Volume 1

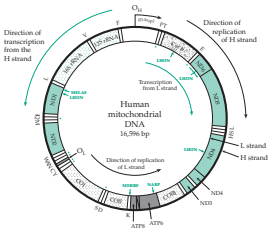
A Brief Table of Contents *Volume 2*

Volume 1

Chapter 1
The Scene of Action

Chapter 2
Amino Acids, Peptides, and Proteins

Chapter 3
Determining Structures and Analyzing Cells



Volume 2

Chapter 17
The Organization of Metabolism

Chapter 18
Electron Transport, Oxidative Phosphorylation, and Hydroxylation

Chapter 24
The Metabolism of Nitrogen and Amino Acids

Chapter 25
Metabolism of Aromatic Compounds and Nucleic Acid Bases

Chapter 26
Biochemical Genetics

Preface

When Volume I was published early in 2001 I thought that Volume II would be ready by the end of the same year. However, updating the first edition to cover the major aspects of the rapidly expanding scope of Biochemistry was more difficult than I had imagined. This second volume brings many topics up-to-date. The first chapter (Chapter 17), which has been available on the Web, is an introduction to metabolism, more extensive than that in Chapter 10. This is followed by specialized chapters on oxidative metabolism, muscle chemistry, and on selected aspects of the metabolism of carbohydrates, lipids, and polyprenyl compounds. Chapter 23 deals with light, photochemistry, and photobiology. Chapter 24 describes metabolism of nitrogen fixation, amino acid synthesis and degradation and chemistry of other nitrogenous compounds. Chapter 25 provides a summary of biosynthesis and catabolism of aromatic compounds including the nucleic acid bases. Chapters 26–29 deal with molecular genetics and the biosynthesis and metabolism of DNA, RNA, and proteins. Chapters 30–32 are introductions to the chemistry of intercellular signaling, brain chemistry, immunochemistry, and development.

Volume II contains a huge amount of information. However, it represents only a tiny fraction of the biochemical knowledge presently available. The many references given may help the reader to get started in consulting this literature. However, the references provide neither a comprehensive review of literature nor an accurate historical record. I hope that my fellow biochemists will forgive me where I have failed to cite their favorite articles. The main purpose of the references is to document the material that I used in preparing the text. The coverage is limited. I used a selection of journals that I could scan quickly, hoping to provide a broad view. However, there are now hundreds of journals that contain biochemical information. An important entrance to this literature is via the World Wide Web, which by now may contain ~10^{11} pages of information. (See D. Butler, *Nature*, **405**, 112-115, 2000). I especially recommend *http://highwire.stanford.edu* which provides free of charges both abstracts and full articles from many journals. I hope that you will read many original papers and not only reviews. Above all I hope that this book will help you to find excitement in the many scientific discoveries that are reported week after week. I am especially appreciative of the efforts made by our artist David J. Sauke, who died suddenly on November 6, 2002. He was designer, artist, compositor, and close friend. I am indebted to Robert R. Louden, Emily L. Osam, and Kim McDermott for taking over David's responsibilities and allowing us to complete the volume in a timely fashion.

Acknowledgments

I wish to express my appreciation to the following reviewers, each of whom read parts of the manuscript, for their generous assistance: George M. Carman, Rutgers University; Guillaume Chanfreau, University of California-Los Angeles; Eric Conn, University of California-Davis; Gloria Culver, Iowa State University; David Daleke, Indiana University; John Golbeck, University of Pennsylvania; Richard Gumport, University of Illinois, Champaign-Urbana; Jack Horowitz, Iowa State University; Craig Jackson, Hemosaga Diagnostics Corporation; Jørgen Johansen, Iowa State University; L. Andrew Lyon, Georgia Institute of Technology; Eric C. Niederhoffer, Southern Illinois University; Jim Olson, Iowa State University; Ivan Rayment, University of Wisconsin; John Robyt, Iowa State University; Kevin Sarge, University of Kentucky; Andrzej Stasiak, Universite de Lausanne; Laurey Steinke, University of Nebraska Medical Center; Marvin Stromer, Iowa State University; Robert W. Thornburg, Iowa State University; Skip Waechter, University of Kentucky.

Special thanks are due Jack Kirsch, University of California, Berkeley and to my colleagues at Iowa State University for providing many of the study questions.

Journal Acknowledgments

The cooperation of the publishers of books and journals in permitting inclusion of material in this book is gratefully acknowledged. The figures listed have been taken directly from the following journals or have been redrawn and adapted from published drawings. The literature citations appear in the chapter bibliographies.

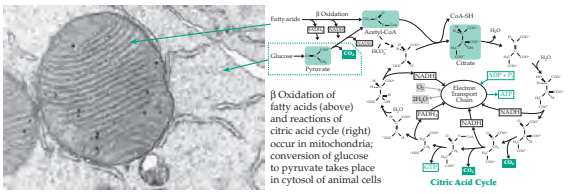
This Page Intentionally Left Blank

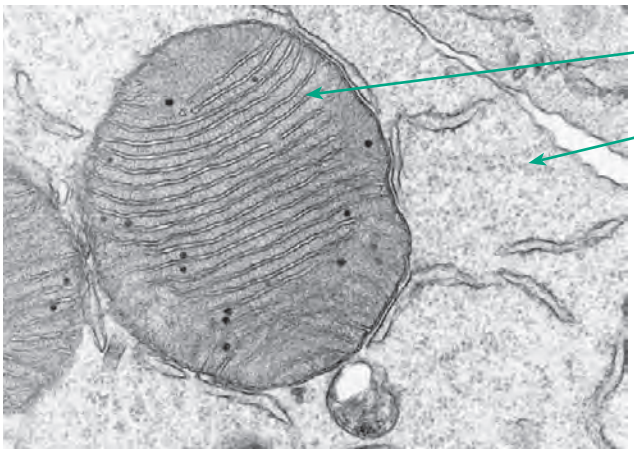


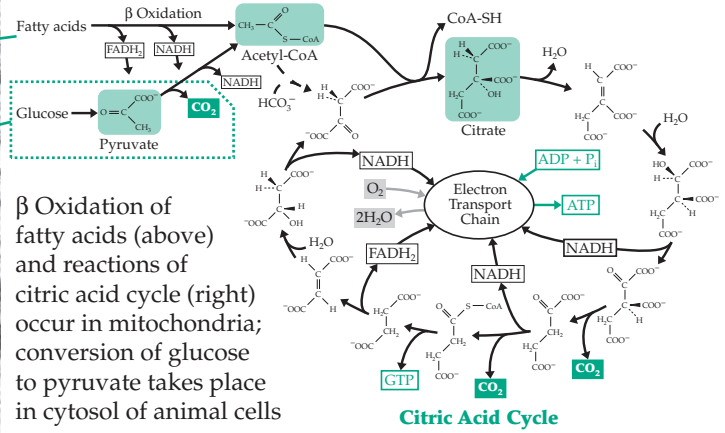
Metabolism, a complex network of chemical reactions, occurs in several different compartments in eukaryotic cells. Fatty acids, a major source of energy for many human cells, are oxidized in the mitochondria via β oxidation and the citric acid cycle. Glucose, a primary source of energy, is converted to pyruvate in the cytosol. Biosynthetic reactions occurring in both compartments form proteins, nucleic acids, storage polymers such as glycogen, and sparingly soluble lipid materials which aggregate to form membranes. Hydrophobic groups in proteins and other polymers also promote self-assembly of the cell. At the same time, oxidative processes, initiated by O_2, increase the water solubility of molecules, leading to metabolic turnover. Micrograph courtesy of Kenneth Moore.

Contents

The Organization of Metabolism

17





β Oxidation of fatty acids (above) and reactions of citric acid cycle (right) occur in mitochondria; conversion of glucose to pyruvate takes place in cytosol of animal cells

Metabolism involves a bewildering array of chemical reactions, many of them organized as complex cycles which may appear difficult to understand. Yet, there is logic and orderliness. With few exceptions, metabolic pathways can be regarded as sequences of the reactions considered in Chapters 12–16 (and summarized in the table inside the back cover) which are organized to accomplish specific chemical goals. In this chapter we will examine the chemical logic of the major pathways of catabolism of foods and of cell constituents as well as some reactions of biosynthesis (anabolism). A few of the sequences have already been discussed briefly in Chapter 10.

A. The Oxidation of Fatty Acids

Hydrocarbons yield more energy upon combustion than do most other organic compounds, and it is, therefore, not surprising that one important type of food reserve, the fats, is essentially hydrocarbon in nature. In terms of energy content the component fatty acids are the most important. Most aerobic cells can oxidize fatty acids completely to CO_2 and water, a process that takes place within many bacteria, in the matrix space of animal mitochondria, in the peroxisomes of most eukaryotic cells, and to a lesser extent in the endoplasmic reticulum.

The carboxyl group of a fatty acid provides a point for chemical attack. The first step is a priming reaction in which the fatty acid is converted to a water-soluble acyl-CoA derivative in which the α hydrogens of the fatty acyl radicals are "activated" (step *a*, Fig. 17-1). This synthetic reaction is catalyzed by **acyl-CoA synthetases** (fatty acid:CoA ligases). It is driven by the hydrolysis of ATP to AMP and two inorganic phosphate ions using the sequence shown in Eq. 10-1 (p. 508). There are isoenzymes that act on short-, medium-, and long-chain fatty acids. Yeast contains at least five of these.[1] In every case the acyl group is activated through formation of an intermediate acyl adenylate; hydrolysis of the released pyrophosphate helps to carry the reaction to completion (see discussion in Section H).

1. Beta Oxidation

The reaction steps in the oxidation of long-chain acyl-CoA molecules to acetyl-CoA were outlined in Fig. 10-4. Because of the great importance of this β oxidation sequence in metabolism the steps are shown again in Fig. 17-1 (steps *b*–*e*). The chemical logic becomes clear if we examine the structure of the acyl-CoA molecule and consider the types of biochemical reactions available. If the direct use of O_2 is to be avoided, the only reasonable mode of attack on an acyl-CoA molecule is dehydrogenation. Removal of the α hydrogen as a proton is made possible by the activating effect of the carbonyl group of the thioester. The β hydrogen can be transferred from the intermediate enolate, as a hydride ion, to the bound FAD present in the **acyl-CoA dehydrogenases** that catalyze this reaction[2–5] (step *b*, Fig. 17-1; see also Eq. 15-23). These enzymes contain FAD, and the reduced coenzyme $FADH_2$ that is formed is reoxidized by an **electron transferring flavoprotein** (Chapter 15), which also contains FAD. This protein carries the electrons abstracted in the oxidation process to the inner membrane of the mitochondrion where they enter the mitochondrial electron transport system,[5a] as depicted in Fig. 10-5 and as discussed in detail in

Chapter 18.

The product of step *b* is always a **trans-Δ^2-enoyl-CoA**. One of the few possible reactions of this unsaturated compound is nucleophilic addition at the β position. The reacting nucleophile is an HO^- ion from water. This reaction step (step *c*, Fig. 17-1) is completed by addition of H^+ at the α position. The resulting **β-hydroxyacyl-CoA** (3-hydroxyacyl-CoA) is dehydrogenated to a ketone by NAD^+ (step *d*).[5b] This series of three reactions is the β oxidation sequence.

At the end of this sequence, the β-oxoacyl-CoA derivative is cleaved (Fig. 17-1, step *e*) by a **thiolase** (see also Eq. 13-35). One of the products is acetyl-CoA, which can be catabolized to CO_2 through the citric acid cycle. The other product of the thiolytic cleavage is an acyl-CoA derivative that is *two carbon atoms shorter than the original acyl-CoA*. This molecule is recycled through the β oxidation process, a two-carbon acetyl unit being removed as acetyl-CoA during each turn of the cycle (Fig. 17-1). The process continues until the fatty acid chain is completely degraded. If the original fatty acid contained an *even* number of carbon atoms in a straight chain, acetyl-CoA is the only product. However, if the original fatty acid contained an *odd* number of carbon atoms, **propionyl-CoA** is formed at the end.

For every step of the β oxidation sequence there is a small family of enzymes with differing chain length preferences.[6,7] For example, in liver mitochondria one acyl-CoA dehydrogenase acts most rapidly on *n*-butyryl and other short-chain acyl-CoA; a second prefers a substrate of medium chain length such as *n*-octanoyl-CoA; a third prefers long-chain substrates such as palmitoyl-CoA; and a fourth, substrates with 2-methyl branches. A fifth enzyme acts specifically on isovaleryl-CoA. Similar preferences exist for the other enzymes of the β oxidation pathway. In *Escherichia coli*

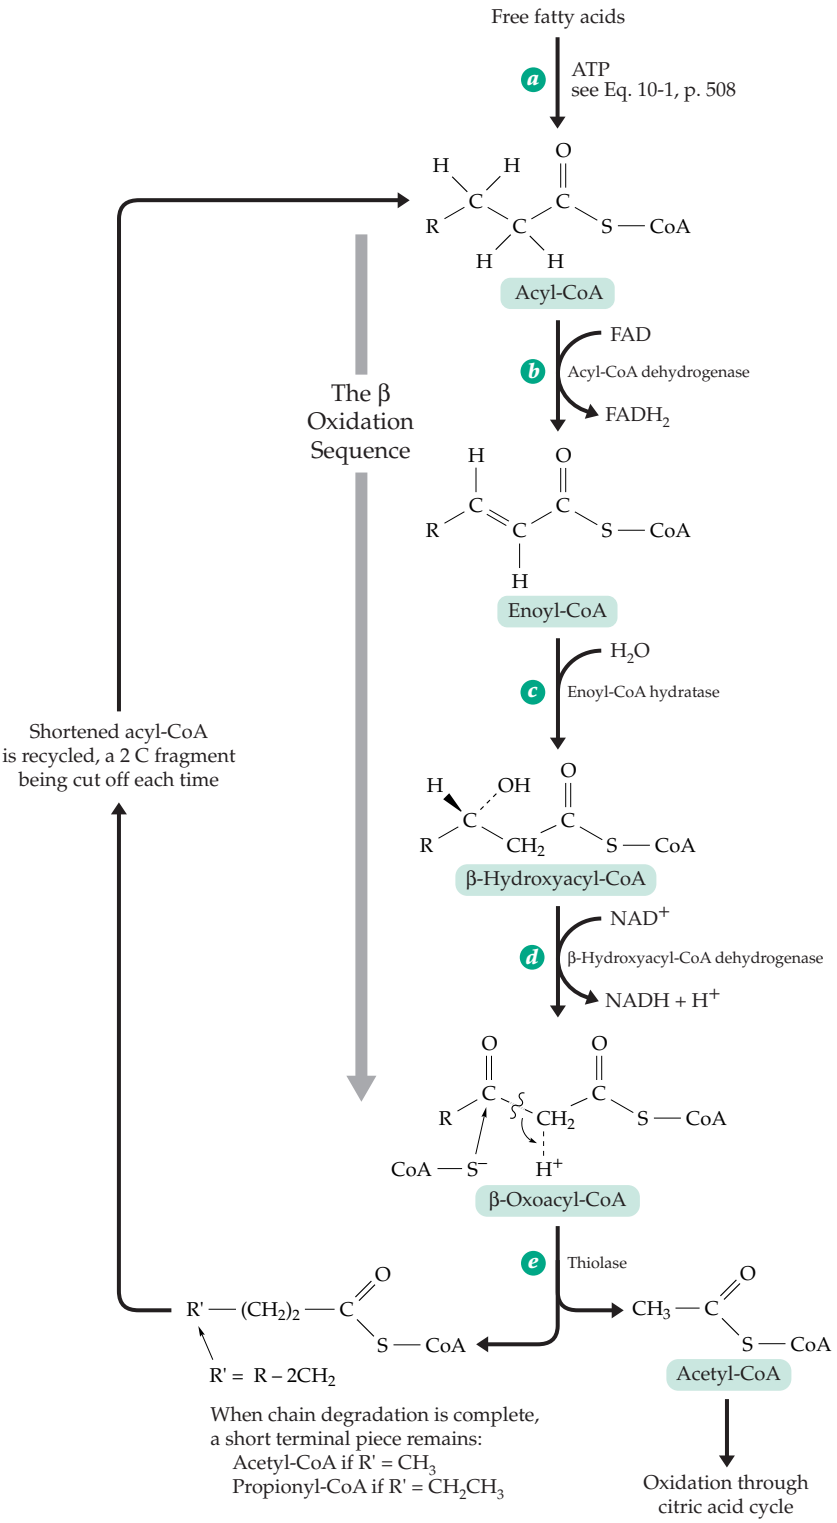


Figure 17-1 The β oxidation cycle for fatty acids. Fatty acids are converted to acyl-CoA derivatives from which 2-carbon atoms are cut off as acetyl-CoA to give a shortened chain which is repeatedly sent back through the cycle until only a 2- or 3-carbon acyl-CoA remains. The sequence of steps *b*, *c*, and *d* also occurs in many other places in metabolism.

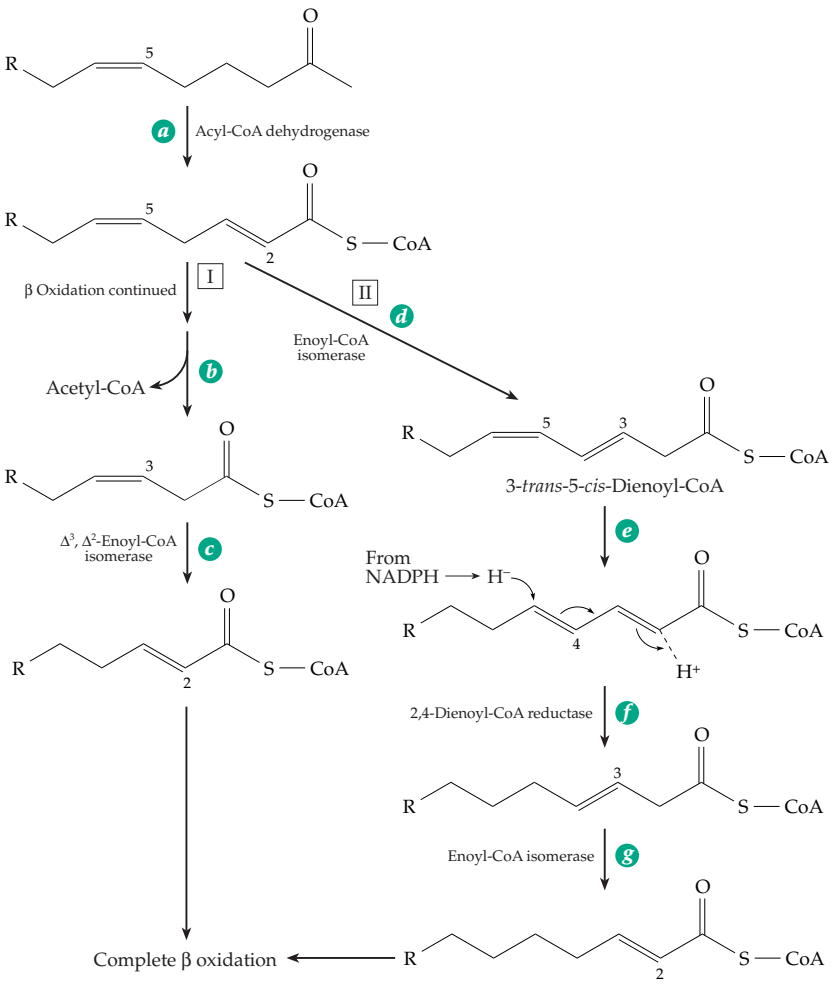
most of these enzymes are present as a complex of multifunctional proteins[8] while the mitochondrial enzymes may be organized as a multiprotein complex.[9,10]

Peroxisomal beta oxidation. In animal cells β oxidation is primarily a mitochondrial process,[5] but it also takes place to a limited extent within peroxisomes and within the endoplasmic reticulum.[11–14] This "division of labor" is still not understood well. Straight-chain fatty acids up to 18 carbons in length appear to be metabolized primarily in mitochondria, but in the liver fatty acids with very long chains are processed largely in peroxisomes.[13] There, a very long-chain acyl-CoA synthetase acts on fatty acids that contain 22 or more carbon atoms.[15] In yeast all β oxidation takes place in peroxisomes,[15,16] and in most organisms, including green plants,[17–18a] the peroxisomes are the most active sites of fatty acid oxidation. However, animal peroxisomes cannot oxidize short-chain acyl-CoA molecules; they must be returned to the mitochondria.[16] The activity of peroxisomes in β oxidation is greatly increased by the presence of a variety of compounds known as **peroxisome proliferators**. Among them are drugs such as aspirin and clofibrate and environmental xenobiotics such as the plasticizer bis-(2-ethyl-hexyl)-phthalate. They may induce as much as a tenfold increase in peroxisomal β oxidation.[11,12,19,19a]

Several other features also distinguish β oxidation in peroxisomes. The peroxisomal flavoproteins that catalyze the dehydrogenation of acyl-CoA molecules to unsaturated enoyl-CoAs (step *b* of Fig. 17-1) are **oxidases** in which the $FADH_2$ that is formed is reoxidized by O_2 to form H_2O_2.[13,20] In peroxisomes the enoyl-hydratase and the NAD^+-dependent dehydrogenase catalyzing steps *c* and *d* of Fig. 17-1 are present together with an enoyl-CoA isomerase (next section) as a trifunctional enzyme consisting of a single polypeptide chain.[21] As in mitochondrial β oxidation the 3-hydroxyacyl-CoA intermediates formed in both animal peroxisomes and plant peroxisomes (glyoxysomes) have the L configuration. However, in fungal peroxisomes as well as in *E. coli* they have the D configuration.[22,23] Further metabolism in these organisms requires an epimerase that converts the D-hydroxyacyl-CoA molecules to L.[24] In the past it has often been assumed that peroxisomal membranes are freely permeable to NAD^+, NADH, and acyl-CoA molecules. However, genetic experiments with yeast and other recent evidence indicate that they are impermeable *in vivo* and that carrier and shuttle mechanisms similar to those in mitochondria may be required.[14,25]

Unsaturated fatty acids. Mitochondrial β oxidation of such unsaturated acids as the Δ^9-oleic acid begins with removal of two molecules of acetyl-CoA to form a Δ^5-acyl-CoA. However, further metabolism is slow. Two pathways have been identified (Eq. 17-1).[26–29b] The first step for both is a normal dehydrogenation to a 2-*trans*-5-*cis*-dienoyl-CoA. In pathway I this intermediate reacts slowly by the normal β oxidation sequence to form a 3-*cis*-enoyl-CoA intermediate which must then be acted upon by an auxiliary enzyme, a *cis*-Δ^3-*trans*-Δ^2-enoyl-CoA isomerase (Eq. 17-1, step *c*), before β oxidation can continue.

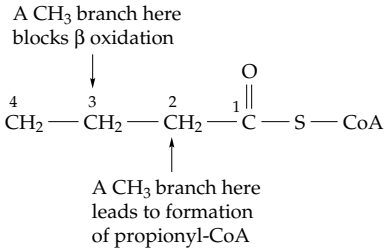
The alternative reductase pathway (II in Eq. 17-1) is often faster. It makes use of an additional isomerase which converts 3-*trans*, 5-*cis*-dienoyl-CoA into the 2-*trans*, 4-*trans* isomer in which the double bonds are conjugated with the carbonyl group.[29] This permits removal of one double bond by reduction with NADPH as shown (Eq. 17-1, step *f*).[29a,29b] The peroxisomal



(17-1)

pathway is similar.[21] However, the intermediate formed in step *e* of Eq. 17-1 may sometimes have the 2-*trans*, 4-*cis* configuration.[17] The NADH for the reductive step *f* may be supplied by an NADP-dependent isocitrate dehydrogenase.[29c] Repetition of steps *a*, *d*, *e*, and *f* of Eq. 17-1 will lead to β oxidation of the entire chain of polyunsaturated fatty acids such as linoleoyl-CoA or arachidonoyl-CoA. Important additional metabolic routes for polyunsaturated fatty acid derivatives are described in Chapter 21.

Branched-chain fatty acids. Most of the fatty acids in animal and plant fats have straight unbranched chains. However, branches, usually consisting of methyl groups, are present in lipids of some microorganisms, in waxes of plant surfaces, and also in polyprenyl chains. As long as there are not too many branches and if they occur only in the even-numbered positions (i.e., on carbons 2, 4, etc.) β oxidation proceeds normally. Propionyl-CoA is formed in addition to acetyl-CoA as a product of the chain degradation. On the other hand, if methyl groups occur in positions 3, 5, etc., β oxidation is blocked at step *d* of Fig. 17-1. A striking example of the effect of such blockage was

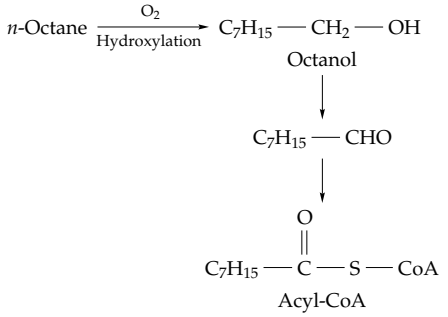


provided by the synthetic detergents in common use until about 1966. These detergents contained a hydrocarbon chain with methyl groups distributed more or less randomly along the chain. Beta oxidation was blocked at many points and the result was a foamy pollution crisis in sewage plants in the United States and in some other countries. Since 1966, only biodegradable detergents having straight hydrocarbon chains have been sold.

In fact, cells *are* able to deal with small amounts of these hard-to-oxidize substrates. The O_2-dependent reactions called α oxidation and ω oxidation are used. These are related also to the oxidation of hydrocarbons which we will consider next.

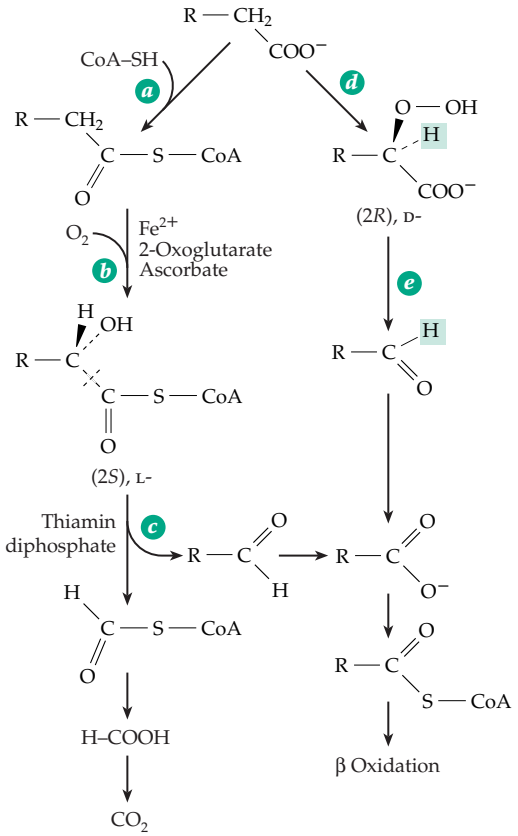
Oxidation of saturated hydrocarbons. Although the initial oxidation step is chemically difficult, the tissues of our bodies are able to metabolize saturated hydrocarbons such as *n*-heptane slowly, and some microorganisms oxidize straight-chain hydrocarbons rapidly.[30,31] Strains of *Pseudomonas* and of the yeast *Candida* have been used to convert petroleum into edible proteins.[9]

The first step in oxidation of alkanes is usually an O_2-requiring **hydroxylation** (Chapter 18) to a primary alcohol. Further oxidation of the alcohol to an acyl-CoA derivative, presumably via the aldehyde (Eq. 17-2), is a frequently encountered biochemical oxidation sequence.



(17-2)

Alpha oxidation and omega oxidation. Animal tissues degrade such straight-chain fatty acids as palmitic acid, stearic acid, and oleic acid almost entirely by β oxidation, but plant cells often oxidize fatty acids one carbon at a time. The initial attack may involve hydroxylation on the α-carbon atom (Eq. 17-3) to form either the D- or the L-2-hydroxy acid.[17,18,32,32a] The L-hydroxy acids are oxidized rapidly, perhaps by dehydrogenation to the oxo acids (Eq. 17-3, step *b*) and oxidative decarboxylation, possibly utilizing H_2O_2 (see Eq. 15-36). The D-hydroxy acids tend to accumulate



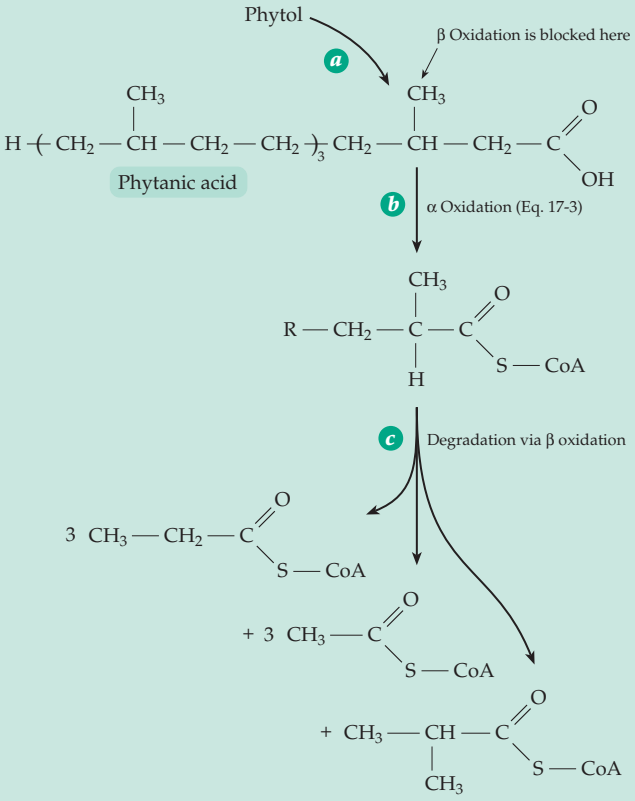
(17-3)

and are normally present in green leaves. However, they too are oxidized further, with retention of the α hydrogen as indicated by the shaded squares in Eq. 17-3, step *e*. This suggests a new type of dehydrogenation with concurrent decarboxylation. Alpha oxidation also occurs to some extent in animal tissues. For example, when β oxidation is blocked by the presence of a methyl side chain, the body may use α oxidation to get past the block (see **Refsum disease**, Box 17-A). As in plants, this occurs principally in the peroxisomes[33–35] and is important for degradation not only of polyprenyl chains but also bile acids. In the brain some of the fatty acyl groups of sphingolipids are hydroxylated to α-hydroxyacyl groups.[36] Alpha oxidation in animal cells occurs after conversion of free fatty acids to their acyl-CoA derivatives (Eq. 7-3, step *a*). This is followed by a 2-oxoglutarate-dependent hydroxylation (step *b*, see also Eq. 18-51) to form the 2-hydroxyacyl-CoA, which is cleaved in a standard thiamin diphosphate-requiring α cleavage (step *c*). The products are formyl-CoA, which is hydrolyzed and oxidized to CO_2, and a fatty aldehyde which is metabolized further by β oxidation.[34a]

In plants α-dioxygenases (Chapter 18) convert free fatty acids into 2(*R*)-hydroperoxy derivatives (Eq. 7-3, step *d*).[32a] These may be decarboxylated to fatty aldehydes (step *e*, see also Eq. 15-36) but may also give rise to a variety of other products. Compounds arising from linoleic and linolenic acids are numerous and include epoxides, epoxy alcohols, dihydroxy acids, short-chain aldehydes, divinyl ethers, and jasmonic acid (Eq. 21-18).[32a]

On other occasions, **omega (ω) oxidation** occurs at the opposite end of the chain to yield a dicarboxylic acid. Within the human body 3,6-dimethyloctanoic acid and other branched-chain acids are degraded largely via ω oxidation. The initial oxidative attack is by a hydroxylase of the cytochrome P450 group (Chapter 18). These enzymes act not only on fatty acids but also on prostaglandins, sterols, and many other lipids. In the animal body fatty acids are sometimes hydroxylated both at the terminal (ω) position and at the next (ω-2 or ω2) carbon. In plants hydroxylation may occur at the ω2, ω3, and ω4 positions as well.[17,37] Dicarboxylates resulting from ω oxidation of straight-chain fatty acids

BOX 17-A REFSUM DISEASE



In this autosomally inherited disorder of lipid metabolism the 20-carbon branched-chain fatty acid **phytanic acid** accumulates in tissues. Phytanic acid is normally formed in the body (step *a* in the accompanying scheme) from the polyprenyl plant alcohol **phytol**, which is found as an ester in the chlorophyll present in the diet (Fig. 23-20). Although only a small fraction of the ingested phytol is oxidized to phytanic acid, this acid accumulates to a certain extent in animal fats and is present in dairy products. Because β oxidation is blocked, the first step (step *b*) in degradation of phytanic acid is α oxidation in peroxisomes.[a] The remainder of the molecule undergoes β oxidation (step *c*) to three molecules of propionyl-CoA, three of acetyl-CoA, and one of isobutyryl-CoA. The disease, which was described by Refsum in 1946, causes severe damage to nerves and brain as well as lipid accumulation and early death.[b–d] This rare disorder apparently results from a defect in the initial hydroxylation. The causes of the neurological symptoms of Refsum disease are not clear, but it is possible that the isoprenoid phytanic acid interferes with prenylation of membrane proteins.[b]

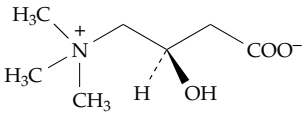
can undergo β oxidation from both ends. The resulting short-chain dicarboxylates, which appear to be formed primarily in the peroxisomes,[38] may be converted by further β oxidation into succinyl-CoA and free succinate.[39] Incomplete β oxidation in mitochondria (Fig. 17-1) releases small amounts of 3(β)-hydroxy fatty acids, which also undergo ω oxidation and give rise to free 3-hydroxydicarboxylic acids which may be excreted in the urine.[40]

2. Carnitine and Mitochondrial Permeability

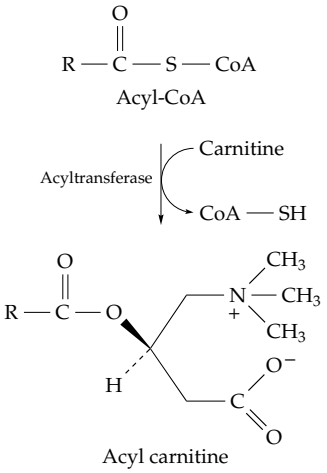
A major factor controlling the oxidation of fatty acids is the rate of entry into the mitochondria. While some long-chain fatty acids (perhaps 30% of the total) enter mitochondria as such and are converted to CoA derivatives in the matrix, the majority are "activated" to acyl-CoA derivatives on the inner surface of the outer membranes of the mitochondria. Penetration of these acyl-CoA derivatives through the mitochondrial inner membrane is facilitated by **L-carnitine**.[41–44]



L-Carnitine

Carnitine is present in nearly all organisms and in all animal tissues. The highest concentration is found in muscle where it accounts for almost 0.1% of the dry matter. Carnitine was first isolated from meat extracts in 1905 but the first clue to its biological action was obtained in 1948 when Fraenkel and associates described a new dietary factor required by the mealworm, *Tenebrio molitor*. At first designated **vitamin B_t**, it was identified in 1952 as carnitine. Most organisms synthesize their own carnitine from lysine side chains (Eq. 24-30). The inner membrane of mitochondria contains a long-chain acyltransferase (carnitine palmitoyltransferase I) that catalyzes transfer of the fatty acyl group from CoA to the hydroxyl group of carnitine (Eq. 17-4).[45–47a] Perhaps acyl carnitine derivatives pass through the membrane more easily than do acyl-CoA derivatives because the positive and negative charges can swing together and neutralize each other as shown in Eq. 17-4. Inside the mitochondrion the acyl group is transferred back from carnitine onto CoA (Eq. 17-4, reverse) by carnitine palmitoyltransferase II prior to initiation of β oxidation.

Tissues contain not only long-chain acylcarnitines but also **acetylcarnitine** and other short-chain acylcarnitines, some with branched chains.[41] By accepting acetyl groups from acetyl-CoA, carnitine causes the release of free coenzyme A which can then be reused.



(17-4)

Thus, carnitine may have a regulatory function. In flight muscles of insects acetylcarnitine serves as a reservoir for acetyl groups. Carnitine acyltransferases that act on short-chain acyl-CoA molecules are also present in peroxisomes and microsomes, suggesting that carnitine may assist in transferring acetyl groups and other short acyl groups between cell compartments. For example, acetyl groups from peroxisomal β oxidation can be transferred into mitochondria where they can be oxidized in the citric acid cycle.[41]

3. Human Disorders of Fatty Acid Oxidation

Mitochondrial β oxidation of fatty acids is the principal source of energy for the heart. Consequently, inherited defects of fatty acid oxidation or of carnitine-assisted transport often appear as serious heart disease (inherited cardiomyopathy). These may involve heart failure, pulmonary edema, or sudden infant death. As many as 1 in 10,000 persons may inherit such problems.[48–50a] The proteins that may be defective include a plasma membrane carnitine transporter; carnitine palmitoyltransferases; carnitine/acylcarnitine translocase; long-chain, medium-chain, and short-chain acyl-CoA dehydrogenases; 2,4-dienoyl-CoA reductase (Eq. 17-1); and long-chain 3-hydroxyacyl-CoA dehydrogenase. Some of these are indicated in Fig. 17-2.

Several cases of genetically transmitted carnitine deficiency in children have been recorded. These children have weak muscles and their mitochondria oxidize long-chain fatty acids slowly. If the inner mitochondrial membrane carnitine palmitoyltransferase II is lacking, long-chain acylcarnitines accumulate in the mitochondria and appear to have damaging effects on membranes. In the unrelated condition of **acute myocardial ischemia** (lack of oxygen, e.g., during a heart attack) there is also a large accumulation of long-chain acylcarnitines.[51,52] These compounds may induce cardiac arrhythmia and may also account for

sudden death from deficiency of carnitine palmitoyltransferase II. Treatment of disorders of carnitine metabolism with daily oral ingestion of several grams of carnitine is helpful, especially for deficiency of the plasma membrane transporter.[50a,53] Metabolic abnormalities may be corrected completely.[50a]

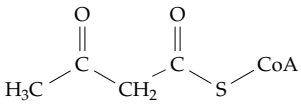
One of the most frequent defects of fatty acid oxidation is deficiency of a mitochondrial acyl-CoA dehydrogenase.[50] If the long-chain-specific enzyme is lacking, the rate of β oxidation of such substrates as octanoate is much less than normal and afflicted individuals excrete in their urine hexanedioic (adipic), octanedioic, and decanedioic acids, all products of ω oxidation.[54] Much more common is the lack of the mitochondrial *medium-chain* acyl-CoA dehydrogenase. Again, dicarboxylic acids, which are presumably generated by ω oxidation in the peroxisomes, are present in blood and urine. Patients must avoid fasting and may benefit from extra carnitine.

A deficiency of very long-chain fatty acid oxidation in peroxisomes is apparently caused by a defective transporter of the ABC type (Chapter 8).[55] The disease, **X-linked adrenoleukodystrophy (ALD)**, has received considerable publicity because of attempts to treat it with "Lorenzo's oil," a mixture of triglycerides of oleic and the C_{22} monoenoic **erucic acid**. The hope has been that these acids would flush out the very long-chain fatty acids that accumulate in the myelin sheath of neurons in the central nervous system and may be responsible for the worst consequences of the disease. However, there has been only limited success.[56,57]

Several genetic diseases involve the development of peroxisomes.[14,35,58,59] Most serious is the **Zellweger syndrome** in which there are no functional peroxisomes. Only "ghosts" of peroxisomes are present and they fail to take up proteins containing the C-terminal peroxisome-targeting sequence SKL.[60,60a] There are many symptoms and death occurs within the first year. Less serious disorders include the presence of catalaseless peroxisomes.[60a]

4. Ketone Bodies

When a fatty acid with an even number of carbon atoms is broken down through β oxidation the last intermediate before complete conversion to acetyl-CoA is the four-carbon **acetoacetyl-CoA**:



Acetoacetyl-CoA

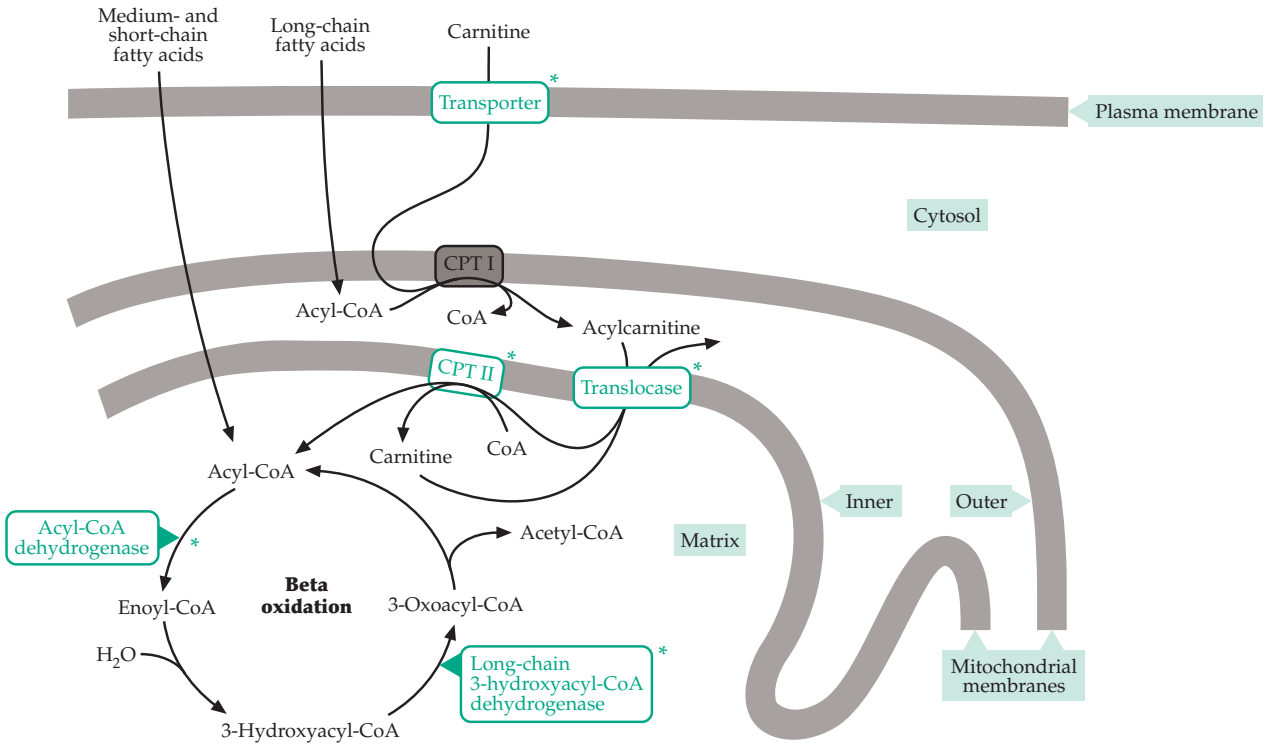


Figure 17-2 Some specific defects in proteins of β oxidation and acyl-carnitine transport causing cardiomyopathy are indicated by the green asterisks. CPT I and CPT II are carnitine palmitoyltransferases I and II. After Kelly and Strauss.[48]

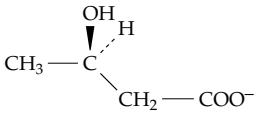
Acetoacetyl-CoA appears to be in equilibrium with acetyl-CoA within the body and is an important metabolic intermediate. It can be cleaved to two molecules of acetyl-CoA which can enter the citric acid cycle. It is also a precursor for synthesis of polyprenyl (isoprenoid) compounds, and it can give rise to free **acetoacetate**, an important constituent of blood. Acetoacetate is a β-oxoacid that can undergo decarboxylation to acetone or can be reduced by an NADH-dependent dehydrogenase to D-3-hydroxybutyrate. Notice that the configuration of this compound is opposite to that of L-3-hydroxybutyryl-CoA which is



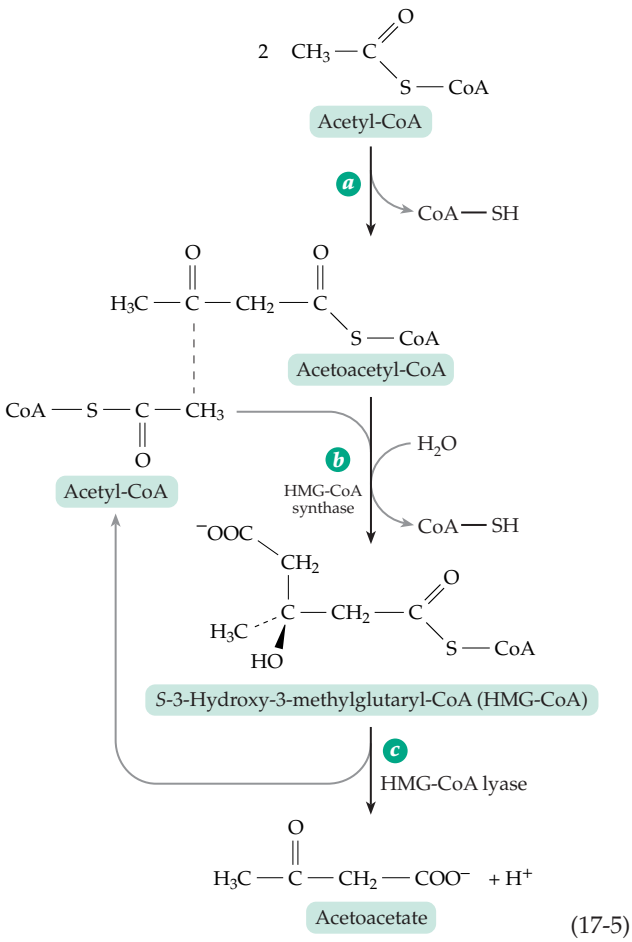
D-3-Hydroxybutyrate

formed during β oxidation of fatty acids (Fig. 17-1). D-3-Hydroxybutyrate is sometimes stored as a polymer in bacteria (Box 21-D).

The three compounds, acetoacetate, acetone, and 3-hydroxybutyrate, are known as **ketone bodies**.[60b] The inability of the animal body to form the glucose precursors, pyruvate or oxaloacetate, from acetyl units sometimes causes severe metabolic problems. The condition known as **ketosis**, in which excessive amounts of ketone bodies are present in the blood, develops when too much acetyl-CoA is produced and its combustion in the critic acid cycle is slow. Ketosis often develops in patients with Type I **diabetes mellitus** (Box 17-G), in anyone with high fevers, and during starvation. Ketosis is dangerous, if severe, because formation of ketone bodies produces hydrogen ions (Eq. 17-5) and acidifies the blood. Thousands of young persons with insulin-dependent diabetes die annually from ketoacidosis.

Rat blood normally contains about 0.07 mM acetoacetate, 0.18 mM hydroxybutyrate, and a variable amount of acetone. These amounts increase to 0.5 mM acetoacetate and 1.6 mM hydroxybutyrate after 48 h of starvation. On the other hand, the blood glucose concentration falls from 6 to 4 mM after 48 h starvation.[61] Under these conditions acetoacetate and hydroxybutyrate are an important alternative energy source for muscle and other tissues.[62,63] Acetoacetate can be thought of as a transport form of acetyl units, which can be reconverted to acetyl-CoA and oxidized in the citric acid cycle.

Some free acetoacetate is formed by direct hydrolysis of acetoacetyl-CoA. In rats, ~11% of the hydroxybutyrate that is excreted in the urine comes from acetoacetate generated in this way.[64] However, most acetoacetate arises in the liver indirectly in a two-step process (Eq. 17-5) that is closely related to the synthesis

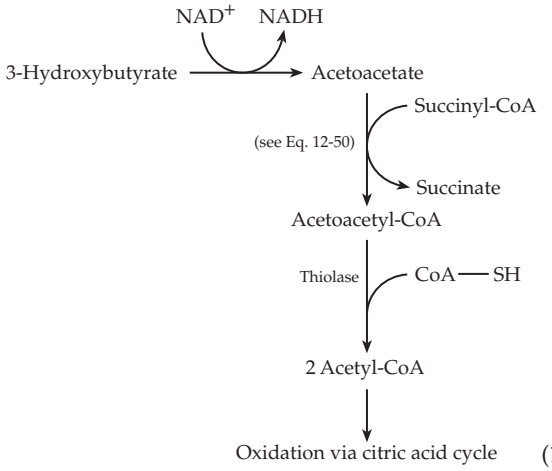


(17-5)

of cholesterol and other polyprenyl compounds. Step *a* of this sequence is a Claisen condensation, catalyzed by 3-hydroxy-3-methyl-glutaryl CoA synthase (HMG-CoA synthase)[64a–c] and followed by hydrolysis of one thioester linkage. It is therefore similar to the citrate synthase reaction (Eq. 13-38). Step *c* is a simple aldol cleavage. The overall reaction has the stoichiometry of a direct hydrolysis of acetoacetyl-CoA. Liver mitochondria contain most of the body's HMG-CoA synthase and are the major site of ketone body formation (**ketogenesis**). Cholesterol is synthesized from HMG-CoA that is formed in the cytoplasm (Chapter 22).

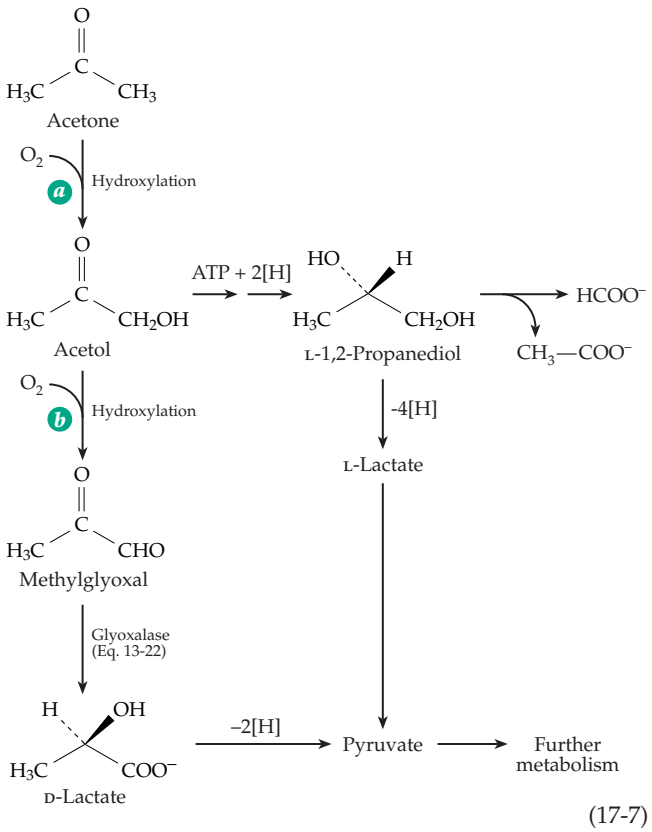
Utilization of 3-hydroxybutyrate or acetoacetate for energy requires their reconversion to acetyl-CoA as indicated in Eq. 17-6. All of the reactions of this sequence may be nearly at equilibrium in tissues that use ketone bodies for energy.[61]

Acetone, in the small amounts normally present in the body, is metabolized by hydroxylation to acetol (Eq. 17-7, step *a*), hydroxylation and dehydration to methylglyoxal (step *b*), and conversion to D-lactate and pyruvate. A second pathway via 1,2-propanediol and L-lactate is also shown in Eq. 17-7. During fasting the acetone content of human blood may rise to as much as 1.6 mM. As much as two-thirds of this may be converted to glucose.[65–69] Accumulation of acetone



(17-6)

appears to induce the synthesis of the hydroxylases needed for methylglyoxal formation,[68] and the pyruvate formed by Eq. 17-7 may give rise to glucose by the gluconeogenic pathway. However, at high acetone concentrations most metabolism may take place through a poorly understood conversion of 1,2-propanediol to acetate and formate or CO_2.[69] No net conversion of acetate into glucose can occur in animals, but isotopic labels from acetate can enter glucose via acetyl-CoA and the citric acid cycle.



(17-7)

B. Catabolism of Propionyl Coenzyme A and Propionate

Beta oxidation of fatty acids with an odd number of carbon atoms leads to the formation of propionyl-CoA as well as acetyl-CoA. The three-carbon propionyl unit is also produced by degradation of cholesterol and other isoprenoid compounds and of isoleucine, valine, threonine, and methionine. Human beings ingest small amounts of free propionic acid, e.g., from Swiss cheese (which is cultivated with propionic acid-producing bacteria) and from propionate added to bread as a fungicide. In **ruminant** animals, such as cattle and sheep, the ingested food undergoes extensive fermentation in the **rumen**, a large digestive organ containing cellulose-digesting bacteria and protozoa. Major products of the rumen fermentations include acetate, propionate, and butyrate. Propionate is an important source of energy for these animals.

1. The Malonic Semialdehyde Pathways

The most obvious route of metabolism of propionyl-CoA is further β oxidation which leads to 3-hydroxypropionyl-CoA (Fig. 17-3, step *a*). This appears to be the major pathway in green plants.[17] Continuation of the β oxidation via steps *a*–*c* of Fig. 17-3 produces the CoA derivative of malonic semialdehyde. The latter can, in turn, be oxidized to malonyl-CoA, a β-oxoacid which can be decarboxylated to acetyl-CoA. The necessary enzymes have been found in *Clostridium kluyveri*,[70] but the pathway appears to be little used.

Nevertheless, malonyl-CoA is a major metabolite. It is an intermediate in fatty acid synthesis (see Fig. 17-12) and is formed in the peroxisomal β oxidation of odd chain-length dicarboxylic acids.[70a] Excess malonyl-CoA is decarboxylated in peroxisomes, and lack of the decarboxylase enzyme in mammals causes the lethal **malonic aciduria**.[70a] Some propionyl-CoA may also be metabolized by this pathway. The modified β oxidation sequence indicated on the left side of Fig. 17-3 is used in green plants and in many microorganisms. 3-Hydroxypropionyl-CoA is hydrolyzed to *free* β-hydroxypropionate, which is then oxidized to malonic semialdehyde and converted to acetyl-CoA by reactions that have not been completely described. Another possible pathway of propionate metabolism is the direct conversion to pyruvate via α oxidation into lactate, a mechanism that may be employed by some bacteria. Another route to lactate is through addition of water to acrylyl-CoA, the product of step *a* of Fig. 17-3. The water molecule adds in the "wrong way," the OH^- ion going to the α carbon instead of the β (Eq. 17-8). An enzyme with an active site similar to that of histidine ammonia-lyase (Eq. 14-48) could

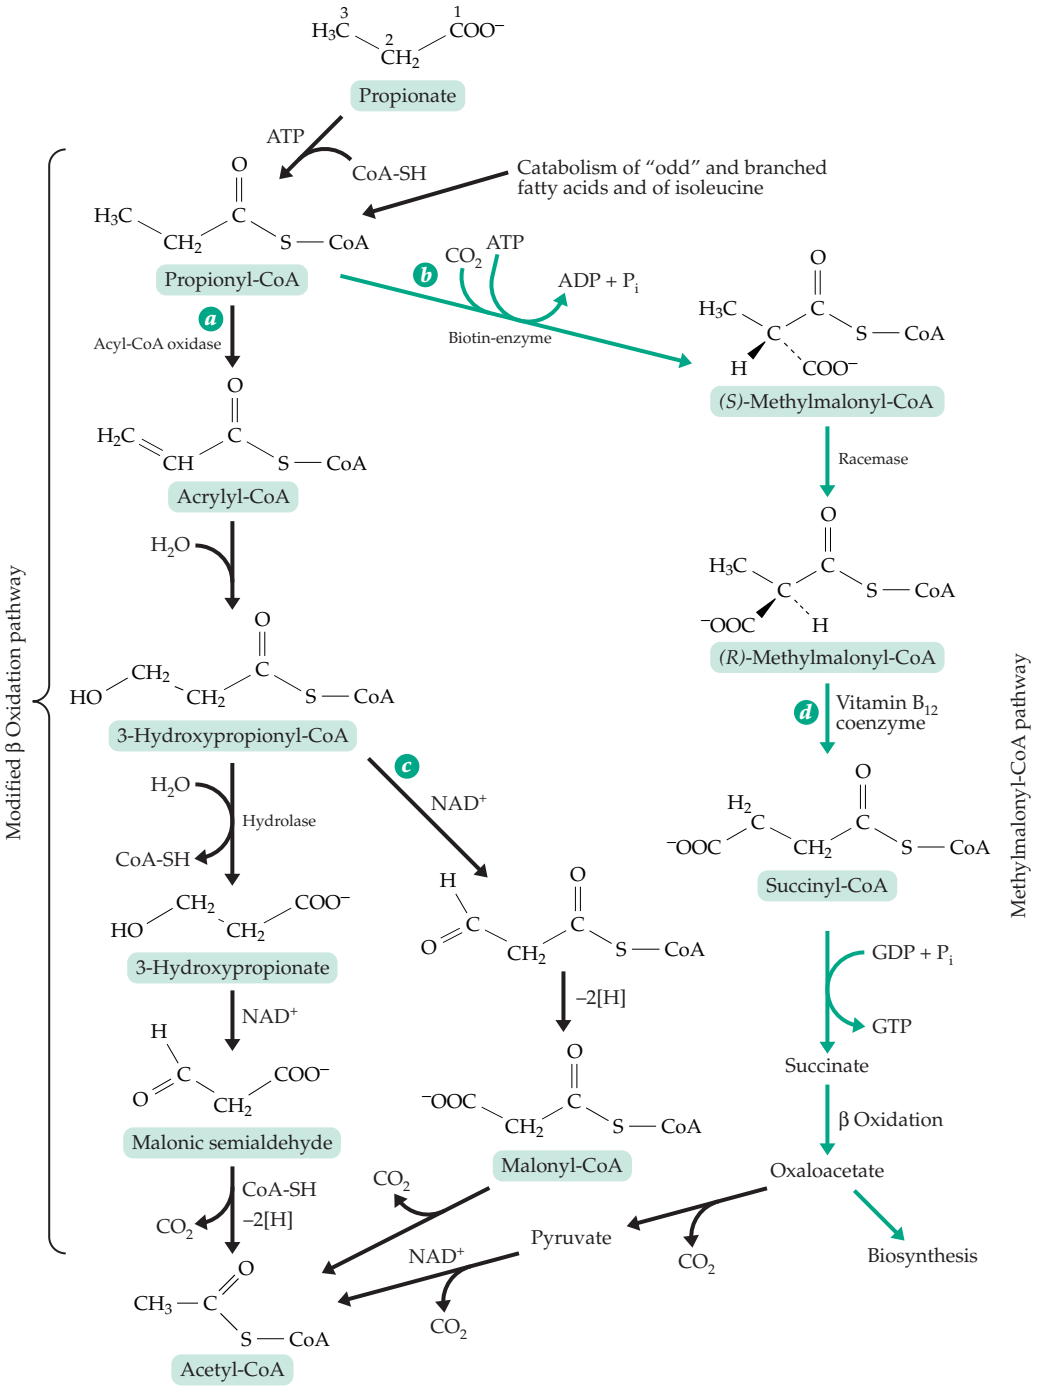


Figure 17-3 Catabolism of propionate and propionyl-CoA. In the names for methylmalonyl-CoA the *R* and *S* refer to the methylmalonyl part of the structure. Coenzyme A is also chiral.

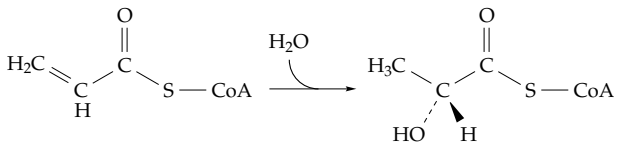
presumably catalyze such a reaction. Lactyl-CoA could be converted to pyruvate readily. *Clostridium propionicum* does interconvert propionate, lactate, and pyruvate via acrylyl-CoA and lactyl-CoA as part of a fermentation of alanine (Fig. 24-19).[71–74] The enzyme that catalyzes hydration of acrylyl-CoA in this case is a complex flavoprotein that may function via a free radical mechanism.[71,72,74]



(17-8)

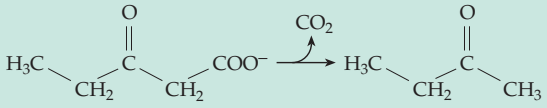
BOX 17-B METHYLMALONIC ACIDURIA

In this hereditary disease up to 1–2 g of methylmalonic acid per day (compared to a normal of <5 mg/day) is excreted in the urine, and a high level of the compound is present in blood. Two causes of the rare disease are known.[a–d] One is the lack of functional vitamin B_{12}-containing coenzyme. This can be a result of a mutation in any one of several different genes involved in the synthesis and transport of the cobalamin coenzyme.[e] Cultured fibroblasts from patients with this form of the disease contain a very low level of the vitamin B_{12} coenzyme (Chapter 16), and addition of excess vitamin B_{12} to the diet may restore coenzyme synthesis to normal. Among elderly patients a smaller increase in methylmalonic acid excretion is a good indicator of vitamin B_{12} deficiency. A second form of the disease, which does not respond to vitamin B_{12}, arises from a defect in the methylmalonyl mutase protein. Methylmalonic aciduria is often a very severe disease, frequently resulting in death in infancy. Surprisingly, some children with the condition are healthy and develop normally.[a,f]

A closely related disease is caused by a deficiency of propionyl-CoA carboxylase.[a] This may be a result of a defective structural gene for one of the two subunits of the enzyme, of a defect in the enzyme that attaches biotin to carboxylases, or of biotinitase, the enzyme that hydrolytically releases biotin from linkage with lysine (Chapter 14). The latter two defects lead to a multiple carboxylase deficiency and to methylmalonyl aciduria as well as ketoacidosis and propionic acidemia.[g]

Both methylmalonic aciduria and propionyl-CoA decarboxylase deficiency are usually accompanied by severe ketosis, hypoglycemia, and hyperglycinemia. The cause of these conditions is not entirely clear. However, methylmalonyl-CoA, which accumulates in methylmalonic aciduria, is a known inhibitor of pyruvate carboxylase. Therefore, ketosis may develop because of impaired conversion of pyruvate to oxaloacetate.

Patients with propionic or methylmalonic acidemia also secrete 2,3-butanediols (D-,L- or meso) and usually also 1,2-propandiol in their urine. Secretion of 1,2-propanediol is also observed during starvation and in diabetic ketoacidosis. Propanediol may be formed from acetone (Eq. 17-7), and butanediols may originate from acetoin, which is a side reaction product of pyruvate dehydrogenase. However, in the metabolic defects under consideration here, acetoin may be formed by hydroxylation of methylethyl ketone which can arise, as does acetone, by decarboxylation of an oxoacid precursor formed by β oxidation.[h]



Methylmalonic aciduria is rare and can be diagnosed incorrectly. In 1989 a woman in St. Louis, Missouri, was convicted and sentenced to life in prison for murdering her 5-month-old son by poisoning with ethylene glycol. While in prison she gave birth to another son who soon fell ill of methylmalonyl aciduria and was successfully treated. Reexamination of the evidence revealed that the first boy had died of the same disease and the mother was released.[i]

2. The Methylmalonyl-CoA Pathway of Propionate Utilization

Despite the simplicity and logic of the β oxidation pathway of propionate metabolism, higher animals use primarily the more complex methylmalonyl-CoA pathway (Fig. 17-3, step *b*). This is one of the two processes in higher animals presently known to depend upon vitamin B_{12}. This vitamin has never been found in higher plants, nor does the methylmalonyl pathway occur in plants. The pathway (Fig. 17-3) begins with the biotin- and ATP-dependent carboxylation of propionyl-CoA. The *S*-methylmalonyl-CoA so formed is isomerized to *R*-methylmalonyl-CoA, after which the methylmalonyl-CoA is converted to succinyl-CoA in a vitamin B_{12} coenzyme-requiring reaction step *d* (Table 16-1). The succinyl-CoA is converted to free succinate (with the formation of GTP compensating for the ATP used initially). The succinate, by β oxidation, is converted to oxaloacetate which is decarboxylated to pyruvate. This, in effect, removes the carboxyl group that was put on at the beginning of the sequence in the ATP-dependent step. Pyruvate is converted by oxidative decarboxylation to acetyl-CoA.

A natural question is "Why has this complex pathway evolved to do something that could have been done much more directly?" One possibility is that the presence of too much malonyl-CoA, the product of the β oxidation pathway of propionate metabolism (Fig. 17-3, pathways *a* and *c*), would interfere with lipid metabolism. Malonyl-CoA is formed in the cytosol during fatty acid biosynthesis and retards mitochondrial β oxidation by inhibiting carnitine palmitoyltransferase I.[46,70a,75] However, a relationship to mitochondrial propionate catabolism is not clear. On the other hand, the tacking on of an extra CO_2 and the use of ATP at the beginning suggests that the *methylmalonyl-CoA pathway* (Fig. 17-3) *is a biosynthetic rather than a catabolic route* (see Section H,4). The methylmalonyl pathway provides a means for converting propionate to oxaloacetate, a transformation that is chemically difficult.

In this context it is of interest that cows, whose metabolism is based much more on acetate than is ours, often develop a severe ketosis spontaneously. A standard treatment is the administration of a large dose of propionate which is presumably effective because of the ease of its conversion to oxaloacetate via the methylmalonyl-CoA pathway. It is possible that this pathway was developed by animals as a means of capturing propionyl units, scanty though they may be, for conversion to oxaloacetate and use in biosynthesis. In ruminant animals, the pathway is especially important. Whereas we have 5.5 mM glucose in our blood, the cow has only half as much, and a substantial fraction of this glucose is derived, in the liver, from the propionate provided by rumen microorganisms.[76] The need for vitamin B_{12} in the formation of propionate by these organisms also accounts for the high requirement for cobalt in the ruminant diet (Chapter 16).

C. The Citric Acid Cycle

To complete the oxidation of fatty acids the acetyl units of acetyl-CoA generated in the β oxidation sequence must be oxidized to carbon dioxide and water.[77] The citric acid (or tricarboxylic acid) cycle by which this oxidation is accomplished is a vital part of the metabolism of almost all aerobic creatures. It occupies a central position in metabolism because of the fact that acetyl-CoA is also an intermediate in the catabolism of carbohydrates and of many amino acids and other compounds. The cycle is depicted in detail in Fig. 10-6 and in an abbreviated form, but with more context, in Fig. 17-4.

1. A Clever Way to Cleave a Reluctant Bond

Oxidation of the chemically resistant two-carbon acetyl group to CO_2 presents a chemical problem. As we have seen (Chapter 13), cleavage of a C–C bond occurs most frequently between atoms that are α and β to a carbonyl group. Such β cleavage is clearly impossible within the acetyl group. The only other common type of cleavage is that of a C–C bond adjacent to a carbonyl group (α cleavage), a thiamin-dependent process (Chapter 14). However, α cleavage would require the prior oxidation (hydroxylation) of the methyl group of acetate. Although many biological hydroxylation reactions occur, they are rarely used in the major pathways of rapid catabolism. Perhaps this is because the overall yield of energy obtainable via hydroxylation is less than that gained from dehydrogenation and use of an electron transport chain.[78]

The solution to the chemical problem of oxidizing acetyl groups efficiently is one very commonly found in nature; a catalytic cycle. Although direct cleavage is impossible, the two-carbon acetyl group of acetyl-CoA *can* undergo a Claisen condensation with a second compound that contains a carbonyl group. The condensation product has more than two carbon atoms, and a β cleavage to yield CO_2 is now possible. Since the cycle is designed to oxidize acetyl units we can regard acetyl-CoA as the **primary substrate** for the cycle. The carbonyl compound with which it condenses can be described as the **regenerating substrate**. To complete the catalytic cycle it is necessary that two carbon atoms be removed as CO_2 from the compound formed by condensation of the two substrates and that the remaining molecule be reconvertible to the original regenerating substrate. The reader may wish to play a

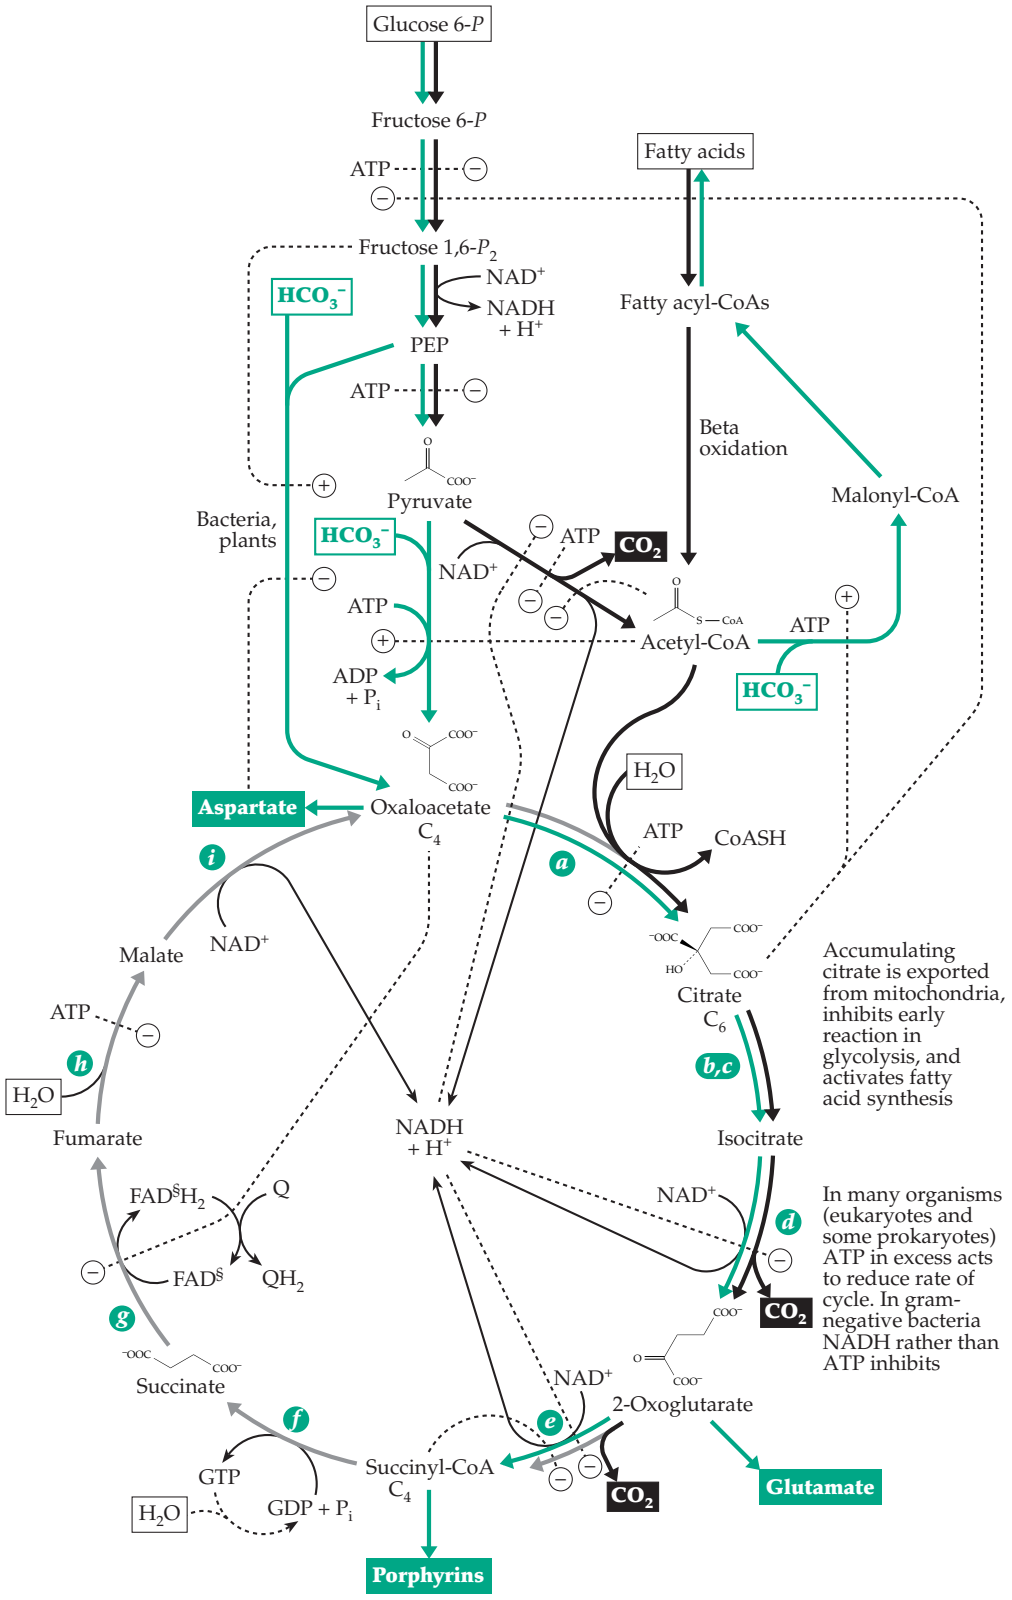

Figure 17-4 The Krebs citric acid cycle. Some of its controlling interactions and its relationship to glycolysis. See also Figure 10-6. Positive and negative regulatory influences, whether arising by allosteric effects or via covalent modification, are indicated by ⊕ or ⊖. Some biosynthetic reaction pathways related to the cycle are shown in green. Steps are lettered to correspond to the numbering in Fig. 10-6, which shows more complete structural formulas. Three molecules of H_2O (boxed) enter the cycle at each turn, providing hydrogen atoms for generation of NADH + H^+ and reduced ubiquinone (QH_2). The covalently attached FAD is designated $FAD^{\S}$.

game by devising suitable sequences of reactions for an acetyl-oxidizing cycle and finding the simplest possible regenerating substrate. Ask yourself whether nature could have used anything simpler than **oxaloacetate**, the molecule actually employed in the citric acid cycle.

The first step in the citric acid cycle (step *a*, Fig. 17-4) is the condensation of acetyl-CoA with oxaloacetate to form citrate. The synthase that catalyzes this condensation also removes the CoA by hydrolysis after it has served its function of activating a methyl hydrogen. This hydrolysis also helps to drive the cycle by virtue of the high group transfer potential of the thioester linkage that is cleaved. Before the citrate can be degraded through β cleavage, the hydroxyl group must be moved from its tertiary position to an adjacent carbon where, as a secondary alcohol, it can be oxidized to a carbonyl group. This is accomplished through steps *b* and *c*, both catalyzed by the enzyme aconitase (Eq. 13-17). Isocitrate can then be oxidized to the β-oxoacid **oxalosuccinate**, which does not leave the enzyme surface but undergoes decarboxylation while still bound (step *d*; also see Eq. 13-45).

The second carbon to be removed from citrate is released as CO_2 through catalysis by the thiamin diphosphate dependent **oxidative decarboxylation** of **2-oxoglutarate** (α-ketoglutarate; Chapter 15). To complete the cycle the four-carbon succinyl unit of succinyl-CoA must be converted back to oxaloacetate through a pathway requiring two more oxidation steps: Succinyl-CoA is converted to free succinate (step *f*) followed by a β oxidation sequence (steps *g*–*i*; Figs. 10-6 and 17-4). Steps *e* and *f* accomplish a substrate-level phosphorylation (Fig. 15-16). Succinyl-CoA is an unstable thioester with a high group transfer potential. Therefore, step *f* could be accomplished by simple hydrolysis. However, this would be energetically wasteful. The cleavage of succinyl-CoA is coupled to synthesis of ATP in *E. coli* and higher plants and to GTP in mammals. Some of the succinyl-CoA formed in mitochondria is used in other ways, e.g., as in Eq. 17-6 and for biosynthesis of porphyrins.

2. Synthesis of the Regenerating Substrate Oxaloacetate

The primary substrate of the citric acid cycle is acetyl-CoA. Despite many references in the biochemical literature to substrates "entering" the cycle as oxaloacetate (or as one of the immediate precursors succinate, fumarate, or malate), *these compounds are not consumed* by the cycle but are completely regenerated; hence the term *regenerating substrate*, which can be applied to any of these four substances. A prerequisite for the operation of a catalytic cycle is that a regenerating substrate be readily available and that its concentration be increased if necessary to accommodate a more rapid rate of reaction of the cycle. Oxaloacetate can normally be formed in any amount needed for operation of the citric acid cycle from **PEP** or from **pyruvate**, both of these compounds being available from metabolism of sugars.

In bacteria and green plants **PEP carboxylase** (Eq. 13-53), a highly regulated enzyme, is responsible for synthesizing oxaloacetate. In animal tissues **pyruvate carboxylase** (Eq. 14-3) plays the same role. The latter enzyme is almost inactive in the absence of the allosteric effector acetyl-CoA. For this reason, it went undetected for many years. In the presence of high concentrations of acetyl-CoA the enzyme is fully activated and provides for synthesis of a high enough concentration of oxaloacetate to permit the cycle to function. Even so, the oxaloacetate concentration in mitochondria is low, only 0.1 to 0.4 x 10^{-6} M (10–40 molecules per mitochondrion), and is relatively constant.[65,79]

3. Common Features of Catalytic Cycles

The citric acid cycle is not only one of the most important metabolic cycles in aerobic organisms, including bacteria, protozoa, fungi, higher plants, and animals, but also *a typical catalytic cycle*. Other cycles also have one or more primary substrates and at least one regenerating substrate. Associated with every catalytic cycle there must be a metabolic pathway that provides for synthesis of the regenerating substrate. Although it usually needs to operate only slowly to replenish regenerating substrate lost in side reactions, the pathway also provides *a mechanism for the net biosynthesis of any desired quantity of any intermediate in the cycle*. Cells draw off from the citric acid cycle considerable amounts of oxaloacetate, 2-oxoglutarate, and succinyl-CoA for synthesis of other compounds. For example, aspartate and glutamate are formed directly from oxaloacetate and 2-oxoglutarate, respectively, by transamination (Eq. 14-25).[79a,b] Citrate itself is exported from mitochondria and used for synthesis of fatty acids. It is often stated that the citric acid cycle functions in biosynthesis, but when intermediates in the cycle are drawn off for synthesis the complete cycle does not operate. Rather, *the pathway for synthesis of the regenerating substrate, together with some of the enzymes of the cycle, is used to construct a biosynthetic pathway.*

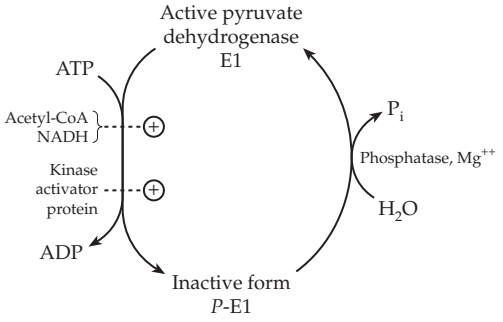
The word **amphibolic** is often applied to those metabolic sequences that are part of a catabolic cycle and at the same time are involved in a biosynthetic (anabolic) pathway. Another term, **anaplerotic**, is sometimes used to describe pathways for the synthesis of regenerating substrates. This word, which was suggested by H. L. Kornberg, comes from a Greek root meaning "filling up."[80]

4. Control of the Cycle

What factors determine the rate of oxidation by the citric acid cycle? As with most other important pathways of metabolism, several control mechanisms operate and different steps may become rate limiting under different conditions.[81] Factors influencing the flux through the cycle include (1) the rate of generation of acetyl groups, (2) the availability of oxaloacetate, and (3) the rate of reoxidation of NADH to NAD^+ in the electron transport chain. As indicated in Fig. 17-4, acetyl-CoA is a positive effector for conversion of pyruvate to oxaloacetate. Thus, acetyl-CoA "turns on" the formation of a substance required for its own further metabolism. However, when no pyruvate is available operation of the cycle may be impaired by lack of oxaloacetate. This may be the case when liver metabolizes high concentrations of ethanol. The latter is oxidized to acetate but it cannot provide oxaloacetate. Accumulating NADH reduces pyruvate to lactate, further interfering with formation of oxaloacetate.[82] In some individuals the accumulating acetyl units cannot all be oxidized in the cycle and instead are converted to the ketone bodies (Section A,4). A similar problem arises during metabolism of fatty acids by diabetic individuals with inadequate insulin. The accelerated breakdown of fatty acids in the liver overwhelms the system and results in ketosis, even though the oxaloacetate concentration remains normal.[83]

The rates of the oxidative steps in the citric acid cycle are limited by the rate of reoxidation of NADH and reduced ubiquinone in the electron transport chain which may sometimes be restricted by the availability of O_2. However, in aerobic organisms this rate is usually determined by the concentration of ADP and/or P_i available for conversion to ATP in the oxidative phosphorylation process (Chapter 18). If catabolism supplies an excess of ATP over that needed to meet the cell's energy needs, the concentration of ADP falls to a low level, cutting off phosphorylation. At the same time, ATP is present in high concentration and acts as a feedback inhibitor for the catabolism of carbohydrates and fats. This inhibition is exerted at many points, a few of which are indicated in Fig. 17-4. Important sites of inhibition are the **pyruvate dehydrogenase complex**,[84–85a] which converts pyruvate into acetyl-CoA; **isocitrate dehydrogenase**,[86,86a] which converts isocitrate into 2-oxoglutarate; and **2-oxoglutarate dehydrogenase**.[87] The enzyme **citrate synthase**, which catalyzes the first reaction of the cycle, is also inhibited by ATP.[88,89]

Mitochondrial pyruvate dehydrogenase, which contains a 60-subunit icosohedral core of dihydrolipoyltransacylase (Fig. 15-14), is associated with three molecules of a two-subunit kinase as well as six molecules of a structural **binding protein** which contains a lipoyl group that can be reduced and acetylated by other subunits of the core protein. The binding protein is apparently essential to the functioning of the dehydrogenase complex but not through its lipoyl group.[90,91] The specific pyruvate dehydrogenase kinase is thought to be one of the most important regulatory proteins involved in controlling energy metabolism in most organisms.[92–92b] Phosphorylation of up to three specific serine hydroxyl groups in the thiamin-containing decarboxylase subunit (designated E1) converts the enzyme into an inactive form (Eq. 17-9). A specific phosphatase reverses the inhibition. The kinase is most active on enzymes whose core lipoyl (E2) subunits are reduced and acetylated, a condition favored by high ratios of [acetyl-CoA] to free [CoASH] and of [NADH] to [NAD^+]. Since the kinase inactivates the enzyme the effect is to decrease the pyruvate dehydrogenase action when the system becomes saturated and NADH and acetyl-CoA accumulate. Conversely, a high [pyruvate] inhibits the kinase and increases the action of the dehydrogenase complex. This system also permits various external signals to be felt. For example, insulin has a pronounced stimulatory effect on mitochondrial energy.[65,92,93] One way in which this may be accomplished is through stimulation of the pyruvate dehydrogenase phosphatase, as indicated in Eq. 17-9. A **kinase activator protein** (Eq. 17-9) may also respond to various external stimuli and may be inhibited by insulin.[92]



(17-9)

The activities of 2-oxoglutarate dehydrogenase,[94] and to a lesser extent of pyruvate and isocitrate dehydrogenases, are increased by increases in the free Ca^{2+} concentration.[87] Calcium ions stimulate the phosphatase that dephosphorylates the deactivated phosphorylated pyruvate dehydrogenase and activate the other two dehydrogenases allosterically, increasing the affinities for the substrates.[87] Phosphorylation of the NAD^+-dependent isocitrate dehydrogenase also decreases its activity. In *E. coli* the isocitrate dehydrogenase kinase and a protein phosphatase exist as a bifunctional protein able to both deactivate the dehydrogenase and restore its activity.[86] For this organism, the decrease in activity forces substrate into the glyoxylate pathway (Section J,4) instead of the citric acid cycle.

BOX 17-C USE OF ISOTOPIC TRACERS IN STUDY OF THE TRICARBOXYLIC ACID CYCLE

The first use of isotopic labeling in the study of the citric acid cycle and one of the first in the history of biochemistry was carried out by Harland G. Wood and C. H. Werkman in 1941.[a,b] The aim was to study the fermentation of glycerol by propionic acid bacteria, a process that was not obviously related to the citric acid cycle. Some succinate was also formed in

$$\text{Glycerol} \rightarrow \text{propionate}^- + H^+ + H_2O$$
$$\Delta G' = -69 \text{ kJ/mol}$$

the fermentation, and on the basis of simple measurements of the fermentation balance reported in 1938 it was suggested that CO_2 was incorporated into oxaloacetate, which was then reduced to succinate. As we now know, this is indeed an essential step in the propionic acid fermentation (Section F,3). At the time ^{14}C was not available but the mass spectrometer, newly developed by A. O. Nier, permitted the use of the stable ^{13}C as a tracer. Wood and Werkman constructed a thermal diffusion column and used it to prepare bicarbonate enriched in ^{13}C and also built a mass spectrometer. By 1941 it was established unequivocally that carbon dioxide was incorporated into succinate by the bacteria.[c]

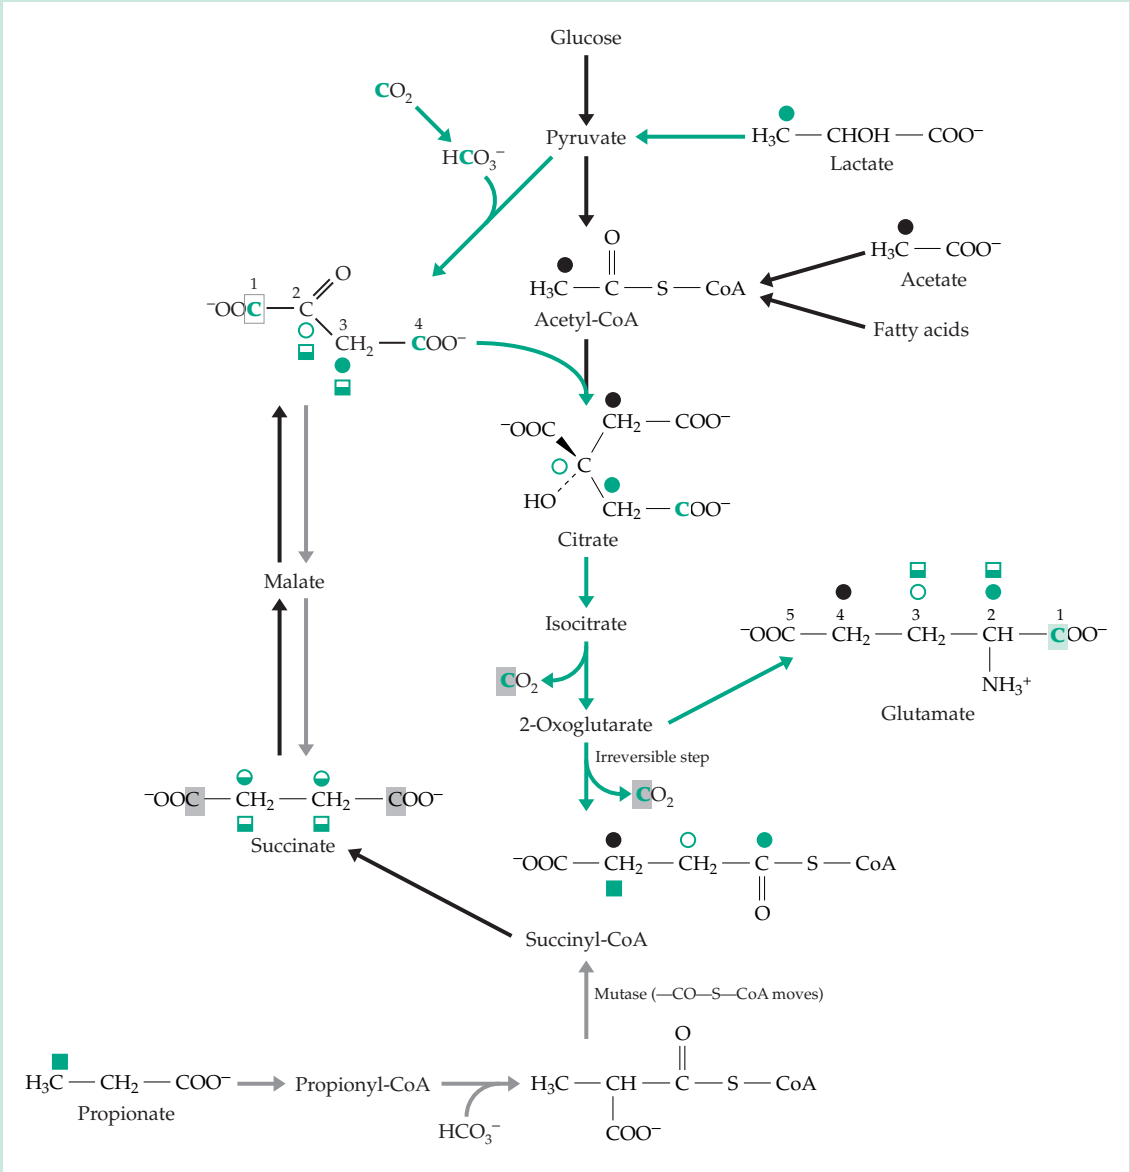
To test the idea that animal tissues could also incorporate CO_2 into succinate Wood examined the metabolism of a pigeon liver preparation to which malonate had been added to block succinate dehydrogenase (Box 10-B). Surprisingly, the accumulating succinate, which arose from oxalocetate via citrate, isocitrate, and 2-oxoglutarate (traced by green arrows in accompanying scheme), contained no ^{13}C. Soon, however, it was shown that CO_2 was incorporated into the carboxyl group of 2-oxoglutarate that is adjacent to the carbonyl group. That carboxyl is lost in conversion to succinate (Fig. 10-6) explains the lack of ^{13}C in succinate. It is of historical interest that these observations were incorrectly interpreted by many of the biochemists of the time. They agreed that *citrate could not be a member of the tricarboxylic acid cycle*. Since citrate is a symmetric compound it was thought that any ^{13}C incorporated into citrate would be present in equal amounts in both terminal carboxyl groups. This would necessarily result in incorporation of ^{13}C into succinate. It was not until 1948 that Ogston popularized the concept that by binding with substrates at three points, enzymes were capable of asymmetric attack upon symmetric substrates.[d] In other words, an enzyme could synthesize citrate with the carbon atoms from acetyl-CoA occupying one of the two $-CH_2COOH$ groups surrounding the prochiral center. Later, the complete stereochemistry of the citric acid cycle was elucidated through the use of a variety of isotopic labels (see p. 704). Some of the results are indicated by the asterisks and daggers in the structures in Fig. 10-6.

