from maximum emissions over a 1-hour period should be compared to the COPC-specific AIEC to calculate the acute hazard quotient ( $AHQ_{inh}$ ). The  $AHQ_{inh}$  can be calculated as follows:

$$AHQ_{inh} = C_{acute} \times 10^{-3} / AIEC \quad (1.51)$$

where

$AHQ_{inh}$  = Acute hazard quotient (unitless)  
 $C_{acute}$  = Acute air concentration ( $\mu\text{g}/\text{m}^3$ )  
 $AIEC$  = Acute inhalation exposure criteria ( $\text{mg}/\text{m}^3$ )  
 0.001 = Conversion factor ( $\text{mg}/\mu\text{g}$ )

Acute hazard quotients should be calculated at the selected acute exposure scenario locations for COPCs specific to emissions from each source and from all facility sources combined. Target levels for acute hazard quotient evaluation is a risk management decision and will be set by the permitting authority.

## 8 AIR TOXICS CHEMICAL AND PHYSICAL PROPERTIES

---

This section describes the fate and transport parameters required for the calculations of the chemical movements from media to media. It also presents some of the estimation techniques to obtain the parameters used in the HHRAP.

### 8.1 Fundamental Physical Properties

The following physical properties are used in most physical chemical calculations and are measured instead of estimated.

**Molecular weight.** Molecular weight ( $MW$ ) of a compound is defined as the sum of atomic weights of all atoms in the compound's molecule.

**Melting point temperature.** Melting point temperature ( $T_m$ ) is the temperature of the compound [in Kelvin (K)] at which the solid state of the compound undergoes a phase change to a liquid phase. At ambient temperatures and at an atmospheric pressure of 1 atm, compounds are either in a solid or liquid state. The compound liquid or solid state is provided in the summary tables of compound-specific parameter values.

**Vapor pressure.** The vapor pressure ( $Vp$ ) of a substance is defined as the pressure in atmospheres exerted by the vapor (gas) of a compound when it is under equilibrium conditions. It provides a semi-quantitative rate at which it will volatilize from soil and/or water.

**Aqueous solubility.** The aqueous solubility ( $S$ ) of a compound is defined as the saturated concentration of the compound in water (mg COPC/L water) at a given temperature and pressure, usually at soil/water temperatures and atmospheric pressure.

## 8.2 Henry's Law Constant

Henry's law constant ( $H$ ) is also referred to as the air-water partition coefficient, and is defined as the ratio of the partial pressure of a compound in air to the concentration of the compound in water at a given temperature under equilibrium conditions. For organics (excluding PCDDs and PCDFs),  $H$  values were calculated from the following theoretical equation (Lyman, Reehl, and Rosenblast 1982) for consistency, using recommended  $MW$ ,  $S$ , and  $V_p$  values provided in the USEPA HHRAP:

$$H = \frac{V_p \cdot MW}{S} \quad (1.52)$$

where

$$\begin{aligned} H &= \text{Henry's law constant (atm} \cdot \text{m}^3/\text{mol)} \\ V_p &= \text{Vapor pressure of COPC (atm)} \\ S &= \text{Solubility of COPC in water (mg COPC/L water)} \end{aligned}$$

## 8.3 Diffusivity of COPCs in Air and Water

Diffusivity or diffusion coefficients in air ( $D_a$ ) and water ( $D_w$ ) are used to calculate the liquid- or gas-phase transfer of a COPC into a waterbody. For organics (except PCDDs and PCDFs), diffusivity values were obtained directly from the CHEMDAT9 model chemical properties database (Worksheet DATATWO.WK1) (USEPA, 1994d).

For compounds not in the USEPA (1994d) database, diffusivity values were obtained by using the WATER8 (USEPA, 1995d) model correlation equations for air and water diffusivities:

For diffusivity values that were not available in these databases,  $D_w$  and  $D_a$  values were calculated using the following equations cited and recommended for use in USEPA (1997g):

$$\begin{aligned} D_{a,i} &= \frac{1.9}{(MW_i)^{2/3}} \\ D_{w,i} &= \frac{22 \cdot 10^{\times 5}}{(MW_i)^{2/3}} \end{aligned} \quad (1.53)$$

For PCDDs and PCDFs, diffusivity values in air and water for (1) 2,3,7,8-TCDD were obtained from USEPA (1994e), and (2) 2,3,7,8-TCDF were obtained from USEPA (1995d). For all other congeners of PCDDs and PCDFs:

1. A default  $D_w$  value of  $8 \times 10^{-6}$  cm<sup>2</sup>/s was used
2.  $D_a$  values were calculated using the following equation recommended by USEPA (1994a):

$$\frac{D_x}{D_y} = \left( \frac{MW_y}{MW_x} \right)^{0.5} \quad (1.54)$$

where

$$\begin{aligned} D_{x,y} &= \text{Diffusivities in air of compounds } x \text{ and } y \text{ (cm}^2/\text{s)} \\ MW_{x,y} &= \text{Molecular weights of compounds } x \text{ and } y \text{ (g/mol)} \end{aligned}$$

$D_a$  values for PCDD congeners were calculated by using the  $D_a$  value and  $MW$  for 2,3,7,8-TCDD.  $D_a$  values for PCDF congeners were calculated using the  $D_a$  value and  $MW$  for 2,3,7,8-TCDF. This approach is consistent with the methodology specified in USEPA (1994a).

## 8.4 Octanol/Water Partitioning Coefficient

The *n*-octanol/water partitioning coefficient ( $K_{ow}$ ) is defined as the ratio of the solute concentration in the water-saturated *n*-octanol phase to the solute concentration in the *n*-octanol-saturated water phase.

## 8.5 Soil Organic Carbon-Water Partition Coefficient

The soil organic carbon-water partition coefficient ( $K_{oc}$ ) or the organic carbon normalized soil sorption coefficient is defined as the ratio of adsorbed compound per unit weight of organic carbon to the aqueous solute concentration. Because of the soil mechanisms that are inherently involved,  $K_{oc}$  values for the ionizing organics and nonionizing organics are discussed separately.

The partitioning of ionizing organic compounds can be significantly influenced by soil pH. Because of the soil mechanisms that are inherently involved, we discuss  $K_{oc}$  values for the ionizing organics and non-ionizing organics separately.

**The soil organic carbon-water partition coefficient for ionizing organic compounds.** Ionizing organic compounds include amines, carboxylic acids, and phenols. These compounds contain the functional groups that ionize under specific pH conditions, and include the following:

- Organic acids: (2,4,6-trichlorophenol; pentachlorophenol; 2,3,4,5-tetrachlorophenol; 2,3,4,6-tetrachlorophenol; 2,4,5-trichlorophenol; 2,4-dichlorophenol; 2-chlorophenol; phenol; 2,4-dimethylphenol; 2-methylphenol; 2,4-dinitrophenol; and benzoic acid)
- Organic bases: (*n*-nitroso-di-*n*-propylamine; *n*-nitrosodiphenylamine, and 4-chloroaniline)

$K_{oc}$  values were estimated on the basis of the assumption that the sorption of ionizing organic compounds is similar to hydrophobic organic sorption, because the soil organic carbon is the dominant sorbent. According to USEPA (1994c), for low pH conditions, these estimated values may overpredict sorption coefficients, because they ignore sorption to components other than organic carbon.

**The soil organic carbon-water partition coefficient for nonionizing organic compounds.** Nonionizing organic compounds are all other organic compounds not listed earlier as ionizing. They include volatile organics, chlorinated pesticides, polynuclear aromatic hydrocarbons (PAHs), and phthalates.

The correlation between  $K_{oc}$  and  $K_{ow}$  can be improved considerably by performing separate linear regressions on two chemical groups. USEPA (1994c) derives the following correlation equations from measured  $K_{oc}$  values cited in USEPA (1994c) and USEPA (1996b):  
For most semivolatile nonionizing organic compounds.

$$\log K_{oc} = 2.8 \times 10^{-4} + (0.983 \times \log K_{ow}) \quad (r^2 = 0.99) \quad (1.55a)$$

For volatile nonionizing organics, chlorinated benzenes, and certain chlorinated pesticides

$$\log K_{oc} = 0.0784 + (0.7919 \times \log K_{ow}) \quad (r^2 = 0.97) \quad (1.55b)$$

For PCDDs and PCDFs, the following correlation equation is used to calculate  $K_{oc}$  values, as cited by USEPA (1994a)

$$\log K_{oc} = \log K_{ow} - 0.21 \quad (r^2 = 1.0) \quad (1.55c)$$

## 8.6 Partitioning Coefficients

Partition coefficients ( $K_d$ ) describe the partitioning of a compound between sorbing material, such as soil, soil pore water, surface water, suspended solids, and bed sediments. For organic compounds,  $K_d$  has been estimated to be a function of the organic-carbon partition coefficient and the fraction of organic carbon in the partitioning media. For metals,  $K_d$  is assumed to be independent of the organic carbon in the partitioning media and, therefore, partitioning is similar in all sorbing media.

**Partitioning coefficients for soil-Water.** The soil-water partition coefficient ( $K_{ds}$ ) describes the partitioning of a compound between soil pore-water and soil particles, and strongly influences the release and movement of a compound into the subsurface soils and underlying aquifer.

**Partitioning coefficients for suspended sediment-surface water.** The suspended sediment-surface water partition coefficient ( $K_{d_{sw}}$ ) describes the partitioning of a compound between surface water and suspended solids or sediments.

**Partitioning coefficients for bottom sediment-sediment pore water.** The bed sediment-sediment pore-water partition coefficient ( $K_{d_{bs}}$ ) describes the partitioning of a compound between the bed sediments and bed sediment pore-water.

For organics (including PCDDs and PCDFs), soil organic carbon is assumed to be the dominant sorbing component in soils and sediments. Therefore,  $Kd$  values were calculated using the following fraction organic carbon ( $f_{oc}$ ) correlation equations:

$$\begin{aligned} Kd_{sw} &= f_{oc,sw} \cdot K_{oc} \\ Kd_s &= f_{oc,s} \cdot K_{oc} \\ Kd_{bs} &= f_{oc,bs} \cdot K_{oc} \end{aligned} \quad (1.56)$$

The fraction organic carbon ( $f_{oc}$ ), from literature searches USEPA (1993d), could range as follows:

- 0.002 to 0.024 in soils for which a midrange value of  $f_{oc,s} = 0.01$  generally can be used.
- 0.05 to 0.1 in suspended sediments for which a midrange value of  $f_{oc,sw} = 0.075$  generally can be used.
- 0.03 to 0.05 in bottom sediments for which a midrange value of  $f_{oc,bs} = 0.04$  generally can be used.

For metals (except mercury),  $Kd$  is governed by factors other than organic carbon, such as pH, redox, iron content, cation exchange capacity, and ion chemistry. Values must be obtained directly from literature. USEPA (1996b) provides values for  $Kd$  that are based on pH, and are estimated by using the MINTEQ2 model, which is a geochemical speciation model. The MINTEQ2 model analyses were conducted under a variety of geochemical conditions and metal concentrations.

## 8.7 Soil Loss Constant Due to Degradation

Soil loss constant due to degradation ( $k_{sg}$ ) reflects loss of a compound from the soil by processes other than leaching. Degradation rates in the soil media include biotic and abiotic mechanisms of transformation. Abiotic degradation includes photolysis, hydrolysis, and redox reactions. Hydrolysis and redox reactions can be significant abiotic mechanisms in soil (USEPA 1990).

Degradation rates can be assumed to follow first order kinetics. Therefore, the half-life ( $t_{1/2}$ ) of compounds can be related to the  $k_{sg}$  as follows:

Ideally,  $k_{sg}$  is the sum of all biotic and abiotic rate constants in the soil. Therefore, if the  $t_{1/2}$  for all of the mechanisms of transformation are known, the degradation rate can be calculated using

$$k_{sg} = \frac{0.693}{t_{1/2}} \quad (1.57)$$

**Fraction of pollutant air concentration in the vapor phase.** For organics, the fraction of pollutant air concentration in the vapor phase ( $F_v$ ) was calculated using the following equation:

$$F_v = 1 - \frac{cS_T}{p_L^E + cS_T} \quad (1.58)$$

If the compound is a liquid at ambient temperatures (that is, when  $p_L^E$  is known), the above equation calculates  $F_v$  using the vapor pressure value recommended for that compound. If the compound

is a solid at ambient temperatures (that is, when  $P_S^E$  is known), the following equation (Bidleman 1988) was used to calculate  $P_L^E$  from  $P_S^E$  for use in the above equation:

$$\ln \left( \frac{P_L^E}{P_S^E} \right) = \frac{\Delta S_f (T_m - T)}{R T} \quad (1.59)$$

where

- $c$  = Junge constant =  $1.7 \times 10^{-04}$  (atm · cm)
- $P_L^E$  = Liquid phase vapor pressure of compound (atm)
- $P_S^E$  = Solid phase vapor pressure of compound (atm)
- $R$  = Universal ideal gas constant (atm · m<sup>3</sup>/mol · K)
- $\Delta S_f$  = Entropy of fusion [ $\Delta S_f/R = 6.79$  (unitless)]
- $S_f$  = Whitby's average surface area of particulates (aerosols)
- $T_a$  = Ambient air temperature (K)—assumed to be 25°C or 298 K

This equation assumes that the Junge constant ( $c$ ) is constant for all compounds. However,  $c$  can depend on (1) the compound (sorbate) molecular weight, (2) the surface concentration for monolayer coverage, and (3) the difference between the heat of desorption from the particle surface and the heat of vaporization of the liquid-phase sorbate.

All metals (except mercury) are assumed to be present in the particulate phase and not in the vapor phase ( $Vp = 0$ ), and assigned  $F_v$  values of zero. Mercury and mercuric chloride are relatively volatile and exist in the vapor phase (USEPA 1997g).  $F_v$  values of 1.0 for mercury and 0.85 for mercuric chloride were estimated. Methyl mercury is assumed not to exist in the air phase and, therefore, assigned an  $F_v$  of zero.

## 8.8 Bioconcentration and Biotransfer Factors for Plants

**Root concentration factor.** The root concentration factor ( $R_{CF}$ ) is used to calculate the below-ground transfer of contaminants from soil to a root vegetable. The RCF was developed based on experiments conducted by Briggs et al. (1982) which measured uptake of compounds into barley roots from growth solution.

For compounds with  $\log K_{ow}$  values of 2.0 and higher, we used the following correlation equation to obtain RCF values:

$$\log (RCF) = 0.77 \log K_{ow} - 1.52 \quad (n = 7, r = 0.981) \quad (1.60)$$

For compounds with  $\log K_{ow}$  values less than 2.0, we used the following correlation equation to obtain RCF values:

$$\log (RCF - 82) = 0.77 \log K_{ow} - 1.52 \quad (1.61)$$

This equation estimates a  $RCF$  value in fresh weight (FW) units, which was then converted to dry weight (DW) units using a moisture content of 87 percent in root vegetables.  $K_{ow}$  values recommended in this HHRAP were used to calculate each  $RCF$  value.

For metals, including mercury, no referenced  $RCF$  values were available in published literature. However, plant-soil biotransfer factors for root vegetables ( $Br_{rootveg}$ ) were available in the literature and, therefore,  $RCF$  values, which were used to calculate  $Br_{rootveg}$  values, are not required for the metals.

**Plant-soil bioconcentration factors in root vegetables.** The plant-soil bioconcentration factor for compounds in root vegetables ( $Br_{rootveg}$ ) accounts for uptake from soil to the belowground root vegetables or produce.

For organics, the following equation, obtained from USEPA (1995b), was used to calculate values for  $Br_{rootveg}$  on a dry weight basis:

$$Br_{rootveg} = \frac{RCF}{Kd_s} \quad (1.62)$$

$Br_{rootveg}$  values were calculated by dividing the  $RCF$  value with the  $Kd_s$  values provided in the main USEPA literature used in this Chapter (USEPA HHRAP).  $Br_{rootveg}$  values for metals can also be obtained from the USEPA HHRAP.

**Plant-soil Bioconcentration factors for aboveground produce and forage.** The plant-soil bioconcentration factor ( $Br$ ) for aboveground produce accounts for the uptake from soil and the subsequent transport of COPCs through the roots to the aboveground plant parts. As addressed in USEPA (1995b), the  $Br$  value for organics is a function of water solubility, which is inversely proportional to  $K_{ow}$ . The  $Br$  value for metals is a function of the bioavailability of the compounds in soil. Plant-soil bioconcentration factors for aboveground produce ( $Br_{ag}$ ) and forage ( $Br_{forage}$ ).

For all organics including PCDDs and PCDFs, (1) the subscript  $ag$  represents aboveground produce which applies to exposed fruits and vegetables, and protected fruits and vegetables, and (2) the subscript  $forage$  represents forage, but the values also apply to silage and grain. For metals, (1) aboveground fruits (both exposed and protected) are represented by  $Br_{ag(fruit)}$ ; (2) aboveground vegetables (both exposed and protected) are represented by  $Br_{ag(veg)}$ , (3) forage is represented by  $Br_{forage}$ , but the values also apply to silage, and (4) grains are represented by  $Br_{grain}$ .

For organics, the following correlation equations were used to calculate values for  $Br_{ag}$  and  $Br_{forage}$  on a dry weight basis:

$$\begin{aligned}\log Br_{ag} &= 1.588 - 0.578 (\log K_{ow})(n = 29, r = 0.73) \\ \log Br_{forage} &= 1.588 - 0.578 (\log K_{ow})(n = 29, r = 0.73)\end{aligned}\quad (1.63)$$

**Air-to-plant biotransfer factors for aboveground produce and forage.** The air-to-plant biotransfer factor is defined as the ratio of COPC concentration in aboveground plant parts to the COPC concentration in air.  $Bv$  values for all organics and metals, were calculated only for aboveground exposed produce (both fruits and vegetables). Aboveground protected produce (both fruits and vegetables) and belowground produce are protected from air-to-plant transfer. According to USEPA (1995b), root vegetables are assumed to be also protected from air-to-plant transfer.

For organics (excluding PCDDs and PCDFs), the  $Bv_{ag}$  and  $Bv_{forage}$  can be calculated using the following correlation equations:

$$\log B_{vol} = 1.065 \log K_{ow} - \log\left(\frac{H}{RT}\right) - 1.654(r = 0.957) \quad (1.64)$$

$$Bv = \frac{\rho_{air} \cdot B_{vol}}{(1 - f_{water}) \cdot \rho_{forage}}$$

where

$$\begin{aligned}B_{vol} &= \text{Volumetric air-to-plant biotransfer factor (fresh-weight basis)} \\ Bv &= \text{Mass based air-to-plant biotransfer factor (dry-weight basis)} \\ \rho_{air} &= 1.19 \text{ g/L (Weast 1981)} \\ \rho_{forage} &= 770 \text{ g/L (Macrady and Maggard 1993)} \\ f_{water} &= 0.85 \text{ (fraction of forage that is water(Macrady and Maggard (1993))}\end{aligned}$$

## 8.9 Biotransfer Factors for Animals

The biotransfer factor for animals ( $Ba$ ) is the ratio of COPC concentration in fresh weight animal tissue to the daily intake of COPC by the animal.

**Biotransfer factors for beef and milk.** The main route of human exposure to many highly lipophilic compounds is through ingestion of contaminated agricultural products such as beef and milk. The transfer of contaminants from environmental media (e.g., air, soil, water) and food (e.g.,

grain, silage) into livestock products (e.g., beef, milk) has historically been either determined by direct measurement of contaminants in livestock products, or predicted using regression models. (Biotransfer factors for beef ( $Ba_{beef}$ ) and milk ( $Ba_{milk}$ )).

*Organic compounds.* When empirical data are lacking for biotransfer of organic chemicals, one of the most widely used approaches to predict contaminant transfer from environmental media and food to beef tissue and milk are the regression models developed by Travis and Arms (1988), which relate chemical octanol-water partition coefficient ( $K_{ow}$ ) to biotransfer into beef and milk. These regressions, however, are hampered by the limited  $\log K_{ow}$  range and questions surrounding the validity of the underlying biotransfer data set. In response, EPA developed a new methodology for predicting beef and milk biotransfer factors.

Using EPA's updated methodology, we predicted biotransfer factors for organic chemicals with the following single equation:

$$\log Ba_{fat} = -0.099 (\log K_{ow})^2 + 1.07 \log K_{ow} - 3.56 \quad (n = 305, r^2 = 0.8259) \quad (1.65)$$

where

$$Ba_{fat} = \text{Biotranfer factor [mg / kg fat] / [mg/d]}$$

$$K_{ow} = \text{Octanol-water portioning coefficient [unitless]}$$

Values for  $Ba_{fat}$  were adjusted to account for the assumed fat content of milk and beef as shown below:

$$Ba_{milk} = 10^{\log Ba_{fat}} \times 0.04$$

$$Ba_{beef} = 10^{\log Ba_{fat}} \times 0.19 \quad (1.66)$$

The  $\log K_{ow}$ 's of the chemicals are used to derive the equation ranged from  $-0.67$  to  $8.2$ . Therefore, compounds with  $\log K_{ow}$  values less than  $-0.67$  were assigned  $Ba_{beef}$  and  $Ba_{milk}$  values corresponding to a  $\log K_{ow}$  value of  $-0.67$ . At the high end of the range, compounds with  $\log K_{ow}$  values greater than  $8.2$  were assigned  $Ba_{beef}$  and  $Ba_{milk}$  values corresponding to a  $\log K_{ow}$  value of  $8.2$ .

*Highly metabolized organic compounds.* The  $Ba_{fat}$  might overestimate biotransfer of highly metabolized chemicals, producing an upper bound estimate for these chemicals. Phthalates and PAHs fall within this group.

One way to account for this potential overestimation is to rely upon a metabolism factor to improve model predictions. For example, EPA developed a metabolism factor of 0.01 (i.e., 99 percent of the chemical ingested is metabolized) for bis-ethylhexyl phthalate (BEHP). When this factor is applied to the biotransfer factors predicted using the regression equation recommended above for BEHP, the biotransfer factors are reduced by two orders of magnitude. These metabolism-adjusted predicted biotransfer factors are close in magnitude to the empirically derived biotransfer factors found in the literature, which supports using this metabolism factor. Unfortunately, EPA has not developed metabolism factors for other organic chemicals, due to limited availability of empirically derived data.

For those highly metabolized chemicals that don't have metabolism factors, we still consider it reasonable to use estimated  $Ba$  values for the following reasons:

- Few chemicals have had all their degradation products identified.
- If identified, the degradation products may in fact be as toxic as, or even more toxic than, the parent compound (the degradation products of PAHs, for example, are toxic). Unless data demonstrates that all degradation products are nontoxic (as is the case for BEHP), the only way to address toxic degradation products in the HHRAP is to include their mass in the mass of the parent chemical.
- The metabolic degradation products may themselves be persistent. For example, DDT is metabolized to DDD and DDE, which remain persistent.