The operation of the citric acid cycle in living cells, organs, and whole animals has also been observed using NMR and mass spectroscopy with ^{13}C-containing compounds. For example, a heart can be perfused with a suitable oxygenated perfusion fluid[e] containing various ^{13}C-enriched substrates such as [U-^{13}C]fatty acids, [2-^{13}C]acetate, [3-^{13}C]L-lactate, or [2,3-^{13}C]propionate.[e–k] NMR spectroscopy allows direct and repeated observation of the ^{13}C nuclei from a given substrate and its entry into a variety of metabolic pathways. Because of the high dispersion of chemical shift values for ^{13}C the NMR resonance for the isotope can be seen at each position within a single compound.

A compound that is especially easy to observe is glutamate. This amino acid, most of which is found in the cytoplasm, is nevertheless in relatively rapid equilibrium with 2-oxoglutarate of the citric acid cycle in the mitochondria. The accompanying scheme shows where isotopic carbon from certain compounds will be located *when it first enters* the citric acid cycle and traces some of the labels into glutamate. For example, uniformly enriched fatty acids will introduce label into the two atoms of the *pro-S* arm of citrate and into 4- and 5-positions of glutamate whereas [2-^{13}C]acetate will introduce label only into the C4 position as marked by ● in the scheme. In the NMR spectrum a singlet resonance at 32.4 ppm will be observed. However, as successive turns of the citric acid cycle occur the isotope will appear in increasing amounts in the adjacent 3-position of glutamate. They will be recognized readily by the appearance of a multiplet. The initial singlet will be flanked by a pair of peaks that arise from spin–spin coupling with the adjacent 3-^{13}C of the [2,3-^{13}C]isotopomer (see accompanying figure). After longer periods of time the central resonance will weaken and the outer pair strengthen as the recycling occurs.

Metabolism with [U-^{13}C]fatty acids gives a labeling pattern similar to that with [2,3-^{13}C]acetate and it has been deduced that heart muscle normally metabolizes principally fatty acids for energy. What will happen to the glutamate C4 resonance if [3-^{13}C]lactate is added to the perfusion solution? It will enter both acetyl-CoA and oxaloacetate as indicated by ● in the following scheme. That will also intro-duce ^{13}C at C3 of glutamate. By looking at spectra at short times the relative amounts of lactate being oxidized via the cycle and that being converted

BOX 17-C (continued)



biosynthetically (anaplerotically) to glutamate can be estimated. There is a complication that has long been recognized. Oxaloacetate can be converted by exchange processes to succinate. Since succinate is symmetric the effect is to put 50% of the label into each of the central atoms of succinate (◒ in scheme). The exchange will then transfer label back into the C2 position of oxaloacetate (○) and through citric acid cycle reactions into C3 of glutamate. Now the C4 NMR resonance will contain an additional pair of peaks arising from spin–spin coupling with C2 but which will have a different coupling constant than that for coupling to C3.

If uniformly labeled [U-^{13}C]acetate is introduced the additional isotopomers, [3,4 - ^{13}C]glutamate and [3,4,5 - ^{13}C]glutamate, will be formed as will others with ^{13}C in the C1 and C5 positions but which will not affect the C4 resonance. A total of nine lines will be seen as illustrated in curve *a* of the accompanying figure. We see that the multiplet patterns arising from mass isotopomers are complex, but they can be predicted accurately with a computer program.[f] Isotopomers of succinate have also been analyzed.[g]

It is also of interest to introduce ^{13}C from propionate labeled in various positions. One of these is illustrated in the scheme. In this case the appearance of multiplets arising from [3,4-^{13}C] glutamate verifies the existence of end-to-end scrambling of the isotope in succinate. However, is the scrambling complete or are some molecules

BOX 17-C USE OF ISOTOPIC TRACERS IN STUDY OF THE TRICARBOXYLIC ACID CYCLE (cont.)

Only the glutamate C4 (left) and C3 (right) resonances are shown. B. Spectrum after perfusion for 30 min. From Malloy *et al*.[r] C. The glutamate C4 resonance of an intact Langendorff-perfused rat heart supplied with 2 mM [2-^{13}C]acetate showing evolution of the multiplet as a function of time after introducing the label. The right panel shows glutamate C4 resonances generated by a computer simulation after turnover of citric acid cycle pools the indicated number of time. From Jeffrey *et al*.[f]

efficiently "channeled" through enzyme–enzyme complexes in such a way as to avoid scrambling? As shown in the scheme, full scrambling would give equal labeling of C2 and C3 of oxaloacetate and of glutamate. Experimentally greater labeling was seen at C3 than at C2 during the first few turns of the cycle suggesting that some channeling does occur.[e]

Isotopomer analysis can also be conducted by mass spectroscopy, which is more sensitive than NMR, using ^{13}C[h,k,l] or ^{2}H labeling.[j] Making use of a technique like that employed by Knoop (Box 10-A), a "chemical biopsy" can be performed on animals or on human beings, who may ingest gram quantities of sodium phenylacetate without harm. The phenylacetate is converted to an amide with glutamine (phenylacetylglutamine) which is excreted in the urine, from which it can easily be recovered for analysis.[l–n] This provides a non-invasive way of studying the operation of the citric acid cycle in the human body. Direct measurement on animal brains[o,p] and on human limbs or brain has also been accomplished by NMR spectroscopy[q] and may become more routine as instrumentation is improved.

Acting to counteract any drop in ATP level, accumulating ADP acts as a positive effector for isocitrate dehydrogenases.

Another way in which the phosphorylation state of the adenylate system can regulate the cycle depends upon the need for GDP in step *f* of the cycle (Fig. 17-4). Within mitochondria, GTP is used largely to reconvert AMP to ADP. Consequently, formation of GDP is promoted by AMP, a compound that arises in mitochondria from the utilization of ATP for activation of fatty acids (Eq. 13-44) and activation of amino acids for protein synthesis (Eq. 17-36).

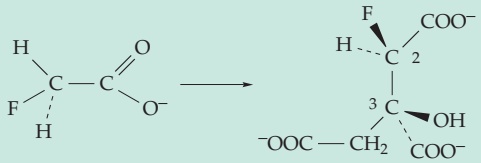
In *E. coli* and some other bacteria ATP does not inhibit citrate synthase but NADH does; the control is via the redox potential of the NAD^+ system rather than by the level of phosphorylation of the adenine nucleotide system.[95] Succinic dehydrogenase may be regulated by the redox state of ubiquinone (Chapter 15). Another mechanism of regulation may be the formation of specific protein–protein complexes between enzymes catalyzing reactions of the cycle.[96–97a] This may permit one enzyme to efficiently have a product of its action transferred to the enzyme catalyzing the next step in the cycle.

5. Catabolism of Intermediates of the Citric Acid Cycle

Acetyl-CoA is the only substrate that can be completely oxidized to CO_2 by the reaction of the citric acid cycle alone. Nevertheless, cells must sometimes

BOX 17-D FLUOROACETATE AND "LETHAL SYNTHESIS"

Among the most deadly of simple compounds is sodium fluoroacetate. The LD_{50} (the dose lethal for 50% of animals receiving it) is only 0.2 mg/kg for rats, over tenfold less than that of the nerve poison diisopropylphosphofluoridate (Chapter 12).[a,b] Popular, but controversial, as the rodent poison "1080," fluoroacetate is also found in the leaves of several poisonous plants in Africa, Australia, and South America. Surprisingly, difluoroacetate $HCF_2–COO^-$ is nontoxic and biochemical studies reveal that monofluoroacetate has no toxic effect on cells until it is converted metabolically in a "lethal synthesis" to 2*R*,3*R*-2-fluorocitrate, which is a competitive inhibitor of aconitase (aconitate hydratase, Eq. 13-17).[b–g] This fact was difficult to understand since citrate formed by the reaction of fluorooxaloacetate and acetyl-CoA has only weak inhibitory activity toward the same enzyme. Yet, it is the fluorocitrate formed from fluorooxaloacetate that contains a fluorine atom at a site that is attacked by aconitase in the citric acid cycle.



2*R*,3*R* 2-Fluoroacetate

The small van der Waals radius of fluorine (0.135 nm), comparable to that of hydrogen (0.12 nm), is often cited as the basis for the ability of fluoro compounds to "deceive" enzymes. However, the high electronegativity and ability to enter into hydrogen bonds may make F more comparable to –OH in metabolic effects. In the case of fluorocitrate it was proposed that the inhibitory isomer binds in the "wrong way" to aconitase in such a manner that the fluorine atom is coordinated with the ferric ion at the catalytic center.[c] However, 2*R*,3*R*-2-fluorocitrate is a simple competitive inhibitor of aconitase but an irreversible poison. It is especially toxic to nerves and also appears to affect mitochondrial membranes. Therefore, this poison may affect some other target, such as a citrate transporter.[d] Fluoroacetate is only one of many known naturally occurring fluorine compounds.[c]

Another example of lethal synthesis is seen in the use of 5-fluorouracil in cancer therapy (Box 15-E). In this compound and in many other fluorine-containing inhibitors the F atom replaces the H atom that is normally removed as H^+ in the enzymatic reaction. The corresponding F^+ cannot be formed.[h] Because of the high electronegativity of fluorine a C–F bond is polarized: $C^{\delta+}–F^{\delta-}$. This may have very large effects on reactivity at adjacent positions. For example, the reactivity of 2-fluoroglycosyl groups toward glycosyl transfer is decreased by several orders of magnitude (p. 597).

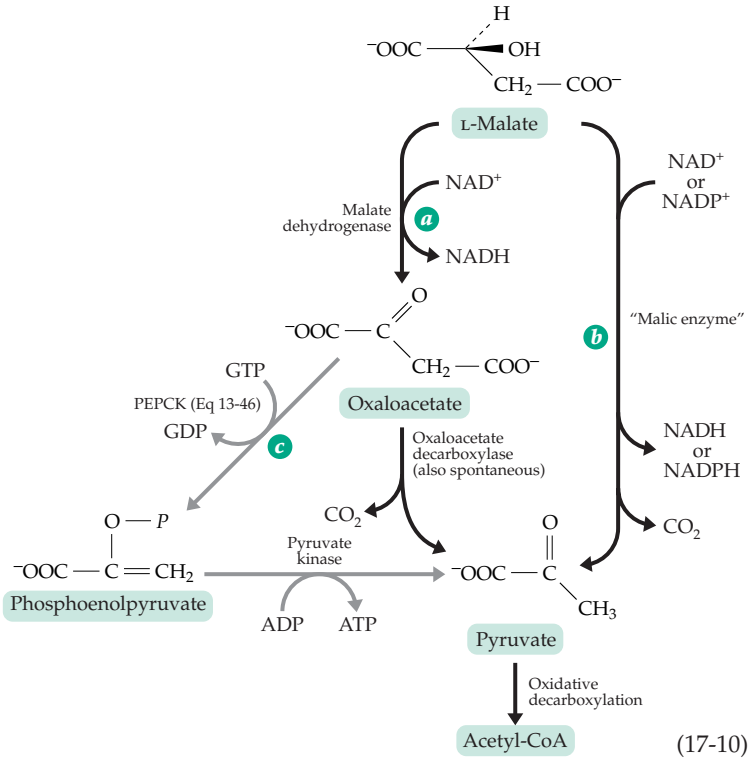
oxidize large amounts of one of the compounds found in the citric acid cycle to CO_2.[98,99] For example, bacteria subsisting on succinate as a carbon source must oxidize it for energy as well as convert some of it to carbohydrates, lipids, and other materials. Complete combustion of *any citric acid cycle intermediate* can be accomplished by conversion to malate followed by oxidation of malate to oxaloacetate (Eq. 17-10, step *a*) and decarboxylation (β cleavage) to pyruvate, or (Eq. 17-10, step *b*) oxidation and decarboxylation of malate by the **malic enzyme** (Eq. 13-45) without free oxaloacetate as an intermediate. Pathway *b* is probably the most important. It is catalyzed by two different malic enzymes present in animal mitochondria. One is specific for $NADP^+$ while the other reacts with NAD^+ as well.[100,101] They both have complex regulatory properties. For example, the less specific NAD^+-utilizing enzyme is allosterically inhibited by ATP but is activated by fumarate, succinate, or isocitrate.[100] Thus, accumulation of citric acid cycle intermediates "turns on" the malic enzyme, allowing the excess to leave the cycle and reenter as acetyl groups. Since the Michaelis constant for malate is high, this will not happen unless malate accumulates, signaling a need for acetyl-CoA. The $NADP^+$-dependent enzyme is activated by a high concentration of free CoA and is inhibited by NADH. Perhaps when glycolysis becomes slow the free CoA level rises and turns on malate oxidation.[101] On the other hand, rapid glycolysis increases the NADH concentration which inhibits the malic enzyme. The result is a buildup of the oxaloacetate concentration and an increase in activity of the citric acid cycle. The malic enzymes are also present in the cytoplasm, where one of them functions as part of an NADPH-generating cycle (Eq. 17-46).



(17-10)

D. Oxidative Pathways Related to the Citric Acid Cycle

In this section we will consider some other catalytic cycles as well as some noncyclic pathways of oxidation of one- and two-carbon substrates that are utilized by microorganisms.

1. The γ-Aminobutyrate Cycle

A modification of the citric acid cycle which involves glutamate and gamma (γ) aminobutyrate (GABA) has an important function in the brain (Fig. 17-5). Both glutamate and γ-aminobutyrate occur in high concentrations in brain (10 and 0.8 mM, respectively). Both are important neurotransmitters, γ-aminobutyrate being a principal neuronal inhibitory substance[102,103] (Chapter 30). In the γ-aminobutyrate cycle acetyl-CoA and oxaloacetate are converted into citrate (step *a*) in the usual way and the citrate is then converted into 2-oxoglutarate. The latter is transformed to L-glutamate either by direct amination (*b*) or by transamination (*c*), the amino donor being γ-aminobutyrate.

γ-Aminobutyrate is formed by decarboxylation of glutamate (Fig. 17-5, step *d*)[104] and is catabolized via transamination (step *e*)[105] to succinic semialdehyde, which is oxidized to succinate[106] and oxaloacetate. The two transamination steps in the pathways may be linked, as indicated in Fig. 17-5, to form a complete cycle that parallels the citric acid cycle but in which 2-oxoglutarate is oxidized to succinate via glutamate and γ-aminobutyrate. No thiamin diphosphate is required, but 2-oxoglutarate is reductively aminated to glutamate. The cycle is sometimes called the **γ-aminobutyrate shunt**, and it plays a significant role in the overall oxidative processes of brain tissue. This pathway is also prominent in green plants.[107–109] For example, under anaerobic conditions the radish *Raphanus sativus* accumulates large amounts of γ-aminobutyrate.[110] Most animal tissues contain very little γ-aminobutyrate, although it has been found in the oviducts of rats at concentrations that exceed those in the brain.[111]

2. The Dicarboxylic Acid Cycle

Some bacteria can subsist solely on glycolate, glycine, or oxalate, all of which

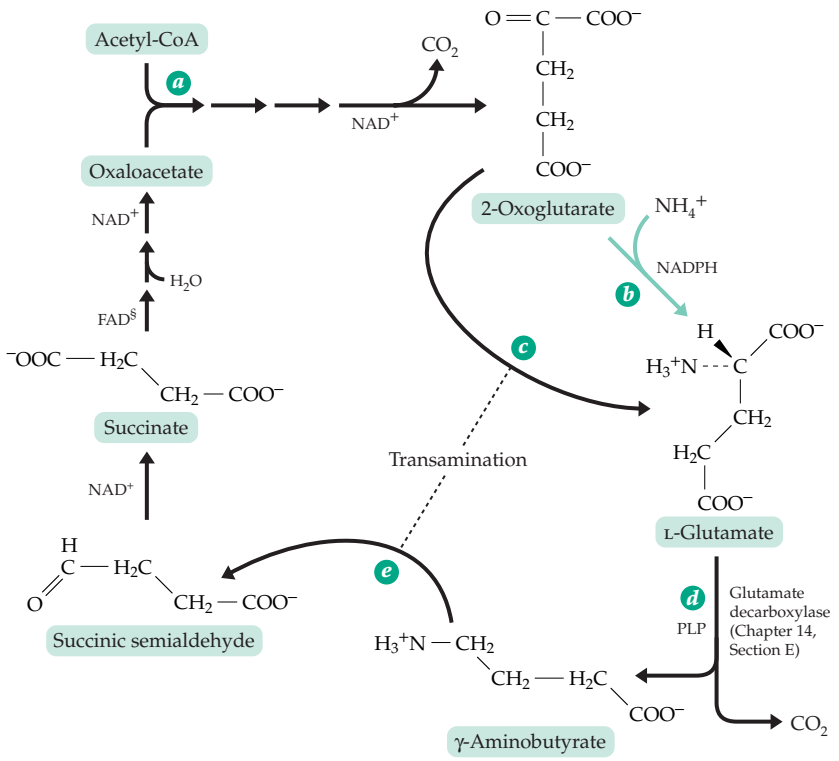


Figure 17-5 Reactions of the γ-aminobutyrate (GABA) cycle.

are converted to glyoxylate (Eq. 17-11). Glyoxylate is oxidized to CO_2 and water to provide energy to the bacteria and is also utilized for biosynthetic purposes. The energy-yielding process is found in the **dicarboxylic acid cycle** (Fig. 17-6), which catalyzes the complete oxidation of glyoxylate. Four hydrogen atoms are removed with generation of two molecules of NADH which can be oxidized by the respiratory chain to provide energy.[112,113] In the dicarboxylic acid cycle glyoxylate is the principal substrate and acetyl-CoA is the regenerating substrate rather than the principal substrate as it is for the citric acid cycle.

The logic of the dicarboxylic acid cycle is simple. Acetyl-CoA contains a potentially free carboxyl group. After the acetyl group of acetyl-CoA has been condensed with glyoxylate and the resulting hydroxyl group has been oxidized, the free carboxyl group appears in oxaloacetate in a position β to the carbonyl group. The carboxyl

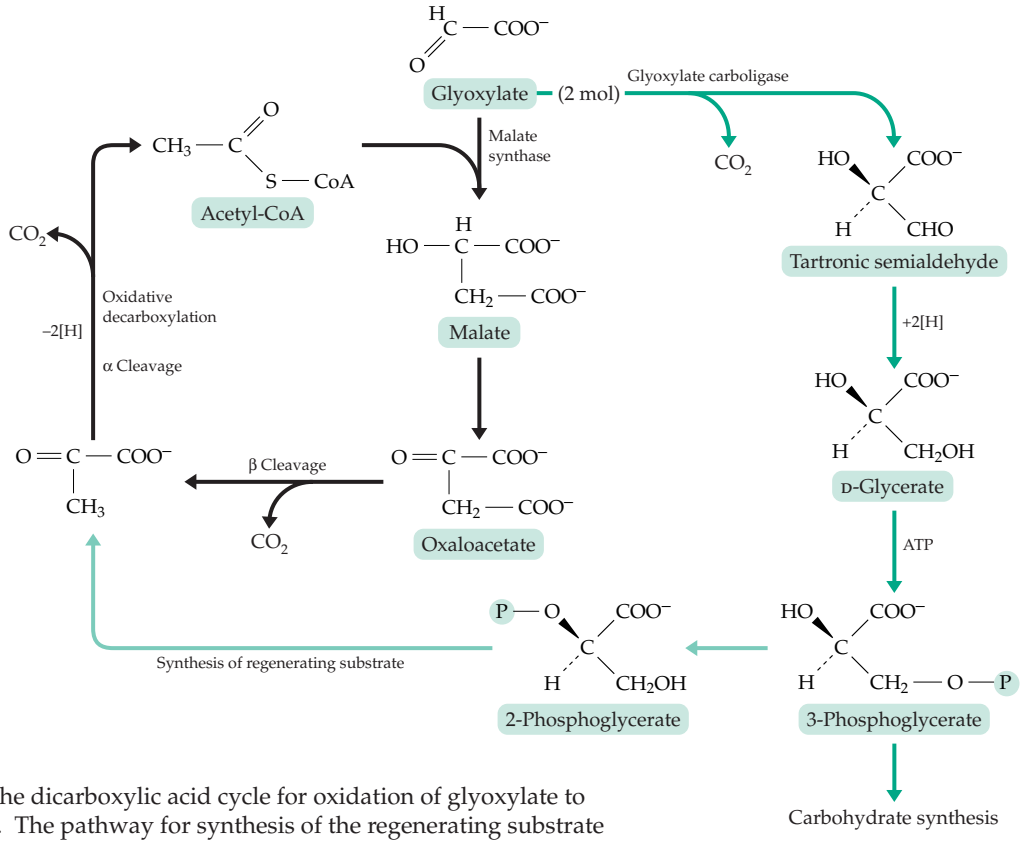

Figure 17-6 The dicarboxylic acid cycle for oxidation of glyoxylate to carbon dioxide. The pathway for synthesis of the regenerating substrate is indicated by green lines. This pathway is also needed for synthesis of carbohydrates and all other cell constituents.

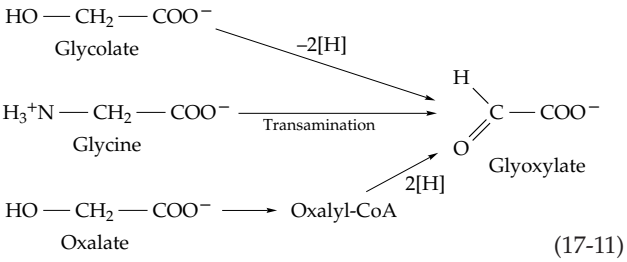

(17-11)

donated by the glyoxylate is still in the α position. A consecutive β cleavage and an oxidative α cleavage release the two carboxyl groups as carbon dioxide to reform the regenerating substrate. The cycle is simple and efficient. Like the citric acid cycle, it depends upon thiamin diphosphate, without which the α cleavage would be impossible. Comparing the citric acid cycle (Fig. 17-2) with the simpler dicarboxylic acid cycle, we see that in the former the initial condensation product citrate contains a hydroxyl group attached to a tertiary carbon atom. With no adjacent hydrogen it is impossible to oxidize it directly to the carbonyl group which is essential for subsequent chain cleavage; hence the dependence on aconitase to shift the OH to an adjacent carbon. Both cycles involve oxidation of a hydroxy acid to a ketone followed by β cleavage and oxidative α cleavage. In the citric acid cycle additional oxidation steps are needed to convert succinate back to oxaloacetate, corresponding to the fact that the citric acid cycle deals with a more reduced substrate than does the dicarboxylic acid cycle.

The synthetic pathway for the regenerating substrate of the dicarboxylic acid cycle is quite complex. Two molecules of glyoxylate undergo α condensation with decarboxylation by glyoxylate carboligase[114] (see also Chapter 14, Section D) to form **tartronic semialdehyde**. The latter is reduced to D-glycerate, which is phosphorylated to 3-phosphoglycerate and 2-phosphoglycerate. Since the phosphoglycerates are carbohydrate precursors, this **glycerate pathway** provides the organisms with a means for synthesis of carbohydrates and other complex materials from glyoxylate alone. At the same time, 2-phosphoglycerate can be converted to pyruvate and the pyruvate, by oxidative decarboxylation, to the regenerating substrate acetyl-CoA.

E. Catabolism of Sugars

In most sugars each carbon atom bears an oxygen atom which facilitates chemical attack by oxidation at any point in the carbon chain. Every sugar contains a potentially free aldehyde or ketone group, and the carbonyl function can be moved readily to adjacent positions by isomerases. Consequently, aldol cleavage is also possible at many points. For these reasons, the metabolism of carbohydrates is complex and varied. A sugar chain can be cut in several places giving rise to a variety of metabolic pathways. However, in the energy economy of most organisms, including human beings, the **Embden–Meyerhof–Parnas** or **glycolysis pathway** by which hexoses are converted to pyruvate (Fig. 17-7) stands out above all others. We have already considered this pathway, which is also outlined in Figs. 10-2 and 10-3. Some history and additional important details follow.

1. The Glycolysis Pathway

The discovery of glycolysis followed directly the early observations of Buchner and of Harden and Young on fermentation of sugar by yeast juice (p. 767). Another line of research, the study of muscle, soon converged with the investigations of alcoholic fermentation. Physiologists were interested in the process by which an isolated muscle could obtain energy for contraction in the absence of oxygen. It was shown by A. V. Hill that glycogen was converted to lactate to supply the energy, and Otto Meyerhof later demonstrated that the chemical reactions were related to those of alcoholic fermentation. The establishment of the structures and functions of the pyridine nucleotides in 1934 (Chapter 15) coincided with important studies by G. Embden in Frankfurt and of J. K. Parnas in Poland. The sequence of reactions in glycolysis soon became clear. All of the 15 enzymes catalyzing the individual steps in the sequence have been isolated and crystallized and are being studied in detail.[115]

Formation of pyruvate. The conversion of glucose to pyruvate requires ten enzymes (Fig. 17-7), and the sequence can be divided into four stages: preparation for chain cleavage (reactions *1*–*3*), cleavage and equilibration of triose phosphates (reactions *4* and *5*), oxidative generation of ATP (reactions *6* and *7*), and conversion of 3-phosphoglycerate to pyruvate (reactions *8*–*10*).

In preparation for chain cleavage, free glucose is phosphorylated to glucose 6-phosphate by ATP under the action of hexokinase (reaction *1*). Glucose 6-phosphate can also arise by cleavage of a glucosyl unit from glycogen by the consecutive action of glycogen phosphorylase (reaction 1*a*) and phosphoglucomutase, which transfers a phospho group from the oxygen at C-1 to that at C-6 (reaction 1*b*) (see also Eq. 12-39 and associated discussion of the mechanism of this enzyme). Why do cells attach phospho groups to sugars to initiate metabolism of the sugars? Four reasons can be given:

(a) The phospho group constitutes an electrically charged handle for binding the sugar phosphate to enzymes.

(b) There is a kinetic advantage in initiating a reaction sequence with a highly irreversible reaction

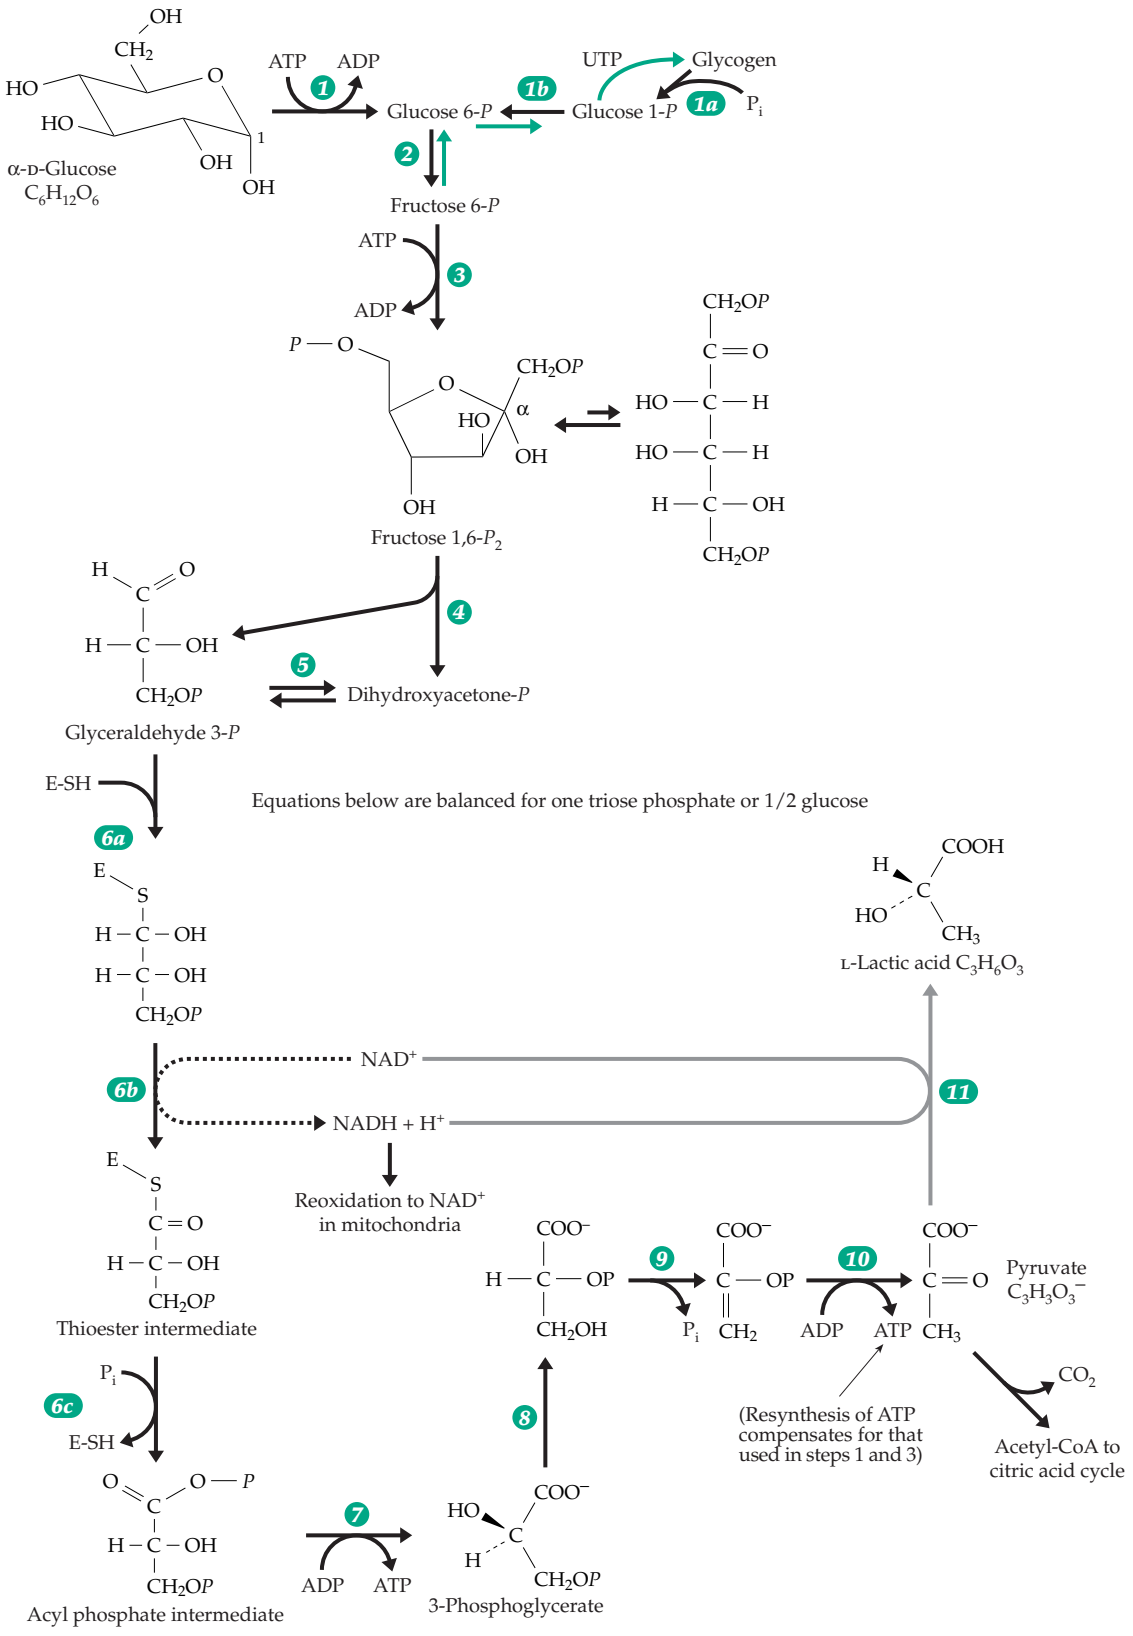

Figure 17-7 Outline of the glycolysis pathway by which hexoses are broken down to pyruvate. The ten enzymes needed to convert D-glucose to pyruvate are numbered. The pathway from glycogen using glycogen phosphorylase is also included, as is the reduction of pyruvate to lactate (step *11*). Steps *6a–7*, which are involved in ATP synthesis via thioester and acyl phosphate intermediates, are emphasized. See also Figures 10-2 and 10-3, which contain some additional information.

such as the phosphorylation of glucose.

(c) Phosphate esters are unable to diffuse out of cells easily and be lost.

(d) There is at least a possibility that the phospho groups may function in catalysis.

Reaction *2* of Fig. 17-7 is a simple isomerization that moves the carbonyl group to C-2 so that β cleavage to two three-carbon fragments can occur. Before cleavage a second phosphorylation (reaction *3*) takes place to form fructose 1,6-bisphosphate. This ensures that when fructose bisphosphate is cleaved by aldolase each of the two halves will have a phosphate handle. This second priming reaction (reaction *3*) is the first step in the series that is unique to glycolysis. The catalyst for the reaction, **phosphofructokinase**, is carefully controlled, as discussed in Chapter 11 (see Fig. 11-2).

Fructose bisphosphate is cleaved by action of an aldolase (reaction *4*) to give glyceraldehyde 3-phosphate and dihydroxyacetone phosphate. These two triose phosphates are then equilibrated by triose phosphate isomerase (reaction *5*; see also Chapter 13). As a result, both halves of the hexose can be metabolized further via glyceraldehyde 3-*P* to pyruvate. The oxidation of glyceraldehyde 3-*P* to the corresponding carboxylic acid, 3-phosphoglyceric acid (Fig. 17-7, reactions *6* and *7*), is coupled to synthesis of a molecule of ATP from ADP and P_i. This means that two molecules of ATP are formed per hexose cleaved, and that two molecules of NAD^+ are converted to NADH in the process.

The conversion of 3-phosphoglycerate to pyruvate begins with transfer of a phospho group from the C-3 to the C-2 oxygen (reaction *8*) and is followed by dehydration through an α, β elimination catalyzed by **enolase** (reaction *9*). The product, phosphoenolpyruvate (PEP), has a high group transfer potential. Its phospho group can be transferred easily to ADP via the action of the enzyme **pyruvate kinase**, to leave the enol of pyruvic acid which is spontaneously converted to the much more stable pyruvate ion (see Eq. 7-59). Because two molecules of PEP are formed from each glucose molecule, the process provides for the recovery of the two molecules of ATP that were expended in the initial formation of fructose 1,6-bisphosphate from glucose. Several isoenzyme forms exist in mammals. Most of these are allosterically activated by fructose 1,6-bisphosphate.[115a,b] However, the enzyme from trypanosomes is activated by fructose 2,6-P_2.[115c]

The further metabolism of pyruvate. In the aerobic metabolism that is characteristic of most tissues of our bodies, pyruvate is oxidatively decarboxylated to acetyl-CoA, which can then be completely oxidized in the citric acid cycle (Fig. 17-4). The NADH produced in reaction *6* of Fig. 17-7, as well as in the oxidative decarboxylation of pyruvate and in subsequent reactions of the citric acid cycle, is reoxidized in the electron transport chain of the mitochondria as described in detail in Chapter 18 (see Fig. 18-5). An important alternative fate of pyruvate is to enter into fermentation reactions. For example, the enzyme lactate dehydrogenase (Fig. 17-7, reaction *11*) catalyzes reduction by NADH of pyruvate to L-lactate, or, for some bacteria, to D-lactate. This reaction can be coupled to the NADH-producing reaction *6* to give a balanced process by which glucose is fermented to lactic acid in the absence of oxygen (see also Eq. 10-3). In a similar process, yeast cells decarboxylate pyruvate (α cleavage) to acetaldehyde which is reduced to ethanol using the NADH produced in reaction *6*. These fermentation reactions are summarized in Fig. 10-3 and, along with many others, are discussed further in Section F of this chapter.

2. Generation of ATP by Substrate Oxidation

The formation of ATP from ADP and P_i is a vital process for all cells. It is usually referred to as "phosphorylation" and includes **oxidative phosphorylation** associated with the passage of electrons through an electron transport chain—usually in mitochondria; **photosynthetic phosphorylation**, a similar process occurring in chloroplasts under the influence of light; and **substrate-level phosphorylation**. Only the last is fully understood chemically. The dehydrogenation of glyceraldehyde 3-*P* and the accompanying ATP formation (reactions *6* and *7*, Fig. 17-7; Fig. 15-6) is the best known example of substrate-level phosphorylation and is tremendously important for yeasts and other microorganisms that live anaerobically. They depend upon this one reaction for their entire supply of energy. The conversion of glucose either to lactate or to ethanol and CO_2 is accompanied by a net synthesis of only two molecules of ATP and it is most logical to view these as arising from oxidation of glyceraldehyde 3-*P*. The formation of ATP from PEP and ADP in reaction *10* of Fig. 17-7 can be regarded as the recapturing of ATP "spent" in the priming reactions of steps *1* and *3*. With a gain of only two molecules of ATP for each molecule of hexose fermented, it is not surprising that yeast must ferment enormous amounts of sugar to meet its energy needs.

Each glucose unit of glycogen stored in our bodies can be converted to pyruvate with an apparent net gain of *three* molecules of ATP. However, two molecules of ATP were needed for the initial synthesis of each hexose unit of glycogen (Fig. 12-2). Therefore, the overall net yield for fermentation of stored polysaccharide is still only two ATP per hexose. The fermentation of glycogen accounts for the very rapid generation of lactic acid during intense muscular activity. However, in most circumstances within aerobic tissues reoxidation of NADH occurs via the electron transport chain of mitochondria with a much higher yield of ATP. Substrate-

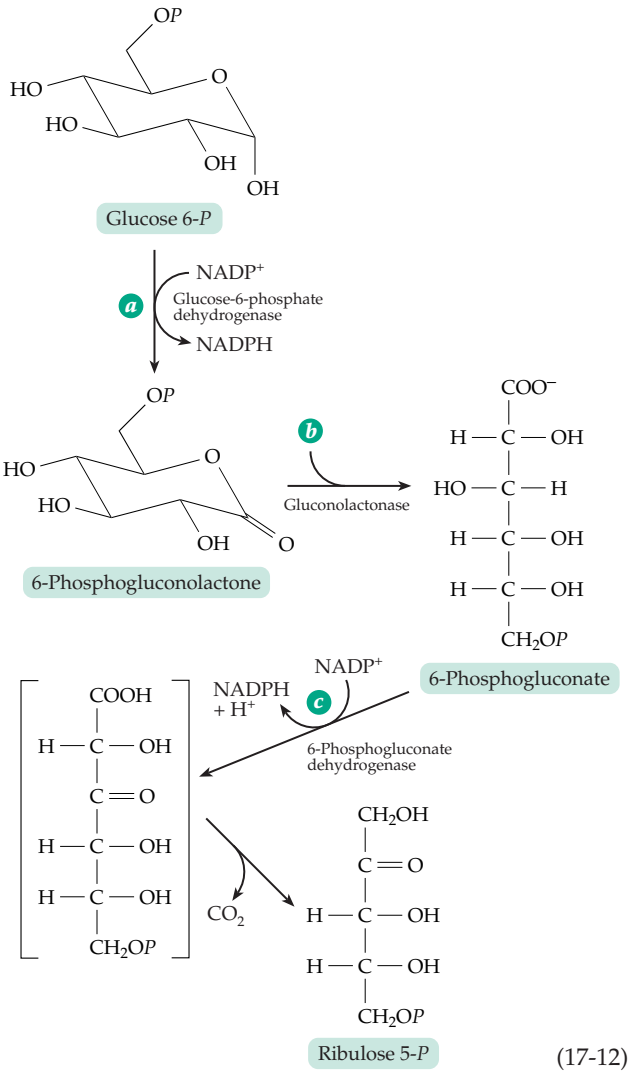
level phosphorylation can also follow oxidative decarboxylation of an α-oxoacid. For example, in the citric acid cycle GTP is formed following oxidative decarboxylation of 2-oxoglutarate (Fig. 17-4, steps *e* and *f*).

3. The Pentose Phosphate Pathways

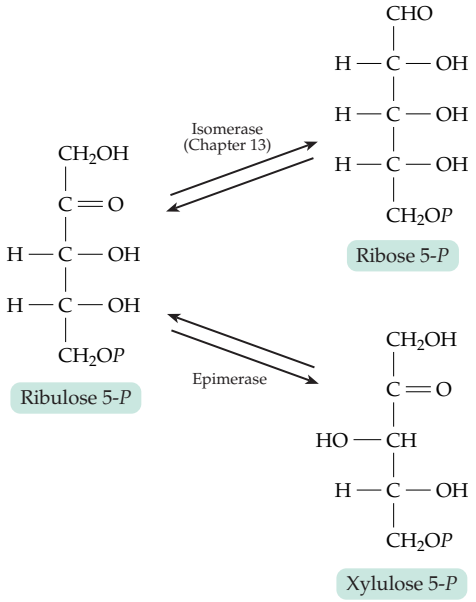
A second way of cleaving glucose 6-phosphate utilizes sequences involving the five-carbon pentose sugars. They are referred to as **pentose phosphate pathways**, the phosphogluconate pathway, or the hexose monophosphate shunt. Historically, the evidence for such routes dates from the experiments of Warburg on the oxidation of glucose 6-*P* to 6-phosphogluconate (Chapter 15). For many years the oxidation remained an enzymatic reaction without a defined pathway. However, it was assumed to be part of an alternative method of degradation of glucose. Supporting evidence was found in the observation that tissues continue to respire in the presence of a high concentration of fluoride ion, a known inhibitor of the enolase reaction and capable of almost completely blocking glycolysis. Some tissues, e.g., liver, are especially active in respiration through this alternative pathway, whose details were elucidated by Horecker and associates.[116,117] We now know that the pentose phosphate pathways are multiple as well as multipurpose. They function in catabolism and also, when operating in the reverse direction, as a **reductive pentose phosphate pathway** that lies at the heart of the sugar-forming reactions of photosynthesis.

The oxidative pentose pathway provides *a means for cutting the chain of a sugar molecule one carbon at a time*, with the carbon removed appearing as CO_2. The enzymes required can be grouped into three distinct systems, all of which are found in the cytosol of animal cells: (i) a dehydrogenation–decarboxylation system, (ii) an isomerizing system, and (iii) a sugar rearrangement system. The dehydrogenation–decarboxylation system cleaves glucose 6-*P* to CO_2 and the pentose phosphate, ribulose 5-*P* (Eq. 17-12). Three enzymes are required, the first being glucose 6-*P* dehydrogenase[117a] (Eq. 17-12, step *a*; see also Eq. 15-10). The immediate product, a lactone, undergoes spontaneous hydrolysis. However, the action of **gluconolactonase** (Eq. 17-12, step *b*) causes a more rapid ring opening. A second dehydrogenation is catalyzed by **6-phosphogluconate dehydrogenase** (Eq. 17-12, step *c*),[117b] and this reaction is immediately followed by a β decarboxylation catalyzed by the same enzyme (as in Eq. 13-45). The value of $\Delta G°$ for oxidation of glucose 6-*P* to ribulose 5-*P* by $NADP^+$ according to Eq. 17-12 is -30.8 kJ mol^{-1}, a negative enough value to drive the [NADPH]/[$NADP^+$] ratio to an equilibrium value of over 2000 at a CO_2 tension of 0.05 atm.

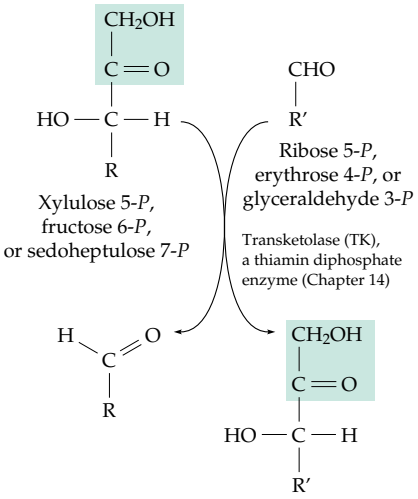
The isomerizing system, consisting of two enzymes,



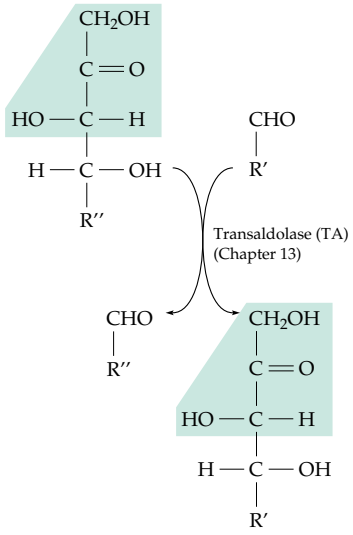
(17-12)



(17-13)



(17-14)



(17-15)

interconverts three pentose phosphates (Eq. 17-13). As a consequence the three compounds exist as an equilibrium mixture. Both xylulose 5-*P* and ribose 5-*P* are needed for further reactions in the pathways.

The ingenious sugar rearrangement system uses two enzymes, **transketolase** and **transaldolase**. Both catalyze chain cleavage and transfer reactions (Eqs. 17-14 and 17-15) that involve the same group of substrates. These enzymes use the two basic types of C–C bond cleavage, adjacent to a carbonyl group (α) and one carbon removed from a carbonyl group (β). Both types are needed in the pentose phosphate pathways just as they are in the citric acid cycle. The enzymes of the pentose phosphate pathway are found in the cytoplasm of both animal and plant cells.[117c] Mammalian cells appear to have an additional set that is active in the endoplasmic reticulum and plants have another set in the chloroplasts.[117c]

An oxidative pentose phosphate cycle. Putting the three enzyme systems together, we can form a cycle that oxidizes hexose phosphates. Three carbon atoms are chopped off one at a time (Fig. 17-8A) leaving a three-carbon triose phosphate as the product. Since the dehydrogenation system works only on glucose 6-*P*, a part of the sugar rearrangement system must be utilized between each of the three oxidation steps. Notice that a C_5 unit (ribose 5-*P*) is used in the first reaction with transketolase but is regenerated at the end of the sequence. This C_5 unit is the regenerating substrate for the cycle. As indicated by the dashed arrows, it is formed readily in any quantity needed by oxidation of glucose 6-*P*. Before the C_5 unit that is formed in each oxidation step can be processed by the sugar rearrangement reactions, it must be isomerized[117c,118,118a,b] from ribulose 5-*P* to xylulose 5-*P*; before the C_5 unit, produced at the end of the sequence in Fig. 17-8, can be reutilized as a regenerating substrate, it must be isomerized to ribose 5-*P*. Thus, the cycle is quite complex. The same C_5 substrates appear at several points in Fig. 17-8A and substrates from different parts of the cycle become scrambled and the pathway does not degrade all the hexose molecules in a uniform manner. For this reason, Zubay described the pentose phosphate pathways as a "swamp."[119]

The oxidative pentose phosphate cycle is often presented as a means for complete oxidation of hexoses to CO_2. For this to happen the C_3 unit indicated as the product in Fig. 17-8A must be converted (through the action of aldolase, a phosphatase, and hexose phosphate isomerase) back to one-half of a molecule of glucose-6-*P* which can enter the cycle at the beginning. On the other hand, alternative ways of degrading the C_3 product glyceraldehyde-*P* are available. For example, using glycolytic enzymes, it can be oxidized to pyruvate and to CO_2 via the citric acid cycle.

As a general rule, NAD^+ is associated with catabolic reactions and it is somewhat unusual to find $NADP^+$ acting as an oxidant. However, in mammals the enzymes of the pentose phosphate pathway are specific for $NADP^+$. The reason is thought to lie in the need of NADPH for biosynthesis (Section I). On this basis, the occurrence of the pentose phosphate pathway in tissues having an unusually active biosynthetic function (liver and mammary gland) is understandable. In these tissues the cycle may operate as indicated in Fig. 17-8A with the C_3 product also being used in biosynthesis. Furthermore, any of the products from C_4 to C_7 may be withdrawn in any desired amounts without disrupting the smooth operation of the cycle. For example, the C_4 intermediate **erythrose 4-*P*** is required in synthesis of aromatic amino acids by bacteria and plants (but not in animals). **Ribose 5-*P*** is needed for formation of several amino acids and of nucleic acids by all organisms. In some circumstances the formation of ribose 5-*P* may be the only essential function for the pentose phosphate pathway.[120]

Several studies of the metabolism of isotopically labeled glucose[121–122a] have been in accord with

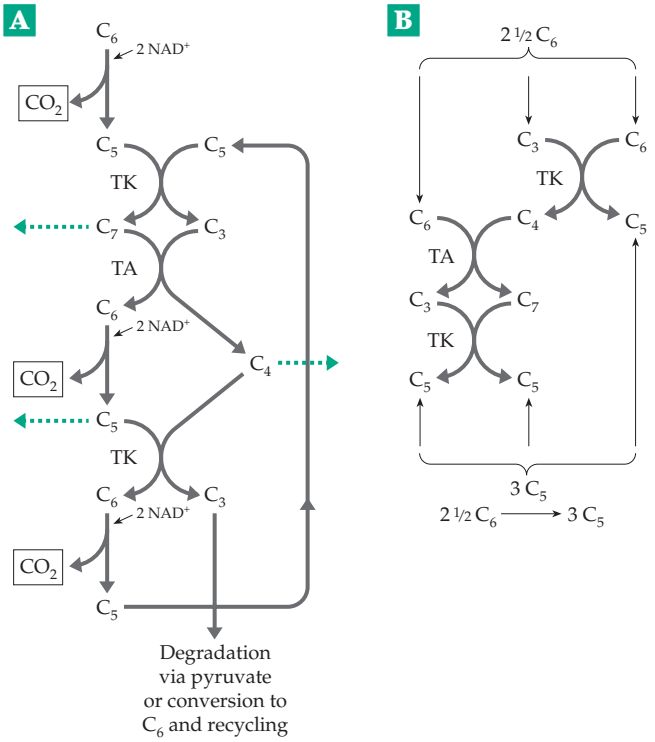


Figure 17-8 The pentose phosphate pathways. (A) Oxidation of a hexose (C_6) to three molecules of CO_2 and a three-carbon fragment with the option of removing C_3, C_4, C_5, and C_7 units for biosynthesis (dashed arrows). (B) Nonoxidative pentose pathways: 2 1/2 C_6 → 3 C_5 or 2 C_6 → 3 C_4 or 3 1/2 C_6 → 3 C_7.

operation of the pentose phosphate pathway as is depicted in Fig. 17-8. However, Williams and associates proposed a modification in the sugar rearrangement sequence in liver[123–126] to include the formation of arabinose 5-*P* (from ribose 5-*P*), an octulose bisphosphate, and an octulose 8-monophosphate. Many investigators argue that these additional reactions are of minor significance.[121,122,127] The measured concentrations of pentose phosphate pathway intermediates in rat livers are close to those predicated for a near-equilibrium state from equilibrium constants measured for the individual steps of Fig. 17-8.[128] Most of the concentrations are in the 4- to 10-μM range but the level of erythrose 4-*P*, which is predicted to be ~ 0.2 μM, is too low to measure.

In contrast to animals, the resurrection plant *Craterostigma plantaginenm* accumulates large amounts of a 2-oxo-octulose. This plant is one of a small group of angiosperms that can withstand severe dehydration and are able to rehydrate and resume normal metabolism within a few hours. During desiccation much of the octulose is converted into sucrose. The plant has extra transketolase genes which may be essential for this rapid interconversion of sugars.[129]

Nonoxidative pentose phosphate pathways. The sugar rearrangement system together with the glycolytic enzymes that convert glucose 6-*P* to glyceraldehyde 3-*P* can function to transform hexose phosphates into pentose phosphates (Fig. 17-8B; Eq. 17-16) which may be utilized for nucleic acid synthesis in erythrocytes and other cells.[130,131]

$$2\tfrac{1}{2}\ C_6 \rightarrow 3\ C_5 \qquad (17\text{-}16)$$

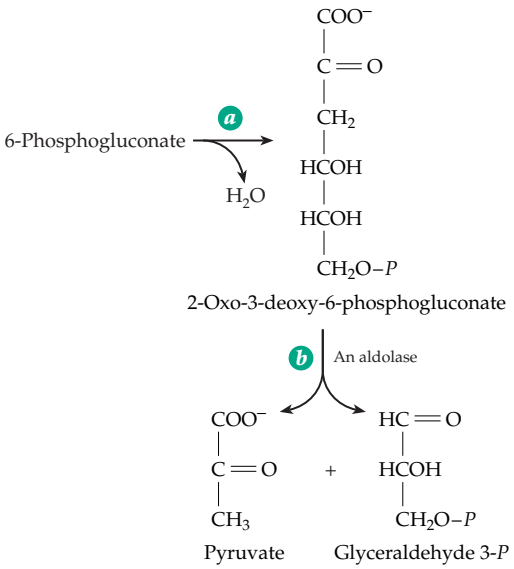
The reader can easily show that the same enzymes will catalyze the net conversion of hexose phosphate to erythrose 4-phosphate or to sedoheptulose 7-phosphate (Eq. 17-17):

$$2\ C_6 \rightarrow 3\ C_4;\quad 3\tfrac{1}{2}\,C_6 \rightarrow 3\ C_7 \qquad (17\text{-}17)$$

An investigation of metabolism of the red lipid-forming yeast *Rhodotorula gracilis* (which lacks phosphofructokinase and is thus unable to break down sugars through the glycolytic pathway) indicated that 20% of the glucose is *oxidized* through the pentose phosphate pathways while 80% is *altered* by the nonoxidative pentose phosphate pathway.[100] However, it is not clear how the C_3 unit used in the nonoxidative pathway (Fig. 17-8B) is formed if glycolysis is blocked. A number of fermentations are also based on the pentose phosphate pathways (Section F,5).

4. The Entner–Doudoroff Pathway

An additional way of cleaving a six-carbon sugar chain provides the basis for the **Entner–Doudoroff pathway** which is used by *Zymomonas lindneri* and many other species of bacteria. Glucose 6-*P* is oxidized first to 6-phosphogluconate, which is converted by dehydration to a 2-oxo-3-deoxy derivative (Eq. 17-18,



(17-18)

step *a*). The resulting 2-oxo-3-deoxy sugar is cleaved by an aldolase (Eq. 17-18, step *b*) to pyruvate and glyceraldehyde 3-*P*, which are then metabolized in standard ways.

F. Fermentation: "Life without Oxygen"

Pasteur recognized in 1860 that fermentation was not a spontaneous process but a result of life in the near absence of air.[132] He realized that yeasts decompose much more sugar under anaerobic conditions than they do aerobically, and that the anaerobic fermentation was essential to the life of these organisms. In addition to the alcoholic fermentation of yeast, there are many other fermentations which have been attractive subjects for biochemical study. If life evolved at a time when no oxygen was available, the most primitive organisms must have used fermentations. They may be the oldest as well as the simplest ways in which cells obtain energy. The enzymes of the glycolysis pathway are found in the small genomes of *Mycoplasma*, *Haemophila*, and *Methanococcus*.[133,134]

Fermentation is also a vital process in the human body. Our muscles usually receive enough oxygen to oxidize pyruvate and to obtain ATP through aerobic metabolism, but there are circumstances in which the oxygen supply is inadequate. During extreme exertion, after most oxygen is consumed, muscle cells produce lactate by fermentation. White muscle of fish and fowl has little aerobic metabolism and normally yields L-lactic acid as a principal end product. Likewise, a variety of tissues within the human body, including the transparent lens and cornea of our eyes, are poorly supplied with blood and depend upon fermentation of glucose to lactic acid. Red blood cells and skin and sometimes adipose tissue are also major producers of lactic acid.[135] Of the ~115 g of lactic acid present in a 70-kg human body, about 29% comes from erythrocytes, 29% from skin, 17% from the brain, and 16% from skeletal muscle.[136] Because lactic acid lowers the pH of cells it must be removed efficiently.

Some of the lactic acid formed in muscle and most of the lactate formed in less aerobic tissues (e.g., adipose tissue)[136a] enters the bloodstream, which normally contains 1–2 mM lactate,[136] and is carried to the liver where it is reoxidized to pyruvate. Part of the pyruvate is then oxidized via the citric acid cycle while a larger part is reconverted to glucose (Section J,5). This glucose may be released into the bloodstream and returned to the muscles. The overall process is known as the **Cori cycle**. Lactic acid accumulates in muscle after vigorous exercise. It is exported to the liver slowly, but if mild exercise continues the lactate may be largely oxidized within muscle via the tricarboxylic acid cycle. Recent NMR studies have shown that lactic acid is formed rapidly during muscular contraction, even when exercise is mild.[136b] During the initial 15 ms of contraction the ATP utilized is regenerated from creatine phosphate (Eq. 6-67). During the remainder of the contraction (up to ~100 ms) glycogen is converted to lactic acid to provide ATP and to replenish the creatine phosphate. In the resting period following contraction most of the lactate is either dehydrogenated to pyruvate and oxidized in mitochondria or exported to other tissues. The glycogen stores in muscle are renewed by synthesis from blood glucose. Lactic acid is a convenient energy carrier and a precursor for gluconeogenesis which can be transferred between tissues easily.[136c] Cancer cells often take advantage of this opportunity to grow rapidly using fermentation of glucose to lactic acid as a source of energy.[136d]

Alcoholic fermentation allows roots of some plants to survive short periods of flooding. Ethanol does not acidify the tissues as does lactic acid, avoiding possible damage from low pH.[137,138] Goldfish can also use the ethanolic fermentation for short times, excreting the ethanol.[139]

1. Fermentations Based on the Embden–Meyerhof Pathway

Homolactic and alcoholic fermentations. The reactions by which glucose can be converted to lactate and, by yeast cells, to ethanol and CO_2 (Figs. 10-3 and 17-7) illustrate several features common to all fermentations. The NADH produced in the oxidation step is reoxidized in a reaction by which substrate is reduced to the final end product. The NAD alternates between oxidized and reduced forms. This coupling of oxidation steps with reduction steps in exact equivalence is characteristic of all true (anaerobic) fermentations. The formation of ATP from ADP and P_i by substrate-level phosphorylation is also common to all fermentations. The stoichiometry is often nearly exact and simple. For example, according to the reaction of Eq. 17-19, which is outlined step-by-step in Fig. 17-7, a net total of two moles of ATP is formed per mole of glucose fermented.

Energy relationships. If we disregard the synthesis of ATP, the equations for the lactic acid and ethanol fermentations are given by Eqs. 17-19 and 17-20.

$$\text{Glucose} \rightarrow 2\ \text{lactate}^- + 2\ \text{H}^+$$
$$\Delta G'\ (\text{pH } 7) = -196\ \text{kJ mol}^{-1}\ (-46.8\ \text{kcal mol}^{-1}) \qquad (17\text{-}19)$$

$$\text{Glucose} \rightarrow 2\ \text{CO}_2 + 2\ \text{ethanol}$$
$$\Delta G^\circ = -235\ \text{kJ mol}^{-1} \qquad (17\text{-}20)$$

The Gibbs energy changes are negative and of sufficient magnitude that the reactions will unquestionably go to completion. However, the synthesis of two molecules of ATP from inorganic phosphate and ADP, a reaction

(Eq. 17-21) for which $\Delta G'$ is substantially positive, is coupled to the fermentation.

$$ADP^{3-} + HPO_4^{2-} + H^+ \rightarrow ATP^{4-} + H_2O$$
$$\Delta G' \text{ (pH 7)} = +34.5 \text{ kJ mol}^{-1} \text{ (Table 6-5)} \quad (17\text{-}21)$$

To obtain the net Gibbs energy change for the complete reaction we must add 2 x 34.5 = +69.0 kJ to the values of $\Delta G'$ for Eqs. 17-19 and 17-20. When this is done we see that the net Gibbs energy changes are still highly negative, that the reactions will proceed to completion, and that these fermentations can serve as an usable energy source for organisms.

Biochemists sometimes divide ΔG for the ATP synthesis in a coupled reaction sequence (in this case +69 kJ) by the overall Gibbs energy decrease for the coupled process (196 or 235 kJ mol^{-1}) to obtain an "efficiency." In the present case the efficiency would be 35% and 29% for coupling of Eq. 17-21 (for 2 mol of ATP) to Eqs. 17-19 and 17-20, respectively. According to this calculation, nature is approximately one-third efficient in the utilization of available metabolic Gibbs energy for ATP synthesis. However, it is important to realize that this calculation of efficiency has no exact thermodynamic meaning. Furthermore, the utilization of ATP formed by a cell for various purposes is far from 100% efficient.

Why are the Gibbs energy decreases for Eqs. 17-19 and 17-20 so large? No overall oxidation takes place; there is only a rearrangement of the existing bonds between atoms of the substrate. Why does this rearrangement of bonds lead to a substantial negative ΔG? An answer is suggested by an examination of the numbers of each type of bond in the substrate and in the products. During the conversion from glucose to two molecules of lactate one C–C bond, one C–O bond, and one O–H bond are lost and one C–H bond and one C=O are gained. If we add up the bond energies for these bonds (Table 6-6) we find that the difference (ΔH) between substrate and products amounts to only about 20 kJ/mol. However, lactic acid contains a carboxyl group, and carboxyl groups have a special stability as a result of resonance. The extra resonance energy of a carboxyl group (Table 6-6) is ~117 kJ (28 kcal) per mole or 234 kJ/mol for two carboxyl groups. This is approximately the same as the Gibbs energy change (Eq. 17-19) for fermentation of glucose to lactate. Thus, the energy available results largely from the rearrangement of bonds by which the carboxyl groups of lactate are formed. Likewise, the resonance stabilization of CO_2 is given by Pauling as 151 kJ/mol, again of just the right magnitude to explain ΔG in alcoholic fermentations (Eq. 17-20).

On this basis we can state as a general rule that fermentations can occur when substrates consisting of largely singly bonded atoms and groups, such as the carbonyl groups that are not highly stabilized by resonance, are converted to products containing carboxyl groups or to CO_2. If we assume an efficiency of ~30%, the energy available will be about sufficient for synthesis of one ATP molecule for each carboxyl group or CO_2 created. Bear in mind that generation of ATP also depends upon availability of a mechanism. It is of interest that most synthesis of ATP is linked directly to the chemical processes by which carboxyl groups or CO_2 molecules are created in a fermentation process. The most important single reaction is the oxidation of the aldehyde group of glyceraldehyde 3-*P* to the carboxyl group of 3-phosphoglycerate (steps *6a*– *6c* and *7* in Fig. 17-7; see also Fig. 15-6).

Compare the fermentation of glucose with the complete oxidation of the sugar to carbon dioxide and water (Eq. 17-22), a process which yeast cells (as well as our own cells) carry out in the presence of air. The overall Gibbs energy change is over 10 times greater than that for fermentation, a fact that permits the cell

$$\text{Glucose} + 6\,O_2 \rightarrow 6\,CO_2 + 6\,H_2O$$
$$\Delta G' = -2872 \text{ kJ } (-686.5 \text{ kcal}) \text{ mol}^{-1} \quad (17\text{-}22)$$

to form an enormously greater quantity of ATP. The net gain in ATP synthesis, accompanying Eq. 17-22, is usually about 38 mol of ATP—19 times more than is available from fermentation of glucose. Thus, the explanation of Pasteur's observation that yeast decomposes much less sugar in the presence of air than in its absence is clear. Also, we can understand why a cell, living anaerobically, must metabolize a very large amount of substrate to grow. (Recall from Chapter 6 that ~1 mol of ATP energy is needed to produce 10 g of cells.)

Variations of the alcoholic and homolactic fermentations. The course of a fermentation is often affected drastically by changes in conditions. Many variations can be visualized by reference to Fig. 17-9, which shows a number of available metabolic sequences. We have already discussed the conversion of glucose to triose phosphate and via reaction pathway *a* to pyruvate, via reaction *c* to lactate, and via reaction *d* to ethanol.

If bisulfite is added to a fermenting culture of yeast, the acetaldehyde formed through reaction *d* is trapped as the bisulfite adduct blocking the reduction of acetaldehyde to ethanol, an essential part of the fermentation. Yeast cells accommodate this change by using the accumulating NADH to reduce half of the triose-*P* to glycerol through pathway *b*. Two enzymes are needed, a dehydrogenase and a phosphatase, to hydrolytically cleave off the phosphate. The balanced reaction is given by Eq. 17-23:

$$\text{Glucose} \rightarrow \text{glycerol} + \text{acetaldehyde (trapped)} + CO_2$$
$$\Delta G' \text{ (pH 7)} = -105 \text{ kJ mol}^{-1} \quad (17\text{-}23)$$

In this reaction only one molecule of CO_2 is produced

but the overall Gibbs energy change is still adequate to make the reaction highly spontaneous. However (referring to Fig. 17-9), we see that the net synthesis of ATP is now apparently zero. The fermentation apparently does not permit cell growth. Nevertheless, it has been used industrially for production of glycerol.

Reduction of dihydroxyacetone phosphate to glycerol phosphate also occurs in insect flight muscle and apparently operates as an alternative to lactic acid formation in that tissue. There is no net gain of ATP in the conversion of free glucose to glycerol phosphate and pyruvate, but using stored glycogen in muscle as the starting material, the dismutation of triose-*P* to glycerol-*P* and pyruvate provides one ATP per glucose unit rapidly during the vigorous contraction of the powerful insect flight muscle. During the slower recovery phase, glycerol-*P* is thought to be reoxidized after entering the mitochondria of these highly aerobic cells. Thus, the transport of glycerol-*P* into mitochondria serves as a means for transporting reducing equivalents derived from reoxidation of NADH into the mitochondria. Indeed, the significance of glycerol-*P* to muscle metabolism may be more related to this function than to the rapid formation of ATP (see Chapter 18).

Why does the glycolysis sequence begin with phosphorylation of glucose by ATP? The phospho groups probably provide convenient handles and doubtless assist in substrate recognition. There may be a kinetic advantage but also a danger. Unless there is adequate regulation the "turbo design," in which ATP is used at the outset to drive glycolysis, may lead to accumulation of phosphorylated intermediates and to inadequate concentrations of ATP and inorganic phosphate.[139a,b] Yeast cells guard against this problem by synthesizing trehalose 6-phosphate, which acts as a feedback inhibitor of hexokinase.[139a] Trypanosomes utilize a different type of control. The enzymes that convert glucose into 3-phosphoglycerate are present in membrane-bounded organelles called **glycosomes**. Phosphoglycerate is exported from them into the cytosol where glycolysis is completed.[139b] Since inorganic phosphate is essential for ATP formation, if the P_i concentration falls too low the rate of fermentation by yeast juice is greatly decreased, an observation made by Harden and Young[139c] in 1906.

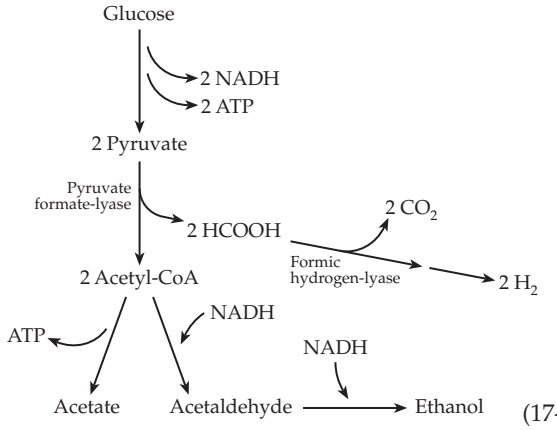
2. The Mixed Acid Fermentation

Enterobacteria, including *E. coli*, convert glucose to ethanol and acetic acid and either formic acid or CO_2 and H_2 derived from it. The stoichiometry is variable but the fermentation can be described in an idealized form as follows:

$$\text{Glucose} + H_2O \rightarrow \text{ethanol} + \text{acetate}^- + H^+ + 2\,H_2 + 2\,CO_2$$

$$\Delta G'\ (\text{pH } 7) = -225\ \text{kJ mol}^{-1} \qquad (17\text{-}24)$$

The details of the process and the oxidation–reduction balance can be pictured as in Eq. 17-25. Pyruvate is cleaved by the pyruvate formate–lyase reaction (Eq. 15-37) to acetyl-CoA and formic acid. Half of the acetyl-CoA is cleaved to acetate via acetyl-*P* with generation of ATP, while the other half is reduced in two steps to ethanol using the two molecules of NADH produced in the initial oxidation of triose phosphate (Eq. 17-25). The overall energy yield is three molecules of ATP per glucose. The "efficiency" is thus (3 x 34.5) ÷ 225 = 46%. Some of the glucose is converted to D-lactic and to succinic acids (pathway *f*, Fig. 17-9); hence the name **mixed acid fermentation**. Table 17-1 gives typical yields of the mixed acid fermentation of *E. coli*. Among the four major products are acetate, ethanol, H_2, and CO_2, as shown in Eq. 17-25. However, at high pH formate accumulated instead of CO_2.



(17-25)

TABLE 17-1
Products of the Mixed Acid Fermentation by *E. coli* at Low and High Values of pH[a]

Product (Millimole formed from 100 mmol of glucose)	pH 6.2	pH 7.8
Acetate	36	39
Ethanol	50	51
H_2	70	0.3
CO_2	88	1.7
Formate	2.4	86
Lactate	79	70
Succinate	11	15
Glycerol	1.4	0.3
Acetoin	0.1	0.2
Butanediol	0.3	0.2

[a] From Tempest, D. W. and Neijssel, O. M.[140] Based on data of Blackwood.[141]

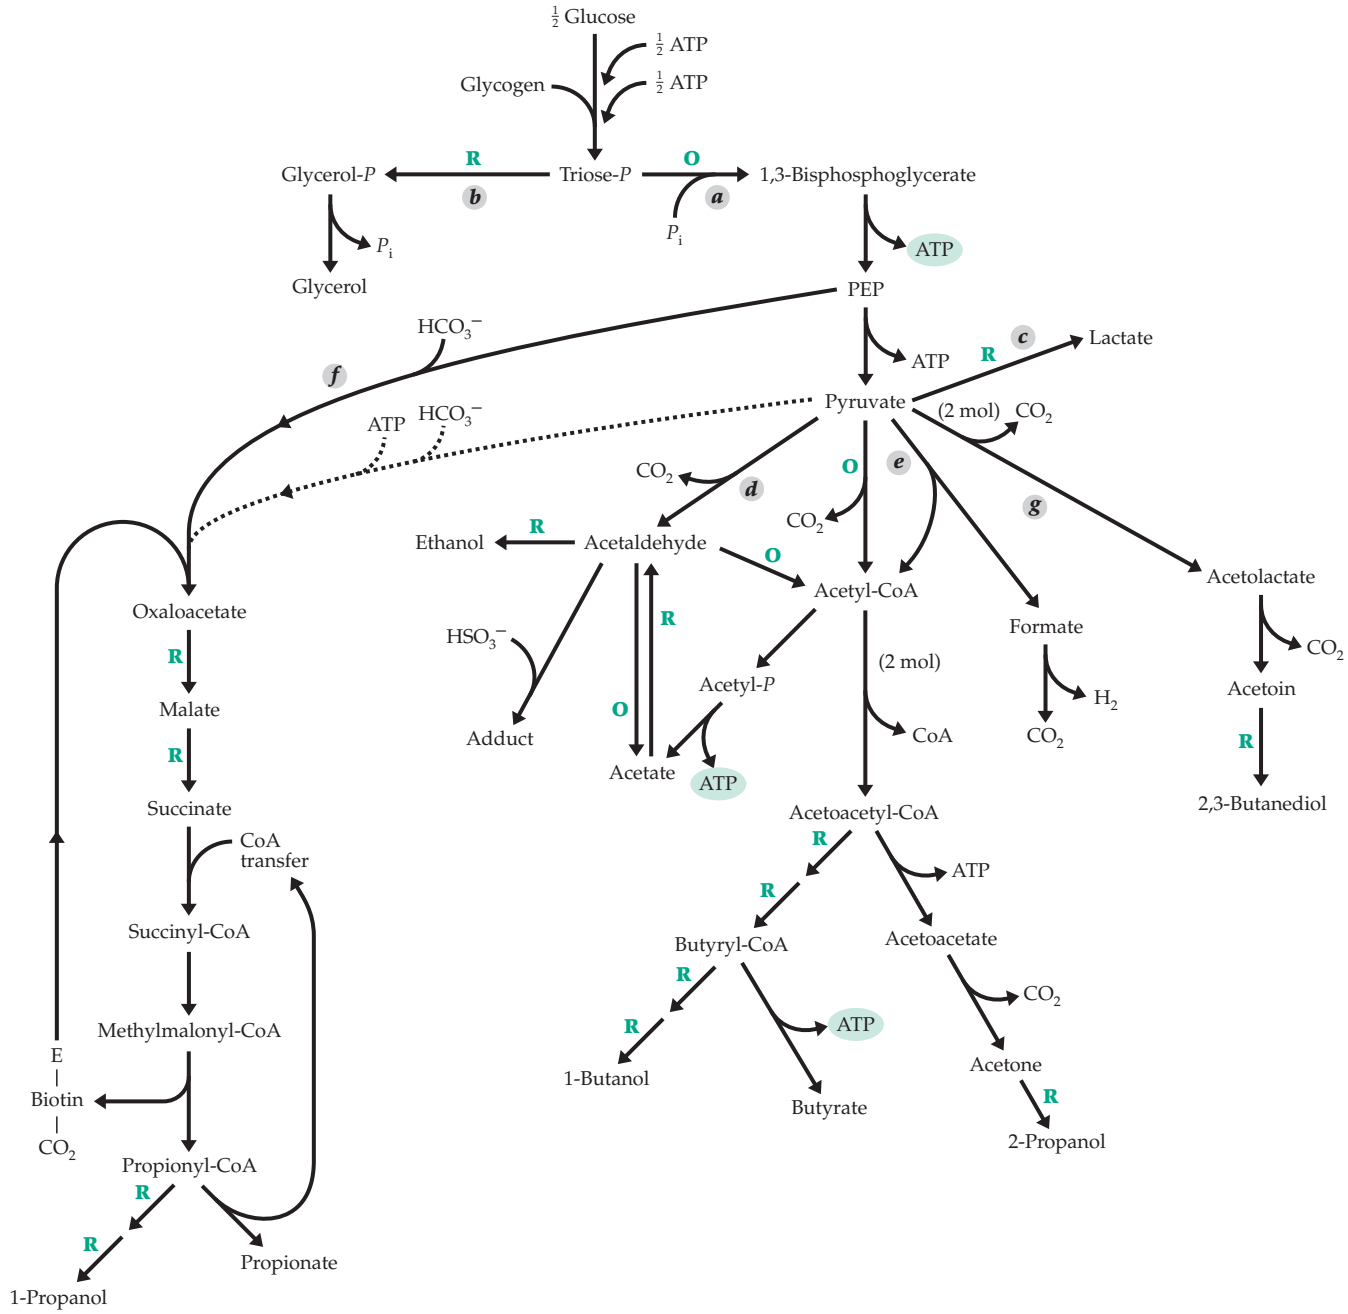


Figure 17-9 Reaction sequences in fermentation based on the Embden–Meyerhof–Parnas pathway. Oxidation steps (producing NADH + H^+) are marked "O"; reduction steps (using NADH + H^+) are marked "R."

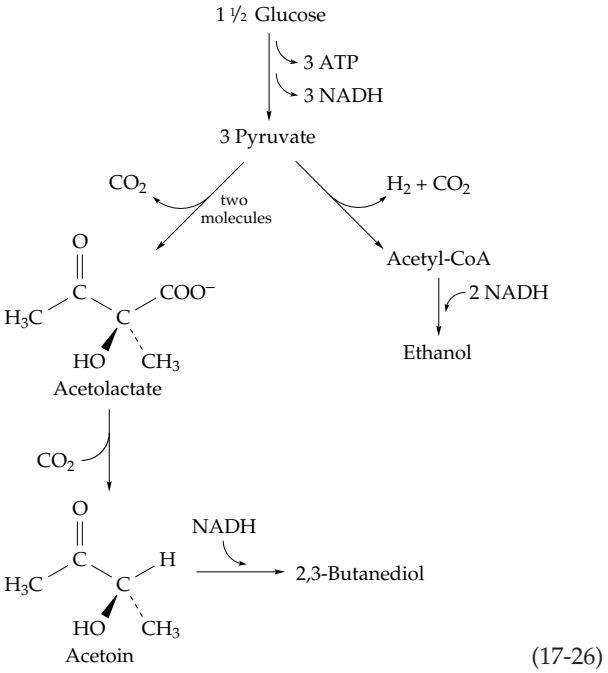
Over one-third of the glucose was fermented to lactate in both cases.

In some mixed acid fermentations (e.g., that of *Shigella*) formic acid accumulates, but in other cases (e.g., with *E. coli* at pH 6) it is converted to CO_2 and H_2 (Eq. 17-25). The equilibration of formic acid with CO_2 and hydrogen is catalyzed by the **formic hydrogen–lyase** system which consists of two iron–sulfur enzymes. The selenium-containing **formate dehydrogenase** (Eq. 16-63) catalyzes oxidation of formate to CO_2 by NAD^+, while a membrane-bound **hydrogenase** (Eq. 16-48) equilibrates NADH + H^+ with $NAD^+ + H_2$. Hydrogenase also serves to release H_2 from excess NADH. Krebs pointed out that an excess of NADH may arise because growth of cells requires biosynthesis of many components such as amino acids. When glucose is the sole source of carbon, biosynthetic reactions involve an excess of oxidation steps over reduction steps.[142] The excess of reducing equivalents may be released as H_2 or

may be used to form highly reduced products such as succinate.

Among such genera as *Aerobacter* and *Serratia* part of the pyruvate formed is condensed with decarboxylation to form ***S* acetolactate**,[143] which is decarboxylated to acetoin (Eq. 17-26; pathway *g* of Fig. 17-9). The acetoin is reduced with NADH to **2,3-butanediol**, while a third molecule of pyruvate is converted to ethanol, hydrogen, and CO_2 (Eq. 17-26). The reaction provides the basis for industrial production of butanediol, which can be dehydrated nonenzymatically to butadiene.



(17-26)

Mixed acid fermentations are not limited to bacteria. For example, trichomonads, parasitic flagellated protozoa, have no mitochondria. They export pyruvate into the bloodstreams of their hosts and also contain particles called **hydrogenosomes** which can convert pyruvate to acetate, succinate, CO_2, and H_2.[144] Hydrogenosomes are bounded by double membranes and have a common evolutionary relationship with both mitochondria and bacteria. The enzyme that catalyzes pyruvate cleavage in hydrogenosomes apparently does not contain lipoate and may be related to the pyruvate–ferredoxin oxidoreductase of clostridia (Eq. 15-35). The hydrogenosomes also contain an active hydrogenase.

Many invertebrate animals are true facultative anaerobes, able to survive for long periods, sometimes indefinitely, without oxygen.[145–147] Among these are *Ascaris* (Fig. 1-14), oysters, and other molluscs. Succinate and alanine are among the main end products of anaerobic metabolism. The former may arise by a mixed acid fermentation that also produces pyruvate. The pyruvate is converted to acetate to balance the fermentation in *Ascaris lumbricoides*, which is in effect an obligate anaerobe. However, in molluscs the pyruvate may undergo transamination with glutamate to form alanine and 2-oxoglutarate; the oxoglutarate may be oxidatively decarboxylated to succinate. The reactions depend upon the availability of a store of glutamate or of other amino acids, such as arginine, that can give rise to glutamate.

3. The Propionic Acid Fermentation

Propionic (propanoic) acid-producing bacteria are numerous in the digestive tract of ruminants. Within the rumen some bacteria digest cellulose to form glucose, which is then converted to lactate and other products. The propionic acid bacteria can convert either glucose or lactate into propionic and acetic acids which are absorbed into the bloodstream of the host. Usually some succinic acid is also formed.

The basis of the propionic acid fermentation is conversion of pyruvate to oxaloacetate by carboxylation and the further conversion through succinate and succinyl-CoA to methylmalonyl-CoA and propionyl-CoA, reactions which are almost the exact reverse of those for the oxidation of propionate in the animal body (Fig. 17-3, pathway *d*). However, whereas the carboxylation of pyruvate to oxaloacetate in the animal body requires ATP, the propionic acid bacteria save one equivalent of ATP by using a carboxyltransferase (p. 725). This enzyme donates a carboxyl group from a preformed carboxybiotin compound generated in the decarboxylation of methylmalonyl-CoA in the next to final step of the reaction sequence (Fig. 17-10). A second molecule of ATP is saved by linking directly the conversion of succinate to succinyl-CoA to the cleavage of propionyl-CoA to propionate through the use of a CoA transferase (Eq. 12-50). To provide for oxidation–reduction balance, two-thirds of the glucose goes to propionate and one-third to acetate (Eq. 17-27):

$$1\tfrac{1}{2}\,\text{Glucose} \rightarrow 2\ \text{propionate}^- + \text{acetate}^- + 3\ H^+ + CO_2 + H_2O$$
$$\Delta G'\ (\text{pH } 7) = -465\ \text{kJ per } 1\tfrac{1}{2}\ \text{mol of glucose} \qquad (17\text{-}27)$$

More carboxyl groups and CO_2 molecules are formed in this fermentation ($2\frac{2}{3}$ per glucose molecule) than in the regular lactic acid fermentation. The yield of ATP (also $2\ \frac{2}{3}$ mol/mol of glucose fermented) is correspondingly greater and $\Delta G'$ is more negative.

Using the same mechanism (Fig. 17-10), propionic acid bacteria are also able to ferment lactate, the product of fermentation by other bacteria, to propionate and acetate (Eq. 17-28). The net gain is one molecule of ATP. This reaction probably accounts for the niche

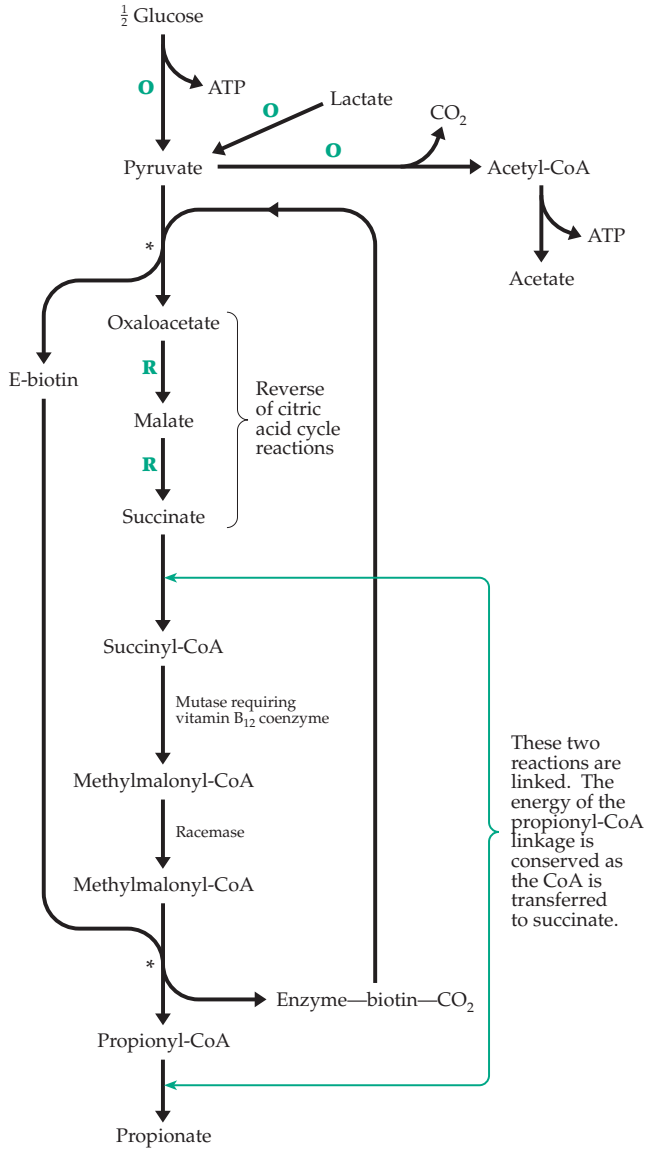


Figure 17-10 Propionic acid fermentation of *Propionobacteria* and *Veillonella*. Oxidation steps are designated by the symbol "O" and reduction steps by "R." The two coupled reactions marked by asterisks are catalyzed by carboxyltransferase.

$$3\ \text{Lactate}^- \rightarrow 2\ \text{propionate}^- + \text{acetate}^- + H_2O + CO_2$$
$$\Delta G'\ (\text{pH } 7) = -171\ \text{kJ per 3 mol of lactate} \qquad (17\text{-}28)$$

in the ecology of the animal rumen that is occupied by propionic acid bacteria.

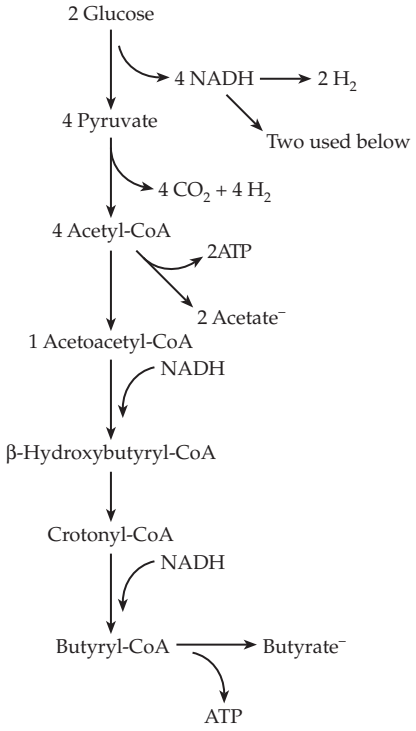
4. Butyric Acid and Butanol-Forming Fermentations

A variety of fermentations are carried out by bacteria of the genus *Clostridium* and by the rumen organisms *Eubacterium (Butyribacterium)* and *Butyrivibrio*.

For example, glucose may be converted to butyric and acetic acids together with CO_2 and H_2 (Eqs. 17-29 and 17-30).

$$2\ \text{Glucose} + 2\ H_2O \rightarrow \text{butyrate}^- + 2\ \text{acetate}^- + 4\ CO_2 + 6\ H_2 + 3\ H^+$$
$$\Delta G'\ (\text{pH } 7) = -479\ \text{kJ per 2 mol of glucose} \qquad (17\text{-}29)$$

The yield of ATP (3½ mol/mol of glucose) is the highest we have discussed giving an efficiency of 50%. Another fermentation yields butanol, isopropanol, ethanol, and acetone.

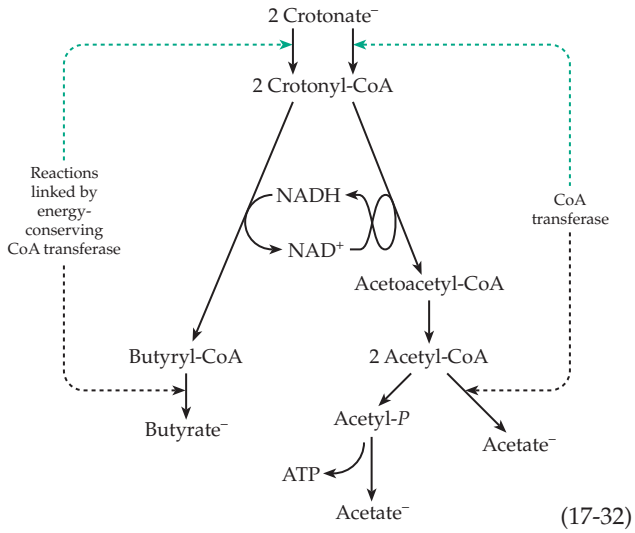


(17-30)

The fermentation of Eq. 17-31 is catalyzed by *Clostridium kluyveri*. The value of $-\Delta G'$ is one of the lowest that we have considered but is still enough to provide easily for the synthesis of one molecule of ATP.

$$2\ \underset{\text{Crotonate}}{CH_3CH{=}CH{-}COO^-} + 2\ H_2O \rightarrow \text{butyrate}^- + 2\ \text{acetate}^- + H^+$$
$$\Delta G'\ (\text{pH } 7) = -105\ \text{kJ mol}^{-1} \qquad (17\text{-}31)$$

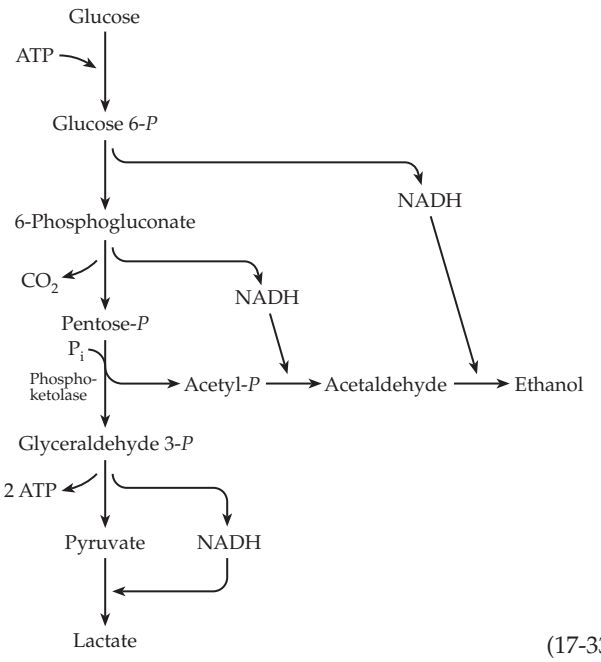
The energy of the butyryl-CoA linkage and of one of the acetyl-CoA linkages is conserved and utilized in the initial formation of crotonyl-CoA (Eq. 17-32). That leaves one acetyl-CoA which can be converted via acetyl-*P* to acetate with formation of ATP.



(17-32)

5. Fermentations Based on the Phosphogluconate and Pentose Phosphate Pathways

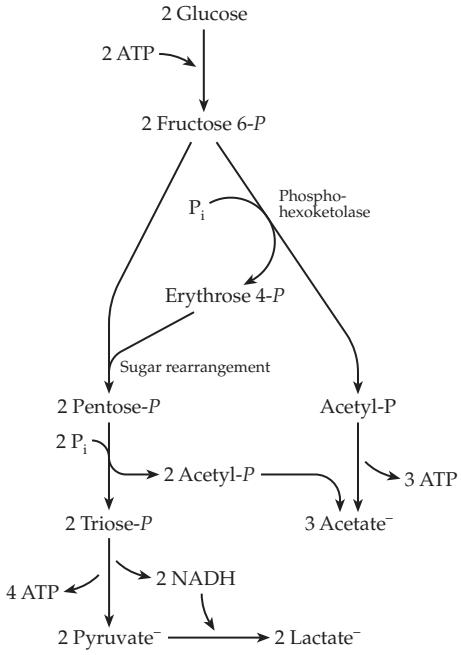
Some lactic acid bacteria of the genus *Lactobacillus*, as well as *Leuconostoc mesenteroides* and *Zymomonas mobilis*, carry out the **heterolactic** fermentation (Eq. 17-33) which is based on the reactions of the pentose phosphate pathway. These organisms lack aldolase, the key enzyme necessary for cleavage of fructose 1,6-bisphosphate to the triose phosphates. Glucose is converted to ribulose 5-*P* using the oxidative reactions of the pentose phosphate pathway. The ribulose-phosphate is cleaved by phosphoketolase (Eq. 14-23) to acetyl-phosphate and glyceraldehyde 3-phosphate, which are converted to ethanol and lactate, respectively. The overall yield is only one ATP per glucose fermented.