It should also be noted that not all chemicals are metabolized at the same rate and may remain in animal tissue as the parent compound through establishment of steady state concentrations. In fact, many of the chemicals in the biotransfer data set, that are actually well predicted, are metabolized to

other compounds. DDT is metabolized to DDE, and lindane (used to derive the regression, but not in the HHRAP) is metabolized to many different compounds. For DDT and lindane, biotransfer factors are well predicted using  $Ba_{fat}$  equation.

Lacking sufficient data to identify all degradation products, characterize all degradation products as nontoxic, and ensure that all potentially toxic degradation products are less persistent than the parent chemical, we consider it reasonably protective to use the  $Ba_{beef}$  and  $Ba_{milk}$  values for the parent chemical as predicted, without adjustment. If a highly metabolized chemical is found to drive the risk assessment, then we recommend re-evaluating the appropriateness of the  $Ba_{beef}$  and  $Ba_{milk}$  values.

**Ionizing organic compounds.** To improve bio-transfer factors (BTF) estimates for organic acids, the USEPA uses the first-order dissociation constant ( $pKa$ ) to account for chemical ionization. For these chemicals,  $K_{ow}$  is a weighted value calculated based on the fraction of the chemical in the neutral form such that:

$$K_{ow} = K_{ow}n \times (FracNeutral) + K_{ow}i \times (1 - FracNeutral) \quad (1.67)$$

where

$$\begin{aligned} K_{ow}n &= \text{Partition coefficient for the neutral species (unitless)} \\ K_{ow}i &= \text{Partition coefficient for the ionized species (mol/L)} \\ FracNeutral &= \text{Fraction of neutral species present for organic acids (unitless).} \end{aligned}$$

Accounting for the fraction of ionizable organics in the neutral form is important because  $K_{ow}$  can vary considerably depending on pH. The cow's small intestine, where chemicals can be absorbed, has a near neutral pH. Therefore, the neutral fraction is determined using a pH equal to 7 in the following equation (Lee et al., 1990):

$$FracNeutral = 1 + 10^{pH - pKa} \quad (1.68)$$

where,

$$pKa = \text{Acid dissociation constant (unitless).}$$

If a value for  $\log K_{ow}i$  is not available, the USEPA estimates  $\log K_{ow}i$  assuming a ratio of  $\log K_{ow}i$  to  $\log K_{ow}n$  of 0.015. This ratio is a conservative value developed by the USEPA to apply to organic acids without data for  $\log K_{ow}i$  (U.S. EPA, 1996).

$Ba_{beef}$  and  $Ba_{milk}$  values are for metals (except cadmium, mercury, selenium, and zinc) are calculated on a fresh weight basis, from Baes et al. (1984). For cadmium, selenium, and zinc, USEPA (1995a) cited Ba values derived by dividing uptake slopes [(g COPC/kg DW tissue)/(g COPC/kg DW feed)], obtained from USEPA (1992b), by a daily consumption rate of 20 kg DW per day for beef and dairy cattle.

The HHRAP assumes that elemental mercury neither deposits onto soils nor transfers to above-ground plant parts. Therefore, there is no transfer of elemental mercury into animal tissue. Therefore, USEPA recommends Ba values of zero for elemental mercury. This based on assumptions made regarding speciation and fate and transport of mercury from emission sources. USEPA derived the  $Ba_{beef}$  and  $Ba_{milk}$  values listed in the HHRAP database for mercuric chloride and methyl mercury from data in USEPA (1997b).

**Biotransfer factors for pork.** For organics (except PCDDs and PCDFs), biotransfer factors for pork ( $Ba_{pork}$ ) values reported in the USEPA HHRAP were derived from  $Ba_{beef}$  values, assuming that pork is 23 percent fat and beef is 19 percent fat. Therefore,  $Ba_{pork}$  values were calculated by multiplying  $Ba_{beef}$  values by their fat content ratio of 1.2 (23/19). This calculation is limited by the assumptions that:

1. COPCs bioconcentrate in the fat tissues.
2. There is minimal effect from differences in metabolism and feeding characteristics between beef cattle and pigs.

For PCDDs and PCDFs,  $Ba_{pork}$  values are calculated using the same methodology used to obtain  $Ba_{beef}$  values by USEPA (1995a). Assuming that milk is 3.5 percent fat and that pork is 23 percent fat, biotransfer factors for pork would be 6.57 times (23/3.5) higher than for milk. Therefore,  $Ba_{pork}$  values were calculated by increasing  $Ba_{milk}$  values by a factor of 6.57. This has the same effect as if the  $Ba_{pork}$  values were calculated by multiplying the  $Ba_{beef}$  values with the fat content ratio of 1.2 (23/19) between pork and beef, as was adopted for the remaining organic compounds.

**Biotransfer factors for chicken and poultry eggs.** Biotransfer factors for chicken ( $Ba_{chicken}$ ) and poultry eggs ( $Ba_{egg}$ ) are expressed as the ratio of the COPC concentration in the fresh weight tissue to the COPC intake from the feed. Biotransfer factors are calculated from bioconcentration factors for chicken and poultry eggs. BCFs are expressed as the ratio of the COPC concentration in the fresh weight tissue to the COPC concentration in dry weight soil.

USEPA recommends deriving the biotransfer factors for chicken  $Ba_{chicken}$  values using the same method used to estimate  $Ba_{beef}$  values, modifying to reflect an assumed fat content of chicken of 14 percent, and eggs of 8 percent. Specifically, USEPA uses the equation to generate  $Ba_{fat}$  values, which were then adjusted to account for the assumed fat content of chicken and eggs as shown below:

$$Ba_{chicken} = 10^{\log Ba_{fat}} \times 0.14$$

$$Ba_{eggs} = 10^{\log Ba_{fat}} \times 0.08 \quad (1.69)$$

These calculations are limited by the assumptions that:

1. Contaminants bioconcentrate in the fat tissues.
2. Effects from differences in metabolism, digestive system, or feeding characteristics between beef cattle and chickens are minimal.

Please note that the scenario of principal concern for chicken and egg contamination is for home grown chickens. The raising of home grown chickens would be characteristic of free range and semi-free range housing conditions where poultry do come in contact with soil, and possibly vegetation, insects, and benthic organisms. The applicability of this scenario to commercial poultry operations characterized by housing conditions that do not provide chickens access to soil would need to be assessed on a case-by-case basis.

**Bioconcentration and bioaccumulation factors for fish.** Bioconcentration and bioaccumulation factors for fish are used for various compounds, depending on the  $K_{ow}$  value of the organic compound. Bioconcentration factors for fish were used for organics (except PCDDs, PCDFs, and PCBs) with a log  $K_{ow}$  value less than 4.0; and for metals (except lead and mercury). Bioaccumulation factors for fish were used for organics (except PCDDs, PCDFs, and PCBs) with a log  $K_{ow}$  value greater than 4.0, lead, and mercuric compounds. Biota-sediment accumulation factors for fish were used for PCDDs, PCDFs, and PCBs.

**Bioconcentration factors for fish.** Bioconcentration factors for fish ( $BCF_{fish}$ ) is the ratio of the COPC concentration in fish to the COPC concentration in the water column where the fish is exposed. It accounts for uptake of COPCs by fish from water passing across the gills.  $BCF$  values for fish were used for all organic compounds with a log  $K_{ow}$  of less than 4.0 (cutoff value with  $BAF_{fish}$ ) and for all metals, except lead and mercury, as cited in USEPA (1995b). This implies that the concentration of COPC in the fish is only due to water intake by the fish, and compounds with a log  $K_{ow}$  of less than 4.0 are assumed not to bioaccumulate.

Our recommended  $BCF$  values don't recognize differences in total versus dissolved water concentrations when calculating fish concentrations from  $BCF_{fish}$  values for compounds with a log  $K_{ow}$  of less than 4.0. Since, dissolved water concentrations is the major contributing factor from compounds with a log  $K_{ow}$  of less than 4.0, all  $BCF_{fish}$  values (regardless of whether they were derived using total or dissolved water concentrations) can be multiplied by the contaminant concentration in the dissolved water column (Cdw) to calculate fish concentrations. This assumption is necessary because:

1. Literature data is often unclear if the water concentrations are dissolved or total concentrations.
2. Most of the literature reviewed indicated that laboratory experiments were conducted using filtered or distilled water; or the experiments were conducted using fresh water, but were filtered before analyses for water concentrations.

Meylan et al. (1999) collected information on measured BCF and other key experimental details for 694 chemicals. Log BCF was then regressed against  $\log K_{ow}$ , and chemicals with significant deviations from the line of best fit were analyzed by chemical structure. The resulting algorithm classifies a substance as either nonionic or ionic, the latter group including carboxylic acids, sulfonic acids and their salts, and quaternary N compounds. Log BCF for nonionics was estimated from  $\log K_{ow}$  and a series of correction factors if applicable; different equations apply for  $\log K_{ow}$  1.0 to 7.0 and  $>7.0$  (Meylan et al. 1999). These equations are as follows:

$$\begin{aligned} \text{For } \log K_{ow} < 1: & \quad \log BCF = 0.50 \\ \text{For } \log K_{ow} \text{ 1 to 7:} & \quad \log BCF = 0.77 \log K_{ow} - 0.7 + \sum \text{Correction Factors} \\ \text{For } \log K_{ow} > 7: & \quad \log BCF = -1.37 \log K_{ow} + 14.4 + \sum \text{Correction Factors} \\ \text{For } \log K_{ow} > 10.5: & \quad \log BCF = 0.50 \end{aligned}$$

For ionic compounds (carboxylic acids, sulfonic acids, and salts, compounds with N of +5 valence), were categorized by  $\log K_{ow}$ , and a log BCF in the range 0.5 to 1.75 was assigned as follows:

$$\begin{aligned} \text{For } \log K_{ow} < 5: & \quad \log BCF = 0.50 \\ \text{For } \log K_{ow} \text{ 5 to 6:} & \quad \log BCF = 0.75 \\ \text{For } \log K_{ow} \text{ 6 to 7:} & \quad \log BCF = 1.75 \\ \text{For } \log K_{ow} \text{ 7 to 9:} & \quad \log BCF = 1.0 \\ \text{For } \log K_{ow} > 9: & \quad \log BCF = 0.50 \end{aligned}$$

USEPA assumes that  $BCF_{fish}$  values calculated using the above equations were:

1. Based on dissolved water concentrations
2. Not lipid-normalized

**Bioaccumulation factors for fish.** Bioaccumulation factors for fish ( $BAF_{fish}$ ) is the ratio of the COPC concentration in fish to the COPC concentration in the water body where the fish are exposed. The  $BAF_{fish}$  accounts for uptake of COPCs by fish from water and sediments passing across the gills, and from consumption of various foods including plankton, daphnids, and other fish.  $BAF_{fish}$  was used for organic compounds (except PCBs, PCDDs, and PCDFs) with a  $\log K_{ow}$  greater than 4.0, lead, and mercuric compounds.

For compounds with a  $\log K_{ow}$  of greater than or equal to 4.0, COPCs can significantly partition into the suspended sediment organic carbon (or particulate phase) of the water column. Therefore, BAF values should be based on total (dissolved and suspended) water column concentrations.