(17-33)

This is generated in the substrate level oxidative phosphorylation catalyzed by phosphoketolase. Metabolic engineering of *Zymomonas* was accomplished by transferring from other bacteria two operons that provide for assimilation of xylose and a complete set of enzymes for the pentose phosphate pathway. The engineered bacteria are able to convert pentose phosphates nonoxidatively (see Fig. 17-8) into glyceraldehyde 3-phosphate, which is converted to ethanol in high yield and with much greater synthesis of ATP than according to Eq. 17-33.[148]

A variation of the heterolactic fermentation is used by *Bifidobacterium* (Eq. 17-34).[149] Phosphoketolase and a **phosphohexoketolase**, which cleaves fructose 6-*P* to erythrose 4-*P* and acetyl-*P*, are required, as are the enzymes of the sugar rearrangement system (Section E,3). The net yield of ATP is 2 ½ molecules per molecule of glucose.



(17-34)

G. Biosynthesis

In this section and sections H – K the general principles and strategy of synthesis of the many carbon compounds found in living things will be considered. Since green plants and autotrophic bacteria are able to assemble all of their needed carbon compounds from CO_2, let us first examine the mechanisms by which this is accomplished. We will also need to ask how some organisms are able to subsist on such simple compounds as methane, formate, or acetate.

1. Metabolic Loops and Biosynthetic Families

As was pointed out in Chapter 10, routes of biosynthesis (anabolism) often closely parallel pathways of biodegradation (catabolism). Thus, catabolism begins with hydrolytic breakdown of polymeric molecules; the resulting monomers are then cleaved into small two- and three-carbon fragments. Biosynthesis begins with formation of monomeric units from small pieces followed by assembly of the monomers into polymers. The mechanisms of the individual reactions of biosynthesis and biodegradation are also often closely parallel. However, in most instances, there are clear-cut differences. A first principle of biosynthesis is that *biosynthetic pathways, although related to catabolic pathways, differ from them in distinct ways and are often catalyzed by completely different sets of enzymes*.

The sum of the pathways of biosynthesis and biodegradation form a continuous loop – a series of reactions that take place concurrently and often within the same part of a cell. Metabolic loops often begin in the central pathways of carbohydrate metabolism with three- or four-carbon compounds such as phosphoglycerate, pyruvate, and oxaloacetate. After loss of some atoms as CO_2 the remainder of the compound rejoins the "mainstream" of metabolism by entering a catabolic pathway leading to acetyl-CoA and oxidation in the citric acid cycle. Not all of the loops are closed within a given species. For example, *human beings are unable to synthesize the vitamins and the "essential amino acids."* We depend upon other organisms to make these compounds, but we do degrade them. Some metabolites, such as uric acid, are excreted by humans and are further catabolized by bacteria. From a chemical viewpoint the whole of nature can be regarded as an enormously complex set of branching and interconnecting metabolic cycles. Thus, the synthetic pathways used by autotrophs are all parts of metabolic loops terminating in oxidation back to CO_2.

It is often not possible to state at what point in a metabolic loop biosynthesis has been completed and biodegradation begins. An end product X that serves one need of a cell may be a precursor to another cell component Y which is then degraded to complete the loop. The reactions that convert X to Y can be regarded as either biosynthetic (for Y) or catabolic (for X).

2. Key Intermediates and Biosynthetic Families

In examining routes of biosynthesis it is helpful to identify some key intermediates. One of these is **3-phosphoglycerate**. This compound is a primary product of photosynthesis and may reasonably be regarded as the starting material from which all other carbon compounds in nature are formed. Phosphoglycerate, in most organisms, is readily interconvertible with both **glucose** and **phosphoenolpyruvate (PEP)**. Any of these three compounds can serve as the precursor for synthesis of other organic materials. A first stage in biosynthesis consists of those reactions by which 3-phosphoglycerate or PEP arise, whether it be from CO_2, formate, acetate, lipids, or polysaccharides.

The further biosynthetic pathways from 3-phosphoglycerate to the myriad amino acids, nucleotides, lipids, and miscellaneous compounds found in cells are complex and numerous. However, the basic features are relatively simple. Figure 17-11 indicates the origins of many substances including the 20 amino acids present in proteins, nucleotides, and lipids. Among the additional key biosynthetic precursors that can be identified from this chart are **glucose 6-phosphate**, **pyruvate**, **oxaloacetate**, **acetyl-CoA**, **2-oxoglutarate**, and **succinyl-CoA**.

The amino acid **serine** originates almost directly from 3-phosphoglycerate. **Aspartate** arises from oxaloacetate and **glutamate** from 2-oxoglutarate. These three amino acids each are converted to "families" of other compounds.[150] A little attention paid to establishing correct family relationships will make the study of biochemistry easier. Besides the serine, aspartate, and glutamate–oxoglutarate families, a fourth large family originates directly from pyruvate and a fifth (mostly lipids) from acetyl-CoA. The aromatic amino acids are formed from erythrose 4-*P* and PEP via the key intermediate **chorismic acid** (Box 9-E; Fig. 25-1). Other families of compounds arise from glucose 6-*P* and from the **pentose phosphates**. These groups have been set off roughly by the boxes outlined in green in Fig. 17-11.

H. Harnessing the Energy of ATP for Biosynthesis

In the past it seemed reasonable to think that some biosynthetic pathways involved exact reversal of catabolic pathways. For example, it was observed that glycogen phosphorylase catalyzed elongation of glycogen branches by transfer of glycosyl groups from glucose 1-phosphate. Likewise, the enzymes needed for the β oxidation of fatty acid derivatives, when isolated from mitochondria, catalyze formation of fatty acyl-CoA derivatives from acetyl-CoA and a reducing agent such as NADH. However, reactant concentrations within cells are rarely appropriate for reversal of a catabolic sequence. For catabolic sequences the Gibbs energy change is usually distinctly negative and reversal requires high concentrations of end products. However, the latter are often removed promptly from the cells. For example, NADH produced in degradation of fatty acids is oxidized to NAD^+ and is therefore never available in sufficient concentrations to reverse the β oxidation sequence.

Nature's answer to the problem of reversing a catabolic pathway lies in the coupling of cleavage of ATP to the biosynthetic reaction. The concept was introduced in Chapter 10, in which one sequence for linking hydrolysis of ATP to biosynthesis was discussed. However, living cells employ several different methods of harnessing the Gibbs energy of hydrolysis of ATP to drive biosynthetic processes. Many otherwise strange aspects of metabolism become clear if it is recognized that they provide a means for coupling ATP cleavage to biosynthesis. A few of the most important of these coupling mechanisms are summarized in this section.

1. Group Activation

Consider the formation of an ester (or of an amide) from a free carboxylic acid and an alcohol (or amine) by elimination of a molecule of water (Eq. 17-35). The reaction is thermodynamically unfavorable with values of $\Delta G'$ (pH 7) ranging from ~ +10 to 30 kJ mol^{-1} depending on conditions and structures of the specific compounds. Long ago, organic chemists learned that such reactions can be made to proceed by careful removal of the water that is generated (Eq. 17-35).

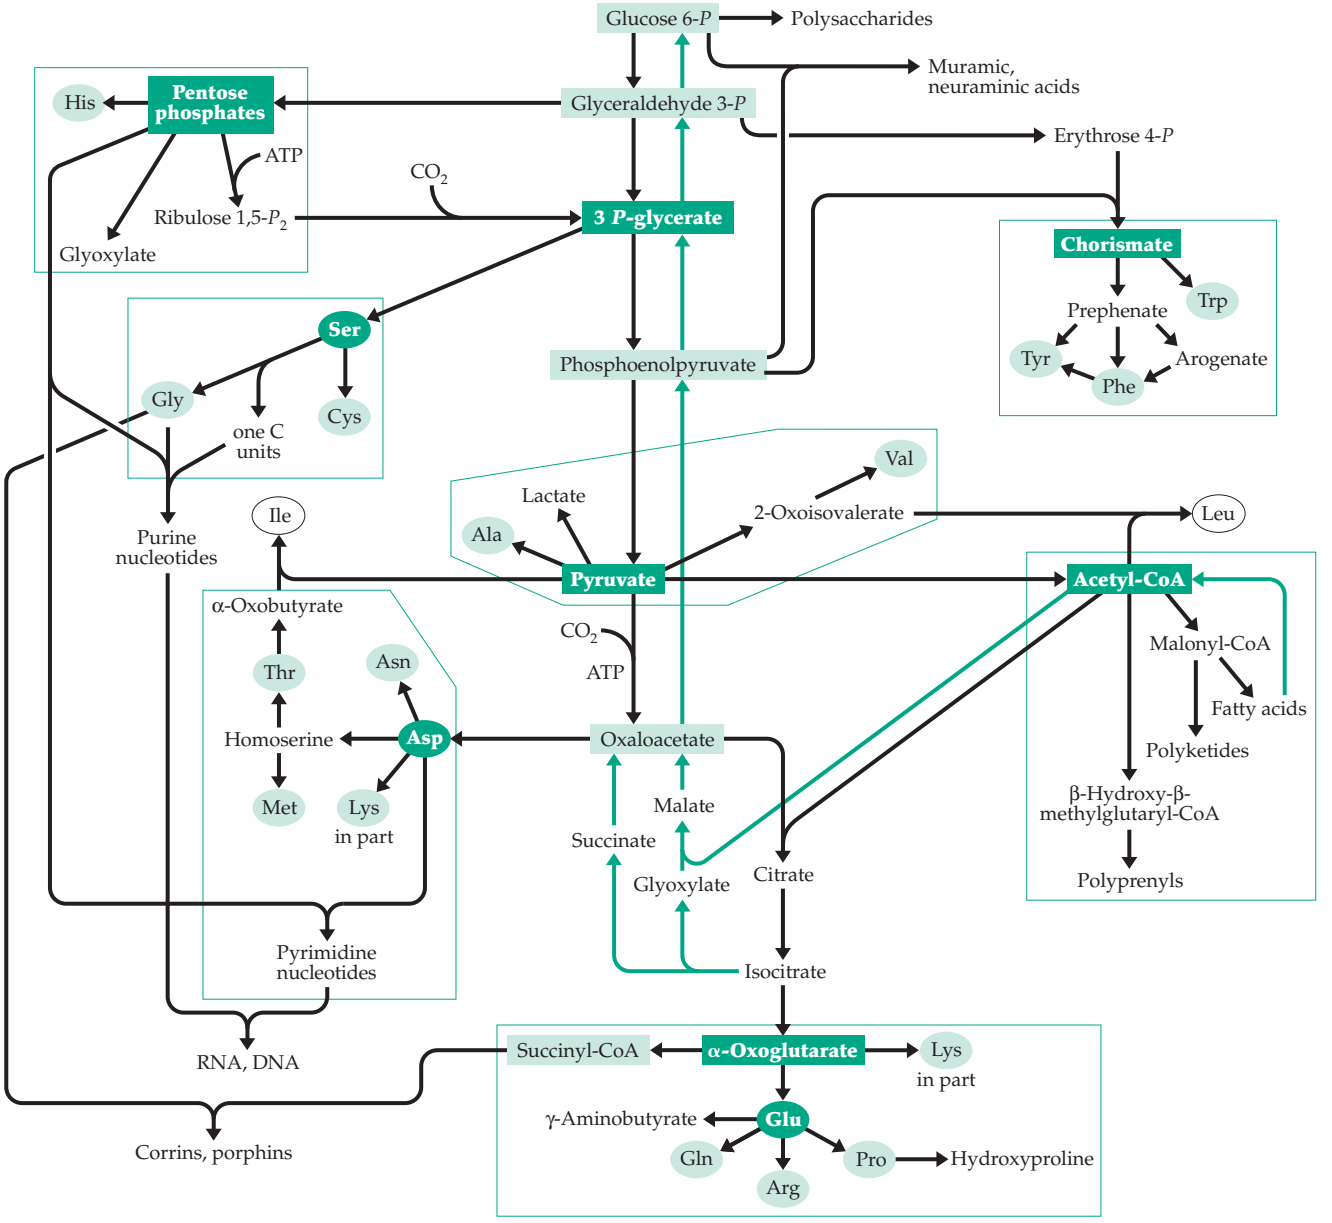


Figure 17-11 Some major biosynthetic pathways. Some key intermediates are enclosed in boxes and the 20 common amino acids of proteins are encircled. Key intermediates for each family are in shaded boxes or elipses. Green lines trace the reactions of the glyoxylate pathway and of glucogenesis.

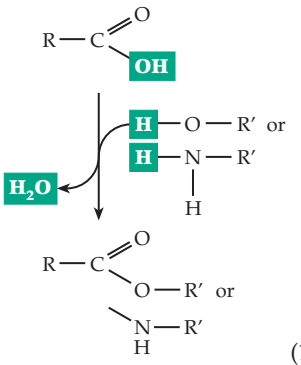
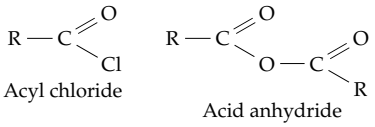


(17-35)

However, it is often better to "activate" the carboxylic acid by conversion to an acyl chloride or an anhydride:



Nucleophilic attack on the carbonyl group of such a compound results in displacement of a good leaving group, Cl^- or $R{-}COO^-$. Nature has followed the same approach in forming from carboxylic acids **acyl phosphates** or **acyl-CoA** derivatives.

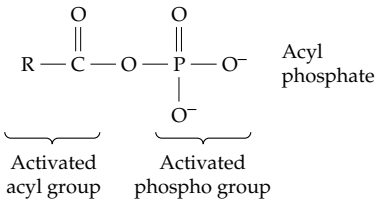
The virtue of these "activated" acyl compounds in biosynthetic reactions was considered in Chapter 12 and Table 15-1. Just as a carboxylic acid can be converted to an active acyl derivative, so other groups can be activated. ATP and other compounds with phospho groups of high group transfer potential are **active phospho** compounds. Sulfate is converted to a phosphosulfate anhydride, an **active sulfo** derivative. Sugars are converted to compounds such as glucose 1-*P* or sucrose, which contain **active glycosyl** groups. The group transfer potentials of the latter, though not as great as that of the phospho groups of ATP, are still high enough to make glucose 1-phosphate and sucrose effective glycosylating reagents. Table 17-2 lists several of the more important activated groups.

Group activation usually takes place at the expense of ATP cleavage.

TABLE 17-2
"Activated" Groups Used in Biosynthesis

Group	Typical activated forms
Phospho	Pyrophosphate; Guanidine phosphate; Enol phosphate; Acyl phosphate
Sulfo	in PAPS (3′-Phosphoadenosine-5′-phosphosulfate)
Acyl	Thioester; Acyl phosphate
Glycosyl	Glycosyl phosphate; Glucosyl; Fructosyl; Sucrose
Enoyl	Enol phosphate
Carbamoyl	Carbamoyl phosphate
Alkyl	*S*-Adenosylmethionine

As pointed out in Chapter 12, acyl phosphates play a central role in metabolism by virtue of the fact that they contain both an activated acyl group and an activated phospho group. The high group transfer potential can be conserved in subsequent reactions *in either one group or the other* (but not in both). Thus, displacement on P by an oxygen of ADP will regenerate ATP and attack on C by an – SH will give a thioester.

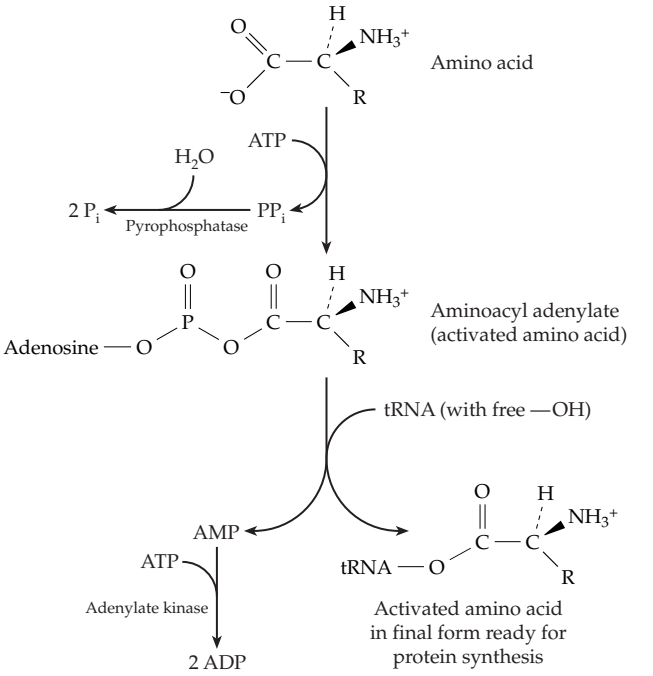


Several of the other compounds in Table 17-2 can also be split in two ways to yield different activated groups, e.g., the phosphosulfate anhydride, enoyl phosphate, and carbamoyl phosphate. It is probably only through intermediates of this type that cleavage of ATP can be coupled to synthesis of activated groups. Such **common intermediates** are essential to the synthesis of ATP by substrate-level phosphorylation (Fig. 15-6).

2. Hydrolysis of Pyrophosphate

The splitting of inorganic pyrophosphate (PP_i) into two inorganic phosphate ions is catalyzed by **pyrophosphatases** (p. 636)[150a,b] that apparently occur universally. Their function appears to be simply to remove the product PP_i from reactions that produce it, shifting the equilibrium toward formation of a desired compound. An example is the formation of **aminoacyl-tRNA** molecules needed for protein synthesis. As shown in Eq. 17-36, the process requires the use of two ATP molecules to activate one amino acid. While the "spending" of two ATPs for the addition of one monomer unit to a polymer does not appear necessary from a thermodynamic viewpoint, it is frequently observed, and there is no doubt that hydrolysis of PP_i ensures that the reaction will go virtually to completion. Transfer RNAs tend to become saturated with amino acids according to Eq. 17-36 even if the concentration of free amino acid in the cytoplasm is low. On the other hand, kinetic considerations may be involved. Perhaps the biosynthetic sequence would move too slowly if it were not for the extra boost given by the removal of PP_i. Part of the explanation for the complexity may depend on control mechanisms which are only incompletely understood.

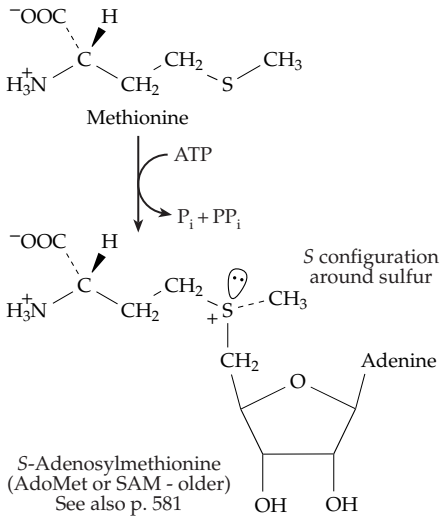
In some metabolic reactions pyrophosphate esters are formed by consecutive transfer of the terminal phospho groups of two ATP molecules onto a hydroxyl



Net: 2 ATP + amino acid + tRNA ⟶ aminoacyl tRNA + 2 ADP + 2 P_i (17-36)

group. Such esters often react with elimination of PP_i, e.g., in polymerization of prenyl units (reaction type 6B, Table 10-1; Fig. 22-1). Again, hydrolysis to P_i follows. Thus, *cleavage of pyrophosphate is a second very general method for coupling ATP cleavage to synthetic reactions*.

Although pyrophosphatases are ubiquitous, there are organisms in which PP_i is conserved by the cell and replaces ATP in several glycolytic reactions. These include *Propionibacterium*,[151,152] sulfate-reducing bacteria,[153] the photosynthetic *Rhodospirillum*, and the parasitic *Entamoeba histolytica*.[152,154] In the latter the internal concentration of PP_i is about 0.2 mM. Green plants also accumulate PP_i at concentrations of up to 0.2 mM.[155] Apparently, pyrophosphate is not always hydrolyzed immediately. Another mystery of metabolism is the accumulation of inorganic **polyphosphate** in chains of tens to many hundreds of phospho groups linked, as in pyrophosphate, by phosphoanhydride bonds. These polyphosphates are present in many bacteria, including *E. coli*, and also in fungi, plants, and animals.[156–156b] They constitute a store of energy as well as of phosphate. Various other functions have also been proposed. A polyphosphate kinase transfers a terminal phospho group from polyphosphate chains onto ADP to form ATP. This source of metabolic energy is evidently essential to the ability of *Pseudomonas aeruginosa* to form biofilms.[156a] Both endophosphatases and exophosphatases, of uncertain function, can degrade the chains hydrolytically. An exophosphatase from *E. coli* can completely hydrolyze polyphosphate chains of 1000 units processively without release of intermediates.[156b]

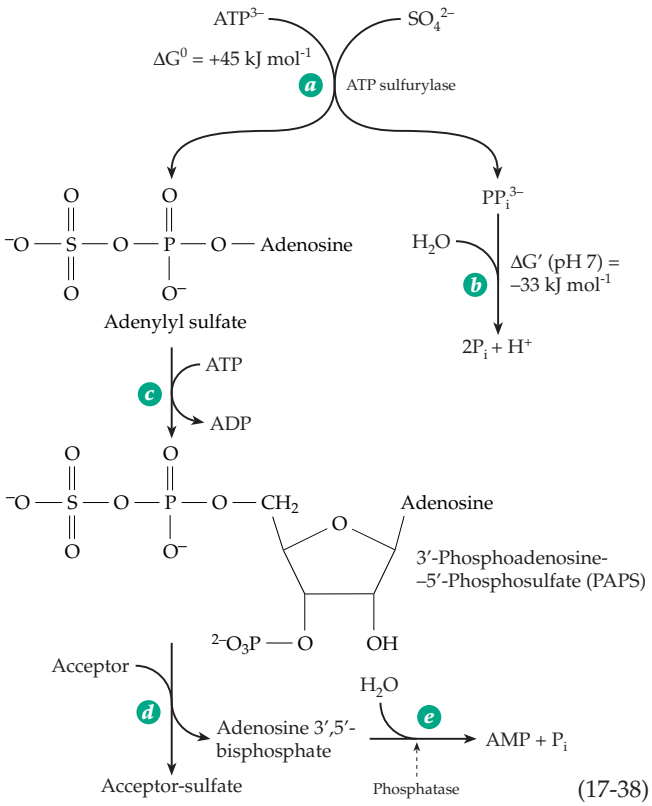


(17-37)

In a few instances group activation is coupled to cleavage of ATP at C-5' presumably with formation of bound tripolyphosphate (PPP$_i$). The latter is hydrolyzed to P$_i$ and PP$_i$ and ultimately to *three* molecules of P$_i$. An example is the formation of *S*-adenosylmethionine[157] shown in Eq. 17-37. The reaction is a displacement on the 5'-methylene group of ATP by the sulfur atom of methionine. While the initial product may be enzyme-bound PPP$_i$, it is P$_i$ and PP$_i$ that are released from the enzyme, the P$_i$ arising from the terminal phosphorus (P$_\gamma$) of ATP.[157] The *S*-adenosylmethionine formed has the *S* configuration around the sulfur.[158]

3. Coupling by Phosphorylation and Subsequent Cleavage by a Phosphatase

A third general method for coupling the hydrolysis of ATP to drive a synthetic sequence is to transfer the terminal phospho group from ATP to a hydroxyl group *somewhere* on a substrate. Then, after the substrate has undergone a synthetic reaction, the phosphate is removed by action of a phosphatase. For example, in the activation of sulfate (Eq. 17-38),[159] the overall standard Gibbs energy change for steps *a* (catalyzed by **ATP sulfurylase**[160,161]) and *b* is distinctly positive (+12 kJ mol^{-1}). The equilibrium concentration of adenylyl sulfate formed in this group activation process is extremely low. Nature's solution to this problem is to spend another molecule of ATP to phosphorylate the 3' – OH of adenosine phosphosulfate. As the latter is formed, it is converted to 3'-phosphoadenosine-5'-phosphosulfate (Eq. 17-38, step *c*) by a kinase, which is often part of a bifunctional enzyme that also contains the active site of ATP sulfurylase.[162–163a] Since the equilibrium in this step lies far toward the right, the product accumulates in a substantial concentration (up to 1 mM in cell-free systems)



(17-38)

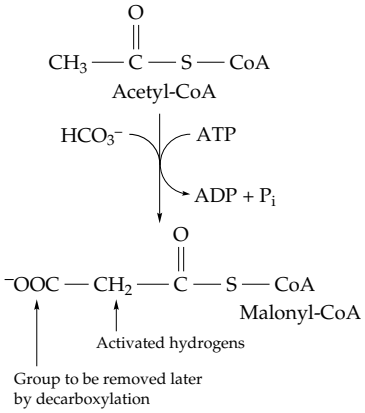
and serves as the active sulfo group donor in formation of sulfate esters. The reaction cycle is completed by two more reactions. In Eq. 17-38, step *d*, the sulfo group is transferred to an acceptor, and in step *e* the extra phosphate group is removed from adenosine 3',5'-bisphosphate by a specific phosphatase. Since the reconversion of AMP to ADP requires expenditure of still a third high-energy linkage of ATP, the overall process makes use of three high-energy phosphate linkages for formation of one sulfate ester.

An analogous use of ATP is found in photosynthetic reduction of carbon dioxide in which ATP phosphorylates ribulose 5-*P* to ribulose bisphosphate and the phosphate groups are removed later by phosphatase action on fructose bisphosphate and sedoheptulose bisphosphate (Section J,2). Phosphatases involved in synthetic pathways usually have a high substrate specificity and are to be distinguished from nonspecific phosphatases which are essentially digestive enzymes (Chapter 12).

4. Carboxylation and Decarboxylation: Synthesis of Fatty Acids

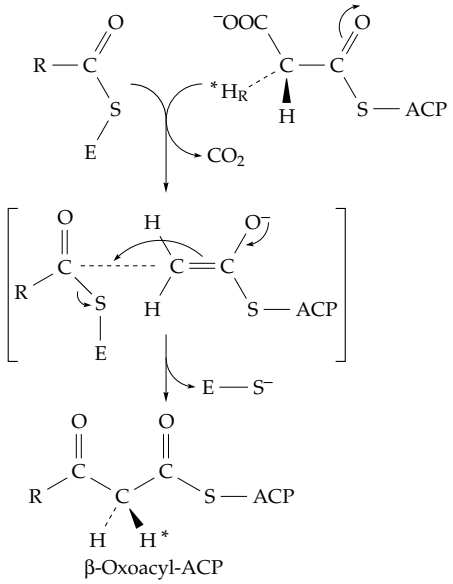
A fourth way in which cleavage of ATP can be coupled to biosynthesis was recognized in about 1958 when Wakil and coworkers discovered that synthesis of fatty acids in animal cytoplasm is stimulated by carbon dioxide. However, when $^{14}CO_2$ was used in

the experiment no radioactivity appeared in the fatty acids formed. Rather, it was found that acetyl-CoA was carboxylated to **malonyl-CoA** in an ATP- and biotin-requiring process (Eq. 17-39; see also Chapter 13). The carboxyl group formed in this reaction is later converted back to CO_2 in a decarboxylation (Fig. 17-12).



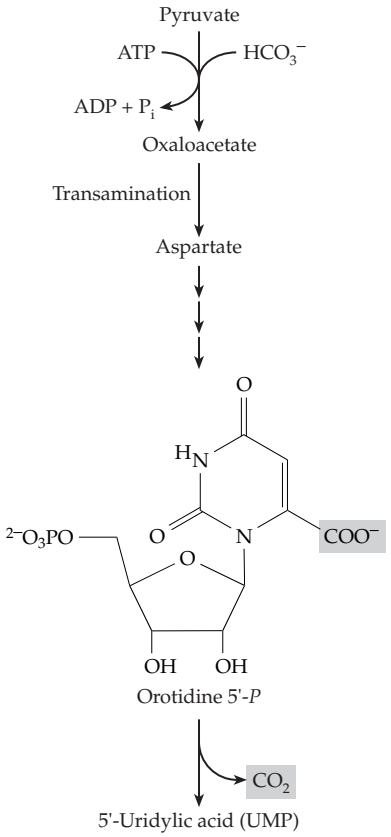
(17-39)

We know now that in most bacteria and green plants both an acetyl group of acetyl-CoA and a malonyl group of malonyl-CoA are transferred (steps *a* and *d* of Fig. 17-12) to the sulfur atoms of the phosphopantetheine groups of a low-molecular-weight **acyl carrier protein** (ACP; Chapter 14). The malonyl group of the malonyl-ACP is then condensed (step *f* of Fig. 17-12) with an acetyl group, which has been transferred from acetyl-ACP onto a thiol group of the enzyme (E in Eq. 17-40). The enolate anion indicated in this equation is generated by decarboxylation of the malonyl-ACP. It is this decarboxylation that drives the reaction to completion and, in effect, links C–C bond formation to the cleavage of the ATP required for the carboxylation step. A related sequence involving multifunctional proteins is used by animals and fungi[164] (Section J,6).



(17-40)

Carboxylation followed by a later decarboxylation is an important pattern in other biosynthetic pathways, too. Sometimes the decarboxylation follows the carboxylation by many steps. For example, pyruvate (or PEP) is converted to uridylic acid (Eq. 17-41; details are shown in Fig. 25-14):



(17-41)

I. Reducing Agents for Biosynthesis

Still another difference between biosynthesis of fatty acids and oxidation (in mammals) is that the former has an absolute requirement for NADPH (Fig. 17-12) while the latter requires NAD^+ and flavoproteins (Fig. 17-1). This fact, together with many other observations, has led to the generalization that *biosynthetic reduction reactions usually require NADPH rather than NADH*. Many measurements have shown that in the cytosol of eukaryotic cells the ratio [NADPH]/[$NADP^+$] is high, whereas the ratio [NADH]/[NAD^+] is low. Thus, the NAD^+/NADH system is kept highly oxidized, in line with the role of NAD^+ as a principal biochemical oxidant, while the $NADP^+$/NADPH system is kept reduced.

The use of NADPH in step *g* of Fig. 17-12 ensures that significant amounts of the β-oxoacyl-ACP derivative are reduced to the alcohol. Another difference between β oxidation and biosynthesis is that the alcohol formed in this reduction step in the biosynthetic process

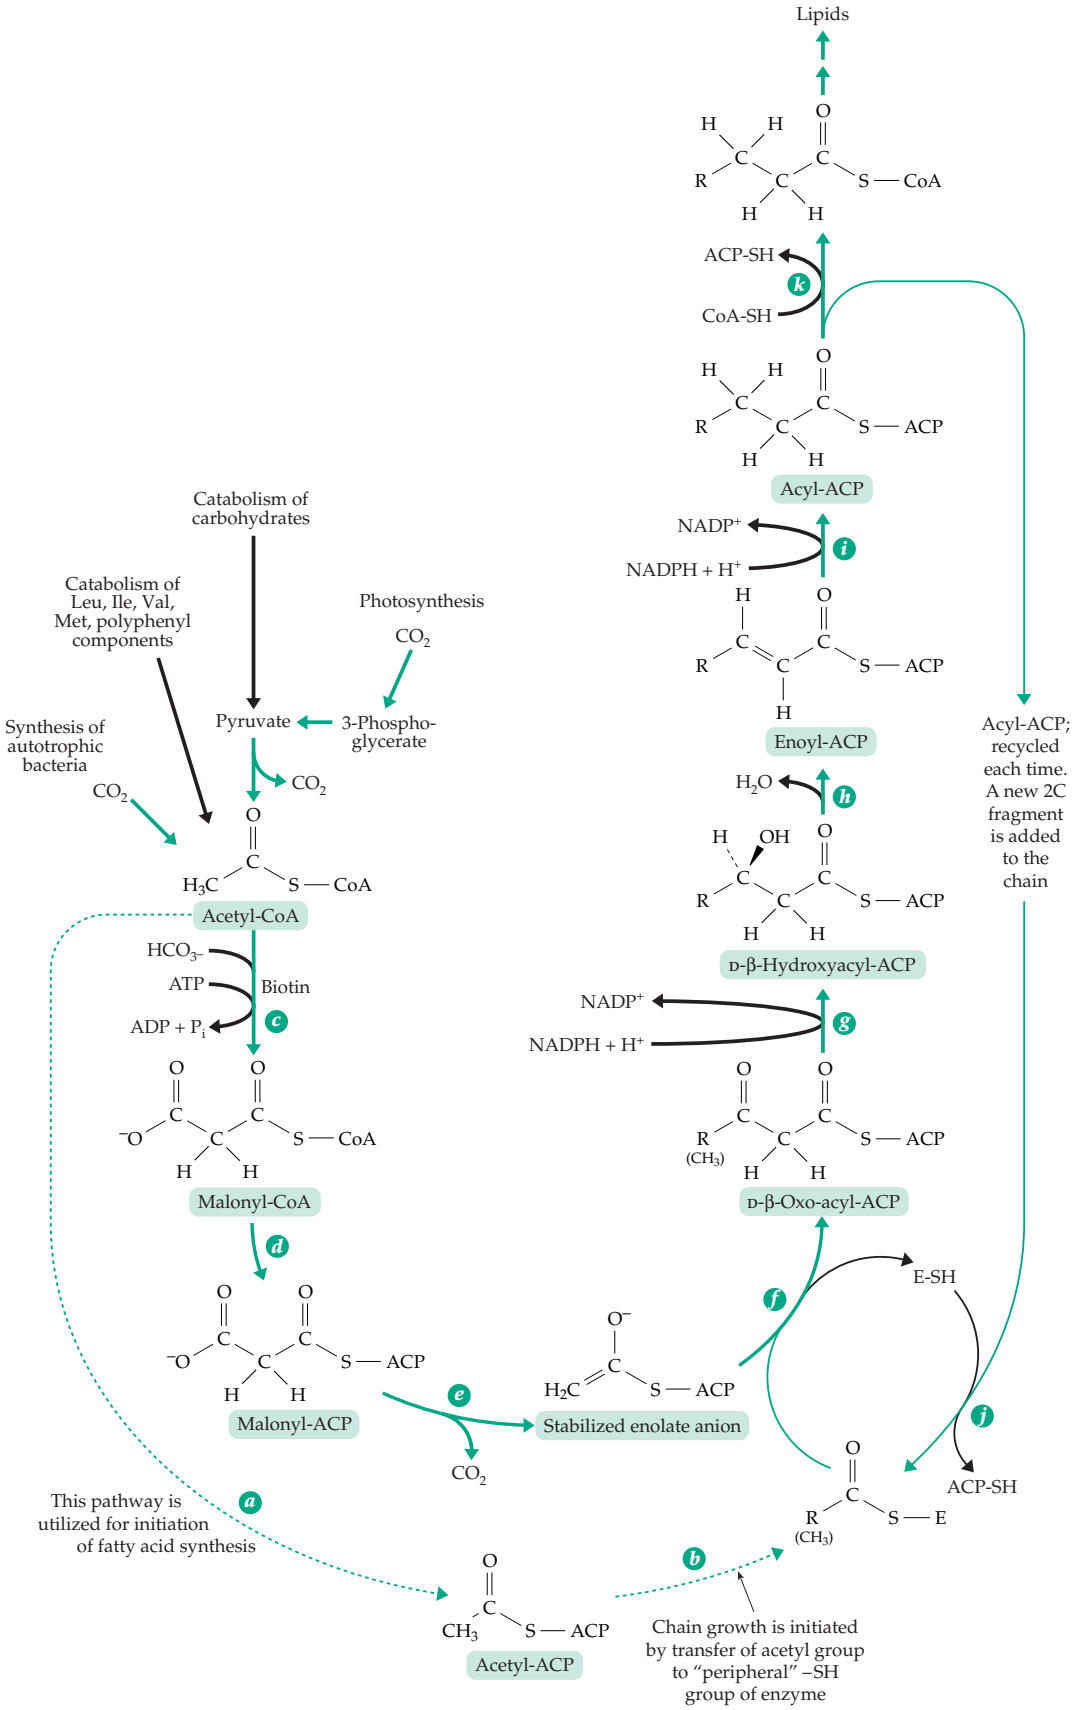


Figure 17-12 The reactions of cytoplasmic biosynthesis of saturated fatty acids. Compare with pathway of β oxidation (Fig. 17-1).

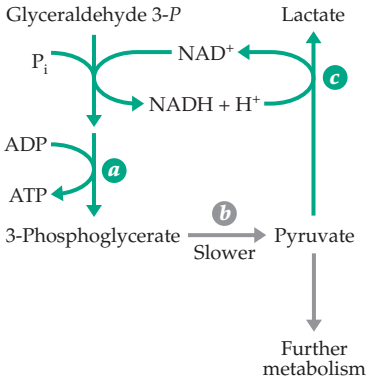
has the D configuration while the corresponding alcohol in β oxidation has the L configuration.

1. Reversing an Oxidative Step with a Strong Reducing Agent

The second reduction step in biosynthesis of fatty acids in the rat liver (step *i*) also required NADPH. The corresponding step in β oxidation utilizes FAD, but NADPH is a stronger reducing agent than $FADH_2$. Therefore, use of a reduced pyridine nucleotide again provides a thermodynamic advantage in pushing the reaction in the biosynthetic direction. Interesting variations have been observed among different species. For example, fatty acid synthesis in the rat requires only NADPH, but the multienzyme complexes from *Mycobacterium phlei*, *Euglena gracilis*, and the yeast *Saccharomyces cerevisiae* all give much better synthesis with a mixture of NADPH and NADH than with NADPH alone.[165] Apparently, NADPH is required in step *g* and NADH in step *i*. This seems reasonable because the equilibrium in step *i* lies far toward the product formation, and NADH at a very low concentration could carry out the reduction.

2. Regulation of the State of Reduction of the NAD and NADP Systems

The ratio $[NAD^+]/[NADH]$ appears to be maintained at a relatively constant value and in equilibrium with a series of different reduced and oxidized substrate pairs. Thus, it was observed that in the cytoplasm of rat liver cells, the dehydrogenations catalyzed by lactate dehydrogenase, *sn*-glycerol 3-phosphate dehydrogenase, and malate dehydrogenase are all at equilibrium with the same ratio of $[NAD^+]/[NADH]$.[166] In one experiment rat livers were removed and frozen in less than 8 s by "freeze-clamping" (Section L,2) and the concentrations of different components of the cytoplasm determined[167]; the ratio $[NAD^+]/[NADH]$ was found to be 634, while the ratio of [lactate]/[pyruvate] was 14.2. From these values an apparent equilibrium constant for reaction *c* of Eq. 17-42 was calculated as $K_c' = 9.0 \times 10^3$. The known equilibrium constant for the reaction (from *in vitro* experiments) is 8.8×10^3 (Eq. 17-43). In a similar way it was shown that several other dehydrogenation reactions are nearly at equilibrium. This conclusion has been confirmed more recently by NMR observations.[168]



(17-42)

$$K_c'\,(\text{pH } 7,\ 38°\text{C}) = \frac{[\text{lactate}]}{[\text{pyruvate}]} \times \frac{[NAD^+]}{[NADH]} = 8.8 \times 10^3 \qquad (17\text{-}43)$$

Now consider Eq. 17-42, step *a*, the ADP- and P_i-requiring oxidation of glyceraldehyde 3-phosphate (Fig. 15-6). Experimental measurements indicated that this reaction is also at equilibrium in the cytoplasm. In one series of experiments the measured phosphorylation state ratio $[ATP]/[ADP][P_i]$ was 709, while the ratio [3-phosphoglycerate]/[glyceraldehyde 3-phosphate] was 55.5. The overall equilibrium constant for Eq. 17-42*a* is given by Eq. 17-44. That calculated from known equilibrium constants is 60.

$$K_a'\,(\text{pH } 7,\ 38°\text{C}) = \frac{[ATP]}{[ADP][P_i]} \times \frac{[\text{3-phosphoglycerate}]}{[\text{glyceraldehyde phosphate}]} \times \frac{[NADH]}{[NAD^+]} = 709 \times 55.5 \times 1/634 = 62 \qquad (17\text{-}44)$$

From these data Krebs and Veech concluded that the oxidation state of the NAD system is determined largely by the phosphorylation state ratio of the adenylate system.[169] If the ATP level is high the equilibrium in Eq. 17-42*a* will be reached at a higher $[NAD^+]/[NADH]$ ratio and lactate may be oxidized to pyruvate to adjust the [lactate]/[pyruvate] ratio.

It is important not to confuse the reactions of Eq. 17-42 as they occur in an aerobic cell with the tightly coupled pair of redox reactions in the homolactate fermentation (Fig. 10-3; Eq. 17-19). The reactions of steps *a* and *c* of Eq. 17-42 are essentially at equilibrium, but the reaction of step *b* may be relatively slow. Furthermore, pyruvate is utilized in many other metabolic pathways and ATP is hydrolyzed and converted to ADP through innumerable processes taking place within the cell. Reduced NAD does not cycle between the two enzymes in a stoichiometric way and the "reducing equivalents" of NADH formed are, in large measure, transferred to the mitochondria. The proper view of the reactions of Eq. 17-42 is that the redox pairs represent a kind of **redox buffer system** that poises the $NAD^+/NADH$ couple at a ratio appropriate for its metabolic function.

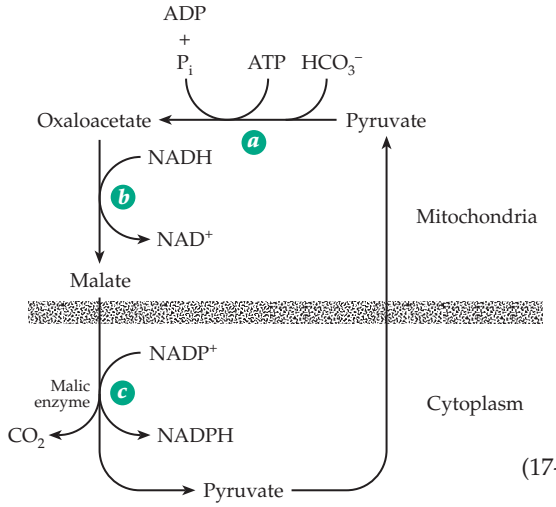
Somewhat surprisingly, within the mitochondria the ratio [NAD^+]/[NADH] is 100 times lower than in the cytoplasm. Even though mitochondria are the site of oxidation of NADH to NAD^+, the intense catabolic activity occurring in the β oxidation pathway and the citric acid cycle ensure extremely rapid production of NADH. Furthermore, the reduction state of NAD is apparently buffered by the low potential of the β-hydroxybutyrate–acetoacetate couple (Chapter 18, Section C,2). Mitochondrial pyridine nucleotides also appear to be at equilibrium with glutamate dehydrogenase.[169]

How is the cytoplasmic [NADPH]/[$NADP^+$] ratio maintained at a value higher than that of [NADH]/[NAD^+]? Part of the answer is from operation of the pentose phosphate pathway (Section E,3). The reactions of Eq. 17-12, if they attained equilibrium, would give a ratio of cytosolic [NADPH]/[$NADP^+$] > 2000 at 0.05 atm CO_2. Compare this with the ratio 1/634 for [NADH/[NAD^+] deduced from the observation on the reactions of Eq. 17-42.

Consider also the following **transhydrogenation** reaction (Eq. 17-45):

$$NADH + NADP^+ \rightarrow NAD^+ + NADPH \quad (17\text{-}45)$$

There are soluble enzymes that catalyze this reaction for which *K* equals ~ 1. Within mitochondria an energy-linked system (Chapter 18) involving the membrane shifts the equilibrium to favor NADPH. However, within the cytoplasm, the reaction of Eq. 17-45 is driven by coupling ATP cleavage to the transhydrogenation via carboxylation followed by eventual decarboxylation. One cycle that accomplishes this is given in Eq. 17-46. The first step (step *a*) is ATP-dependent carboxylation of pyruvate to oxaloacetate, a reaction that occurs only within mitochondria (Eq. 14-3). Oxaloacetate can be reduced by malate dehydrogenase using NADH (Eq. 17-46, step *b*), and the resulting malate can be exported from the mitochondria. In the cytoplasm the malate is oxidized to pyruvate, with decarboxylation, by the malic enzyme (Eq. 13-45). The malic enzyme (Eq. 17-46, step *c*) is specific for $NADP^+$, is very active, and also appears to operate at or near equilibrium within the cytoplasm. On this basis, using known equilibrium constants, it is easy to show that the ratio [NADPH]/[$NADP^+$] will be ~ 10^5 times higher at equilibrium than the ratio [NADH]/[NAD^+].[169,170]



(17-46)

Since NADPH is continuously used in biosynthetic reactions, and is thereby reconverted to $NADP^+$, the cycle of Eq. 17-46 must operate continuously. As in Eq. 17-42, a true equilibrium does not exist but steps *b* and *c* are both essentially at equilibrium. These equilibria, together with those of Eq. 17-42 for the NAD system, ensure the correct redox potential of both pyridine nucleotide coenzymes in the cytoplasm.

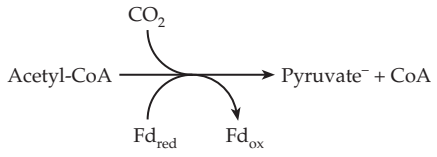
Malate is not the only form in which C_4 compounds are exported from mitochondria. Much oxaloacetate is combined with acetyl-CoA to form citrate; the latter leaves the mitochondria and is cleaved by the ATP-dependent citrate-cleaving enzymes (Eq. 13-39). This, in effect, exports both acetyl-CoA (needed for lipid synthesis) and oxaloacetate which is reduced to malate within the cytoplasm. Alternatively, oxaloacetate may be transaminated to aspartate. The aspartate, after leaving the mitochondria, may be converted in another transamination reaction back to oxaloacetate. All of these are part of the nonequilibrium process by which C_4 compounds diffuse out of the mitochondria before completing the reaction sequence of Eq. 17-46 and entering into other metabolic processes. Note that the reaction of Eq. 17-46 leads to the *export* of reducing equivalents from mitochondria, the opposite of the process catalyzed by the malate–aspartate shuttle which is discussed in Chapter 18 (Fig. 18-18). The two processes are presumably active under different conditions.

While the difference in the redox potential of the two pyridine nucleotide systems is clear-cut in mammalian tissues, in *E. coli* the apparent potentials of the two systems are more nearly the same.[171]

3. Reduced Ferredoxin in Reductive Biosynthesis

Both the NAD^+ and $NADP^+$ systems have standard electrode potentials $E°'$ (pH 7) of −0.32 V. However, because of the differences in concentration ratios, the NAD^+ system operates at a less negative potential (−0.24 V) and the $NADP^+$ system at a more negative potential (−0.38 V) within the cytoplasm of eukaryotes. In green plants and in many bacteria a still more powerful reducing agent is available in the form of reduced ferredoxin. The value of $E°'$ (pH 7) for clostridial ferredoxin is −0.41 V, corresponding to a Gibbs energy change for the two-electron reduction of a substrate ~18 kJ mol^{-1} more negative than the corresponding

value of $\Delta G'$ for reduction by NADPH. Using reduced ferredoxin (Fd) some photosynthetic bacteria and anaerobic bacteria are able to carry out reductions that are virtually impossible with the pyridine nucleotide system. For example, pyruvate and 2-oxoglutarate can be formed from acetyl-CoA (Eq. 15-35) and succinyl-CoA, respectively (Eq. 17-47).[172–173a] In our bodies the reaction of Eq. 17-47, with NAD^+ as the oxidant, goes only in the opposite direction and is essentially irreversible.



$\Delta G'$ (pH 7) = +17 kJ mol^{-1} (17-47)

J. Constructing the Monomer Units

Now let us consider the synthesis of the monomeric units from which biopolymers are made. How can simple one-carbon compounds such as CO_2 and formic acid be incorporated into complex carbon compounds? How can carbon chains grow in length or be shortened? How are branched chains and rings formed?

1. Carbonyl Groups in Chain Formation and Cleavage

Except for some vitamin B_{12}-dependent reactions, the cleavage or formation of carbon–carbon bonds usually depends upon the participation of carbonyl groups. For this reason, carbonyl groups have a central mechanistic role in biosynthesis. The activation of hydrogen atoms β to carbonyl groups permits β condensations to occur during biosynthesis. Aldol or Claisen condensations require the participation of two carbonyl compounds. Carbonyl compounds are also essential to thiamin diphosphate-dependent condensations and the aldehyde pyridoxal phosphate is needed for most C–C bond cleavage or formation within amino acids.

Because of the importance of carbonyl groups to the mechanism of condensation reactions, much of the assembly of either straight-chain or branched-carbon skeletons takes place between compounds in which the average oxidation state of the carbon atoms is similar to that in carbohydrates (or in formaldehyde, H_2CO). The diversity of chemical reactions possible with compounds at this state of oxidation is a maximum, a fact that may explain why carbohydrates and closely related substances are major biosynthetic precursors and why the average state of oxidation of the carbon in most living things is similar to that in carbohydrates.[174] This fact may also be related to the presumed occurrence of formaldehyde as a principal component of the earth's atmosphere in the past and to the ability of formaldehyde to condense to form carbohydrates.

In Fig. 17-13 several biochemicals have been arranged according to the oxidation state of carbon. Most of the important biosynthetic intermediates lie within ± 2 electrons per carbon atom of the oxidation state of carbohydrates. As the chain length grows, they tend to fall even closer. It is extremely difficult to move through enzymatic processes between 2C, 3C, and 4C compounds (i.e., vertically in Fig. 17-13) except at the oxidation level of carbohydrates or somewhat to its right, at a slightly higher oxidation level. On the other hand, it is often possible to move horizontally with ease using oxidation–reduction reactions. Thus, fatty acids are assembled from acetate units, which lie at the same oxidation state as carbohydrates and, after assembly, are reduced.

Among compounds of the same overall oxidation state, e.g., acetic acid and sugars, the oxidation states of individual carbon atoms can be quite different. Thus, in a sugar every carbon atom can be regarded as immediately derived from formaldehyde, but in acetic acid one end has been oxidized to a carboxyl group and the other has been reduced to a methyl group. Such internal oxidation–reduction reactions play an important role in the chemical manipulations necessary to assemble the carbon skeletons needed by a cell. Decarboxylation is a feature of many biosynthetic routes. Referring again to Fig. 17-13, notice that many of the biosynthetic intermediates such as pyruvate, oxoglutarate, and oxaloacetate are more oxidized than the carbohydrate level. However, their decarboxylation products, which become incorporated into the compounds being synthesized, are closer to the oxidation level of carbohydrates.

2. Starting with CO_2

There are three known pathways by which autotrophic organisms can use CO_2 to synthesize triose phosphates or 3-phosphoglycerate, three-carbon compounds from which all other biochemical substances can be formed.[175–177] The first of these is the **reductive tricarboxylic cycle.** This is a reversal of the oxidative citric acid cycle in which reduced ferredoxin is used as a reductant in the reaction of Eq. 17-47 to incorporate CO_2 into pyruvate. Succinyl-CoA can react with CO_2 in the same type of reaction to form 2-oxoglutarate, accomplishing the reversal of the only irreversible step in the citric acid cycle. Using these reactions photosynthetic bacteria and some anaerobes that can generate a high ratio of reduced to oxidized ferredoxin carry out the reductive tricarboxylic acid cycle. Together with

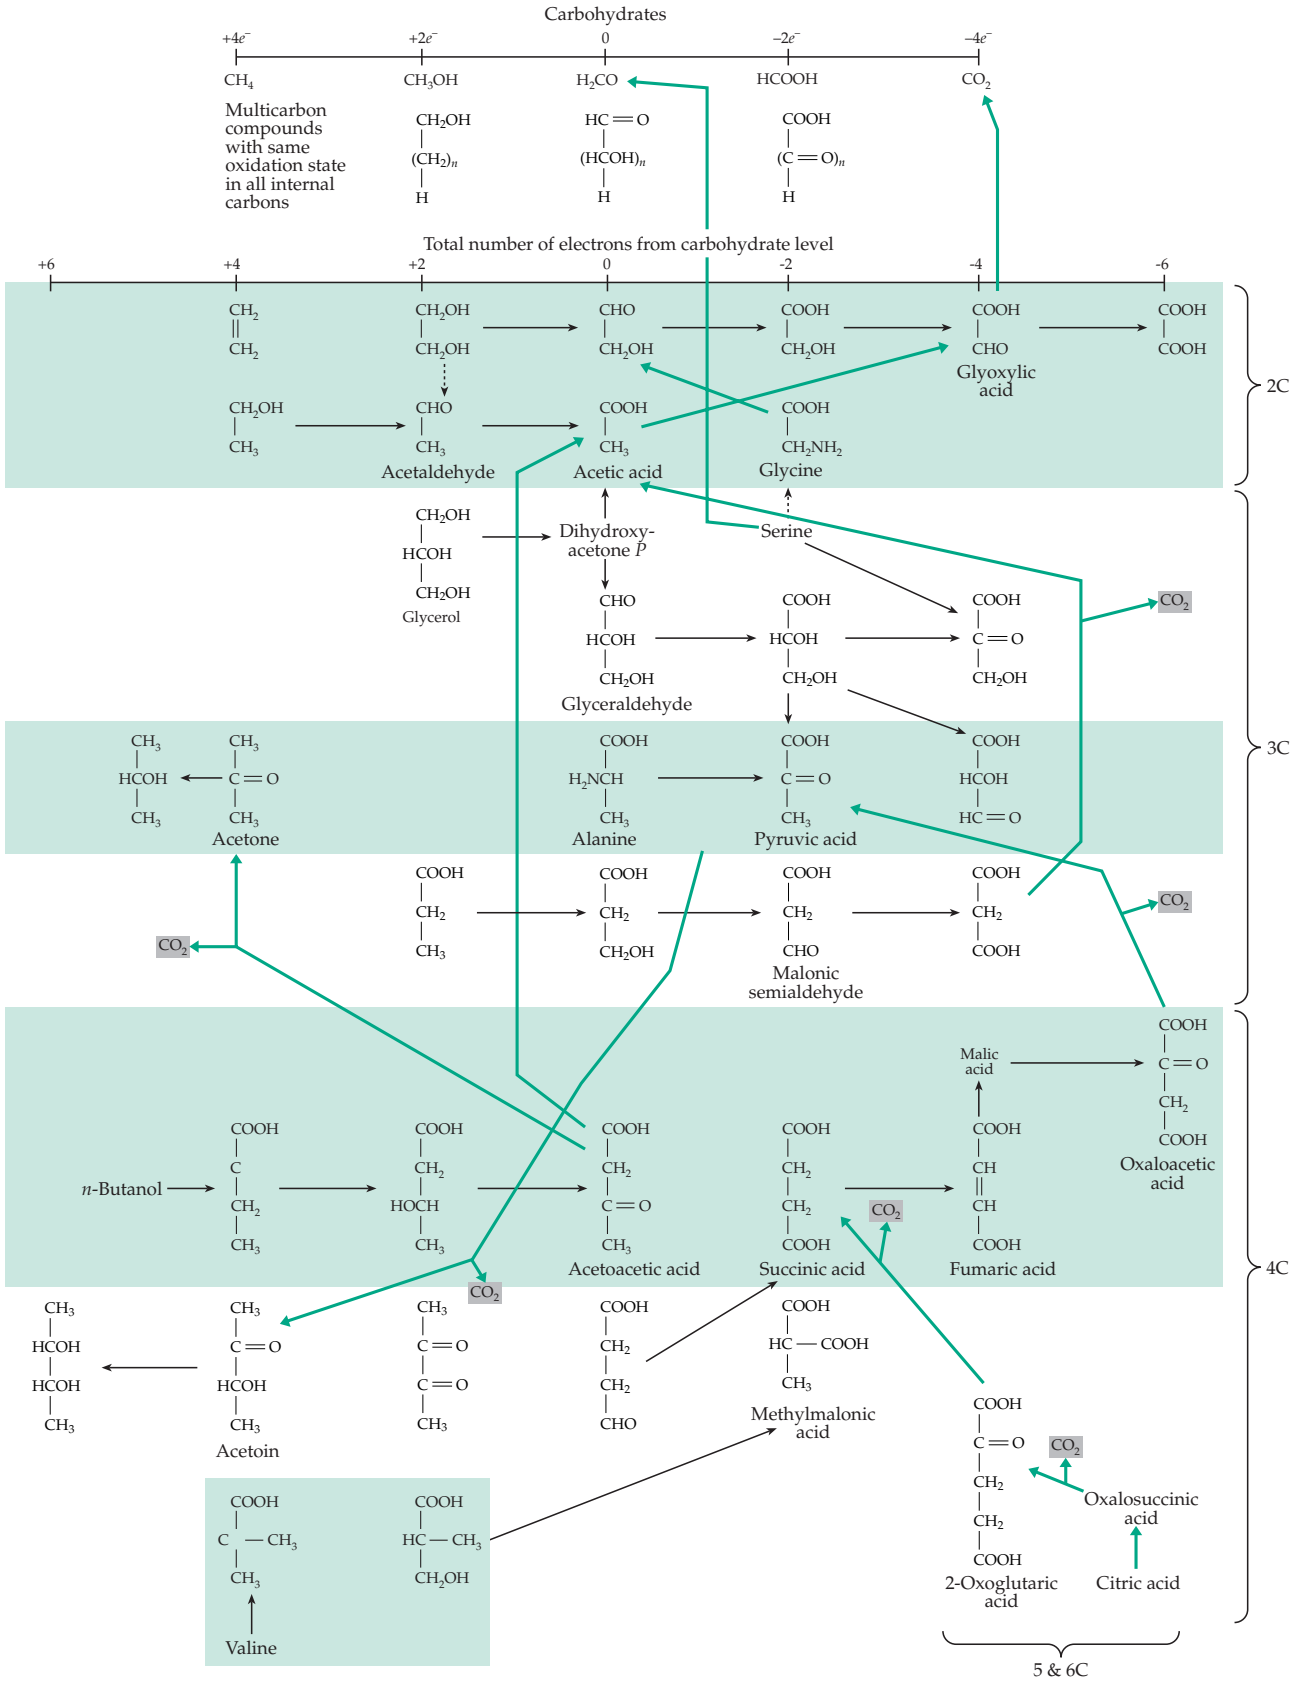


Figure 17-13 Some biochemical compounds arranged in order of average oxidation state of the carbon atoms and by carbon-chain lengths. Black horizontal arrows mark some biological interconversions among compounds with the same chain length, while green lines show changes in chain length and are often accompanied by decarboxylation.

Eq. 17-47, the cycle provides for the complete synthesis of pyruvate from CO_2.[178,179]

A quantitatively much more important pathway of CO_2 fixation is the **reductive pentose phosphate pathway** (ribulose bisphosphate cycle or **Calvin–Benson cycle**; Fig. 17-14). This sequence of reactions, which takes place in the chloroplasts of green plants and also in many chemiautotrophic bacteria, is essentially a way of reversing the oxidative pentose phosphate pathway (Fig. 17-8). The latter accomplishes the complete oxidation of glucose or of glucose 1-phosphate by $NADP^+$ (Eq. 17-48):

$$\begin{aligned}\text{Glucose 1-}P^{2-} + ATP^{4-} + 8\ H_2O + 12\ NADP^+ \rightarrow \\ 6\ CO_2 + 12\ NADPH + ADP^{3-} + 2HPO_4^{2-} + 13\ H^+ \\ \Delta G'\ (\text{pH } 7) = -299\ \text{kJ mol}^{-1}\end{aligned} \qquad (17\text{-}48)$$

It would be almost impossible for a green plant to fix CO_2 using photochemically generated NADPH by an exact reversal of Eq. 17-48 because of the high positive Gibbs energy change. To solve this thermodynamic problem the reductive pentose phosphate pathway has been modified in a way that couples ATP cleavage to the synthesis.

The **reductive carboxylation** system is shown within the green shaded box of Fig. 17-14. Ribulose 5-phosphate is the starting compound and in the first step one molecule of ATP is expended to form **ribulose 1,5-bisphosphate**. The latter is carboxylated and cleaved to two molecules of 3-phosphoglycerate. This reaction was discussed in Chapter 13. The reductive step (step *c*) of the system employs NADPH together with ATP. Except for the use of the NADP system instead of the NAD system, it is exactly the reverse of the glyceraldehyde phosphate dehydrogenase reaction of glycolysis. Looking at the first three steps of Fig. 17-14 it is clear that in the reductive pentose phosphate pathway three molecules of ATP are utilized for each CO_2 incorporated. On the other hand, in the oxidative direction *no* ATP is generated by the operation of the pentose phosphate pathway.

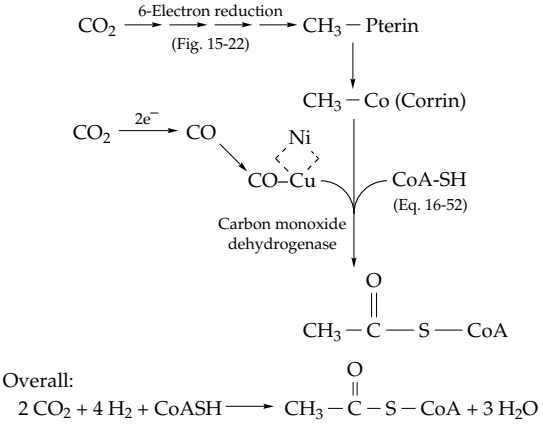
The reactions enclosed within the shaded box of Fig. 17-14 do not give the whole story about the coupling mechanism. A phospho group was transferred from ATP in step *a* and to complete the hydrolysis it must be removed in some future step. This is indicated in a general way in Fig. 17-14 by the reaction steps *d*, *e*, and *f*. Step *f* represents the action of specific phosphatases that remove phospho groups from the seven-carbon sedoheptulose bisphosphate and from fructose bisphosphate. In either case the resulting ketose monophosphate reacts with an aldose (via transketolase, step *g*) to regenerate ribulose 5-phosphate, the CO_2 acceptor. The overall reductive pentose phosphate cycle (Fig. 17-14B) is easy to understand as a reversal of the oxidative pentose phosphate pathway in which the oxidative decarboxylation system of Eq. 17-12 is replaced by the reductive carboxylation system of Fig. 17-14A. The scheme as written in Fig. 17-14B shows the incorporation of three molecules of CO_2. The reductive carboxylation system operates three times with a net production of one molecule of triose phosphate. As with other biosynthetic cycles, any amount of any of the intermediate metabolites may be withdrawn into various biosynthetic pathways without disruption of the flow through the cycle.

The overall reaction of carbon dioxide reduction in the Calvin–Benson cycle (Fig. 17-14) becomes

$$\begin{aligned}6\ CO_2 + 12\ NADPH + 18\ ATP^{4-} + 11\ H_2O \rightarrow \\ \text{glucose-1-}P^{2-} + 12\ NADP^+ + 18\ ADP^{3-} \\ 17\ HPO_4^{2-} + 6\ H^+\end{aligned} \qquad (17\text{-}49)$$

The Gibbs energy change $\Delta G'$ (pH 7) is now −357 kJ mol^{-1} instead of the +299 kJ mol^{-1} required to reverse the reaction of Eq. 17-48.

The third pathway for reduction of CO_2 to acetyl-CoA is utilized by acetogenic bacteria, by methanogens, and probably by sulfate-reducing bacteria.[179–181] This **acetyl-CoA pathway** (or **Wood–Ljungdahl pathway**) involves reduction by H_2 of one of the two molecules of CO_2 to the methyl group of methyltetrahydromethanopterin in methanogens and of methyltetra-hydrofolate in acetogens. The pathway utilized by methanogens is illustrated in Fig. 15-22.[182–184] A similar process utilizing H_2 as the reductant is employed by acetogens.[179,185–188a] In both cases a methyl corrinoid is formed and its methyl group is condensed with a molecule of carbon monoxide bound to a copper ion in a Ni–Cu cluster.[189a,b] The resulting acetyl group is transferred to a molecule of coenzyme A as illustrated in Eq. 16-52.[189] The bound CO is formed by reduction of CO_2, again using H_2 as the reductant.[190] The overall reaction for acetyl-CoA synthesis is given by Eq. 17-50. Conversion of acetyl-CoA to pyruvate via Eq. 17-47 leads into the glucogenic pathway.



(17-50)

An alternative pathway by which some acetogenic bacteria form acetate is via reversal of the glycine decarboxylase reaction of Fig. 15-20. Methylene-THF is formed by reduction of CO_2, and together with NH_3 and CO_2 a lipoamide group of the enzyme and PLP forms glycine. The latter reacts with a second methylene-THF to form serine, which can be deaminated to pyruvate and assimilated. Methanogens may use similar pathways but ones that involve methanopterin (Fig. 15-17).[191]

3. Biosynthesis from Other Single-Carbon Compounds

Various bacteria and fungi are able to subsist on such one-carbon compounds as methane, methanol, methylamine, formaldehyde, and formate.[192–197] Energy is obtained by oxidation to CO_2. **Methylotrophic bacteria** initiate oxidation of methane by hydroxylation (Chapter 18) and dehydrogenate the resulting methanol or exogenous methanol using the PPQ cofactor (Eq. 15-51).[198] Further dehydrogenation to formate and of formate to CO_2 via formate dehydrogenase (Eq. 16-63) completes the process. Some methylotrophic bacteria incorporate CO_2 for biosynthetic purposes via the ribulose bisphosphate (Calvin–Benson) cycle but many use pathways that begin with formaldehyde (or methylene-THF). Others employ variations of the reductive pentose phosphate pathway to convert formaldehyde to triose phosphate. In one of these, the **ribulose monophosphate cycle** or Quayle cycle,[192,193] ribulose 5-*P* undergoes an aldol condensation with formaldehyde to give a 3-oxo-hexulose 6-phosphate (Eq. 17-51, step *a*). The latter is isomerized to fructose 6-*P* (Eq. 17-51, step *b*). If this equation is applied to the

BOX 17-E ^{14}C AND THE CALVIN–BENSON CYCLE

The chemical nature of photosynthesis had intrigued chemists for decades but little was learned about the details until radioactive ^{14}C became available. Discovered in 1940 by Ruben and Kamen, the isotope was available in quantity by 1946 as a product of nuclear reactors. Initial studies of photosynthesis had been conducted by Ruben and Kamen using ^{11}C but ^{14}C made rapid progress possible. In 1946 Melvin Calvin and Andrew A. Benson began their studies that elucidated the mechanism of incorporation of CO_2 into organic materials.

A key development was two-dimensional paper chromatography with radioautography (Box 3-C). A suspension of the alga *Chlorella* (Fig. 1-11) was allowed to photosynthesize in air. At a certain time, a portion of $H^{14}CO_3$ was injected into the system, and after a few seconds of photosynthesis with ^{14}C present the suspension of algae was run into hot methanol to denature proteins and to stop the reaction. The soluble materials extracted from the algal cells were concentrated and chromatographed; radioautographs were then prepared. It was found that after 10 s of photosynthesis in the presence of $^{14}CO_2$, the algae contained a dozen or more ^{14}C labeled compounds. These included malic acid, aspartic acid, phosphoenolpyruvate, alanine, triose phosphates, and other sugar phosphates and diphosphates. However, *during the first five seconds a single compound, 3-phosphoglycerate, contained most of the radioactivity*.[a,b] This finding suggested that a two-carbon regenerating substrate might be carboxylated by $^{14}CO_2$ to phosphoglycerate. Search for this two-carbon compound was unsuccessful, but Benson, in Calvin's laboratory, soon identified ribulose bisphosphate,[c] which kinetic studies proved to be the true regenerating substrate.[c,d] Its carboxylation and cleavage[e] represent the first step in what has come to be known as the Calvin–Benson cycle (Fig. 17-14).[f]

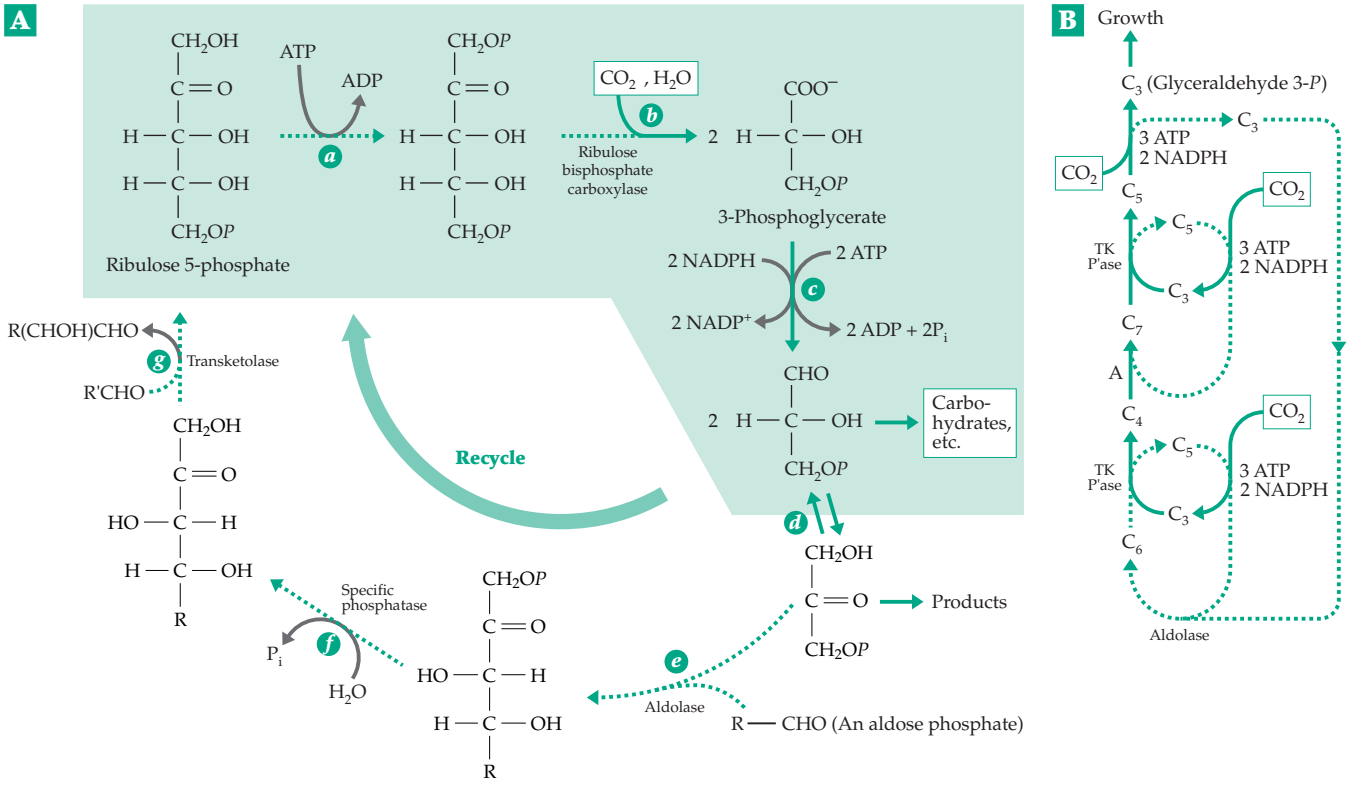

Figure 17-14 (A) The reductive carboxylation system used in reductive pentose phosphate pathway (Calvin–Benson cycle). The essential reactions of this system are enclosed within the dashed box. Typical subsequent reactions follow. The phosphatase action completes the phosphorylation–dephosphorylation cycle. (B) The reductive pentose phosphate cycle arranged to show the combining of three CO_2 molecules to form one molecule of triose phosphate. Abbreviations are RCS, reductive carboxylation system (from above); A, aldolase, Pase, specific phosphatase; and TK, transketolase.

three C_5 sugars three molecules of fructose 6-phosphate will be formed. One of these can be phosphorylated by ATP to fructose 1,6-bisphosphate, which can be cleaved by aldolase. One of the resulting triose phosphates can then be removed for biosynthesis and the second, together with the other two molecules of fructose 6-*P*, can be recycled through the sugar rearrangement sequence of Fig. 17-8B to regenerate the three ribulose 5-*P* molecules that serve as the regenerating substrate.

In bacteria, which lack formate dehydrogenase, formaldehyde can be oxidized to CO_2 to provide energy beginning with the reactions of Eq. 17-51. The resulting fructose 6-*P* is isomerized to glucose 6-*P*, which is then dehydrogenated via Eq. 17-12 to form CO_2 and the regenerating substrate ribulose 5-phosphate.

A number of pseudomonads and other bacteria convert C_1 compounds to acetate via tetrahydrofolic acid-bound intermediates and CO_2 using the **serine pathway**[179,192,193] shown in Fig. 17-15. This is a cyclic process for converting one molecule of formaldehyde (bound to tetrahydrofolate) plus one of CO_2 into acetate. The regenerating substrate is **glyoxylate**. Before condensation with the "active formaldehyde" of methylene THF, the glyoxylate undergoes transamination to glycine (Fig. 17-15, step *a*). The glycine plus formaldehyde forms serine (step *b*), which is then transaminated to hydroxypyruvate, again using step *a*. Glyoxylate plus formaldehyde could have been joined in a thiamin-dependent condensation. However, as in the γ-aminobutyrate shunt (Fig. 17-5), the coupled transamination step of Fig 17-15 permits use of PLP-dependent C–C bond formation.

Conversion of hydroxypyruvate to PEP (Fig. 17-15) involves reduction by NADH and phosphorylation by ATP to form 3-phosphoglycerate, which is converted to PEP as in glycolysis. The conversion of malate to acetate and glyoxylate via malyl-CoA and isocitrate lyase (Eq. 13-40) forms the product acetate and regenerates glyoxylate. As with other metabolic cycles, various intermediates, such as PEP, can be withdrawn for biosynthesis. However, there must be an independent route of synthesis of the regenerating substrate glyoxylate. One way in which this can be accomplished is to form glycine via the reversal of the glycine decarboxylase pathway as is indicated by the shaded green lines in Fig. 17-15.

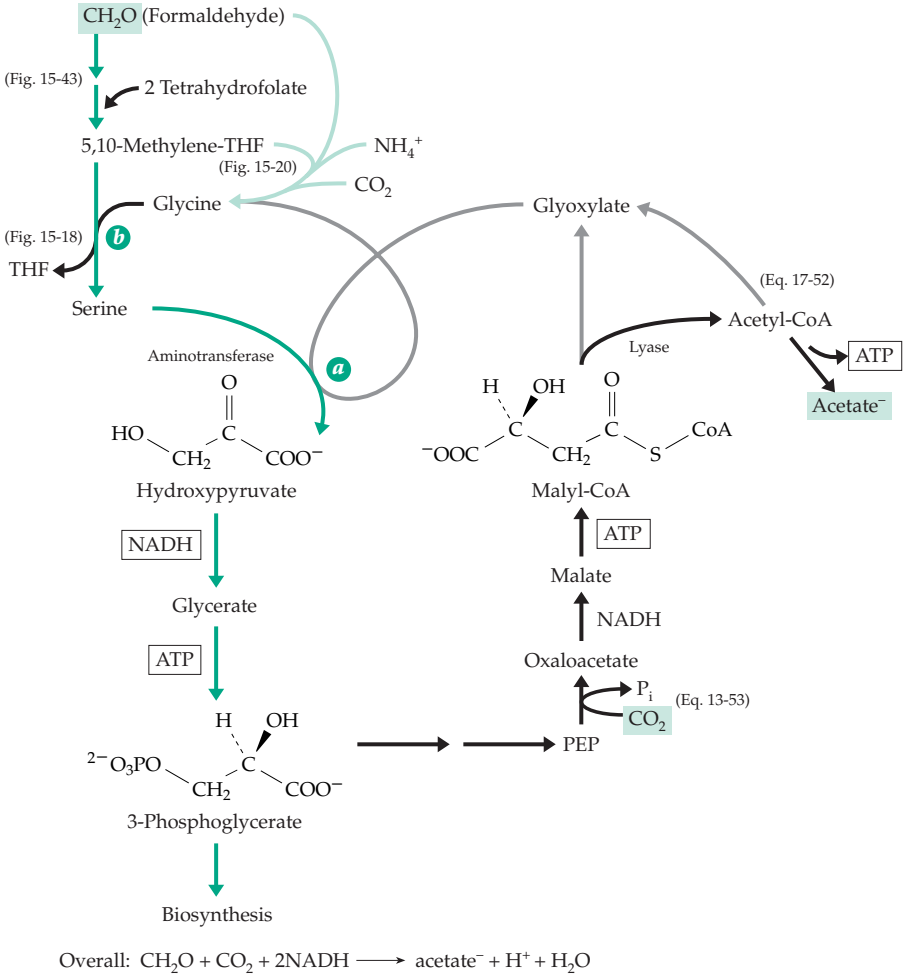

Figure 17-15 One of the serine pathways for assimilation of one-carbon compounds.

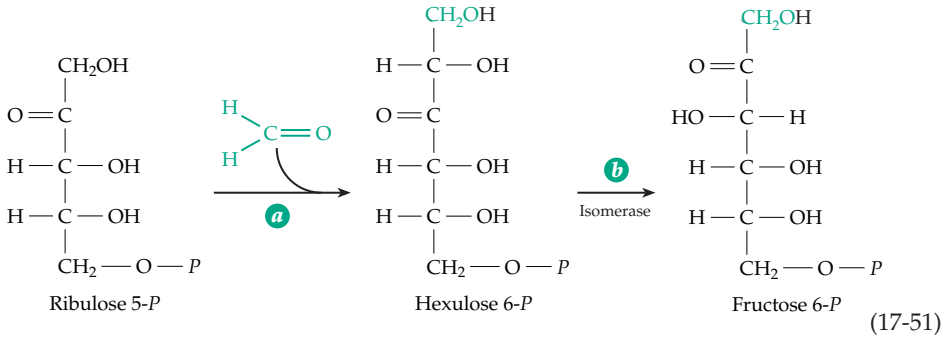

(17-51)

4. The Glyoxylate Pathways

The reductive carboxylation of acetyl-CoA to pyruvate (Eq. 17-47) occurs only in a few types of bacteria. For most species, from microorganisms to animals, the oxidative decarboxylation of pyruvate to acetyl-CoA is irreversible. This fact has many important consequences. For example, carbohydrate is readily converted to fat; because of the irreversibility of this process, excess calories lead to the deposition of fats. However, in animals fat cannot be used to generate most of the biosynthetic intermediates needed for formation of carbohydrates and proteins because those intermediates originate largely from C_3 units.

This limitation on the conversion of C_2 acetyl units to C_3 metabolites is overcome in many organisms by

the **glyoxylate cycle** (Fig. 17-16), which converts *two* acetyl units into one C_4 unit. The cycle provides a way for organisms, such as *E. coli*,[111,199] *Saccharomyces*,[200] *Tetrahymena*, and the nematode *Caenorhabditis*,[201] to subsist on acetate as a sole or major carbon source. It is especially prominent in plants that store large amounts of fat in their seeds (**oil seeds**). In the germinating oil seed the glyoxylate cycle allows fat to be converted rapidly to sucrose, cellulose, and other carbohydrates needed for growth.

A key enzyme in the glyoxylate cycle is **isocitrate lyase**, which cleaves isocitrate (Eq. 13-40) to succinate and glyoxylate. The latter is condensed with a second acetyl group by the action of **malate synthase** (Eq. 13-38). The L-malate formed in this reaction is dehydrogenated to the regenerating substrate oxaloacetate. Some of the reaction steps are those of the citric acid cycle and it appears that in bacteria there is no spatial separation of the citric acid cycle and glyoxylate pathway. However, in plants the enzymes of the glyoxylate cycle are present in specialized peroxisomes known as **glyoxysomes**.[60] The glyoxysomes also contain the enzymes for β oxidation of fatty acids, allowing for efficient conversion of fatty acids to **succinate**. This compound is exported from the glyoxysomes and enters the mitochondria where it undergoes β oxidation to oxaloacetate. The latter can be converted by PEP carboxylase (Eq. 13-53) or by PEP carboxykinase (Eq. 13-46) to PEP.

An **acetyl-CoA-glyoxylate** cycle, which catalyzes oxidation of acetyl groups to glyoxylate, can also be constructed from isocitrate lyase and citric acid cycle

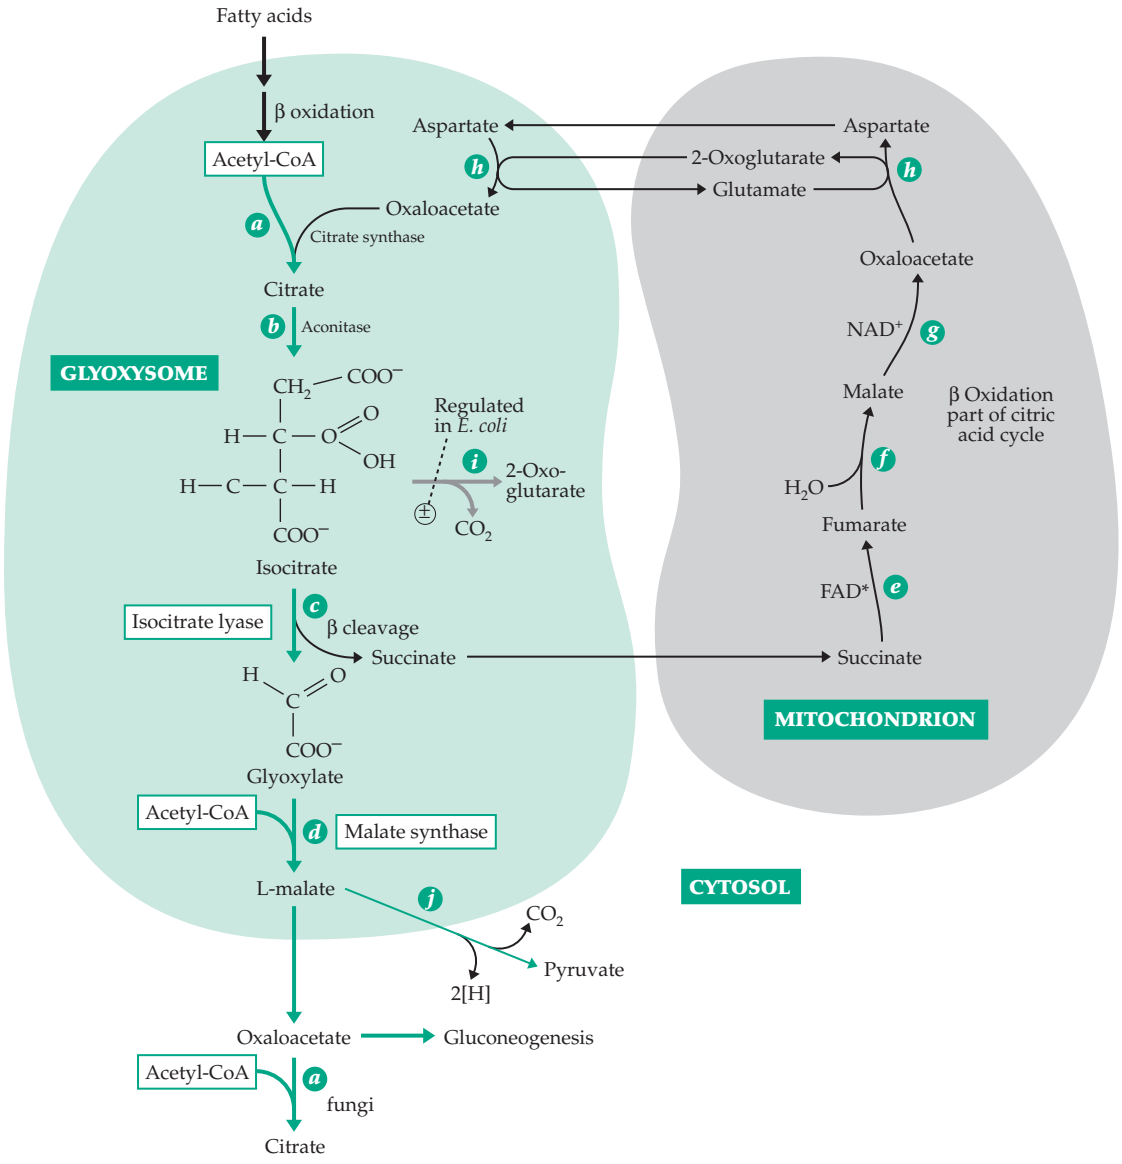

Figure 17-16 The glyoxylate pathway. The green line traces the pathway of labeled carbon from fatty acids or acetyl-CoA into malate and other products.

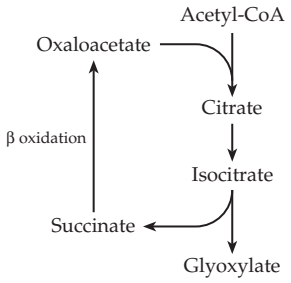
enzymes. Glyoxylate is taken out of the cycle as the product and succinate is recycled (Eq. 17-52). The independent pathway for synthesis of the regenerating substrate oxaloacetate is condensation of glyoxylate with acetyl-CoA (malate synthetase) to form malate and oxidation of the latter to oxaloacetate as in the main cycle of Fig. 17-16.



(17-52)

5. Biosynthesis of Glucose from Three-Carbon Compounds

Now let us consider the further conversion of PEP and of the triose phosphates to **glucose 1-phosphate**, the key intermediate in biosynthesis of other sugars and polysaccharides. The conversion of PEP to glucose 1-*P* represents a reversal of part of the glycolysis sequence. It is convenient to discuss this along with **gluconeogenesis**, the reversal of the complete glycolysis sequence from lactic acid. This is an essential part of the Cori cycle (Section F) in our own bodies, and the same process may be used to convert pyruvate derived from deamination of alanine or serine (Chapter 24) into carbohydrates.

Just as with the pentose phosphate cycle, an exact reversal of the glycolysis sequence (Eq. 17-53) is precluded on thermodynamic grounds. Even at very high values of the phosphorylation state ratio R_p, the reaction:

$$2\ \text{Lactate}^- + 3\ \text{ATP}^{4-} + 2\ \text{H}_2\text{O} \rightarrow \text{C}_6\text{H}_{10}\text{O}_5\ (\text{glycogen}) + 3\ \text{ADP}^{3-} + 3\ \text{HPO}_4^{2-} + \text{H}^+$$

$$\Delta G'\ (\text{pH } 7) = +107\ \text{kJ per glycosyl unit} \qquad (17\text{-}53)$$

would be unlikely to go to completion. The actual pathways used for gluconeogenesis (Fig. 17-17, green lines) differ from those of glycolysis (black lines) in three significant ways. First, while glycogen breakdown is initiated by the reaction with inorganic phosphate catalyzed by phosphorylase (Fig. 17-17, step *a*), the biosynthetic sequence from glucose 1-*P*, via uridine diphosphate glucose (Fig. 17-17, step *b*; see also Eq. 17-56), is coupled to cleavage of ATP. Second, in the catabolic process (glycolysis) fructose 6-*P* is converted to fructose 1,6-P_2 through the action of a kinase (Fig. 17-17, step *c*), which is then cleaved by aldolase. The resulting triose phosphate is degraded to PEP. In glucogenesis a phosphatase is used to form fructose *P* from fructose P_2 (Fig. 17-17, step *d*). Third, during gly-colysis PEP is converted to pyruvate by a kinase with generation of ATP (Fig. 17-17, step *e*). During glucogenesis pyruvate is converted to PEP indirectly via oxaloacetate (Fig. 17-17, steps *f* and *g*) using pyruvate carboxylase (Eq. 14-3) and PEP carboxykinase (Eq. 13-46). This is another example of the coupling of ATP cleavage through a carboxylation–decarboxylation sequence. The net effect is to use two molecules of ATP (actually one ATP and one GTP) rather than *one* to convert pyruvate to PEP.

The overall reaction for reversal of glycolysis to form glycogen (Eq. 17-54) now has a comfortably negative standard Gibbs energy change as a result of coupling the cleavage of 7 ATP to the reaction.

$$2\ \text{Lactate}^- + 7\ \text{ATP}^{4-} + 6\ \text{H}_2\text{O} \rightarrow \text{glycogen} + 7\ \text{ADP}^{3-} + 7\ \text{HPO}_4^{2-} + 5\ \text{H}^+$$

$$\Delta G'\ (\text{pH } 7) = -31\ \text{kJ mol}^{-1}\ \text{per glycosyl unit} \qquad (17\text{-}54)$$

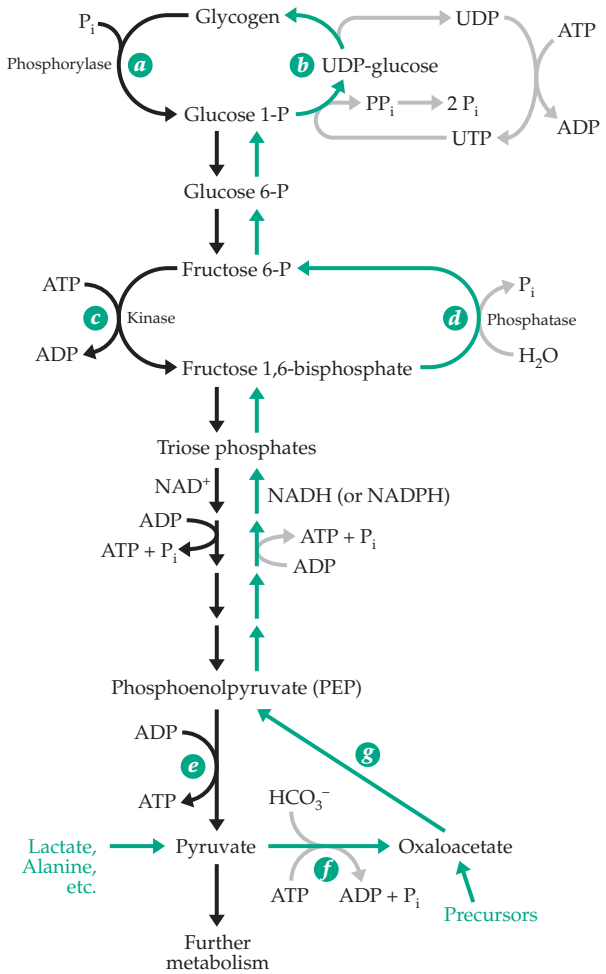


Figure 17-17 Comparison of glycolytic pathway (left) with pathway of gluconeogenesis (right, green arrows).

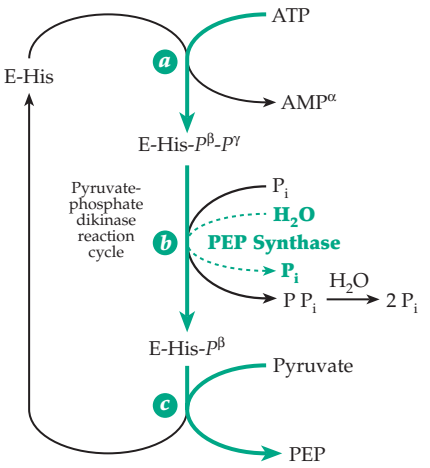
Two enzymes that are able to convert pyruvate directly to PEP are found in some bacteria and plants. In each case, as in the animal enzyme system discussed in the preceding paragraph, the conversion involves expenditure of two high-energy linkages of ATP. The **PEP synthase** of *E. coli* first transfers a pyrophospho group from ATP onto an imidazole group of histidine in the enzyme (Eq. 17-55). A phospho group is hydrolyzed from this intermediate (dashed green line in Eq. 17-55, step *b*), ensuring that sufficient intermediate E–His–*P* is present. The latter reacts with pyruvate to form PEP.[202,203] **Pyruvate–phosphate dikinase** is a similar enzyme first identified in tropical grasses and known to play an important role in the CO_2 concentrating system of the so-called "C_4 plants" (Chapter 23).[204] The same enzyme participates in gluconeogenesis in *Acetobacter*. The reaction cycle for this enzyme is also portrayed in Eq. 17-55. In this case P_i, rather than water, is the attacking nucleophile in Eq. 17-55 and PP_i is a product. The latter is probably hydrolyzed by pyrophosphatase action, the end result being an overall reaction that is the same as with PEP synthase. Kinetic and positional isotope exchange studies suggest that the P_i must be bound to pyruvate–phosphate dikinase before the bound ATP can react with the imidazole group.[202] Likewise, AMP doesn't dissociate until P_i has reacted to form PP_i.



(17-55)

6. Building Hydrocarbon Chains with Two-Carbon Units

Fatty acid chains are taken apart two carbon atoms at a time by β oxidation. Biosynthesis of fatty acids reverses this process by using the two-carbon acetyl unit of acetyl-CoA as a starting material. The coupling of ATP cleavage to this process by a carboxylation–decarboxylation sequence, the role of acyl carrier protein (Section H,4), and the use of NADPH as a reductant (Section I) have been discussed and are summarized in Fig. 17-12, which gives the complete sequence of reactions for fatty acid biosynthesis. Why does β oxidation require CoA derivatives while biosynthesis requires the more complex acyl carrier protein (ACP)? The reason may involve control. ACP is a complex handle able to hold the growing fatty acid chain and to guide it from one enzyme to the next. In *E. coli* the various enzymes catalyzing the reactions of Fig. 17-12 are found in the cytosol and behave as independent proteins. The same is true for fatty acid synthases of higher plants which resemble those of bacteria.[205,205a]

It is thought that the ACP molecule lies at the center of the complex and that the growing fatty acid chain on the end of the phosphopantetheine prosthetic group moves from one subunit to the other.[164,206] The process is started by a **primer** which is usually acetyl-CoA in *E. coli*. Its acyl group is transferred first to the central molecule of ACP (step *a*, Fig. 17-12) and then to a "peripheral" thiol group, probably that of a cysteine side chain on a separate protein subunit (step *b*, Fig. 17-12). Next, a malonyl group is transferred (step *d*) from malonyl-CoA to the free thiol group on the ACP. The condensation (steps *e* and *f*) occurs with the freeing of the peripheral thiol group. The latter does not come into use again until the β-oxoacyl group formed has undergone the complete sequence of reduction reactions (steps *g*–*i*). Then the growing chain is again transferred to the peripheral –SH (step *j*) and a new malonyl unit is introduced on the central ACP.

After the chain reaches a length of 12 carbon atoms, the acyl group tends to be transferred off to a CoA molecule (step *k*) rather than to pass around the cycle again. Thus, chain growth is terminated. This tendency systematically increases as the chain grows longer.

In higher animals as well as in *Mycobacterium*,[207] yeast,[208] and *Euglena*, the **fatty acid synthase** consists of only one or two multifunctional proteins. The synthase from animal tissues has seven catalytic activities in a single 263-kDa 2500-residue protein.[209] The protein consists of a series of domains that contain the various catalytic activities needed for the entire synthetic sequence. One domain contains an ACP-like site with a bound 4'-phosphopantetheine as well as a cysteine side chain in the second acylation site. This synthase produces free fatty acids, principally the C_{16} palmitate. The final step is cleavage of the acyl-CoA by a thioesterase, one of the seven enzymatic activities of the synthase. See Chapter 21 for further discussion.

7. The Oxoacid Chain Elongation Process

As mentioned in Section 4, glyoxylate can be converted to oxaloacetate by condensation with acetyl-CoA (Fig. 17-16) and the oxaloacetate can be decarboxylated to pyruvate. This sequence of reactions resembles that of the conversion of oxaloacetate to 2-oxoglutarate in the citric acid cycle (Fig. 17-4). *Both*

are examples of a frequently used general chain elongation process for α-oxo acids. This sequence, which is illustrated in Fig. 17-18, has four steps: (1) condensation of the α-oxo acid with an acetyl group, (2) isomerization by dehydration and rehydration (catalyzed by aconitase in the case of the citric acid cycle), (3) dehydrogenation, and (4) β decarboxylation. In many cases steps 3 and 4 are combined as a single enzymatic reaction. The isomerization of the intermediate hydroxy acid in step 2 is required because the hydroxyl group, which is attached to a tertiary carbon bearing no hydrogen, must be moved to the adjacent carbon atom before oxidation to a ketone can take place. However, in the case of glyoxylate, isomerization is not necessary because R = H.

It may be protested that the reaction of the citric acid cycle by which oxaloacetate is converted to oxoglutarate does not follow exactly the pattern of Fig. 17-18. The carbon dioxide removed in the decarboxylation step does not come from the part of the molecule donated by the acetyl group but from that formed from oxaloacetate. However, the end result is the same. Furthermore, there are two known citrate-forming enzymes with different stereospecificities (Chapter 13), one of which leads to a biosynthetic pathway strictly according to the sequence of Fig. 17-18.

At the bottom of Fig. 17-18 several stages of the α-oxo acid elongation process are arranged in tandem. We see that glyoxylate (a product of the acetyl-CoA–glyoxylate cycle) can be built up systematically to

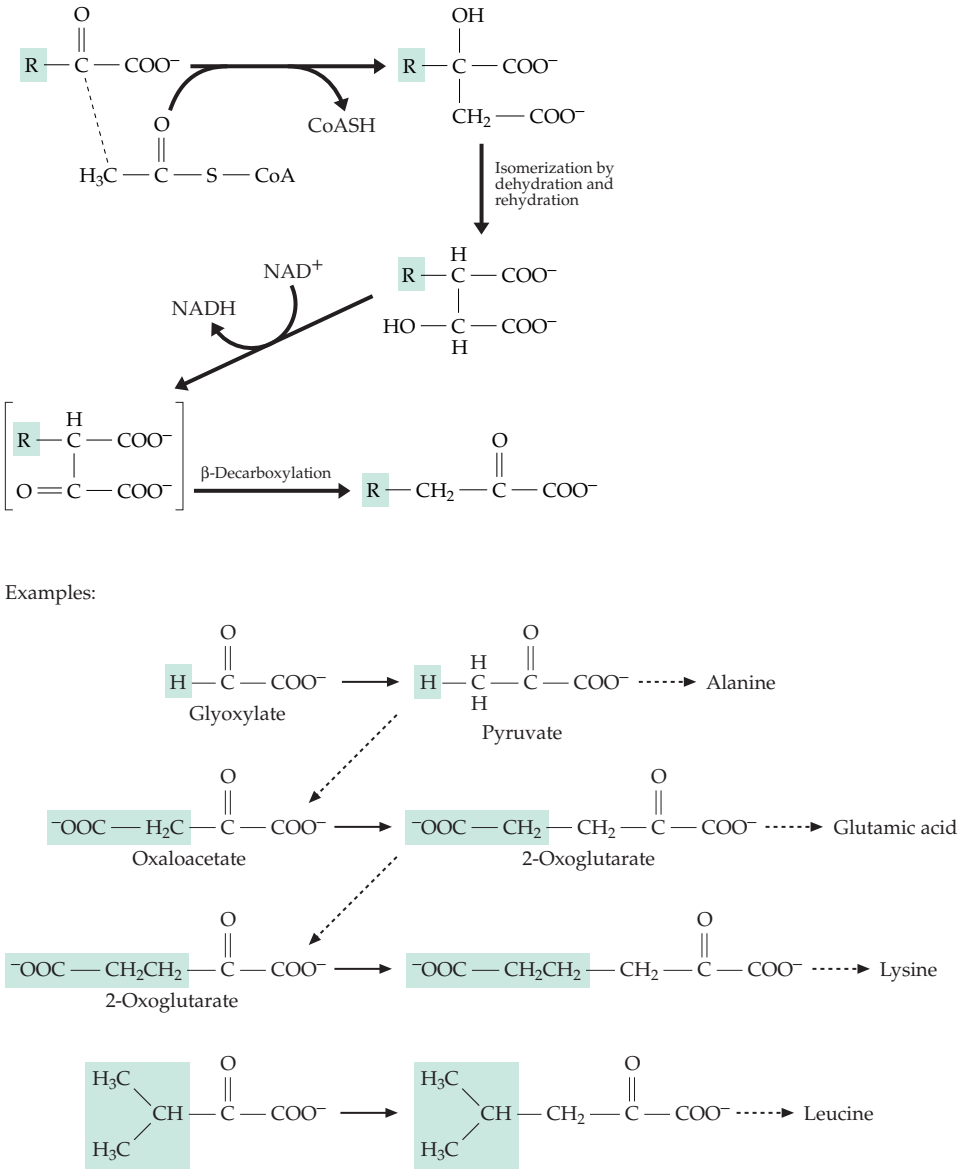


Figure 17-18 The oxoacid chain elongation process.

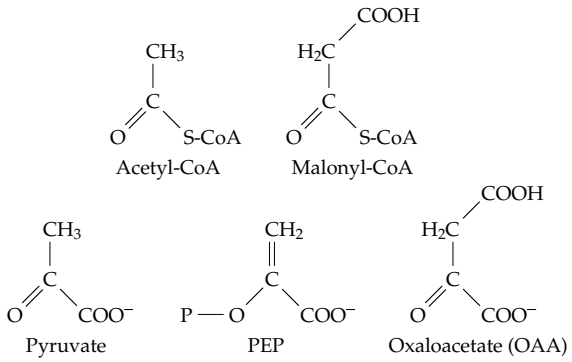
pyruvate, oxaloacetate, 2-oxoglutarate, and 2-oxoadipate (a precursor of lysine) using this one reaction sequence. Methanogens elongate 2-oxoadipate by one and two carbon atoms using the same sequence to give 7- and 8-carbon dicarboxylates.[210]

8. Decarboxylation as a Driving Force in Biosynthesis

Consider the relationship of the following prominent biosynthetic intermediates one to another:



Utilization of acetyl-CoA for the synthesis of long-chain fatty acids occurs via carboxylation to malonyl-CoA. *We can think of the malonyl group as a β-carboxylated acetyl group*. During synthesis of a fatty acid the carboxyl group is lost, and only the acetyl group is ultimately incorporated into the fatty acid. In a similar way *pyruvate can be thought of as an α-carboxylated acetaldehyde and oxaloacetate as an α- and β-dicarboxylated acetaldehyde*. During biosynthetic reactions these three- and four-carbon compounds also often undergo decarboxylation. Thus, they both can be regarded as "activated acetaldehyde units." Phosphoenolpyruvate is an α-carboxylated phosphoenol form of acetaldehyde and undergoes both decarboxylation and dephosphorylation before contributing a two-carbon unit to the final product.

It is of interest to compare two chain elongation processes by which two-carbon units are combined. In the synthesis of fatty acids the acetyl units are condensed and then are reduced to form straight hydrocarbon chains. In the oxo-acid chain elongation mechanism, the acetyl unit is introduced but is later decarboxylated. Thus, the chain is increased in length by one carbon atom at a time. These two mechanisms account for a great deal of the biosynthesis by chain extension. However, there are other variations. For example, glycine (a carboxylated methylamine), under the influence of pyridoxal phosphate and with accompanying decarboxylation, condenses with succinyl-CoA (Eq. 14-32) to extend the carbon chain and at the same time to introduce an amino group. Likewise, serine (a carboxylated ethanolamine) condenses with palmitoyl-CoA in biosynthesis of sphingosine (as in Eq. 14-32). Phosphatidylserine is decarboxylated to phosphatidylethanolamine in the final synthetic step for that phospholipid (Fig. 21-5).

9. Stabilization and Termination of Chain Growth by Ring Formation

Biochemical substances frequently undergo cyclization to form stable five- and six-atom ring structures. The three-carbon glyceraldehyde phosphate exists in solution primarily as the free aldehyde (and its covalent hydrate) but glucose 6-phosphate exists largely as the cyclic hemiacetal. In this ring form no carbonyl group is present and further chain elongation is inhibited. When the hemiacetal of glucose 6-*P* is enzymatically isomerized to glucose 1-*P* the ring is firmly locked. Glucose 1-*P*, in turn, serves as the biosynthetic precursor of polysaccharides and related compounds, in all of which the sugar rings are stable. Ring formation can occur in lipid biosynthesis, too. Among the **polyketides** (Chapter 21), polyprenyl compounds (Chapter 22), and aromatic amino acids (Chapter 25) are many substances in which ring formation has occurred by ester or aldol condensations followed by reduction and elimination processes. This is a typical sequence for biosynthesis of highly stable aromatic rings.

10. Branched Carbon Chains

Branched carbon skeletons are formed by standard reaction types but sometimes with addition of rearrangement steps. Compare the biosynthetic routes to three different branched five-carbon units (Fig. 17-19) The first is the use of a **propionyl group** to initiate formation of a branched-chain fatty acid. Propionyl-CoA is carboxylated to methylmalonyl-CoA, whose acyl group is transferred to the acyl carrier protein before condensation. Decarboxylation and reduction yields an acyl-CoA derivative with a methyl group in the 3-position.

The second five-carbon branched unit, in which the branch is one carbon further down the chain, is an intermediate in the biosynthesis of **polyprenyl** (isoprenoid) compounds and steroids. Three two-carbon units are used as the starting material with decarboxylation of one unit. Two acetyl units are first condensed to form acetoacetyl-CoA. Then a third acetyl unit, which has been transferred from acetyl-CoA onto an SH group of the enzyme, is combined with the acetoacetyl-CoA through an ester condensation. The thioester linkage to the enzyme is hydrolyzed to free the product **3-hydroxy-3-methylglutaryl-CoA** (HMG-CoA). This sequence is illustrated in Eq. 17-5. The thioester group of HMG-CoA is reduced to the

alcohol **mevalonic acid**, a direct precursor to isopentenyl pyrophosphate, from which the polyprenyl compounds are formed (Fig. 22-1).

The third type of carbon-branched unit is 2-oxoisovalerate, from which valine is formed by transamination. The starting units are two molecules of pyruvate which combine in a thiamin diphosphate-dependent α condensation with decarboxylation. The resulting α-acetolactate contains a branched chain but is quite unsuitable for formation of an α amino acid. A rearrangement moves the methyl group to the β position (Fig. 24-17), and elimination of water from the diol forms the enol of the desired α-oxo acid (Fig. 17-19). The precursor of isoleucine is formed in an analogous way by condensation, with decarboxylation of one molecule of pyruvate with one of 2-oxobutyrate.

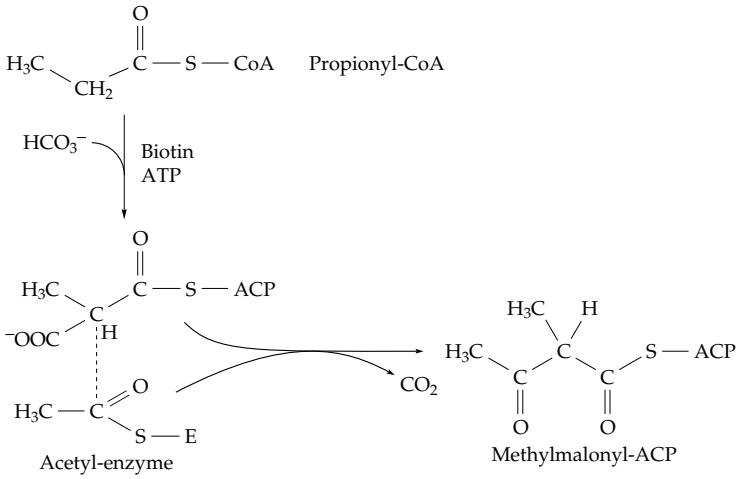
K. Biosynthesis and Modification of Polymers

There are three chemical problems associated with the assembly of a protein, nucleic acid, or other biopolymer. The first is *to overcome thermodynamic barriers*. The second is *to control the rate of synthesis*, and the third is *to establish the pattern or sequence in which the monomer units are linked together*. Let us look briefly at how these three problems are dealt with by living cells.

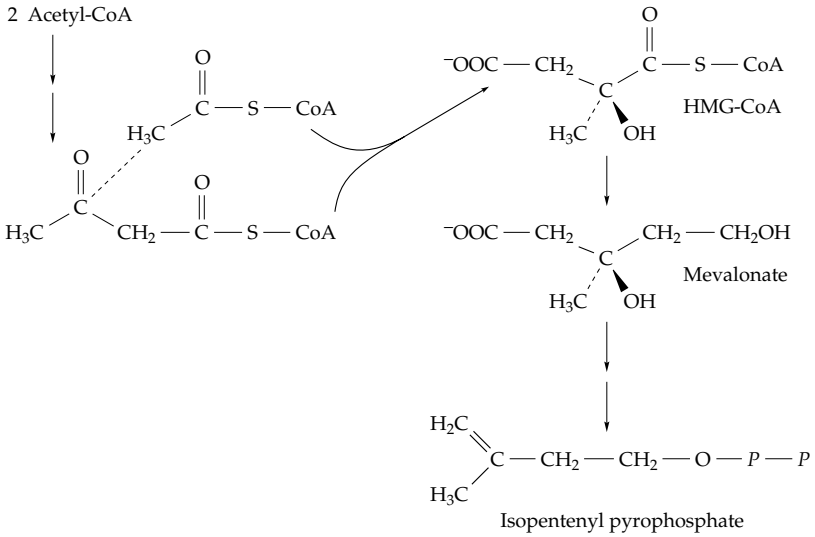
1. Peptides and Proteins

Activation of amino acids for incorporation into oligopeptides and proteins can occur via two routes of acyl activation. In the first of these an **acyl phosphate** (or acyl adenylate) is formed and reacts with an amino group to form a peptide linkage (Eq. 13-4). The tripeptide **glutathione** is formed in two steps of this type (Box 11-B). In the second method of activation **aminoacyl**

1. Starter piece for branched-chain fatty acids



2. Polyisoprenoid compounds



3. Branched-chain amino acids

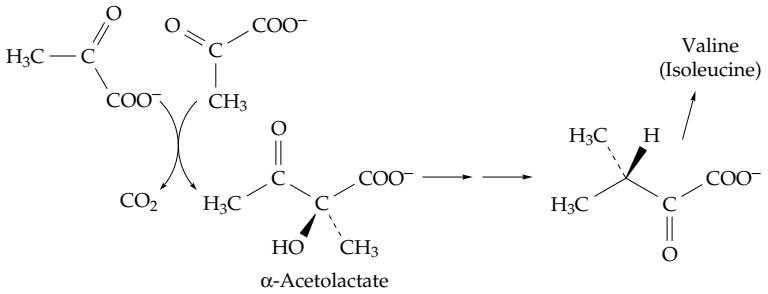


Figure 17-19 Biosynthetic origins of three five-carbon branched structural units. Notice that decarboxylation is involved in driving each sequence.

adenylates are formed. They transfer their activated aminoacyl groups onto specific tRNA molecules during synthesis of proteins (Eq. 17-36). In other cases activated aminoacyl groups are transferred onto –SH groups to form intermediate **thioesters**. An example is the synthesis of the antibiotic **gramicidin S** formed by *Bacillus brevis*. The antibiotic is a cyclic decapeptide with the following five-amino-acid sequence repeated twice in the ringlike molecule[211]:

$$(\text{–D-Phe–L-Pro–L-Val–L-Orn–L-Leu–})_2$$

The soluble enzyme system responsible for its synthesis contains a large 280-kDa protein that not only activates the amino acids as aminoacyl adenylates and transfers them to thiol groups of 4'-phosphopantetheine groups covalently attached to the enzyme but also serves as a template for joining the amino acids in proper sequence.[211–214] Four amino acids—proline, valine, ornithine (Orn), and leucine—are all bound. A second enzyme (of mass 100 kDa) is needed for activation of phenylalanine. It is apparently the activated phenylalanine (which at some point in the process is isomerized from L- to D-phenylalanine) that initiates polymer formation in a manner analogous to that of fatty acid elongation (Fig. 17-12). Initiation occurs when the amino group of the activated phenylalanine (on the second enzyme) attacks the acyl group of the aminoacyl thioester by which the activated proline is held. Next, the freed imino group of proline attacks the activated valine, etc., to form the pentapeptide. Then two pentapeptides are joined and cyclized to give the antibiotic. The sequence is absolutely specific, and it is remarkable that this relatively small enzyme system is able to carry out each step in the proper sequence. Many other peptide antibiotics, such as the bacitracins, tyrocidines,[215] and enniatins, are synthesized in a similar way,[213,216,217] as are depsipeptides and the immunosuppresant cyclosporin. A virtually identical pattern is observed for formation of **polyketides**,[218,219] whose chemistry is considered in Chapter 21.

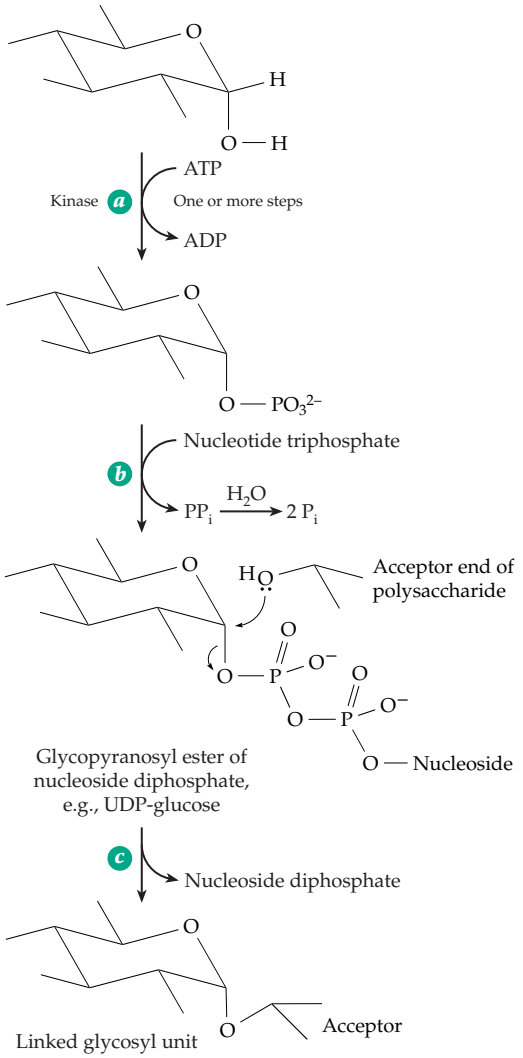
While peptide antibiotics are synthesized according to enzyme-controlled polymerization patterns, both proteins and nucleic acids are made by **template mechanisms**. The sequence of their monomer units is determined by genetically encoded information. A key reaction in the formation of proteins is the transfer of activated aminoacyl groups to molecules of tRNA (Eq. 17-36). The tRNAs act as carriers or adapters as explained in detail in Chapter 29. Each **aminoacyl-tRNA synthetase** must recognize the correct tRNA and attach the correct amino acid to it. The tRNA then carries the activated amino acid to a ribosome, where it is placed, at the correct moment, in the active site. **Peptidyltransferase**, using a transacylation reaction, in an *insertion mechanism* transfers the C terminus of the growing peptide chain onto the amino group of the new amino acid to give a tRNA-bound peptide one unit longer than before.

2. Polysaccharides

Incorporation of a sugar monomer into a polysaccharide also involves cleavage of two high-energy phosphate linkages of ATP. However, the activation process has its own distinctive pattern (Eq. 17-56). Usually a sugar is first phosphorylated by a kinase or a kinase plus a phosphomutase (Eq. 17-56, step *a*). Then a nucleoside triphosphate (NuTP) reacts under the influence of a second enzyme with elimination of pyrophosphate and formation of a **glycopyranosyl ester** of the nucleoside diphosphate, more often known as a **sugar nucleotide** (Eq. 17-56, step *b*). The inorganic pyrophosphate is hydrolyzed by pyrophosphatase while the sugar nucleotide donates the activated glycosyl group for polymerization (Eq. 17-56, step *c*). In this step the glycosyl group is transferred with displacement of the nucleoside diphosphate. Thus, the overall process involves first the cleavage of ATP to ADP and P_i, and then the cleavage of a nucleoside triphosphate to a nucleoside diphosphate plus P_i. The nucleoside triphosphate in Eq. 17-56, step *b* is sometimes ATP, in which case the overall result is the splitting of two molecules of ATP to ADP. However, as detailed in Chapter 20, the whole series of nucleotide "handles" serve to carry various activated glycosyl units.

What determines the pattern of incorporation of sugar units into polysaccharides? Homopolysaccharides, like cellulose and the linear amylose form of starch, contain only one monosaccharide component in only one type of linkage. A single synthetase enzyme can add unit after unit of an activated sugar (UDP glucose or other sugar nucleotide) to the growing end. However, at least two enzymes are needed to assemble a branched molecule such as that of the glycogen molecule. One is the synthetase; the second is a **branching enzyme**, a transglycosylase. After the chain ends attain a length of about ten monosaccharide units the branching enzyme attacks a glycosidic linkage somewhere in the chain. Acting much like a hydrolase, it forms a glycosyl enzyme (or a stabilized carbocation) intermediate. The enzyme does not release the severed chain fragment but transfers it to another nearby site on the branched polymer. In the synthesis of glycogen, the chain fragment is joined to a free 6-hydroxyl group of the glycogen, creating a new branch attached by an α-1,6-linkage.

Other carbohydrate polymers consist of **repeating oligosaccharide units**. Thus, in hyaluronan units of glucuronic acid and N-acetyl-D-glucosamine alternate (Fig. 4-11). The "O antigens" of bacterial cell coats (p. 180) contain repeating subunits made up of a "block" of four or five different sugars. In these and

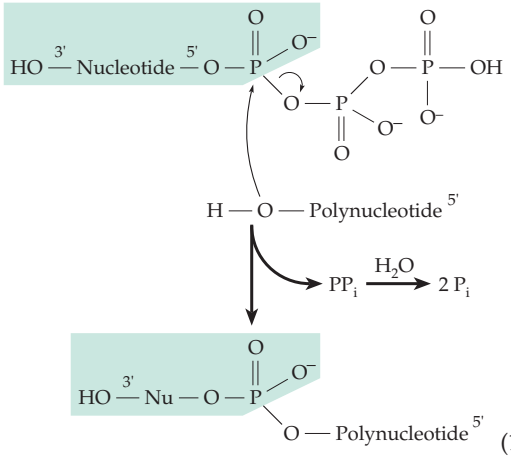


(17-56)

many other cases the pattern of polymerization is established by the specificities of individual enzymes. An enzyme capable of joining an activated glucosyl unit to a growing polysaccharide will do so only if the proper structure has been built up to that point. In cases where a block of sugar units is transferred it is usually *inserted* at the nonreducing end of the polymer, which may be covalently attached to a protein. Notice that the insertion mode of chain growth exists for lipids, polysaccharides, and proteins.

3. Nucleic Acids

The activated nucleotides are the nucleoside 5'-triphosphates. The ribonucleotides ATP, GTP, UTP, and CTP are needed for RNA synthesis and the 2'-deoxyribonucleotide triphosphates, dATP, dTTP, dGTP, and dCTP for DNA synthesis. In every case, the addition of activated monomer units to a growing polynucleotide chain is catalyzed by an enzyme that



(17-57)

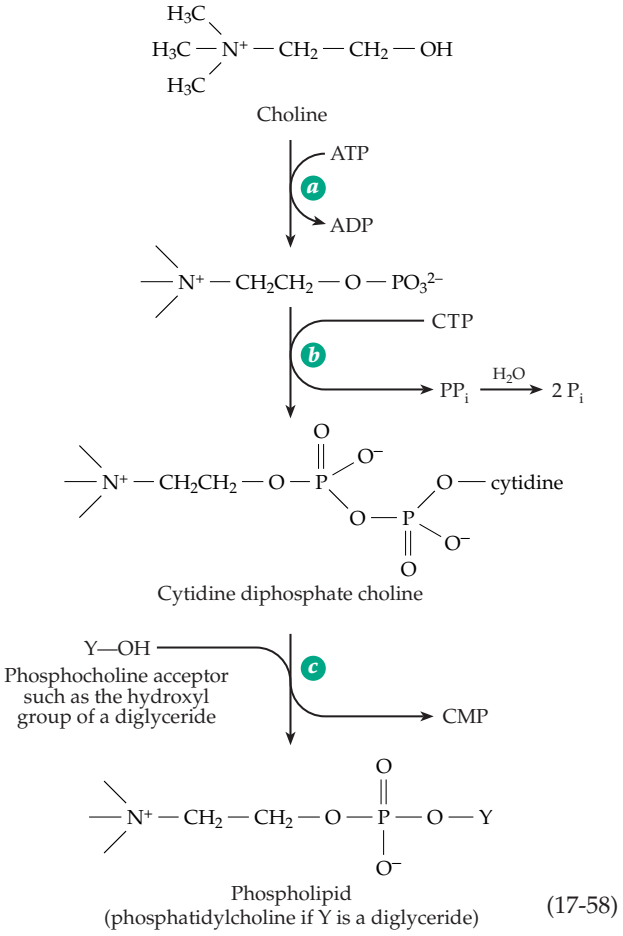
binds to the template nucleic acid. The choice of the proper nucleotide unit to place next in the growing strand is determined by the nucleotide already in place in the complementary strand, a matter that is dealt with in Chapters 27 and 28. The chemistry is a simple displacement of pyrophosphate (Eq. 17-57). The 3'-hydroxyl of the polynucleotide attacks the phosphorus atom of the activated nucleoside triphosphate. Thus, *nucleotide chains always grow from the 5′ end, with new units being added at the 3′ end*.

4. Phospholipids and Phosphate–Sugar Alcohol Polymers

Choline and ethanolamine are activated in much the same way as are sugars. For example, choline can be phosphorylated using ATP (Eq. 17-58, step *a*) and the phosphocholine formed can be further converted (Eq. 17-58, step *b*) to **cytidine diphosphate choline**. Phosphocholine is transferred from the latter onto a suitable acceptor to form the final product (Eq. 17-58, step *c*). The polymerization pattern differs from that for polysaccharide synthesis. When the sugar nucleotides react, the entire nucleoside diphosphate is eliminated (Eq. 17-56), but CDP-choline and CDP-ethanolamine react with elimination of CMP (Eq. 17-58, step *c*), leaving one phospho group in the final product. The same thing is true in the synthesis of the bacterial teichoic acids (Chapter 8). Either CDP-glycerol or CDP-ribitol is formed first and polymerization takes place with elimination of CMP to form the alternating phosphate–sugar alcohol polymer.[220]

5. Irreversible Modification and Catabolism of Polymers

While polymers are being synthesized continuously by cells, they are also being modified and torn down. Nothing within a cell is static. As discussed in Chapters



(17-58)

10 and 29, everything turns over at a slower or faster rate. Hydrolases attack all of the polymers of which cells are composed, and active catabolic reactions degrade the monomers formed. Membrane surfaces are also altered, for example, by hydroxylation and glycosylation of both glycoproteins and lipid head groups. It is impossible to list all of the known modification reactions of biopolymers. They include hydrolysis, methylation, acylation, isopentenylation, phosphorylation, sulfation, and hydroxylation. Precursor molecules are cut and trimmed and often modified further to form functional proteins or nucleic acids. Phosphotransferase reactions splice RNA transcripts to form mRNA and a host of alterations convert precursors into mature tRNA molecules (Chapter 28). Even DNA, which remains relatively unaltered, undergoes a barrage of chemical attacks. Only because of the presence of an array of repair enzymes (Chapter 27) does our DNA remain nearly unchanged so that faithful copies can be provided to each cell in our bodies and can be passed on to new generations.

L. Regulation of Biosynthesis

A simplified view of metabolism is to consider a cell as a "bag of enzymes." Indeed, much of metabolism can be explained by the action of several thousand enzymes promoting specific reactions of their substrates. These reactions are based upon the natural chemical reactivities of the substrates. However, the enzymes, through the specificity of their actions and through association with each other,[96,221–223] channel the reactions into a selected series of metabolic pathways. The reactions are often organized as cycles which are inherently stable. We have seen that biosynthesis often involves ATP-dependent reductive reactions. *It is these reductive processes that produce the less reactive nonpolar lipid groupings and amino acid side chains so essential to the assembly of insoluble intracellular structures.* Oligomeric proteins, membranes, microtubules, and filaments are all the natural result of aggregation caused largely by hydrophobic interactions with electrostatic forces and hydrogen bonding providing specificity. A major part of metabolism is the creation of complex molecules that aggregate spontaneously to generate structure. This structure includes the lipid-rich cytoplasmic membranes which, together with embedded carrier proteins, control the entry of substances into cells. Clearly, the cell is now much more than a bag of enzymes, containing several compartments, each of which contains its own array of enzymes and other components. Metabolite concentrations may vary greatly from one compartment to another.

The reactions that modify lipids and glycoproteins provide a driving force that assists in moving membrane materials generated internally into the outer surface of cells. Other processes, including the breakdown by lysosomal enzymes, help to recycle membrane materials. Oxidative attack on hydrophobic materials such as the sterols and the fatty acids of membrane lipids results in their conversion into more soluble substances which can be degraded and completely oxidized. The flow of matter within cells tends to occur in metabolic loops and some of these loops lead to formation of membranes and organelles and to their turnover. This flow of matter, which is responsible for growth and development of cells, is driven both by hydrolysis of ATP coupled to biosynthesis and by irreversible degradative alterations of polymers and lipid materials. It also provides for transient formation and breakup of complexes of macromolecules, which may be very large, in response to varying metabolic needs.

Anything that affects the rate of a reaction involved in either biosynthesis or degradation of any component of the cell will affect the overall picture in some way. Thus, every chemical reaction that contributes to a quantitatively significant extent to metabolism has

some controlling influence. Since molecules interact with each other in so many ways, reactions of metabolic control are innumerable. Small molecules act on macromolecules as effectors that influence conformation and reactivity. Enzymes act on each other to break covalent bonds, to oxidize, and to crosslink. Transferases add phospho, glycosyl, methyl, and other groups to various sites. The resulting alterations often affect catalytic activities. The number of such interactions significant to metabolic control within an organism may be in the millions. Small wonder that biochemical journals are filled with a confusing number of postulated control mechanisms.

Despite this complexity, some regulatory mechanisms stand out clearly. The control of enzyme synthesis through feedback repression and the rapid control of activity by feedback inhibition (Chapter 11) have been considered previously. Under some circumstances, in which there is a constant growth rate, these controls may be sufficient to ensure the harmonious and proportional increase of all constitutents of a cell. Such may be the case for bacteria during logarithmic growth (Box 9-B) or for a mammalian embryo growing rapidly and drawing all its nutrients from the relatively constant supply in the maternal blood.

Contrast the situation in an adult. Little growth takes place, but the metabolism must vary with time and physiological state. The body must make drastic readjustments from normal feeding to a starvation situation and from resting to heavy exercise. The metabolism needed for rapid exertion is different from that needed for sustained work. A fatty diet requires different metabolism than a high-carbohydrate diet. The necessary control mechanisms must be rapid and sensitive.

1. Glycogen and Blood Glucose

Two special features of glucose metabolism in animals are dominant.[224] The first is the storage of glycogen for use in providing muscular energy rapidly. This is a relatively short-term matter but the rate of glycolysis can be intense: The entire glycogen content of muscle could be exhausted in only 20 s of anaerobic fermentation or in 3.5 min of oxidative metabolism.[225] There must be a way to turn on glycolysis quickly and to turn it off when it is no longer needed. At the same time, it must be possible to reconvert lactate to glucose or glycogen (gluconeogenesis). The glycogen stores of the muscle must be repleted from glucose of the blood. If insufficient glucose is available from the diet or from the glycogen stores of the liver, it must be synthesized from amino acids.

The second special feature of glucose metabolism is that certain tissues, including brain, blood cells, kidney medulla, and testis, ordinarily obtain most of their energy through oxidation of glucose.[226,227] For this reason, the glucose level of blood cannot be allowed to drop much below the normal 5 mM. The mechanism of regulation of the blood glucose level is complex and incompletely understood. A series of hormones are involved.

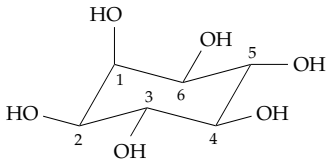
Insulin. This 51-residue cross-linked polypeptide (Fig. 7-17) is synthesized in the pancreatic islets of Langerhans, a tissue specialized for synthesis and secretion into the bloodstream of a series of small peptide hormones. One type of islet cells, the β cells, forms primarily insulin which is secreted in response to high (> 5mm) blood [glucose].[228] Insulin has a wide range of effects on metabolism,[228a] which are discussed in Chapter 11, Section G. Most of these effects are thought to arise from binding to insulin receptors (Figs. 11-11 and 11-12) and are mediated by cascades such as that pictured in Fig. 11-13.[229–232c] The end result is to increase or decrease activities of a large number of enzymes as is indicated in Table 17-3. Some of those are also shown in Fig. 17-20, which indicates interactions with the tricarboxylic acid cycle and lipid metabolism. Binding of insulin to the extracellular domain of its dimeric receptor induces a conformational change that activates the intracellular tyrosine kinase domains of the two subunits. Recent studies suggest that in the activated receptor the two transmembrane helices and the internal tyrosine kinase domains move closer together, inducing the essential autophosphophosphorylation.[232b] The kinase domain of the phosphorylated receptor, in turn, phosphorylates several additional proteins, the most important of which seem to be the insulin receptor substrates IRS-1 and IRS-2. Both appear to be essential in different tissues.[232d,e] Phosphorylated forms of these proteins initiate a confusing variety of signaling cascades.[232f–i]

One of the most immediate effects of insulin is to stimulate an increased rate of uptake of glucose by muscle and adipocytes (fat cells) and other insulin-sensitive tissues. This uptake is accomplished largely by movement of the glucose transporter GLUT4 (Chapter 8) from internal "sequestered" storage vesicles located near the cell membrane into functioning positions in the membranes.[232f,j–m] Activation of this translocation process apparently involves IRS-1 and phosphatidylinositol (PI) 3-kinase, which generates PI-3,4,5-P_3 (Fig. 11-9).[232c,n,o] The latter induces the translocation. However, the mechanism remains obscure. The process may also require a second signaling pathway which involves action of the insulin receptor kinase on an adapter protein known as **CAP**, a transmembrane caveolar protein **flotillin**, and a third protein **Cbl**, a known cellular protooncogene. Phosphorylated Cbl forms a complex with CAP and flotillin in a "lipid raft" which induces the exocytosis of the sequestered GLUT4 molecules.[232o,p]

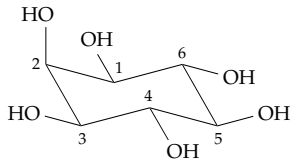
TABLE 17-3
Some Effects of Insulin on Enzymes

Name of Enzyme	Type of Regulation
A. Activity increased	
Enzymes of glycolysis	
Glucokinase	Transcription induced
Phosphofructokinase	via 2,6-fructose P_2
Pyruvate kinase	Dephosphorylation
6-Phosphofructo-2-kinase	Dephosphorylation
Enzymes of glycogen synthesis	
Glucokinase	Transcription
Glycogen synthase (muscle)	Dephosphorylation
Enzymes of lipid synthesis	
Pyruvate dehydrogenase (adipose)	Dephosphorylation (Eq. 17-9)
Acetyl-CoA carboxylase	Dephosphorylation
ATP-citrate lyase	Phosphorylation
Fatty acid synthase	
Lipoprotein lipase	
Hydroxymethylglutaryl-CoA reductase	
B. Activity decreased	
Enzymes of gluconeogenesis	
Pyruvate carboxylase	
PEP carboxykinase	Transcription inhibited
Fructose 1,6-bisphosphate	
Glucose 6-phosphatase	
Enzymes of lipolysis	
Triglyceride lipase	
(hormone-sensitive lipase)	Dephosphorylation
Enzymes of glycogenolysis	
Glycogen phosphorylase	
C. Other proteins affected by insulin	
Glucose transporter GLUT4	Redistribution
Ribosomal protein S6	Phosphorylation by $p90^{rsk}$
IGF-II receptor	Redistribution
Transferrin receptor	Redistribution
Calmodulin	Phosphorylation

A clue to another possible unrecognized mechanism of action for insulin comes from the observation that urine of patients with non-insulin-dependent diabetes contains an unusual isomer of inositol, D-*chiro*-inositol.[233,234]



D-*chiro*-Inositol



myo-Inositol
(numbered as D)

Plasma of such individuals contains an antagonist of insulin action, an inositol phosphoglycan containing *myo*-inositol as a cyclic 1,2-phosphate ester and galactosamine and mannose in a 1:1:3 ratio.[235] This appears to be related to the glycosyl phosphatidylinositol (GPI) membrane anchors (Fig. 8-13). It has been suggested that such a glycan, perhaps containing *chiro*-inositol, is released in response to insulin and serves as a second messenger for insulin.[235–236a] This hypothesis remains unproved.[237] However, insulin does greatly stimulate a GPI-specific phospholipase C, at least in yeast.[237a] Another uncertainty surrounds the possible cooperation of chromium (Chapter 16) in the action of insulin.

How do the insulin-secreting pancreatic β cells sense a high blood glucose concentration? Two specialized proteins appear to be involved. The sugar transporter **GLUT2** allows the glucose in blood to equilibrate with the free glucose in the β cells,[237b] while **glucokinase** (hexokinase IV or D) apparently serves as the glucose sensor.[228,238] Despite the fact that glucokinase is a monomer, it displays a cooperative behavior toward glucose binding, having a low affinity at low [glucose] and a high affinity at high [glucose]. Mutant mice lacking the glucokinase gene develop early onset diabetes which is mild in heterozygotes but severe and fatal within a week of birth for homozygotes.[239,240] These facts alone do not explain how the sensor works and there are doubtless other components to the signaling system.

A current theory is that the increased rate of glucose catabolism in the β cells when blood [glucose] is high leads to a high ratio of [ATP]/[ADP] which induces closure of ATP-sensitive K^+ channels and opening of voltage-gated Ca^{2+} channels.[241] This could explain the increase in [Ca^{2+}] within β cells which has been associated with secretion of insulin[242,243] and which is thought to induce the exocytosis in insulin storage granules. The internal [Ca^{2+}] in pancreatic islet cells is observed to oscillate in a characteristic way that is synchronized with insulin secretion.[243]

Glucagon. This 29-residue peptide is the principal hormone that counteracts the action of insulin. Glucagon acts primarily on liver cells (hepatocytes) and adipose tissue and is secreted by the α cells of the islets of Langerhans in the pancreas, the same tissue whose β cells produce insulin, if the blood glucose concentration falls much below 2 mM.[244–250] Like the insulin-secreting β cells, the pancreatic α cells contain glucokinase, which may be involved in sensing the drop in glucose concentration. However, the carrier GLUT2 is not present and there is scant information on the sensing mechanism.[248]

Glucagon promotes an increase in the blood glucose level by stimulating breakdown of liver glycogen, by inhibiting its synthesis, and by stimulating gluconeogenesis. All of these effects are mediated by cyclic AMP through cAMP-activated protein kinase (Fig. 11-4) and through fructose 2,6-P_2 (Fig. 11-4 and next section). Glucagon also has a strong effect in promoting the release of glucose into the bloodstream. **Adrenaline** has similar effects, again mediated by cAMP. However, glucagon affects the liver, while adrenaline affects many tissues. **Glucocorticoids** such as cortisol (Chapter 22) also promote gluconeogenesis and the accumulation of glycogen in the liver through their action on gene transcription.

The release of glucose from the glycogen stores in the liver is mediated by **glucose 6-phosphatase**, which is apparently embedded within the membranes of the endoplasmic reticulum. A labile enzyme, it consists of a 357-residue catalytic subunit,[251,252] which may be associated with other subunits that participate in transport.[252,253] A deficiency of this enzyme causes the very severe type 1a **glycogen storage disease** (see Box 20-D).[251,253] Only hepatocytes have significant glucose 6-phosphatase activity.

2. Phosphofructo-1-Kinase in the Regulation of Glycolysis

The metabolic interconversions of glucose 1-*P*, glucose 6-*P*, and fructose 6-*P* are thought to be at or near equilibrium within most cells. However, the phosphorylation by ATP of fructose 6-*P* to fructose 1,6-P_2 catalyzed by phosphofructose-1-kinase (Fig. 11-2, step *b*; Fig. 17-17, top center) is usually far from equilibrium. This fact was established by comparing the mass action ratio [fructose 1,6-P_2] [ADP]/[fructose 6-P] [ATP] measured within tissues with the known equilibrium constant for the reaction. At equilibrium this mass action ratio should be equal to the equilibrium constant (Section I,2). The experimental techniques for determining the four metabolite concentrations that are needed for evaluation of the mass action ratio in tissues are of interest. The tissues must be frozen very rapidly. This can be done by compressing them between large liquid nitrogen-cooled aluminum clamps. For details see Newsholme and Start,[225] pp. 30 – 32. Tissues can be cooled to – 80°C in less than 0.1 s in this manner. The frozen tissue is then powdered, treated with a frozen protein denaturant such as perchloric acid, and analyzed. From data obtained in this way, a mass action ratio of 0.03 was found for the phosphofructo-1-kinase reaction in heart muscle.[225] This is much lower than the equilibrium constant of over 3000 calculated from the value of $\Delta G'$ (pH 7) = −20.1 kJ mol^{-1}. Thus, like other biochemical reactions that are nearly irreversible thermodynamically, this reaction is far from equilibrium in tissues.

The effects of ATP, AMP, and fructose 2,6-bisphosphate on phosphofructokinase have been discussed in Chapter 11, Section C. Fructose 2,6-P_2 is a potent allosteric activator of phosphofructokinase and a strong competitive inhibitor of fructose 1,6-bisphosphatase (Fig. 11-2). It is formed from fructose 6-*P* and ATP by the 90-kDa bifunctional phosphofructo-2-kinase/fructose 2,6-bisphosphatase. Thus, the same protein forms and destroys this allosteric effector. Since the bifunctional enzyme is present in very small amounts, the rate of ATP destruction from the substrate cycling is small.

Glucagon causes the concentration of *liver* fructose 2,6-P_2 to drop precipitously from its normal value. This, in turn, causes a rapid drop in glycolysis rate and shifts metabolism toward gluconeogenesis. At the same time, liver glycogen breakdown is inceased and glucose is released into the bloodstream more rapidly. The effect on fructose 2,6-P_2 is mediated by a cAMP-dependent protein kinase which phosphorylates the bifunctional kinase/phosphatase in the liver.[254] This modification greatly reduces the kinase activity and strongly activates the phosphatase, thereby destroying the fructose 2,6-P_2. The changes in activity appear to be largely a result of changes in the appropriate K_m values which are increased for fructose 6-*P* and decreased for fructose 2,6-P_2.[255]

3. Gluconeogenesis

If a large amount of lactate enters the liver, it is oxidized to pyruvate which enters the mitochondria. There, part of it is oxidized through the tricarboxylic acid cycle. However, if [ATP] is high, pyruvate dehydrogenase is inactivated by phosphorylation (Eq. 17-9) and the amount of pyruvate converted to oxaloacetate and malate (Eq. 17-46) may increase. Malate may leave the mitochondrion to be reoxidized to oxaloacetate, which is then converted to PEP and on to glycogen (heavy green arrows in Fig. 17-20). When [ATP] is high, phosphofructokinase is also blocked, but the fructose 1,6-bisphosphatase, which hydrolyzes one phosphate group from fructose 1,6-P_2 (Fig. 11-2, step *d*), is active. If the glucose content of blood is low, the glucose 6-*P* in the liver is hydrolyzed and free glucose is secreted. Otherwise, most of the glucose 6-*P* is converted to glycogen. Muscle is almost devoid of glucose 6-phosphatase, the export of glucose not being a normal activity of that tissue.

Gluconeogenesis in liver is strongly promoted by glucagon and adrenaline. The effects, mediated by cAMP, include stimulation of fructose 1,6-bisphosphatase and inhibition of phosphofructo-1-kinase, both caused by the drop in the level of fructose 2,6-P_2.[254,256] The conversion of pyruvate to PEP via oxaloacetate is also promoted by glucagon. This occurs primarily by stimulation of pyruvate carboxylase (Eq. 14-3).[257,258] However, it has been suggested that the most important mechanism by which glucagon enhances gluconeogenesis is through stimulation of mitochondrial respiration, which in turn may promote gluconeogenesis.[257]

The conversion of oxaloacetate to PEP by PEP-carboxykinase (PEPCK, Eq. 14-43; Fig. 17-20) is another control point in gluconeogenesis. Insulin inhibits gluconeogenesis by decreasing transcription of the mRNA for this enzyme.[259–261a] Glucagon and cAMP stimulate its transcription. The activity of PEP carboxykinase[262] is also enhanced by Mn^{2+} and by very low concentrations of Fe^{2+}. However, the enzyme is readily inactivated by Fe^{2+} and oxygen.[263] Any regulatory significance is uncertain.

Although the regulation of gluconeogenesis in the liver may appear to be well understood, some data indicate that the process can occur efficiently in the presence of high average concentrations of fructose 2,6-P_2. A possible explanation is that liver consists of several types of cells, which may contain differing concentrations of this inhibitor of gluconeogenesis.[264] However, mass spectroscopic studies suggest that glucose metabolism is similar throughout the liver.[265]

4. Substrate Cycles

The joint actions of phosphofructokinase and fructose 1,6-bisphosphatase (Fig. 11-2, steps *b* and *c*; see also Fig. 17-20) create a substrate cycle of the type discussed in Chapter 11, Section F. Such cycles apparently accomplish nothing but the cleavage of ATP to ADP and P_i (ATPase activity). There are many cycles of this type in metabolism and the fact that they do not ordinarily cause a disastrously rapid loss of ATP is a consequence of the tight control of the metabolic pathways involved. In general, only one of the two enzymes of Fig. 11-2, steps *b* and *c*, is fully activated at any time. Depending upon the metabolic state of the cell, degradation may occur with little biosynthesis or biosynthesis with little degradation. Other obvious substrate cycles involve the conversion of glucose to glucose 6-*P* and hydrolysis of the latter back to glucose (Fig. 17-20, upper left-hand corner), the synthesis and breakdown of glycogen (upper right), and the conversion of PEP to pyruvate and the reconversion of the latter to PEP via oxaloacetate and malate (partially within the mitochondria).

While one might suppose that cells always keep substrate cycling to a bare minimum, experimental measurements on tissues *in vivo* have indicated surprisingly high rates for the fructose 1,6-bisphosphatase–phosphofructokinase cycle in mammalian tissues when glycolytic flux rates are low and also for the pyruvate → oxaloacetate → PEP → pyruvate cycle.[266] As pointed out in Chapter 11, by maintaining a low rate of substrate cycling under conditions in which the carbon flux is low (in either the glycolytic or gluconeogenic direction) the system is more sensitive to allosteric effectors than it would be otherwise. However, when the flux through the glycolysis pathway is high the relative amount of cycling is much less and the amount of ATP formed approaches the theoretical 2.0 per glucose.[267]

Substrate cycles generate heat, a property that is apparently put to good use by cold bumblebees whose thoracic temperature must reach at least 30°C before they can fly. The insects apparently use the fructose bisphosphatase–phosphofructokinase substrate cycle (Fig. 11-2, steps *b* and *c*) to warm their flight muscles.[268] It probably helps to keep us warm, too.

5. Nuclear Magnetic Resonance, Isotopomer Analysis, and Modeling of Metabolism

As as been pointed out in Boxes 3-C and 17-C, the use of ^{13}C and other isotopic tracers together with NMR and mass spectroscopy have provided powerful tools for understanding the complex interrelationships among the various interlocking pathways of metabolism. In Box 17-C the application of ^{13}C NMR to the

citric acid cycle was described. Similar approaches have been used to provide direct measurement of the glucose concentration in human brain (1.0 ± 0.1 mM; 4.7 ± 0.3 mM in plasma)[226] and to study gluconeogenesis[269–271] as well as fermentation.[271a] Similar investigations have been made using mass spectroscopy.[272] The metabolism of acetate through the glycoylate pathway in yeast has been observed by ^{13}C NMR.[200] Data obtained from such experiments are being used in attempts to model metabolism and to understand how flux rates through the various pathways are altered in response to varying conditions.[65,273–276]

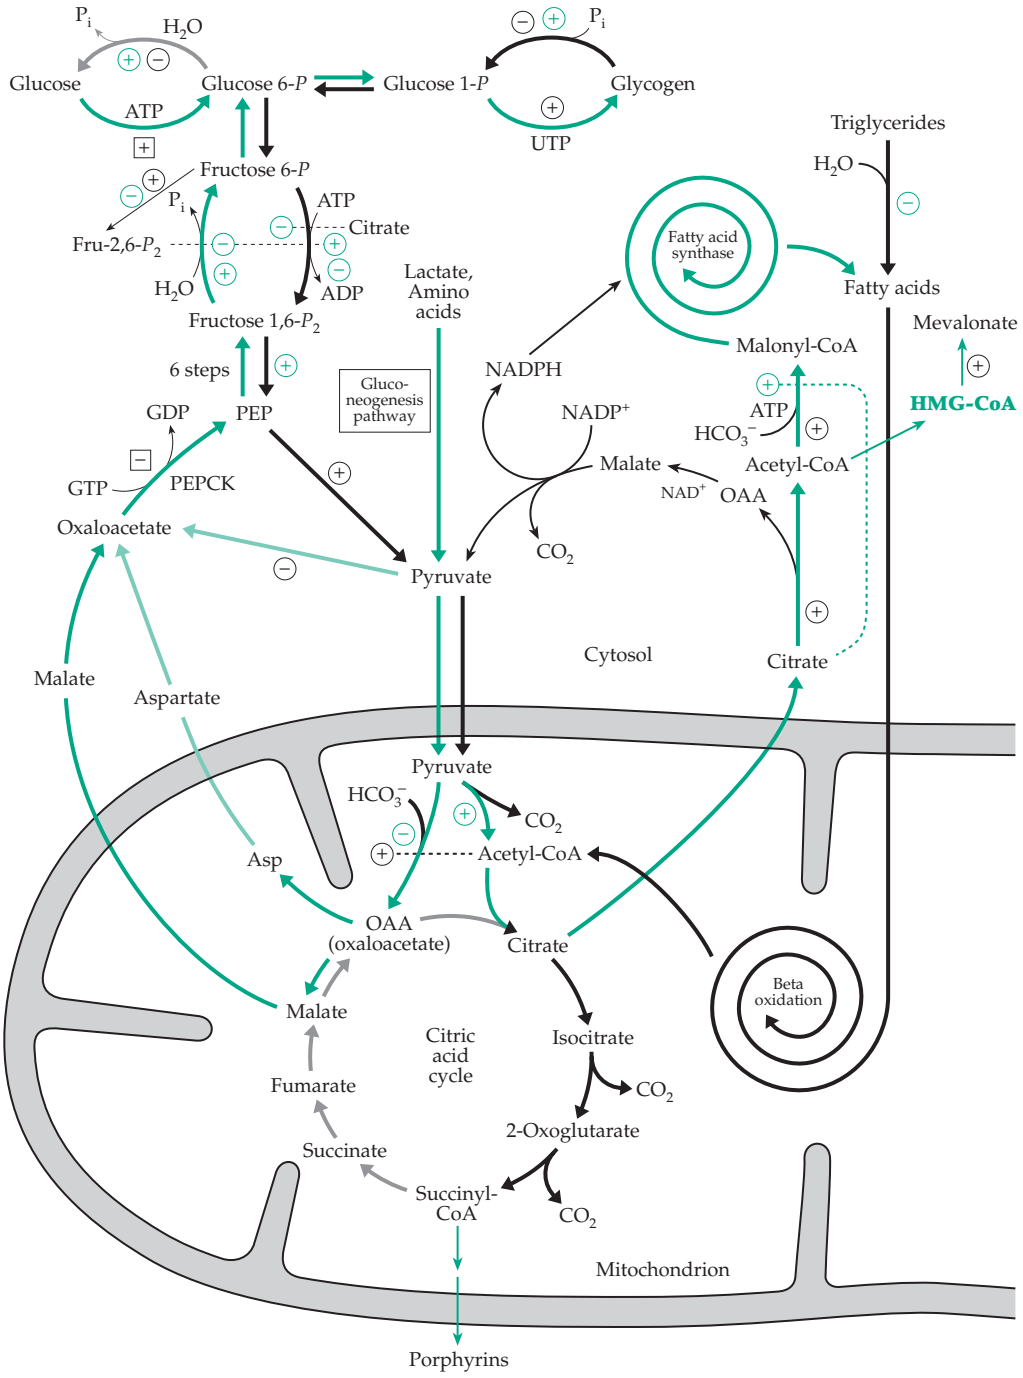


Figure 17-20 The interlocking pathways of glycolysis, gluconeogenesis, and fatty acid oxidation and synthesis with indications of some aspects of control in hepatic tissues. Some effects of insulin via indirect action on enzymes ⊕, ⊖, or on transcription ⊞, ⊟. Effects of glucagon ⊕, ⊖.

6. The Fasting State

During prolonged fasting, glycogen supplies are depleted throughout the body and fats become the principal fuels. Both glucose and pyruvate are in short supply. While the hydrolysis of lipids provides some glycerol (which is phosphorylated and oxidized to dihydroxyacetone-*P*), the quantity of glucose precursors formed in this way is limited. Since the animal body cannot reconvert acetyl-CoA to pyruvate, there is a continuing need for both glucose and pyruvate. The former is needed for biosynthetic processes, and the latter is a precursor of oxaloacetate, the regenerating substrate of the citric acid cycle. For this reason, during fasting the body readjusts its metabolism. As much as 75% of the glucose need of the brain can gradually be replaced by ketone bodies derived from the breakdown of fats (Section A,4).[277] Glucocorticoids (e.g., cortisol; Chapter 22) are released from the adrenal glands. By inducing enzyme synthesis, these hormones increase the amounts of a variety of enzymes within the cells of target organs such as the liver. Glucocorticoids also appear to increase the sensitivity of cell responses to cAMP and hence to hormones such as glucagon.[268]

The overall effects of glucocorticoids include an increased release of glucose from the liver (increased activity of glucose 6-phosphatase), an elevated blood glucose and liver glycogen, and a decreased synthesis of mucopolysaccharides. The reincorporation of amino acids released by protein degradation is inhibited and synthesis of enzymes degrading amino acids is enhanced. Among these enzymes are tyrosine and alanine aminotransferases, enzymes that initiate amino acid degradation which gives rise to the glucogenic precursors fumarate and pyruvate.

The inability of the animal body to form the glucose

BOX 17-F LACTIC ACIDEMIA AND OTHER DEFICIENCIES IN CARBOHYDRATE METABOLISM

The lactate concentration in blood can rise from its normal value of 1–2 mM to as much as 22 mM after very severe exercise such as sprinting, but it gradually returns to normal, requiring up to 6–8 h, less if mild exercise is continued. However, continuously high lactic acid levels are observed when enzymes of the gluconeogenic pathway are deficient or when oxidation of pyruvate is partially blocked.[a,b] Severe and often lethal deficiencies of the four key gluconeogenic enzymes pyruvate carboxylase, PEP carboxykinase, fructose 1,6-bisphosphatase, and glucose 6-phosphatase are known.[b] Pyruvate carboxylase deficiency may be caused by a defective carboxylase protein, by an absence of the enzyme that attaches biotin covalently to the three mitochondrial biotin-containing carboxylases (Chapter 14, Section C), or by defective transport of biotin from the gut into the blood. The latter types of deficiency can be treated successfully with 10 mg biotin per day.

Deficiency of pyruvate dehydrogenase is the most frequent cause of lactic acidemia.[a,c] Since this enzyme has several components (Fig. 15-15), a number of forms of the disease have been observed. Patients are benefitted somewhat by a high-fat, low-carbohydrate diet. Transient lactic acidemia may result from infections or from heart failure. One treatment is to administer dichloroacetate, which stimulates increased activity of pyruvate dehydrogenase, while action is also taken to correct the underlying illness.[d] Another problem arises if a lactate transporter is defective so that lactic acid accumulates in muscles.[e]

A different problem results from deficiency of enzymes of glycolysis such as phosphofructokinase (see Box 20-D), phosphoglycerate mutase, and pyruvate kinase. Lack of one isoenzyme of phosphoglycerate mutase in muscle leads to intolerance to strenuous exercise.[f] A deficiency in pyruvate kinase is one of the most common defects of glycolysis in erythrocytes and leads to a shortened erythrocyte lifetime and hereditary hemolytic anemia.[g]

Deficiency of the first enzyme of the pentose phosphate pathway, glucose 6-phosphate dehydrogenase, is widespread.[h] Its geographical distribution suggests that, like the sickle-cell trait, it confers some resistance to malaria. A partial deficiency of 6-phosphogluconolactonase (Eq. 17-12, step *b*) has also been detected within a family and may have contributed to the observed hemolytic anemia.[i]

precursors pyruvate or oxaloacetate from acetyl units is sometimes a cause of severe metabolic problems. Ketosis, which was discussed in Section A,4, develops when too much acetyl-CoA is produced and not efficiently oxidized in the citric acid cycle. Ketosis occurs during starvation, with fevers, and in insulin-dependent diabetes (see also Box 17-G). In cattle, whose metabolism is based much more on acetate than is ours, spontaneously developing ketosis is a frequent problem.

7. Lipogenesis

A high-carbohydrate meal leads to an elevated blood glucose concentration. The glycogen reserves within cells are filled. The ATP level rises, blocking the citric acid cycle, and citrate is exported from mitochondria (Fig. 17-20). Outside the mitochondria citrate is cleaved by the ATP-requiring citrate lyase (Eq. 14-37) to acetyl-CoA and oxaloacetate. The oxaloacetate can be reduced to malate and the latter oxidized with $NADP^+$ to pyruvate (Eq. 17-46), which can again enter the mitochondrion. In this manner acetyl groups are exported from the mitochondrion as acetyl-CoA which can be carboxylated, under the activating influence of citrate, to form malonyl-CoA, the precursor of fatty acids. The NADPH formed from oxidation of the malate provides part of the reducing equivalents needed for fatty acid synthesis. Additional NADPH is available from the pentose phosphate pathway. Thus, excess carbohydrate is readily converted into fat by our bodies. These reactions doubtless occur to some extent in most cells, but they are quantitatively

BOX 17-G DIABETES MELLITUS

The most prevalent metabolic problem affecting human beings is diabetes mellitus.[a–c] Out of a million people about 400 develop **type I** (or juvenile-onset) **insulin-dependent diabetes mellitus** (IDDM) between the ages of 8 and 12. Another 33,000 (over 3%) develop diabetes by age 40–50, and by the late 70s over 7% are affected. A propensity toward diabetes is partially hereditary, and recessive susceptibility genes are present in a high proportion of the population. The severity of the disease varies greatly. About half of the type I patients can be treated by diet alone, while the other half must receive regular insulin injections because of the atrophy of the insulin-producing cells of the pancreas. Type I diabetes sometimes develops very rapidly with only a few days of ravenous hunger and unquenchable thirst before the onset of ketoacidosis. Without proper care death can follow quickly. This suggested that a virus infection might cause the observed death of the insulin-secreting β cells of the pancreatic islets. However, the disease appears to be a direct result of an autoimmune response (Chapter 31). Antibodies directed against such proteins as insulin, glutamate decarboxylase,[d,e] and a tyrosine phosphatase[f] of the patient's own body are present in the blood. There may also be a direct attack on the β cells by T cells of the immune system (see Chapter 31).[g,h] The events that trigger such autoimmune attacks are not clear, but there is a strong correlation with susceptibility genes, in both human beings[i,j] and mice.[k,l]

Adults seldom develop type I diabetes but often suffer from **type II** or **non-insulin-dependent diabetes mellitus** (NIDDM). This is not a single disease but a syndrome with many causes. There is usually a marked decrease in sensitivity to insulin (referred to as **insulin resistance**) and poor uptake and utilization of glucose by muscles.[m] In rare cases this is a result of a mutation in the gene for the insulin molecule precursors (Eq. 10-8) or in the gene regulatory regions of the DNA.[n,o] Splicing of the mRNA[p] may be faulty or there may be defects in the structure or in the mechanisms of activation of the insulin receptors (Figs. 11-11 and 11-12).[q] The number of receptors may be too low or they may be degraded too fast to be effective. About 15% of persons with NIDDM have mutations in the insulin substrate protein IRS-1 (Chapter 11, Section G) but the significance is not clear.[m,r] Likewise, the causes of the loss of sensitivity of insulin receptors as well as other aspects of insulin resistance are still poorly understood.[s] In addition, prolonged high glucose concentrations result in decreased insulin synthesis or secretion, both of which are also complex processes. After synthesis the insulin hexamer is stored as granules of the hexamer $(insulin)_6Zn_2$ (Fig. 7-18) in vesicles at low pH. For secretion to occur the vesicles must first dock at membrane sites and undergo exocytosis. The insulin dissolves, releasing the Zn^{2+}, and acts in the monomeric form.[t] Because the mechanisms of action of insulin are still not fully understood, it is difficult to interpret the results of the many studies of diabetes mellitus.

A striking symptom of diabetes is the high blood glucose level which may range from 8 to 60 mM. Lower values are more typical for mild diabetes because when the glucose concentration exceeds the renal threshold of ~8 mM the excess is secreted into the urine. Defective utilization of glucose seems to be tied to a failure of glucose to exert proper

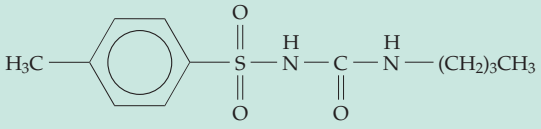
BOX 17-G DIABETES MELLITUS (continued)

feedback control. The result is that gluconeogenesis is increased with corresponding breakdown of proteins and amino acids. The liver glycogen is depleted and excess nitrogen from protein degradation appears in the urine. In IDDM diabetes the products of fatty acid degradation accumulate, leading to ketosis. The volume of urine is excessive and tissues are dehydrated.

Although the acute problems of diabetes, such as coma induced by ketoacidosis, can usually be avoided, it has not been possible to prevent long-term complications that include cataract formation and damage to the retina and kidneys. Most diabetics eventually become blind and half die within 15–20 years. Many individuals with NIDDM develop insulin-dependent diabetes in later life as a result of damage to the pancreatic β cells. The high glucose level in blood appears to be a major cause of these problems. The aldehyde form of glucose reacts with amino groups of proteins to form Schiff bases which undergo the Amadori rearrangement to form ketoamines (Eq. 4-8). The resulting modified proteins tend to form abnormal disulfide crosslinkages. Crosslinked aggregates of lens proteins may be a cause of cataract. The accumulating glucose-modified proteins may also induce autoimmune responses that lead to the long-term damage to kidneys and other organs. Another problem results from reduction of glucose to sorbitol (Box 20-A). Accumulation of sorbitol in the lens may cause osmotic swelling, another factor in the development of cataracts.[w,x] Excessive secretion of the 37-residue polypeptide **amylin**, which is synthesized in the β cells along with insulin, is another frequent complication of diabetes.[u,v] Amylin precipitates readily within islet cells to form **amyloid deposits** which are characteristic of NIDDM.

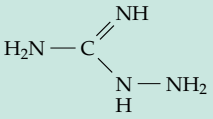
For many persons with diabetes regular injections of insulin are essential. Insulin was discovered in 1921 in Toronto by Banting and Best, with a controversial role being played by Professor J. J. R. Macleod, who shared the Nobel prize with Banting in 1923.[y,z] In 1922 the first young patients received pancreatic extracts and a new, prolonged life.[z–bb] Persons with IDDM are still dependent upon daily injections of insulin, but attempts are being made to treat the condition with transplanted cells from human cadavers.[cc] Animal insulins are suitable for most patients, but allergic reactions sometimes make **human insulin** essential. The human hormone, which differs from bovine insulin in three positions (Thr in human vs Ala in bovine at positions 8 of the A chain and 30 of the B chain and Ile vs Val at position 10 of the A chain), is now produced in bacteria using recombinant DNA. Nonenzymatic laboratory synthesis of insulin has also been achieved, but it is difficult to place the disulfide crosslinks in the proper positions. New approaches mimic the natural synthesis, in which the crosslinking takes place in proinsulin (Fig. 10-7).

NIDDM is strongly associated with obesity,[dd] and dieting and exercise often provide adequate control of blood glucose. Sulfonylurea drugs such as the following induce an increase in the number of insulin receptors formed and are also widely used in treatment of the condition.[ee,ff] These drugs bind to and inhibit ATP-sensitive K^+ channels in the β cell membranes. A defect in this sulfonylurea receptor has been associated with excessive insulin secretion



1-Butyl-*p*-tolylsulfonylurea

in infants.[17] New types of drugs are being tested.[gg–kk] These include inhibitors of aldose reductase,[ii] which forms sorbitol; compounds such as aminoguanidine, which inhibit formation of advanced products of glycation and newly discovered fungal metabolites that activate insulin receptors.[jj]



Aminoguanidine

most important in the liver, in fat cells of adipose tissue, and in mammary glands. The process is also facilitated by insulin, which promotes the activation of pyruvate dehydrogenase (Eq. 17-9) and of fatty acid synthase of adipocytes.[277a] Activity of fatty acid synthase seems to be regulated by the rate of transcription of its gene, which is controlled by a transcription factor designated either as **adipocyte determination and differentiation factor-1** (**ADD-1**) or **sterol regulatory element-binding protein-1c** (**SREBP-1c**). This protein (ADD-1/SREBP-1c) may be a general mediator of insulin action.[277b] The nuclear DNA-binding protein known as **peroxisome proliferator-activated receptor gamma** (**PPAR$_\gamma$**) is also involved in the control of insulin action, a conclusion based directly on discovery of mutations in persons with type II diabetes.[277c] A newly discovered hormone **resistin**, secreted by adipocytes, may also play a role.[277d] Another adipocyte hormone, **leptin**, impairs insulin action.[277e] Recent evidence suggests that both insulin and leptin may have direct effects on the brain which also influence blood glucose levels.[277f] Malonyl-CoA, which may also play a role in insulin secretion,[278,279] inhibits carnitine palmitoyltransferase I (CPT I; Fig. 17-2), slowing fatty acid catabolism.[280]

Study Questions

1. Write out a complete step-by-step mechanism for the reactions by which citrate can be synthesized from pyruvate and then exported from mitochondria for use in the biosynthesis of fatty acids. Include a chemically reasonable mechanism for the action of ATP–citrate lyase, which catalyzes the following reaction:

   $$\text{ATP + citrate + CoA-SH} \rightarrow \text{Acetyl-CoA + oxaloacetate + ADP + } P_i$$

   Show how this reaction can be incorporated into an ATP-driven cyclic pathway for generating NADPH from NADH.

2. Show which parts (if any) of the citric acid cycle are utilized in each of the following reactions and what, if any, additional enzymes are needed in each case.
   a. Oxidation of acetyl-CoA to CO_2
   b. Catabolism of glutamate to CO_2
   c. Biosynthesis of glutamate from pyruvate
   d. Formation of propionate from pyruvate

3. Here is a possible metabolic reaction for a fungus.

   $$\text{L-Leucine} + \text{2-oxoglutarate}^{2-} + 2\,{}^1\!/_2\,O_2 \rightarrow \text{L-glutamate}^- + \text{citrate}^{3-} + H_2O + 2H^+$$
   $$\Delta G^{\circ\prime}\ (\text{pH } 7) = -1026\ \text{kJ/mol}$$

   Suggest a metabolic pathway for this reaction. Is it thermodynamically feasible?

4. It has been suggested that in *Escherichia coli* pyruvate may act as the regenerating substrate for a catalytic cycle by which glyoxylate, $OHC–COO^-$, is oxidized to CO_2. Key enzymes in this cycle are thought to be a 2-oxo-4-hydroxyglutarate aldolase and 2-oxoglutarate dehydrogenase. Propose a detailed pathway for this cycle.

5. Some bacteria use a "dicarboxylic acid cycle" to oxidize glyoxylate $OHC–COO^-$ to CO_2. The regenerating substrate for this cycle is acetyl-CoA. It is synthesized from glyoxylate by a complex pathway that begins with conversion of two molecules of glyoxylate to tartronic semialdehyde: $^-OOC–CHOH–CHO$. The latter is then dehydrogenated to D-glycerate.

   Write out a detailed scheme for the dicarboxylate cycle. Also indicate how glucose and other cell constituents can be formed from intermediates created in this biosynthetic pathway.

6. Some bacteria that lack the usual aldolase produce ethanol and lactic acid in a 1:1 molar ratio via the "heterolactic fermentation." Glucose is converted to ribulose 5-phosphate via the pentose phosphate pathway enzymes. A thiamin diphosphate-dependent "phosphoketolase" cleaves xylulose 5-phosphate in the presence of inorganic phosphate to acetyl phosphate and glyceraldehyde 3-phosphate.

   Propose a mechanism for the phosphoketolase reaction and write a balanced set of equations for the fermentation.

7. Bacteria of the genera *Aerobacter* and *Serratia* ferment glucose according to the following equation:

   $$1\,{}^1\!/_2\,\text{Glucose} \rightarrow \text{2,3-butanediol} + 3\,CO_2 + H_2 + \text{ethanol}$$

   Write out a detailed pathway for the reactions. Use the pyruvate formate–lyase reaction. What yield of ATP do you expect per molecule of glucose fermented?

8. Some Clostridia ferment glucose as follows:

   $$2\ \text{Glucose} + 2\,H_2O \rightarrow \text{butyrate}^- + 2\ \text{acetate}^- + 4\,CO_2 + 6\,H_2 + 3\,H^+$$
   $$\Delta G^{\circ\prime}\ (\text{pH } 7) = -479\ \text{kJ/mol of butyrate formed}$$

   Write out detailed pathways. How much ATP do you think can be formed per glucose molecule fermented?

9. Propionic acid bacteria use the following fermentation:

   $$1\,{}^1\!/_2\,\text{Glucose} \rightarrow 2\ \text{propionate} + \text{acetate}^- + 3\,H^+ + CO_2 + H_2O$$
   $$\Delta G^{\circ\prime} = -464\ \text{kJ/mol of acetate formed}$$

   Write out a detailed pathway for the reactions. How much ATP can be formed per molecule of glucose?

10. Consider the following reaction which can occur in the animal body:

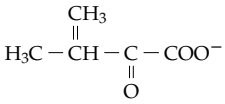
    $$2\ \text{Lactate}^-\ (C_3H_5O_3^-) + \text{CoASH} + 2\ \text{NAD}^+ \rightarrow \text{butyryl-CoA}\ (C_4H_7O–S–\text{CoA}) + 2\,CO_2 + 2\ \text{NADH} + H_2O$$
    $$\Delta G^{\circ\prime}\ (\text{pH } 7) \sim 70\ \text{kJ/mol of butyryl-CoA formed}$$

    Outline the sequence of reactions involved in this

transformation. Do you think that any ATP will either be used or generated in the reaction? Explain.

11. Leucine, an essential dietary constituent for human beings, is synthesized in many bacteria and plants using pyruvate as a starting material. Outline this pathway of metabolism and illustrate the chemical reaction mechanisms involved in each step.

12. Write a step-by-step sequence for all of the chemical reactions involved in the biosynthesis of L-leucine from 2-oxoisovalerate:



Notice that this compound contains one carbon atom less than leucine. Start by condensing 2-oxoisovalerate with acetyl-CoA in a reaction similar to that of citrate synthase. Use structural formulas. Show all intermediate structures and indicate what coenzymes are needed. Use curved arrows to indicate the flow of electrons in each step.

13. Some fungi synthesize lysine from 2-oxoglutarate by elongating the chain using a carbon atom derived from acetyl-CoA to form the 6-carbon 2-oxoadipate. The latter is converted by an ATP-dependent reduction to the ε-aldehyde. Write out reasonable mechanisms for the conversion of 2-oxoglutarate to the aldehyde. The latter is converted on to L-lysine by a non–PLP-dependent transamination via saccharopine (Chapter 24).

14. Outline the pathway for biosynthesis of L-leucine from glucose and NH_4^+ in autotrophic organisms. In addition, outline the pathways for degradation of leucine to CO_2, water, and NH_4^+ in the human body. For this overall pathway or "metabolic loop," mark the locations (one or more) at which each of the following processes occurs.
    a. Synthesis of a thioester by dehydrogenation
    b. Substrate-level phosphorylation
    c. Thiamin-dependent α condensation
    d. Oxoacid chain-elongation process
    e. Transamination
    f. Oxidative decarboxylation of an α-oxoacid
    g. Partial β oxidation
    h. Thiolytic cleavage
    i. Claisen condensation
    j. Biotin-dependent carboxylation

15. A photosynthesizing plant is exposed to $^{14}CO_2$. On which carbon atoms will the label first appear in glucose?

16. The Calvin–Benson cycle and the pentose phosphate pathway (Eq. 17-12) have many features in common but run in opposite directions. Since the synthesis of glucose from CO_2 requires energy, the energy expenditure for the two processes will obviously differ. Describe the points in each pathway where a Gibbs energy difference is used to drive the reaction in the desired direction.

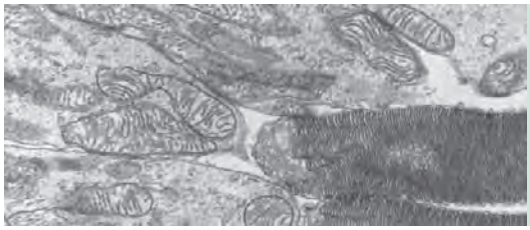
17. Draw the structure of ribulose 1(^{14}C), 5-bisphosphate. Enter an asterisk (*) next to carbon 1 to show that this position is ^{14}C-labeled.

    Draw the structures of the products of the ribulose bisphosphate carboxylase reaction, indicating the radioactive carbon position with an asterisk.

18. A wood-rotting fungus is able to convert glucose to oxalate approximately according to the following equation:

    Glucose + 5 O_2 → 2 Oxalic acid ($C_2O_4H_2$) + 2 CO_2 + 4 H_2O

    Propose a mechanism. See Munir *et al.*[281] for details.



Electrons flowing through the electron transport chains in the membranes of the mitochondria, (at the left) in this thin section through the retina of a kangaroo rat (*Dipodomys ordi*) generates ATP. The ATP provides power for the synthesis and functioning of the stacked photoreceptor disks seen at the right. The outer segment of each rod cell (See Fig. 23-40), which may be 15–20 mm in length, consists of these disks, whose membranes contain the photosensitive protein pigment rhodopsin. Absorption of light initiates an electrical excitation which is sent to the brain. Electron Transport, Oxidative Phosphorylation, and Hydroxylation

18

In this chapter we will look at the processes by which reduced carriers such as NADH and $FADH_2$ are oxidized within cells. Most familiar to us, because it is used in the human body, is **aerobic respiration**. Hydrogen atoms of NADH, $FADH_2$, and other reduced carriers appear to be transferred through a chain of additional carriers of increasingly positive reduction potential and are finally combined with O_2 to form H_2O. In fact, the hydrogen nuclei move freely as protons (or sometimes as H^- ions); it is the *electrons* that are deliberately transferred. For this reason, the chain of carriers is often called the **electron transport chain**. It is also referred to as the **respiratory chain**.

Because far more energy is available to cells from oxidation of NADH and $FADH_2$ than can be obtained by fermentation, the chemistry of the electron transport chain and of the associated reactions of ATP synthesis assumes great importance. A central question becomes "How is ATP generated by flow of electrons through this series of carriers"? Not only is most of the ATP formed in aerobic and in some anaerobic organisms made by this process of **oxidative phosphorylation**, but the solar energy captured during photosynthesis is used to form ATP in a similar manner. The mechanism of ATP generation may also be intimately tied to the function of membranes in the transport of ions. In a converse manner, the mechanism of oxidative phosphorylation may be related to the utilization of ATP in providing energy for the contraction of muscles.

In some organisms, especially bacteria, energy may be obtained through oxidation of H_2, H_2S, CO, or Fe^{2+} rather than of the hydrogen atoms removed from organic substrates. Furthermore, some bacteria use **anaerobic respiration** in which NO_3^-, SO_4^{2-}, or CO_2 act as oxidants either of reduced carriers or of reduced inorganic substances. In the present chapter, we will consider these energy-yielding processes as well as the chemistry of reactions of oxygen that lead to incorporation of atoms from O_2 into organic compounds.

The oxidative processes of cells have been hard to study, largely because the enzymes responsible are located in or on cell membranes. In bacteria the sites of electron transport and oxidative phosphorylation are on the inside of the plasma membrane or on membranes of mesosomes. In eukaryotes they are found in the inner membranes of the mitochondria and, to a lesser extent, in the endoplasmic reticulum. For this reason we should probably start with a closer look at mitochondria, the "power plants of the cell."

A. The Architecture of the Mitochondrion

Mitochondria are present in all eukaryotic cells that use oxygen in respiration, but the number per cell and the form and size vary.[1–4] Certain tiny trypanosomes have just *one* mitochondrion but some oocytes have as many as 3×10^5. Mammalian cells typically contain several hundred mitochondria and liver cells[5] more than 1000. Mammalian sperm cells may contain 50–75 mitochondria,[6] but in some organisms only one very large helical mitochondrion, formed by the fusion of many individual mitochondria, wraps around the base of the tail. Typical mitochondria appear to be about the size of cells of *E. coli*. However, study of ultrathin serial sections of a single yeast cell by electron microscopy has shown that, under some growth conditions, all of the mitochondria are interconnected.[7]

In every case a mitochondrion is enclosed by two

concentric membranes, an *outer* and an *inner* membrane, each ~5–7 nm thick (Figs. 18-1, 18-2). The inner membrane is folded to form the **cristae**. The number of cristae, the form of the cristae, and the relative amount of the internal **matrix** space are variable. In liver there is little inner membrane and a large matrix space, while in heart mitochondria there are more folds and a higher rate of oxidative phosphorylation. The enzymes catalyzing the tricarboxylic acid cycle are also unusually active in heart mitochondria. A typical heart mitochondrion has a volume of 0.55 μm^3; for every cubic micrometer of mitochondrial volume there are 89 μm^2 of inner mitochondrial membranes.[9]

Mitchondria can swell and contract, and forms other than that usually seen in osmium-fixed electron micrographs have been described. In some mitochondria the cristae are swollen, the matrix volume is much reduced, and the **intermembrane space** between the membranes is increased. Rapidly respiring mitochondria fixed for electron microscopy exhibit forms that have been referred to as "energized" and "energized-twisted."[10] The micrograph (Fig. 18-1) and drawing (Fig. 18-2) both show a significant amount of intermembrane space. However, electron micrographs of mitochondria from rapidly frozen aerobic tissues show almost none.[11] Recent studies by electron microscopic tomography show cristae with complex tubular structures. The accepted simple picture of mitochondrial structure (Fig. 18-1) is undergoing revision.[12–12b] The isolated mitochondria that biochemists have studied may be fragments of an interlinked **mitochondrial reticulum** that weaves its way through the cell.[12b] However, this reticulum may not be static but may break and reform. The accepted view that the mitochondrial matrix space is continuous with the internal space in the cristae is also the subject of doubts. Perhaps they are two different compartments.[12a]

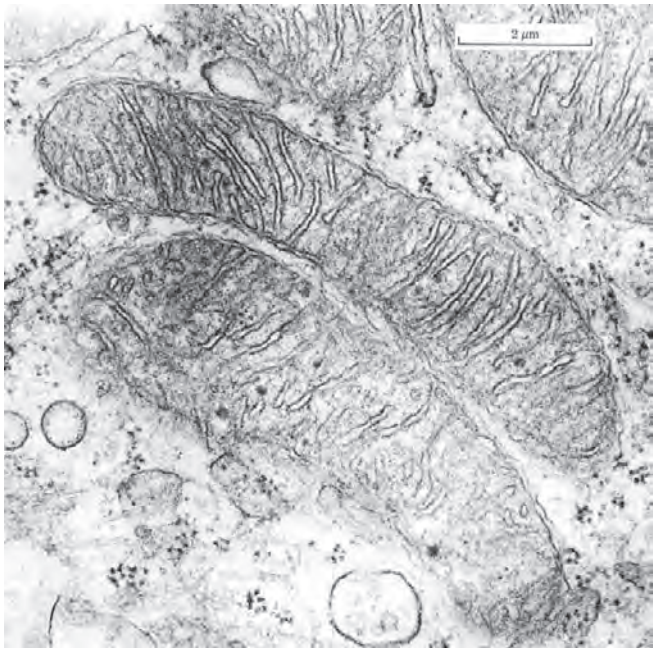

Figure 18-1 Thin section of mitochondria of a cultured kidney cell from a chicken embryo. The small, dark, dense granules within the mitochondria are probably calcium phosphate. Courtesy of Judie Walton.

1. The Mitochondrial Membranes and Compartments

The outer membranes of mitochondria can be removed from the inner membranes by osmotic rupture.[13] Analyses on separated membrane fractions show that *the outer membrane* is less dense (density ~1.1 g / cm^3) than the inner (density ~1.2 g / cm^3). It is highly permeable to most substances of molecular mass 10 kDa or less because of the presence of pores of ~2 nm diameter. These are formed by **mitochondrial porins**,[14–17] which are similar to the outer membrane porins of gram-negative bacteria (Fig. 8-20). The ratio of phospholipid to protein (~0.82 on a weight basis) is much higher than in the inner membrane. Extraction of the phospholipids by acetone destroys the membrane. Of the lipids present, there is a low content of cardiolipin, a high content of phosphatidylinositol and cholesterol, and no ubiquinone.

The inner membrane is impermeable to many substances. Neutral molecules of <150 Da can penetrate the membranes, but the permeability for all other materials including small ions such as H^+, K^+, Na^+, and Cl^- is tightly controlled. The ratio of phospholipid to protein in the inner membrane is ~0.27, and cardiolipin makes up ~20% of the phospholipid present. Cholesterol is absent. Ubiquinone and other components of the respiratory chain are all found in the inner membrane. Proteins account for 75% of the mass of the membrane.

Another characteristic of the inner mitochondrial membrane is the presence of projections on the inside surface, which faces the mitochondrial matrix. See Fig. 18-14. These spherical 85-kDa particles, discovered by Fernandez Moran in 1962 and attached to the membrane through a "stalk", display ATP-hydrolyzing (ATPase) activity. The latter was a clue that the knobs might participate in the *synthesis* of ATP during oxidative phosphorylation. In fact, they are now recognized as a complex of proteins called **coupling factor 1** (F_1) or **ATP synthase**.

In addition to bacterialike mitochondrial ribosomes and small circular molecules of DNA, mitochondria may contain variable numbers of dense granules of calcium phosphate, either $Ca_3(PO_4)_2$ or hydroxylapatite (Fig. 8-34),[4,18] as well as of phospholipoprotein.[4]

Quantitatively the major constituents of the matrix space are a large number of proteins. These account for about 56% by weight of the matrix material and exist in a state closer to that in a protein crystal than in a true solution.[19–20a] Mitochondrial membranes also contain proteins, both tightly bound relatively non-polar intrinsic proteins and extrinsic proteins bound to the membrane surfaces. The other mitochondrial compartment, the intermembrane space, may normally be very small but it is still "home" for a few enzymes.

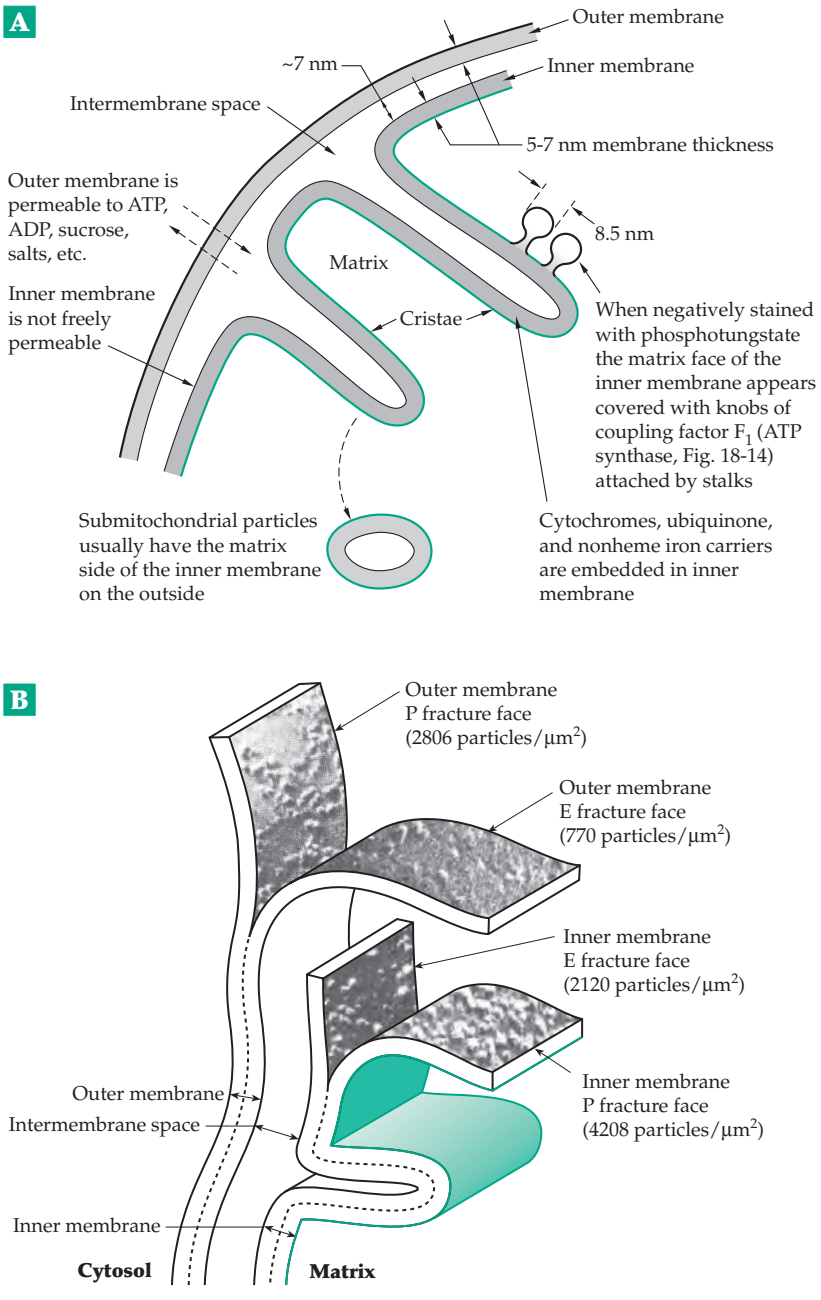

Figure 18-2 (A) Schematic diagram of mitochondrial structure. (B) Model showing organization of particles in mitochondrial membranes revealed by freeze-fracture electron microscopy. The characteristic structural features seen in the four half-membrane faces (EF and PF) that arise as a result of fracturing of the outer and inner membranes are shown. The four smooth membrane surfaces (ES and PS) are revealed by etching. From Packer.[8]

2. The Chemical Activities of Mitochondria

Mention of mitochondria usually brings to the mind of the biochemist the **citric acid cycle,** the **β oxidation pathway** of fatty acid metabolism, and **oxidative phosphorylation**. In addition to these major processes, many other chemical events also occur. Mitochondria concentrate Ca^{2+} ions and control the entrance and exit of Na^+, K^+, dicarboxylates, amino acids, ADP, P_i and ATP, and many other substances.[16] Thus, they exert regulatory functions both on catabolic and biosynthetic sequences. The glycine decarboxylase system (Fig. 15-20) is found in the mitochondrial matrix and is especially active in plant mitochondria (Fig. 23-37). Several cytochrome P450-dependent hydroxylation reactions, important to the biosynthesis and catabolism of steroid hormones and to the metabolism of vitamin D, take place within mitochondria. Mitochondria make only a few of their own proteins but take in several hundred other proteins from the cytoplasm as they grow and multiply.