The following equation cited in USEPA (1995f) is recommended to convert the BAF based on total water concentrations to a BAF based on dissolved water concentrations:

$$f_{fd} = \frac{1}{1 + \frac{(DOC)(K_{ow})}{10} + (POC)(K_{ow})} \quad (1.70)$$

where

$$\begin{aligned} f_{fd} &= \text{fraction of COPC that is freely dissolved in water} \\ DOC &= \text{concentration of dissolved organic carbon, kg organic carbon/L water} \\ POC &= \text{concentration of particulate organic carbon, kg organic carbon/L water} \end{aligned}$$

Since, the model was derived from a study conducted at Lake Ontario, DOC and POC values for Lake Ontario were used. Values cited in USEPA (1995f) were:

$$\begin{aligned} \text{DOC} &= 2 \times 10^{-6} \text{ kg/L} \\ \text{POC} &= 7.5 \times 10^{-9} \text{ kg/L} \end{aligned} \quad (1.71)$$

A *BAF* based on dissolved water concentrations can be calculated from a *BAF* based on total water concentrations as follows:

$$BAF(\text{dissolved}) = \frac{BAF(\text{total})}{f_{fd}} - 1 \quad (1.72)$$

For all organics (except PCBs, PCDDs, and PCDFs) with a  $\log K_{ow}$  greater than or equal to 4.0, the FCM, which accounts for accumulation through the food chain in addition to water, becomes greater than 1. Therefore, a  $BAF_{fish}$ , which takes the food chain into consideration, is more appropriate than a  $BCF_{fish}$ .

For all organics with a  $\log K_{ow}$  greater than or equal to 4.0, *BAFs* were derived using one of following these methods:

1. *BAF* = Field measured *BAF* or *BCF*, adjusted for dissolved water concentrations
2. *BAF* = Laboratory measured *BCF* multiplied by a FCM for either trophic level 3 or 4 fish

Both field and laboratory measured values were derived from various literature sources cited in USEPA (1999a). FCMs were obtained from USEPA (1995f).

For lead, the food-chain multiplier becomes greater than one; therefore, a *BAF* is more appropriate. The  $BAF_{fish}$  value reported in this HHRAP for lead was obtained as a geometric mean from various literature sources described in USEPA (1999a). Since metals are assumed insoluble under neutral conditions, the dissolved and total water concentrations are almost equal. However, for consistency, the  $BAF_{fish}$  value for lead was adjusted for dissolved fractions.

**Biota-sediment accumulation factor for fish.** For PCDDs, PCDFs, and PCBs, bioaccumulation factors for fish ( $BSAF_{fish}$ ) values should be used instead of *BAFs* for fish.  $BSAF_{fish}$  values reported in this HHRAP were obtained from USEPA (1994a).

$BSAF_{fish}$  accounts for the transfer of COPCs from the bottom sediment to the lipid in fish. Homologue group  $BSAF_{fish}$  values obtained from USEPA (1994a) were either measured or estimated values that were based on a whole fish lipid content of 7 percent and an organic carbon content of 3 percent. The  $BSAF_{fish}$  values reported in this HHRAP are consistent with the values presented in primary guidance documents.

## 9 HUMAN HEALTH BENCHMARKS

---

The following sections discuss carcinogenic and noncarcinogenic toxicity benchmarks of compounds. The toxicity information provided in the HHRAP is for informational purposes to help permitting authorities explain the basis for selecting contaminants of concern. Since toxicity benchmarks and slope factors may change as additional toxicity research is conducted, permitting authorities should consult with the most current version of EPA's Integrated Risk Information System (IRIS) and Health Effects Assessment Summary Tables (HEAST) before completing a risk assessment to ensure that the toxicity data used in the risk assessment is based upon the most current agency consensus.

### 9.1 Reference Dose (Rfd) and Reference Concentration (RfC)

Reference dose is defined as a daily intake rate of a compound estimated to pose no appreciable risk of deleterious effects over a specific exposure duration (USEPA 1989e). Reference concentration is

defined as the concentration of a compound estimated (with uncertainty spanning perhaps an order of magnitude) to pose no appreciable risk of deleterious effects over a specific exposure duration (USEPA 1989e).

## 9.2 Oral Cancer Slope Factor, Inhalation CSF, and Inhalation Unit Risk Factor

Oral cancer slope factor (*CSF*), *inhalation CSF*, and *inhalation* unit risk factor (*URF*) values for all compounds can be obtained from IRIS and HEAST.

## 9.3 Explanation of Calculated Toxicity Benchmark Values

The preference for health benchmarks is to obtain values from IRIS or HEAST. The following methodology was used to calculate missing benchmarks using available benchmarks that are based on route-to-route extrapolation:

1. *Oral RfDs* presented in IRIS/HEAST/EPA reviewed documents were used if available. missing oral *RfDs* were calculated from the *RfC* assuming route-to-route extrapolation using the following equation:

$$\text{Oral RfD} = \frac{\text{RfC} \cdot 20 \text{ m}^3/\text{d}}{70 \text{ kg BW}} \quad (1.73)$$

2. *Oral CSFs* presented in IRIS/HEAST/EPA reviewed documents were used when available. In the case of missing oral *CSFs*:
  - a. *Oral CSF* = *Inhalation CSF*, or
  - b. *Oral CSF* = *Inhalation CSF* calculated from *Inhalation URF* assuming route-to-route extrapolation.
3. For *inhalation URFs*, values were obtained from IRIS/HEAST/EPA reviewed documents. If the *inhalation URFs* were not available they were calculated from *oral CSF*, using the following equation:

$$\text{Inhalation URF} = \frac{\text{Oral CSF} \cdot 20 \text{ m}^3/\text{d}}{70 \text{ kg} \times 1000 \text{ } \mu\text{g}/\text{mg}} \quad (1.74)$$

4. The *inhalation CSFs* presented in IRIS/HEAST/EPA should be used when available.
  - a. If no *inhalation CSF* was available; it was calculated from *inhalation URF*, using the following equation:

$$\text{Inhalation CSF} = \frac{\text{Inhalation URF} \cdot 70 \text{ kg}}{20 \text{ m}^3/\text{d}} \times 1000 \text{ } \mu\text{g}/\text{mg} \quad (1.75)$$

- b. If no *inhalation URF* was available; the following was assumed based on route-to-route extrapolation:

$$\text{Inhalation CSF} = \text{Oral CSF} \quad (1.76)$$

## 10 TERMINOLOGY AND VARIABLE IN HUMAN HEALTH RISK ASSESSMENT

---

$\rho_{air}$	= Density of air ( $\text{g}/\text{cm}^3$ )
$\rho_{forage}$	= Density of forage ( $\text{g}/\text{cm}^3$ )

$Ba_{beef}$	= Biotransfer factor in beef (mg COPC/kg FW tissue)/(mg COPC/d)
$Ba_{chicken}$	= Biotransfer factor in chicken (mg COPC/kg FW tissue)/(mg COPC/d)
$Ba_{egg}$	= Biotransfer factor in eggs (mg COPC/kg FW tissue)/(mg COPC/d)
$Ba_{milk}$	= Biotransfer factor in milk (mg COPC/kg FW tissue)/(mg COPC/d)
$Ba_{pork}$	= Biotransfer factor in pork (mg COPC/kg FW tissue)/(mg COPC/d)
$BAF_{fish}$	= Bioaccumulation factor in fish (mg COPC/kg FW tissue)/(mg COPC/L total water column)
$BCF_{fish}$	= Bioconcentration factor in fish (L/kg FW or unitless)
$Br_{ag}$	= Plant-soil bioconcentration factor in aboveground produce ( $\mu\text{g COPC/g DW plant}$ )/( $\mu\text{g COPC/g DW soil}$ ) (unitless)
$Br_{forage/silage}$	= Plant-soil bioconcentration factor in forage and silage ( $\mu\text{g COPC/g DW plant}$ )/( $\mu\text{g COPC/g DW soil}$ ) (unitless)
$Br_{grain}$	= Plant-soil bioconcentration factor in grain ( $\mu\text{g COPC/g DW grain}$ )/( $\mu\text{g COPC/g DW soil}$ ) unitless
$Br_{rootveg}$	= Plant-soil bioconcentration factor for belowground produce ( $\mu\text{g COPC/g DW plant}$ )/( $\mu\text{g COPC/g DW soil}$ ) (unitless)
$BSAF_{fish}$	= Biota-sediment accumulation factor in fish (mg COPC/kg lipid tissue)/(mg COPC/kg sediment) (unitless)
$B_{vol}$	= Volumetric air-to-leaf biotransfer factor in leaf ( $\mu\text{g COPC/L FW plant}$ )/( $\mu\text{g COPC/L air}$ ) (unitless)
$Bv_{ag}$	= COPC air-to-plant biotransfer factor for aboveground produce ( $\mu\text{g COPC/g DW plant}$ )/( $\text{mg COPC/g air}$ ) (unitless)
$Bv_{forage/silage}$	= Air-to-plant biotransfer factor in forage and silage ( $\mu\text{g COPC/g DW plant}$ )/( $\mu\text{g COPC/g air}$ ) (unitless)
$c$	= Junge constant = $1.7 \times 10^{-04}$ (atm.cm)
$D_a$	= Diffusivity of COPC in air ( $\text{cm}^2/\text{s}$ )
$D_w$	= Diffusivity of COPC in water ( $\text{cm}^2/\text{s}$ )
$f_{oc,bs}$	= Fraction of organic carbon in bottom sediment (unitless)
$f_{oc,s}$	= Fraction of organic carbon in soil (unitless)
$f_{oc,sw}$	= Fraction of organic carbon in suspended sediment (unitless)
$f_{water}$	= Fraction of COPC in water (unitless)
$F_v$	= Fraction of COPC air concentration in vapor phase (unitless)
$F_w$	= Fraction of wet deposition that adheres to plant surfaces (unitless)
$H$	= Henry's law constant
$CSF_{inhalation}$	= Inhalation cancer slope factor ( $\text{mg}/\text{kg} \cdot \text{d}$ ) <sup>-1</sup>
$URF_{inhalation}$	= Inhalation unit risk factor ( $\mu\text{g}/\text{m}^3$ ) <sup>-1</sup>
$Kd_s$	= Soil-water partition coefficient ( $\text{mL water/g soil OR cm}^3 \text{ water/g soil}$ )
$Kd_{sw}$	= Suspended sediment-surface water partition coefficient ( $\text{L water/kg suspended sediment OR cm}^3 \text{ water/g suspended sediment}$ )
$Kd_{bs}$	= Bed sediment-sediment pore water partition coefficient ( $\text{L water/kg bottom sediment OR cm}^3 \text{ water/g bottom sediment}$ )
$K_{ow}$	= Octanol/water partitioning coefficient ( $\text{mg COPC/L octanol}$ )/( $\text{mg COPC/L octanol}$ )
$K_{oc}$	= Soil organic carbon-water partition coefficient ( $\text{mL water/g soil}$ )
$ks_g$	= COPC soil loss constant due to biotic and abiotic degradation ( $\text{year}^{-1}$ )
$M_w$	= Molecular weight of COPC ( $\text{g/mol}$ )
$p_L^E$	= Liquid-phase vapor pressure of COPC (atm)
$p_S^E$	= Solid-phase vapor pressure of COPC (atm)
Oral CSF	= Oral cancer slope factor ( $\text{mg}/\text{kg} \cdot \text{d}$ ) <sup>-1</sup>
$R$	= Universal gas constant ( $\text{atm} \cdot \text{m}^3/\text{mol} \cdot \text{K}$ )
$RCF$	= Root concentration factor ( $\text{mg COPC/g DW plant}$ )/( $\text{mg COPC/mL soil water}$ )
$RfC$	= Reference concentration ( $\text{mg}/\text{m}^3$ )
$RfD$	= Reference dose ( $\text{mg}/\text{kg}/\text{d}$ )
$R_p$	= Interception factor of edible portion of plant (unitless)
$S$	= Solubility of COPC in water ( $\text{mg COPC/L water}$ )
$\Delta S_f$	= Entropy of fusion [ $\Delta S_f/R = 6.79$ (unitless)]

$S_T$	=	Whitby's average surface area of particulates (aerosols)
	=	$3.5 \times 10^{-06} \text{ cm}^2/\text{cm}^3$ air for background plus local sources
	=	$1.1 \times 10^{-05} \text{ cm}^2/\text{cm}^3$ air for urban sources
$t_{1/2}$	=	Half-time of COPC in soil (days)
$T_a$	=	Ambient air temperature (K)
$T_m$	=	Melting point temperature (K)
$TEF$	=	Toxicity equivalency factor (unitless)
$V_p$	=	Vapor pressure of COPC (atm)

## 1 INTRODUCTION

---

A fuel cell is an electrochemical device that converts the chemical energy of a fuel directly into electrical energy. The basic physical structure of a fuel cell consists of an electrolyte layer in contact with a porous anode and cathode on either side. In a typical fuel cell, gaseous fuels are fed continuously to the anode (negative electrode) and an oxidant (i.e., oxygen from air) is fed continuously to the cathode (positive electrode); electrochemical reactions take place at the electrodes usually with the help of catalysts to produce an electric current. Through the electrochemical reactions, chemical energy is converted to electrical energy without combustion producing pure water and a nominal amount of heat that can be recycled into other functions (via cogeneration), and a small amount of carbon dioxide (CO<sub>2</sub>).