Where within the mitochondria are specific enzymes localized? One approach to this question is to see how easily the enzymes can be dissociated from mitochondria. Some enzymes come out readily under hypotonic conditions. Some are released only upon sonic oscillation, suggesting that they are inside the matrix space. Others, including the cytochromes and the flavoproteins that act upon succinate and NADH, are so firmly embedded in the inner mitochondrial membranes that they can be dissociated only through the use of non-denaturing detergents.

Because the enzymes of the citric acid cycle[20a] (with the exception of succinate dehydrogenase) and β oxidation are present in the matrix, the reduced electron carriers must approach the inner membrane from

the matrix side (the M side). Thus, the embedded enzymes designed to oxidize NADH, succinate, and other reduced substrates must be accessible from the matrix side. However, *sn*-glycerol 3-phosphate dehydrogenase, a flavoprotein, is accessible from the "outside" of the cytoplasmic (C side) of the inner membrane.[21] Fluorescent antibodies to cytochrome *c* bind only to the cytoplasmic (intermembrane) side of the inner membrane, but antibodies to cytochrome oxidase label both sides, which suggested that this protein complex spans the membrane.[22] However, oxidation of cytochrome *c* by cytochrome oxidase occurs only on the cytoplasmic surface.[22] Antibodies to the ATP synthase that makes up the knobs bind strictly to the matrix side.

The outer mitochondrial membrane contains monoamine oxidase, cytochrome b_5, fatty acyl-CoA synthase, and enzymes of cardiolipin synthesis[22a] as well as other proteins. Cardiolipin (diphosphatidylglycerol; Fig. 21-4) is found only in the inner mitochondrial membrane and in bacteria. It is functionally important for several mitochondrial enzymes including cytochrome oxidase and cytochome bc_1.[22a–c] It is also essential to photosynthetic membranes for which an exact role in an interaction between the lipid membrane and the associated protein has been revealed by crystallography.[22d] In other respects the composition of the inner mitochondrial membrane resembles that of the membranes of the endoplasmic reticulum. Isoenzyme III of adenylate kinase, a key enzyme involved in equilibrating ATP and AMP with ADP (Eq. 6-65), is one of the enzymes present in the intermembrane space. A number of other kinases, as well as sulfite oxidase, are also present between the membranes.[4]

As mentioned in Box 6-D, mitochondria sometimes take up calcium ions. The normal total concentration of Ca^{2+} is ~1 mM and that of free Ca^{2+} may be only ~0.1 μM.[22e,f] However, under some circumstances mitochondria accumulate large amounts of calcium, perhaps acting as a Ca^{2+} buffer.[22g,f] The so called ryanodine receptors (Fig. 19-21), prominent in the endoplasmic reticulum, have also been found in heart mitochondria, suggesting a function in control of calcium oscillations.[22i,j] On the other hand, accumulation of calcium by mitochondria may be pathological and the activation of Ca^{2+}-dependent proteases may be an initial step in apoptosis.[22h,22k]

TABLE 18-1
Catalog of Mitochondrial Genes[a]

3. The Mitochondrial Genome

Each mitochondrion contains several molecules of DNA (**mtDNA**), usually in a closed, circular form, as well as the ribosomes, tRNA molecules, and enzymes needed for protein synthesis.[1,23–26] With rare exceptions almost all of the mitochondrial DNA in a human cell is inherited from the mother.[6,26a] The size of the DNA circles varies from 16–19 kb in animals[27] to over 200 kb in many higher plants. Complete sequences of many mitochondrial DNAs are known.[28,28a] Among these are the 16,569 bp human mtDNA,[29] the 16,338 bp bovine mtDNA, the 16,896 bp mtDNA of the wallaroo *Macropus robustus*,[30] and the 17,533 bp mtDNA of the amphibian *Xenopus laevis*.[31,32] The sea urchin *Paracentotus lividus* has a smaller 15,697 bp genome. However, the order of the genes in this and other invertebrate mtDNA is different from that in mammalian mitochondria.[33] Protozoal mtDNAs vary in size from ~5900 bp for the

parasitic malaria organism *Plasmodium falciparum*[34,35] to 41,591 bp for *Acanthamoeba castellani*[36] and 69,034 bp for the fresh water flagellate *Reclinomonas americana*.[26,37]

All of the mammalian mtDNAs are organized as shown in Fig. 18-3. The two strands of the DNA can be separated by virtue of their differing densities. The heavy (H) strand has a 5'→3' polarity in a counterclockwise direction in the map of Fig. 18-3, while the light (L) strand has a clockwise polarity. From the sequences 13 genes for specific proteins, 2 genes for ribosomal RNA molecules, and 22 genes for transfer RNAs have been identified. The genes are listed in Table 18-1 and have also been marked on the map in Fig. 18-3. The map also shows the tRNA genes, labeled with standard one-letter amino acid abbreviations, and the directions of transcription. Most of the protein genes are on the H-strand. One small region, the D-loop, contains an origin of replication and control signals for transcription (see Chapters 27 and 28).

The genes in mammalian mtDNA are closely packed with almost no nucleotides between them. However, the 19.5-kb mtDNA of *Drosophila* contains an (A+T)-rich region, which varies among species.[38] In the much larger 78-kb genome of yeast *Saccharomyces cerevisiae* many (A+T)-rich spacer regions are present.[39] The yeast mitochondrial genome also contains genes for several additional proteins. Mitochondria of *Reclinomonas americana* contain 97 genes, including those for 5S RNA, the RNA of ribonuclease P as well as a variety of protein coding genes. Perhaps this organism is primitive, resembling the original progenitor of eukaryotic life.[26] The mtDNA of trypanosomes is present in the large mitochondrion or kinetoplast as 40–50 "maxicircles" ~20–35 kb in size, together with 5000–10,000 "minicircles", each of 645–2500 bp (see Fig. 5-16). The latter encode **guide RNA** for use in RNA editing (Chapter 28). The large mitochondrial DNAs of higher plants, e.g., *Arabidopsis* (Table 18-1), also contain additional protein genes as well as large segments of DNA between the genes. The genome of the turnip (*Brassica campestris*) exists both as a 218-kb **master chromosome** and smaller 83- and 135-kb incomplete chromosomes, a pattern existing for most land plants.[40–42] The muskmelon contains 2500 kb of mitochondrial DNA (mtDNA). On the other hand, most mtDNA of the liverwort *Marchantia polymorpha* consists of 186-kb linear duplexes.[42a]

The compact size of the mammalian genome is dependent, in part, on alterations in the genetic code, as shown in Table 18-2, and a modification of tRNA structures that permits mitochondria to function with a maximum of 22 tRNAs (Chapter 28).[43–45] However, the more primitive *Reclinomonas* utilizes the standard genetic code in its mitochondria.[26] The mammalian mitochondrial genes contain no introns, but some yeast mitochondrial genes do. Furthermore, some of the introns contain long open reading frames. At least two of these genes-within-genes encode enzymes that excise the introns.

Why does mtDNA contain *any* protein genes, or why does mtDNA even exist? It seems remarkable that the cells of our bodies make the 100 or so extra proteins (encoded in the nucleus) needed for replication, transcription, amino acid activation, and mitochondrial ribosome formation and bring these into the mitochondria for the sole purpose of permitting the synthesis there of 13 proteins. The explanation is not evident. What are the 13 proteins?

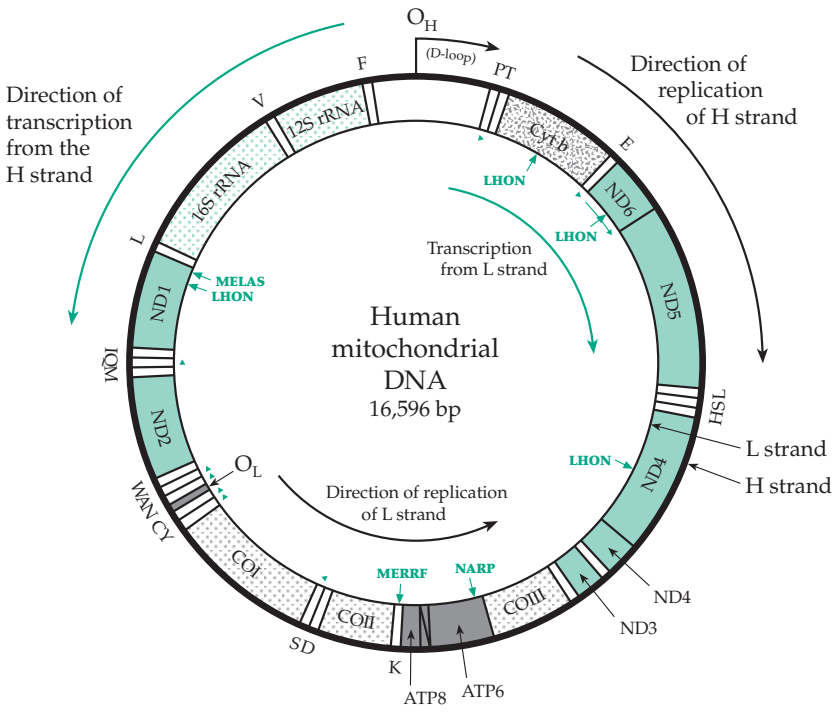

Figure 18-3 Genomic map of mammalian mitochondrial DNA. The stippled areas represent tRNA genes which are designated by the single-letter amino acid code; polarity is counterclockwise except for those marked by green arrow heads. All protein-coding genes are encoded on the H strand (with counterclockwise polarity), with the exception of ND6, which is encoded on the L strand. COI, COII, and COIII: cytochrome oxidase subunits I, II, and III; Cyt *b*: cytochrome *b*; ND: NADH dehydrogenase; ATP:ATP synthase. O_H and O_L: the origins of H and L strand replication, respectively. After Wallace[46] and Shoffner and Wallace.[45] Positions of a few of many known mutations that cause serious diseases are marked using abbrevations defined in Box 18-B.

TABLE 18-2
Alterations in the Genetic Code in the DNA of Animal Mitochondria

Codons	Nuclear DNA[a]	Mitochondrial DNA
AGA, ACG	Arg	Termination
AUA	Ile	Met
UGA	Termination	Trp

[a] See Table 5-5 for the other "standard" codons.

Three are the large functional subunits of cytochrome oxidase, one is cytochrome *b*, and seven are subunits of the NADH dehydrogenase system (Complex I). Two are subunits of ATP synthase. These are all vitally involved in the processes of electron transport and oxidative phosphorylation, but so are other proteins that are imported from the cytoplasm.

One gene in yeast mtDNA is especially puzzling. The *var 1* gene encodes a mitochondrial ribosomal protein, whose sequence varies with the strain of yeast. The gene is also involved in unusual recombinational events.[47] Another unusual aspect of yeast mitochondrial genetics is the frequent appearance of "petite" mutants, which grow on an agar surface as very small colonies. These have lost a large fraction of their mitochondrial DNA and, therefore, the ability to make ATP by oxidative phosphorylation. The remaining petite mtDNA may sometimes become integrated into nuclear DNA.[48] A few eukaryotes that have no aerobic metabolism also have no mitochondria.[49]

4. Growth and Development

Mitochondria arise by division and growth of preexisting mitochondria. Because they synthesize only a few proteins and RNA molecules, they must import many proteins and other materials from the cytoplasm. A mitochondrion contains at least 100 proteins that are encoded by nuclear genes.[50,50a] The mechanisms by which proteins are taken up by mitochondria are complex and varied. Many of the newly synthesized proteins carry, at the N terminus, presequences that contain **mitochondrial targeting signals**[51–53] (Chapter 10). These amino acid sequences often lead the protein to associate with receptor proteins on the outer mitochondrial membrane and subsequently to be taken up by the mitochondria. While the targeting sequences are usually at the N terminus of a polypeptide, they are quite often internal. The N-terminal sequences are usually removed by action of the **mitochondrial processing peptidase** (MPP) in the matrix, but internal targeting sequences are not removed.[52] Targeting of proteins to mitochondria may be assisted by **mRNA binding proteins** that guide appropriate mRNAs into the vicinity of mitochondria or other organelles.[53]

In addition to targeting signals, polypeptides destined for the inner mitochondrial membrane contain additional **topogenic signals** that direct the polypeptide to its destination. These topogenic signals are distinct from the targeting signals, which they sometimes follow. Topogenic signals are usually hydrophobic sequences, which may become transmembrane segments of the protein in its final location.[52,54] The uptake of many proteins by mitochondria requires the electrical potential that is usually present across the inner membrane (Section E). The fact that mitochondrial proteins usually have higher isoelectric points and carry more positive charges at neutral pH favors uptake.[55] In addition, chaperonins assist in

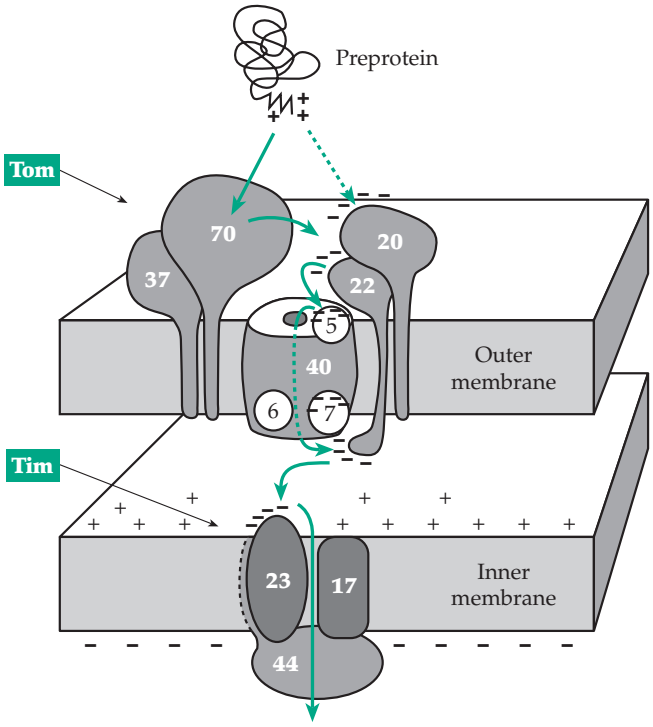

Figure 18-4 Schematic diagram of the protein transport machinery of mitochondrial membranes labeled according to the uniform nomenclature.[57] Subunits of outer membrane receptors and translocase are labeled Tom (translocase of outer membrane) and those of the inner membrane Tim (translocase of inner membrane). They are designated Tom70, etc., according to their sizes in kilodaltons (kDa). Preproteins are recognized by receptor Tom70•Tom 37 and / or by Tom22•Tom20. Clusters of negative charges on many components help guide the preprotein through the uptake pores in one or both membranes.[50,58] See Pfanner *et al.*,[57] Schatz,[50,50a] and Gabriel *et al.*[50b]

unfolding the protein to be taken up, assist in transport of some proteins,[50a] and may help the imported proteins to assemble into oligomeric structures.[51–53,56]

Protein uptake also requires a set of special proteins described as the **translocase of the outer mitochondrial membrane** (**Tom**) and **translocase of the mitochondrial inner membrane** (**Tim**). Subunits that form the receptor targets and transport pores are designated, according to their approximate molecular masses in kD as Tom70, Tim23, etc. (Fig. 18-4).[57] Preproteins are recognized by the receptor complexes Tom70 • Tom37 and / or Tom22 • Tom20 on the mitochondrial surface. They then enter the **general import pore** formed by Tom40, Tom6, and Tom7 with the assistance of a small integral membrane protein Tom5, which has a positively charged C-terminal membrane anchor segment and a negatively charged N-terminal portion that may bind to the positively charged mitochondrial targeting sequences.[50,59] A number of other translocase components, including Tom20 and Tom22 of the outer membrane and Tim23 of the inner membrane, also have acidic extramembranous domains.[58] This suggested an "acid chain" hypothesis according to which the targeting signal interacts consecutively with a series of acidic protein domains that help to guide it across the two membranes.[50a,58,59] A series of small proteins, Tim8, 9, 10, 12, 13, function in yeast mitochondria to mediate the uptake of metabolite transporters. A defect in the human nuclear gene for a protein that resembles Tim8 causes **deafness dystonia**, a recessive X-linked neurodegenerative disorder.[59a,b]

B. Electron Transport Chains

During the 1940s, when it had become clear that formation of ATP in mitochondria was coupled to electron transport, the first attempts to pick the system apart and understand the molecular mechanism began. This effort led to the identification and at least partial characterization of several flavoproteins, iron-sulfur centers, ubiquinones, and cytochromes, most of which have been described in Chapters 15 and 16. It also led to the picture of mitochondrial electron transport shown in Fig. 10-5 and which has been drawn in a modern form in Fig. 18-5.

1. The Composition of the Mitochondrial Electron Transport System

Because of the difficulty of isolating the electron transport chain from the rest of the mitochondrion, it is easiest to measure ratios of components (Table 18-3). Cytochromes a, a_3, b, c_1, and c vary from a 1:1 to a 3:1 ratio while flavins, ubiquinone, and nonheme iron occur in relatively larger amounts. The much larger amount of pyridine nucleotides is involved in carrying electrons from the various soluble dehydrogenases of the matrix to the immobile carriers in the inner membrane, while ubiquinone has a similar function within the lipid bilayer of mitochondrial membranes.

TABLE 18-3
Ratios of Components in the Electron Transport Chain of Mitochondria[a,b]

Electron carrier	Rat liver mitochondria	Beef heart mitochondria
Cytochrome a_3	1.0	1.1
Cytochrome a	1.0	1.1
Cytochrome b	1.0	1.0
Cytochrome c_1	0.63	0.33–0.51
Cytochrome c	0.78	0.66–0.85
Pyridine nucleotides	24	
Flavins	3	1
Ubiquinone	3–6	7
Copper		2.2
Nonheme iron		5.5

[a] From Wainio, W. W. (1970) *The Mammalian Mitochondrial Respiratory Chain*, Academic Press, New York, and references cited therein.
[b] Molecular ratios are given. Those for the cytochromes refer to the relative numbers of heme groups.

What are the molar concentrations of the electron carriers in mitochondrial membranes? In one experiment, cytochrome b was found in rat liver mitochondria to the extent of 0.28 μmol/g of protein. If we take a total mitochondrion as about 22% protein, the average concentration of the cytochrome would be ~0.06 mM. Since all the cytochromes are concentrated in the inner membranes, which may account for 10% or less of the volume of the mitochondrion, the concentration of cytochromes may approach 1 mM in these membranes. This is sufficient to ensure rapid reactions with substrates.

2. The Sequence of Electron Carriers

Many approaches have been used to deduce the sequence of carriers through which electron flow takes place (Fig. 18-5). In the first place, it seemed reasonable to suppose that the carriers should lie in order of increasing oxidation–reduction potential going from left to right of the figure. However, since the redox potentials existing in the mitochondria may be somewhat different from those in isolated enzyme preparations, this need not be strictly true.

The development by Chance of a dual wavelength spectrophotometer permitted easy observation of the state of oxidation or reduction of a given carrier within mitochondria.[60] This technique, together with the study of specific inhibitors (some of which are indicated in Fig. 18-5 and Table 18-4), allowed some electron transport sequences to be assigned. For example, blockage with **rotenone** and **amytal** prevented reduction of the cytochrome system by NADH but allowed reduction by succinate and by other substrates having their own flavoprotein components in the chain. Artificial electron acceptors, some of which are shown in Table 18-5, were used to bypass parts of the chain as indicated in Fig. 18-5.

Submitochondrial particles and complexes. Many methods have been employed to break mitochondrial membranes into submitochondrial particles that retain an ability to catalyze some of the reactions of the chain.[61] For example, the Keilin–Hartree preparation of heart muscle is obtained by homogenizing mitochondria and precipitation at low pH.[62] The resulting particles have a low cytochrome *c* content and do not carry out oxidative phosphorylation.

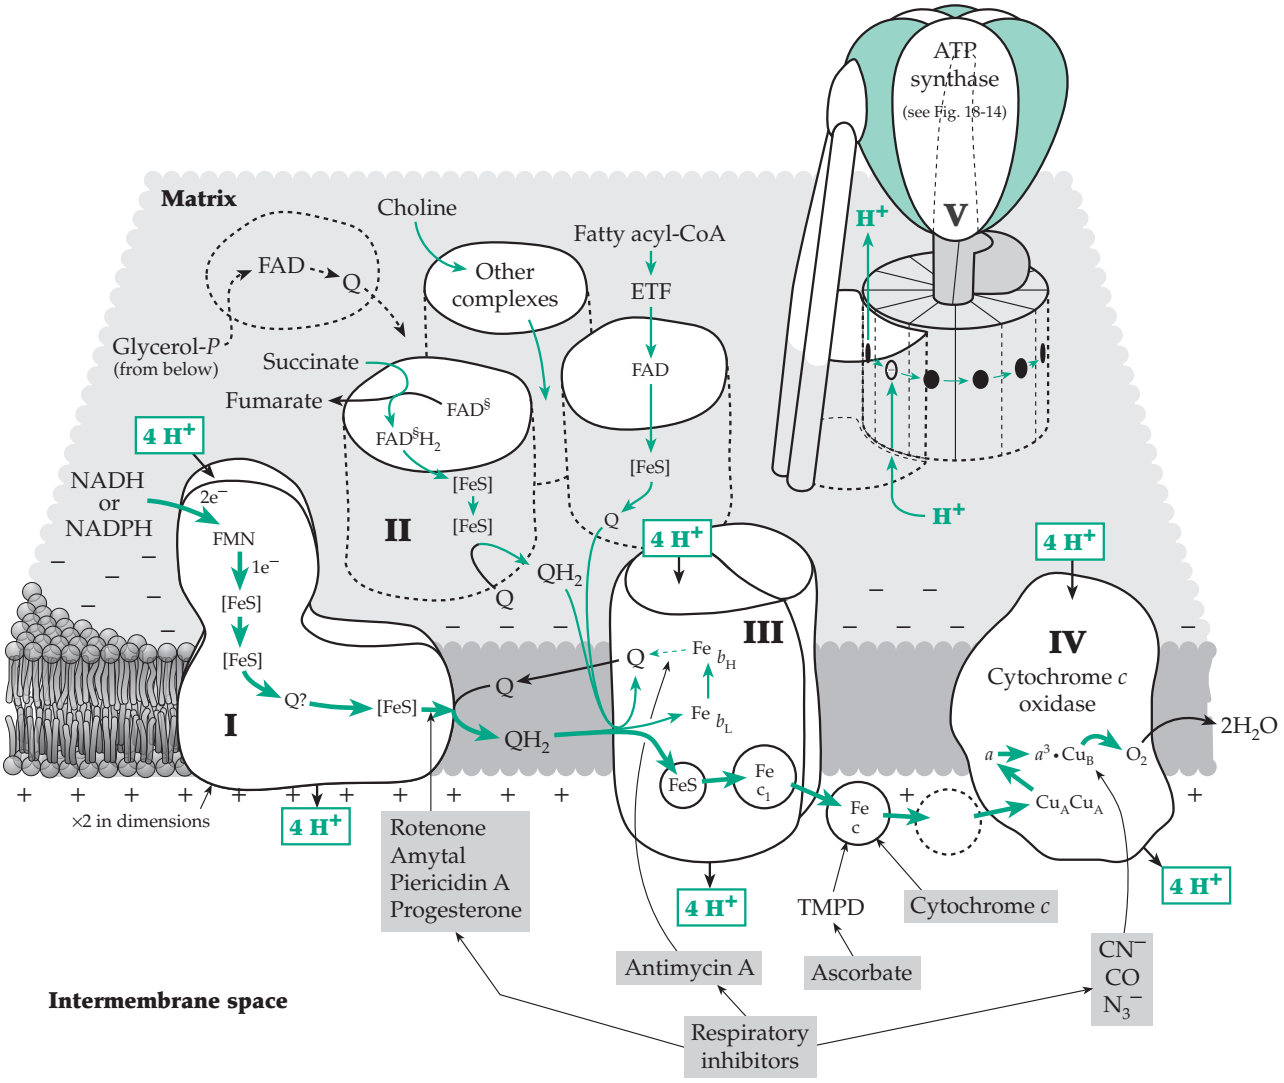

Figure 18-5 A current concept of the electron transport chain of mitochondria. Complexes I, III, and IV pass electrons from NADH or NADPH to O_2, one NADH or two electrons reducing one O to H_2O. This electron transport is coupled to the transfer of about 12 H^+ from the mitochondrial matrix to the intermembrane space. These protons flow back into the matrix through ATP synthase (V), four H^+ driving the synthesis of one ATP. Succinate, fatty acyl-CoA molecules, and other substrates are oxidized via complex II and similar complexes that reduce ubiquinone Q, the reduced form QH_2 carrying electrons to complex III. In some tissues of some organisms, glycerol phosphate is dehydrogenated by a complex that is accessible from the intermembrane space.

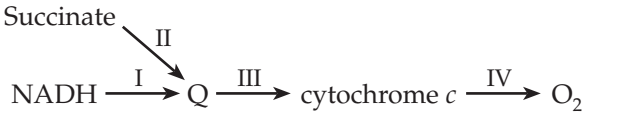
However, they do transport electrons and react with O_2. Other electron transport particles have been prepared by sonic oscillation. Under the electron microscope such particles appear to be small membranous vesicles resembling mitochondrial cristae.

Many detergents are strong denaturants of proteins, but some of them disrupt mitochondrial membranes without destroying enzymatic activity. A favorite is **digitonin** (Fig. 22-12), which causes disintegration of the outer membrane. The remaining fragments of inner membrane retain activity for oxidative phosphorylation. Such submitochondrial particles can be fractionated further by chemical treatments. Separate complexes can be obtained by treating the inner membranes with the nondenaturing detergent cholate (Fig. 22-10) and isolating the complexes by differential salt fractionation using ammonium sulfate. The isolated complexes I – IV catalyze reactions of four different portions of the electron transport process[63–65] as indicated in Eq. 18-1:



(18-1)

These complexes are usually named as follows: I, **NADH-ubiquinone oxidoreductase**; II, **succinate-ubiquinone oxidoreductase**; III, **ubiquinol-cytochrome *c* oxidoreductase**; IV, **cytochrome *c* oxidase**. The designation **complex V** is sometimes applied to ATP synthase (Fig. 18-14). Chemical analysis of the electron transport complexes verified the probable location of some components in the intact chain. For example, a high iron content was found in both complexes I and II and copper in complex IV.

We now recognize not only that these complexes are discrete structural units but also that they are functional units. Complete X-ray crystallographic structures are available for complexes III and IV and for much of the ATP synthase complex. As is indicated in Fig. 18-5, complexes I – IV are linked by two soluble electron carriers, ubiquinone and cytochrome *c*.

The lipid-soluble ubiquinone (Q) is present in both bacterial and mitochondrial membranes in relatively large amounts compared to other electron carriers (Table 18-2). It seems to be located at a point of convergence of the NADH, succinate, glycerol phosphate, and choline branches of the electron transport chain. Ubiquinone plays a role somewhat like that of NADH, which carries electrons between dehydrogenases in the cytoplasm and from soluble dehydrogenases in the aqueous mitochondrial matrix to flavoproteins embedded in the membrane. Ubiquinone transfers electrons plus protons between proteins within the

BOX 18-A HISTORICAL NOTES ON RESPIRATION

Animal respiration has been of serious interest to scientists since 1777, when Lavoisier concluded that foods undergo slow combustion within the body, supposedly in the blood. In 1803–1807, Spallanzani established for the first time that the tissues were the actual site of respiration, but his conclusions were largely ignored. In 1884, MacMunn discovered that cells contain the heme pigments, which are now known as **cytochromes**. However, the leading biochemists of the day dismissed the observations as experimental error, and it was not until the present century that serious study of the chemistry of biological oxidations began.[a,b]

Recognition that substrates are oxidized by **dehydrogenation** is usually attributed to H. Wieland. During the years 1912–1922 he showed that synthetic dyes, such as methylene blue, could be substituted for oxygen and would allow respiration of cells in the absence of O_2. Subsequent experiments (see Chapter 15) led to isolation of the soluble pyridine nucleotides and flavoproteins and to development of the concept of an electron transport chain.

Looking at the other end of the respiratory chain, Otto Warburg[c,d] noted in 1908 that all aerobic cells contain iron. Moreover, iron-containing charcoal prepared from blood catalyzed nonenzymatic oxidation of many substances, but iron-free charcoal prepared from cane sugar did not. Cyanide was found to inhibit tissue respiration at low concentrations similar to those needed to inhibit nonenzymatic catalysis by iron salts. On the basis of these investigations, Warburg proposed in 1925 that aerobic cells contain an iron-based *Atmungsferment* (respiration enzyme), which was later called **cytochrome oxidase**. It was inhibited by carbon monoxide.

Knowing that carbon monoxide complexes of hemes are dissociated by light, Warburg and Negelein, in 1928, determined the photochemical **action spectrum** (see Chapter 23) for reversal of the carbon monoxide inhibition of respiration of the yeast *Torula utilis*. The spectrum closely resembled the absorption spectrum of known heme derivatives (Fig. 16-7). Thus, it was proposed that O_2, as well as CO, combines with the iron of the heme group in the Atmungsferment.

Meanwhile, during 1919–1925, David Keilin, while peering through a microscope equipped with a spectroscopic ocular at thoracic muscles of flies and other insects, observed a pigment with four distinct absorption bands. At first he thought it was derived by some modification of hemoglobin, but when he found the same pigment in fresh baker's yeast, he recognized it as an important new substance. In his words:[e]

One day while I was examing a suspension of yeast freshly prepared from a few bits of compressed yeast shaken vigorously with a little water in a test-tube, I failed to find the characteristic four-banded absorption spectrum, but before I had time to remove the suspension from the field of vision of the microspectroscope the four absorption bands suddenly reappeared. This experiment was repeated time after time and always with the same result: the absorption bands disappeared on shaking the suspension with air and reappeared within a few seconds on standing.

I must admit that this first visual perception of an intracellular respiratory process was one of the most impressive spectacles I have witnessed in the course of my work. Now I have no doubt that cytochrome is not only widely distributed in nature and completely independent of haemoglobin, but that it is an intracellular respiratory pigment which is much more important than haemoglobin.

Keilin soon realized that three of the absorption bands, those at 604, 564, and 550 nm (*a*, *b*, and *c*), represented different pigments, while the one at 521 nm was common to all three. Keilin proposed the names cytochromes *a*, *b*, and *c*. The idea of an electron transport or respiratory chain followed[e] quickly as the flavin and pyridine nucleotide coenzymes were recognized to play their role at the dehydrogenase level. Hydrogen removed from substrates by these carriers could be used to oxidize reduced cytochromes. The latter would be oxidized by oxygen under the influence of cytochrome oxidase.

In 1929, Fiske and Subbarow,[d,f–h] curious about the occurrence of purine compounds in muscle extracts, discovered and characterized ATP. It was soon shown (largely through the work of Lundsgaard and Lohman)[f] that hydrolysis of ATP provided energy for muscular contraction. At about the same time, it was learned that synthesis of ATP accompanied glycolysis. That ATP could also be formed as a result of electron transport became clear following an observation of Engelhardt[h,i] in 1930, that methylene blue stimulated ATP synthesis by tissues.

The study of electron transport chains and of oxidative phosphorylation began in earnest after Kennedy and Lehninger,[j] in 1949, showed that mitochondria were the site not only of ATP synthesis but also of the operation of the citric acid cycle and fatty acid oxidation pathways. By 1959, Chance had introduced elegant new techniques of spectrophotometry that led to formulation of the electron

BOX 18-A (continued)

transport chain as follows:

Substrate → pyridine nucleotides → flavoprotein → cyt b → cyt c → cyt a → cyt a_3 → O_2

Since that time, some new components have been added, notably the ubiquinones and iron-sulfur proteins, but the basic form proposed for the chain was correct.

membrane bilayer. Membranes also contain **ubiquinone-binding proteins**,[66,67] which probably hold the ubiquinone that is actively involved in electron transport. Perhaps some ubiquinone molecules function as fixed carriers. There is also uncertainty about the number of sites at which ubiquinone functions in the chain.

Mitochondrial electron transport in plants and fungi. Plant mitochondria resemble those of mammals in many ways, but they contain additional dehydrogenases and sometimes utilize alternative pathways of electron transport,[68–73] as do fungi.[74] Mitochondria are impermeable to NADH and NAD^+. Animal mitochondria have shuttle systems (see Fig. 18-16) for bringing the reducing equivalents of NADH into mitochondria and to the NADH dehydrogenase that faces the matrix side of the inner membrane. However, plant mitochondria also have an NADH dehydrogenase on the *outer* surface of the inner membrane (Fig. 18-6). This enzyme transfers electrons to ubiquinone, is not inhibited by rotenone (see Fig. 18-5), and also acts on NADPH. Inside the mitochondria a high-affinity NADH dehydrogenase resembles complex I of animal mitochondria and is inhibited by rotenone.[73] There is also a low-affinity NADH dehydrogenase, which is insensitive to rotenone. Some plant mitochondria respire slowly in the presence of cyanide. They utilize an **alternative oxidase** that replaces complex III and cytochome *c* oxidase and which is not inhibited by antimycin or by cyanide (Fig. 18-6).[68,71,75] It is especially active in thermogenic plant tissues (Box 18-C). A

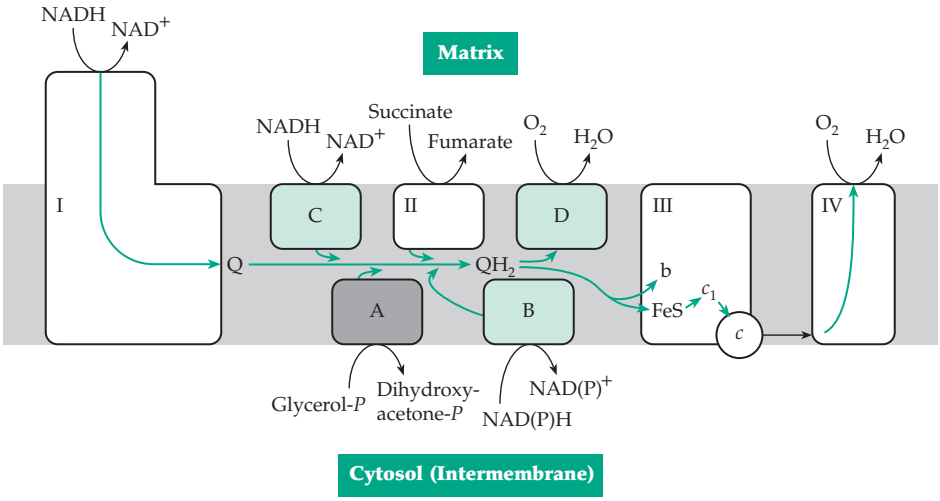

Figure 18-6 Schematic diagram of some mitochondrial dehydrogenase and oxidase complexes of plants and also the glycerol phosphate dehydrogenase of animals, which is embedded in the inner membrane. Complexes I–IV are also shown. (A) The glycerol phosphate dehydrogenase of some animal tissues. It is accessible from the intermembrane space on the cytosolic side. (D) The plant alternative oxidase. Ubiquinone, Q. The three green stippled dehydrogenases are not coupled to proton pumps or ATP synthesis. After Hoefnagel *et al.*[73]

BOX 18-B DEFECTS OF MITOCHONDRIAL DNA

A mutation in any of the 13 protein subunits, the 22 tRNAs, or the two rRNAs whose genes are carried in mitochondrial DNA may possibly cause disease. The 13 protein subunits are all involved in electron transport or oxidative phosphorylation. The syndromes resulting from mutations in mtDNA frequently affect oxidative phosphorylation (OXPHOS) causing what are often called "OXPHOS diseases."[a–g] Mitochondrial oxidative phosphorylation also depends upon ~100 proteins encoded in the nucleus. Therefore, OXPHOS diseases may result from defects in either mitochondrial or nuclear genes. The former are distinguished by the fact that they are inherited almost exclusively maternally. Most mitochondrial diseases are rare. However, mtDNA is subject to rapid mutation, and it is possible that accumulating mutants in mtDNA may be an important component of aging.[h–k]

The first recognition of mitochondrial disease came in 1959. A 30-year old Swedish woman was found to have an extremely high basal metabolic rate (180% of normal), a high caloric intake (>3000 kcal / day), and an enormous perspiration rate. She had developed these symptoms at age seven. Examination of her mitochondria revealed that electron transport and oxidative phosphorylation were very loosely coupled. This explains the symptoms. However, the disease (Luft disease) is extremely rare and the underlying cause isn't known.[i] Its recognition did focus attention on mitochondria, and by 1988, 120 different mtDNA defects had been described.[e,i]

Some OXPHOS disorders, including Luft disease, result from mutations in nuclear DNA. A second group arise from point mutations in mtDNA and a third group involve deletions, often very large, in mtDNA. Persons with these deletions survive because they have both mutated and normal mtDNA, a condition of **heteroplasmy** of mtDNA. As these persons age their disease may become more severe because they lose many normal mitochondria.[d,e]

The names of mitochondrial diseases are often complex and usually are described by abbreviations. Here are a few of them: **LHON**, Lebers hereditary optical neuropathy; **MERRF**, myoclonic epilepsy and ragged-red-fiber disease; **MELAS**, mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes; **NARP**, neurological muscle weakness, ataxia, and retinitis pigmentosa; **Leigh disease — SNE**, subacute necrotizing encephalomyelopathy; **KSS**, Kearns–Sayre syndrome; **CPEO**, chronic progressive external ophthalmoplegia. LHON is a hereditary disease that often leads to sudden blindness from death of the optic nerve especially among males. Any one of several point mutations in subunits ND1, 2, 4, 5, and 6 of NADH dehydrogenase (complex I; Figs. 18-3 and 18-5), cytochrome *b* of complex II, or subunit I of cytochrome oxidase may cause this syndrome. Most frequent is an R340H mutation of the ND4 gene at position 11,778 of mtDNA (Fig. 18-3).[e,l,m] It may interfere with reduction of ubiquinone.[n] Mutations in the ND1 gene at position 3460 and in the ND6 gene at position 14484 or in the cytochrome *b* gene at position 15257 cause the same disease.[l] The most frequent (80–90%) cause of MERRF, which is characterized by epilepsy and by the appearance of ragged red fibers in stained sections of muscle, is an A → G substitution at position 8344 of mtDNA in the TψC loop (Fig. 5-30) of mitochondrial $tRNA^{Lys}$. A similar disease, MELAS, is accompanied by strokes (not seen in MERRF) and is caused in 80% of cases by an A → G substitution in the dihydrouridine loop (Fig. 5-30) of mitochondrial $tRNA^{Leu}$.[o] CPEO, Leigh disease, and KSS often result from large deletions of mtDNA.[p] NARP and related conditions have been associated with an L156R substitution in the ATPase 6 gene of ATP synthase.[q]

Can mitochondrial diseases be treated? Attempts are being made to improve the function of impaired mitochondria by adding large amounts of ubiquinone, vitamin K, thiamin, riboflavin, and succinate to the diet.[e] One report suggests that mitochondrial decay during aging can be reversed by administration of *N*-acetylcarnitine.[k]

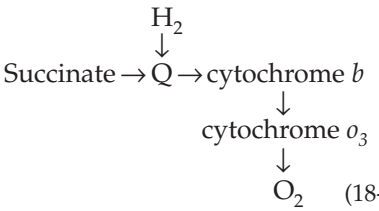
similar oxidase is present in trypanosomes.[72] Neither the rotenone-insensitive dehydrogenases nor the alternative oxidases are coupled to synthesis of ATP.

Electron transport chains of bacteria. The bacterial electron transport systems are similar to that of mitochondria but simpler. Bacteria also have a variety of alternative pathways that allow them to adapt to various food sources and environmental conditions.[76,77] The gram-negative soil bacterium *Paracoccus denitrificans*, which has been called "a free-living mitochondrion," has a mammalian-type respiratory system. Its complexes I–IV resemble those of animals and of fungi,[78–79] but *Paracoccus* has fewer subunits in each complex. Complex I of *E. coli* is also similar to that of our own bodies.[79–80] However, other major flavoprotein dehydrogenases in *E. coli* act on D-lactate and *sn*-3-glycerol phosphate.[81] Pyruvate is oxidized by a membrane-bound flavoprotein (Fig. 14-2). All of these enzymes pass electrons to ubiquinone-8 (Q_8).[82] Succinate dehydrogenase of *E. coli* resembles that of mitochondria,[83] and the ubiquinol oxidase of *Paracoccus* resembles complexes III + IV of mitochondria. It can be resolved into a three-subunit bc_1 complex, a three-subunit c_1aa_3 complex, and another 57-kDa peptide.[84] The last contains a 22-kDa cytochrome c_{552}, which is considerably larger than mitochondrial cytochrome *c*.

The cytochrome aa_3 terminal oxidase is produced constitutively, i.e., under all conditions. However, when cells are grown on succinate or H_2 another set of enzymes is produced with the *b*-type cytochrome o_3 as the terminal **quinol oxidase** (Eq. 18-2).[85]



(18-2)

Two terminal quinol oxidase systems, both related to cytochrome *c* oxidase, are utilized by *E. coli* to oxidize ubiquinol-8. When cultured at high oxygen tensions, cytochrome bo_3 (also called cytochrome *bo*) is the major oxidase. It utilizes heme *o* (Fig. 16-5) instead of heme *a*. However, at low oxygen tension, e.g., in the late logarithmic stage of growth, the second oxidase, cytochrome *bd*, is formed.[76,86–88a] It contains two molecules of the chlorin heme *d* (Fig. 16-5), which appear to be involved directly in binding O_2. This terminal oxidase system is present in many bacteria and can utilize either O_2 or nitrite as the oxidant. A simpler electron transport chain appears to be involved in the oxidation of pyruvate by *E. coli*. The flavoprotein pyruvate oxidase passes electrons to Q_8, whose reduced form can pass electrons directly to cytochrome *d*. Incorporation of these two pure protein complexes and ubiquinone-8 into phospholipid vesicles has given an active reconstituted chain.[82] Other bacteria utilize a variety of quinol oxidase systems, which contain various combinations of cytochromes: aa_3, caa_3, *cao*, bo_3, and ba_3.[88b,c]

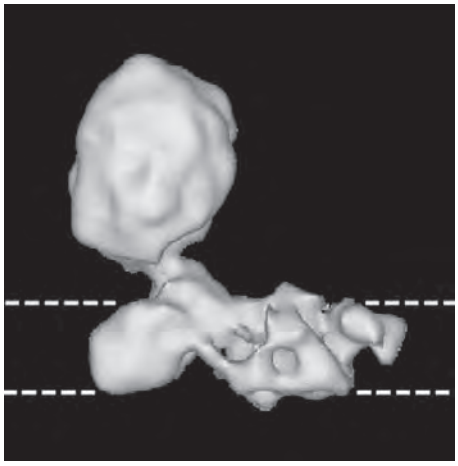


Figure 18-7 Three-dimensional image of bovine NADH-Ubiquinone oxidoreductase (complex I) reconstructed from individual images obtained by electron cyro-microscopy. The resolution is 2.2 nm. The upper portion projects into the mitochondrial matrix while the horizontal part lies within the membrane as indicated. Courtesy of N. Grigorieff.[90]

3. Structures and Functions of the Individual Complexes I – IV and Related Bacterial Assemblies

What are the structures of the individual electron transport complexes? What are the subunit compositions? What cofactors are present? How are electrons transferred? How are protons pumped? We will consider these questions for each of complexes I–IV, as found in both prokaryotes and eukaryotes.[88d,e]

Complex I, NADH-ubiquinone oxidoreductase. Complex I oxidizes NADH, which is generated within the mitochondrial matrix by many dehydrogenases. Among these are the pyruvate, 2-oxoglutarate, malate, and isocitrate dehydrogenases, which function in the tricarboxylic acid cycle; the β-oxoacyl-CoA dehydrogenase of the β oxidation system for fatty acids; and 2-hydroxybutyrate, glutamate, and proline dehydrogenases. All produce NADH, which reacts with the flavoprotein component of complex I. Whether from bacteria,[79] fungal mitochondria,[89] or mammalian mitochondria[89a,90] complex I exists as an L-shaped object, of which each of the two arms is ~23 nm long. One arm projects into the matrix while the other lies largely within the inner mitochondrial membrane (Fig. 18-7). The mitochondrial complex, which has a mass of ~1 MDa, has the same basic structure as the 530-kDa bacterial complex. However, the arms are thicker in the mitochondrial complex. Analysis of the denatured proteins by gel electrophoresis revealed at least 43 peptides.[78,90] Bound to some of these are the electron carriers FMN, Fe_2S_2, and Fe_4S_4 clusters, ubiquinone or other quinones, and perhaps additional unidentified cofactors.[79] Complex I from *E. coli* is smaller, containing only 14 subunits. These are encoded by a cluster of 14 genes, which can be directly related by their sequences to subunits of mitochondrial complex I and also to the corresponding genes of *Paracoccus denitrificans*.[80,91] Complex I of *Neurospora* contains at least 35 subunits.[89] The 14 subunits that are present both in bacteria and in mitochondria probably form the structural core of the complex. The other subunits thicken, strengthen, and rigidify the arms. Some of the "extra" subunits have enzymatic activities that are not directly related to electron transport. Among these are a 10-kDa prokaryotic type acyl carrier protein (ACP), which may be a relic of a bacterial fatty acid synthase, reflecting the endosymbiotic origin of mitochondria.[92] Also present is a 40-kDa NAD(P)H dependent reductase / isomerase, which may be involved in a biosynthetic process, e.g., synthesis of a yet unknown redox group.[79,92]

In all cases, FMN is apparently the immediate acceptor of electrons from NADH. From the results of extrusion of the Fe–S cores (Chapter 16) and EPR measurements it was concluded that there are three tetranuclear (Fe_4S_4) iron–sulfur centers and at least two binuclear (Fe_2S_2) centers[93,94] as well as bound ubiquinone.[95] Chemical analysis of iron and sulfide suggested up to eight Fe–S clusters per FMN, while gene sequences reveal potential sites for formation of six Fe_4S_4 clusters and two Fe_2S_2 clusters.[78] Treatment of complex I with such "chaotropic agents" as 2.5 M urea or 4 M sodium trichloroacetate followed by fractionation with ammonium sulfate[95] gave three fractions:

(1) A soluble NADH dehydrogenase consisting of a 51-kDa peptide that binds both the FMN and also one tetranuclear Fe – S cluster (designated N3) and a 24-kDa peptide that carries a binuclear Fe–S center designated N1b. (2) A 75-kDa peptide bearing two binuclear Fe–S centers, one of which is called N1a and also 47-, 30-, and 13-kDa peptides. One of these carries tetranuclear center N4. (3) A group of insoluble, relatively nonpolar proteins, one of which carries tetranuclear cluster N2. It may be the immediate donor of electrons to a ubiquinone held by a ubiquinone-binding protein designated QP-N. In bacteria seven of these are homologs of the seven NADH dehydrogenase subunits encoded by mtDNA (Fig. 18-3). A 49-kDa subunit of complex I in the yeast *Yarrowia lipolytica* is strikingly similar to the hydrogen reactive subunit of NiFe hydrogenases (Fig. 16-26).[95a] These proteins are thought to lie within the membrane arm and to form ~55 transmembrane α helices. Ubiquinone may also function as a carrier within complex I,[96,97] and there may be a new redox cofactor as well.[79] The following tentative sequence (Eq. 18-3) for electron transfer within complex I (with apparent $E^{\circ\prime}$ values of carriers) has been suggested. By equilibration with external redox systems, the redox potentials of these centers within the mitochondria have been estimated and are given (in V) in Eq. 18-3. The presence of a

$$\begin{array}{lccccccccl} & & & & & & & & & \text{rotenone} \\ \text{NADH} \rightarrow \text{FMN} \rightarrow & \text{N1a} & \rightarrow & (\text{N3}, & \text{N1b}, & \text{N4}) & \rightarrow & \text{N2} & \rightarrow \text{QP-N} \dashrightarrow & \text{Q} \\ & \text{Fe}_2\text{S}_2 & & \text{Fe}_4\text{S}_4 & \text{Fe}_2\text{S}_2 & \text{Fe}_4\text{S}_4 & & \text{Fe}_4\text{S}_4 & \ominus & \\ -0.32 & & -0.38 & & -0.24 & & -0.21 & \text{V} & & \end{array} \qquad (18\text{-}3)$$

large fraction of the bound ubiquinone as a free radical suggests that the quinone functions as a one-electron acceptor rather than a two-electron acceptor. A characteristic of complex I is inhibition by rotenone or piericidin, both of which block electron transport at the site indicated in Fig. 18-5.

Complex II, succinate-ubiquinone oxidoreductase. Complex II, which carries electrons from succinate to ubiquinone, contains covalently linked 8^{α}-(*N*-histidyl)-FAD (Chapter 15) as well as Fe–S centers and one or more ubiquinone-binding sites. There are four subunits whose structures and properties have been highly conserved among mitochondria and bacteria and also in **fumarate reductases**. The latter function in the opposite direction during anaerobic respiration with fumarate as the terminal oxidant, both in bacteria[98–99a] and in parasitic helminths and other eukaryotes that can survive prolonged anaerobic conditions (Chapter 17, Section F,2).[100] Complex II from *E. coli* consists of 64-, 27-, 14-, and 13-kDa subunits, which are encoded by genes *sdhCDAB* of a single operon.[101–103] The two larger hydrophilic subunits associate to form the readily soluble succinate dehydrogenase. The 64-kDa subunit carries the covalently bound FAD while the 27-kDa subunit carries three Fe–S centers. The two small 13- and 14-kDa subunits form a hydrophobic anchor and contain a ubiquinol-binding site (QD-S)[103] as well as a heme that may bridge the two subunits[102] to form cytochrome b_{556}. The functions of the heme is uncertain. The soluble mammalian succinate dehydrogenase resembles closely that of *E. coli* and contains three Fe – S centers: binuclear S1 of $E^{\circ\prime}$ 0 V, and tetranuclear S2 and S3 of –0.25 to –0.40 and + 0.065 V, respectively. Center S3 appears to operate between the –2 and –1 states of Eq. 16-17 just as does the cluster in the *Chromatium* high potential iron protein. The function of the very low potential S2 is not certain, but the following sequence of electron transport involving S1 and S3 and the bound ubiquinone QD–S[66] has been proposed (Eq. 18-4).

$$\text{Succinate} \rightarrow (\text{FAD*, S1}) \rightarrow \text{S3} \rightarrow \text{QP–S} \rightarrow \text{Q} \qquad (18\text{-}4)$$

In addition to complexes I and II several other membrane-associated FAD-containing dehydrogenase systems also send electrons to soluble ubiquinone. These include dehydrogenases for choline, *sn*-glycerol 3-phosphate, and the electron-transfer protein (ETF) of the fatty acyl-CoA β oxidation system (Fig. 18-5). The last also accepts electrons from dehydrogenases for sarcosine (*N*-methylglycine), dimethylglycine, and other substrates. The *sn*-glycerol 3-phosphate dehydrogenase is distinguished by its accessibility from the intermembrane (cytosolic) face of the inner mitochondrial membrane (Fig. 18-6).

Complex III (ubiquinol-cytochrome c oxidoreductase or cytochrome bc_1 complex). Mitochondrial complex III is a dimeric complex, each subunit of which contains 11 different subunits with a total molecular mass of ~240 kDa per monomer.[104–107] However, in many bacteria the complex consists of only three subunits, cytochrome *b*, cytochrome c_1, and the high potential (~0.3 V) Rieske iron-sulfur protein, which is discussed in Chapter 16, Section A,7. These three proteins are present in all bc_1 complexes. In eukaryotes the 379-residue cytochrome *b* is mitochondrially encoded. Although there is only one cytochrome *b* gene in the mtDNA, two forms of cytochrome *b* can be seen in absorption spectra: b_H (also called b_{562} or b_K) and lower potential b_L (also called b_{566} or b_T).[107a,b]

X-ray diffraction studies have revealed the complete 11-subunit structure of bovine bc_1 complex[104,106–107] as well as a nearly complete structure of the chicken bc_1 complex (Fig. 18-8).[105] The bovine complex contains 2166 amino acid residues per 248-kDa monomer and

exists in crystals as a 496-kDa dimer and probably functions as a dimer.[106-107] The two hemes of cytochrome *b* are near the two sides of the membrane, and the Fe–S and cytochrome c_1 subunits are on the surface next to the intermembrane space (Fig. 18-8). On the matrix side (bottom in Fig. 18-8A) are two large ~440 residue "core" subunits that resemble subunits of the mitochondrial processing protease. They may be evolutionary relics of that enzyme.[106,108,108a] Mitochondrial cytochrome b_H has an $E°'$ value of +0.050 V, while that of b_L is −0.090 V at pH 7.[109] That of the Rieske Fe–S protein is + 0.28 V.[110]

The sequence of electron transport within complex III has been hard to determine in detail. For reasons discussed in Section C, the "Q-cycle" shown in Fig. 18-9 has been proposed.[111–114a] As is indicated in Fig. 18-9, complex II accepts electrons from QH_2 and passes them consecutively to the Fe–S protein, cytochrome c_1, and the external cytochrome *c*. However, half of the electrons are recycled through the two heme groups of cytochrome *b*, as is indicated in the figure and explained in the legend. The X-ray structure (Fig. 18-8) is consistent with this interpretation. Especially intriguing is the fact that the Fe_2S_2 cluster of the Rieske protein subunit has been observed in two or three different conformations.[105–107,114a-c] In Fig. 18-8C the structures of two conformations are superimposed. The position of the long helix at the right side is unchanged but the globular domain at the top can be tilted up to bring the Fe_2S_2 cluster close to the heme of cytochrome c_1, or down to bring the cluster close to heme b_L. Movement between these two positions is probably part of the catalytic cycle.[115]

The simpler cytochrome bc_1 complexes of bacteria such as *E. coli*,[102] *Paracoccus dentrificans*,[116] and the photosynthetic *Rhodobacter capsulatus*[117] all appear to function in a manner similar to that of the large mitochondrial complex. The bc_1 complex of *Bacillus subtilis* oxidizes reduced **menaquinone** (Fig. 15-24) rather than ubiquinol.[118] In chloroplasts of green plants photochemically reduced **plastoquinone** is oxidized by a similar complex of cytochrome *b*, *c*-type cytochrome *f*, and a Rieske Fe–S protein.[119–120a] This cytochrome b_6f complex delivers electrons to the copper protein plastocyanin (Fig. 23-18).

The electron acceptor for complex III is cytochrome *c*, which, unlike the other cytochromes, is water soluble and easily released from mitochondrial membranes. Nevertheless, it is usually present in a roughly 1:1 ratio with the fixed cytochromes, and it seems unlikely that it is as free to diffuse as are ubiquinone and NAD^+.[121,122] However, a small fraction of the cytochrome *c* may diffuse through the intermembrane space and accept electrons from cytochrome b_5, which is located in the outer membrane.[123] Cytochrome *c* forms a complex with cardiolipin (diphosphatidylglycerol), a characteristic component of the inner mitochondrial membrane.[124]

Complex IV. Cytochrome c oxidase (ubiquinol-cytochrome c oxidoreductase). Complex IV from mammalian mitochondria contains 13 subunits. All of them have been sequenced, and the three-dimensional structure of the complete complex is known (Fig. 18-10).[125–127] The simpler cytochrome *c* oxidase from *Paracoccus denitrificans* is similar but consists of only three subunits. These are homologous in sequence to those of the large subunits I, II, and III of the mitochondrial complex. The three-dimensional structure of the *Paracoccus* complex is also known. Its basic structure is nearly identical to that of the catalytic core of subunits I, II, and III of the mitochondrial complex (Fig. 18-10,A).[128] All three subunits have transmembrane helices. Subunit III seems to be structural in function, while subunits I and II contain the oxidoreductase centers: two hemes *a* (*a* and a_3) and two different copper centers, Cu_A (which contains two Cu^{2+}) and a third Cu^{2+} (Cu_B) which exists in an EPR-silent exchange coupled pair with a_3. Bound Mg^{2+} and Zn^{2+} are also present in the locations indicated in Fig. 18-10.

The Cu_A center has an unusual structure.[130–132] It was thought to be a single atom of copper until the three-dimensional structure revealed a dimetal center, whose structure follows. The Cu_B-cytochrome a_3 center is also unusual. A histidine ring is covalently attached to tyrosine.[133–135a] Like the tyrosine in the active site of galactose oxidase (Figs. 16-29, 16-30), which carries a covalently joined cysteine, that of cytochrome oxidase may be a site of tyrosyl radical formation.[135]

Cytochrome *c* oxidase accepts four electrons, one at a time from cytochrome *c*, and uses them to reduce O_2 to two H_2O. Electrons enter the oxidase via the Cu_A center and from there pass to the cytochrome *a* and on to the cytochrome $a_3 - Cu_B$ center where the reduction of O_2 takes place. A possible sequence of steps in the catalytic cycle is given in Fig. 18-11. Reduction of O_2 to two H_2O requires four electrons and also four protons. An additional four protons are evidently pumped across the membrane for each catalytic cycle.[136–138] The overall reaction is:

$$4\,e^- + 8\,H^+_{IN} + O_2 \longrightarrow 2\,H_2O + 4\,H^+_{OUT} \qquad (18\text{-}5)$$

The reaction of O_2 with cytochrome *c* oxidase to form the oxygenated species A (Fig. 18-11) is very rapid, occurring with apparent lifetime τ (Eq. 9-5) of ~8–10 μs.[139] Study of such rapid reactions has depended upon a flow-flash technique developed by Greenwood and Gibson.[136,140,141] Fully reduced cytochrome oxidase is allowed to react with carbon monoxide, which binds to the iron in cytochrome a_3 just as does O_2. In fact, it was the spectroscopic observation that only half of the

Quinones, phospholipids, and detergent molecules are not shown for clarity. The presumed membrane bilayer is represented by a gray band. (B) Isolated close-up view of the two conformations of the Rieske protein (top and long helix at right) in contact with cytochrome *b* (below), with associated heme groups and bound inhibitors, stigmatellin, and antimycin. The isolated heme of cytochrome c_1 (left, above) is also shown. (C) Structure of the intermembrane (external surface) domains of the chicken bc_1 complex. This is viewed from within the membrane, with the transmembrane helices truncated at roughly the membrane surface. Ball-and-stick models represent the heme group of cytochrome c_1, the Rieske iron–sulfur cluster, and the disulfide cysteines of subunit 8. SU, subunit; cyt, cytochrome. From Zhang *et al.*[105]

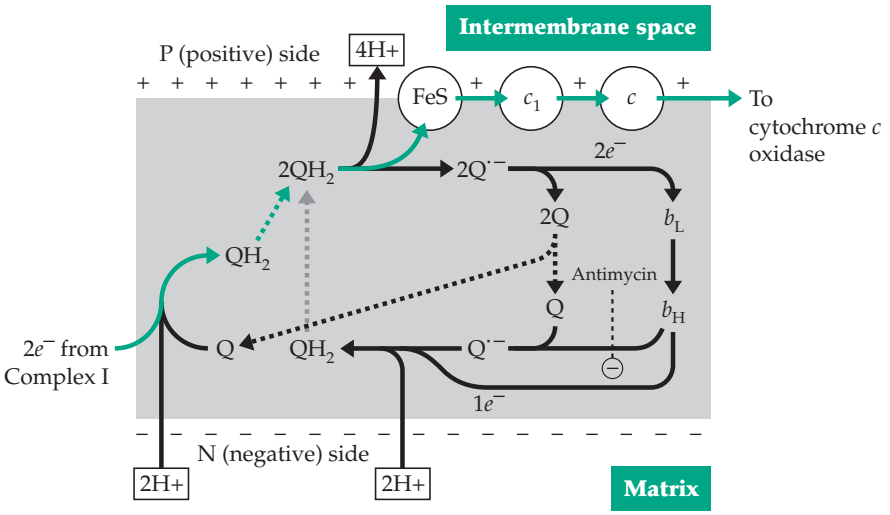

Figure 18-9 Proposed routes of electron transfer in mitochondrial complex III according to Peter Mitchell's Q cycle. Ubiquinone (Q) is reduced to QH_2 by complex I (left side of diagram) using two H^+ taken up from the matrix (leaving negative charges on the inner membrane surface). After diffusing across the bilayer (dashed line) the QH_2 is oxidized in the two steps with release of the two protons per QH_2 on the positive (P) side of the membrane. In the two-step oxidation via anionic radical Q^- one electron flows via the Rieske Fe–S protein and the cytochrome c_1 heme to external cytochrome c. The other electron is transferred to heme b_L of cytochrome b, then across the membrane to heme b_H which now reduces Q to Q^-. A second QH_2 is dehydrogenated in the same fashion and the electron passed through the cytochrome b centers is used to reduce Q^- to QH_2 with uptake from the matrix of 2 H^+. The resulting QH_2 diffuses back across the membrane to function again while the other Q diffuses back to complex I. The net result is pumping of 4 H^+ per 2 e^- passed through the complex. Notice that in the orientation used in this figure the matrix is at the bottom, not the top as in Figs. 18-4 and 18-5.

cytochrome a combined with CO that led Keilin to designate the reactive component a_3. This CO complex is mixed with O_2-containing buffer and irradiated with a laser pulse to release the CO and allow O_2 to react. The first rapid reaction observed is the binding of O_2 (step c in Fig. 18-11). Formation of a peroxy intermediate from the initial oxygenated form (A in Fig. 18-11) is very fast. The O – O bond of O_2 has already been cleaved in form P (Fig. 18-11), which has until recently been thought to be the peroxy intermediate. In fact, spectroscopic measurements indicate that form P contains an oxo-ferryl ion with the second oxygen of the original O_2 converted to an OH ion and probably coordinated with Cu_B.[136a,136c,142,142a–c] P may also contain an organic radical, perhaps formed from tyrosine 244 as indicated in Fig. 18-11.

A second relaxation time of $\tau = 32–45$ μs has been assigned[139] to the conversion of the peroxide intermediate P to P′. A third relaxation time ($\tau = 100–140$ μs) is associated with the oxidation of Cu_A by a (not shown in Fig. 18-11).[143] This electron transfer step limits the rate of step f of Fig. 18-11. Another reduction step with $\tau \sim 1.2$ ms is apparently associated with electron transfer in step h. This slowest step still allows a first-order reaction rate of ~800 s^{-1}.

When O_2 reacts with cytochrome c oxidase, it may be bound initially to either the a_3 iron or to Cu_B, but in the peroxy intermediate P it may bind to both atoms. Oxyferryl compound F (Fig. 8-11) as well as radical species, can also be formed by treatment of the oxidized

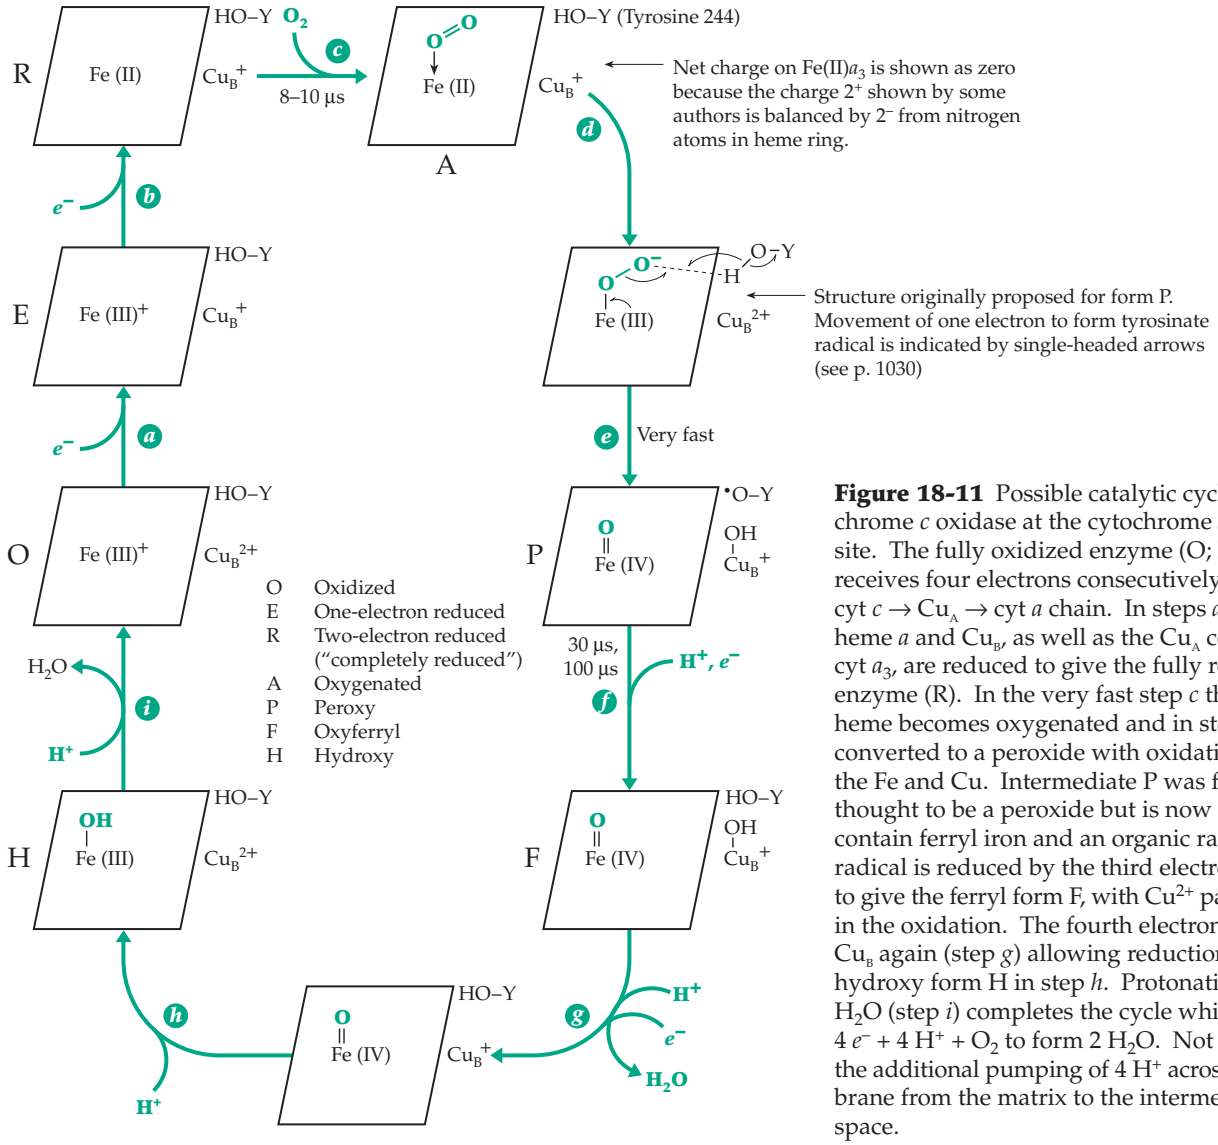

Figure 18-11 Possible catalytic cycle of cytochrome *c* oxidase at the cytochrome $a_3 - Cu_B$ site. The fully oxidized enzyme (O; left center) receives four electrons consecutively from the cyt $c \rightarrow Cu_A \rightarrow$ cyt *a* chain. In steps *a* and *b* both heme *a* and Cu_B, as well as the Cu_A center and cyt a_3, are reduced to give the fully reduced enzyme (R). In the very fast step *c* the cyt a_3 heme becomes oxygenated and in step *d* is converted to a peroxide with oxidation of both the Fe and Cu. Intermediate P was formerly thought to be a peroxide but is now thought to contain ferryl iron and an organic radical. This radical is reduced by the third electron in step *f* to give the ferryl form F, with Cu^{2+} participating in the oxidation. The fourth electron reduces Cu_B again (step *g*) allowing reduction to the hydroxy form H in step *h*. Protonation to form H_2O (step *i*) completes the cycle which utilizes 4 e^- + 4 H^+ + O_2 to form 2 H_2O. Not shown is the additional pumping of 4 H^+ across the membrane from the matrix to the intermembrane space.

enzyme O with hydrogen peroxide.[143a-144] Use of various inhibitors has also been important in studying this enzyme. Cyanide, azide, and sulfide ions, as well as carbon monoxide, are powerful inhibitors. Cyanide specifically binds to the Fe^{3+} form of cytochrome a_3 preventing its reduction,[145] while CO competes with O_2 for its binding site. A much-used reagent that modifies carboxyl groups in proteins, and which inhibits many proton translocating proteins, is dicyclohexyl carbodiimide (Eq. 3-10).[146] The step-by-step flow of electrons through cytochrome *c* oxidase seems quite well defined. However, one of the most important aspects is unclear. How is the pumping of protons across the membrane coupled to electron transport?[137,138,142,147,147a] Many recent studies have employed directed mutation of residues in all four subunits to locate possible proton pathways or channels.[148–152] Most ideas involve movement through hydrogen bonded chains (Eq. 9-94), which may include the carboxylate groups of the bound hemes.[153] Conformational changes may be essential to the gating of proton flow by electron transfers.[143]

The surface of the matrix side of cytochrome oxidase contains histidine and aspartate side chains close together. It has been suggested that they form a proton collecting antenna that contains groups basic enough to extract protons from the buffered matrix and guide them to a proton conduction pathway.[154] Calcium ions also affect proton flow.[153a,b] We will return to this topic in Section C,3 (p. 1040).

C. Oxidative Phosphorylation

During the 1940s when it had become clear that formation of ATP from ADP and inorganic phosphate

was coupled to electron transport in mitochondria, intensive efforts were made to discover the molecular mechanisms. However, nature sometimes strongly resists attempts to pry out her secrets, and the situation which prevailed was aptly summarized by Ephraim Racker: "Anyone who is not confused about oxidative phosphorylation just doesn't understand the situation."[155] The confusion is only now being resolved.

1. The Stoichiometry (P/O Ratio) and Sites of Oxidative Phosphorylation

Synthesis of ATP *in vitro* by tissue homogenates was demonstrated in 1937 by Kalckar, who has written a historical account.[156] In 1941, Ochoa[157] obtained the first reliable measurement of the P/O ratio, the *number of moles of ATP generated per atom of oxygen utilized* in respiration. The P/O ratio is also equal to the number of moles of ATP formed for each pair of electrons passing through an electron transport chain. Ochoa established that for the oxidation of pyruvate to acetyl-CoA and CO_2, with two electrons passed down the mitochondrial electron transport chain, the P/O ratio was ~3. This value has since been confirmed many times.[158–160] However, experimental difficulties in measuring the P/O ratio are numerous.[161] Many errors have been made, even in recent years, and some investigators[162] have contended that this ratio is closer to 2.5 than to 3. One method for measuring the P/O ratio is based on the method of determining the amount of ATP used that is described in the legend to Fig. 15-2.

The experimental observation of a P/O ratio of ~3 for oxidation of pyruvate and other substrates that donate NADH to the electron transport chain led to the concept that there are *three sites for generation of ATP*. It was soon shown that the P/O ratio was only 2 for oxidation of succinate. This suggested that one of the sites (site I) is located between NADH and ubiquinone and precedes the diffusion of QH_2 formed in the succinate pathway to complex III.

In 1949, Lehninger used ascorbate plus tetramethylphenylene-diamine (TMPD, Table 18-4) to introduce electrons into the chain at cytochrome *c*. The sequence ascorbate → TMPD → cytochrome *c* was shown to occur nonenzymatically. Later, it became possible to use cytochrome *c* as an electron donor directly. In either case only one ATP was generated, as would be anticipated if only site III were found to the right of cytochrome *c*. Site I was further localized by Lardy, who used hexacyanoferrate (III) (ferricyanide) as an artificial oxidant to oxidize NADH in the presence of antimycin *a*. Again a P/O ratio of one was observed. Finally, in 1955, Slater showed that passage of electrons from succinate to cytochrome c also gave only one ATP, the one generated at site II. The concept of three sites of ATP formation became generally accepted. However, as we shall see, these sites are actually proton-pumping sites, and there may be more than three of them.

Respiratory control and uncoupling. With proper care relatively undamaged mitochondria can be isolated. Such mitochondria are said to be **tightly coupled**. By this we mean that electrons cannot pass through the electron transport chain without generation of ATP. If the concentration of ADP or of P_i becomes too low, both phosphorylation and respiration cease. This **respiratory control** by ADP and P_i is a property of undamaged mitochondria. It may seem surprising that damaged mitochondria or submitochondrial particles are often able to transfer electrons at a faster rate than do undamaged mitochondria. However, electron transfer in damaged mitochondria occurs *without synthesis of ATP* and with no slowdown as the ADP concentration drops. A related kind of **uncoupling** of electron transport from ATP synthesis is brought about by various lipophilic anions called **uncouplers**, the best known of which is **2,4-dinitrophenol**. Even before the phenomenon of uncoupling was discovered, it had been known that dinitrophenol substantially increased the respiration rates of animals. The compound had even been used (with some fatal results) in weight control pills. The chemical basis of uncoupling will be considered in Section D.

"States" of mitochondria and spectrophotometric observation. Chance and Williams defined five **states** of tightly coupled mitochondria[60,163]; of these, states 3 and 4 are most often mentioned. If no oxidizable substrate or ADP is added the mitochondria have a very low rate of oxygen uptake and are in state 1. If oxidizable substrate and ADP are added rapid O_2 uptake is observed, the rate depending upon the rate of flow of electrons through the electron transport chain. This is state 3. As respiration occurs the coupled phosphorylation converts ADP into ATP, exhausting the ADP. Respiration slows to a very low value and the mitochondria are in state 4. If the substrate is present in excess, addition of more ADP will return the mitochondria to state 3.

Chance and associates employed spectrophotometry on intact mitochondria or submitochondrial particles to investigate both the sequence of carriers and the sites of phosphorylation. Using the dual wavelength spectrophotometer, the light absorption at the absorption maximum (λ_{max}) of a particular component was followed relative to the absorption at some other reference wavelength (λ_{ref}). The principal wavelengths used are given in Table 18-6. From these measurements the state of oxidation or reduction of each one of the carriers could be observed in the various states and in the presence of inhibitors. The

TABLE 18-6
Wavelengths of Light Used to Measure States of Oxidation of Carriers in the Electron Transport Chain of Mitochondria[a]

Carrier	λ_{max} (nm)[b]	λ_{ref} (nm)

experiments served to establish that electrons passing down the chain do indeed reside for a certain length of time on particular carriers. That is, in a given state each carrier exists in a defined ratio of oxidized to reduced forms ([ox] / [red]). Such a result would not be seen if the entire chain functioned in a cooperative manner with electrons passing from the beginning to the end in a single reaction. By observing changes in the ratio [ox] / [red] under different conditions, some localization of the three phosphorylation sites could be made. In one experiment antimycin *a* was added to block the chain ahead of cytochrome c_1. Then tightly coupled mitochondria were allowed to go into state 4 by depletion of ADP. Since the concentration of oxygen was high and cytochrome a_3 has a low K_m for O_2 (~3 μM) cytochrome a_3 was in a highly oxidized state. Cytochrome *a* was also observed to be oxidized, while cytochrome c_1 and *c* remained reduced. The presence of this **crossover point** suggested at the time that cytochrome *c* might be at or near one of the "energy conservation sites." Accounts of more recent experiments using the same approach are given by Wilson *et al*.[164]

2. Thermodynamics and Reverse Electron Flow

From Table 6-8 the value of $\Delta G'$ for oxidation of one mole of NADH by oxygen (1 atm) is −219 kJ. At a pressure of ~10^{-2} atm O_2 in tissues the value is −213 kJ. However, when the reaction is coupled to the synthesis of three molecules of ATP ($\Delta G'$ = +34.5 kJ mol^{-1}) the net Gibbs energy change for the overall reaction becomes $\Delta G'$ = −110 kJ mol^{-1}. This is still very negative. However, we must remember that the concentrations of ATP, ADP, and P_i can depart greatly from the 1:1:1 ratio implied by the $\Delta G'$ value.

An interesting experiment is to allow oxidative phosphorylation to proceed until the mitochondria reach state 4 and to measure the **phosphorylation state ratio R_p**, which equals the value of [ATP] / [ADP][P_i] that is attained. This mass action ratio, which has also been called the "phosphorylation ratio" or "phosphorylation potential" (see Chapter 6 and Eq. 6-29), often reaches values greater than 10^4–10^5 M^{-1} in the cytosol.[164] An extrapolated value for a zero rate of ATP hydrolysis of log R_p = 6.9 was estimated. This corresponds (Eq. 6-29) to an increase in group transfer potential (ΔG of hydrolysis of ATP) of 39 kJ/mol. It follows that the overall value of ΔG for oxidation of NADH in the coupled electron transport chain is less negative than is $\Delta G'$. If synthesis of three molecules of ATP is coupled to electron transport, the system should reach an equilibrium when $R_p = 10^{6.4}$ at 25°C, the difference in ΔG and $\Delta G'$ being 3RT ln Rp = 3 x 5.708 x 6.4 = 110 kJ mol^{-1}. This value of Rp is, within experimental error, the same as the maximum value observed.[165] There apparently is an almost true equilibrium among NADH, O_2, and the adenylate system if the P/O ratio is 3.

Within more restricted parts of the chain it is possible to have *reversed electron flow*. Consider the passage of electrons from NADH, partway through the chain, and back out to fumarate, the oxidized form of the succinate–fumarate couple. The Gibbs energy change $\Delta G'$ (pH 7) for oxidation of NADH by fumarate is −67.7 kJ mol^{-1}. In uncoupled mitochondria electron flow would always be from NADH to fumarate. However, in tightly coupled mitochondria, in which ATP is being generated at site I, the overall value of $\Delta G'$ becomes much less negative. If $R_p = 10^4$ M^{-1}, $\Delta G'$ for the coupled process becomes approximately zero (−67.7 + 68 kJ mol^{-1}). Electron flow can easily be reversed so that succinate reduces NAD^+. Such ATP-driven reverse flow occurs under some physiological conditions within mitochondria of living cells, and some anaerobic bacteria generate all of their NADH by reversed electron flow (see Section E).

Another experiment involving equilibration with the electron transport chain is to measure the "observed potential" of a carrier in the chain as a function of the concentrations of ATP, ADP, and P_i. The observed

potential E is obtained by measuring log([ox] / [red]) and applying Eq. 18-6 in which $E°'$ is the known midpoint potential of the couple (Table 6-8) and n is the number of electrons required to reduce one molecule of the carrier. If the system is equilibrated with a "redox buffer" (Chapter 6), E can be fixed at a preselected value. For example, a 1:1 mixture of succinate and fumarate would fix E at +0.03 V while the couple 3-hydroxybutyrate-acetoacetate in a 1:1 ratio would fix it at $E°' = -0.266$ V. Consider the potential of cytochrome b_{562} (b_H), which has an $E°'$ value of 0.030 V. Substituting this in Eq. 18-7 and using $E = -0.266$ V (as obtained by equilibration with 3-hydroxybutyrate–acetoacetate), it is easy to calculate that at equilibrium the ratio [ox] / [red] for cytochrome b_{562} is about 10^{-5}. In other words, in the absence of O_2 this cytochrome will be kept almost completely in the reduced form in an uncoupled mitochondrion.

$$E = \frac{-\Delta G}{nF} = E°' + \frac{0.0592}{n}\log\frac{[\text{ox}]}{[\text{red}]} = \text{observed potential of carrier} \quad (18\text{-}6)$$

However, if the electron transport between 3-hydroxybutyrate and cytochrome b_{562} is tightly coupled to the synthesis of one molecule of ATP, the observed potential of the carrier will be determined not only by the imposed potential E_i of the equilibrating system but also by the phosphorylation state ratio of the adenylate system (Eq. 18-7). Here $\Delta G'_{ATP}$ is the group transfer potential ($-\Delta G'$ of hydrolysis) of ATP at pH 7 (Table 6-6), and n' is the number of electrons passing through the chain required to synthesize one ATP. In the upper part of the equation n is the number of electrons required to reduce the carrier, namely one in the case of cytochrome b_{562}.

From Eq. 18-7 it is clear that in the presence of a high phosphorylation state ratio a significant fraction of cytochrome b_{562} may remain in the reduced form at equilibrium. Thus, if $R_p = 10^4$, if $E°'$ for cytochrome b_{562} is 0.030 V, if $n' = 2$, and the potential E is fixed at –0.25 V using the hydroxybutyrate–acetoacetate couple, we calculate, from Eq. 18-7, that the ratio [ox] / [red] for cytochrome b_{562} will be 1.75. Now, if R_p is varied the observed potential of the carrier should change as predicted by Eq. 18-7. This variation has been observed.[164] For a tenfold change in R_p the observed potential of cytochrome b_{562} changed by 0.030 V, just that predicted if $n' = 2$. On the other hand, the observed potential of cytochrome c varied by 0.059 V for every tenfold change in the ratio. This is just as expected if $n' = 2$, and if synthesis of two molecules of

$$E(\text{observed}) = E^{\circ\prime} + \frac{0.0592}{n}\log_{10}\frac{[\text{ox}]}{[\text{red}]}$$
$$= E_i + \frac{\Delta G'_{\text{ATP}}}{96.5n'} + \frac{RT}{n'F}\ln\frac{[\text{ATP}]}{[\text{ADP}][\text{P}_i]}$$
$$= E_i + \frac{0.358}{n'} + \frac{0.0592}{n'}\log_{10} R_{\text{P}} \qquad (18\text{-}7)$$

ATP is coupled to the electron transport to cytochrome *c*. Thus, we have experimental evidence that when one-electron carriers such as the cytochromes are involved, the passage of *two electrons* is required to synthesize one molecule of ATP. Furthermore, from experiments of this type it was concluded that the sites of phosphorylation were localized in or related to complexes I, III, and IV.

Another kind of experiment is to equilibrate the electron transport chain with an external redox pair of known potential using *uncoupled* mitochondria. The value of $E^{\circ\prime}$ of a particular carrier can then be measured by observation of the ratio [ox] / [red] and applying Eq. 18-7. While changes in the equilibrating potential E will be reflected by changes in [ox] / [red] the value of $E^{\circ\prime}$ will remain constant. The $E^{\circ\prime}$ values of Fe–S proteins and copper atoms in the electron transport chain have been obtained by equilibrating mitochondria, then rapidly freezing them in liquid nitrogen, and observing the ratios [ox] / [red] by EPR at 77K (Table 18-7).

The values of $E^{\circ\prime}$ of the mitochondrial carriers fall into four **isopotential groups** at ~−0.30, ~0, ~+0.22, and ~+0.39 V (Table 18-7). When tightly coupled mitochondria are allowed to go into state 4 (low ADP, high ATP, O_2 present but low respiration rate), the observed potentials change. That of the lowest isopotential group (which includes NAD^+/ NADH) falls to ~−0.38 V, corresponding to a high state of reduction of the carriers to the left of the first phosphorylation site in Fig. 18-4. Groups 2 and 3 remain close to their midpoint potentials at ~−0.05 and +0.26 V. In this condition the potential difference between each successive group of carriers amounts to ~0.32 V, just enough to balance the formation of one molecule of ATP for each two electrons passed at a ratio $R_p \approx 10^4$ M^{-1} (Eq. 18-7).

Two cytochromes show exceptional behavior and appear twice in Table 18-7. The midpoint potential $E^{\circ\prime}$ of cytochrome b_{566} (b_L) changes from −0.030 V in the absence of ATP to +0.245 V in the presence of a high concentration of ATP. On the other hand, $E^{\circ\prime}$ for cytochrome a_3 drops from +0.385 to 0.155 V in the presence of ATP. These shifts in potential must be related to the coupling of electron transport to phosphorylation.

3. The Mechanism of Oxidative Phosphorylation

It was natural to compare mitochondrial ATP synthesis with substrate-level phosphorylations, in which high-energy intermediates are generated *by the passage of electrons through the substrates*. The best known example is oxidation of the aldehyde group of glyceraldehyde 3-phosphate to an acyl phosphate, which, after transfer of the phospho group to ADP, becomes a carboxylate group (Fig. 15-6). The Gibbs energy of oxidation of the aldehyde to the carboxylate group provides the energy for the synthesis of ATP. However, this reaction differs from mitochondrial electron transport in that *the product, 3-phosphoglycerate, is not reconverted to glyceraldehyde 3-phosphate*. Electron carriers of the respiratory chain must be regenerated in some cyclic process. Because of this, it was difficult to imagine practical mechanisms for oxidative phosphorylation that could be related to those of substrate level phosphorylation. Nevertheless, many efforts were made over a period of several decades to find such high-energy intermediates.

Search for chemical intermediates. An early hypothetical model, proposed by Lipmann,[166] is shown in Fig. 18-12. Here A, B, and C are three electron carriers in the electron transport chain. Carrier C is a better oxidizing agent than B or A. Carrier B has some special chemistry that permits it, in the reduced state, to react with group Y of a protein (step *b*) to form Y–BH_2. The latter, an unidentified adduct, is converted by oxidation with carrier C (step *c*) to a "high energy" oxidized form indicated as Y ~ B. Once the possibility of generating such an intermediate is conceded, it is easy to imagine plausible ways in which the energy of this intermediate could be transferred into forms with which we are already familiar. For example, another protein X could react (step *d*) to form X ~ Y in which the X ~ Y linkage could be a thioester, an acyl phosphate, or other high-energy form. Furthermore, it might not be necessary to have two proteins; X and Y could be different functional groups of the same protein. They might be nonprotein components, e.g., Y might be a phospholipid.

Generation of ATP by the remaining reactions (steps *e* and *f* of Fig. 18-12) is straightforward. For example, if X ~ Y were a thioester the reactions would be the reverse of Eq. 12-48. These reaction steps would also be responsible for observed exchange reactions, for example, the mitochondrially catalyzed exchange of inorganic phosphate ($H^{32}PO_4^{2-}$) into the terminal position of ATP. Mitochondria and submitochondrial particles also contain ATP-hydrolyzing **(ATPase)** activity, which is thought to depend upon the same machinery that synthesizes ATP in tightly coupled mitochondria. In the scheme of Fig. 18-12, ATPase

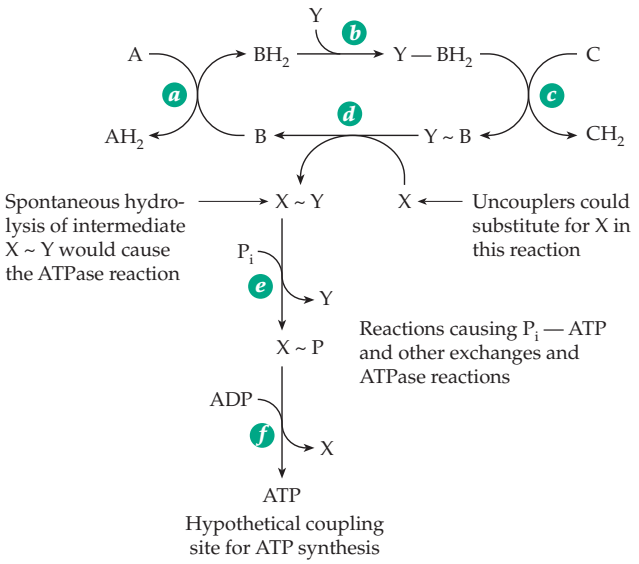

Figure 18-12 An early proposal for formation of ATP via "high-energy" chemical intermediates.

activity would be observed if hydrolysis of X ~ Y were to occur. Partial disruption of the system would lead to increased ATPase reactivity, as is observed. Uncouplers such as the dinitrophenolate ion or arsenate ion, acting as nucleophilic displacing groups, could substitute for a group such as X. Spontaneous breakdown of labile intermediates would permit oxidation to proceed unimpaired. Since there are three different sites of phosphorylation, we might expect to have three different enzymes of the type Y in the scheme of Fig. 18-12, but it would be necessary to have only one X.

In Lipmann's original scheme group Y was visualized as adding to a carbon–carbon double bond to initiate the sequence. Isotopic exchange reactions ruled out the possibility that either ADP or P_i might serve as Y, but it was attractive to think that a bound phosphate ion, e.g., in a phospholipid or coenzyme, could be involved. Y ~ B of Fig. 18-12 would be similar in reactivity to an acyl phosphate or thioester. However, whatever the nature of Y ~ B, part of group Y would be left attached to B after the transfer of Y to X. For example, if Y were Y'OH compound X ~ OY' would be formed, and the carrier would be left in step *d* in the form of B–OH. Elimination of a hydroxyl group would be required to regenerate B. Perhaps nature has shunned this mechanism because there is no easy way to accomplish such an elimination. Many variations on the scheme of Fig. 18-12 were proposed,[166] and some were discussed in the first edition of this textbook.[167] However, as attractive as these ideas may have seemed, *all attempts to identify discrete intermediates that might represent X ~ Y failed. Furthermore, most claims to have seen Y ~ B by any means have been disproved.*

Peter Mitchell's chemiosmotic theory. To account for the inability to identify high energy intermediates as well as the apparent necessity for an intact membrane, Peter Mitchell, in 1961, offered his **chemiosmotic theory** of oxidative phosphorylation.[168–175a] aThis theory also accounts for the existence of **energy-linked processes** such as the accumulation of cations by mitochondria. The principal features of the Mitchell theory are illustrated in Fig. 18-13. Mitchell proposed

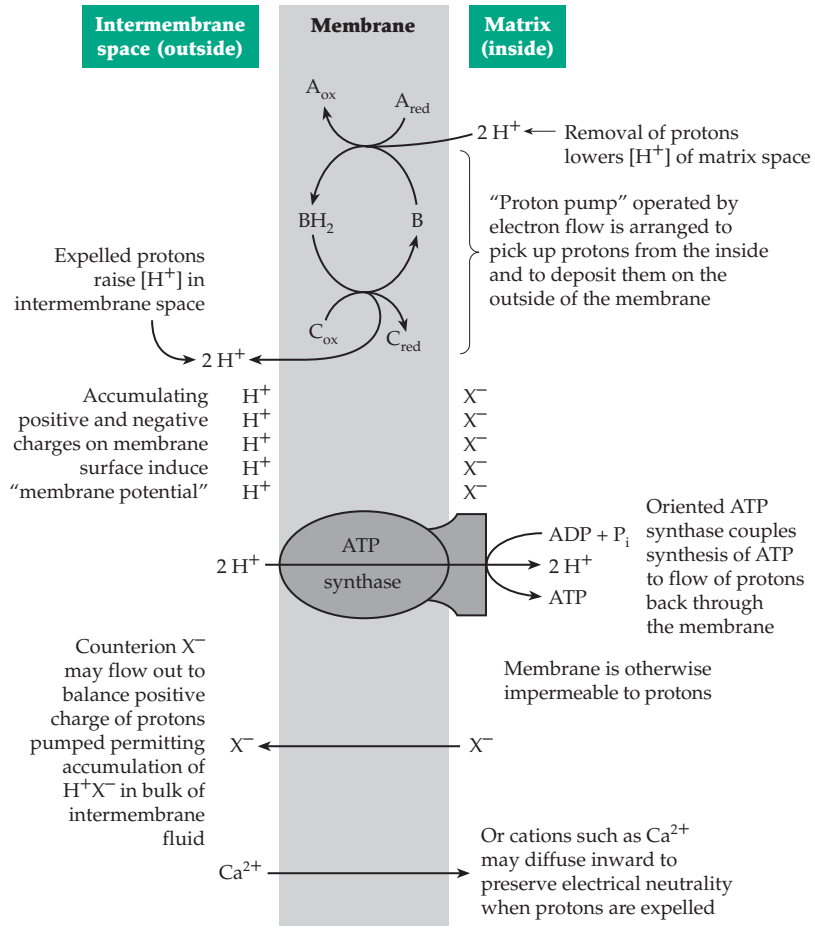

Figure 18-13 Principal features of Mitchell's chemiosmotic theory of oxidative phosphorylation.

that the inner membrane of the mitochondrion is a closed, proton-impermeable **coupling membrane**, which contains **proton pumps** operated by electron flow and which cause protons to be expelled through the membrane from the matrix space. As indicated in Fig. 18-13, an oxidized carrier B, upon reduction to BH_2, acquires two protons. These protons do not necessarily come from reduced carrier AH_2, and Mitchell proposed that they are picked up from the solvent on the matrix side of the membrane. Then, when BH_2 is reoxidized by carrier C, protons are released on the outside of the membrane. On the basis of existing data, *Mitchell assumed a stoichiometry of two protons expelled for each ATP synthesized*. It followed that there should be three different proton pumps in the electron transport chain corresponding to the three phosphorylation sites.

The postulated proton pumps would lead either to bulk accumulation of protons in the intermembrane space and cytoplasm, with a corresponding drop in pH, *or to an accumulation of protons along the membrane itself*. The latter would be expected if counterions X^- do not pass through the membrane with the protons. The result in such a case would be the development of a **membrane potential**, a phenomenon already well documented for nerve membranes (Chapter 8).

A fundamental postulate of the chemiosmotic theory is the presence of an oriented ATP synthase that utilizes the Gibbs energy difference of the proton gradient to drive the synthesis of ATP (Fig. 18-9). Since $\Delta G'$ (pH 7) for ATP synthesis is +34.5 kJ mol^{-1} and, if as was assumed by Mitchell, the passage of two protons through the ATP synthase is required to form one ATP, the necessary pH gradient (given by Eq. 6-25 or Eq. 18-9 with $E_m = 0$) would be 34.5/(2 x 5.708) = 3.0 pH units at 25°C. On the other hand, if the phosphorylation state ratio is ~10^4 M^{-1}, the pH difference would have to be 5 units. Most investigators now think that 4 H^+ per ATP are needed by the synthase. If so, a pH difference of 2.5 units would be adequate. Various experiments have shown that passage of electrons does induce a pH difference, and that an artifically induced pH difference across mitochondrial membranes leads to ATP synthesis. However, pH gradients of the required size have not been observed. Nevertheless, if the membrane were charged as indicated in Fig. 18-13, without accumulation of protons in the bulk medium, a membrane potential would be developed, and this could drive the ATP synthase, just as would a proton gradient.

The mitochondrial membrane potential E_m (or $\Delta\psi$) is the potential difference measured across a membrane relative to a reference electrode present in the surrounding solution.[176] For both mitochondria and bacteria E_m normally has a negative value. The Gibbs energy change $\Delta\psi_H+$ for transfer of one mole of H^+ from the inside of the mitochondrion to the outside, against the concentration and potential gradients, is given by Eq. 18-8. This equation follows directly from Eqs. 6-25

$$\begin{aligned}\Delta G_H + &= 2.303\, RT\, \Delta\text{pH} - E_m F \\ &= 5.708\, \Delta\text{pH} - 96.5\, E_m \text{ kJ/mol at 25°C}\end{aligned}$$
$$\text{where } \Delta\text{pH} = \text{pH (inside)} - \text{pH (outside)} \qquad (18\text{-}8)$$

and 6-63 with n = 1. The same information is conveyed in Eq. 18-9, which was proposed by Mitchell for what he calls the **total protonic potential difference Δp**.

$$\begin{aligned}p \text{ (volts)} &= E_m \text{(volts)} - 2.303\,\frac{RT}{F}\quad \text{pH} \\ \Delta p \text{ (mV)} &= E_m \text{(mV)} - 59.2\,\Delta \text{ pH at 25°C} \\ E_m &= \Delta\psi\end{aligned} \qquad (18\text{-}9)$$

Mitchell was struck by the parallel between the force and flow of electrons, which we call electricity, and the force and flow of protons, which he named **proticity**.[174] This led one headline writer in *Nature*[177] to describe Mitchell as "a man driven by proticity," but if Mitchell is right, as seems to be the case, we are all driven by proticity! Mitchell also talked about **protonmotive** processes and referred to Δp as the **protonmotive force**. Although it is a potential rather than a force, this latter name is a popular designation for Δp.

The reader should be aware that considerable confusion exists with respect to names and definitions.[176] For example, the ΔG_H+ of Eq. 18-8 can also be called the **proton electrochemical potential** $\Delta\mu_H+$, which is analogous to the chemical potential μ of an ion (Eq. 6-24) and has units of kJ/mol (Eq. 18-10).

$$\begin{aligned}-\Delta G_H+ &= \Delta\mu_H+ = F\,\Delta p \\ &= 96.5\,\Delta p \text{ kJ/mol at 25°C}\end{aligned} \qquad (18\text{-}10)$$

However, many authors use $\Delta\mu_H+$ as identical to the protonmotive force Δp.

From Eq. 18-9 or Eq. 18-10 it can be seen that a membrane potential E_m of −296 mV at 25°C would be equivalent to a 5.0 unit change in pH and would be sufficient, if coupled to ATP synthesis via 2 H^+, to raise R_p to 10^4 M^{-1}. Any combination of ΔpH and E_m providing Δp of −296 mV would also suffice. If the ratio H^+/ATP = 4, Δp of −148 mV would suffice.

The chemiosmotic hypothesis had the great virtue of predicting the following consequences which could be tested: (1) electron-transport driven proton pumps with defined stoichiometries and (2) a separate ATP synthase, which could be driven by a pH gradient or membrane potential. Mitchell's hypothesis was initially greeted with skepticism but it encouraged many people, including Mitchell and his associate Jennifer Moyle, to test these predictions, which were soon found to be correct.[178]

Observed values of E_m and pH. One of the problems[179] in testing Mitchell's ideas has been the difficulty of reliably measuring Δp. To evaluate the pH term in Eq. 18-10 measurements have been made with microelectrodes and indicator dyes. However, the most reliable approach has been to observe the distribution of weak acids and bases across the mitochondrial membrane.[180] This is usually done with a suspension of freshly isolated active mitochondria. The method has been applied widely using, for example, methylamine. A newer method employs an isotope exchange procedure to measure the pH-sensitive carbonic anhydrase activity naturally present in mitochondria.[181]

The measurement of E_m ($\Delta\psi$) is also difficult.[179] Three methods have been used: (1) measurement with microelectrodes; (2) observation of fluorescent probes; (3) distribution of permeant ions. Microelectrodes inserted into mitochondria[182] have failed to detect a significant value for E_m. Fluorescent probes are not very reliable,[179,183] leaving the distribution of permeant ions the method of choice. In this method a mitochondrial suspension is exposed to an ion that can cross the membrane but which is not pumped or subject to other influences that would affect its distribution. Under such conditions the ion will be distributed according to Eq. 18-11. The most commonly used ions are K^+, the same ion that is thought to reflect the membrane potential of nerve axons (Chapter 30), or Rb^+. To make the inner mitochondrial membrane permeable to K^+, valinomycin (Fig. 8-22) is added. The membrane potential, with n = 1 in Eq. 9-1, becomes:

$$E_m = -59.2\ ([K^+]_{inside} / [K^+]_{outside})\ \text{volts} \qquad (18\text{-}11)$$

In these experiments respiring mitochondria are observed to take up the K^+ or Rb^+ to give a high ratio of K^+ inside to that outside and consequently a negative E_m. There are problems inherent in the method. The introduction of a high concentration of ion perturbs the membrane potential, and there are uncertainties concerning the contribution of the Donnan equilibrium (Eq. 8-5) to the observed ion distribution.[184]

In most instances, either for mitochondrial suspensions or whole bacteria, ΔpH is less negative than −0.5 unit making a contribution of, at most, −30 mV to Δp. The exception is found in the thylakoid membranes of chloroplasts (Chapter 23) in which protons are pumped into the thylakoid vesicles and in which the internal pH falls dramatically upon illumination of the chloroplasts.[185] The ΔpH reaches a value of −3.0 or more units and Δp is ~180 mV, while E_m remains ~0. Reported values of E_m for mitochondria and bacteria range from −100 to −168 mV and Δp from −140 to −230 mV.[172,179] Wilson concluded that E_m for actively respiring mitochondria, using malate or glutamate as substrates, attains maximum (negative) values of E_m = −130 mV and Δp = −160 mV.[179] However, Tedeschi and associates[183,184] argued that E_m is nearly zero for liver mitochondria and seldom becomes more negative than −60 mV for any mitochondria.

A crucially important finding is that submitochondrial particles or vesicles from broken chloroplasts will synthesize ATP from ADP and P_i, when an artificial pH gradient is imposed.[172,186] Isolated purified F_1F_0 ATPase from a thermophilic *Bacillus* has been coreconstituted into liposomes with the light-driven proton pump **bacteriorhodopsin** (Chapter 23). Illumination induced ATP synthesis.[187] These observations support Mitchell's proposal that the ATP synthase is both spatially separate from the electron carriers in the membrane and utilizes the protonmotive force to make ATP. Thus, the passage of protons from the outside of the mitochondria back in through the ATP synthase induces the formation of ATP. What is the stoichiometry of this process?

It is very difficult to measure the flux of protons across the membrane either out of the mitochondria into the cytoplasm or from the cytoplasm through the ATP synthase into the mitochondria. Therefore, estimates of the stoichiometry have often been indirect. One argument is based on thermodynamics. If Δp attains values no more negative than −160 mV and R_p within mitochondria reaches at least $10^4\ M^{-1}$, we must couple ΔG_H of −15.4 kJ/mol to ΔG of formation of ATP of +57.3 kJ/mol. To do this four H^+ must be translocated per ATP formed. Recent experimental measurements with chloroplast ATP synthase[188] also favor four H^+. It is often proposed that one of these protons is used to pump ADP into the mitochondria via the ATP-ADP exchange carrier (Section D). Furthermore, if R_p reaches $10^6\ M^{-1}$ in the cytoplasm, it must exceed $10^4\ M^{-1}$ in the mitochondrial matrix.

Proton pumps driven by electron transport. What is the nature of the proton-translocating pumps that link Δp with electron transport? In his earliest proposals Mitchell suggested that electron carriers, such as flavins and ubiquinones, each of which accepts two protons as well as two electrons upon reduction, could serve as the proton carriers. Each pump would consist of a pair of oxidoreductases. One, on the inside (matrix side) of the coupling membrane, would deliver two electrons (but no protons) to the carrier (B in Fig. 18-13). The two protons needed for the reduction would be taken from the solvent in the matrix. The second oxidoreductase would be located on the outside of the membrane and would accept two electrons from the reduced carrier (BH_2 in Fig. 18-13) leaving the two released protons on the outside of the membrane. To complete a "loop" that would allow the next carrier to be reduced, electrons would have to be transferred through fixed electron carriers embedded in the

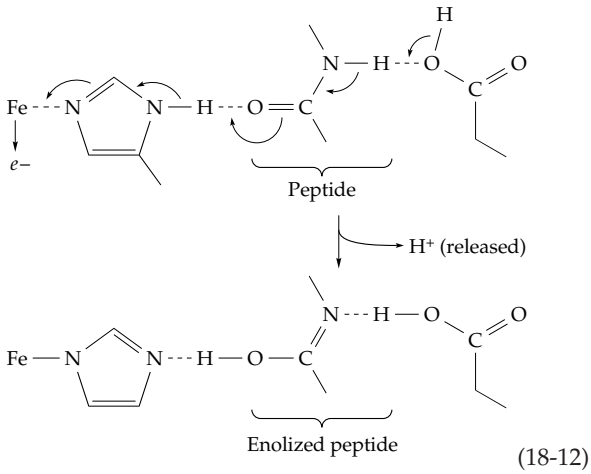
membrane from the reduced electron acceptor (C_{red} in Fig. 18-13) to the oxidized form of the oxidoreductase to be used as reductant for the next loop. These loops, located in complexes I and III of Fig. 18-5, would pump three protons per electron or six H^+/O. With a P/O ratio of three this would provide two H^+ per ATP formed. Mitchell regarded this stoichiometry as appropriate.

The flavin of NAD dehydrogenase was an obvious candidate for a carrier, as was ubiquinone. However, the third loop presented a problem. Mitchell's solution was the previously discussed **Q cycle**, which is shown in Fig. 18-9. This accomplishes the pumping in complex III of 2 H^+/e^-, the equivalent of two loops.[111] However, as we have seen, the magnitude of Δp suggests that 4 H^+, rather than 2 H^+, may be coupled to synthesis of one ATP. If this is true, mitochondria must pump 12 H^+/O rather than six when dehydrogenating NADH, or eight H^+/O when dehydrogenating succinate.

The stoichiometry of proton pumping was measured by Lehninger and associates using a fast-responding O_2 electrode and a glass pH electrode.[189,190] They observed an export of eight H^+/O for oxidation of succinate rat liver mitochondria in the presence of a permeant cation that would prevent the buildup of E_m, and four H^+/O (2 H^+/e^-) for the cytochrome oxidase system. These are equivalent to two H^+/e^- at each of sites II and III as is indicated in Fig. 18-4. Some others have found lower H^+/e^- ratios.

If two H^+/e^- are pumped out of mitochondria, where do we find the pumping sites? One possibility is that protons are pumped through the membrane by a **membrane Bohr effect**, so named for its similarity to the Bohr effect observed upon oxygenation of hemoglobin. In the latter case (Chapter 7), the pK_a values of certain imidazole and terminal amino groups are decreased when O_2 binds. This may result, in part, from an electrostatic effect of O_2 in inducing a partial positive charge in the heme. This partial charge may then cause a decrease in the pK_a values of nearby groups. Similarly, complete loss of an electronic charge from a heme group or an iron–sulfur protein in the electron transport chain would leave a positive charge, an electron "hole," which could induce a large change in the pK_a of a neighboring group. One manifestation of this phenomenon may be a strong pH dependence of the reduction potential (Eq. 16-19).

Protons that could logically be involved in a membrane Bohr effect are those present on imidazole rings coordinated to Fe or Cu in redox proteins. Removal of an electron from the metal ion could be accompanied by displacement of electrons within the imidazole, within a peptide group that is hydrogen-bonded to an imidazole, or within some other acidic group. A hypothetical example is illustrated in Eq. 18-12 in which a carboxyl group loses a proton when "handed" a second. If the transiently enolized peptide linkage formed in



(18-12)

this process is tautomerized back to its original state before the iron is reduced again, the proton originally present on the carboxyl group will be released. It is easy to imagine that a proton could then be "ferried" in (as in Eq. 9-96) from the opposite side of the membrane to reprotonate the imidazole group and complete the pumping process.

In view of the large number of metal-containing electron carriers in the mitochondrial chain, there are many possible locations for proton pumps. However, the presence of the three isopotential groups of Table 18-7 suggests that the pumps are clustered in complexes I-III as pictured in Fig. 18-5. One site of pumping is known to be in the cytochrome *c* oxidase complex. When reconstituted into phospholipid, the purified complex does pump protons in response to electron transport, H^+/e^- ratios of ~1 being observed.[136,137,147,191] As mentioned in Section B,3 a large amount of experimental effort has been devoted to identifying proton transport pathways in cytochrome *c* oxidase and also in the cytochrome bc_1 (complex II).[192] Proton pumping appears to be coupled to chemical changes occurring between intermediates P and F of Fig. 18-11, between F and O,[136,193] and possibly between O and R.[137,138] Mechanisms involving direct coupling of chemical changes at the A_3Cu_B center and at the Cu_A dimetal center have been proposed.[147,194]

How do protons move from the pumping sites to ATP synthase molecules? Since protons, as H_3O^+, are sufficiently mobile, ordinary diffusion may suffice. Because of the membrane potential they will tend to stay close to the membrane surface, perhaps being transported on phosphatidylethanolamine head groups (see Chapter 8). According to the view of R. J. P. Williams protons are not translocated across the entire membrane by the proton pumps, but flow through the proteins of the membrane to the ATP synthase.[195] There the protons induce the necessary conformational changes to cause ATP synthesis. A related idea is that transient high-energy intermediates

generated by electron transport within membranes are proton-carrying conformational isomers. When an electron is removed from an electron-transporting metalloprotein, the resulting positively charged "hole" could be stable for some short time, while the protein diffused within the membrane until it encountered an F_0 protein of an ATP synthase. Then it might undergo an induced conformational change at the same time that it "handed" the Bohr effect proton of Eq. 18-14 to the F_0 protein and simultaneously induced a conformational change in that protein. The coupling of proton transport to conformational changes seems plausible, when we recall that the induction of conformational changes within proteins almost certainly involves rearrangement of hydrogen bonds.

A consequence of the chemiosmotic theory is that there is no need for an integral stoichiometry between protons pumped and ATP formed or for an integral P/O ratio. There are bound to be inefficiencies in coupling, and Δp is also used in ways other than synthesis of ATP.

4. ATP Synthase

In 1960, Racker and associates[196,197] discovered that the "knobs" or "little mushrooms" visible in negatively stained mitochondrial fragments or fragments of bacterial membranes possess ATP-hydrolyzing (**ATPase)** activity. Earlier the knob protein had been recognized as one of several **coupling factors** required for reconstitution of oxidative phosphorylation by submitochondrial particles.[197] Electron micrographs showed that the submitochondrial particles consist of closed vesicles derived from the mitochondrial cristae, and that the knobs (Fig. 18-14A) are on the *outside* of the vesicles. They can be shaken loose by ultrasonic oscillation with loss of phosphorylation and can be added back with restoration of phosphorylation. The knob protein became known as **coupling factor F_1**. Similar knobs present on the outside of the thylakoids became **CF_1**and those inside thermophilic bacteria **TF_1**. The ATPase activity of F_1 was a clue that *the knobs were really ATP synthase*. It also became clear that a portion of the ATP synthase is firmly embedded in the membranes. This part became known as **F_0**. Both the names F_1F_0 ATP synthase and F_1F_0 ATPase are applied to the complex, the two names describing different catalytic activities. The ATPase activity is usually not coupled to proton pumping but is a readily measurable property of the F_1 portion. In a well-coupled submitochondrial particle the ATPase activity will be coupled to proton transport and will represent a reversal of the ATP synthase activity.

The synthase structure. The F_1 complex has been isolated from *E. coli*,[204,205] other bacteria,[206,207] yeast,[208a,b] animal tissues,[199,209–211] and chloroplasts.[212–214] In every case it consists of five kinds of subunits with the stoichiometry $\alpha_3\beta_3\gamma\delta\varepsilon$.[214a,b] The F_0 complex of *E. coli* contains three subunits designated a,b, and c. All of these proteins are encoded in one gene cluster, the *unc* operon (named for uncoupled mutants), with the following order:

I	*B*	*E*	*F*	*H*	*A*	*G*	*D*	*C*	– – – Gene symbol
i	a	c	b	δ	α	γ	β	ε	– – – Subunit symbol

Here I is the regulatory gene (as in Fig. 28-1). The *E. coli* F_0 appears to have approximately the unusual stoichiometry $ab_2c_{9\text{-}11}$. This suggested the possibility that 12 c subunits form a ring with D_6 or D_{12} symmetry, the latter being illustrated in the structural proposal shown in Fig. 18-14E. However, crystallographic evidence suggests that there may be 10, not 12 subunits.[214c]

Mitochondrial ATP synthase of yeast contains at least 13 different kinds of subunits[208] and that of animals[215] 16, twice as many as in *E. coli*. Subunits α, β, γ, a, b, and c of the mitochondrial synthase correspond to those of *E. coli*. However, the mitochondrial homolog of *E. coli* δ is called the **oligomycin-sensitivity-conferring protein** (OSCP).[216–218] It makes the ATPase activity sensitive to oligomycin. The mitochondrial δ subunit corresponds to ε of *E. coli* or of chloroplasts.[217,219] Mitochondrial ε has no counterpart in bacteria.[209,220] In addition,[209,215] mitochondria contain subunits called d, e, f, g, A6L, F6, and IF_1, the last being an 84-residue inhibitor, a regulatory subunit.[221] The subunits of yeast ATP synthase correspond to those of the animal mitochondrial synthase but include one additional protein (**h**).[208a]

	F_1							F_0							
E. coli	α	β	γ		δ		ε	a	b	c					
Mitochondria	α	β	γ	OSCP		δ	ε	IF_1	a	b	c	d	e	f	g	A6L	F6

Six of the relatively large (50–57 kDa) α and β subunits associate to an $\alpha_3\beta_3$ complex that constitutes the knobs.[202,210] Chemical crosslinking, directed mutation, electron cryomicroscopy,[222,222a] and high-resolution X-ray diffraction measurements[199,207,211,223,224] have established that the α and β subunits alternate in a quasisymmetric cyclic head that contains active sites for ATP formation in the three β subunits (Fig. 18-14C–E). The α subunits also contain ATP-binding sites, but they are catalytically inactive, and their bound MgATP does not exchange readily with external ATP and can be replaced by the nonhydrolyzable AMP-PNP (Fig. 12-31) with retention of activity. The $\alpha_3\beta_3$ complex is associated with the F_0 part by a slender **central stalk**

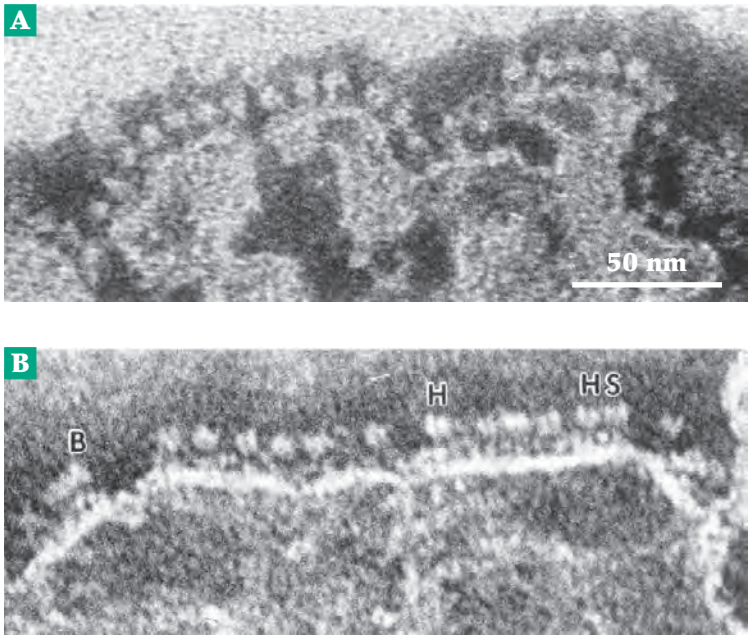


Figure 18-14 ATP synthase and vacuolar ATPase. (A) "Knobs" of ATP synthase on mitochondrial membranes negatively stained with phosphotungstate. (B) Vacuolar proton-pumping ATPase from an intact vacuolar membrane stained in the same way. Some images have been marked to indicate well-resolved head groups (H), stalks (S), and basal components (B). (A) and (B) are from Dschida and Bowman.[198] Courtesy of Barry J. Bowman. (C) Ribbon model of the atomic structure of the F_1 part of bovine heart mitochondrial ATP synthase. This section through the knob, which is drawn schematially at the upper right, shows one α subunit, containing bound ADP, α_{DP}, to the left and one empty β subunit, β_E, to the right. In the center are the N and C termini of subunit γ. The arrow points to a disruption in the β sheet of the subunit structure in the β_E conformation. The asterisk marks a loop that would collide with the C-terminal part of subunit γ if the latter were rotated. (D) View of the F_1 ATP synthase from the membrane side. The section shown contains the nucleotide binding sites. Subunits with empty sites are labeled α_E and β_E. Those with bound ADP are labeled α_{DP} and β_{DP}, and those with bound ATP α_{TP} and β_{TP}. Deviation from perfect threefold symmetry can be seen in this view. (C) and (D) are from Abrahams *et al.*[199] Courtesy of John E. Walker. (E) A recent model of the *E. coli* ATP synthase. The $\alpha_3\beta_3$ head contains the ATP-synthesizing sites in the β subunits. The $\alpha_3\beta_3$ complex and also subunits a, b, and δ remain stationary and form the stator for a protic engine, whose rotor consists of 12 c subunits and attached γ and ε subunits. Rotation is induced by the membrane potential or difference in H^+ activity on the two sides of the membrane. The carboxylate group of Asp 61 in each c subunit must be protonated to –COOH in order for it to move away from the entrance channel in subunit a. The presence of the positively charged Arg 210 near the exit channel in subunit a induces release of the proton when the c subunit has rotated almost 360°. According to this picture, 12 protons are required for one rotation with synthesis of three molecules of ATP. After Elston *et al.*[200] and Zhou *et al.*[201] See also Junge *et al.*[202] and Engelbrecht and Junge.[203]

or **shaft**. Much effort has gone into establishing the subunit composition of the shaft and the F_0 parts of the structure. As is indicated in Fig. 18-14E, subunits γ and ε of the *E. coli* enzyme are both part of the central shaft.[219,225,226] The same is true for the mitochondrial complex, in which the δ subunit corresponds to bacterial ε.[227] The role of this subunit is uncertain. It is part of the shaft but is able to undergo conformational alterations that can permit its C-terminal portion to interact either with F_0 or with the $\alpha_3\beta_3$ head.[227,227a] The unique ε subunit of mitochondrial ATPase appears also to be part of the shaft.[220]

The most prominent component of the central shaft is the 270-residue subunit γ, which associates loosely with the $\alpha_3\beta_3$ head complex but more tightly with F_0. About 40 residues at the N terminus and 60 at the C terminus form an α-helical coiled coil, which is visible in Fig. 18-14E[199,211] and which protrudes into the central cavity of the $\alpha_3\beta_3$ complex. Because it is asymmetric, the γ subunit apparently acts as a rotating camshaft to physically alter the α and β subunits in a cyclic manner. Asymmetries are visible in Fig. 18-14D.[211] The central part of subunit γ forms a more globular structure, which bonds with the c subunits of F_0.[205] Exact structures are not yet clear.

The δ subunit of *E. coli* ATP synthase (OSCP of mitochondria) was long regarded as part of the central stalk. However, more recent results indicate that it is found in a **second stalk**, which joins the $\alpha_3\beta_3$ complex to F_0. The central stalk rotates, relative to the second stalk. The second stalk may be regarded as stationary and part of a **stator** for a protic engine.[228,229] This stalk has been identified[230] in electron micrographs of chloroplast F_1F_0 and by crosslinking studies. As is depicted in Fig. 18-14E, a major portion of the second stalk is formed by two molecules of subunit b. Recent results indicate that bacterial subunit δ (mitochondrial OSCP) extends further up than is shown in Fig. 18-14, and together with subunit F6 may form a cap at the top of the $\alpha_3\beta_3$ head.[230a, 230b]

The F_0 portion of bacterial ATP synthase, which is embedded in the membrane, consists of one 271-residue subunit a, an integral membrane protein probably with five transmembrane helices,[231,232] two 156-residue b subunits, and ~twelve 79-residue c subunits. The c subunit is a proteolipid, insoluble in water but soluble in some organic solvents. The structure of monomeric c in chloroform:methanol:H_2O (4:4:1) solution has been determined by NMR spectroscopy. It is a hairpin consisting of two antiparallel α helices.[233] Twelve of the c subunits are thought to assemble into a ring with both the N and C termini of the subunit chains in the periplasmic (or intermembrane) face of the membrane.[234,235] The ratio of c to a subunits has been difficult to measure but has been estimated as 9–12. The fact that both genetically fused c_2 dimers and c_3 trimers form function F_0 suggested that they assemble to a c_{12} ring as shown in Fig. 18-14E.[236] However, the recent crystallographic results that revealed a C_{10} ring[214c] raise questions about stoichiometry.

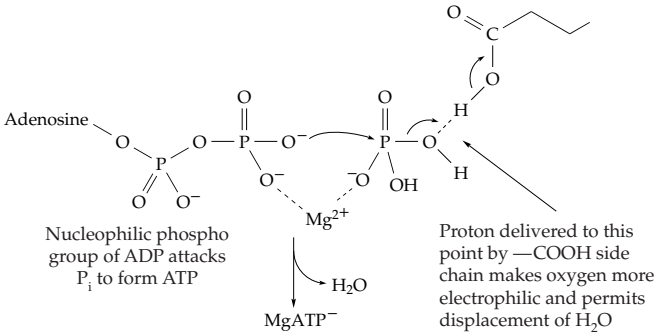
Since ATP synthesis takes place in F_1, it has long been thought that the F_0 part of the ATP synthase contains a "proton channel," which leads from the inside of the mitochondria to the F_1 assemblage.[146] Such a channel would probably not be an open pore but a chain of hydrogen-bonded groups, perhaps leading through the interior of the protein and able to transfer protons via icelike conduction. One residue in the c subunit, Asp 61, which lies in the center of the second of the predicted transmembrane helices, is critical for proton transport.[236a] Natural or artificial mutants at this position (e.g., D61G or D61N) do not transport protons. This carboxyl group also has an unusually high reactivity and specificity toward the protein-modifying reagent dicyclohexylcarbodiimide (DCCD; see Eq. 3-10).[146,237] Modification of a single c subunit with DCCD blocks the proton conductance.

An interesting mutation is replacement of alanine 62 of the c subunit with serine. This mutant will support ATP synthase using Li^+ instead of H^+.[237] Certain alkylophilic bacteria, such as *Propionigenium modestum*, have an ATP synthase that utilizes the membrane potential and a flow of Na^+ ions rather than protons through the c subunits.[238–240c] The sodium transport requires glutamate 65, which fulfills the same role as D61 in *E. coli*, and also Q32 and S66. Study of mutants revealed that the polar side chains of all three of these residues bind Na^+, that E65 and S66 are needed to bind Li^+, and that only E65 is needed for function with H^+.

The a subunit is also essential for proton translocation.[231,232,241] Structural work on this extremely hydrophobic protein has been difficult, but many mutant forms have been studied. Arginine 210 is essential as are E219 and H245. However, if Q252 is mutated to glutamate, E219 is no longer essential.[241] One of the OXPHOS diseases (NARP; Box 18-B) is a result of a leucine-to-arginine mutation in human subunit a.[241a] The b subunit is an elongated dimer, largely of α-helical structure.[242,243] Its hydrophobic N terminus is embedded in the membrane,[229,244] while the hydrophilic C-terminal region interacts with subunit σ of F_1, in the stator structure (Fig. 18-14E). Some of the F_0 subunits (d, e, f, g, A6L) may form a collar around the lower end of the central stalk.[210a,b]

How is ATP made? No covalent intermediates have been identified, and isotopic exchange studies indicate a direct dehydration of ADP and P_i to form bound ATP.[245] For the nucleophilic terminal phospho group of ADP to generate a high-energy linkage directly by attack on the phosphorus atom of P_i an OH^- ion must be eliminated (Eq. 18-13). This is not a probable reaction at pH 7, but it would be reasonable at low pH. Thus, one function of the oriented ATP

synthase might be to deliver one or more protons flowing in from F_0 specifically to the oxygen that is to be eliminated (Eq. 18-13). As we have seen (Section 2), on thermodynamic grounds 3–4 protons would probably be needed. Perhaps they could be positioned nearby to exert a large electrostatic effect, or they could assist in releasing the ATP formed from the synthase by inducing a conformational change. However, it isn't clear how protons could be directed to the proper spots.



(18-13)

Paul Boyer's binding change mechanism. Boyer and associates suggested that ATP synthesis occurs rapidly and reversibly in a closed active site of the ATP synthase in an environment that is essentially anhydrous. ATP would then be released by an energy-dependent conformational change in the protein.[245–249] Oxygen isotope exchange studies verified that a rapid interconversion of bound ADP, P_i, and ATP does occur. Studies of soluble ATP synthase, which is necessarily uncoupled from electron transport or proton flow, shows that ATP is exceedingly tightly bound to F_1 as expected by Boyer's mechanism.[248] According to his **conformational coupling** idea, protons flowing across the membrane into the ATP synthase would in some way induce the conformational change necessary for release of ATP.

The idea of conformational coupling of ATP synthesis and electron transport is especially attractive when we recall that ATP is used in muscle to carry out mechanical work. Here we have the hydrolysis of ATP coupled to motion in the protein components of the muscle. It seems reasonable that ATP should be formed as a result of motion induced in the protein components of the ATPase. Support for this analogy has come from close structural similarities of the F_1 ATPase β subunits and of the active site of ATP cleavage in the muscle protein myosin (Chapter 19).

A simple version of Boyer's binding change mechanism is shown in Figure 18-15. The three F_1 β subunits are depicted in three different conformations. In O the active site is open, in T it is closed, and if ATP is present in the active site it is tightly bound. In the low affinity L conformation ligands are bound weakly. In step *a* MgADP and P_i enter the L site while MgATP is still present in the T site. In step *b* a protonic-energy-dependent step causes synchronous conformational changes in all of the subunits. The tight site opens and MgATP is free to leave. At the same time MgADP and P_i in the T site are converted spontaneously to tightly bound ATP. The MgATP is in reversible equilibrium with MgADP + P_i, which must be bound less tightly than is MgATP. That is, the high positive value of $\Delta G'$ for formation of ATP must be balanced by a corresponding negative $\Delta G'$ for a conformational or electronic reorganization of the protein in the T conformation. Opening of the active site in step *b* of Fig. 18-15 will have a high positive $\Delta G'$ unless it is coupled to proton flow throught F_0. Of three sites in the subunits, one binds MgATP very tightly (K_d ~ 0.1 μM) while the other sites bind less tightly (K_d ~ 20 μM).[250,251] However, it has been very difficult to establish binding constants or K_m values for the ATPase reaction.[248] Each of the three β sites probably, in turn, becomes the high-affinity site, consistent with an ATP synthase mechanism involving protein conformational changes.

Rotational catalysis. Boyer suggested that there is a cyclic rotation in the conformations of the three β subunits of the ATP synthase, and that this might involve rotation about the stalk. By 1984, it had been shown that bacterial flagella are rotated by a protonic motor (Chapter 19), and a protic rotor for ATP synthase had been proposed by Cox *et al.*[252] and others.[245] However, the b subunits were thought to be in the central stalk.[222] More recently chemical crosslinking experiments,[201,253] as well as electron microscopy, confirmed the conclusion that an intact stator structure must also be present as in Fig. 18-14E.[202] The necessary second stalk is visible in CF_1F_0 ATPase of chloroplasts[230] and also in the related vacuolar ATPase, a proton or Na^+ pump from a clostridium.[254] See also Section 5. Another technique, **polarized absorption recovery after photobleaching**, was applied after labeling of Cys 322, the penultimate residue at the C terminus of the γ subunit with the dye eosin. After photobleaching with a laser beam the polarization of the light absorption by the dye molecule relaxed because of rotation. Relaxation was observed when ATP was added but not with ADPPNP.[202,255,256]

The most compelling experiments were performed by Noji *et al.*[202,257–260] They prepared the $\alpha_3\beta_3\gamma$ subcomplex of ATPase from a thermophilic bacterium. The complex was produced in *E. coli* cells from the cloned genes allowing for some "engineering" of the proteins. A ten-histidine "tag" was added at the N termini of the β subunits so that the complex could be "glued" to a microscope coverslip coated with a nickel complex with a high affinity for the His tags. The γ subunit shafts protrude upward as shown in Fig. 18-16. The γ subunit was mutated to replace its

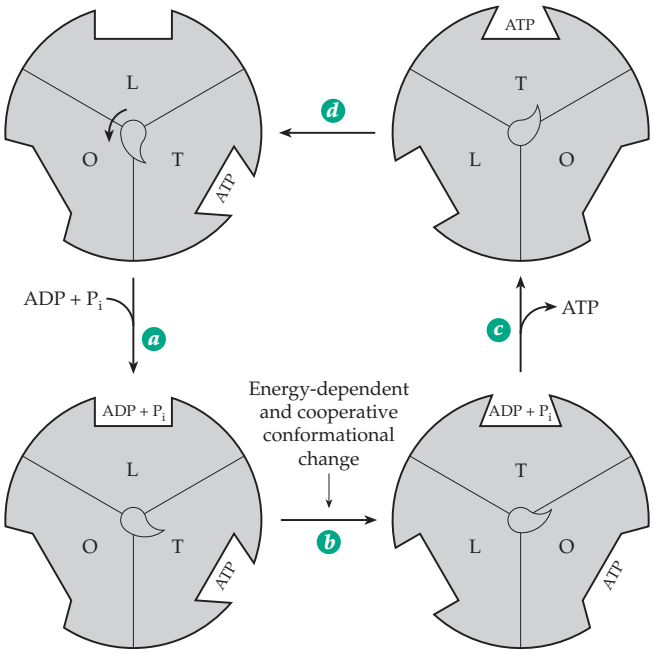


Figure 18-15 Boyer's binding change mechanism for ATP synthase in a simple form. After Boyer[245] but modified to include a central camshaft which may drive a cyclic alteration in conformations of the subunits. The small "pointer" on this shaft is not to be imagined as real but is only an indicator of rotation with induced conformational changes. The rotation could occur in 120° steps rather than the smaller steps suggested here.

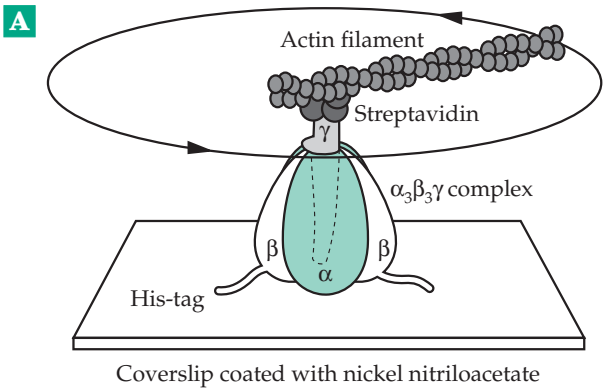
only cysteine by serine and to introduce a cysteine in place of Ser 107 of the stalk region of γ. The new cysteine was biotinylated and attached to streptavidin (see Box 14-B) which was also attached to a fluorescently labeled actin filament (Fig. 7-10) ~1–3 μm in length as shown in Fig. 18-16. The actin fiber rotated in a counterclockwise direction when ATP was added but did not rotate with AMPPNP. At low ATP concentrations the rotation could be seen to occur in discrete 120° steps.[258,261,262] Each 120° step seems to consist of ~90° and ~30° substeps, each requiring a fraction of a millisecond.[262a] The ATPase appears to be acting as a **stepper motor**, hydrolysis of a single ATP turning the shaft 120°. Rotation at a rate of ~14 revolutions per second would require the hydrolysis of ~42 ATP per second. If the motor were attached to the F_0 part it would presumably pump four (or perhaps three) H^+ across a membrane for each ATP hydrolyzed. Acting in reverse, it would make ATP. A modification of the experiment of Fig. 18-16 was used to demonstrate that the c subunits also rotate with respect to the $\alpha_3\beta_3$ head.[262b] Other experiments support rotation of the c ring relative to subunit a.[262c,d]

Still to be answered are important questions. How does ATP hydrolysis turn the shaft? Are four H^+ pumped for each step, or are there smaller single proton substeps? Is the simple picture in Fig. 18-15 correct or, as proposed by some investigators,[263–265] must all three β subunits be occupied for maximum catalytic activity?[266] How is the coupling of H^+ transport to mechanical motion accomplished?[267,267a–d]



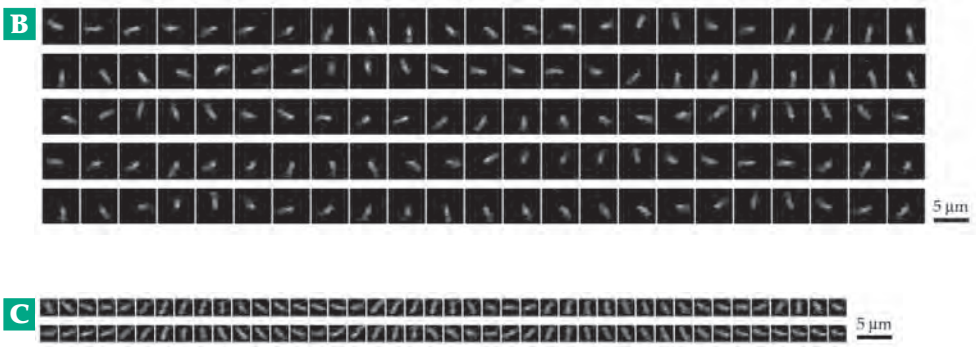


Figure 18-16 (A) The system used for observation of the rotation of the γ subunit in the $\alpha_3\beta_3\gamma$ subcomplex. The observed direction of the rotation of the γ subunit is indicated by the arrows. (B) Sequential images of a rotating actin filament attached as in (A). (C) Similar images obtained with the axis of rotation near the middle of the filament. The images correspond to the view from the top in (A). Total length of the filament, 2.4 μm; rotary rate, 1.3 revolutions per second; time interval between images, 33 ms. From Noji *et al.*[258]

5. ATP-driven Proton Pumps

Not all proton pumps are driven by electron transport. ATP synthase is reversible, and if Δp is low, hydrolysis of ATP can pump protons out of mitochondria or across bacterial plasma membranes.[268] Cells of *Streptococcus faecalis*, which have no respiratory chain

and form ATP by glycolysis, use an F_1F_0 ATP synthase complex to pump protons out to help regulate cytoplasmic pH.[268] Similar **vacuolar (V-type) H^+-ATPases** or V_1V_0 ATPases pump protons into vacuoles, Golgi and secretory vesicles, coated vesicles, and lysosomes[198,269-270] in every known type of eukaryotic cell.[271,272] These proton pumps are similar in appearance (Fig. 18-14,B) and in structure to F_1F_0 ATPases.[272a–c] The 65- to 77-kDa A subunits and 55- to 60-kDa B subunits are larger than the corresponding F_1F_0 α and β subunits. Accessory 40-, 39-, and 33-kDa subunits are also present in V_1. The V_0 portion appears to contain a hexamer of a 16-kDa proteolipid together with 110- and 21-kDa subunits.[271] V-type ATPases are also found in archaebacteria[271,273] and also in some clostridia[254] and other eubacteria.[273a] A type of proton pump, the **V-PPase**, uses hydrolysis of inorganic pyrophosphate as a source of energy.[274] It has been found in plants, in some phototrophic bacteria, and in acidic calcium storage vesicles (acidocalcisomes) of trypanosomes.[274a]

Other ATP-dependent proton pumps are present in the plasma membranes of yeast and other fungi[274b] and also in the acid-secreting parietal cells of the stomach (Fig. 18-17). The H^+-ATPase of *Neurospora* pumps H^+ from the cytoplasm without a counterion. It is electrogenic.[275,275a] However, the gastric H^+,K^+-ATPase exchanges H_3O^+ for K^+ and cleaves ATP with formation of a phosphoenzyme.[276] It belongs to the family of P-type ion pumps that includes the mammalian Na^+,K^+-ATPase (Fig. 8-25) and Ca^{2+}-ATPase (Fig. 8-26). These are discussed in Chapter 8. The H^+,K^+-ATPases, which are widely distributed within eukaryotes, are also similar, both in sequence and in the fact that a phospho group is transferred from ATP onto a carbox-ylate group of an aspartic acid residue in the protein. All of them, including a Mg-ATPase of *Salmonella*, are two-subunit proteins. A large catalytic α subunit contains the site of phosphorylation as well as the ATP- and ion-binding sites. It associates noncovalently with the smaller heavily glycosylated β subunit.[276–278] For example, the rabbit H^+,K^+-ATPase consists of a 1035-residue α chain which has ten transmembrane segments and a 290-residue β chain with a single transmembrane helix and seven N-linked glycosylation sites.[278]

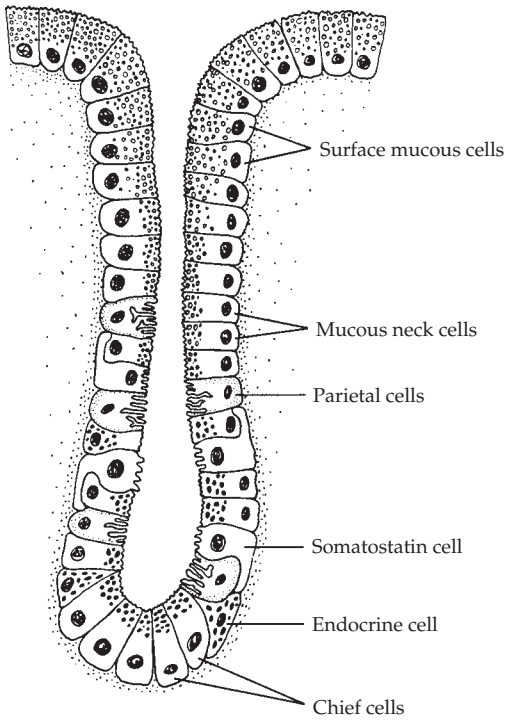

Figure 18-17 Schematic diagram of an acid-producing oxyntic gland of the stomach. The normal human stomach contains about 10^9 parietal (oxyntic) cells located in the walls of these glands. From Wolfe and Soll.[279] Modified from Ito. These glands also produce mucus, whose role in protecting the stomach lining from the high acidity is uncertain.[280]

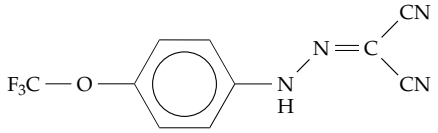
6. Uncouplers and Energy-linked Processes in Mitochondria

Many compounds that uncouple electron transport from phosphorylation, like 2,4-dinitrophenol, are weak acids. Their anions are nucleophiles. According to the scheme of Fig. 18-12, they could degrade a high energy intermediate, such as Y ~ B, by a nucleophilic attack on Y to give an inactive but rapidly hydrolyzed derivative of Y. On the other hand, according to Mitchell's hypothesis uncouplers facilitate the transport of protons back into the mitochondria thereby destroying Δp. The fact that the anions of the uncouplers are large, often aromatic, and therefore soluble in the lipid bilayer supports this interpretation; the protonated uncouplers can diffuse into the mitochondria and the anion can diffuse back out. Mitochondria can also be uncoupled by a combination of ionophores, e.g., a mixture of valinomycin (Fig. 8-22), which carries K^+ into the mitochondria, plus nigericin, which catalyzes an exchange of K^+ (out) for H^+ (in).[172]

The uncoupler carbonyl cyanide *p*-(trifluoromethoxy)phenylhydrazone (FCCP) and related compounds are widely used in biochemical studies. Their action can be explained only partially by increased proton conduction.

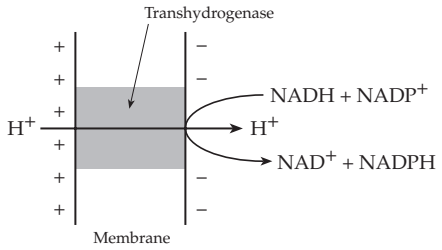


Carbonyl cyanide *p*-(trifluoromethoxy)phenylhydrazone (FCCP)

Uncoupling is sometimes important to an organism. The generation of heat by uncoupling is discussed in Box 18-C. The fungus *Bipolaris maydis* caused a crisis in maize production when it induced pore formation in mitochondrial membranes of a special strain used in production of hybrid seeds.[281,282]

Synthesis of ATP by mitochondria is inhibited by oligomycin, which binds to the OSCP subunit of ATP synthase. On the other hand, there are processes that require energy from electron transport and that are not inhibited by oligomycin. These **energy-linked processes** include the transport of many ions across the mitochondrial membrane (Section E) and reverse electron flow from succinate to NAD^+ (Section C,2). Dinitrophenol and many other uncouplers block the reactions, but oligomycin has no effect. This fact can be rationalized by the Mitchell hypothesis if we assume that Δp can drive these processes.

Another energy-linked process is the **transhydrogenase** reaction by which NADH reduces $NADP^+$ to form NADPH. In the cytoplasm various other reactions are used to generate NADPH (Chapter 17, Section I), but within mitochondria a membrane-bound transhydrogenase has this function.[283–286a] It couples the transhydrogenation reaction to the transport of one (or possibly more than one) proton back into the mitochondria (Eq. 18-14). A value of Δp of −180 mV could increase the ratio of [NADPH] / [$NADP^+$] within mitochondria by a factor of as much as 1000.



(18-14)

Transhydrogenases function in a similar way within bacteria. Whether from *E. coli*, photosynthetic bacteria, or bovine mitochondria, transhydrogenases have similar structures.[285] Two 510-residue α subunits associate with two 462-residue β subunits to form an $\alpha_2\beta_2$ tetramer with 10−14 predicted transmembrane helices. The α subunits contain separate NAD(H) and NADP(H) binding sites. A conformational change appears to be associated with the binding or release of the $NADP^+$ or NADPH.[287]

D. Transport and Exchange across Mitochondrial Membranes

Like the external plasma membrane of cells, the inner mitochondrial membrane is selective. Some nonionized materials pass through readily but the transport of ionic substances, including the anions of the dicarboxylic and tricarboxylic acids, is restricted. In some cases energy-dependent active transport is involved but in others one anion passes inward in exchange for another anion passing outward. In either case specific translocating carrier proteins are needed.

Solutes enter mitochondria through pores in thousands of molecules of the **voltage-gated anion-selective channel VDAC**, also known as mitochondrial porin.[15,16,288,289] In the absence of a membrane potential these pores allow free diffusion to molecules up to ~1.2 kDa in mass and may selectively permit passage of anions of 3- to 5-kDa mass. However, a membrane potential greater than ~20 mV causes the pores to close. NADH also decreases permeability. In the closed state the outer membrane becomes almost impermeant to ATP.[289,290]

An example of energy-dependent transport is the uptake of Ca^{2+} by mitochondria. As indicated in the lower part of Fig. 18-13, there are two possibilities for preservation of electrical neutrality according to the chemiosmotic theory. Counterions X^- may flow out to balance the protons discharged on the outside. On the other hand, if a cation such as Ca^{2+} flows inward to balance the two protons flowing outward, neutrality will be preserved and the mitochondrion will accumulate calcium ions. Experimentally such accumulations via a **calcium uniporter**[4] are observed to accompany electron transport. In the presence of a suitable ionophore energy-dependent accumulation of potassium ions also takes place.[291] In contrast, an **electroneutral exchange** of one Ca^{2+} for two Na^+ is mediated by a Na^+–Ca^{2+} exchanger.[292,293] It permits Ca^{2+} to leave mitochondria. A controversial role of mitochondria in accumulating Ca^{2+} postulates a special **rapid uptake mode** of exchange (see p. 1049).[294]

It is thought that glutamate enters mitochondria as the monoanion Glu^- in exchange for the dianion of aspartate Asp^{2-}. Like the uptake of Ca^{2+} this exchange is driven by Δp. Since a membrane potential can be created by this exchange in the absence of Δp, the process is electrogenic.[4] In contrast, an **electroneutral** exchange of malate^{2-} and 2-oxoglutarate^{2-} occurs by means of carriers that are not energy-linked.[295,296] This dicarboxylate transporter is only one of 35 structurally related mitochondrial carriers identified in the complete genome of yeast.[296,297] Another is the **tricarboxylic transporter** (citrate transport protein) which exchanges the dianionic form of citrate for malate, succinate, isocitrate, phosphoenolpyruvate, etc.[298,298a,b]

The important **adenine nucleotide carrier** takes ADP into the mitochondrial matrix for phosphorylation in a 1:1 ratio with ATP that is exported into the cytoplasm.[299-300b] This is one of the major rate-determining processes in respiration. It has been widely accepted that the carrier is electrogenic,[300]

BOX 18-C USING METABOLISM TO GENERATE HEAT: THERMOGENIC TISSUES

A secondary but important role of metabolism in warm-blooded animals is to generate heat. The heat evolved from ordinary metabolism is often sufficient, and an animal can control its temperature by regulating the heat exchange with the environment. Shivering also generates heat and is used from birth by pigs.[a] However, this is insufficient for many newborn animals, for most small mammals of all ages, and for animals warming up after hibernation. The need for additional heat appears to be met by **brown fat**, a tissue which contrasts strikingly with the more abundant white adipose tissue. Brown fat contains an unusually high concentration of blood vessels, many mitochondria with densely packed cristae, and a high ratio of cytochrome *c* oxidase to ATP synthase. Also present are a large number of sympathetic nerve connections, which are also related to efficient generation of heat. Newborn humans have a small amount of brown fat, and in newborn rabbits it accounts for 5–6% of the body weight.[b–d] It is especially abundant in species born without fur and in hibernating animals. Swordfish also have a large mass of brown adipose tissue that protects their brains from rapid cooling when traveling into cold water.[a]

The properties of brown fat pose an interesting biochemical question. Is the energy available from electron transport in the mitochondria dissipated as heat because ATP synthesis is uncoupled from electron transport? Or does ATP synthesis take place but the resulting ATP is hydrolyzed wastefully through the action of ATPases? Part of the answer came from the discovery that mitochondria of brown fat cells synthesize a 32-kDa **uncoupling protein** (UCP1 or thermogenin). It is incorporated into the inner mitochondrial membranes where it may account for 10–15% of total protein.[d–f] This protein, which is a member of a family of mitochondrial membrane metabolic carriers (Table 18-8), provides a "short-circuit" that allows the protonmotive force to be dissipated rapidly, perhaps by a flow of protons out through the uncoupling protein.[g–i] Synthesis of the uncoupling protein is induced by exposure to cold, but when an animal is warm the uncoupling action is inhibited.

The uncoupling protein resembles the ATP/ADP and phosphate *anion* carriers (Table 18-8),[g,i] which all have similar sizes and function as homodimers. Each monomeric subunit has a triply repeated ~100-residue sequence, each repeat forming two transmembrane helices. Most mitochondrial transporters carry anions, and UCP1 will transport Cl^-.[h,i] However, the relationship of chloride transport to its real function is unclear. Does the protein transport H^+ into, or does it carry HO^- out from, the mitochondrial matrix?[g,h] Another possibility is that a fatty acid anion binds H^+ on the intermembrane surface and carries it across into the matrix as an unionized fatty acid. The fatty acid anion could then pass back out using the anion transporter function and assisted by the membrane potential.[h,i]

The uncoupling protein is affected by several control mechanisms. It is inhibited by nucleotides such as GDP, GTP, ADP, and ATP which may bind at a site corresponding to that occupied by ATP or ADP in the ADP/ATP carrier.[i] Uncoupling is stimulated by noradrenaline,[f] which causes a rapid increase in heat production by brown fat tissues, apparently via activation of adenylate cyclase. Uncoupling is also stimulated by fatty acids.[j] Recently UCP1 and related uncoupling proteins have been found to require both fatty acids and **ubiquinone** for activity.[jj,jk]

It has been suggested that brown adipose tissue may also function to convert excess dietary fat into heat and thereby to resist obesity.[k–m] Mice lacking the gene for the mitochondrial uncoupling protein are cold-sensitive but not obese. However, other proteins, homologous to UCP1, have been discovered. They may partially compensate for the loss.[m,h]

The bombardier beetle generates a hot, quinone-containing defensive discharge, which is sprayed in a pulsed jet from a special reaction chamber at a temperature of 100°C.[n–p] The reaction mixture of 25% hydrogen peroxide and 10% hydroquinone plus methylhydroquinone is stored in a reservoir as shown in the accompanying figure and reacts with explosive force when it comes into contact with catalase and peroxidases in the reaction chamber. The synthesis and storage of 25% H_2O_2 poses interesting biochemical questions!

Some plant tissues are thermogenic. For example, the spadix (or inflorescence, a sheathed floral spike) of the skunk cabbage *Symplocarpus foetidus* can maintain a 15–35°C higher temperature than that of the surrounding air.[q] The voodoo lily in a single day heats the upper end of its long spadex to a temperature 22°C above ambient, volatilizing a foul smelling mixture of indoles and amines.[r,s] This is accomplished using the alternative oxidase system[s] (Box D in Fig. 18-6). The lotus flower maintains a temperature of 30–35°C, while the ambient temperature may vary from 10–30°C.[t] While the volatilization of insect attractants may be the primary role for thermogenesis in plants, the warm flowers may also offer an important reward to insect pollinators. Beetles and bees require thoracic temperatures above 30°C to initiate flight and, therefore,

BOX 18-C (continued)

benefit from the warm flowers.[t] While in flight bees vary their metabolic heat production by altering their rate of flight, hovering, and other changes in physical activity.[u]

bringing in ADP^{3-} and exporting ATP^{4-} in an exchange driven by Δp. However, an electroneutral exchange, e.g., of ADP^{3-} for ATP^{3-}, may also be possible. The carrier is an ~300-residue 32-kDa protein, which is specifically inhibited by the plant glycoside **atractyloside** or the fungal antibiotic **bongkrekate**. The carrier is associated with bound cardiolipin.[301] This one transporter accounts for ~10% of all of the mitochondrial protein.[302,303]

A separate dimeric carrier allows P_i to enter, probably as $H_2PO_4^-$.[304-305a] This ion enters mitochondria in an electroneutral fashion, either in exchange for OH^- or by cotransport with H^+. A less important carrier[306] exchanges HPO_4^{2-} for $malate^{2-}$. Several other transporters help to exchange organic and inorganic ions. One of them allows pyruvate to enter mitochondria in exchange for OH^- or by cotransport with H^+. Some of the identified carriers are listed in Table 18-8. As discussed in Chapter 8, exchange carriers are also important in plasma membranes of organisms from bacteria to human beings. For example, many metabolites enter cells by cotransport with Na^+ using the energy of the Na^+ gradient set up across the membrane by the Na^+,K^+ pump.

Under some circumstances the inner membrane develops one or more types of large-permeability pore. An increase in Ca^{2+} may induce opening of an unselective pore which allows rapid uptake of Ca^{2+}.[294,307,307a] A general anion-specific channel may be involved in volume homeostasis of mitochondria.[308]

Mitochondria are not permeable to NADH. However, reactions of glycolysis and other dehydrogenations in the cytoplasm quickly reduce available NAD^+ to NADH. For aerobic metabolism to occur, the "reducing equivalents" from the NADH must be transferred into the mitochondria. Fungi and green plants have solved

the problem by providing *two* NADH dehydrogenases embedded in the inner mitochondrial membranes (Fig. 18-6). One faces the matrix space and oxidizes the NADH produced in the matrix while the second faces outward to the intermembrane space and is able to oxidize the NADH formed in the cytoplasm. In animals the reducing equivalents from NADH enter the mitochondria indirectly. There are several mechanisms, and more than one may function simultaneously in a tissue.

In insect flight muscle, as well as in many mammalian tissues, NADH reduces dihydroxyacetone phosphate. The resulting *sn*-3-glycerol *P* passes through the permeable outer membrane of the mitochondria, where it is reoxidized to dihydroxyacetone phosphate by the FAD-containing glycerol-phosphate dehydrogenase embedded in the outer surface of the inner membrane (Figs. 18-5, 18-6). The dihydroxyacetone can then be returned to the cytoplasm. The overall effect of this **glycerol-phosphate shuttle** (Fig. 18-18A) is to provide for mitochondrial oxidation of NADH produced in the cytoplasm. In heart and liver the same function is served by a more complex **malate–aspartate shuttle** (Fig. 18-18B).[309] Reduction of oxaloacetate to malate by NADH, transfer of malate into mitochondria, and reoxidation with NAD^+ accomplishes the transfer of reduction equivalents into the mitochondria. Mitochondrial membranes are not very permeable to oxaloacetate. It returns to the cytoplasm mainly via transamination to aspartate, which leaves the mitochondria together with 2-oxoglutarate. At the same time glutamate enters the mitochondria in exchange for aspartate. The 2-oxoglutarate presumably exchanges with the entering malate as is indicated in Fig. 18-18B. The export of aspartate may be energy-linked as a result of the use of an electrogenic carrier that exchanges glutamate$^-$ + H^+ entering mitochondria for aspartate$^-$ leaving the mitochondria. Thus, Δp may help to expel aspartate from mitochondria and to drive the shuttle.

The glycerol-phosphate shuttle, because it depends upon a mitochondrial flavoprotein, provides ~ 2 ATP per electron pair (P / O = 2), whereas the malate–aspartate shuttle may provide a higher yield of ATP. The glycerol-phosphate shuttle is essentially irreversible, but the reactions of the malate–aspartate shuttle can be reversed and utilized in gluconeogenesis (Chapter 17).

TABLE 18-8
Some Mitochondrial Membrane Transporters[a]

Ion Diffusing In	Ion Diffusing Out	Comment[b]
ADP^{3-}	ATP^{3-}	
or ADP^{3-}	ATP^{4-}	Electrogenic symport
$H_2PO_4^- + H^+$		Electroneutral symport

[b] Unless indicated otherwise the transporters are *antiporters* that catalyze an electroneutral ion exchange.

E. Energy from Inorganic Reactions

Some bacteria obtain all of their energy from inorganic reactions. These **chemolithotrophs** usually have a metabolism that is similar to that of heterotrophic organisms, but they also have the capacity to obtain all of their energy from an inorganic reaction. In order to synthesize carbon compounds they must be able to fix CO_2 either via the reductive pentose phosphate cycle or in some other way. The chloroplasts of green plants, using energy from sunlight, supply the organism with both ATP and the reducing agent NADPH (Chapter 17). In a similar way the lithotrophic bacteria obtain both energy and reducing materials from inorganic reactions.

Chemolithotrophic organisms often grow slowly, making study of their metabolism difficult.[310] Nevertheless, these bacteria usually use electron transport chains similar to those of mitochondria. ATP is formed by oxidative phosphorylation, the amount formed per electron pair depending upon the number of proton-pumping sites in the chain. This, in turn, depends upon the electrode potentials of the reactions involved. For example, H_2, when oxidized by O_2, leads to passage of electrons through the entire electron transport chain with synthesis of ~3 molecules of ATP per electron pair. On the other hand, oxidation by O_2 of nitrite, for which $E^{\circ\prime}$ (pH 7) = +0.42 V, can make use only of the site III part of the chain. Not only is the yield of ATP less than in the oxidation of H_2 but also there is another problem. Whereas reduced pyridine

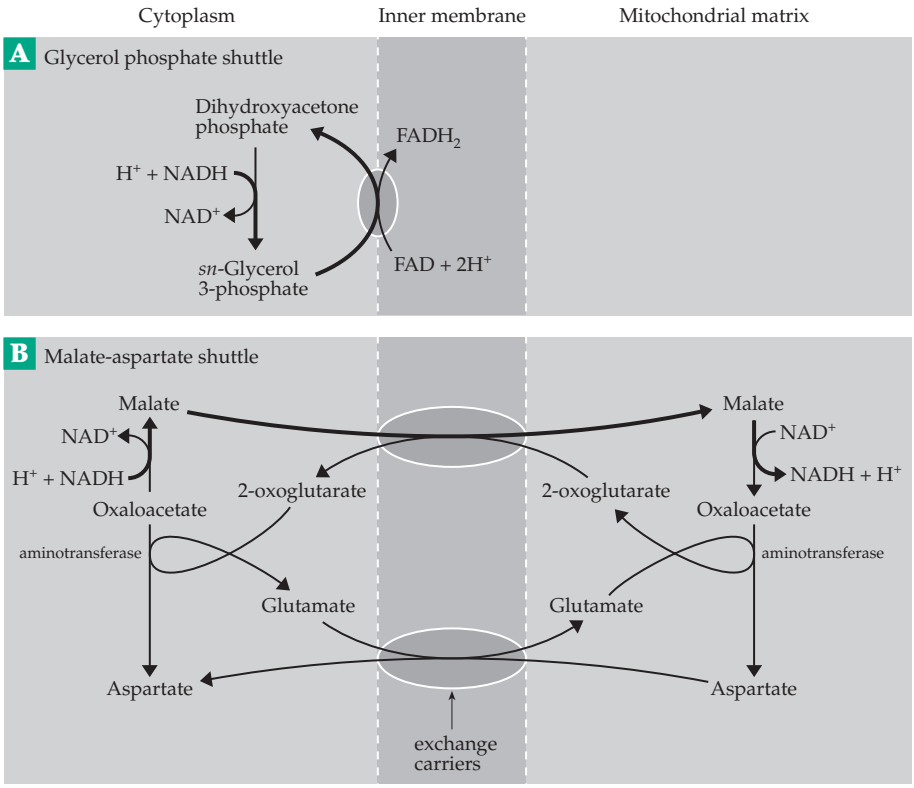

Figure 18-18 (A) The glycerol-phosphate shuttle and (B) the malate–aspartate shuttle for transport from cytoplasmic NADH into mitochondria. The heavy arrows trace the pathway of the electrons (as 2H) transported.

nucleotides needed for biosynthesis can be generated readily from H_2, nitrite is not a strong enough reducing agent to reduce NAD^+ to NADH. The only way that reducing agents can be formed in cells utilizing oxidation of nitrite as an energy source is via *reverse electron flow* driven by hydrolysis of ATP or by Δp. Such reverse electron flow is a common process for many chemolithotrophic organisms.

Let us consider the inorganic reactions in two groups: (1) oxidation of reduced inorganic compounds by O_2 and (2) oxidation reactions in which an inorganic oxidant, such as nitrate or sulfate, substitutes for O_2. The latter reactions are often referred to as **anaerobic respiration**.

1. Reduced Inorganic Compounds as Substrates for Respiration

The hydrogen-oxidizing bacteria. Species from several genera including *Hydrogenomonas*, *Pseudomonas*, and *Alcaligenes* oxidize H_2 with oxygen:

$$H_2 + 1/2\ O_2 \rightarrow H_2O$$
$$\Delta G^\circ = -237.2 \text{ kJ mol}^{-1} \qquad (18\text{-}15)$$

Some can also oxidize carbon monoxide:

$$CO + 1/2\ O_2 \rightarrow CO_2$$
$$\Delta G^\circ = -257.1 \text{ kJ mol}^{-1} \qquad (18\text{-}16)$$

The hydrogen bacteria can also oxidize organic compounds using straightforward metabolic pathways. The key enzyme is a membrane-bound nickel-containing hydrogenase (Fig. 16-26), which delivers electrons from H_2 into the electron transport chain.[310a] A second soluble hydrogenase (sometimes called **hydrogen dehydrogenase**) transfers electrons to $NADP^+$ to form NADPH for use in the reductive pentose phosphate cycle and for other biosynthetic purposes.

Nitrifying bacteria. Two genera of soil bacteria oxidize ammonium ion to nitrite and nitrate (Eqs. 18-17 and 18-18).[311]

$$NH_4^+ + 3/2\ O_2 \rightarrow NO_2^- + 2\ H^+ + H_2O \text{ (}\textit{Nitrosomonas}\text{)}$$
$$\Delta G' \text{ (pH 7)} = -272 \text{ kJ mol}^{-1} \qquad (18\text{-}17)$$

$$NO_2^- + 1/2\ O_2 \rightarrow NO_3^- \text{ (}\textit{Nitrobacter}\text{)}$$
$$\Delta G' \text{ (pH 7)} = -76 \text{ kJ mol}^{-1} \qquad (18\text{-}18)$$

The importance of these reactions to the energy metabolism of the bacteria was recognized in 1895 by Winogradsky, who first proposed the concept of chemiautotrophy. Because the nitrifying bacteria grow

slowly (generation time ~10–12 h) it has been hard to get enough cells for biochemical studies and progress has been slow. The reaction catalyzed by *Nitrosomonas* (Eq. 18-17) is the more complex; it occurs in two or more stages and is catalyzed by two enzymes as illustrated in Fig. 18-19. The presence of hydrazine blocks oxidation of hydroxylamine (NH_2OH) in step *b* and permits that intermediate to accumulate. The oxidation of ammonium ion by O_2 to hydroxylamine (step *a*) is endergonic with $\Delta G'$ (pH 7) = 16 kJ mol^{-1} and is incapable of providing energy to the cell. It occurs by a hydroxylation mechanism (see Section G). On the other hand, the oxidation of hydroxylamine to nitrite by O_2 in step *b* is highly exergonic with $\Delta G'$ (pH 7) = −228 kJ mol^{-1}. The hydroxylamine oxidoreductase that catalyzes this reaction is a trimer of 63-kDa subunits, each containing seven *c*-type hemes and an unusual heme P450, which is critical to the enzyme's function[312–314a] and which is covalently linked to a tyrosine as well as to two cysteines.

The electrode potentials for the two- and four-electron oxidation steps are indicated in Fig. 18-19. It is apparent that step *b* can feed four electrons into the electron transport system at about the potential of ubiquinone. Two electrons are needed to provide a cosubstrate (Section G) for the ammonia monooxygenase and two could be passed on to the terminal cytochrome aa_3 oxidase. The stoichiometry of proton pumping in complexes III and IV is uncertain, but if it is assumed to be as shown in Fig. 18-19 and similar to that in Fig. 18-5, there will be ~13 protons available to be passed through ATP synthase to generate ~3 ATP per NH_3 oxidized. However, to generate NADH for reductive biosynthesis *Nitrosomonas* must send some electrons to NADH dehydrogenase (complex I) using reverse electron transport, a process that depends upon Δp to drive the reaction via a flow of protons through the NADH dehydrogenase from the periplasm back into the bacterial cytoplasm (Fig. 18-19).

Nitrobacter depends upon a simpler energy-yielding reaction (Eq. 18-18) with a relatively small Gibbs energy decrease. The two-electron oxidation delivers electrons to the electron transport chain at $E^{\circ\prime}$ = +0.42 V. The third oxygen in NO_3^- originates from H_2O, rather than from O_2 as might be suggested by Eq. 18-18.[316,317] It is reasonable to anticipate that a single molecule of ATP should be formed for each pair of electrons reacting with O_2. However, *Nitrobacter* contains a confusing array of different cytochromes in its membranes.[311] Some of the ATP generated by passage of electrons from nitrite to oxygen must be used to drive a reverse flow of electrons through both a bc_1-type complex and NADH dehydrogenases. This generates reduced pyridine nucleotides required for biosynthetic reactions (Fig. 18-20).

An interesting feature of the structure of *Nitrobacter* is the presence of several double-layered membranes which completely envelop the interior of the cell. Nitrite entering the cell is oxidized on these membranes and cannot penetrate to the interior, where it might have toxic effects.

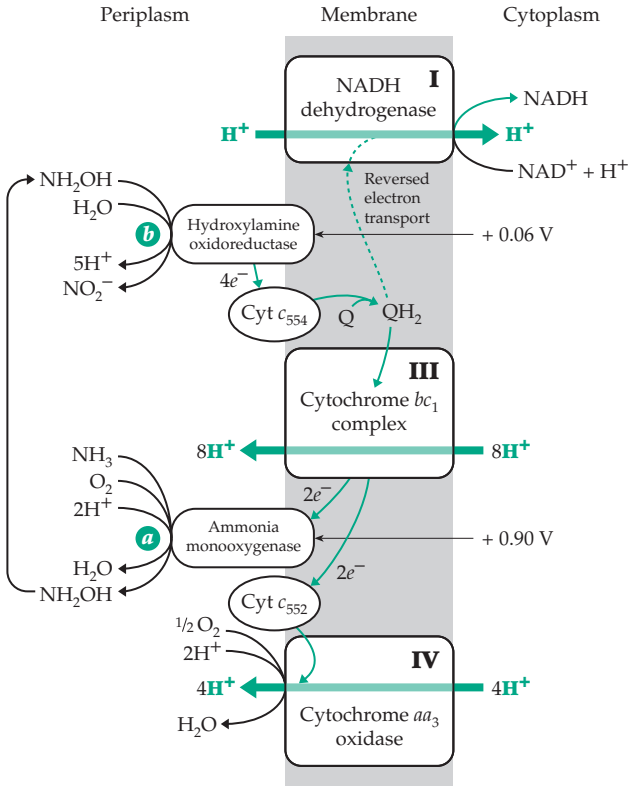

Figure 18-19 The ammonia oxidation system of the bacterium *Nitrosomonas*. Oxidation of ammonium ion (as free NH_3) according to Eq. 18-17 is catalyzed by two enzymes. The location of ammonia monooxygenase (step *a*) is uncertain but hydroxylamine oxidoreductase (step *b*) is periplasmic. The membrane components resemble complexes I, III, and IV of the mitochondrial respiratory chain (Fig. 18-5) and are assumed to have similar proton pumps. Solid green lines trace the flow of electrons in the energy-producing reactions. This includes flow of electrons to the ammonia monooxygenase. Complexes III and IV pump protons out but complex I catalyzes reverse electron transport for a fraction of the electrons from hydroxylamine oxidoreductase to NAD^+. Modified from Blaut and Gottschalk.[315]

The sulfur-oxidizing bacteria. Anaerobic conditions prevail in marine sediments, in poorly stirred swamps, and around hydrothermal vents at the bottom of the sea. Sulfate-reducing bacteria form high concentrations (up to mM) of H_2S (in equilibrium with HS^- and S^{2-})[318–320] This provides the substrate for bacteria of the genus *Thiobacillus*, which are able to oxidize sulfide, elemental sulfur, thiosulfate, and sulfite to sulfate and live where the aerobic and anaerobic regions meet.[311,321–323] Most of these small gram-negative

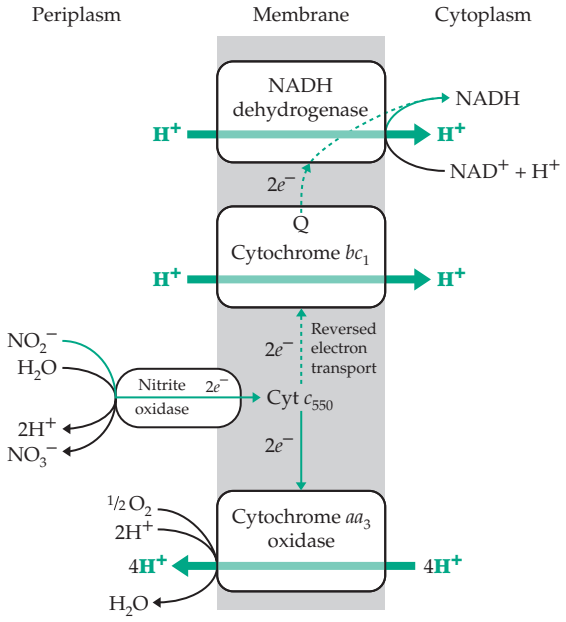

Figure 18-20 Electron transport system for oxidation of the nitrite ion to the nitrate ion by *Nitrobacter*. Only one site of proton pumping for oxidative phosphorylation is available. Generation of NADH for biosynthesis requires two stages of reverse electron transport.

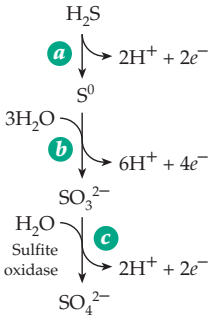
organisms, found in water and soil, are able to grow in a simple salt medium containing an oxidizable sulfur compound and CO_2. One complexity in understanding their energy-yielding reactions is the tendency of sulfur to form chain molecules. Thus, when sulfide is oxidized, it is not clear that it is necessarily converted to monoatomic elemental sulfur as indicated in Eq. 18-19. Elemental sulfur (S_8^0) often precipitates. In *Beggiotoa*, another sulfide-oxidizing bacterium, sulfur is often seen as small globules within the cells. Fibrous sulfur precipitates are often abundant in the sulfide-rich layers of ponds, lakes, and oceans.[318]



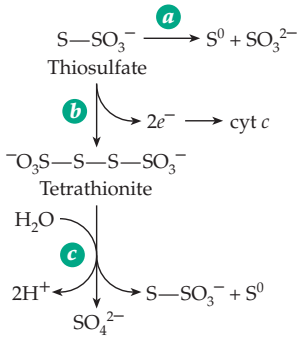
(18-19)

The reactions of Eq. 18-19 occur in the periplasmic space of some species.[315,323a,324] Steps *a* and *b* of Eq. 18-19 are catalyzed by a 67-kDa sulfide dehydrogenase in the periplasm of a purple photosynthetic bacterium.[324] The enzyme consists of a 21-kDa subunit containing two cytochrome *c*-like hemes, presumably the site of binding of S^{2-}, and a larger 46-kDa FAD-containing flavoprotein resembling glutathione reductase.[324] The molybdenum-containing sulfite oxidase (Fig. 16-32), which is found in the intermembrane space of mitochondria, may be present in the periplasmic space of these bacteria. However, there is also an intracellular pathway for sulfite oxidation (see Eq. 18-22).

The sulfide-rich layers inhabited by the sulfur oxidizers also contain thiosulfate, $S_2O_3^{2-}$. It may arise, in part, from reaction of glutathione with elemental sulfur:

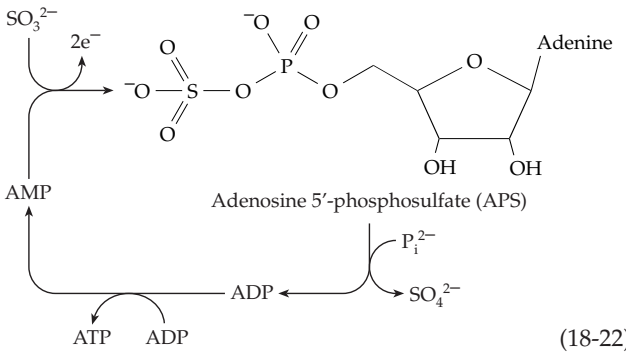
$$\text{GSH} + S_8^0 \rightarrow \text{G—S—}S_8\text{—H} \qquad (18\text{-}20)$$

The linear polysulfide obtained by this reaction may be oxidized, the sulfur atoms being removed from the chain either one at a time to form sulfite or two at a time to form thiosulfate.[322,322a] Thiosulfate is oxidized by all species, the major pathway beginning with cleavage to S^0 and SO_3^{2-} (Eq. 18-21, step *a*). At high thiosulfate concentrations some may be oxidized to tetrathionate (step *b*), which is hydrolyzed to sulfate (step *c*).



(18-21)

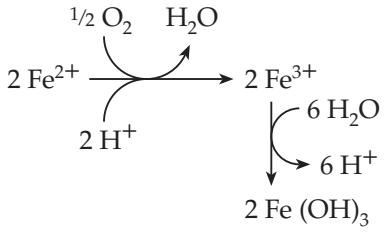
Oxidation of sulfite to sulfate within cells occurs by a pathway through **adenosine 5'-phosphosulfate** (**APS**, adenylyl sulfate). Oxidation via APS (Eq. 18-22) provides a means of substrate-level phosphorylation,



(18-22)

the only one known among chemolithotrophic bacteria. No matter which of the two pathways of sulfite oxidation is used, thiobacilli also obtain energy via electron transport. With a value of $E°'$ (pH 7) of −0.454 V [$E°'$ (pH 2) = −0.158 V] for the sulfate–sulfite couple an abundance of energy may be obtained. Oxidation of sulfite to sulfate produces hydrogen ions. Indeed, pH 2 is optimal for the growth of *Thiobacillus thiooxidans*, and the bacterium withstands 5% sulfuric acid.[322]

The "iron bacterium" *Thiobacillus ferrooxidans* obtains energy from the oxidation of Fe^{2+} to Fe^{3+} with subsequent precipitation of ferric hydroxide (Eq. 18-23). However, it has been recognized recently that a previously unknown species of Archaea is much more important than *T. ferrooxydans* in catalysis of this reaction.[324a]



(18-23)

Since the reduction potential for the Fe(II) / Fe(III) couple is + 0.77 V at pH 7, the energy obtainable in this reaction is small. These bacteria always oxidize reduced sulfur compounds, too. Especially interesting is their oxidation of **pyrite**, ferrous sulfide (Eq. 18-24). The Gibbs energy change was calculated from published data[325] using a value of $G_f°$ for Fe $(OH)_3$ of

$$2\ FeS + 4\tfrac{1}{2}\ O_2 + 5\ H_2O \rightarrow 2\ Fe(OH)_3 + 2\ SO_4^{2-} + 4\ H^+$$
$$\Delta G'\ (pH\ 2) = -1340\ kJ \qquad (18\text{-}24)$$

−688 kJ mol^{-1} estimated from its solubility product. Because sulfuric acid is generated in this reaction, a serious water pollution problem is created by the bacteria living in abandoned mines. Water running out of the mines often has a pH of 2.3 or less.[326]

Various invertebrates live in S^{2-}-containing waters. Among these is a clam that has symbiotic sulfur-oxidizing bacteria living in its gills. The clam tissues apparently carry out the first step in oxidation of the sulfide.[327] Among the animals living near sulfide-rich thermal vents in the ocean floor are giant 1-meter-long tube worms. Both a protective outer tube and symbiotic sulfide-oxidizing bacteria protect them from toxic sulfides.[319,320]

2. Anaerobic Respiration

Nitrate as an electron acceptor. The use of nitrate as an alternative oxidant to O_2 is widespread among bacteria. For example, *E. coli* can subsist anaerobically by reducing nitrate to nitrite (Eq. 18-25).[311,328] The respiratory (dissimilatory) nitrate reductase that

$$NO_3^- + 2\ H^+ + 2e^- \rightarrow NO_2^- + H_2O$$
$$E°'\ (pH7) = +0.421\ V \qquad (18\text{-}25)$$

catalyzes the reaction is a large three-subunit molybdenum-containing protein. The enzyme is present in the plasma membrane, and electrons flow from ubiquinone through as many as six heme and Fe–S centers to the molybdenum atom.[328-329] A second molybdoenzyme, formate dehydrogenase (discussed in Chapter 16), appears to be closely associated with nitrate reductase. Formate is about as strong a reducing agent as NADH (Table 6-8) and is a preferred electron donor for the reduction of NO_3^- (Eq. 18-26).[329a,b] Since cytochrome *c* oxidase of the electron transport chain is bypassed, one less ATP is formed than when O_2 is the oxidant. Nitrate is the oxidant preferred by bacteria grown under anaerobic conditions. The

$$HCOO^- + NO_3^- + H^+ \rightarrow NO_2^- + CO_2 + H_2O$$
$$\Delta G'\ (pH\ 7) = 165\ kJ\ mol^{-1} \qquad (18\text{-}26)$$

presence of NO_3^- induces the synthesis of nitrate reductase and represses the synthesis of alternative enzymes such as **fumarate reductase**,[330,331] which reduces fumarate to succinate (see also p. 1027). On the other hand, if NO_3^- is absent and fumarate, which can be formed from pyruvate, is present, synthesis of fumarate reductase is induced. Although it is a much weaker oxidant than is nitrate ($E^{o'}$ = 0.031 V), fumarate is still able to oxidize H_2 or NADH with oxidative phosphorylation. Like the related succinate dehydrogenase, fumarate reductase of *E. coli* is a flavoprotein with associated Fe / S centers. It contains covalently linked FAD and Fe_2S_2, Fe_4S_4, and three-Fe iron–sulfur centers.[332] In some bacteria a soluble periplasmic cytochrome c_3 carried out the fumarate reduction step.[332a] Trimethylamine *N*-oxide[330,333] or dimethylsulfoxide (DMSO; Eq. 16-62)[334,335] can also serve as alternative oxidants for anaerobic respiration using appropriate molybdemum-containing reductases (Chapter 16).

Reduction of nitrite: denitrification. The nitrite formed in Eq. 18-25 is usually reduced further to ammonium ions (Eq. 18-27). The reaction may not be important to the energy metabolism of the bacteria, but it provides NH_4^+ for biosynthesis. This six-electron reduction is catalyzed by a hexaheme protein containing six *c*-type hemes bound to a single 63-kDa polypeptide chain.[336,337]

$$NO_2^- + 8\ H^+ + 6\ e^- \rightarrow 2\ H_2O + NH_4^+ \qquad (18\text{-}27)$$

Several types of **denitrifying bacteria**[315,338–340]

use either nitrate or nitrite ions as oxidants and reduce nitrite to N_2. A typical reaction for *Micrococcus denitrificans* is oxidation of H_2 by nitrate (Eq. 18-28). *Thiobacillus denitrificans*, like other thiobacilli, can oxidize

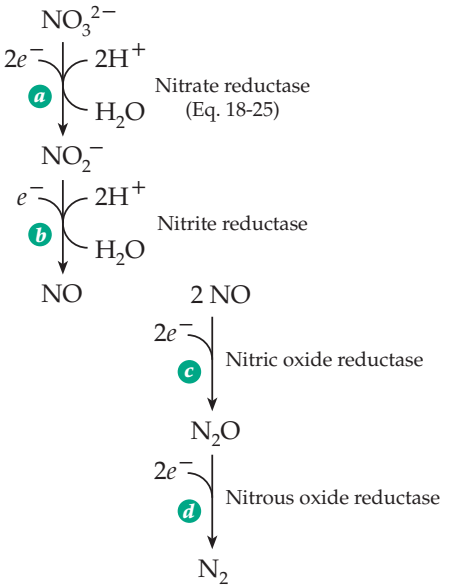
$$5\ H_2 + 2\ NO_3^- + 2\ H^+ \rightarrow N_2 + 6\ H_2O$$
$$\Delta G'\ (\text{pH } 7) = -561\ \text{kJ mol}^{-1}\ \text{of nitrate reduced or}$$
$$-224\ \text{kJ mol}^{-1}\ \text{of } H_2\ \text{oxidized} \qquad (18\text{-}28)$$

sulfur as well as H_2S or thiosulfate using nitrate as the oxidant (Eq. 18-29):

$$5\ S + 6\ NO_3^- + 2\ H_2O \rightarrow 5\ SO_4^{2-} + 3\ N_2 + 4\ H^+$$
$$\Delta G'\ (\text{pH } 7) = -455\ \text{kJ mol}^{-1}\ \text{of nitrate reduced or}$$
$$-546\ \text{kJ mol}^{-1}\ \text{of S oxidized} \qquad (18\text{-}29)$$

The reactions begin with reduction of nitrate to nitrite (Eq. 18-25) and continue with further reduction of nitrite to nitric oxide, **NO**; nitrous oxide, $\mathbf{N_2O}$; and dinitrogen, $\mathbf{N_2}$. A probable arrangement of the four enzymes needed for the reactions of Eq. 18-30 in *Paracoccus denitrificans* is shown in Fig. 18-21. See also pp. 884, 885.