A fuel cell operates in a fashion similar to a continuous battery, producing electricity as a result of an electrochemical reaction between two gases (primarily hydrogen and oxygen). However, it differs in several respects. The battery is an energy storage device. The maximum energy available is determined by the amount of chemical reactants stored within the battery itself. The battery will cease to produce electrical energy when the chemical reactants are exhausted (i.e., discharged). In a secondary battery, recharging regenerates the reactants, which involves putting energy into the battery from an external source. The fuel cell, on the other hand, is an energy conversion device that theoretically has the capability of producing electrical energy for as long as fuel and oxidant are supplied to the electrodes. See Fig 1.1.

## 2 FUEL CELL DESCRIPTIONS

### 2.1 Alkaline Fuel Cell

As the name implies, an Alkaline Fuel Cell (AFC) is characterized by an alkaline electrolyte. The electrolyte in this fuel cell typically is concentrated (85 wt%) KOH and is operated at temperatures less than 120°C. NaOH has also been used in this type of fuel cell when operated at higher temperatures (approximately 250°C). The electrolyte is retained in a matrix (usually asbestos), and a wide range of electrocatalysts can be used (e.g., Ni, Ag, metal oxides, and noble metals). Therefore, the electrolyte contains  $K^+$  and  $OH^-$ . The electrolyte is sandwiched between an anode electrode and a cathode electrode. When hydrogen ( $H_2$ ) generated from a fuel in an upstream reformer is charged to an anode electrode,  $H_2$  reacts with the hydroxide ion ( $OH^-$ ) to produce water and electrons ( $2e^-$ ). While being transported from the anode to the cathode, the electrons pass through a power driver and transfer power from the fuel cell to a loading system such as an automobile motor. At the cathode, the electrons react with water and oxygen to produce hydroxide ion. The hydroxide ions then travel to the anode for reacting with  $H_2$ , thus completing the fuel cell cycle. The main electrochemical reactions occurring in AFCs include (see Fig. 1.2):

1. Fuel: Natural gas (which is first sent to a fuel reformer to produce  $H_2$ )
2. Anode reaction:  $H_2 + 2OH^- \rightarrow 2H_2O + 2e^-$
3. Cathode reaction:  $1/2O_2 + H_2O + 2e^- \rightarrow 2OH^-$
4. Overall reaction:  $H_2 + 1/2O_2 \rightarrow H_2O$

FIGURE 1.2 Schematic of an alkaline fuel cell.

## 2.2 Direct Fuel Cell

A direct fuel cell is a type of fuel cell in which a hydrocarbon fuel, such as methanol, is fed directly to the fuel cell stack without requiring a reformer to generate hydrogen.

**Direct hydrogen fuel cell.** A direct hydrogen fuel cell is a fuel cell that is directly powered by pure hydrogen as the fuel rather than by the hydrogen that is produced from the reformation of hydrocarbon fuels (gasoline, diesel, propane, and natural gas).

**Direct methanol fuel cell.** As the name implies, a direct methanol fuel cell (DMFC) is characterized by the direct use of liquid methanol as a fuel. Unlike many other fuel cell types, a DMFC does not need a reformer and that has the potential to reduce the overall weight and cost of a fuel cell engine. As shown in the chemical reaction equations below, a methanol/water solution (approximately 3 percent methanol) is introduced to anode electrocatalysts that spontaneously break the methanol molecules apart. Once broken up, the carbon atom combines with the oxygen atoms from the methanol and water at the electrode to form  $\text{CO}_2$ . The hydrogen atoms are further divided into hydrogen protons ( $\text{H}^+$ ) and electrons ( $\text{e}^-$ ). The hydrogen protons pass through an electrolyte membrane to the cathode. Meanwhile, the electrons are forced to travel through an external circuit to the embedded cathode electrocatalysts where the hydrogen atoms (hydrogen protons) and electrons are reunited and are combined with oxygen to produce water. The main electrochemical reactions occurring in DMFCs include (see Fig. 1.3):

1. Fuel: Liquid methanol
2. Anode oxidation reaction:  $\text{CH}_3\text{OH} + \text{H}_2\text{O} \rightarrow \text{CO}_2 + 6\text{H}^+ + 6\text{e}^-$
3. Cathode reduction reaction:  $6\text{H}^+ + 3/2\text{O}_2 + 6\text{e}^- \rightarrow 3\text{H}_2\text{O}$
4. Overall reaction:  $\text{CH}_3\text{OH} + \text{H}_2\text{O} + 3/2\text{O}_2 \rightarrow \text{CO}_2 + 3\text{H}_2\text{O}$

### 2.3 Metal Air Fuel Cell

As the name implies, a metal air fuel cell (MAFC) is characterized by the use of metals as fuels. The fuel metals include zinc, aluminum, and magnesium. The power stored in these metals is quite high (energy density) and therefore it is possible to achieve impressive power densities with such systems. Using a zinc/air fuel cell as an example, it consists of a zinc anode, which is surrounded by an aqueous electrolyte (KOH). For the cathode, often a layer of carbon is used, which offers good electrical conductivity and allows the air to circulate through the cathode. The oxygen from the air moves through the carbon cathode and gets in touch with the electrolyte. As a result, the zinc of the anode gets oxidized and ZnO is generated. The free electrons released by this reaction can be used to drive an external electrical load.

The cell produces electrical power as long as metallic zinc is available. When zinc is used for the anode, it is possible to convert the ZnO back to zinc by an external electrolysis process, which consumes energy. So it is possible to achieve a closed loop for the fuel zinc. The main electrochemical reactions occurring in MAFCs include (see Fig. 1.4):

1. Fuel: Zinc, aluminum, and magnesium
2. Anode reaction:  $\text{Zn} + 2(\text{OH})^- \rightarrow \text{ZnO} + \text{H}_2\text{O} + 2\text{e}^-$
3. Cathode reaction:  $1/2\text{O}_2 + \text{H}_2\text{O} + 2\text{e}^- \rightarrow 2(\text{OH})^-$
4. Complete reaction:  $\text{Zn} + 1/2\text{O}_2 \rightarrow \text{ZnO}$

### 2.4 Molten Carbonate Fuel Cell

As the name implies, a molten carbonate fuel cell (MCFC) is characterized by a molten carbonate electrolyte. Generally operating at high temperatures [650°C (1200°F)], an MCFC consists of a molten electrolyte of alkaline lithium and potassium carbonates ( $\text{Li}_2\text{CO}_3/\text{K}_2\text{CO}_3$ ), in which the

species  $\text{CO}_3^{2-}$  is transported from the cathode to the anode. The high operating temperature is needed to achieve the molten state of the carbonates to provide sufficient conductivity of the electrolyte. An advantage associated with this high temperature is that noble metal catalysts are not required for the electrochemical oxidation and reduction processes that occur within the cell. Molten carbonate fuel cells are being developed for natural gas and coal-based power plants for the industrial and electric utility sectors. The anode process involves a reaction between hydrogen and carbonate ions  $\text{CO}_3^{2-}$  from the electrolyte that produces water and carbon dioxide ( $\text{CO}_2$ ) while releasing electrons. The cathode process combines oxygen from the oxidant stream with  $\text{CO}_2$  and with electrons from the anode to produce carbonate ions that enter the electrolyte.

It is a common practice in an MCFC system that the  $\text{CO}_2$  generated at the anode will be recycled to the cathode where it is consumed. This will require devices that will either: (i) transfer the  $\text{CO}_2$  from the anode exit gas to the cathode inlet gas ( $\text{CO}_2$  transfer device); or (ii) supply  $\text{CO}_2$  from an alternate source. The main electrochemical reactions occurring in MCFCs include (see Fig. 1.5):

1. Fuel: Natural gas and coal
2. Anode reaction:  $\text{H}_2 + \text{CO}_3^{2-} \rightarrow \text{H}_2\text{O} + \text{CO}_2 + 2\text{e}^-$
3. Cathode reaction:  $1/2\text{O}_2 + \text{CO}_2 + 2\text{e}^- \rightarrow \text{CO}_3^{2-}$
4. Overall reaction:  $\text{H}_2 + 1/2\text{O}_2 \rightarrow \text{H}_2\text{O}$

## 2.5 Phosphoric Acid Fuel Cell

Obviously, a phosphoric acid fuel cell (PAFC) uses concentrated phosphoric acid ( $\text{H}_3\text{PO}_4$ ) as its electrolyte. A silicon carbide matrix is used to contain the acid. Both anode and cathode electrodes that are made from platinum (Pt) and/or its alloys also function as catalysts. Temperatures of about 390°F

or 200°C and acid concentrations of 100 percent  $\text{H}_3\text{PO}_4$  are commonly used now while the operating pressure can exceed 8 atm. The main electrochemical reactions occurring in PAFCs include:

1. Fuel: If a hydrocarbon such as natural gas is used as the fuel, reforming of the fuel by the reaction  $\text{CH}_4 + \text{H}_2\text{O} = 3\text{H}_2 + \text{CO}$ , followed by shifting of the reformat by the reaction  $\text{CO} + \text{H}_2\text{O} = \text{H}_2 + \text{CO}_2$  are required to generate the fuel needed by the cell. CO is a poison when present in a concentration greater than 0.5 percent. Any sulfur compounds present in the fuel also have to be removed prior to use in the cell (upstream of the reformer) to a concentration of <0.1 ppmV. The fuel cell itself, however, can tolerate a maximum of 50 ppmV of sulfur compounds (see Fig. 1.6).
2. Anode reaction:  $\text{H}_2 \rightarrow 2\text{H}^+ + 2\text{e}^-$
3. Cathode reaction:  $1/2\text{O}_2 + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{H}_2\text{O}$
4. Overall reaction:  $\text{H}_2 + 1/2\text{O}_2 \rightarrow \text{H}_2\text{O}$