Two types of dissimilatory nitrite reductases catalyze step *b* of Eq. 18-30. Some bacteria use a copper-containing enzyme, which contains a type 1 (blue) copper bound to a β barrel domain of one subunit and a type 2 copper at the catalytic center. The type 1 copper is thought to receive electrons from the small copper-containing carrier pseudoazurin (Chapter 16).[341–342b]



(18-30)

More prevalent is **cytochrome cd_1** nitrite reductase.[340,343–346] The water-soluble periplasmic enzyme is a homodimer of ~60-kDa subunits, each containing a *c*-type heme in a small N-terminal domain and **heme d_1**, a ferric dioxoisobacteriochlorin (Fig. 16-6). The

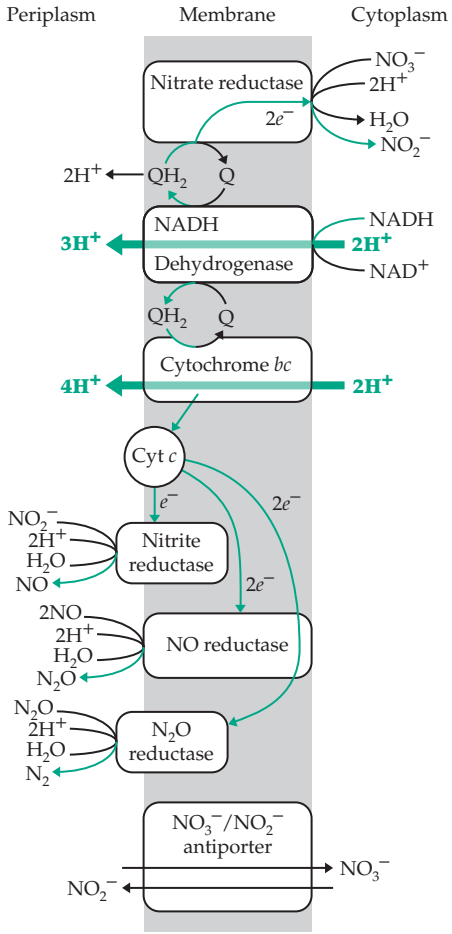


Figure 18-21 Organization of the nitrate reduction system in the outer membrane of the bacterium *Paracoccus dinitrificans* as outlined by Blaut and Gottschalk.[315] The equations are not balanced as shown but will be balanced if two NO_3^- ions are reduced to N_2 by five molecules of NADH (see also Eq. 18-28). Although this will also require seven protons, about 20 additional H^+ will be pumped to provide for ATP synthesis.

latter is present in the central channel of an eight-bladed β-sheet propeller[345-346g] similar to that in Fig. 15-23A. The heme d_1 is unusual in having its Fe atom ligated by a tyrosine hydroxyl oxygen, which may be displaced to allow binding of NO_3^-. The electron required for the reduction is presumably transferred from the electron transfer chain in the membrane to the heme *d*, via the heme *c* group.[347] Cytochrome cd_1 nitrite reductases have an unexpected second enzymatic activity. They catalyze the four-electron reduction of O_2 to H_2O, as does cytochrome *c* oxidase. However, the rate is much slower than that of nitrite reduction.[340,348]

The enzyme catalyzing the third step of Eq. 18-30 (step *c*), **nitric oxide reductase**, is an unstable membrane-bound protein cytochrome *bc* complex.[349,350]

It has been isolated as a two-subunit protein, but genetic evidence suggests the presence of additional subunits.[350] The small subunit is a cytochrome *c*, while the larger subunit is predicted to bind two protohemes as well as a nonheme iron center. This protein also shows sequence homology with cytochrome *c* oxidase. It contains no copper, but it has been suggested that a heme *b*–nonheme Fe center similar to the heme *a*–Cu_B center of cytochrome *c* oxidase may be present. It may be the site at which the nitrogen atoms of two molecules of NO are joined to form N_2O.[350,351] A different kind of NO reductase is utilized by the denitrifying fungus *Fusarium oxysporum*. It is a cytochrome P450 but with an unusually low redox potential (−0.307 V). This **cytochrome P450$_{nor}$** does not react with O_2 (as in Eq. 18-57) but binds NO to its heme Fe^{3+}, reduces the complex with two electrons from NADH, then reacts with a second molecule of NO to give N_2O and H_2O.[352]

Reduction of N_2O to N_2 by bacteria (Eq. 18-30, step *d*) is catalyzed by the copper-containing nitrous oxide reductase. The purple enzyme is a dimer of 66-kDa subunits, each containing four atoms of Cu.[353] It has spectroscopic properties similar to those of cytochome *c* oxidase and a dinuclear copper–thiolate center similar to that of Cu_A in cytochrome *c* oxidase (p. 1030). The nature of the active site is uncertain.[354]

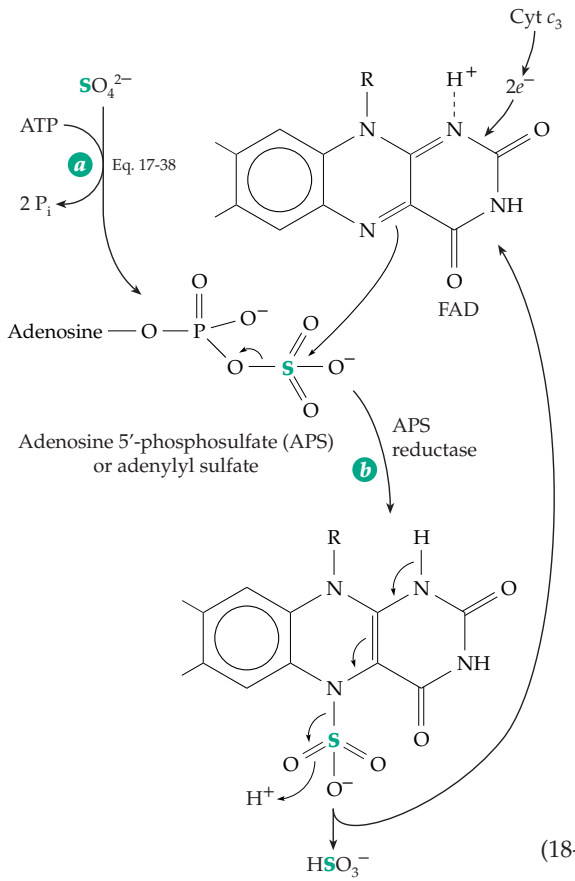
Sulfate-reducing and sulfur-reducing bacteria. A few obligate anaerobes obtain energy by using sulfate ion as an oxidant.[355–356a] For example, *Desulfovibrio desulfuricans* catalyzes a rapid oxidation of H_2 with reduction of sulfate to H_2S (Eq. 18-31).

$$4\,H_2 + SO_4^{2-} + 2\,H^+ \rightarrow H_2S + 4\,H_2O$$
$$\Delta G'\ (\text{pH } 7) = -154\ \text{kJ mol}^{-1}\ \text{of sulfate reduced} \qquad (18\text{-}31)$$

While this may seem like an esoteric biological process, the reaction is quantitatively significant. For example, it has been estimated that within the Great Salt Lake basin bacteria release sulfur as H_2S in an amount of 10^4 metric tons (10^7 kg) per year.[357]

The reduction potential for sulfate is extremely low ($E°'$, pH 7 = −0.454 V), and organisms are not known to reduce it directly to sulfite. Rather, a molecule of ATP is utilized to form adenosine 5'-phosphosulfate (APS) through the action of **ATP sulfurylase** (ATP:sulfate adenylyltransferase, Eq. 17-38).[358,359] APS is then reduced by cytochrome c_3 (Eq. 18-32, step *b*). The 13-kDa low-potential ($E°'$, pH 7 = 0.21 V) cytochrome c_3 contains four heme groups (Figure 16-8C) and is found in high concentration in sulfate-reducing bacteria.[360,361] Some of these bacteria have larger polyheme cytochromes *c*.[361a] For example, *Desulfovibrio vulgaris* forms a 514-residue protein carrying 16 hemes organized as four cytochrome c_3-like domains.[362] Each heme in cytochrome c_3 has a distinct redox potential within the range −0.20 to −0.40 V.[361–363]

APS is reduced (Eq. 18-32, step *b*) by **APS reductase**, a 220-kDa iron–sulfur protein containing FAD and several Fe−S clusters. An intermediate in the reaction may be the adduct of sulfite with FAD, which may be formed as in Eq. 18-32. The initial step in this hypothetical mechanism is displacement on sulfur by a strong nucleophile generated by transfer of electrons from reduced ferredoxin to cytochrome c_3 to the flavin.[364]



(18-32)

Bisulfite produced according to Eq. 18-32 is reduced further by a **sulfite reductase,** which is thought to receive electrons from flavodoxin, cyt c_3, and a hydrogenase. ATP synthesis is coupled to the reduction. Sulfite reductases generally contain both siroheme and Fe_4S_4 clusters (Fig. 16-19). They appear to be able to carry out the 6-electron reduction to sulfide without accumulation of intermediates.[365,366] However, in contrast to the assimilatory sulfite reductases present in many organisms, the dissimilatory nitrite reductases of sulfur-reducing bacteria may also release some thiosulfate $S_2O_3^{2-}$.[367] A possible role of menaquinone (vitamin K_2), present in large amounts in *Desulfovibrio*, has been suggested.[311] Although *Desulfovibrio* can obtain their energy from Eq. 18-31, they are not true autotrophs and must utilize compounds such as acetate together with CO_2 as a carbon source.

Some thermophilic archaeobacteria are able to live with CO_2 as their sole source of carbon and reduction of elemental sulfur with H_2 (Eq. 18-33) as their sole source of energy.[368,369]

$$H_2 + S^0 \rightarrow H_2S$$
$$\Delta G^\circ = -27.4 \text{ kJ mol}^{-1} \qquad (18\text{-}33)$$

This is remarkable in view of the small standard Gibbs energy decrease. Some species of the archaeobacterium *Sulfolobus* are able either to live aerobically oxidizing sulfide to sulfate with O_2 (Eq. 18-22) or to live anaerobically using reduction of sulfur by Eq. 18-33 as their source of energy.[369]

The sulfate-reducing bacterium *Desulfovibrio sulfodismutans* carries out what can be described as "inorganic fermentations" which combine the oxidation of compounds such as sulfite or thiosulfate (as observed for sulfur-oxidizing bacteria; Eq. 18-22), with reduction of the same compounds (Eq. 18-34).[370,370a] Dismutation of $S_2O_3^{2-}$ plus H_2O to form SO_4^{2-} and H_2S also occurs but with a less negative Gibbs energy change.

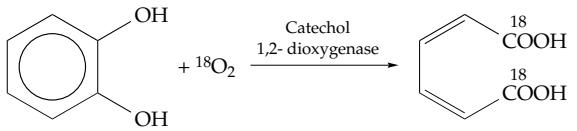
$$4\ SO_3^{2-} + H^+ \rightarrow 3\ SO_4^{2-} + HS^-$$
$$\Delta G' \text{ (pH 7)} = -185 \text{ kJ/mol} \qquad (18\text{-}34)$$

A strain of *Pseudomonas* obtains all of its energy by reducing sulfate using phosphite, which is oxidized to phosphate.[370b]

Methane bacteria. The methane-producing bacteria (Chapter 15) are also classified as chemiautotrophic organisms. While they can utilize substances such as methanol and acetic acid, they can also reduce CO_2 to methane and water using H_2 (Fig. 15-22). The electron transport is from hydrogenase, perhaps through ferredoxin to formate dehydrogenase and via the deazaflavin F_{420} and $NADP^+$ to the methanopterin-dependent dehydrogenases that carry out the stepwise reduction of formate to methyl groups (Fig. 16-28). Generation of ATP probably involves proton pumps, perhaps in internal coupling membranes .[315,371]

F. Oxygenases and Hydroxylases

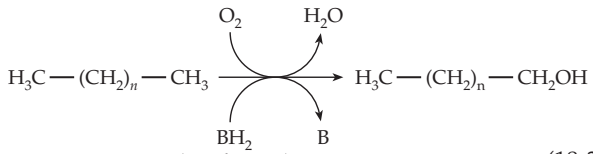
For many years the idea of dehydrogenation dominated thinking about biological oxidation. Many scientists assumed that the oxygen found in organic substances always came from water, e.g., by addition of water to a double bond followed by dehydrogenation of the resulting alcohol. Nevertheless, it was observed that small amounts of O_2 were essential, even to anaerobically growing cells.[372] In 1955, Hayaishi and Mason independently demonstrated that ^{18}O was sometimes incorporated into organic compounds directly from $^{18}O_2$ as in Eq. 18-35. Today a bewildering variety of **oxygenases** are



Catechol *Cis,cis*-muconic acid (18-35)

known to function in forming such essential metabolites as sterols, prostaglandins, and active derivatives of vitamin D. Oxygenases are also needed in the catabolism of many substances, often acting on nonpolar groups that cannot be attacked readily by other types of enzyme.[372]

Oxygenases are classified either as **dioxygenases** or as **monooxygenases**. The monooxygenases are also called mixed function oxidases or **hydroxylases**. Dioxygenases catalyze incorporation of two atoms of oxygen as in Eq. 18-35, but monooxygenases incorporate only one atom. The other oxygen atom from the O_2 is converted to water. A typical monooxygenase-catalyzed reaction is the hydroxylation of an alkane to an alcohol (Eq. 18-36).



(18-36)

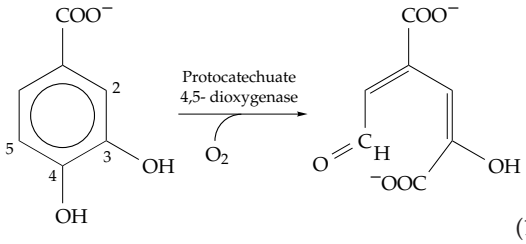
A characteristic of the monooxygenases is that an additional reduced substrate, a **cosubstrate** (BH_2 in Eq. 18-36), is usually required to reduce the second atom of the O_2 molecule to H_2O.

Since O_2 exists in a "triplet" state with two unpaired electrons, it reacts rapidly only with transition metal ions or with organic radicals (Chapter 16). For this reason, most oxygenases contain a transition metal ion, usually of iron or copper, or contain a cofactor, such as FAD, that can easily form a radical or act on a cosubstrate or substrate to form a free radical.

1. Dioxygenases

Among the best known of the oxygenases that incorporate both atoms of O_2 into the product are those that participate in the biological degradation of aromatic compounds by cleaving double bonds at positions between two OH groups as in Eq. 18-35 or adjacent to one OH group of an *ortho* or *para* hydroxyl pair.[373] A much studied example is **protocatechuate 3,4-dioxygenase**,[373–375] which cleaves its substrate

between the two OH groups (*intradiol cleavage*) as in Eq. 18-35. A different enzyme, **protocatechuate 4,5-dioxygenase**,[357] cleaves the same substrate next to just one of the two OH groups (*extradiol cleavage*; Eq. 18-37) to form the aldehyde α-hydroxy-δ-carboxymuconic semialdehyde. Another extradiol cleaving enzyme, **protocatechuate 2,3-dioxygenase**, acts on the same substrate. Many other dioxygenases attack related substrates.[376–380] Intradiol-cleaving enzymes are usually iron-tyrosinate proteins (Chapter 16) in which the



(18-37)

iron is present in the Fe(III) oxidation state and remains in this state throughout the catalytic cycle.[375] The enzymes usually have two subunits and no organic prosthetic groups. For example, a protocatechuate 3,4-dioxygenase from *Pseudomonas* has the composition $(\alpha\beta Fe)_{12}$ with subunit masses of 23 (α) and 26.5 (β) kDa. The iron is held in the active site cleft between the α and β subunits by Tyr 408, Tyr 447, His 460, and His 462 of the β subunit and a water molecule.[375] These enzymes and many other oxygenases probably assist the substrate in forming radicals that can react with O_2 to form organic peroxides. Some plausible intermediate species are pictured in Fig. 18-22. The reactions are depicted as occurring in two-electron steps. However, O_2 is a diradical, and it is likely that the Fe^{3+}, which is initially coordinated to both phenolate groups of the ionized substrate, assists in forming an organic free radical that reacts with O_2.

Extradiol dioxygenases have single Fe^{2+} ions in their active sites. The O_2 probably binds to the Fe^{2+} and may be converted transiently to an Fe^{3+}-superoxide complex which adds to the substrate. Some extradiol dioxygenases require an Fe_2S_2 ferredoxin to reduce any Fe^{3+}-enzyme that is formed as a side reaction back to the Fe^{2+} state.[381] Possible intermediates are given in Fig. 18-22 (left side) with two-electron steps used to save space and to avoid giving uncertain details about free radical intermediates. Formation of the organic radical is facilitated by the iron atom, which may be coordinated initially to both phenolate groups of the ionized substrate. The peroxide intermediates, for both types of dioxygenases, may react and be converted to various final products by several mechanisms.[382]

Tryptophan dioxygenase (indoleamine 2,3-dioxygenase)[383] is a heme protein which catalyzes the reaction of Eq. 18-38. The oxygen atoms designated by

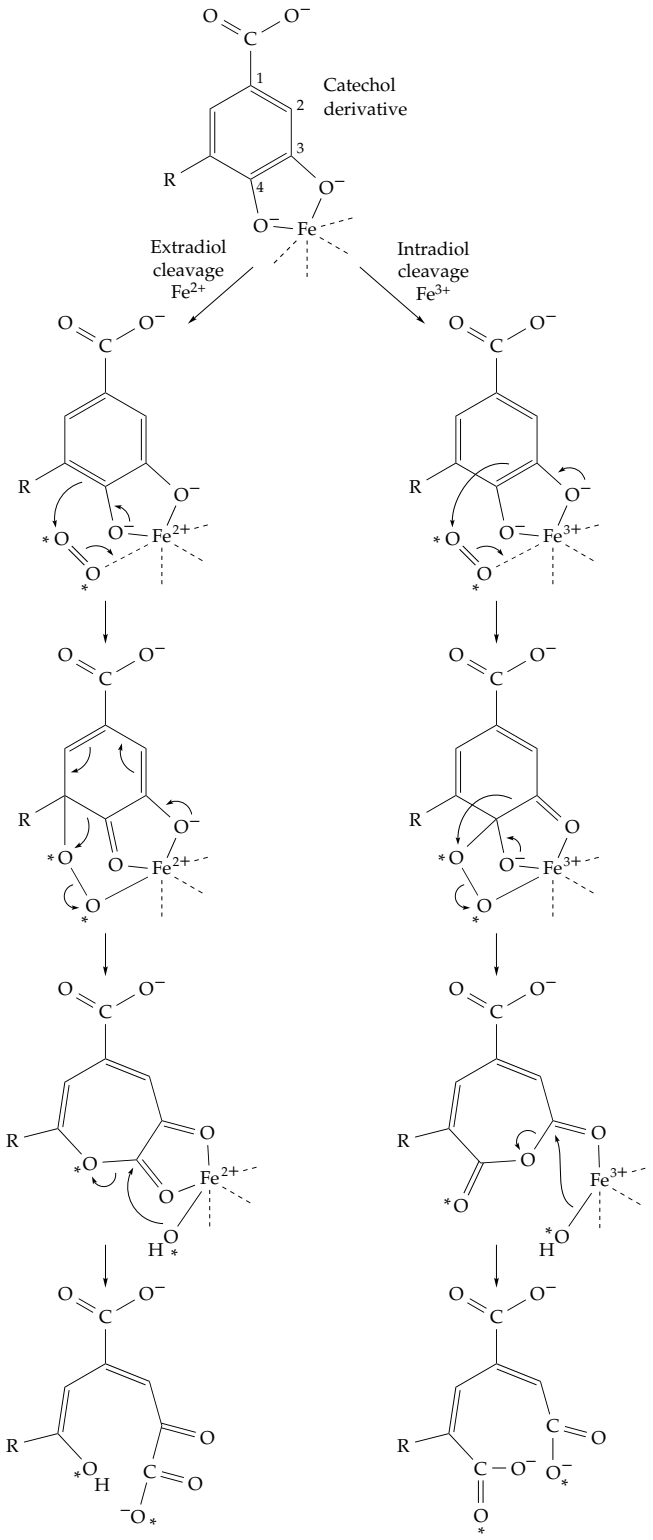


Figure 18-22 Some possible intermediates in the action of extradiol (left) and intradiol (right) aromatic dioxygenases. Although the steps depict the flow of pairs of electrons during the formation and reaction of peroxide intermediates, the mechanisms probably involve free radicals whose formation is initiated by O_2. The asterisks show how two atoms of labeled oxygen can be incorporated into final products. After Ohlendorf *et al.*[374]

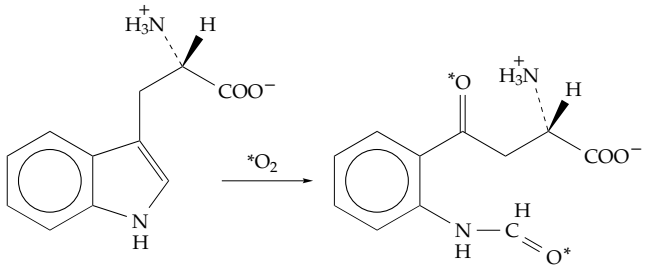
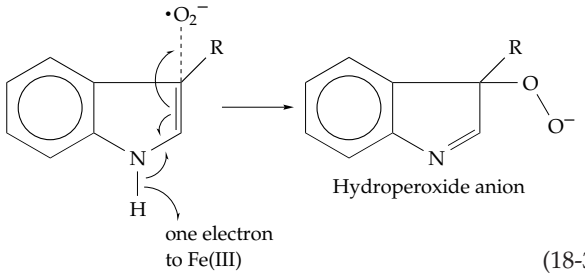
the asterisks are derived from O_2. Again, the first step is probably the formation of a complex between Fe(II) and O_2, but tryptophan must also be present before this can occur. At 5°C the enzyme, tryptophan, and O_2 combine to give an altered spectrum reminiscent of that of compound III of peroxidase (Fig. 16-14). This oxygenated complex may, perhaps, then be converted to a complex of Fe(II) and superoxide ion.



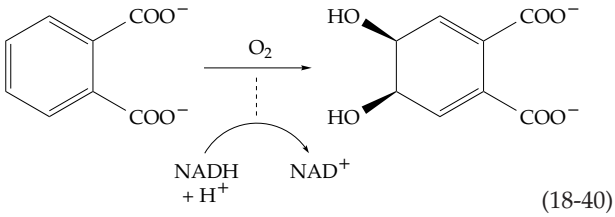
(18-38)

There is much evidence, including inhibition by superoxide dismutase and stimulation by added potassium superoxide,[384] that the superoxide anion radical is the species that attacks the substrate (Eq. 18-39). In this reaction one electron is returned to the Fe(III) form of the enzyme to regenerate the original Fe(II) form. Subsequent reaction of the hydroperoxide anion would give the observed products.



(18-39)

Some dioxygenases require a cosubstrate. For example, **phthalate dioxygenase**[385] converts phthalate to a *cis*-dihydroxy derivative with NADH as the cosubstrate (Eq. 18-40). Similar double hydroxylation reactions catalyzed by soil bacteria are known for benzene, benzoate,[386] toluene, naphthalene, and several other aromatic compounds.[386a] The formation of the *cis*-glycols is usually followed by dehydrogenation or oxidative decarboxylation by NAD^+ to give a catechol, whose ring is then opened by another dioxygenase reaction (Chapter 25). An elimination of Cl^- follows dioxygenase action on *p*-chlorophenylacetate and produces 3,4-dihydroxyphenylacetate as a product. Pthalate dioxygenases consist of two subunits. The 50-kDa dioxygenase subunits receive electrons from reductase subunits that contain a Rieske-type Fe–S



(18-40)

centers and bound FMN.[387] The dioxygenase also contains an Fe_2S_2 center, and electrons flow from NADH to FMN and through the two Fe–S centers to the Fe^{2+} of the active site.[387–388]

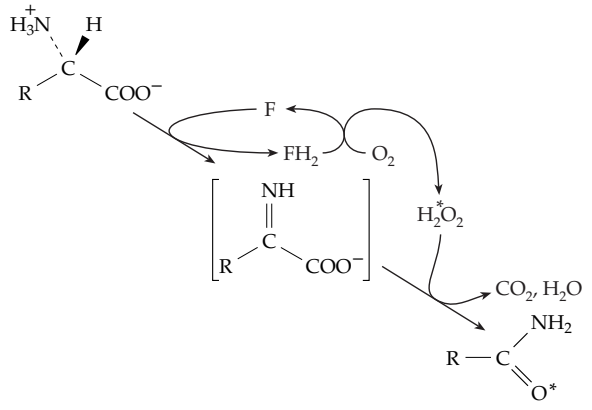
Lipoxygenases catalyze oxidation of polyunsaturated fatty acids in plant lipids. Within animal tissues the lipoxygenase-catalyzed reaction of arachidonic acid with O_2 is the first step in formation of **leukotrienes** and other mediators of inflammation. These reactions are discussed in Chapter 21.

2. Monooxygenases

Two classes of monooxygenases are known. Those requiring a cosubstrate (BH_2 of Eq. 18-36) in addition to the substrate to be hydroxylated are known as **external monooxygenases**. In the other group, the **internal monooxygenases**, some portion of the substrate being hydroxylated also serves as the cosubstrate. Many internal monooxygenases contain flavin cofactors and are devoid of metal ions.

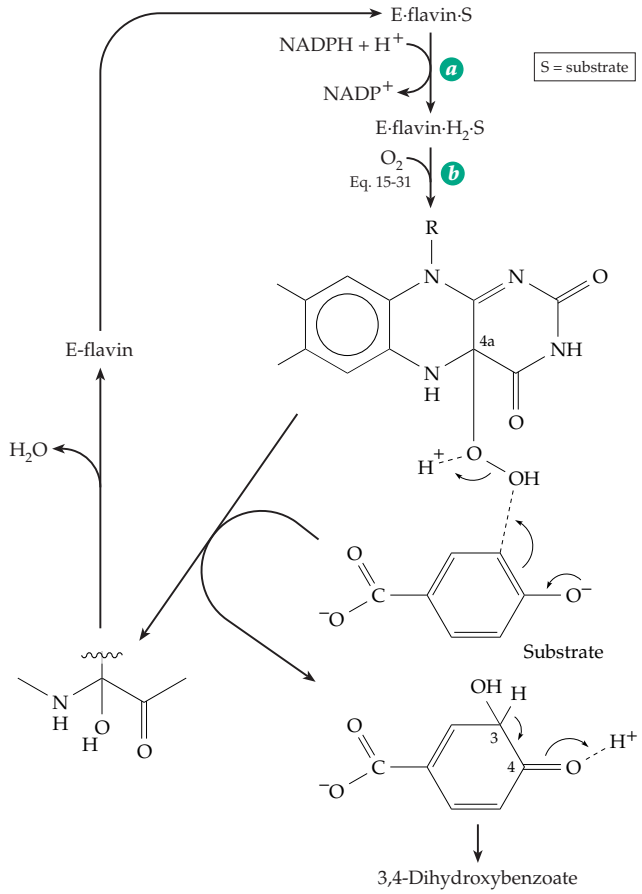
Flavin-containing monooxygenases. One group of flavin-dependent monooxygenases form H_2O_2 by reaction of O_2 with the reduced flavin and use the H_2O_2 to hydroxylate 2-oxoacids. An example is **lactate monooxygenase,** which apparently dehydrogenates lactate to pyruvate and then oxidatively decarboxylates the pyruvate to acetate with H_2O_2 (Eq. 15-36). One atom of oxygen from O_2 is incorporated into the acetate formed.[389,390] In a similar manner, the FAD-containing bacterial **lysine monooxygenase** probably catalyzes the sequence of reactions shown in Eq. 18-41.[391] When native lysine monooxygenase was treated with sulfhydryl-blocking reagents the resulting modified enzyme produced a 2-oxoacid, ammonia, and H_2O_2, just the products predicted from the hydrolytic decomposition of the bracketed intermediate of Eq. 18-41. Similar bacterial enzymes act on tryptophan and phenylalanine.[392]

NADPH can serve as a cosubstrate of flavoprotein monooxygenase by first reducing the flavin, after which the reduced flavin can react with O_2 to generate the hydroxylating reagent.[393] An example is the bacterial **4-hydroxybenzoate hydroxylase** which forms 3,4-dihydroxybenzoate.[394] The 43-kDa protein consists of three domains, the large FAD-binding domain being folded in nearly the same way as that of glutathione reductase (Fig. 15-10). The 4-hydroxybenzoate binds



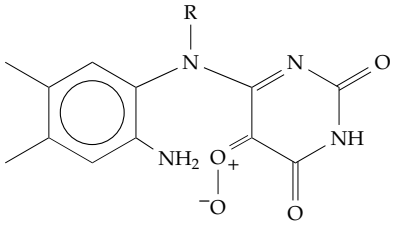
(18-41)

first into a deep cleft below the N-5 edge of the isoalloxazine ring of the FAD; then the NADH binds. Spectroscopic studies have shown the existence of at least three intermediates. The first of these has been identified as the 4a-peroxide whose formation (Eq. 15-31) is discussed in Chapter 15. The third intermediate is the corresponding 4a-hydroxyl compound. The substrate hydroxylation must occur in a reaction with the flavin peroxide, presumably with the phenolate anion form of the substrate (Eq. 18-42).[395] The initial hydroxylation product is tautomerized to form the product 3,4-dihydroxybenzoate.

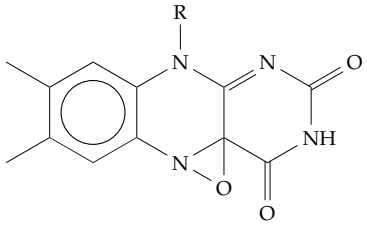


(18-42)

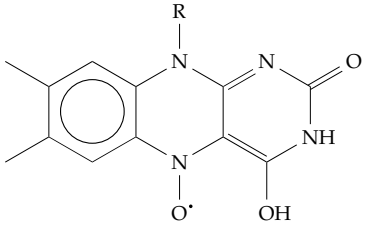
According to this mechanism, one of the two oxygen atoms in the hydroperoxide reacts with the aromatic substrate, perhaps as OH^+ or as a superoxide radical. A variety of mechanisms for activating the flavin peroxide to give a more potent hydroxylating reagent have been proposed. These include opening of the central ring of the flavin to give a carbonyl oxide intermediate which could transfer an oxygen atom to the substrate,[396] elimination of H_2O to form an **oxaziridine,**[397] or rearrangment to a **nitroxyl radical**.[398] Any of these might be an active electrophilic hydroxylating reagent. However, X-ray structural studies suggest that conformational changes isolate the substrate–FAD-enzyme complex from the medium stabilizing the 4a peroxide via hydrogen bonding[399–400] in close proximity to the substrate. Reaction could occur by the simple mechanism of Eq. 18-42, a mechanism also supported by ^{19}F NMR studies with fluorinated substrate analogs[401] and other investigations.[401a,b]



Carbonyl oxide



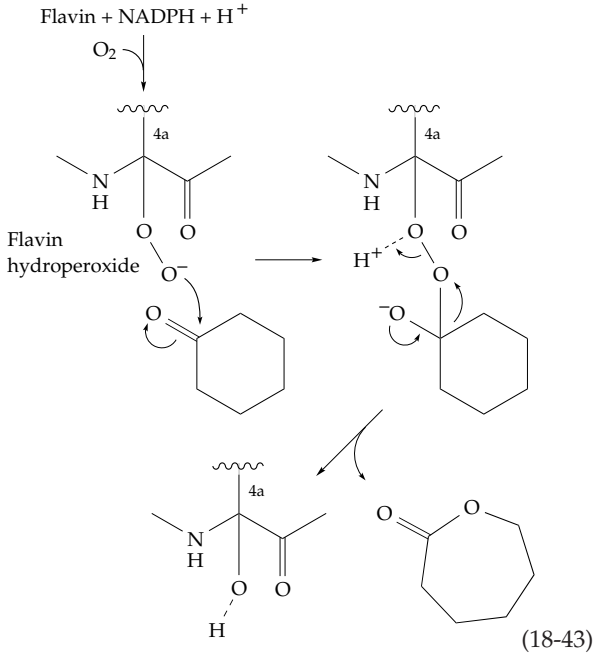
An oxaziridine



A nitroxyl radical

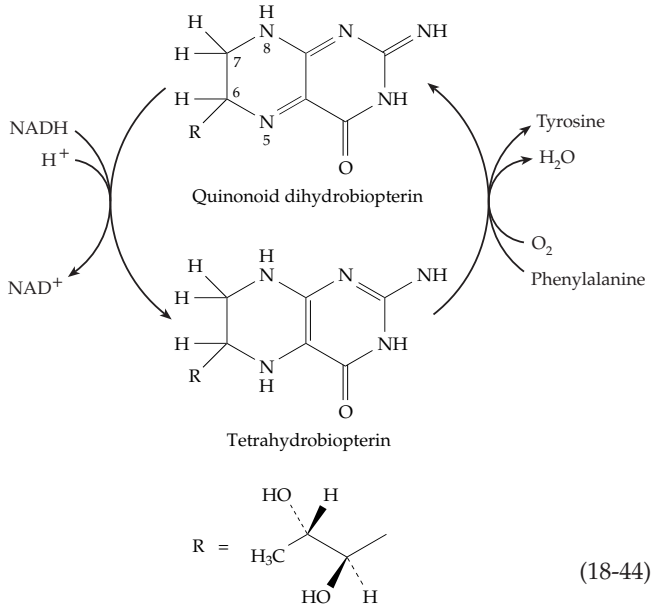
Related flavin hydroxylases act at nucleophilic positions on a variety of molecules[393,402] including phenol,[403] salicylate,[404] anthranilate,[405] *p*-cresol,[406] 4-hydroxyphenylacetate,[407,408] and 4-aminobenzoate.[409] Various microsomal flavin hydroxylases are also known.[410] Flavin peroxide intermediates are also able to hydroxylate some electrophiles.[411] For example, the bacterial **cyclohexanone oxygenase** catalyzes

the ketone to lactone conversion of Eq. 18-43.[411a] The mechanism presumably involves the nucleophilic attack of the flavin hydroperoxide on the carbonyl group of the substrate followed by rearrangement. This parallels the Baeyer–Villiger rearrangement that results from treatment of ketones with peracids.[393] Cyclohexanone oxygenase also catalyzes a variety of other reactions,[412] including conversion of sulfides to sulfoxides.



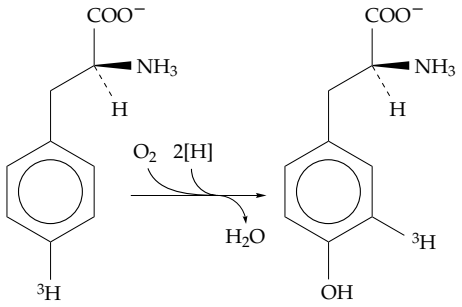
(18-43)

Reduced pteridines as cosubstrates. A dihydro form of biopterin (Fig. 15-17) serves as a cosubstrate, that is reduced by NADPH (Eq. 18-44) in hydroxylases that act on phenylalanine, tyrosine, and tryptophan.



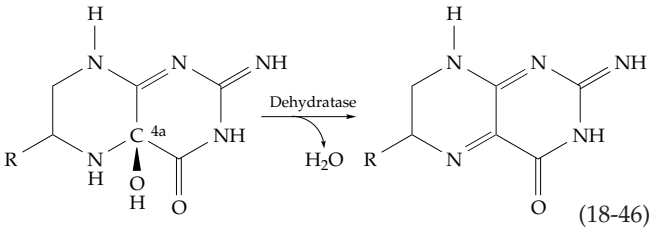
(18-44)

The tetrahydrobiopterin formed in this reaction is similar in structure to a reduced flavin. The mechanism of its interaction with O_2 could reasonably be the same as that of 4-hydroxybenzoate hydroxylase. However, **phenylalanine hydroxylase**, which catalyzes the formation of tyrosine (Eq. 18-45), a dimer of 451-residue subunits, contains one Fe per subunit,[413–415a] whereas flavin monooxygenases are devoid of iron. **Tyrosine hydroxylase**[416–419a] and **tryptophan hydroxylase**[420] have very similar properties. All three enzymes contain regulatory, catalytic, and tetramerization domains as well as a common Fe-binding motif in their active sites.[413,421,421a]



(18-45)

The role of the iron atom in these enzymes must be to accept an oxygen atom from the flavin peroxide, perhaps forming a reactive ferryl ion and transferring the oxygen atom to the substrate, e.g., as do cytochromes P450 (see Eq. 18-57). The 4*a*-hydroxytetrahydrobiopterin, expected as an intermediate if the mechanism parallels that of Eq. 18-42, has been identified by its ultraviolet absorption spectrum.[422] A ring-opened intermediate has also been ruled out for phenylalanine hydroxylase.[423] However, the 4*a* –OH adduct has been observed by ^{13}C-NMR spectroscopy. Its absolute configuration is 4*a*(S) and the observation of an ^{18}O-induced shift in the ^{13}C resonance of the 4*a*-carbon atom[424] confirms the origin of this oxygen from $^{18}O_2$ (see Eq. 18-42). A "stimulator protein" needed for rapid reaction of phenylalanine hydroxylase has been identified as a **4*a*-carbinolamine dehydratase** (Eq. 18-46).[425–426] This protein also has an unexpected function as part of a complex with transcription factor HNF1 which is found in nuclei of liver cells.[425a,426]



(18-46)

Dihydrobiopterin can exist as a number of isomers. The quinonoid form shown in Eqs. 18-44 and 18-46 is

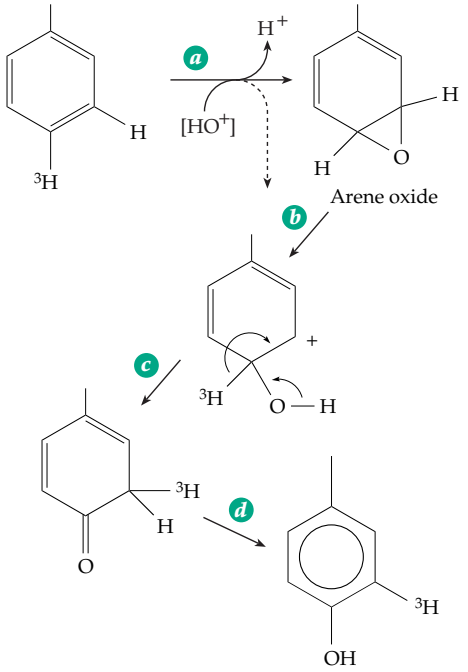
a tautomer of 7,8-dihydrobiopterin, the form generated by dihydrofolate reductase (Chapter 15). A pyridine nucleotide-dependent **dihydropteridine reductase**[427–429] catalyzes the left-hand reaction of Eq. 18-44.

The hereditary absence of phenylalanine hydroxylase, which is found principally in the liver, is the cause of the biochemical defect **phenylketonuria** (Chapter 25, Section B).[430,430a] Especially important in the metabolism of the brain are tyrosine hydroxylase, which converts tyrosine to 3,4-dihydroxyphenylalanine, the rate-limiting step in biosynthesis of the catecholamines (Chapter 25), and tryptophan hydroxylase, which catalyzes formation of 5-hydroxytryptophan, the first step in synthesis of the neurotransmitter 5-hydroxytryptamine (Chapter 25). All three of the pterin-dependent hydroxylases are under complex regulatory control.[431,432] For example, tyrosine hydroxylase is acted on by at least four kinases with phosphorylation occurring at several sites.[431,433,433a] The kinases are responsive to nerve growth factor and epidermal growth factor,[434] cAMP,[435] Ca^{2+} + calmodulin, and Ca^{2+} + phospholipid (protein kinase C).[436] The hydroxylase is inhibited by its endproducts, the catecholamines,[435] and its activity is also affected by the availability of tetrahydrobiopterin.[436]

Hydroxylation-induced migration. A general result of enzymatic hydroxylation of aromatic compounds is the intramolecular migration of a hydrogen atom or of a substituent atom or group as is shown for the ^3H atom in Eq. 18-45.[437] Dubbed the NIH shift (because the workers discovering it were in a National Institutes of Health laboratory), the migration tells us something about possible mechanisms of hydroxylation. In Eq. 18-45 a tritium atom has shifted in response to the entering of the hydroxyl group. The migration can be visualized as resulting from electrophilic attack on the aromatic system, e.g., by an oxygen atom from Fe(N)=O or by OH^+ (Eq. 18-47).

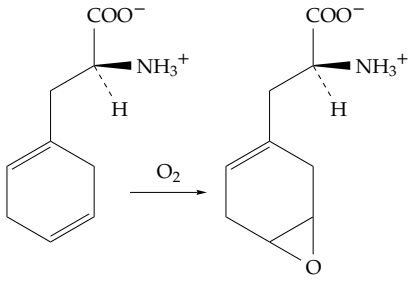
Such an attack could lead in step *a* either to an **epoxide** (**arene oxide**) or directly to a carbocation as shown in Eq. 18-47. Arene oxides can be converted, via the carbocation step *b*, to end products in which the NIH shift has occurred.[438] The fact that phenylalanine hydroxylase also catalyzes the conversion of the special substrate shown in Eq. 18-48 to a stable epoxide, which cannot readily undergo ring opening, also supports this mechanism.

Operation of the NIH shift can cause migration of a large substituent as is illustrated by the hydroxylation of 4-hydroxyphenylpyruvate (Eq. 18-49), a key step in the catabolism of tyrosine (Chapter 25). Human 4-hydroxyphenylpyruvate dioxygenase is a dimer of 43-kDa subunits.[439] A similar enzyme from *Pseudomonas* is a 150-kDa tetrameric iron-tyrosinate protein, which must be maintained in the reduced Fe(II) state for catalytic activity.[440] Although this enzyme is a



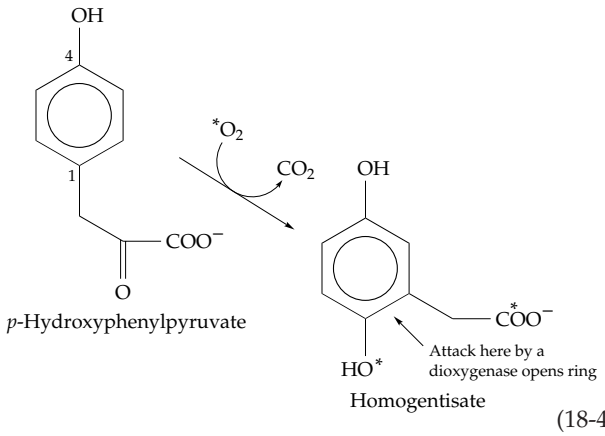
(18-47)

dioxygenase, it is probably related in its mechanism of action to the 2-oxoglutarate-dependent monooxygenases discussed in the next section (Eqs. 18-51, 18-52). It probably uses the oxoacid side chain of the substrate



(18-48)

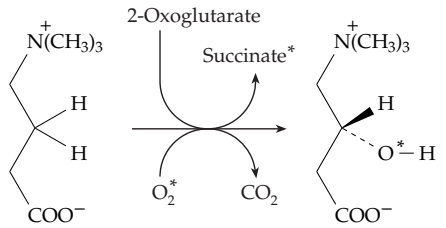
to generate a reactive oxygen intermediate such as Fe(IV)=O by the decarboxylative mechanism of Eqs. 18-50 and 18-51. The iron-bound oxygen attacks C1 of



(18-49)

the aromatic ring, the electron-donating *p*-hydroxyl group assisting. This generates a hydroxylated carbocation of the type shown in Eq. 18-47 in which the whole two-carbon side chain undergoes the NIH shift.

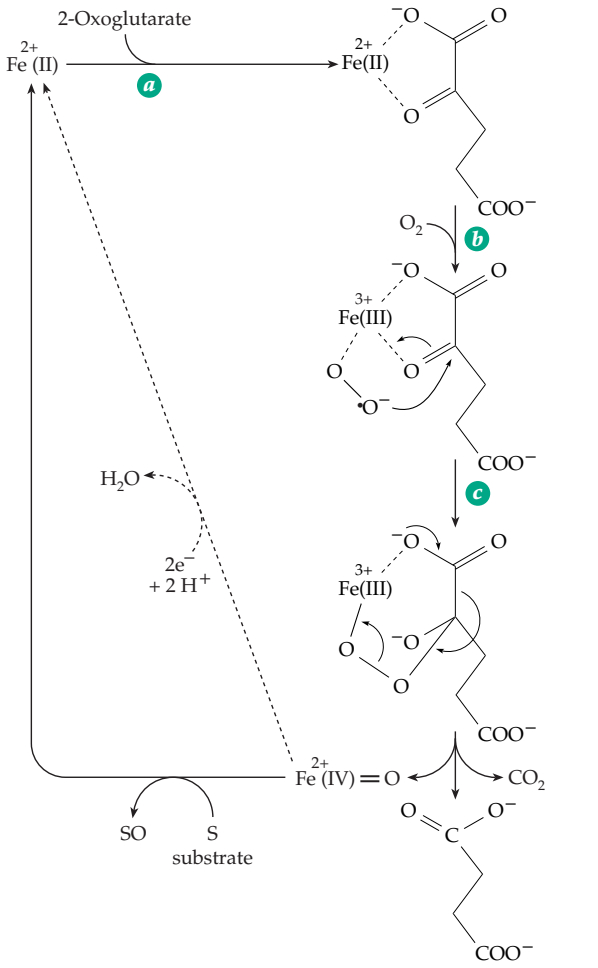
2-Oxoglutarate as a decarboxylating cosubstrate. Several oxygenases accept hydrogen atoms from 2-oxoglutarate, which is decarboxylated in the process to form succinate. Among these are enzymes catalyzing hydroxylation of residues of proline in both the 3- and 4-positions (Eq. 8-6)[441–444] and of lysine in the 5-position (Eq. 8-7)[445,446] in the collagen precursor **procollagen**. The hydroxylation of prolyl residues also takes place within the cell walls of plants.[447] Similar enzymes hydroxylate the β-carbon of aspartyl or asparaginyl side chains in EGF domains (Table 7-3) of proteins.[441] Thymine[448] and taurine[449,449a] are acted on by related dioxygenases. A bacterial oxygenase initiates the degradation of the herbicide 2,4-dichlorophenoxyacetic acid (2,4-D) using another 2-oxoglutarate-dependent hydroxylase.[450,451] In the human body a similar enzyme hydroxylates γ-butyrobetaine to form carnitine (Eq. 18-50).[452] All of



γ-Butyrobetaine ʟ-Carnitine (18-50)

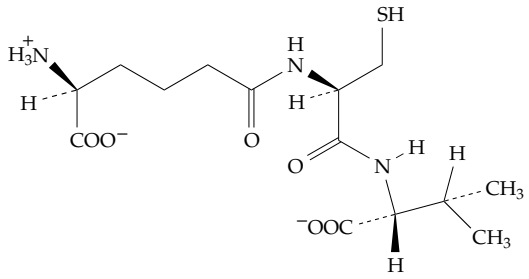
these enzymes contain iron and require ascorbate, whose function is apparently to prevent the oxidation of the iron to the Fe(III) state.

When $^{18}O_2$ is used for the hydroxylation of γ-butyrobetaine (Eq. 18-51), one atom of ^{18}O is found in the carnitine and one in succinate. The reaction is stereospecific and occurs with retention of configuration at C-3, the *pro*-R hydrogen being replaced by OH while the *pro*-S hydrogen stays.[453] Under some conditions these enzymes decarboxylate 2-oxoglutarate in the absence of a hydroxylatable substrate, the iron being oxidized to Fe^{3+} and ascorbate being consumed stoichiometrically.[454] A plausible mechanism (Eq. 18-51) involves formation of an Fe(II)–O_2 complex, conversion to Fe(III)$^+$ $^\bullet O_2^-$, and addition of the superoxide ion to 2-oxoglutarate to form an adduct.[451,455] Decarboxylation of this adduct could generate the oxidizing reagent, perhaps Fe(IV)=O. In the absence of substrate S the ferryl iron could be reconverted to Fe(II) by a suitable reductant such as ascorbate. In the absence of ascorbate the Fe(IV) might be reduced to a catalytically inert Fe(III) form.

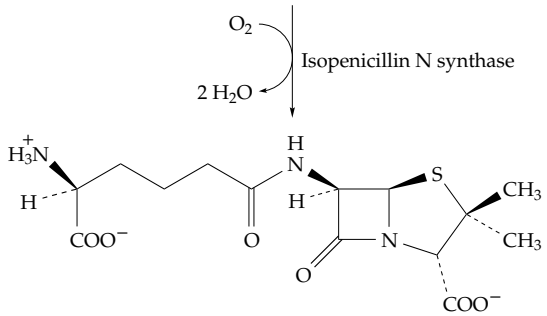


(18-51)

An unusual oxygenase with a single Fe^{2+} ion in its active site closes the four-membered ring in the biosynthesis of penicillins (Eq. 18-52). It transfers four



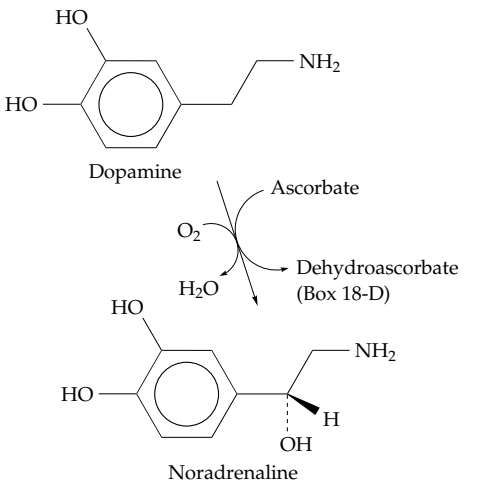
ʟ-δ-(α-Aminoadipoyl)-ʟ-cysteinyl-ᴅ-valine



Isopenicillin N (18-52)

hydrogen atoms from its dipeptide substrate to form two molecules of water and the product isopenicillin N.[456,457] Sequence comparison revealed several regions including the Fe-binding sites that are homologous with the oxoacid-dependent oxygenases. A postulated mechanism for **isopenicillin N synthase** involves formation of an Fe^{3+} superoxide anion complex as in Eq. 18-51. However, instead of attack on an oxoacid as in Eq. 18-51, it removes a hydrogen from the substrate to initiate the reaction sequence.[457] Other related oxygenases include **aminocyclopropane-1-carboxylate oxidase** (Eq. 24-35); **deacetoxycephalosporin C synthase**,[457a] an enzyme that converts penicillins to cephalosporins (Box 20-G); and **clavaminate synthase**,[458,459] an enzyme needed for synthesis of the β-lactamase inhibitor clavulanic acid, and **clavaminate synthase**.[458,459] This 2-oxoglutarate-dependent oxygenase catalyzes three separate reactions in the synthesis of the clinically important β-lactamase inhibitor clavulanic acid. The first step is similar to that in Eq. 18-50. The second is an oxidative cyclization and the third a desaturation reaction.

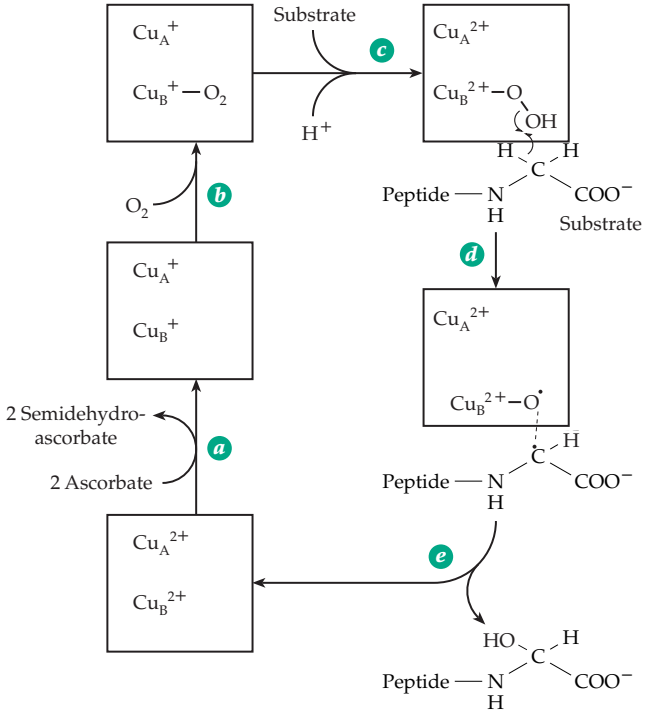
Copper-containing hydroxylases. Many Fe(II)-containing hydroxylases require a reducing agent to maintain the iron in the reduced state, and ascorbate is often especially effective. In addition, ascorbate is apparently a true cosubstrate for the copper-containing **dopamine β-hydroxylase**, an enzyme required in the synthesis of noradrenaline according to Eq. 18-53. This reaction takes place in neurons of the brain and in the adrenal gland, a tissue long known as especially rich in ascorbic acid. The reaction requires two molecules of ascorbate, which are converted in two one-electron steps to **semidehydroascorbate**.[460] Both the structure of this free radical and that of the fully oxidized form of vitamin C, **dehydroascorbic acid**, are shown in Box 18-D. Dopamine β-hydroxylase is a 290-kDa tetramer, consisting of a pair of identical disulfide-crosslinked homodimers, which contains two Cu ions per subunit.[461]



(18-53)

A similar copper-dependent hydroxylase constitutes the N-terminal domain of the **peptidylglycine α-amidating enzyme** (Eq. 10-11). This bifunctional enzyme hydroxylates C-terminal glycines in a group of neuropeptide hormones and other secreted peptides. The second functional domain of the enzyme cleaves the hydroxylated glycine to form a C-terminal amide group and glyoxylate.[462–464b] The three-dimensional structure of a 314-residue catalytic core of the hydroxylase domain is known.[463] Because of similar sequences and other properties, the structures of this enzyme and of dopamine β-hydroxylase are thought to be similar. The hydroxylase domain of the α-amidating enzyme is folded into two eight-stranded antiparallel jelly-roll motifs, each of which binds one of the two copper ions. Both coppers can exist in a Cu(II) state and be reduced by ascorbate to Cu(I). One Cu (Cu_A) is held by three imidazole groups and is thought to be the site of interaction with ascorbate. The other copper, Cu_B, which is 1.1 nm away from Cu_A, is held by two imidazoles. The substrate binds adjacent to Cu_B.[463]

The reaction cycle of these enzymes begins with reduction of both coppers from Cu(II) to Cu(I) (Eq. 18-54, step *a*). Both O_2 and substrate bind (steps *b* and *c*, but not necessarily in this order). The O_2 bound to Cu_B is reduced to a peroxide anion that remains bound to Cu_B. Both Cu_A and Cu_B donate one electron, both being oxidized to Cu(II). These changes are also included in step *c* of Eq. 18-54. One proposal is that the resulting peroxide is cleaved homolytically while removing the *pro-S* hydrogen of the glycyl residue.



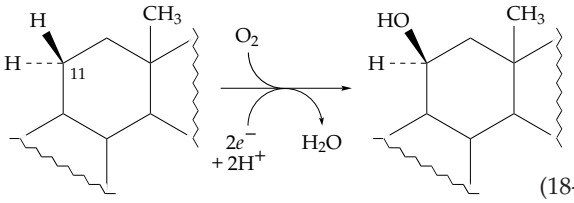
(18-54)

The resulting glycyl radical couples with the oxygen radical that is bound to Cu_B (step *e*).

A variety of other copper hydroxylases are known. For example, **tyrosinase**, which contains a binuclear copper center, catalyzes both hydroxylation of phenols and aromatic amines and dehydrogenation of the resulting catechols or *o*-aminophenols (Eq. 16-57). As in hemocyanin, the O_2 is thought to be reduced to a peroxide which bridges between the two copper atoms. Methane-oxidizing bacteria, such as *Methylococcus capsulatus*, oxidize methane to methanol to initiate its metabolism. They do this with a copper-containing membrane-embedded monooxygenase whose active site is thought to contain a trinuclear copper center. Again a bridging peroxide may be formed and may insert an oxygen atom into the substrate.[465,466] The same bacteria produce a soluble methane monooxygenase containing a binuclear iron center.

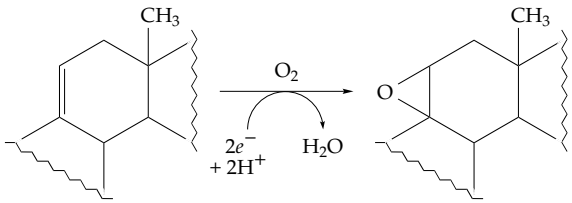
Hydroxylation with cytochrome P450. An important family of heme-containing hydroxylases, found in most organisms from bacteria to human beings, are the cytochromes P450. The name comes from the fact that in their reduced forms these enzymes form a complex with CO that absorbs at 450 nm. In soil bacteria cytochromes P450 attack compounds of almost any structure. In the adrenal gland they participate in steroid metabolism,[467,468] and in the liver microsomal cytochromes P450 attack drugs, carcinogens, and other xenobiotics (foreign compounds).[469–471] They convert cholesterol to bile acids[472] and convert vitamin D,[473] prostaglandins, and many other metabolites to more soluble and often biologically more active forms. In plants cytochromes P450 participate in hydroxylation of fatty acids at many positions.[474] They play a major role in the biosynthetic phenylpropanoid pathway (Fig. 25-8) and in lignin synthesis.[475] More than 700 distinct isoenzyme forms have been described.[476,476a]

Cytochromes P450 are monooxygenases whose cosubstrates, often NADH or NADPH, deliver electrons to the active center heme via a separate flavoprotein and often via an iron-sulfur protein as well.[476a,b] A typical reaction (Eq. 18-55) is the 11 β-hydroxylation of a steroid, an essential step in the biosynthesis of steroid hormones (Fig. 22-11). The hydroxyl group is introduced without inversion of configuration. The same enzyme converts unsaturated derivatives to epoxides (Eq. 18-56), while other cytochromes P450



(18-55)

epoxidize olefins.[477] Epoxide hydrolases, which act by a mechanism related to haloalkane dehalogenase (Fig. 12-1), convert the epoxides to diols.[478] Cytochromes P450 are able to catalyze a bewildering array of other



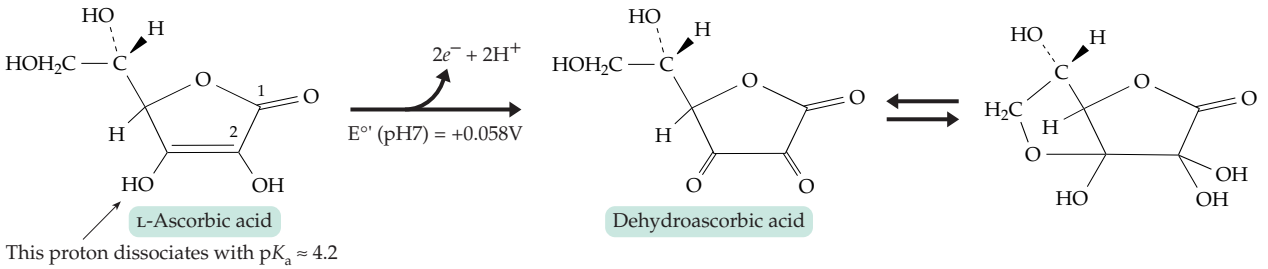
(18-56)

reactions[479–481] as well. Most of these, such as conversion of amines and thioesters to *N*- or *S*-oxides, also involve transfer of an oxygen atom to the substrate. Others, such as the reduction of epoxides, *N*-oxides, or nitro compounds, are electron-transfer reactions.

Several different cytochromes P450 are present in mammalian livers.[470] All are bound to membranes of the endoplasmic reticulum and are difficult to solubilize. Biosynthesis of additional forms is induced by such agents as phenobarbital,[470] 3-methylcholanthrene,[469] dioxin,[482] and ethanol.[483] These substances may cause as much as a 20-fold increase in P450 activity. Another family of cytochrome P450 enzymes is present in mitochondria.[483a] A large number of cytochrome P450 genes have been cloned and sequenced. Although they are closely related, each cytochrome P450 has its own gene. There are at least ten families of known P450 genes and the total number of these enzymes in mammals may be as high as 200. Microorganisms, from bacteria to yeast, produce many other cytochromes P450.

Microsomal cytochromes P450 receive electrons from an **NADPH-cytochrome P450** reductase, a large 77-kDa protein that contains one molecule each of FAD and FMN.[484–485a] It is probably the FAD which accepts electrons from NADPH and the FMN which passes them on to the heme of cytochrome P450. Cytochrome b_5 is also reduced by this enzyme,[486] and some cytochromes P450 may accept one electron directly from the flavin of the reductase and the second electron via cytochrome b_5. However, most bacterial and mitochondrial cytochromes P450 accept electrons only from small iron–sulfur proteins. Those of the adrenal gland receive electrons from the 12-kDa **adrenodoxin**.[487,488] This small protein of the ferredoxin class contains one Fe_2S_2 cluster and is, therefore, able to transfer electrons one at a time from the FAD-containing NADPH-adrenodoxin reductase[489] to the cytochrome P450. The camphor 5-monoxygenase from *Pseudomonas putida* consists of three components: an FAD-containing reductase, the Fe_2S_2 cluster-containin **putidaredoxin**,[489a] and cytochrome $P450_{cam}$.[490] Some other bacterial

BOX 18-D VITAMIN C: ASCORBIC ACID



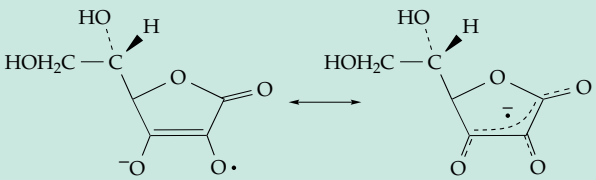
Hemorrhages of skin, gums, and joints were warnings that death was near for ancient sea voyagers stricken with **scurvy**. It was recognized by the year 1700 that the disease could be prevented by eating citrus fruit, but it was 200 years before efforts to isolate vitamin C were made. Ascorbic acid was obtained in crystalline form in 1927,[a–e] and by 1933 the structure had been established. Only a few vertebrates, among them human beings, monkeys, guinea pigs, and some fishes, require ascorbic acid in the diet; most species are able to make it themselves. Compared to that of other vitamins, the nutritional requirement is large.[e] Ten milligrams per day prevents scurvy, but subclinical deficiency, as judged by fragility of small capillaries in the skin, is present at that level of intake. "Official" recommendations for vitamin C intake have ranged from 30 to 70 mg / day. A more recent study[f] suggests 200 mg / day, a recommendation that is controversial.[g]

The biological functions of vitamin C appear to be related principally to its well-established reducing properties and easy one-electron oxidation to a free radical or two-electron reduction to **dehydroascorbic acid**. The latter is in equilibrium with the hydrated hemiacetal shown at the beginning of this box as well as with other chemical species.[h–j] Vitamin C is a weak acid which also has metal complexing properties.

Ascorbate, the anion of ascorbic acid, tends to be concentrated in certain types of animal tissues and may reach 3 mM or more in leukocytes, in tissues of eyes and lungs, in pituitary, adrenal, and parotid glands,[k,l] and in gametes.[m] Uptake into vesicles of the endoplasmic reticulum may occur via glucose transporters.[n] Ascorbate concentrations are even higher in plants and may exceed 10 mM in chloroplasts.[o] In animals the blood plasma ascorbate level of 20–100 μM is tightly controlled.[p,q] Cells take up ascorbate but any excess is excreted rapidly in the urine.[q] Both in plasma and within cells most vitamin C exists as the reduced form, ascorbate. When it is formed, the oxidized dehydroascorbate is reduced back to ascorbate or is degraded. The lactone ring is readily hydrolyzed to 2,3-dioxogulonic acid, which can undergo decarboxylation and oxidative degradation, one product being oxalate (see Fig. 20-2).[r] Tissues may also contain smaller amounts of L-ascorbic acid 2-sulfate, a compound originally discovered in brine shrimp. It is more stable than free ascorbate and may be hydrolyzed to ascorbate in tissues.[s]

In the chromaffin cells of the adrenal glands and in the neurons that synthesize catecholamines as neurotransmitters, ascorbate functions as a cosubstrate for dopamine β-hydroxylase (Eq. 18-53).[t,u] In fibroblasts it is required by the prolyl and lysyl hydroxylases and in hepatocytes by homogentisate dioxygenase (Eq. 18-49). Any effect of ascorbic acid in preventing colds may be a result of increased hydroxylation of procollagen and an associated stimulation of procollagen secretion.[v] High levels of ascorbate in guinea pigs lead to more rapid healing of wounds.[w] An important function of ascorbate in the pituitary and probably in other endocrine glands is in the α-amidation of peptides (Eq. 10-11).[x,y] Together with Fe(II) and O_2 ascorbate is a powerful nonenzymatic hydroxylating reagent for aromatic compounds. Like hydroxylases, the reagent attacks nucleophilic sites, e.g., converting phenylalanine to tyrosine. Oxygen atoms from $^{18}O_2$ are incorporated into the hydroxylated products. While H_2O_2 is formed in the reaction mixture, it cannot replace ascorbate. The relationship of this system to biochemical functions of ascorbate is not clear. An unusual function for vitamin C has been proposed for certain sponges that are able to etch crystalline quartz (SiO_2) particles from sand or rocks.[z]

Ascorbate is a major antioxidant, protecting cells and tissues from damage by free radicals, peroxides, and other metabolites of O_2.[p,r,aa,bb] It is chemically suited to react with many biologically important radicals and is present in high enough concentrations to be effective. It probably functions in cooperation with glutathione (Box 11-B),[cc] α-tocopherol (Fig. 15-24),[dd] and lipoic acid.[ee] Ascorbate can react with radicals in one-election transfer reactions to give the monodehydroascorbate radical[aa]:



BOX 18-D (continued)

Two ascorbate radicals can react with each other in a disproportionation reaction to give ascorbate plus dehydroascorbate. However, most cells can reduce the radicals more directly. In many plants this is accomplished by NADH + H^+ using a flavoprotein **monodehydroascorbate reductase**.[o] Animal cells may also utilize NADH or may reduce dehydroascorbate with reduced glutathione.[cc,ff] Plant cells also contain a very active blue copper ascorbate oxidase (Chapter 16, Section D,5), which catalyzes the opposite reaction, formation of dehydroascorbate.[gg] A heme ascorbate oxidase has been purified from a fungus.[hh] Action of these enzymes initiates an oxidative degradation of ascorbate, perhaps through the pathway of Fig. 20-2.

Ascorbate can also serve as a signal. In cultured cells, which are usually deficient in vitamin C, addition of ascorbate causes an enhanced response to added iron, inducing synthesis of the iron storage protein ferritin.[ii] Ascorbate indirectly stimulates transcription of procollagen genes[v] and decreases secretion of insulin by the pancreas.[jj] However, since its concentration in blood is quite constant this effect is not likely to cause a problem for a person taking an excess of vitamin C.

Should we take extra vitamin C to protect us from oxygen radicals and slow down aging? Linus Pauling, who recommended an intake of 0.25–10 g / day, maintained that ascorbic acid also has a specific beneficial effect in preventing or ameliorating symptoms of the common cold.[j,kk] However, critics point out that unrecognized hazards may exist in high doses of this seemingly innocuous compound. Ascorbic acid has antioxidant properties, but it also promotes the generation of free radicals in the presence of Fe(III) ions, and it is conceivable that too much may be a bad thing.[ll] Catabolism to oxalate may promote formation of calcium oxalate kidney stones. Under some conditions products of dehydroascorbic acid breakdown may accumulate in the lens and contribute to cataract formation.[i,mm,nn] However, dehydroascorbate, or its decomposition products, apparently *protects* low-density lipoproteins against oxidative damage.[bb] Pauling pointed out that nonhuman primates synthesize within their bodies many grams of ascorbic acid daily, and that there is little evidence for toxicity. Pauling's claim that advanced cancer patients are benefited by very high (10 g daily) doses of vitamin C has been controversial, and some studies have failed to substantiate the claim.[oo,pp]

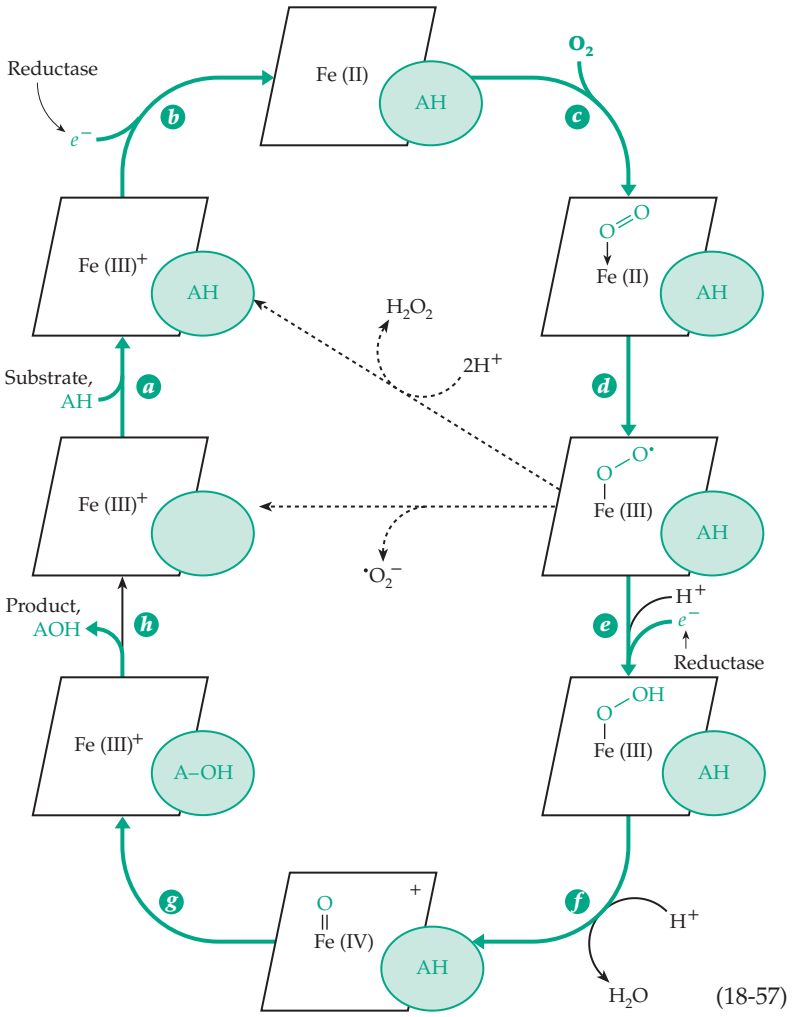
cytochrome P450s, such as a soluble fatty acid hydroxylase from *Bacillus megaterium*, have reductase domains with tightly bound FMN and FAD bound to the same polypeptide chain as is the heme.[491]

All cytochromes P450 appear to have at their active sites a molecule of heme with a thiolate anion as an axial ligand in the fifth position (Fig. 18-23). These relatively large heme proteins of ~ 45- to 55-kDa mass may consist of as many as 490 residues. Only a few three-dimensional structures are known,[490,492–494] and among these there are significant differences. However, on the basis of a large amount of experimental effort[487,495,496] it appears that all cytochromes P450 act by basically similar mechanisms.[474,496a,b,497] As indicated in Eq. 18-57, the substrate AH binds to the protein near the heme, which must be in the Fe(III) form. An electron delivered from the reductase then reduces the iron to the Fe(II) state (Eq. 18-57, step *b*). Then O_2 combines with the iron, the initial oxygenated complex formed in step *c* being converted to an Fe(III)-superoxide complex (Eq. 18-57, step *d*). Subsequent events are less certain.[497a] Most often a second electron is transferred in from the reductase (Eq. 18-57, step *e*) to give a peroxide complex of Fe(III), which is then converted in step *f* to a ferryl iron form, as in the action of peroxidases (Fig. 16-14). This requires transfer of two H^+ into the active site. The ferryl Fe(IV)=O donates its oxygen atom to the substrate regenerating the Fe(III) form of the heme (step *g*) and releasing the product (step *h*).

Microsomal cytochromes P450 often form hydrogen peroxide as a side product. This may arise directly from the Fe–O–O^- intermediate shown in Eq. 18-57. Some cytochromes P450 use this reaction in reverse to carry out hydroxylation utilizing peroxides instead of O_2 (Eq. 18-58).

$$AH + ROOH \rightarrow AOH + ROH \qquad (18\text{-}58)$$

Cytochromes P450 often convert drugs or other foreign compounds to forms that are more readily excreted.[499] However, the result is not always beneficial. For example, 3-methylcholanthrene, a strong inducer of cytochrome P450, is converted to a powerful carcinogen by the hydroxylation reaction.[500] See also Box 18-E.



(18-57)

Other iron-containing oxygenases. Hydroxylases with properties similar to those of cytochrome P450 but containing nonheme iron catalyze ω-oxidation of alkanes and fatty acids in certain bacteria, e.g., *Pseudomonas oleovarans*. A flavoprotein rubredoxin reductase, is also required.[501] The methylotrophs *Methylococcus* and *Methylosinus* hydroxylate methane using as cosubstrate NADH or NADPH (Eq. 18-59). A soluble complex consists of 38-kDa reductase containing FAD and an Fe_2S_2

$$CH_4 + O_2 + NADH + H^+ \rightarrow CH_3OH + H_2O + NAD^+ \qquad (18\text{-}59)$$

center, a small 15-kDa component, and a 245-kDa hydroxylase with an $(\alpha\beta\gamma)_2$ composition and a three-dimensional structure[502–503] similar to that of ribonucleotide reductase (Chapter 16, Section A,9). Each large α subunit contains a diiron center similar to that shown in Fig. 16-20C. It is likely that O_2 binds between the two iron atoms in the Fe(II) oxidation state and, oxidizing both irons to Fe(III), is converted to a bridging peroxide group as shown in Eq. 18-60. In this intermediate, in which the two metals are held rigidly by the surrounding ligands including a bridging carboxylate side chain, the O–O bond may be broken as in Eq. 18-60, steps *a* and *b*, to generate an Fe(IV)–$O^\bullet$ radical that may

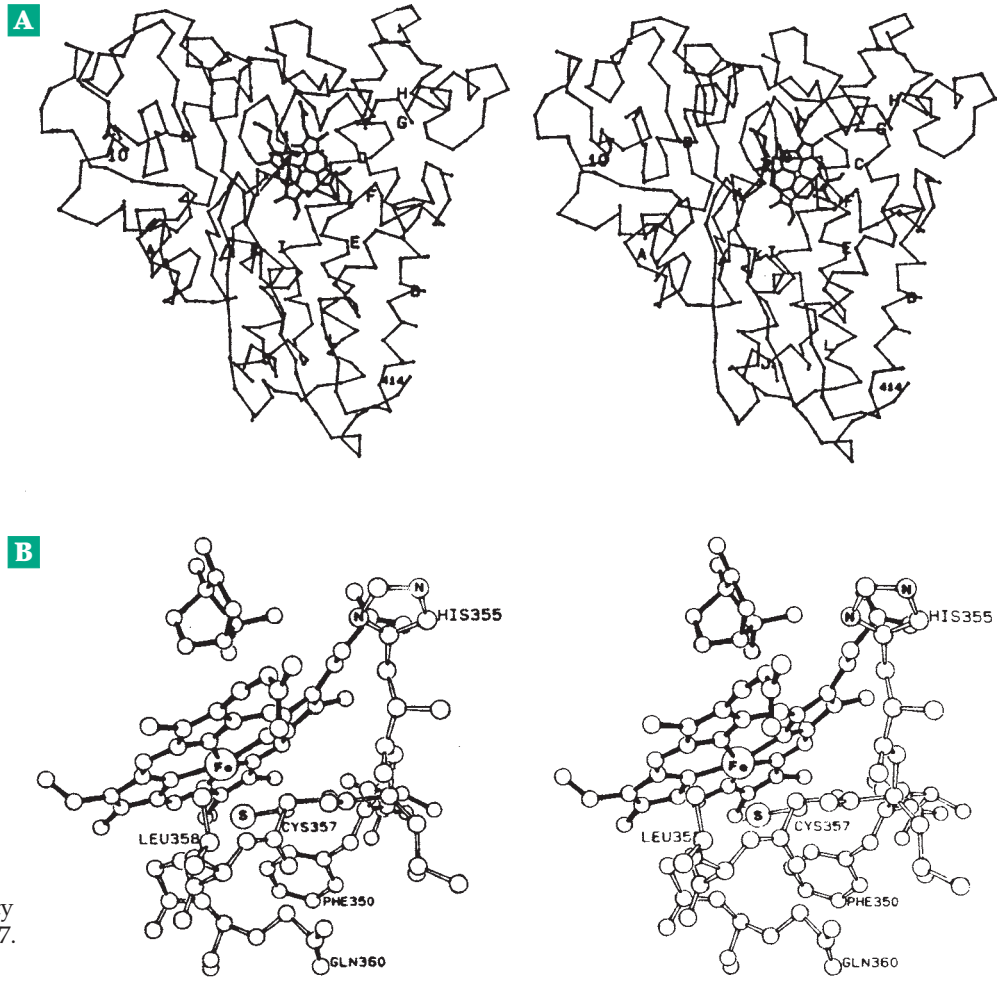


Figure 18-23 (A) Stereoscopic α-carbon backbone model of cytochrome $P450_{cam}$ showing the locations of the heme and of the bound camphor molecule. (B) View in the immediate vicinity of the thiolate ligand from Cys 357. From Poulos *et al.*[498]

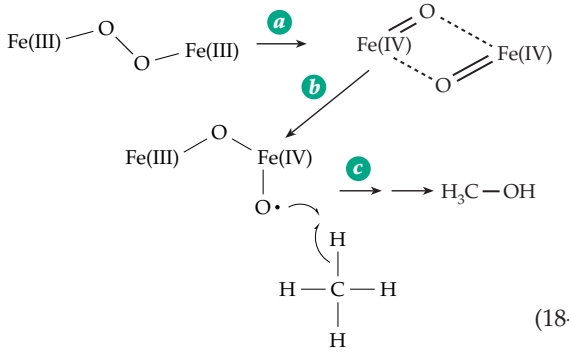
remove a hydrogen atom from the substrate (step *c*) and undergo subsequent reaction steps analogous to those in the cytochrome P450 reaction cycle.[504–506]



(18-60)

A group of related bacterial enzymes hydroxylate alkanes,[507] toluene,[508] phenol,[509] and other substrates.[509a] Eukaryotic fatty acid desaturases (Fig. 16-20B) belong to the same family.[508] Some bacteria use cytochrome P450 or other oxygenase to add an oxygen atom to an alkene to form an epoxide. For example, propylene may be converted to either *R* or *S* epoxypropane which may be hydrolyzed, rearranged by a coenzyme M-dependent reaction, and converted to acetoacetate, which can be used as an energy source.[509a,b]

Nitric oxide and NO synthases. Nitric oxide (NO) is a reactive free radical whose formula is often written as •NO to recognize this characteristic. However, NO is not only a toxic and sometimes dangerous metabolite but also an important hormone with functions in the circulatory system, the immune system, and the brain.[510–512] The hormonal effects of NO are discussed in Chapter 30, but it is appropriate here to mention a few reactions. Nitric oxide reacts rapidly with O_2 to form nitrite (Eq. 18-61).

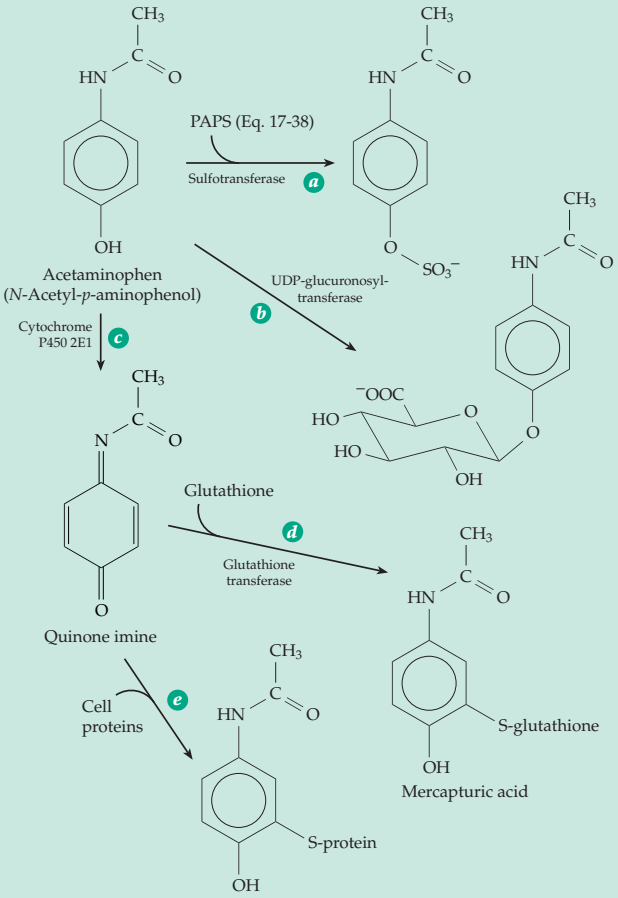
$$4\ NO + O_2 + 2\ H_2O \rightarrow 4\ NO_2^- + 4\ H^+ \qquad (18\text{-}61)$$

It also combines very rapidly with superoxide anion radical to form **peroxynitrite** (Eq. 18-62).[513] This is another reactive oxidant which, because of its relatively high pK_a of 6.8, is partially protonated and able to diffuse through phospholipids within cells.[514,515]

BOX 18-E THE TOXICITY OF ACETAMINOPHEN

Most drugs, as well as toxins and other xenobiotic compounds, enter the body through membranes of the gastrointestinal tract, lungs, or skin. Drugs are frequently toxic if they accumulate in the body. They are often rather hydrophobic and are normally converted to more polar, water-soluble substances before elimination from the body. Two major types of reaction take place, usually in the liver. These are illustrated in the accompanying scheme for acetaminophen (*N*-acetyl-*p*-aminophenol), a widely used analgesic and antipyretic (fever relieving) nonprescription drug sold under a variety of trade names: (1) A large water-soluble group such as sulfate[a] or glucuronate is transferred onto the drug by a nucleophilic displacement reaction (steps *a* and *b* of scheme). (2) Oxidation, demethylation, and other alterations are catalyzed by one or more of the nearly 300 cytochrome P450 monooxygenases present in the liver (step *c*). Oxidation products may be detoxified by glutathione S-transferases, step *d* (see also Box 11-B).[b,c,cc]

These reactions protect the body from the accumulation of many compounds but in some cases can cause serious problems. The best known of these involves acetaminophen. Its oxidation by cytochrome P450 2E1 or by prostaglandin H synthase[d] yields a highly reactive quinone imine which reacts with cell proteins.[e] Since the cytochrome P450 oxidation can occur in two steps, a reactive intermediate radical is also created.[c,f] At least 20 drug-labeled proteins arising in this way have been identified.[c] Both addition of thiol groups of proteins to the quinone imine (step *e* of scheme) and oxidation of protein thiols occur.[g] Mitochondria suffer severe damage,[h] some of which is related to induction of Ca^{2+} release.[i]



Acetaminophen is ordinarily safe at the recommended dosages, but large amounts exhaust the reserve of glutathione and may cause fatal liver damage. By 1989, more than 1000 cases of accidental or intentional (suicide) overdoses had been reported with many deaths. Prompt oral or intravenous administration of *N*-acetylcysteine over a 72-hour period promotes synthesis of glutathione and is an effective antidote.[j]

Similar problems exist for many other drugs. Both acetaminophen and phenacetin, its ethyl ether derivative, may cause kidney damage after many years of use.[k,l] Metabolism of phenacetin and several other drugs varies among individuals. Effective detoxification may not occur in individuals lacking certain isoenzyme forms of cytochrome P450.[m] Use of the anticancer drugs daunomycin (daunorubicin; Figs. 5-22 and 5-23) and adriamycin is limited by severe cardiac toxicity arising from free radicals generated during oxidation of the drugs.[n] These are only a few examples of the problems with drugs, pesticides, plasticizers, etc.

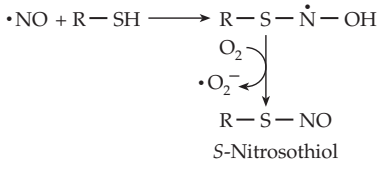
$$^{\bullet}NO + {}^{\bullet}O_2^- \rightarrow O{=}N{-}O{-}O^- \qquad (18\text{-}62)$$

NO binds to the iron atoms in accessible heme groups such as those of hemoglobin[516] and of guanylate cylases,[517,518] and in some Fe – S proteins such as aconitase. Some blood-sucking insects utilize salivary heme proteins called **nitrophorins** to carry NO into host tissues where it activates guanylate cyclase causing vasodilation. Nitrophorins also bind histamine and inhibit blood coagulation, which assists feeding.[518a,b] In the presence of a suitable oxidant such as O_2, nitric oxide reacts with thiol groups of proteins and small molecules to give **S-nitrosothiols** (Eq. 18-63).[511,519-520]



S-Nitrosothiol (18-63)

However, the physiological mechanisms of formation of these *S*-nitroso compounds is not clear.[520–521] One mechanism may involve conversion by O_2 to nitrous anhydride.[511,522]

$$2\ NO + O_2 \rightarrow ON{-}O{-}NO \qquad (18\text{-}64)$$

Nucleophilic attack on this compound by –SH, $-NH_2$, and other nucleophiles would yield *S*-nitroso and *N*-nitroso compounds with release of nitrous oxide N_2O.

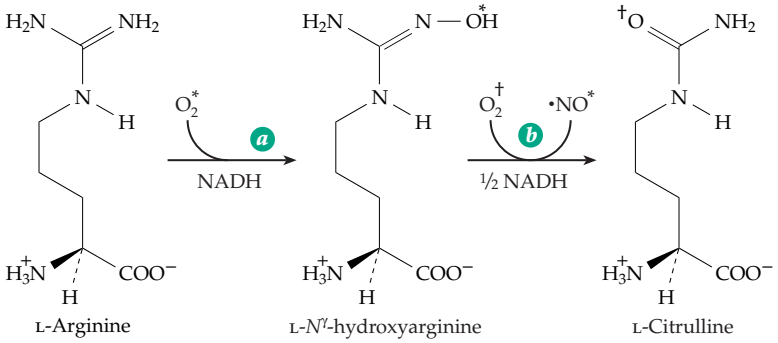
The relatively stable *S*-nitrosothiols derived from glutathione, cysteine, and proteins such as hemoglobin[516] may be important storage and transport forms of NO. If so, mechanisms of release of NO are important. A simple homolytic cleavage of R–S–NO to NO plus a thiyl radical R–S$^{\bullet}$ has often been assumed. However, rapid cleavage requires catalysis by a transition metal ion or reaction with reducing agents such as ascorbate or other thiols.[523,524] *S*-Nitrosothiols may also give rise to nitrosonium (NO^+) or nitroxy (NO^-) ions.[524]

NO synthases are oxygenases that carry out a two-step oxidation of L-arginine to L-citrulline with production of NO. In the first step, a normal monooxygenase reaction, L-N^{γ}-hydroxyarginine is formed (Eq. 18-65, step *a*). In the second step (Eq. 18-65, step *b*) NO is formed in a three-electron oxidation. In this equation the symbols $_*$ and † indicate positions of incorporation of labeled O_2 atoms in the intermediate and final products.

The human body contains three types of nitric oxide synthase known as **neuronal** (nNOS or NOS1), **inducible** (iNOS or NOS2), and **endothelial** (eNOS or NOS3).[511a–f] These enzymes have a broad distribution within various tissues, but NOS1 is especially active in neurons and NOS3 in endothelial cells. The inducible NOS2 originally discovered in macrophages is transcriptionally regulated. When these phagocytic cells are at rest the activity of NOS2 is very low, but it becomes highly active after induction by cytokines or by the lipopolysaccharides of bacterial cell membranes.[525,526] Both NOS1 and NOS2 are constitutively expressed but require calcium ions, which bind to a calmodulin domain of the protein. The inducible NOS2 doesn't require added Ca^{2+} but does contain the calmodulin domain. NOS3 carries an N-terminal myristoyl group as well as cysteines that may be palmitoylated. It is located in caveolae of plasma membranes and in Golgi complexes.[527,528]

Nucleotide sequences revealed a close similarity of NO synthases to cytochrome P450 reductase.[525,529,530] Study of spectra suggested that NO synthases, in which the heme is held by a thiolate sulfur of a cysteine side chain, might be specialized cytochromes P450.[531] However, although the heme in NO synthases is bound by a thiolate group the protein fold is unlike that of cytochromes P450.[532,533] The NO synthases all share a three-component structure.[534] In the NOS2 from macrophages residues 1–489 form the catalytic oxygenase domain, residues 499–530 bind calmodulin, and residues 531–1144 form the reductase domain.[535] The last contains a binding site for NADPH as well as bound FMN and FAD. The reductase domain structure can be modeled after that of cytochrome P450 reductase.[533] Electrons from NADPH are apparently transferred to FAD, then to FMN, and then to the catalytic site.[525]

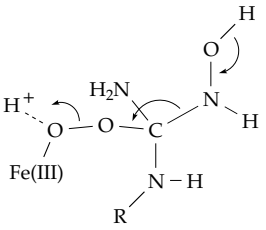
The least understood aspect of NO synthases is the requirement for tetrahydrobiopterin, BH_4, the same coenzyme required by the other pterin-dependent monooxygenases (Eq. 18-44). The presence of this coenzyme in the reduced BH_4 form is essential for step *a* of Eq. 18-65 but not for step *b*. This suggests that in step *a* an organic peroxide might be generated by BH_4 and used to form an oxo-iron hydroxylating reagent.



L-Arginine L-N^{γ}-hydroxyarginine L-Citrulline (18-65)

However, there is no evidence for the expected quinonoid dihydropterin, and the three-dimensional structure suggested that BH_4 plays a structural role in mediating essential conformational changes.[532,535a,b] Nevertheless, newer data indicate a role in electron transfer.[535c]

Step *b* of Eq. 18-65 is an unusual three-electron oxidation, which requires only one electron to be delivered from NADPH by the reductase domain. Hydrogen peroxide can replace O_2 in this step.[536] A good possibility is that a peroxo or superoxide complex of the heme in the Fe(III) state adds to the hydroxyguanidine group. For example, the following structure could arise from addition of Fe(III)–O–O$^-$:

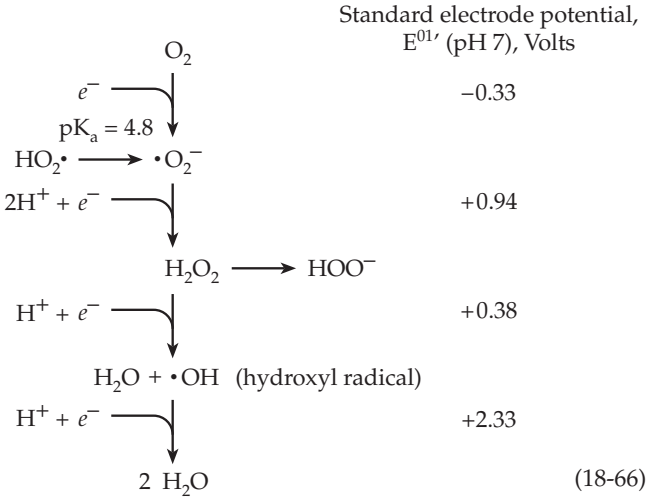


Breakup as indicated by the arrows on this structure would give Fe(III)–OH, citrulline, and O=N–H, **nitroxyl**. This is one electron ($e^- + H^+$) more reduced than •NO. Perhaps the adduct forms from Fe(III)–O–O•. On the other hand, there is evidence that NO synthases may produce nitroxyl or nitroxyl ion NO^- as the initial product.[537–538] NO and other products such as N_2O and NO_2^- may arise rapidly in subsequent reactions. Nitrite is a major oxidation product of NO in tissues.[538a] The chemistry of NO in biological systems is complex and not yet fully understood. See also pp. 1754, 1755.

G. Biological Effects of Reduced Oxygen Compounds

Although molecular oxygen is essential to the aerobic mode of life, it is toxic at high pressures. Oxidative damage from O_2 appears to be an important cause of aging and also contributes to the development of cancer. Reduced forms of oxygen such as superoxide, hydrogen peroxide, and hydroxyl radicals are apparently involved in this toxicity.[539,540] The same agents are deliberately used by phagocytic cells such as the neutrophils (polymorphonuclear leukocytes) to kill invading bacteria or fungi and to destroy malignant cells.[541]

The reactions shown with vertical arrows in Eq. 18-66 can give rise to the reduced oxygen compounds. The corresponding standard redox potential at pH 7 for each is also given.[539,542–544] As indicated by the low value of the redox potential for the O_2 / $O_2^{\bullet -}$ couple, the formation of superoxide by reduction of O_2 is spontaneous only for strongly reducing one-electron donors. Superoxide ion is a strong reductant, but at the same time a powerful one-electron oxidant, as is indicated by the high electrode potential of the $O_2^{\bullet -}$/ H_2O_2 couple.