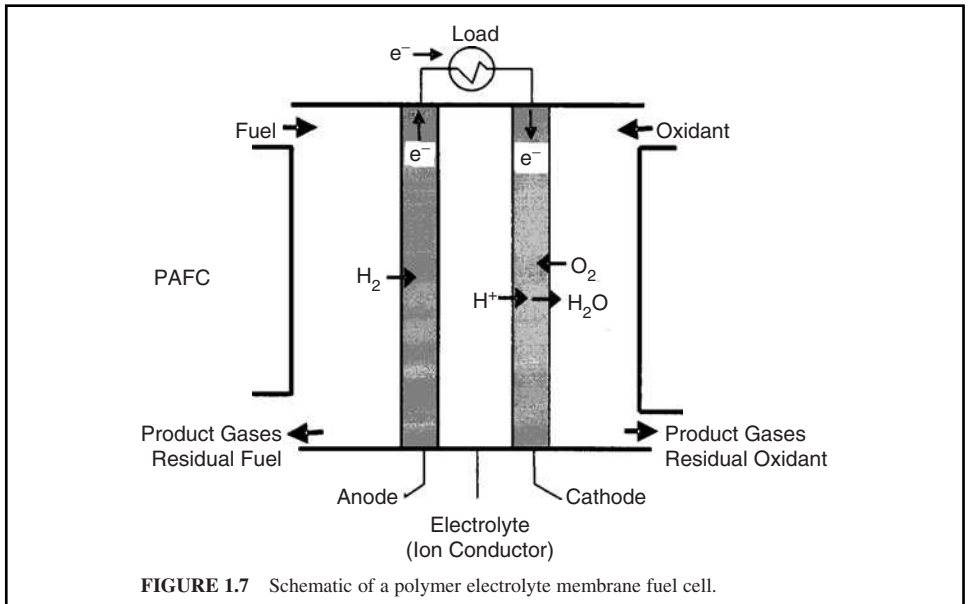

## 2.6 Polymer Electrolyte Membrane Fuel Cell

The polymer electrolyte membrane fuel cell (PEMFC) is also known as the proton exchange membrane fuel cell. In a PEMFC, the electrolyte is sandwiched between two Pt-impregnated porous electrodes. Within the cell,  $\text{H}_2$  at the anode provides protons ( $\text{H}^+$ ) that pass through the electrolyte and releases electrons ( $\text{e}^-$ ) that pass through an external circuit to reach the cathode. The protons diffuse through the membrane to the cathode to react with the  $\text{O}_2$  being supplied to the cathode while picking up the electrons and forming water at the cathode. The fuel cells typically run at low temperatures (<100°C) and pressures (<5 atm). It is the leading fuel cell technology for use in the automobile application. The main electrochemical reactions occurring in PEMFCs include:

1. Fuel: Natural gas is usually the primary fuel for a PEMFC, hence an upstream reformer and shift converter are then required. The cells are not sulfur<sup>-</sup> or CO<sup>-</sup> tolerant (see Fig. 1.7).
2. Anode reaction:  $\text{H}_2 \rightarrow 2\text{H}^+ + 2\text{e}^-$
3. Cathode reaction:  $1/2\text{O}_2 + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{H}_2\text{O}$
4. Overall reaction:  $\text{H}_2 + 1/2\text{O}_2 \rightarrow \text{H}_2\text{O}$

**FIGURE 1.6** Schematic of a phosphoric acid fuel cell.

**FIGURE 1.7** Schematic of a polymer electrolyte membrane fuel cell.

## 2.7 Pressurized Solid Oxide Fuel Cell

The pressurized solid oxide fuel cell (PSOFC) is used in a hybrid system. A solid oxide fuel cell is operated under high pressures such that its hot pressurized exhaust gases are used to drive a micro-turbine generator for additional power generation. For more information, see <http://fuelcells.si.edu/so/sox3.htm>, 2004.

## 2.8 Regenerative Fuel Cell or Reversible Fuel Cell

A regenerative fuel cell or reversible fuel cell is a fuel cell that is capable of producing electricity from  $H_2$  and  $O_2$  and uses electricity in the reverse direction (e.g., via electrolysis) to create the  $H_2$  and  $O_2$  in the first place.

## 2.9 Solid Oxide Fuel Cell

A single solid oxide fuel cell (SOFC) unit consists of two electrodes (an anode and a cathode) separated by an electrolyte. Fuel (usually  $H_2$  or  $CH_4$ ) arrives at the anode, where it is oxidized by oxygen ions coming from the electrolyte, thereby releasing electrons ( $e^-$ ) to an external circuit. On the other side of the fuel cell, an oxidant ( $O_2$  or air) is fed to the cathode, where it supplies the oxygen ions ( $O^{2-}$ ) for the electrolyte by accepting electrons from the external circuit. The electrolyte conducts these ions between the electrodes, maintaining overall electrical charge balance. The flow of electrons in the external circuit provides useful power.

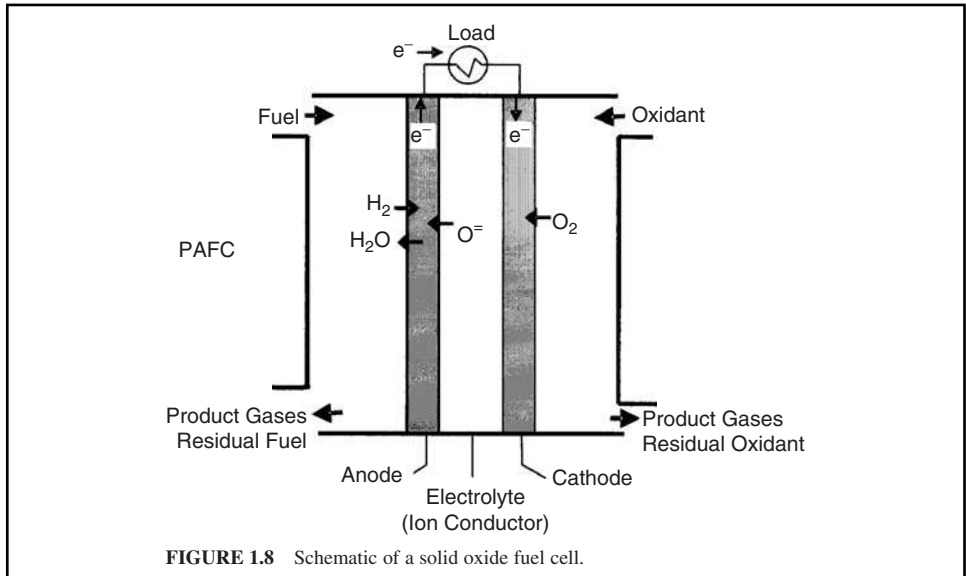

An SOFC is one of the two high temperature fuel cell types (along with molten carbonate fuel cells) that operate at temperatures near  $800^\circ\text{C}$  to  $1000^\circ\text{C}$ . Due to its high operating temperature, the solid oxide fuel cell is typically fueled by a direct feed of pressurized natural gas. Internal reforming of the natural gas produces hydrogen and carbon monoxide that are oxidized in the fuel cell to produce electricity. Because of the ability to oxidize carbon monoxide, various hydrocarbons can be reformed inside the SOFC without the need for carbon monoxide clean up. This simplifies the system considerably and adds fuel flexibility. Owing to the high temperature of operation, the fuel cell relies heavily on the use of ceramic materials for the electrodes, electrolyte, and interconnecting elements.

The most widely used ceramic electrolyte is zirconia stabilized with 8 to 10 percent of yttria. This is a solid, nonporous metal oxide, typically  $ZrO_2$  doped with  $Y_2O_3$  and is referred to as yttrium-stabilized zirconia (YSZ), which is used to transport the oxygen ion from cathode to anode. Because of the solid electrolyte, SOFCs can minimize corrosion, leakage, and electrolyte management problems normally associated with liquid electrolytes and because of the high-temperature operation, internal reforming can be achieved. The anode is typically constructed from an electronically conducting nickel/yttria-stabilized zirconia "cermet" (Ni/YSZ), a blend of various ceramic and metallic constituents. The cathode is made of conducting metallic materials such as perovskite and lanthanum manganate ( $LaMnO_3$ ). To generate a suitable voltage, fuel cells are not operated as single units but as a series or array of units or "stack," with a doped lanthanum chromite (e.g.,  $La_{0.8}Ca_{0.2}CrO_3$ ) interconnect joining the anodes and cathodes of adjacent units.

SOFCs are a leading technology for use in stationary fuel cell applications (e.g., in residences or for supplementary power). The fuel reactions and the electrochemical reactions occurring in SOFCs include:

1. Fuel processes: CO and hydrocarbons such as methanol can also be used as fuels in an SOFC. At high temperatures within the cell, it is feasible for the steam reforming reaction ( $CH_4 + H_2O \rightarrow 3H_2 + CO$ ) and the water gas shift reaction ( $CO + H_2O \rightarrow H_2 + CO_2$ ) to take place efficiently to produce the  $H_2$  that is to be oxidized at the anode. Any sulfur compounds present in the fuel have to be removed prior to use in the cell to a concentration of  $<0.1$  ppmV.
2. Anode reactions:  $H_2 + O^{2-} \rightarrow H_2O + 2e^-$ ;  $CO + O^{2-} \rightarrow CO_2 + 2e^-$
3. Cathode reaction:  $O_2 + 4e^- \rightarrow 2O^{2-}$
4. Overall reaction:  $O_2 + H_2 + CO \rightarrow H_2O + CO_2$  (see Fig. 1.8)

### 3 CALCULATIONS OF CARNOT EFFICIENCY AND FUEL CELL EFFICIENCY

#### 3.1. Combustion and Carnot Efficiency

Over 85 percent of the world's energy is obtained by combustion of fossil fuels. Combustion involves the reaction of fuels such as coal, oil, and natural gas with oxygen to produce hot gases at temperatures as high as a 1500°C. The energy in the hot gases is then converted to mechanical energy in engines or turbines. Following extraction of part of the energy of the hot gases in the engines, the hot gas cools and is exhausted. The energy efficiency of converting heat to work is governed by the difference in the inlet and exhaust temperatures in the engine. The larger this difference, the higher the efficiency. The maximum efficiency limit of such heat engines is termed the Carnot efficiency and is given by the expression:

$$\varepsilon = \frac{T_{\text{in}} - T_{\text{out}}}{T_{\text{in}}} \quad (1.1)$$

where  $\varepsilon$  is the Carnot efficiency,  $T_{\text{in}}$  is the inlet temperature, and  $T_{\text{out}}$  is the exhaust temperature. The temperatures are expressed in Kelvin. For a natural gas turbine operating between 1500°C (1773.5 K) and 600°C (873.5 K), the maximum efficiency or the Carnot limit as per Eq.(1.1) is about 50 percent. This Carnot efficiency limit is not achieved because of other energy losses in the process of conversion. In power boilers or conventional internal combustion engines, efficiency levels achieved are closer to 35 percent.

#### 3.2 Fuel Cells and Energy Conversion

Unlike heat engines, which utilize the heat generated by the combustion of fuels, fuel cells harness the energy of the electrons in the fuel molecules directly. To have access to the electrons involved in

the oxidation process, the electron generation from a fuel oxidation reaction and the electron acceptance by oxygen molecules are arranged to happen at different electrodes. Following this, the flow of electrons between these two electrodes is intercepted through an electrical load where the energy of the electrons is harnessed. These processes are schematically shown in Fig. 1.9 for the reaction of hydrogen with oxygen.

In the hydrogen-oxygen fuel cell shown in Fig. 1.9, energetic electrons are generated by the oxidation of hydrogen to protons. These electrons travel to the oxygen electrode where they reduce molecular oxygen to water. The reactions occurring at the two electrodes are called electrochemical reactions because they involve electron movement and chemical change. The electrode that is the source of the more energetic electrons becomes the negative electrode. The electrode that accepts electrons is the positive electrode.

At equilibrium, when no energy is delivered to the load, the electromotive force,  $E$ , that is developed between the two electrodes is related to the molar free energy change  $\Delta G$  of the overall cell reaction and is expressed by the Nernst equation, which is:

$$\Delta G = -nFE \tag{1.2}$$

where  $n$  is the number moles of electrons transferred in the overall reaction,  $F$  is the Faraday constant (96468 C/mol of electrons), and  $E$  is the electromotive force. The free energy change represents the maximum useful energy that can be derived from the particular cell reaction.

Under standard conditions, the free energy change,  $\Delta G^\circ$ , can be used to calculate the standard electromotive force (EMF) of the cell,  $E^\circ$ , as follows.

$$\Delta G^\circ = -nFE^\circ \tag{1.3}$$

The  $\Delta G^\circ$  for the hydrogen-oxygen fuel cell reaction is  $-237$  kJ for every mole of hydrogen oxidized, and for the product water in the liquid state (Dole-02 et al., 2002). The standard EMF is then calculated to be 1.228 V. Thus, under standard conditions, the maximum observable cell voltage is 1.228 V.

Under standard conditions the enthalpy change,  $\Delta H^\circ$  represents the overall energy change comprises of the free energy change and an energy term associated with the entropy change,  $\Delta S^\circ$ , by the following equation:

$$\Delta H^\circ = \Delta G^\circ + T\Delta S^\circ \quad (1.4)$$

where:  $T$  is absolute temperature in Kelvin.

Thus,  $\Delta G^\circ$  represents a portion of the enthalpy change that can be converted to work. Even when the process is carried out under reversible conditions, the portion of  $\Delta H^\circ$  represented by  $T\Delta S$ , always appears as heat.

The maximum efficiency of conversion of the enthalpy change in a fuel oxidation reaction to useful work through a fuel cell reaction is given by:

$$\varepsilon = \frac{\text{work}_{\max}}{\Delta H^\circ} \quad (1.5)$$

Substituting from Eqs. (1.3) and (1.4),

$$\varepsilon = \frac{\Delta G^\circ}{\Delta H^\circ} \quad \text{or} \quad \varepsilon = 1 - \frac{T\Delta S^\circ}{\Delta H^\circ} \quad (1.6)$$

$\varepsilon$  is termed the maximum thermal efficiency. For the hydrogen oxidation reaction, ( $\Delta H^\circ = -285.8$  kJ/mol (Dole-02 et al., 2002)). Thus, the maximum thermal efficiency that can be achieved in a hydrogen-oxygen fuel cell under standard conditions (298K and 1 atm) is 83 percent.

A heat engine with a Carnot efficiency limit of 83 percent will need to operate over a large temperature differential of about 1800 K (for example,  $T_{in} = 2200$  K and  $T_{out} = 373$  K, Carnot Efficiency =  $[(2200 - 373)/2200 = 83\%]$ ). Cycling over such large temperature differentials usually presents challenges for the choice of materials. Therefore, the possibility of achieving high conversion efficiencies with fuel cells under benign isothermal conditions is very attractive.

### 3.3 Practical Efficiencies in Fuel Cells

During operation of a fuel cell, there are processes that occur at the interface of the electrodes, in the electrode structure and the body of the electrolyte that results in energy losses. Such losses result in a cell voltage lower than the standard EMF,  $E^\circ$ . The losses that lead to a reduction in cell voltage are termed *polarization losses*. The voltage efficiency,  $\varepsilon_{\text{voltage}}$ , under practical conditions is thus the ratio of the actual voltage observed,  $V_{\text{cell}}$  and the standard EMF,  $E^\circ$ .

$$\varepsilon_{\text{voltage}} = \frac{V_{\text{cell}}}{E^\circ} \quad (1.7)$$

When only part of the fuel is used in the generation of electricity and the rest of it is consumed with the generation of heat, the fuel efficiency,  $\varepsilon_{\text{fuel}}$ , may be defined as

$$\varepsilon_{\text{fuel}} = \frac{n_{\text{used}}}{n_{\text{total}}} \quad (1.8)$$

where,  $n_{\text{used}}$  is the fuel used to produce useful energy from the reaction and  $n_{\text{total}}$  is the total fuel used during the reaction. Thus, the thermal conversion efficiency under practical conditions,  $\varepsilon_{\text{practical}}$ , is a product of the theoretical thermal efficiency, voltage efficiency, and fuel efficiency.

$$\varepsilon_{\text{practical}} = 0.83\varepsilon_{\text{voltage}} \cdot \varepsilon_{\text{fuel}} \quad (1.9)$$

For a hydrogen-oxygen fuel cell operating at a cell voltage of 0.7 V, and consuming about 98 percent of the hydrogen for electricity production, the practical thermal efficiency is calculated to be 46 percent, that means,

$$\begin{aligned}\varepsilon_{\text{practical}} &= 0.83\varepsilon_{\text{voltage}} \cdot \varepsilon_{\text{fuel}} && (1.10) \\ &= 0.83 (V_{\text{cell}}/E^{\circ}) 0.98 \\ &= 0.83 [0.7/1.228] 0.98 \\ &= 46\%\end{aligned}$$

Thus, polarization losses lower the practical thermal efficiencies significantly.

 Centrifugal fans, 3.130, 131  
 Centrifugal force, 3.180  
 Centrifugal pumps, 1.275

- Centrifugal separators, **3.292**
- Centrifugation (sludge dewatering), **1.684**
- Centrifuge sludge thickening, **1.662–665**
- Chamber sizing (incinerators), **2.232–234**
- Channel dam reaeration, **1.142, 144**
- Characteristics:  
     of wastewater, **1.450–457**  
     of water, **1.112, 154, 177, 182, 324**
- Charles' (Charles-Gay Lussac) law, **2.6–7**
- Charles-Gay-Lussac law, **1.249**
- Chemical adsorption (chemisorption), **3.45–46**
- Chemical coal cleaning, **3.102**
- Chemical conditioning of sludge, **1.677**
- Chemical constituents of wastewater,  
     **1.453–456**
- Chemical equilibrium, **2.7–8**
- Chemical kinetics, **2.8–13**
- Chemical oxygen demand (COD), **1.78, 452, 454–456, 468**
- Chemistry, **1.31–44**  
     chemical reactions and dosages,  
         **1.42–44**  
     density, **1.31–33**  
     mixing solutions, **1.40–41**  
     pH, **1.37–40**  
     solutions, **1.33–37**  
     specific gravity, **1.31–33**
- Chevron blade separators, **3.294**
- Che'zy equation for uniform flow, **1.281–282**
- Chicken, toxics in, **4.60–64, 105**
- Chick's law, **1.161, 426**
- Chick-Watson model, **1.426**
- Child resident exposure scenario  
     (air toxics), **4.26**
- Chloramine, **1.421–423**  
     in dechlorination, **1.611, 614**  
     and inactivation of *Giardia lamblia*, **1.430, 437, 438**  
     and inactivation of viruses, **1.431**  
     and pH of water, **1.325**
- Chloramine inactivation, **1.437–438**
- Chlorinated compounds, combustion of,  
     **2.180–181**
- Chlorinated organic wastes processing, **2.477–478**
- Chlorination, **1.418–425, 611–618**
- Chlorine:  
     available chlorine, **1.421**  
     chlorine, **1.611–614**  
     free available, **1.418–421**  
     free residual, **1.421**
- Chlorine dioxide (ClO<sub>2</sub>), **1.424–425**
- Chloroform, **1.334–335, 729**
- Chlorophyll, in lakes and reservoirs,  
     **1.187–188**
- Churchill equation, **1.105**
- Churchill-Buckingham method, **1.115–118**
- Ciba-Geigy heating value, **2.52–53**
- Circles, areas and circumference of, **1.27**
- Circular basin design, **1.512–514**
- Circulating bed combustors, **2.345**
- Citrate scrubbers, **3.113–114**
- Cladothrix*, **1.588**
- Clarifiers (*see* Sedimentation tanks)
- Class A biosolids, **1.689–690**
- Class B biosolids, **1.690**
- Clean Lakes Program (CLP), **1.175–203**  
     diagnostic/feasibility study (phase 1),  
         **1.177–179**  
     eligibility for financial assistance, **1.175**  
     implementation (phase 2), **1.180**  
     in-lake monitoring, **1.181–188**  
     lake budgets, **1.197–200**  
     lake use support analysis, **1.191–197**  
     objectives of, **1.175**  
     post-restoration monitoring (phase 3),  
         **1.180**  
     soil loss rate, **1.201–203**  
     state lake classification survey, **1.175–177**  
     trophic state index, **1.188–190**  
     types of funds, **1.175**  
     watershed protection approach,  
         **1.180–181**
- Clean Water Act (CWA), **1.175, 191, 192**
- Clean-side fans, **3.130**
- Closed systems, **2.127**
- Coagulation (water supply), **1.357–363**
- Coal ash, **2.441** (*See also* Ash stabilization)
- Coal combustion emission factors, **3.22**
- Coal desulfurization, **3.102**
- Coal gas gasification, **3.103–104**
- Coal liquefaction, **3.104**
- Code of Federal Registration (CFR), **1.677, 678, 688**
- Coefficients:  
     of contraction, **1.267**  
     of correlation, **1.60–63, 65**  
     of diffusion, **1.138, 234**  
     of dilution, **1.426**  
     of discharge, **1.267, 299, 301, 302, 490**  
     of drag, **1.364, 367, 376**  
     of endogenous decay, **1.523**

Coefficients (*Cont.*):

- of entrance, **1.267**
  - of internal friction of backfill, **1.481**
  - of oxygen saturation, **1.564**
  - of permeability, **1.214, 216, 218, 219**
  - of regression, **1.60**
  - of retention capacity of soil, **1.235**
  - of roughness, **1.258, 259, 289**
  - of runoff, **1.467**
  - of storage of aquifers, **1.222, 223**
  - of surface roughness, **1.473**
  - of transmissibility, **1.223**
  - of variance, **1.468**
- Coldwell-Lawrence diagrams, **1.383**
- Coliform density, **1.154–160**
- Collection efficiency, **2.13–15**
- baghouses, **3.209**
  - electrostatic precipitators, **3.188–189**
  - emission control systems, **2.356–358**
  - venturi scrubbers, **3.230–241**
- Collection forces, particulate emissions, **3.143–146**
- Collins-Selleck model, **1.616–618**
- Combination liquid-/gas-phase wet scrubbers, **3.280–286**
- Combined available chlorine, **1.421**
- Combined carbon oxidation, **1.636, 638, 639, 644–648**
- Combined kinetic expression for nitrification, **1.639–640**
- Combined nitrification in attached growth reactors, **1.644–648**
- Combined sewers, **1.458–459**
- Combustion, **2.15, 181–183**
- air required for (*see* Combustion air)
  - basic principles of, **2.148**
  - calculations for processes, **2.317–333**
  - of carbon tetrachloride with methane gas, **2.191–193**
  - of chlorinated compounds, **2.180–181**
  - complete, **2.152–156**
  - correction factors in, **2.175–177**
  - efficiency of, **2.177–180**
  - enthalpy, **2.319**
  - F*-factor for stoichiometric combustion, **2.327–328**
  - fuel, **2.148–149**
  - heat balance, **2.317–318, 323–327**
  - heat of, **2.33–35, 123**
  - ignition temperatures for, **2.122**

Combustion (*Cont.*):

- incineration vs., **2.15**
  - incomplete, **2.157**
  - lean, **2.68**
  - mixing in, **2.128**
  - molar weights of common compounds for, **2.63**
  - oxygen amount for, **2.68–69**
  - of propane, **2.181–191**
  - rich, **2.68**
  - specific heat, **2.318–319**
  - temperature, **2.319–322**
    - adding excess air to control furnace exit temperature, **2.320–321**
    - hazardous waste incinerators, **2.305, 307–311**
    - heat loss estimation, **2.322**
    - mass balance to achieve 1800° gas temperature, **2.321–322**
    - theoretical air for complete combustion, **2.320**
  - of waste fuel of several components, **2.193–197**
  - of waste with feeding rate of 300 lb/h, **2.198–199**
    - (*See also* Incineration)
- Combustion air, **2.159, 178–179, 327, 329–333** (*See also* Air combustion)
- Combustion constants, **2.173–174**
- Combustion controls, **2.348–349**
- Combustion efficiency (CE), **2.177–180**
- Combustion limits (flammability), **2.29**
- Combustion modification, **3.98–100**
- Combustion process monitoring, **2.564–569**
- Combustion systems:
- components of, **2.171–173**
  - design of, **2.333**
  - resource recovery systems (*see* Resource recovery systems)
  - (*See also* Waste combustion systems)
- Commercial waste combustion, **2.334–335**
- Comminutors, **1.490**
- Complete (stoichiometric) combustion, **2.152–156, 327, 328**
- Complete incineration, **2.156–157**
- Complete mix (activated sludge), **1.522–525, 527–533, 554**
- Complete mixing, **1.138, 145, 361–362, 545**
- Complete vacuum, **2.70**
- Completeness (of measures), **1.68**

- Compliance standards:  
 for drinking water, 1.324–332  
 for wastewater effluent, 1.131, 486–487  
 (*See also* Regulations)
- Composting (sludge stabilization), 1.677
- Compressed liquids, 2.88
- Compression settling, 1.506–507
- Concentration, conversion of units for, 1.5
- Concentration factor, 1.657–658, 661
- Concentration standards, 3.10–12
- Condensation (gaseous emissions), 3.86–96  
 basic processes, 3.86–87  
 contact condensers, 3.86–89, 92  
 surface condensers, 3.89–92
- Conduction (heat), 2.37–39
- Cone of depression, 1.208–211, 223,  
 237–238
- Cones, volume of, 1.28
- Confined aquifers, 1.207, 208, 717–722
- Constant percentage growth rate, 1.317
- Constant pressure heat capacity, 2.32
- Constant pressure specific heat, 2.77
- Constant volume heat capacity, 2.32
- Constant volume specific heat, 2.77
- Contact condensers, 3.86–89, 92
- Contact power theory, 3.237–240
- Contact stabilization (activated sludge),  
 1.556–557
- Contact time:  
 in *CT* value, 1.426–429, 439  
 and DO concentration, 1.342  
 in effluent disinfection, 1.611, 615–618  
 in flocculation, 1.363  
 of GAC and water, 1.407  
 in with RBCs, 1.591  
 in recarbonation basin, 1.625  
 and retention time, 1.462
- Containerized solid wastes, 2.546
- Contaminant transport (pathway),  
 1.233–235
- Contamination:  
 and adsorption performance, 3.51  
 of drinking water, 1.325, 331  
 of groundwater, 1.233–236  
 (*See also* Pollutants)
- Continuous feed two-chamber waste  
 incinerator with heat recovery boiler,  
 2.336, 338
- Control mass, 2.127
- Controlled-air combustion (*see* Starved-air  
 combustion/incineration)
- Controlled-air incinerators, 2.493, 495–498
- Convection (heat), 2.38–43
- Conventional process:  
 for activated-sludge, 1.550–552  
 for nitrogen control, 1.633–635
- Conversion:  
 common conversion factors, 2.384  
 of measurements, 1.3–8  
 between wet and dry basis analyses, 2.23
- Cooper-Jacob method (unsteady flows),  
 1.225–226
- Copper, 1.723  
 coefficient of roughness for,  
 1.259, 261  
 in drinking water, 1.326, 331  
 in runoff, 1.468  
 in sewage biosolids, 1.691, 696
- Copper sulfate, 1.185–186
- Cornfield, 1.698–702
- Correction-factor:  
 for altitude, 1.573  
 in channel dam reaeration, 1.142  
 and *CT* value determination, 1.428, 435  
 for DO saturation concentrations, 1.77  
 elevation, 1.107  
 in gas transfer models, 1.341, 342  
 in Hardy-Cross method, 1.274  
 for larger flumes, 1.307  
 for nitrogenous *KN* in wastewater effluent,  
 1.127  
 for oxygen transfer, 1.569  
 pH, 1.640  
 in QA plan, 1.65  
 for resin, 1.396, 399  
 for salinity surface tension, 1.569  
 for surface area in wastewater treatment,  
 1.595  
 temperature, 1.334, 640  
 water quality, 1.144
- Cost of pumping (CP), 1.279–281
- Countercurrent flow absorber, 3.29
- Crematory waste incinerators, 2.337
- Critical depth (water flow), 1.292–294
- Critical point (vapor mixtures), 2.88, 89
- Critical point of oxygen sag curve,  
 1.119–130
- Critical pressure (vapor mixtures), 2.89
- Critical state (vapor mixtures), 2.88, 89
- Critical temperature (vapor mixtures), 2.89
- Critical time ( $t_c$ ), 1.119
- Critical value for DO deficiency, 1.119, 564

- Critical velocity, 1.292, 293, 378  
 Crossflow absorbers, 3.268–270  
*Cryptosporidium*, 1.427  
*CT* (concentration x contact time) values, 1.427–439  
 Cumulative distribution curve, 3.154–156  
 Cycle (cyclic) processes, 2.127  
 Cyclones, 3.177–186  
   arrangement of, 3.182–186  
   design factors, 3.179–180  
   performance factors, 3.180–182  
   types of, 3.178, 179  
 Cyclonic separators, 2.354; 3.292, 293  
 Cyclonic spray scrubbers, 3.280–281  
 Cylinders, area and volume of, 1.27  
 Cylindrical adsorbers, 3.52–54
- Daily difference method, 1.84  
 Dairy products, COPC concentration estimates for, 4.56–58  
 Dalton's law, 1.333, 2.80  
 Dams, 1.141–143  
 Darcy's law, 1.213–217, 233  
 Darcy-Weisback equation, 1.254, 256–258, 263  
 Data quality indicators, 1.65–69  
   accuracy, 1.68  
   bias, 1.65  
   completeness, 1.68  
   method detection limit, 1.68–69  
   precision, 1.66–68  
 Dechlorination (wastewater), 1.614–615  
 Declining growth method (estimation), 1.318  
 Deep shaft reactor (activated sludge), 1.562–563  
 Deficient air combustion, 2.165–166  
   (See also Starved-air combustion/incineration)  
 Denitrification, 1.648–652  
   with RBC, 1.650–652  
   (See also Nitrogen control)  
 Denitrogenation, fuel, 3.97, 98  
 Density ( $\rho$ ), 1.31–33; 2.15–17  
   air, 2.5  
   algal, 1.65, 153  
   of backfill, 1.481  
   bacterial, 1.13, 155–161, 181, 192, 457, 516, 606, 611, 613, 616, 618, 689–690  
   conversion of units for, 1.7  
   of fluid in pipes, 1.251  
   Density ( $\rho$ ) (*Cont.*):  
     of GAC, 1.406  
     of grit, 1.491  
     of HCl, 1.41  
     mass, 1.247, 364  
     microbial, 1.426, 589  
     of organic loading, 1.147, 615  
     of perfect gas, 1.249  
     population, 1.458, 466  
     of sand, 1.379  
     for screening, 1.490  
     of sediment particles, 1.367, 370, 495  
     silt density index, 1.413  
     sludge, 1.416–417, 539–540  
     of soil, 1.234  
     of solutions, 1.34  
     and specific gravity, 1.31–33  
     and specific weight, 1.244  
     stack gas, 2.392  
     water, 1.7, 8, 13, 31, 32, 248, 336, 367, 368, 376  
     of water plant residuals, 1.416–417  
 Deoxygenation coefficient ( $K_2$ ), 1.80, 103, 115  
 Deoxygenation rate, 1.84–95  
   in field, 1.112  
   in laboratory, 1.112  
   logarithmic formula, 1.93–94  
   moment method, 1.88–93  
   rapid methods, 1.94–95  
   slope method, 1.85–87  
   streams and rivers, 1.84–95, 104  
   temperature effect on, 1.95–98  
 Depressed sewers (inverted siphons), 1.475–477  
 Design:  
   of packed towers, 1.345–351  
   of storm drainage systems, 1.464  
 Design average flow (wastewater), 1.462  
 Design peak flow (wastewater), 1.462  
 Design wastewater flow rates, 1.461–462  
 Destruction and removal efficiency (DRE), 2.9, 17–20  
   calculation of, 2.381–383  
   for hazardous waste compliance, 2.294–298  
   public perception of, 2.151  
 Desulfurization, 3.102, 104–115  
 Detention time, 1.48  
 Detention time multiplier, 1.508–509

- Determination:
- of  $CT$  values, 1.427–439
  - of deoxygenation rate  $k_d$ , 1.113
  - of excess air, 3.15–17
  - $K_1$  and BOD, 1.81–102
  - of  $k_r$ , 1.118–119
  - of lateral radius of influence, 1.238–240
    - direct measurement method, 1.239
    - Theis equation method, 1.239–240

 Liquid residue incineration, 3.127  
 Liquid saturation line, 2.89  
 Liquid waste combustion systems:  
   standards compliance calculations,  
   2.408–411  
   waste feed, 2.546

- Liquid wastes, 2.334
- Liquid-phase contacting wet scrubbers, 3.260–266
- Loading, defined, 2.13
- Loading point (absorption), 3.31
- Loading rate:
  - annual pollutant loading rate for biosolids, 1.691
  - areal (stabilization ponds), 1.599–602
  - conversion of units for, 1.5–6
  - of nitrification, 1.638
  - sludge, 1.680, 685
  - solids, 1.506, 608–610, 657, 660–661, 666–667, 672–678, 687
  - street and road runoff, 1.470–471
  - surface (overflow), 1.370–372, 498, 619
  - surface (water pumping), 1.49
- Loads:
  - heat, 2.31–32
  - on sewer lines, 1.480–482
    - for buried sewers, 1.480–482
    - for trench condition, 1.481–482
- Logarithms, 1.9–10
- Logistic curve method (water supply population estimates), 1.318–319
- Log-log regression, 1.63
- Log-normal distribution, 3.155, 157–166
- Low heating value (LHV), 2.48–51, 180
- Low NO<sub>x</sub> burners, 3.100
- Low voltage two-stage ESPs, 3.187–188
- Lower explosive limit (LEL), 2.29
- Lower heating value (LHV), 2.48
- Ludzack-Ettinger process (nitrogen removal), 1.632
- Macroinvertebrate biotic index (MBI), 1.162
- Macroinvertebrate tolerance list (IEPA), 1.711–715
- Macrophytes:
  - in lake use support analysis, 1.191–196
  - in lakes and reservoirs, 1.177, 178, 181, 187
  - in streams and rivers, 1.75, 111
- Magnesium oxide scrubbers, 3.113
- Manganese removal (water supply), 1.402–405
- Manganese zeolite process, 1.404–405
- Manholes, 1.474–475
- Manning equation, 1.258, 259, 261–263, 282–284
- Manufacturers' empirical design approach (RBCs), 1.592–598