(18-66)

1. The Respiratory Burst of Neutrophils

Some 25 x 10^9 neutrophils circulate in an individual's blood, and an equal number move along the surfaces of red blood cells. Invading microorganisms are engulfed after they are identified by the immune system as foreign. Phagocytosis is accompanied by a rapid many-fold rise in the rate of oxygen uptake as well as an increased glucose metabolism. One purpose of this **respiratory burst**[545–548] is the production of reduced oxygen compounds that kill the ingested microorganisms. In the very serious **chronic granulomatous disease** the normal respiratory burst does not occur, and bacteria are not killed.[549] The respiratory burst seems to be triggered not by phagocytosis itself, but by stimulation of the neutrophil by chemotactic formylated peptides such as formyl-Met-Leu-Phe[550] and less rapidly by other agonists such as phorbol esters.

The initial product of the respiratory burst appears to be superoxide ion O_2^-. It is formed by an **NADPH oxidase,** which transports electrons from NADPH to O_2 probably via a flavoprotein and cytochrome b_{558}. Either the flavin or the cytochrome b_{558} must donate one electron to O_2 to form the superoxide anion.

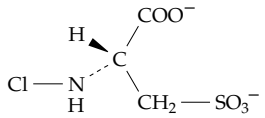
$$\text{NADPH} \rightarrow \text{FAD} \rightarrow \text{cyt } b_{558} \rightarrow O_2 \qquad (18\text{-}67)$$

Flavocytochrome b_{558} (also called b_{-245}) has the unusually low redox potential of −0.245 V. It exists in phagocytic cells as a heterodimer of membrane-associated subunits p22-*phox* and gp91-*phox* where *phox* indicates phagocytic oxidase. The larger 91-kDa

subunit contains two heme groups as well as one FAD and the presumed NADPH binding site.[548,551–552a] The mechanism of interaction with O_2 is unclear. Unlike hemoglobin but like other cytochromes *b*, cytochrome b_{558} does not form a complex with CO.[553] NADPH oxidase also requires two cytosolic components p47-*phox* and p67-*phox*. In resting phagocytes they reside in the cytosol as a 240-kDa complex with a third component, p40-*phox*, which may serve as an inhibitor.[548,554] Upon activation of the phagocyte in response to chemotactic signals the cytosolic components undergo phosphorylation at several sites,[554] and protein p47-*phox* and p67-*phox* move to the membrane and bind to and with the assistance of the small G protein Rac[552a,554a] activate flavocytochrome b_{558}. Phosphorylation of p47-*phox* may be especially important.[555]

In the X-chromosome-linked type of chronic granulomatous disease flavocytochrome b_{558} is absent or deficient, usually because of mutation in gp91-*phox*.[556,557] In an autosomal recessive form the superoxide-forming oxidase system is not activated properly. In some patients protein kinase C fails to phosphorylate p47-*phox*.[556,558] Less severe symptoms arise from deficiences in myeloperoxidase, chloroperoxidase (Chapter 16), glucose 6-phosphate dehydrogenase, glutathione synthetase, and glutathione reductase. The importance of these enzymes can be appreciated by examination of Fig. 18-24, which illustrates the relationship of several enzymatic reactions to the formation of superoxide anion and related compounds. Not only neutrophils but monocytes, macrophages, **natural killer cells** (NK cells), and other phagocytes apparently use similar chemistry in attacking ingested cells (Chapter 31).[559] Superoxide-producing NADH oxidases have also been found in nonphagocytic cells in various tissues.[559a]

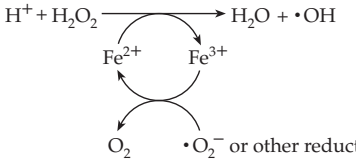
What kills the ingested bacteria and other microorganisms? Although superoxide anion is relatively unreactive, its protonated form $HO_2\bullet$, is very reactive. Since its pK_a is 4.8, there will be small amounts present even at neutral pH. Some of the $^\bullet O_2^-$ may react with NO to form peroxynitrite (Eq. 18-62).[559b] Peroxynitrite, in turn, can react with the ubitquitous CO_2 to give $^\bullet CO_3^-$ and $^\bullet NO_2$ radicals.[559c] Peroxynitrite anion also reacts with metalloenzyme centers[559d] and causes nitration and oxidation of aromatic residues in proteins.[559d,e] However, neutrophils contain active superoxide dismutases, and most of the superoxide that is formed is converted quickly to O_2 and H_2O_2. The latter may diffuse into the phagosomes as well as into the extracellular space. The H_2O_2 itself is toxic, but longer lived, more toxic oxidants are also formed. Reaction of H_2O_2 with **myeloperoxidase** (Chapter 16) produces hypochlorous acid, **(HOCl;** Eqs. 16-12, Fig. 18-24) and **chloramines** such as NH_2Cl, RNHCl, and $RNCl_2$. An important intracellular chloramine may be that of taurine.



Chloramine formed from taurine

Human neutrophils use HOCl formed by myeloperoxidase to oxidize α-amino acids such as tyrosine to reactive aldehydes that form adducts with –SH, $–NH_2$, imidazole, and other nucleophilic groups.[560] They also contain NO synthases, which form NO, peroxynitrite (Fig. 18-24), and nitrite.[561,562]

Hydroxyl radicals •OH, which attack proteins, nucleic acids, and a large variety of other cellular constituents, may also be formed. Although too reactive to diffuse far, they can be generated from H_2O_2 by Eq. 18-68. This reaction involves catalysis by Fe ions as shown.[562a]



(18-68)

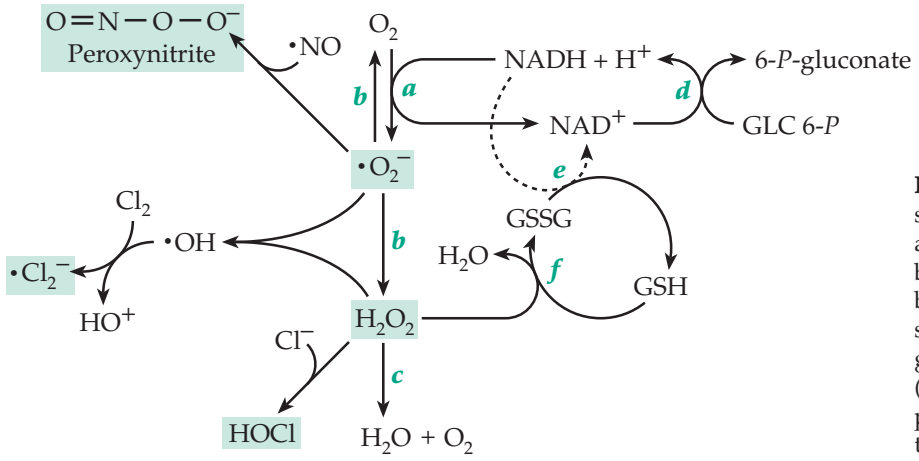


Figure 18-24 Some reactions by which superoxide anions, hydrogen peroxide and related compounds are generated by neutrophils and to a lesser extent by other cells: (*a*) NADPH oxidase, (*b*) superoxide dismutase, (*c*) catalase, (*d*) glucose-6-phosphate dehydrogenase, (*e*) glutathione reductase, (*f*) glutathione peroxidase. Abbrevations: GSH, glutathione; GSSB, oxidized glutathione.

Because Fe^{3+} is present in such low concentrations, there is uncertainty as to the biological significance of this reaction.[563] However, other iron compounds may function in place of Fe^{3+} and Fe^{2+} in Eq. 18-68.[564] A mixture of ferrous salts and H_2O_2 (Fenton reagent) has long been recognized as a powerful oxidizing mixture, which generates •OH or compounds of similar reactivity.[564–567] Ascorbate, and various other compounds, can also serve as the reductant in Eq. 18-68.[568]

Eosinophils, whose presence is stimulated by parasitic infections, have a peroxidase which acts preferentially on Br^- to form HOBr.[569] This compound can react with H_2O_2 more efficiently than does HOCl (Eq. 16-16) to form the very reactive **singlet oxygen.**[570] Singlet oxygen can also be generated from H_2O_2 and $\bullet O_2$ by Eq. 18-69[571] and also photochemically.[572]

$$\bullet O_2^- + H_2O_2 \rightarrow {}^1O_2({}^1\Delta_g) + OH + OH^- \qquad (18\text{-}69)$$

Additional killing mechanisms used by phagocytes include acidification of the phagocytic lysosomes with the aid of a proton pump[573] and formation of toxic peptides. For example, bovine neutrophils produce the bacteriocidal peptide RLCRIVVIRVCR which has a disulfide crosslinkage between the two cysteine residues.[574] Microorganisms have their own defenses against the oxidative attack by phagocytes. Some bacteria have very active superoxide dismutases. The protozoan *Leishmania* produces an acid phosphatase that shuts down the production of superoxide of the host cells in response to activating peptides.[575]

A respiratory burst accompanies fertilization of sea urchin eggs.[576,577] In this case, the burst appears to produce H_2O_2 as the major or sole product and is accompanied by release of **ovoperoxidase** from cortical granules. This enzyme uses H_2O_2 to generate **dityrosine crosslinkages** between tyrosine side chains during formation of the fertilization membrane. Defensive respiratory bursts are also employed by plant cells.[578,579] See also Box 18-B.

2. Oxidative Damage to Tissues

Superoxide anion radicals are formed not only in phagocytes but also as an accidental by-product of the action of many flavoproteins,[580,581] heme enzymes, and other transition metal-containing proteins. An example is xanthine oxidase. It is synthesized as xanthine dehydrogenase which is able to use NAD^+ as an oxidant, but upon aging, some is converted into the $\bullet O_2^-$-utilizing xanthine oxidase (Chapter 16). This occurs extensively during ischemia. When oxygen is readmitted to a tissue in which this conversion of xanthine dehydrogenase to xanthine oxidase has occurred, severe oxidative injury may occur.[582] In animals the intravenous administration of superoxide dismutase or pretreatment with the xanthine oxidase inhibitor **allopurinol** (Chapter 25) prevents much of the damage, suggesting that superoxide is the culprit.

Hydrogen peroxide is also generated within cells[583] by flavoproteins and metalloenzymes and by the action of superoxide dismutase on $\bullet O_2^-$. Since H_2O_2 is a small uncharged molecule, it can diffuse out of cells and into other cells readily. If it reacts with Fe(II), it can be converted within cells to •OH radicals according to Eq. 18-68. Such radicals and others have been detected upon readmission of oxygen to ischemic animal hearts.[584,585] It has also been suggested that NADH may react with Fe(III) compounds in the same way as does O_2^- in Eq. 18-68 to provide a mechanism for producing hydroxyl radicals from H_2O_2.[539] Nitric oxide, formed by the various NO synthases in the cytosol and in mitochondria[586] and by some cytochromes P450,[587] is almost ubiquitous and can also lead to formation of peroxynitrate (Eq. 18-62). Thus, the whole range of reduced oxygen compounds depicted in Eq. 18-24 are present in small amounts throughout cells.

There is little doubt that these compounds cause extensive damage to DNA, proteins, lipids, and other cell constituents.[539,540,563,588] For example, one base in 150,000 in nuclear DNA is apparently converted from guanine to 8-hydroxyguanine presumably as a result of attack by oxygen radicals.[589] In mitochondrial DNA one base in 8000 undergoes this alteration. This may be a result of the high rate of oxygen metabolism in mitochondria and may also reflect the lack of histones and the relatively inefficient repair of DNA within mitochondria. Proteins undergo chain cleavage, crosslinking, and numerous side chain modification reactions.[588] Dissolved O_2 can react directly with exposed glycyl residues in protein backbones to create glycyl radicals which may lead to chain cleavage as in Eq. 15-39.[588a] Iron–sulfur clusters, such as the Fe_4S_4 center of aconitase (Fig. 13-4), are especially sensitive to attack by superoxide anions.[588a–c] "Free iron" released from the Fe–S cluster may catalyze formation of additional damaging radicals.

Antioxidant systems. Cells have numerous defenses against oxidative damage.[563,590,591] Both within cells and in extracellular fluids superoxide dismutase (Eq. 16-27) decomposes superoxide to O_2 and H_2O_2. The H_2O_2 is then broken down by catalase (Eq. 16-8) to O_2 and H_2O. In higher animals the selenoenzyme glutathione peroxidase (Chapter 16) provides another route for decomposition of H_2O_2 and lipid peroxides of membranes. The oxidized glutathione formed is reduced by NADPH. The system has a critical role within erythrocytes (Box 15-H). In chloroplasts an analogous system utilizes ascorbate peroxidase, ascorbate, and glutathione to break down peroxides.[592]

$$NADPH + H^+ \rightarrow \text{glutathione} \rightarrow \text{ascorbate} \rightarrow H_2O_2 \quad (18\text{-}70)$$

Ascorbate,[593–594] glutathione, NADPH,[594a] and tocopherols (Box 15-G)[595] all act as scavengers of free radicals such as O_2^-, $^\bullet OH$ and $ROO^\bullet$, $^\bullet CO_3^-$, and of singlet oxygen. Antioxidant protection is needed in extracellular fluids as well as within cells. In addition to glutathione and ascorbate, bilirubin,[596] uric acid,[597] melatonin,[598,598a] circulating superoxide dismutase, and the copper protein ceruloplasmin (Chapter 16) all act as antioxidants. Methionine residues of proteins may have a similar function.[599] Various proteins and small chelating compounds such as citrate tie up Fe^{3+} preventing it from promoting radical formation. Tocopherols, ubiquinols, and lipoic acid[600,600a–c] protect membranes. Beta carotene (Fig. 22-5), another lipid-soluble antioxidant, is the most effective quencher of singlet O_2 that is known. Even nitric oxide, usually regarded as toxic, sometimes acts as an antioxidant.[601] Trehalose protects plants against oxidative damage.[601a]

An increasing number of proteins are being recognized as protectants against oxidative damage. The exposed –SH and $-SCH_3$ groups of cysteine and methionine residues in proteins may function as appropriately located scavengers which may donate electrons to destroy free radicals or react with superoxide ions to become sulfonated. The thioredoxin (Box 15-C) and glutathione (Eq. 18-70) systems, in turn, reduce the protein radicals formed in this way.[601b–d] Methionine sulfoxide, both free and in polypeptides, is reduced by **methionine sulfoxide reductase** in organisms from bacteria to humans.[601e–g] Biotin, together with biotin sulfoxide reductase,[601h] may provide another antioxidant system. Some bacteria utilize glutathione-independent **alkylperoxide reductases** to scavenge organic peroxides.[601i] while mammals accomplish the same result with **peroxiredoxins** and with thioredoxin.[601j] Many other proteins will doubtless be found to participate in defense against oxidative damage. Oxygen is always present and its reactions in our bodies are essential. Generation of damaging reduced oxygen compounds and radicals is inevitable. Evolution will select in favor of many proteins that have been modified to minimize the damage.

Antioxidant enzymes do not always protect us. There was great excitement when it was found that victims of a hereditary form of the terrible neurological disease **amyotrophic lateral sclerosis** (**ALS**; see also Chapter 30) carry a defective gene for Cu / Zn-superoxide dismutase (SOD; Eq. 16-27).[602–603b] This discovery seemed to support the idea that superoxide anions in the brain were killing neurons. However, it now appears that in some cases of ALS the defective SOD is *too active*, producing an excess of H_2O_2, which damages neurons.

Transcriptional regulation of antioxidant proteins. Certain proteins with easily accessible Fe–S clusters, e.g., aconitase, are readily inactivated by oxidants such as peroxynitrite.[540,604] At least two proteins of this type function as transcription factors in *E. coli*. These are known as **SoxR** and **OxyR**. The SoxR protein is sensitive to superoxide anion, which carries out a one-electron oxidation on its Fe_2S_2 centers.[540,605–607] In its oxidized form SoxR is a transcriptional regulator that controls 30–40 genes, among them several that are directly related to "**oxidative stress.**"[608] These include genes for manganese SOD, glucose-6-phosphate dehydrogenase, a DNA repair nuclease, and aconitase (to replace the inactivated enzyme). The OxyR protein, which responds to elevated $[H_2O_2]$, is activated upon oxidation of a pair of nearby –SH groups to form a disulfide bridge.[607,609] It controls genes for catalase, glutathione reductase, an alkyl hydroperoxide reductase,[610,610a] and many others. Similar transcriptional controls in yeast result in responses to low doses of H_2O_2 by at least 167 different proteins.[608] Animal mitochondria also participate in sensing oxidant levels.[611,612] (See also Chapter 28, Section C,6.)

Study Questions

1. Reticulocytes (immature red blood cells) contain mitochondria that are capable of both aerobic and anaerobic oxidation of glucose. In an experiment using these cells, incubated in oxygenated Krebs–Ringer solution with 10 mM glucose, the addition of antimycin A produced the following changes in metabolite concentration after 15 min (From Ghosh, A. K. and Sloviter, H. A. (1973) *J. Biol. Chem.* **248**, 3035–3040). Interpret the observed changes in ATP, ADP, and AMP concentrations (see tabulation). Express the concentration of each component after addition of antimycin as a percentage of that before addition. Then plot the resulting figures for each compound in the sequence found in glycolysis, i.e., label the *X* axis as follows:

Metabolite	Abbreviation	Concentrations (mmol/1 of cells) Before addition of antimycin	After addition of antimycin
Glucose 6-phosphate	G6P	460	124
Fructose 6-phosphate	F6P	150	30
Fructose 1,6-bisphosphate	FBP	8	33
Triose phosphates	TP	18	59
3-Phosphoglycerate	3PGA	45	106
2-Phosphoglycerate	2PGA	26	19
Phosphoenolpyruvate	PEP	46	34
Pyruvate	Pyr	126	315
Lactate	Lac	1125	8750
ATP		2500	1720
ADP		280	855
AMP		36	206

2. The following problem can be solved using standard reduction potentials (Table 6-8). Use $E°'$ (pH 7) values for NAD^+, enzyme-bound FAD, and fumarate of −0.32, 0.0, and −0.03 volts, respectively. Values of numerical constants are given in Table 6-1.

   a) Derive an equation relating the equilibrium constant for a reaction, K_{eq}, to differences in E_0'.

   b) Calculate the numerical values of K_{eq} for the reactions

   $$\text{Succinate} + NAD^+ \rightarrow \text{Fumarate} + NADH + H^+$$

   $$\text{Succinate} + FAD \rightarrow \text{Fumarate} + FADH_2$$

   at pH 7 and 25°C. The values should be calculated for succinate and the oxidant in the numerator.

3. Compare the catalytic cycles of the following enzymes:

   Peroxidase
   Cytochrome *c* oxidase
   Cytochrome P450

4. What chemical properties are especially important for the following compounds in the electron transport complexes of mitochondria?

   FAD or FMN
   Ubiquinone (coenzyme Q)
   Cytochrome *c*

5. Describe the operation of the F_1F_0ATP synthase of mitochondrial membranes.

6. In studies of mitochondrial function the following stoichiometric ratios have been measured.

   a) The P/O ratio: number of molecules of ATP formed for each atom of oxygen (as O_2) taken up by isolated mitochondria under specified conditions.
   b) The ratio of H^+ ions translocated across a mitochondrial inner membrane to the molecules of ATP formed.
   c) The ratio of H^+ ions pumped out of a mitochondrion to the number of molecules of ATP formed.

   Discuss the experimental difficulties in such measurements. How do uncertainties affect conclusions about the mechanism of ATP synthase? Are the ratios in (b) and (c) above necessarily equal? Explain.

7. Compare P/O ratios observed for mitochondrial respiration with the following substrates and conditions:

Study Questions

a) Oxidation of NADH by O_2.
b) Oxidation of succinate by O_2.
c) Dehydrogenation of ascorbate by O_2.

How would the ratio of ATP formed to the number of electrons passing from NADH through the respiratory chain differ for these three oxidants: O_2, fumarate, nitrite?

8. What is the mitochondrial glycerol phosphate shuttle? Is it utilized by plant cells? Explain.

9. What chemical reactions are included in these two important components of the nitrogen cycle (see also Fig. 24-1)?

Nitrification
Denitrification

10. What is the difference between a dioxygenase and a monooxygenase? What is meant by a cosubstrate for a monooxygenase?

11. The enzyme *p*-hydroxybenzoate hydroxylase utilizes a cosubstrate together with O_2 to form 3,4-dihydroxybenzoate. Indicate the mechanisms by which the bound FAD cofactor participates in the reaction.

12. What pterin-dependent hydroxylation reactions are important to the human body? Point out similarities and differences between flavin and pterin hydroxylase mechanisms.

13. Describe the basic properties of nitric oxide synthases (NOSs) and their varied functions in the body. What are the three different types of NOS? In what ways do they differ?

14. List several compounds that cause oxidative stress in cells and describe some chemical and physiological characteristics of each.

15. Propylene glycol is metabolized by several aerobic bacteria to acetoacetate, which can be catabolized as an energy source (see references 509a and 509b). The first step is conversion to an epoxide which reacts further in coenzyme M-dependent and CO_2-dependent reactions to form acetoacetate. Can you propose chemical mechanisms?

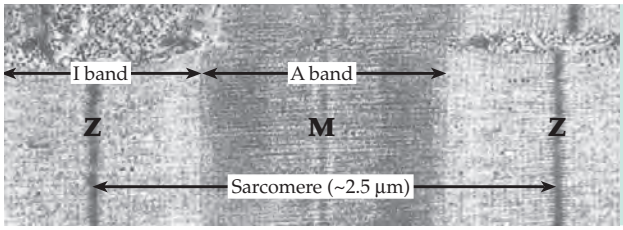
16. A group of slow-growing denitrifying bacteria obtain energy by oxidizing ammonium ions anaerobically with nitrite ions.[613,614]

$$NO_2^- + NH_4^+ \rightarrow N_2 + 2\,H_2O$$

Intermediate metabolites are hydroxylamine (H_2NOH) and hydrazine (N_2H_4). The reaction takes place within internal vesicles known as **anammoxosomes**. Unusual cyclobutane- and cyclohexane-based lipids in their membranes are thought to partially prevent the escape of the toxic intermediates from the anammoxosomes.[614]

Four protons may move from the cytoplasm into the vesicles for each ammonium ion oxidized. Can you write a reaction sequence? What is the Gibbs energy change for the reaction? How is ATP generated? See p. 1052.

Notes



Electron micrograph of a thin longitudinal section of a myofibril from pig muscle. The basic contractile unit is the **sarcomere**, which extends from one Z line to the next. Thin **actin** filaments are anchored at the M lines and the thick **myosin** filaments at the Z lines. The (anisotropic) A bands are regions of overlap of interdigitated thick and thin filaments, while the I ("isotropic") bands are devoid of thick filaments. The ATP-driven contraction of muscle involves sliding of the interdigitated filaments and shortening of the sarcomere to ~1.8 µm. Micrograph courtesy of Marvin Stromer

19 The Chemistry of Movement

The swimming of bacteria, the flowing motion of the ameba, the rapid contraction of voluntary muscles, and the slower movements of organelles and cytoplasm within cells all depend upon transduction of chemical energy into mechanical work.

A. Motility of Bacteria

The smallest organs of propulsion are the bacterial flagella (Figs. 1-1, 1-3), and we have been able to unravel some of the mystery of movement by looking at them. When a cell of *E. coli* or *Salmonella* swims smoothly, each flagellum forms a left-handed superhelix with an ~2.3 µm pitch. Rotation of these "propellors" at rates of 100–200 revolutions / s (100–200 Hz) or more[1,2] in a counterclockwise direction, as viewed from the distal end of the flagellum, drives the bacterium forward in a straight line.[3–8] Several flagella rotate side-by-side as a bundle.[4] The observed velocities of 20–60 µm / s are remarkably high in comparison with the dimensions of the bacteria. Also remarkable is the fact that a cell may travel straight for a few seconds, but then tumble aimlessly for about 0.1 s before again moving in a straight line in a different direction. The tumbling occurs when the flagellum reverses its direction of rotation and also changes from a left-handed to a right-handed superhelix, which has just half the previous pitch.

Such behavior raised many questions. What causes reversal of direction of the propellor? Why do the bacteria tumble? How does a bacterium "decide" when to tumble? How is the flagellum changed from a left-handed to a right-handed superhelix? How does this behavior help the bacterium to find food? Most intriguing of all, what kind of motor powers the flagella? The answers are complex, more than 50 genes being needed to specify the proteins required for assembly and operation of the motility system of *E. coli* or *Salmonella typhimurium*.[9]

1. The Structure and Properties of Bacterial Flagella

Twenty or more structural proteins are present from the base to the tip of a complete bacterial flagellum. However, over most of their length the long thin shafts (Figs. 1-1, 19-1) are composed of subunits of single proteins called **flagellins**. Flagellin molecules have a high content of hydrophobic amino acids and, in *Salmonella*, contain one residue of the unusual N^{ε}-methyllysine. The subunits are arranged in a helix of outside diameter ~20 nm in which they also form 11 nearly longitudinal rows or **protofilaments**.[10–12a] Each subunit gives rise to one of the projections seen in the stereoscopic view in Fig. 19-1B. The flagella usually appear under the electron microscope to be supercoiled (Fig 19-1C–E) with a long "wavelength" (pitch) of ~2.5 µm. The supercoiled structure is essential for function, and mutant bacteria with straight flagella are nonmotile. Under some conditions and with some mutant flagellins, straight flagella, of the type shown in Fig. 19-1B, are formed. There is a central hole which is surrounded by what appears to be inner and outer tubes with interconnecting "spokes." However, all of the 494-residue flagellin subunits presumably have identical conformations, and each subunit contributes to both inner and outer tubes as well as to the outer projections. **Basal bodies** (Fig. 19-2) anchor the flagella to the cell wall and plasma membrane and contain the protic motors (Fig. 19-3) that drive the flagella.[14–16]

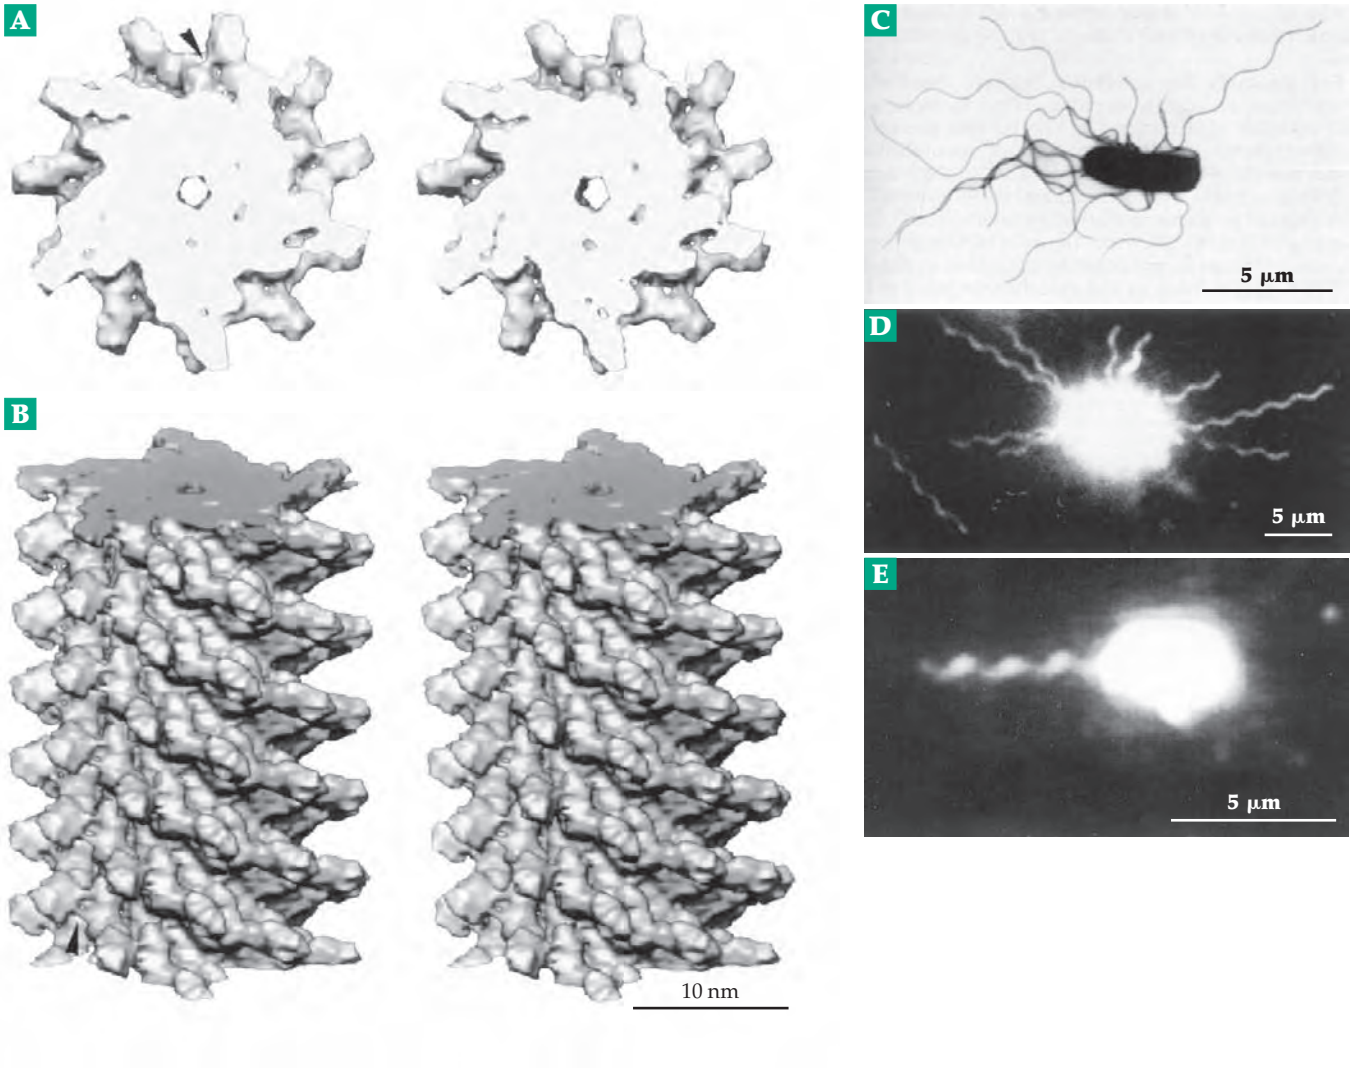

Figure 19-1 (A) Axial view of a 5-nm thick cross-section of the flagellar filament shown in (B). The 11 subunits form two turns of the one-start helix. (B) Stereoscopic oblique view of a 30-nm long section of a flagellum of *Salmonella typhimurium*. This is a straight flagellum from a nonmotile strain of bacteria. The structure was determined to a resolution of 0.9 nm by electron cryomicroscopy. From Mimori *et al.*[11] Courtesy of Keiichi Namba. Aizawa.[3] (D) Dark-field light micrograph of a flagellated cell of *S. typhimurium* with flagella dispersed during tumbling (see text). Courtesy of R. M. Macnab.[3] (E) Image of a cell of *Vibrio alginolyticus* obtained with dark-field illumination showing the single polar flagellum.[13] Because the illumination was strong, the size of the cell body and the thickness of the flagellum in the image appear large. Courtesy of Michio Homma.

Quasiequivalence. There are two distinct types of straight flagella: one (R) in which the protofilaments have a right-handed twist (as in Fig. 19-1) and the other (L) in which the protofilaments have a left-handed twist. These arise from two different conformations of the subunit proteins. Native supercoiled flagella contain a mixture of flagellins in the R- and L-states with all subunits in a given protofilament being in the same state. The supercoiling of the filament cannot be explained by stacking of identical subunits but is thought to arise because of an asymmetric distribution of protofilaments in a given state around the filament.[17–19a] Here, as with the icosahedral viruses (Chapter 7), quasiequivalence permits formation of a structure that would be impossible with full equivalence of subunits. The corkscrew shape of the flagellum is essential to the conversion of the motor's torque into a forward thrust.[18] Certain mutants of *Salmonella* have "curly" flagella with a superhelix of one-half the normal pitch. The presence of *p*-fluorophenylalanine in the growth medium also produces curly flagella, and normal flagella can be transformed to curly ones by a suitable change of pH. More important for biological function, the transformation from normal to curly also appears to take place during the tumbling of bacteria associated with chemotaxis.[17]

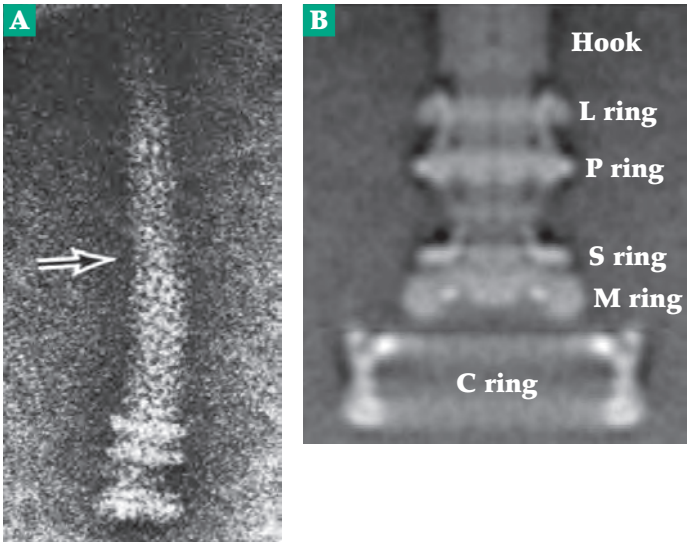

Figure 19-2 (A) Electron micrograph of a flagellum from *E. coli* stained with uranyl acetate. The M-and S-rings are seen at the end. Above them are the P-ring, thought to connect to the peptidoglycan layer, and the L-ring, thought to connect to the outer membrane or lipopolysaccharide layer (see Fig. 8-28). An arrow marks the junction between hook and thinner filament. From DePamphilis and Adler.[14] The hook is often bent to form an elbow. (B) Average of ~100 electron micrographs of frozen-hydrated preparations of basal bodies showing the cytoplasmic C-ring (see Fig. 19-3) extending from the thickened M-ring. From DeRosier.[16]

Growth of flagella. Iino added *p*-fluorophenylalanine to a suspension of bacteria, whose flagella had been broken off at various distances from the body.[20] Curly ends appeared as the flagella grew out. Unlike the growth of hairs on our bodies, the flagella grew from the outer ends. Because no free flagellin was found in the surrounding medium, it was concluded that the flagellin monomers are synthesized within the bacterium, then pass out, perhaps in a partially unfolded form, through the 2- to 3-nm diameter hole[10,12] in the flagella, and bind at the ends.[21] Flagella of *Salmonella* grow at the rate of 1 µm in 2–3 min initially, then more slowly until they attain a length of ~15 µm. More recent studies have provided details. The hook region (Fig. 19-3) grows first to a length of ~55 nm by addition to the basal-body rod of ~140 subunits of protein **FlgE**. During growth a **hook cap** formed from subunits **FlgD** prevents the FlgE subunits from passing out into the medium.[22,23] Hook subunits are added beneath the cap, moving the cap outward. Hook growth is terminated by protein **FlgK** (also called hook-associated protein Hap1). This protein displaces the hook cap and initiates growth of the main filament.[24] The first 10–20 subunits added are those of the FlgK (Fig. 19-3). These are followed by 10–20 subunits of **FlgL** (Hap3), a modified flagellin whose mechanical properties can accomodate the stress induced in the flagella by their rotation.[25] FlgJ is also needed for rod formation.[25a]

Growth of the flagellum to a length of up to 20 µm continues with subunits of **FliC** that are added at the tip, which is now covered by a dodecamer of the **cap protein FliD** (HAP2).[24,26,26a,b] Its 5-fold rotational symmetry means that this "star-cap" does not form a perfect plug for the 11-fold screw-symmetry of the flagellum, a fact that may be important in allowing new flagellin subunits to add at the growing tip. If the cap protein is missing, as in some *FliD* mutants, a large amount of flagellin leaks into the medium.[24]

Still unclear is how the protein synthesis that is taking place on the ribosomes in the bacterial cytoplasm is controlled and linked to "export machinery" at the base of the flagellin. As indicated in Fig. 19-3, the genetically identified proteins FlhA, FliH, and FliI are involved in the process that sends the correct flagellin subunits through the growing flagellum at the appropriate time. FliI contains an ATPase domain.[26c] FliS protein may be an export chaperone.[26d]

2. Rotation of Flagella

A variety of experiments showed that the flagellum is a rigid propellor that is rotated by a "motor" at the base. For example, a bacterium, artificially linked by means of antibodies to a short stub of a flagellum of another bacterium, can be rotated by the second bacterium. Rotation of cells tethered to a cover slip has also been observed. Although it is impossible to see individual flagella on live bacteria directly, bundles of flagella and even single filaments (Fig. 19-1C) can be viewed by dark-field light microscopy.[8,29] Normal flagella appear to have a left-handed helical form, but curly *Salmonella* flagella, which have a superhelix of one-half the normal pitch, form a right-handed helix.[5] Normal bacteria swim in straight lines but periodically "tumble" before swimming in a new random direction. This behavior is part of the system of **chemotaxis** by which the organism moves toward a food supply.[30] Curly mutants tumble continuously. When bacteria tumble the flagella change from normal to curly. The pitch is reversed and shortened. A proposed mechanism for the change of pitch involves propagation of cooperative conformational changes down additional

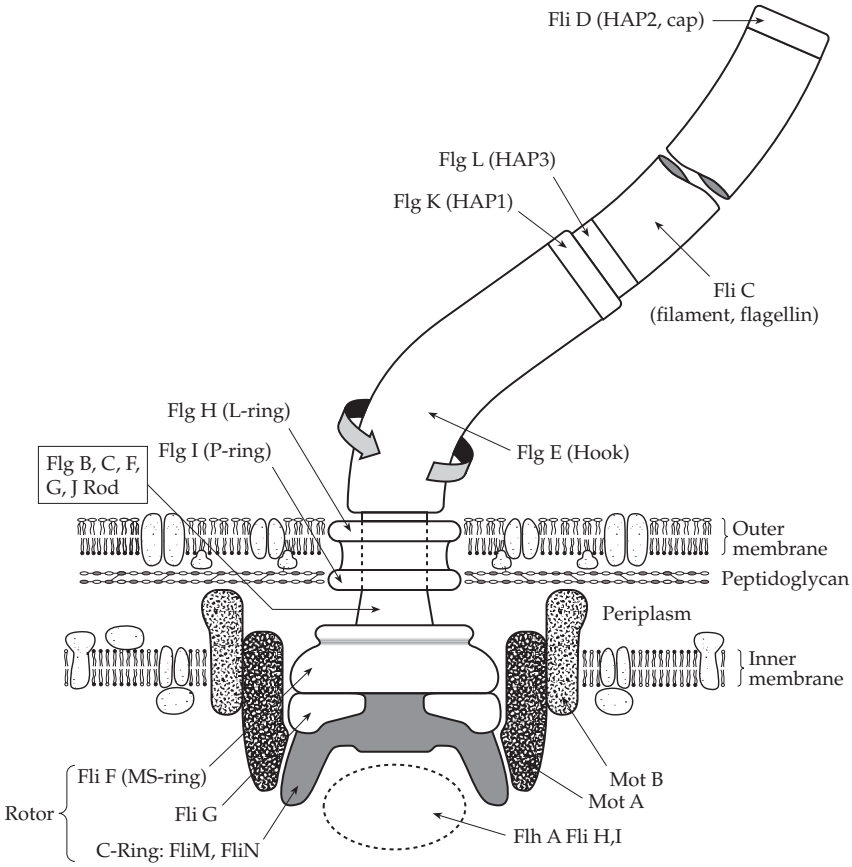

Figure 19-3 Schematic drawing of bacterial flagellar motor. Based on drawings of Berg,[27] Zhou and Blair,[28] and Elston and Oster.[1]

rows of flagellin subunits.[31]

There are no muscle-type proteins in the flagella. By incubating flagellated bacteria with penicillin and then lysing them osmotically, Eisenbach and Adler obtained cell envelopes whose flagella would rotate in a counterclockwise fashion if a suitable artificial electron donor was added.[32] This and other evidence showed that ATP is not needed. Rather, the torque developed is proportional to the **protonmotive force** and, under some circumstances, to ΔpH alone. It is the flow of protons from the external medium into the cytoplasm that drives the flagella.[8] Movement of *E. coli* cells in a capillary tube can also be powered by an external voltage.[33] In alkalophilic strains of *Bacillus* and some *Vibrio* species a sodium ion gradient will substitute.[13] Several hundred protons or Na^+ ions must pass through the motor per revolution.[8] Some estimates, based on energy balance,[29] are over 1000. However, Na^+-dependent rotation at velocities of up to 1700 Hz has been reported for the polar flagellum of *Vibrio alginolyticus*. It is difficult to understand how the bacterium could support the flow of 1000 Na^+ per revolution to drive the flagellum.[2]

What kind of protic motor can be imagined for bacterial flagella? Electron microscopy reveals that the flagellar hook is attached to a rod that passes through the cell wall and is, in turn, attached to a thin disc, the **M-ring** (or MS-ring), which is embedded in the cytoplasmic membrane both for gram-positive and gram-negative bacteria (Fig. 19-3). Two additional rings are present above the M-ring of flagella from gram-negative bacteria. The P-ring interacts with the peptidoglycan layer, and the L-ring contacts the outer membrane (lipopolysaccharide; Fig. 19-3). A logical possibility is that the M-ring, which lies within the plasma membrane, is the rotor, and a ring of surrounding protein subunits is the stator for the motor (Fig. 19-4).[34,35] Glagolev and Skulachev suggested in 1978 that attraction between $-COO^-$ and $-NH_3^+$ groups provides the force for movement.[34] Protons passing down an H^+-conducting pathway from the outer surface could convert $-NH_2$ groups to $-NH_3^+$, which would then be attracted to the $-COO^-$ groups on the stator subunits. When these two oppositely charged groups meet, a proton could be transferred from $-NH_3^+$ to $-COO^-$ destroying the electrostatic attraction. At the same time, movement of the M-ring would bring the next $-NH_2$ group to the H^+-conducting pathway from the outside. The $-COOH$ of the stator would now lose its proton through a conducting pathway to the inside of the bacterium, the proximity of the new $-NH_3^+$ assisting in this proton release. Since that time, other models based on electrostatic interactions have been advanced.[1,29,36]

Approximately 40 genes are required for assembly of the flagella, but mutations in only five motility genes have produced bacteria with intact flagella that do not rotate. Among these genes are *motA*, *mot B*, *FliG*, *FliM*, and *FliN*.[16,29,37,37a] Infection with a lambda transducing bacteriophage carrying functional *motB* genes restores motility to *motB* mutants by inducing synthesis of the motB protein. Block and Berg observed rotation of single bacteria tethered to a coverslip by their flagella. As the synthesis of the motB protein increased,the flagellar rotation rate increased in as many as 16 steps. This suggested that as many as 16 subunits of the *motB* gene product may contribute to the operation of the motor.[38] Later studies suggest eight subunits[39] rather than 16.

Both the M-ring and the thin S-ring, which lies directly above it and is now usually referred to as the MS-ring, are formed from ~20–25 subunits of the 61-kDa **FliF** protein.[39] Both the MotA and MotB proteins are embedded in the inner bacterial membrane and appear to form a circular array of "studs" around the M-ring.[16] MotA has a large cytosolic domain as well as four predicted transmembrane helices[40] while MotB has a large periplasmic domain and probably binds to the peptidoglycan.[37,41,41a] The MotA and MotB proteins, which bind to each other, are thought to form the ~8 functional units in the stator of the motor.[37] Proteins FliG, FliM, and FliN are evidently parts of the rotor assembly. FliM and FliN form an additional ring, the cytoplasmic or **C-ring**, which had been difficult to see in early electron microscopy. As many as 40 of each of these subunits may be present in the ring.[42,43] A ring of FliG subunits joins the C-ring to the MS-ring (Fig. 19-3). FliE is also a part of the basal body.[25a]

From study of mutants it has been concluded that three charged residues of FliG, R279, D286, and D287 are directly involved in generation of torque by the motor.[44] Side chains of these residues may interact with the cytoplasmic domains of MotA and MotB. Residues R90 and E98 of MotA may be involved in controlling proton flow through the motor units.[28,44] The two prolines P173 and P122 are also essential for torque generation.[28]

There are obvious similarities between the flagellar motors and the protic turbines of ATP synthases (Fig. 18-14), but there are also substantial differences. It apparently takes about 12 protons for one revolution of the ATP synthase but about 1000, or ~125 per motor unit, for rotation of a bacterial flagellum. Elston and Oster propose an ion turbine more complex than that of ATP synthase. They suggest that the rotor might contain about 60 slanted rows of positively charged groups spaced as shown in Fig. 19-4. The motor is reversible, i.e., it can rotate in either direction. One possibility is that the subunits alter their conformations cooperatively in such a way that the slant of the rows of charged groups is reversed. Other possibilities for altering the constellation of charges via conformational changes can be imagined.[1] See also Thomas *et al*.[44a]

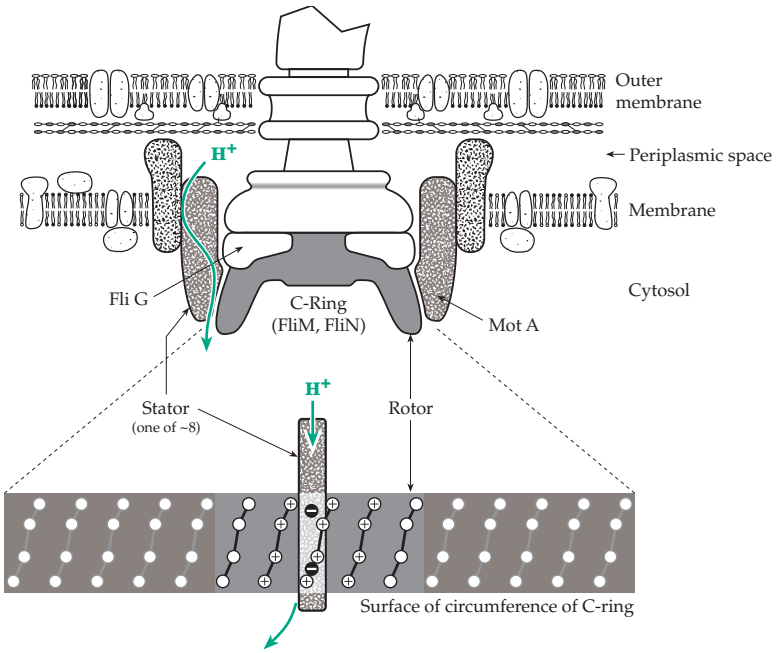

Figure 19-4 Schematic drawing of a hypothetical configuration of rotor and one stator unit in a flagellar motor as proposed by Elston and Oster.[1] The rotor can hold up to 60 positive charges provided by protons flowing from the periplasm through the stator motor units that surround the C-ring and hopping from one site to the next along the slanted lines. The rotor is composed of 15 repeating units, each able to accommodate four protons. Negative charges on the stator units are 0.5 nm from the rotor charges at their closest approach. For details see the original paper.

3. Chemotaxis

The flagellar motor is reversible, and in response to some signal from the bacterium it will turn in the opposite direction. At the same time, the flagellin subunits and those of the hook undergo conformational changes that change the superhelical twist. Perhaps synchronous conformational changes in the M-ring also are associated with the change in direction of rotation and are induced by interaction with a **switch complex** that lies below the M-ring. This consists of proteins FliG, FliM, and FliN.[44b] Mutations in any one of these proteins lead to the following four phenotypes: absence of flagella, paralyzed flagella, or flagella with the switch biased toward clockwise or toward counterclockwise rotation.[45]

What signals a change in direction of rotation? The answer lies in the attraction of bacteria to compounds that they can metabolize. Bacteria will swim toward such compounds but away from repellent substances, a response known as **chemotaxis**. Cells of *E. coli* swim toward higher concentrations of L-serine (but not of D-serine), of L-aspartate, or of D-ribose.

Phenol and Ni^{2+} ions are repellent.[46–48] By what mechanism can a minuscule prokaryotic cell sense a concentration gradient? It is known that the plasma membrane contains receptor proteins, whose response is linked to control of the flagella. Since the dimensions of a bacterium are so small, it would probably be impossible for them to sense the difference in concentration between one end and the other end of the cell. The chemotatic response apparently results from the fact that a bacterium swims for a relatively long time without tumbling when it senses that the concentration of the attractant is increasing with *time*. When it swims in the opposite direction and the concentration of attractant decreases, it tumbles sooner.[49]

Koshland[47] proposed that as the membrane receptors become increasingly occupied with the attractant molecule, the rate of formation v_f of some compound X, within the membrane or within the bacterium, is increased (Eq. 19-1). When [X] rises higher than a threshold level, tumbling is induced. At the same time, X is destroyed at a velocity of v_d.

$$\xrightarrow{v_f} [X] \xrightarrow{v_d} \qquad (19\text{-}1)$$

Subsequently, a readjustment of v_f and v_d occurs such that the concentration of X falls to its normal steady state level. X would act directly on the flagellar motor.

The receptors for L-serine[50–51a] and L-aspartate[52,53] are 60-kDa proteins encoded by genes *tsr* and *tar* in *Salmonella* or *E. coli*.[46,54] These proteins span the inner plasma membrane of the bacteria as shown in Figs. 11-8 and 19-5. The functioning of the receptor has been discussed in some detail in Chapter 11. However, there is still much that is not understood. The symmetric head, whose structure is known (Fig. 11-8), has two binding sites, but the aspartate receptor binds only one aspartate tightly. There is substantial evidence that suggests a piston-type sliding of one helix toward the cytoplasm as part of the signaling mechanism.[54a] While the flagella are distributed around the cell, the receptors appear to be clustered at the cell poles.[55]

Proteins encoded by genes *cheA*, *cheW*, *cheY* and *cheZ, cheB,* and *ChR* are all involved in controlling chemotaxis.[48,56] Their functions are indicated in the scheme of Fig. 19-5. All of the corresponding protein products have been isolated and purified, and the whole chemotaxis system has been reconstituted in phospholipid vesicles.[57] Gene *CheA* encodes a 73-kDa protein kinase, which binds as a dimer to the cytoplasmic domains of the related aspartate, serine, and ribose/galactose receptors with the aid of a coupling protein, cheW (Fig. 19-5). A great deal of effort has been expended in trying to understand how binding of an attractant molecule to the periplasmic domain of the receptor can affect the activity of the CheA kinase, but the explanation is unclear. There is a consensus that a small but distinct conformational alteration is transmitted through the receptor.[58–61a] An apparently α-helical region containing methylation sites (Fig. 19-5) appears to be critically involved in the signaling, responding not only to occupancy of the receptor site but also to intracellular pH and temperature and to methylation. Mutation of the buried Gly 278 found in this region to branched hydrophobic amino acids, such as Val or leucine, locks the receptor in state with a superactivated CheA kinase, while *substitution* of Gly 278 with aspartate leaves the kinase *inactive*.[61] Occupancy of the normal receptor site with ligand (aspartate, serine, etc.,) dramatically decreases the kinase activity.

The CheA protein is an autokinase which, upon activation by the receptor, becomes phosphorylated on N^{ε} of the imidazole ring of His 48. It then transfers this phospho group from His 48 to the carboxylate of Asp 57 of the 654-residue protein **CheY**, which is known as the **response regulator**.[62–65d] The unregulated flagellum rotates counterclockwise (CCW). *Phospho-CheY* (CheY-*P*, which qualifies as X in Eq. 19-1) *carries the message to the flagellar motor to turn clockwise (CW).* This is apparently accomplished through the binding of CheY-*P* to the N-terminal portion of protein FliM. This presumably induces a conformational change, which is propagated to FliG and to all of the proteins of the rotor and flagellar rod, hook, and filament.[45,65,66,66a] The flagella fly apart, and the bacterium tumbles and heads randomly in a new direction.

Tumbling occurs most often when receptors are unoccupied, and the bacteria change directions often, as if lost. However, if a receptor is occupied by an attractant, the activity of CheY is decreased and less CheY-*P* will be made. The carboxyl phosphate linkage in this compound is labile and readily hydrolyzed, a process hastened by the phosphatase **CheZ**.[67–69] Consequently, in the presence of a high enough attractant concentration the tumbling frequency is decreased, CCW flagellar rotation occurs, and the bacterium swims smoothly for a relatively long time.

There are still other important factors. Occupancy of the receptor by a ligand makes the receptor protein itself a substrate for the chemotaxis-specific methyltransferase encoded by the *cheR* gene.[62,70,71] This enzyme transfers methyl groups from *S*-adenosylmethionine to specific glutamate side chains of the receptor to form methyl esters. In the aspartate receptor there are four such glutamate residues in a large cytoplasmic domain that includes the C terminus. Two of these glutamates are initially glutamines and can undergo methylation only if they are deaminated first.[72] An esterase encoded by the *cheB* gene[72] removes the methyl ester groupings as methanol.

The action of the CheR methyltransferase is apparently unregulated, but the esterase activity of CheB is controlled by the phosphorylation state of the

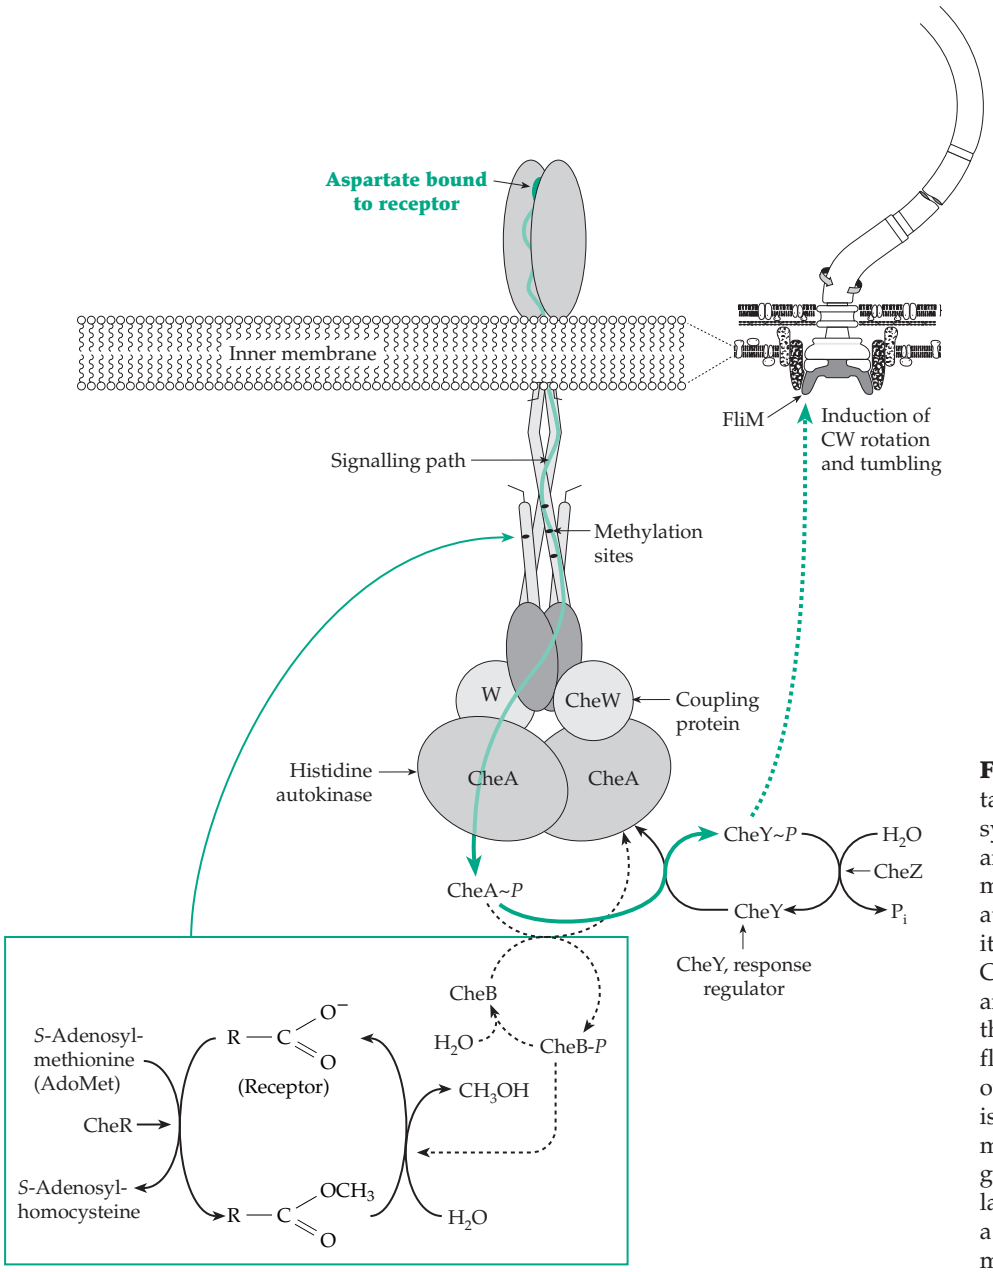

Figure 19-5 Schematic representation of an important chemotactic system of *E. coli*, *S. typhimurium*, and other bacteria. The transmembrane receptor activates the autokinase CheA, which transfers its phospho group to proteins CheY and CheB to form CheY-*P* and CheB-*P*. CheY-*P* regulates the direction of rotation of the flagella, which are distributed over the bacterial surface. CheR is a methyltransferase which methylates glutamate carboxyl groups in the receptor and modulates the CheA activity. CheZ is a phosphatase and CheB-*P* a methylesterase.

autokinase CheA. CheB competes with CheY (Fig. 19-5), and CheB-*P* is the active form of the esterase. After a chemotactic stimulus the level of CheA-*P* falls and so does the activity of the methylesterase. The number of methyl groups per receptor rises making the CheA kinase more active and opposing the decrease in kinase activity caused by receptor occupancy. The system is now less sensitive to the attractant; the bacterium has *adapted* to a higher attractant concentration.[62,73,73a] It tumbles more often unless the attractant concentration rises; if it is headed toward food tumbling is still inhibited. If it is headed away from the attractant the levels of both CheY-*P* and ChB-*P* rise. A high level of fumarate within the cell also acts on the switch–motor complex and favors CW rotation.[74]

For some bacterial attractants such as D-galactose, D-ribose, maltose, and dipeptides[75] the corresponding binding proteins,[38,76] which are required for the sugar uptake (e.g., Fig. 4-18A), are also necessary for chemotaxis. The occupied binding proteins apparently react with membrane-bound receptors to trigger the chemotactic response. The aspartate receptor (*tar* gene product) appears also to be the receptor for the maltose-binding protein complex,[47] and both the aspartate and the serine receptor (*tsr* gene product) also mediate thermotaxis and pH taxis.[77,77a] Clusters of identical receptors may function cooperatively to provide high sensitivity and dynamic range.[77b]

B. Muscle

There is probably no biological phenomenon that has excited more interest among biochemists than the movement caused by the contractile fibers of muscles. Unlike the motion of bacterial flagella, the movement of muscle is directly dependent on the hydrolysis of ATP as its source of energy. Several types of muscle exist within our bodies. **Striated** (striped) **skeletal muscles** act under voluntary control. Closely related are the **involuntary striated heart muscles,** while **smooth involuntary muscles** constitute a third type. Further distinctions are made between fast-twitch and slow-twitch **fibers**. **Fast-twitch fibers** have short isometric contraction times, high maximal velocities for shortening, and high rates of ATP hydrolysis. They occur predominately in white muscle. Because of the absence of the strong oxidative metabolism found in red muscles, fast-twitch fibers fatigue rapidly. Although red muscle sometimes contains fast-twitch fibers, it more often consists of **slow-twitch fibers,** which have a longer contraction time, low shortening velocity, and low ATPase. They are more resistant to fatigue[56] than fast-twitch fibers.[78] Embryonic muscle contains fast-twitch fibers as well as embryonic forms which contract slowly.[79] Some organisms contain specialized types of muscle. For example, the asynchronous flight muscles of certain insects cause the wings to beat at rates of 100–1000 Hz. In these muscles nerve impulses are used only to start and to stop the action; otherwise the cycle of contraction and relaxation continues automatically.[80] The adductor muscles, which close the shells of oysters and clams, can sustain large tensions for long periods of time with little expenditure of energy. This is accomplished by a **catch mechanism**.[81]

1. The Structural Organization of Striated Muscle

Skeletal muscles consist of bundles of long **muscle fibers,** which are *single cells* of diameter 10–100 μm formed by the fusion of many embryonic cells. The lengths are typically 2–3 cm in mammals but may sometimes be as great as 50 cm. Each fiber contains up to 100–200 nuclei. Typical cell organelles are present but are often given special names. Thus, the plasma membrane (plasmalemma) of muscle fibers is called the **sarcolemma**. The cytoplasm is **sarcoplasm,** and mitochondria may be called **sarcosomes**. The major characteristic of muscle is the presence of the contractile **myofibrils**, organized bundles of proteins 1–2 μm in diameter and not separated by membranes from the cytoplasm. Since they occupy most of the cytoplasm, a substantial number of myofibrils are present in each muscle fiber.

In the light microscope cross striations with a repeating distance of ~2.5 μm can be seen in the myofibrils (Figs. 19-6 and 19-7). The space between two of the dense **Z-discs** (Z lines) defines the **sarcomere**, the basic contractile unit. In the center of the sarcomere is a dense **A-band** (anisotropic band). The name refers to the intense birefringence of the band when viewed with plane polarized light. Straddling the Z-discs are less dense **I-bands** (the abbreviation stands for isotropic, a misnomer, for although the bands lack birefringence, they are not isotropic). Weakly staining **M-lines** (usually visible only with an electron microscope) mark the centers of the A-bands and of the sarcomeres.

The fine structure of the sarcomere was a mystery until 1953, when H. E. Huxley, examining thin sections of skeletal muscle with the electron microscope, discovered a remarkably regular array of interdigitated protein filaments.[82,83] **Thick filaments**, 12–16 nm in diameter and ~1.6 μm long, are packed in a hexagonal array on 40- to 50-nm centers throughout the A-bands (Fig. 19-6B). Between these thick filaments are **thin filaments** only 8 nm in diameter and extending from the Z-line for a length of ~1.0 μm. When contracted muscle was examined, it was found that the I-bands had become so thin that they had nearly disappeared and that the amount of overlap between the thick and the thin filaments had increased. This indicated that contraction had consisted of the sliding movement of the thick and thin filaments with respect to each other.[84] In skeletal muscle the sarcomere shortens to a length of ~2 μm, but in insect flight muscle a much smaller shortening occurs repetitively at a very high rate.

2. Muscle Proteins and Their Structures

The myofibrillar proteins make up 50–60% of the total protein of muscle cells. Insoluble at low ionic strengths, these proteins dissolve when the ionic strength exceeds ~0.3 and can be extracted with salt solutions. Analysis of isolated mammalian myofibrils[86] shows that nine proteins account for 96% or more of the protein; **myosin**, which constitutes the bulk of the thick filaments, accounts for 43% and **actin**, the principal component of the thin filaments, 22%.

Actin and the thin filaments. There are at least six forms of actin in adult mammalian tissues: α-cardiac, α-skeletal muscle, α- and γ-smooth muscle, β- and γ-cytoplasmic.[87–89] All of them are closely homologous, e.g., the 42-kDa α-skeletal muscle actin differs in only 4 of 375 residues from the α-cardiac form and only in 6 residues from the γ-smooth form. In almost all organisms actins contain one residue of N^{δ}-methylhistidine at position 73.[87,88,90] Actin is an unusual protein in that

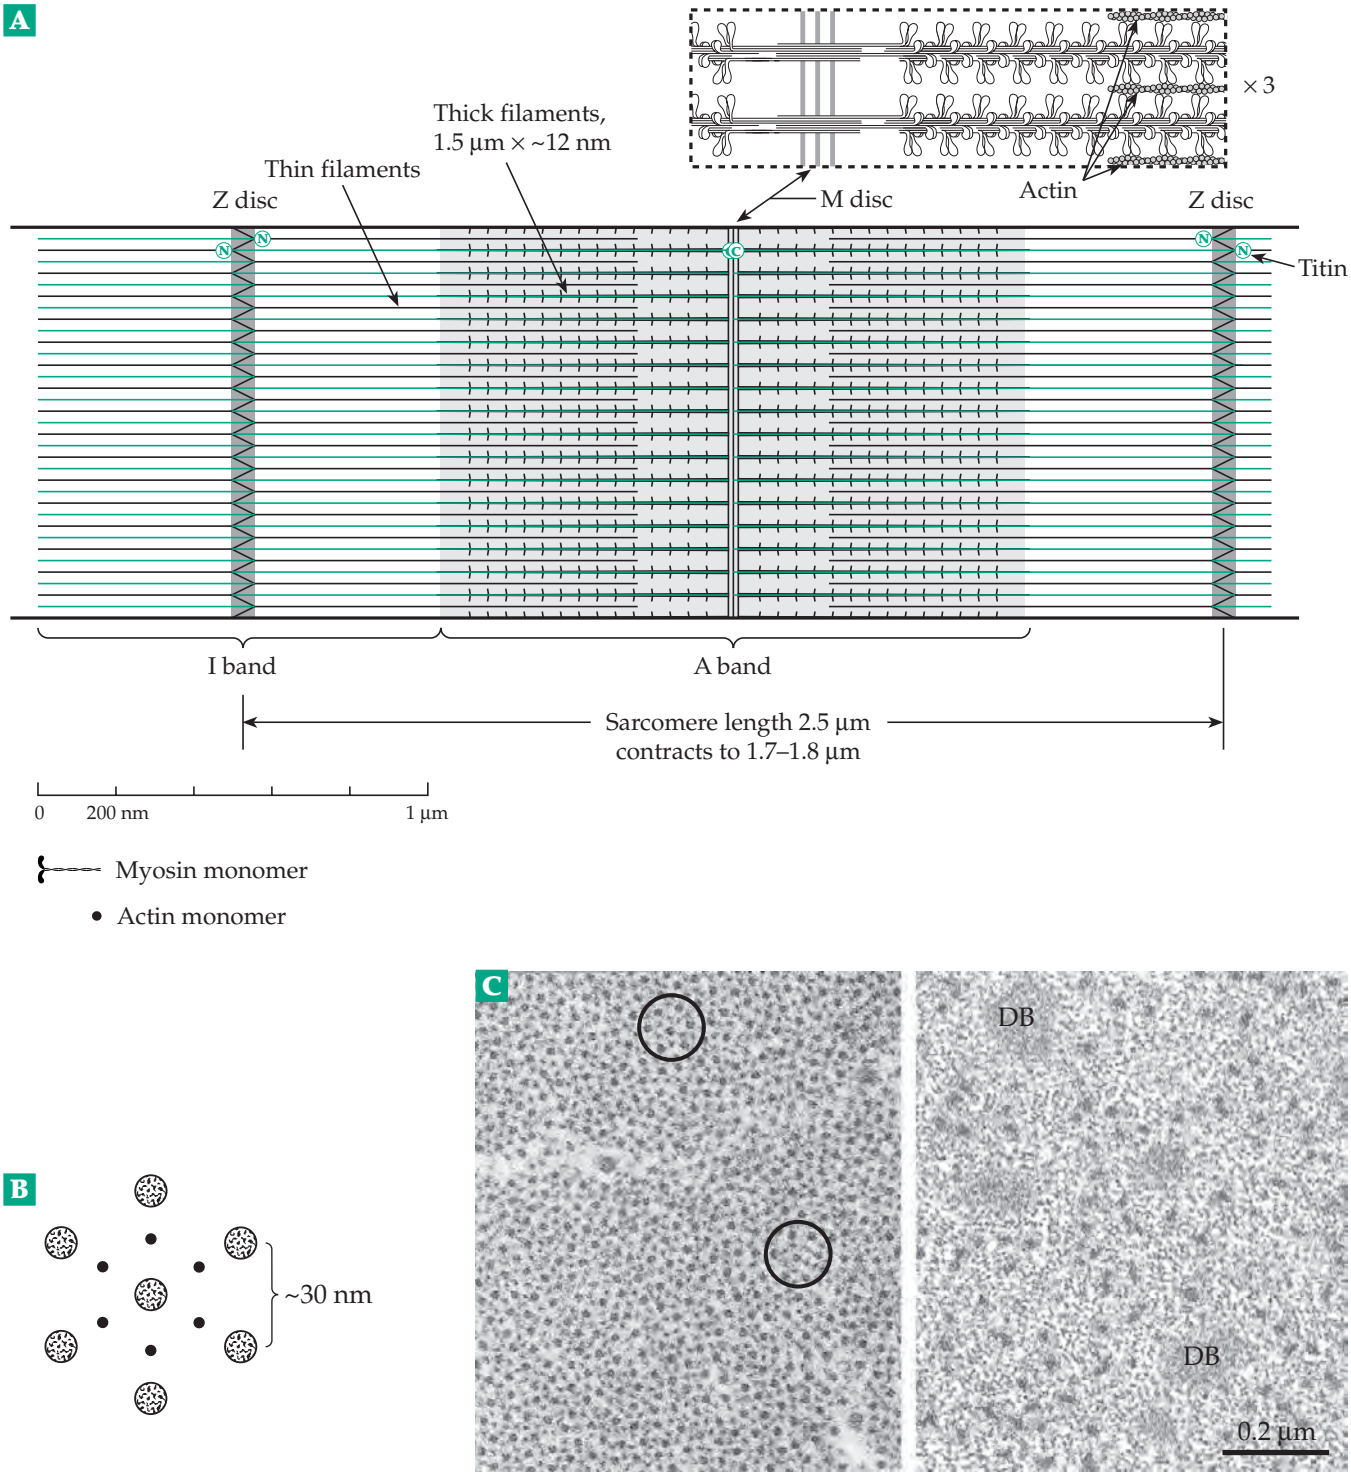

Figure 19-6 (A) The structure of a typical sarcomere of skeletal muscle. The longitudinal section depicted corresponds to that of the electron micrograph, Fig. 19-7A. The titin molecules in their probable positions are colored green. The heads of only a fraction of the myosin molecules are shown protruding toward the thin actin filaments with which they interact. A magnified section at the top is after Spudich.[85] It shows the interactions of the myosin heads with the thin filaments at the right-hand edge. (B) A sketch showing the arrangement of thick and thin filaments as seen in a transverse section of a striated muscle fiber. (C) Left: electron micrograph of a transverse section of a glycerated rabbit psoas muscle. The hexagonal arrangement of six thin filaments around one thick filament can be seen in the center of the circle. Six other thick filaments form a larger concentric circle as in (B). Right: transverse section of a smooth muscle fiber. Notice the irregular arrangement of thick and thin filaments. Filaments of intermediate diameter are also present, as are dense bodies (DB). The latter are characteristically present in smooth muscle.

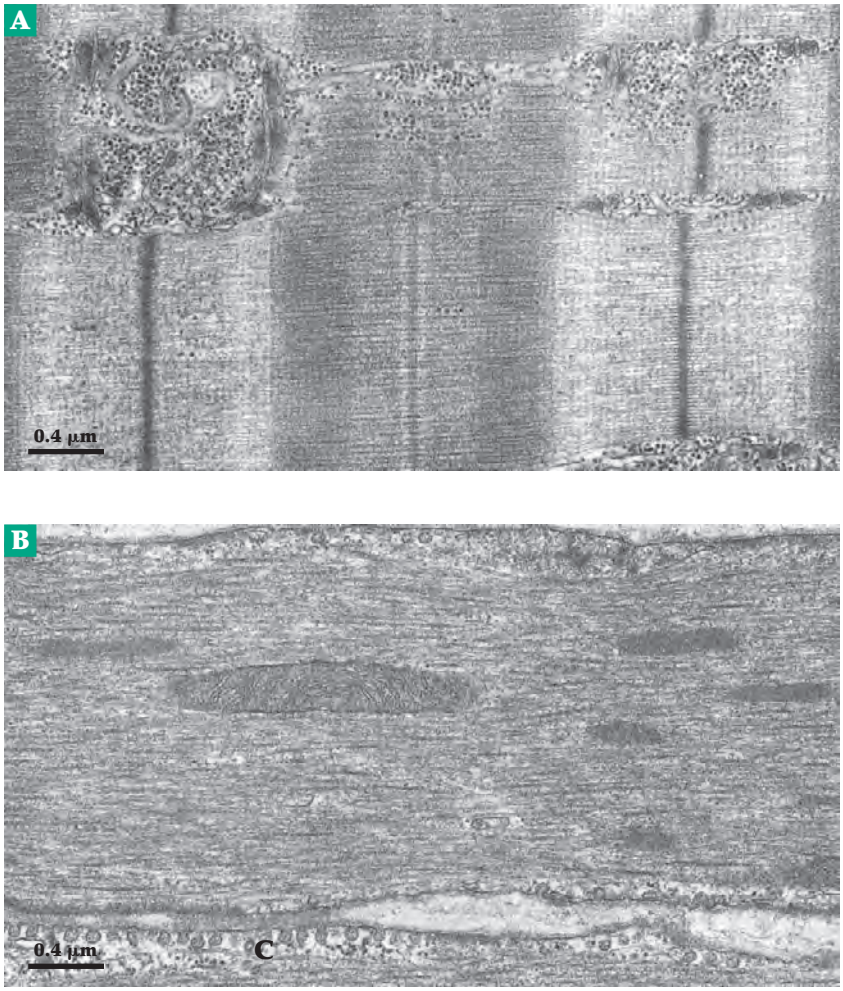

Figure 19-7 (A) Electron micrograph of a longitudinal section of a mammalian skeletal muscle (pig biceps muscle). The tissue was doubly fixed, first with formaldehyde and glutaraldehyde, then with osmium tetroxide. It was then stained with uranyl acetate and lead citrate. The section shows a white muscle fiber containing few mitochondria and narrow Z-lines. The Z-discs (marked Z), M-line, A- and I-bands, and thick and thin filaments can all be seen clearly. The periodicity of ~40 nm along the thin filaments corresponds to the length of the tropomyosin molecules, and the cross striation is thought to represent bound tropomyosin and troponin. The numerous dense particles in the upper part of the micrograph are glycogen granules, while the horizontal membranous structures are longitudinal tubules of the sarcoplasmic reticulum (endoplasmic reticulum). These come into close apposition to the T tubules leading from the surface of the muscle fiber. The T tubules (T) are visible in longitudinal section at the upper left of the micrograph on both sides of the Z-line and in cross-section in the upper right-hand corner. There a T tubule is seen lying between two lateral cisternae of the sarcoplasmic reticulum. (B) Longitudinal section of smooth muscle (chicken gizzard) fixed as in A. Thick filaments (Th), which are considerably thicker than those in striated muscle and less regular, can be seen throughout the section. They are surrounded by many thin filaments, which are often joined to dense bodies (DB). A mitochondrion (Mi) is seen in the center of the micrograph, and at the lower edge is a boundary between two adjacent cells. Notice the caveolae (C), which are present in large numbers in the plasma membrane and which are extremely active in smooth muscle. Micrographs courtesy of Marvin Stromer.

it can exist in both a filamentous and a soluble state. The interconversion between them is of great physiological importance. Actin filaments dissolve in a low ionic strength medium containing ATP to give the soluble, monomeric **G-actin**. Each G-actin monomer usually contains one molecule of bound ATP and a calcium ion.

Because of its tendency to polymerize, G-actin has been difficult to crystallize. However, it forms crystalline complexes with several other proteins, e.g., deoxyribonuclease I,[91] a fragment of gelsolin, and profilin,[92] which block polymerization and it has recently been crystallized as the free ADP complex.[92a] The three-dimensional structure of the actin is nearly the same in all cases. The molecule folds into four domains, the ATP binding site being buried in a deep cleft. The atomic structure (Fig. 7-10) resembles that of hexokinase, of glycerol kinase, and of an ATP-binding domain of a chaperonin of the Hsp 70 family.[90] As with the kinases, actin can exist in a closed and more open conformations, one of which is seen in the profilin complex. Addition of 1 mM Mg^{2+} or 0.1 M KCl to a solution of G-actin leads to spontaneous transformation into filaments of **F-actin** (Figs. 7-10 and 19-9) each containing 340–380 actin monomers and resembling the thin filaments of muscle.[93-94a] The ATP bound in the F-actin filament is hydrolyzed within ~100 s to ADP and P_i. However, the hydrolysis is not as rapid as polymerization so that a "cap" of ATP-containing monomers may be found at each end of the filament.[94,95,95a] There is a striking similarity to the binding of nucleotides to microtubule subunits (Fig. 7-33) and in the contractile tail sheath of bacteriophage (Box 7-C).

The two ends of the F-actin filaments have different surfaces of the monomer exposed and grow at different rates. This has been demonstrated by allowing the myosin fragment called heavy meromyosin (HMM; see Fig. 19-10) to bind to (or "decorate") an actin filament. The

myosin heads bind at an angle, all pointed in one direction. This gives a "pointed" appearance to one end and a "barbed" appearance at the other. When monomeric actin is added to such an HMM-decorated F-actin filament the barbed ends grow much faster than the pointed ends.[94,96] In the intact sarcomere the ends that become pointed when decorated are free, while the opposite barbed ends of the filaments are attached at the Z-line (Fig. 19-6A). The existence in the cytoplasm of proteins that "cap" the fast-growing end of actin filaments thereby preventing further growth[96,97] suggests that cap proteins may be present at the ends of the thin filaments of the myofibrils.

Titin and nebulin. The third most abundant protein (10%), titin (also called **connectin**),[98–100a] is one of the largest of known proteins. Titin cDNA from human cardiac muscle encodes a 26,926-residue chain. Several tissue-specific isoforms of the protein are created by alternative mRNA splicing.[101] A single titin molecule stretches ~1200 nm from the Z-disc, where the N terminus is bound, to the M-line, where the C-terminal domain is attached (Fig. 19-8A). Thoughout much of the A-band titin binds to the thick filament and appears to be part of a scaffold for maintenance of the sarcomere structure. The I-band portion of titin has elastic properties that allow it to lengthen greatly or to shorten as the sarcomere changes length.[98,100,102]

Under the electron microscope titin appears as a flexible beaded string ~4 nm in diameter. Most of the molecule is made up of repetitive domains of two types. In human cardiac titin there are 132 folded domains that resemble type III fibronectin repeats and 112 immunoglobulin-like domains.[98] In a "PEVK region," between residues 163 and 2174, 70% of the residues are Pro, Glu, Val, or Lys. The titin molecule may be organized as polyproline helices in this elastic region.[102a] At the C terminus of titin 800 residues, including a Ser / Thr protein kinase domain, are found within the M-line.

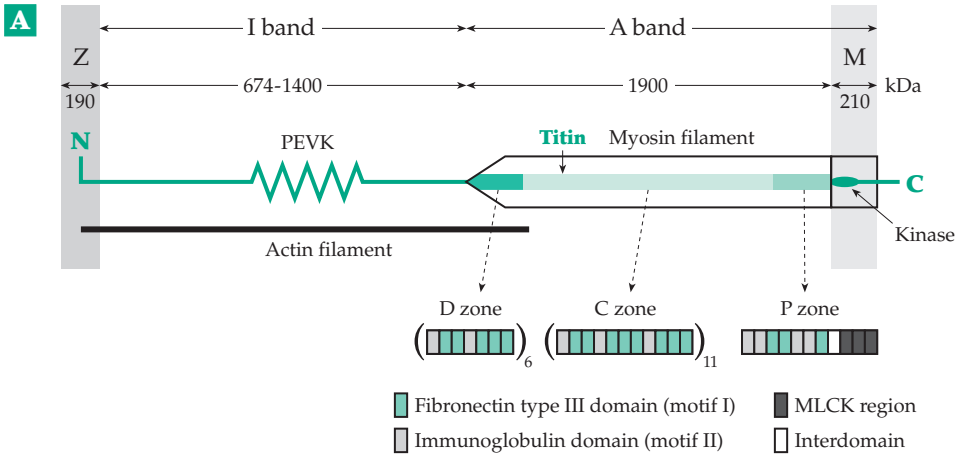
Another very large protein, **nebulin** (3% of the total protein),[103] appears to be stretched alongside the thin filaments. In the electron microscope it appears as a flexible, beaded string ~4 nm in diameter. Ninety-seven percent of the 6669-residue human nebulin is organized as 185 copies of an ~ 35-residue module.[104,105] Nebulin has a proline residue at about every 35th position, possibly corresponding in length to the pitch of the actin helix (Fig. 7-10). At the C terminus is an SH3 domain (see Fig. 11-14), which is preceded by a 120-residue segment rich in potential phosphorylation sites.[106] This part of the peptide chain is anchored in the Z-discs (Fig. 19-8B, C). The three extreme N-terminal modules of nebulin bind to tropomodulin, which caps the pointed ends of thin filments.[106a] Avian cardiac muscle contains a much shorter 100-kDa protein called **nebulette**, which resembles the C-terminal parts of nebulin. Nebulin has been described as encoding a blueprint for thin filament architecture.[99,103]

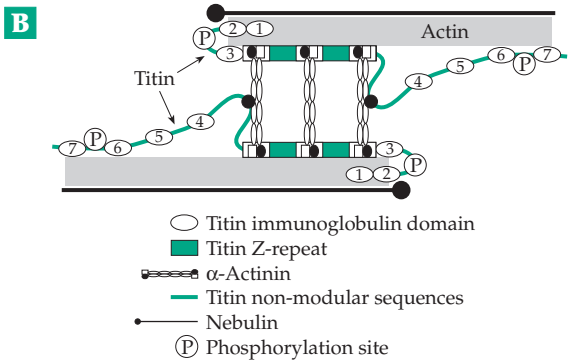
Proteins of the M-line and Z-disc. The M-line region contains the structural protein **myomesin**, which binds to both titin and myosin and holds the two together.[107] Fast skeletal and cardiac fibers also contain another **M-protein**, which may bridge between myosin filaments. Both the C-terminal region of nebulin and the N termini of pairs of titin molecules meet in the Z-disc, where they are bound into a lattice containing **α-actinin**[98,108-109b] and other proteins (Fig. 19-8B). The dimeric α-actinin, a member of the spectrin family, has a subunit mass of ~97 kDa.[109a] Found primarily in the Z-discs, it is also present in nonmuscle cells in stress fibers and at other locations in the cytoskeleton (Chapter 7). It may anchor actin filaments to various structures outside of the sarcomere.[110] In the dense Z-disc of insect flight muscle a regular hexagonal lattice of α-actinin[111] and a large (500–700 kDa) modular protein called **kettin**[112,112a,b] bind the thin filaments of opposite polarity together.

The **C-protein** (thick filaments), myomesin (M-line protein), and α-actinin (Z-line protein)[110,113,114] each provide 2% of the protein in the myofibril. Less than 1% each of 11 or more other proteins may also be present within the sarcomere.[86,115] Several of these, including the cytoskeletal proteins **desmin** and **vimentin**, and **synemin** surround the Z-discs.[116,116a]

The regulatory proteins troponin and tropomyosin. These two proteins are also associated with the filaments, each one contributing ~5% to the total protein of myofibrils. Tropomyosin is an elongated α-helical coiled-coil molecule, each molecule of which associates with seven actin subunits of an actin filament. Troponin consists of three subunits known as troponins C, T, and I. The elongated troponin T binds to tropomyosin. Troponin I is an inhibitor of the interaction of myosin and actin necessary for muscle contraction. Troponin C, a member of the calmodulin family (Fig. 6-8), binds Ca^{2+} and induces conformational changes that relieve the inhibition and allow contraction to occur. Nebulin is also thought to bind to tropomyosin. A possible arrangement of one of the tropomyosin–troponin–nebulin complexes that lie along the length of the thin filaments is shown schematically and as a three-dimensional model in Figs. 19-8C and D. These proteins are discussed further in Section 4. Figure 19-9 shows a model of the thin filaments with tropomyosin coiled-coil molecules on each side. The troponin subunits are not shown.

Myosins. There are 15 distinct families of proteins within the myosin superfamily.[117–120] They vary greatly in size, but all of them bind and hydrolyze ATP, and all bind to actin. Most have C-terminal tails. At their N





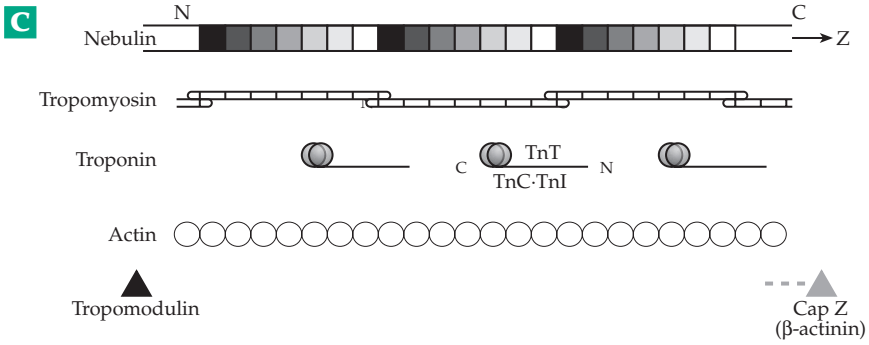


Figure 19-8 (A) Schematic drawing showing one molecule of titin (connectin) in a half sarcomere and its relationship to thick myosin filaments and thin actin filaments. The complex repeat patterns of fibronectin type III, immunoglobulin, in the three zones D, C, and P are also indicated.[98] See Maruyama.[98,98a] (B) Schematic drawing of the molecular structure of the sarcomere Z-disc. Titin, which is thought to parallel the thin filaments through the I-band, consists of various modules that are numbered from the N termini. In the Z-disc titin binds to α-actin, shown here as three vertical rods, and also to actin or actin-binding proteins. The SH3 domain (shown as a sphere) of nebulin and the N terminus of titin may interact. Regulatory phosphorylation sites are marked P. From Young *et al.*[108] Courtesy of Mathias Gautel. (C) Hypothetical model of a composite regulatory complex containing nebulin, tropomyosin, and troponin on the thin filaments of a skeletal muscle sarcomere. Each seven-module nebulin super-repeat (squares with graded shading) binds one tropomyosin, possible through the seven charge clusters along the length of each tropomyosin, and one troponin complex (shaded spheres with a tail). This complex consists of TnT, TnI, and TnC in orientations indicated by the N and C termini. Each nebulin super-repeat binds to seven actin monomers (open circles) along the thin filament. **Tropomodulin** caps the pointed ends of actin filaments and Cap Z, the "barbed ends." From Wang *et al.*[103]

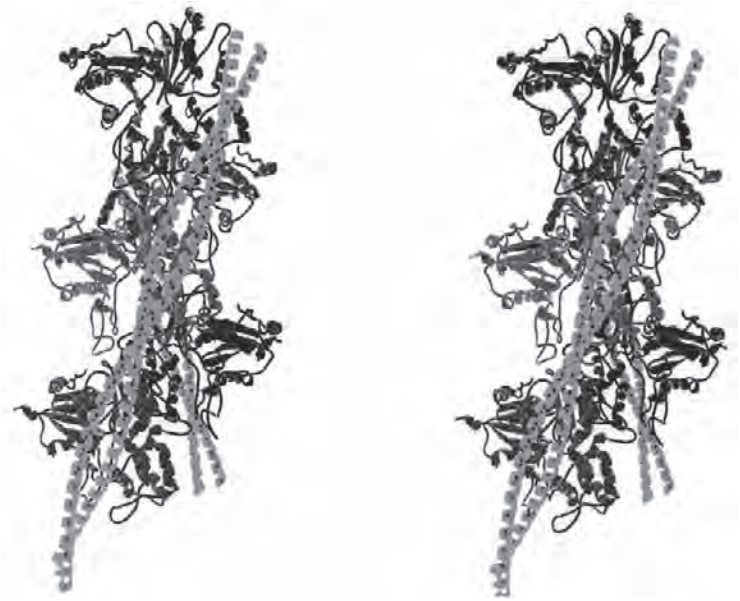

Figure 19-9 Stereoscopic ribbon drawing of the proposed structure of a thin actin filament with tropomyosin coiled-coils bound on opposing sides.[124] Five actin nomomers are assembled in the structure as is also illustrated in Fig. 7-10. From Lorenz *et al*.[125] Courtesy of Michael Lorenz.

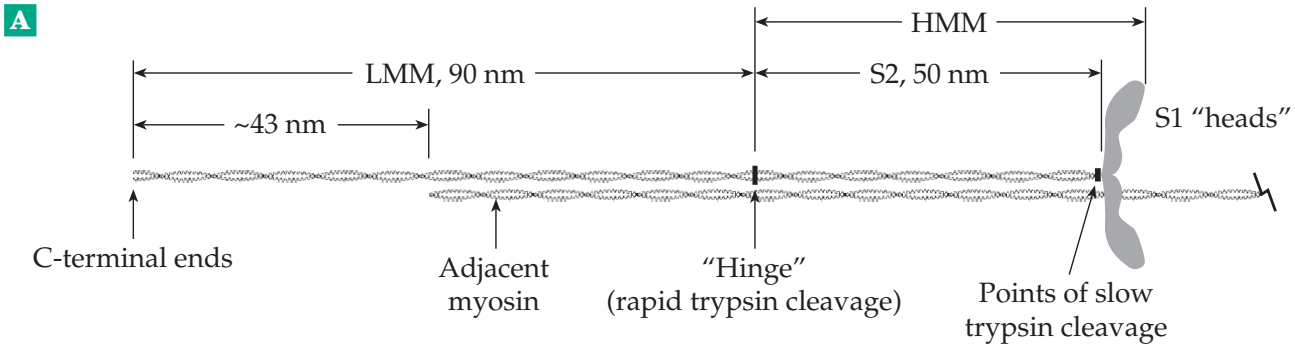
termini are one or two globular heads, which contain the catalytic centers in which ATP hydrolysis occurs. Sizes vary from 93 kDa for a myosin with a very short tail from *Toxoplasma*[118] to over 300 kDa. Myosins I, found in ameboid organisms and also in our own bodies (for example in the microvilli of the brush border of intestinal epithelial cells), are small single-headed molecules.[117,121] Myosins II are the "conventional" myosins of myofibrils and are often referred to simply as myosin. However, each of the three muscle types (skeletal, cardiac, and smooth) has its own kind of myosin II.[121a–c] Likewise, at least six different genes have been identified for the light chains of the myosin heads.[122] Fast and slow muscle as well as embryonic muscle have their own light chains. Each myosin II molecule consists of two identical ~230-kDa **heavy chains,** which are largely α-helical, together with two pairs of smaller 16- to 21-kDa **light chains**. Human skeletal muscle heavy chains contain 1938 residues of which the first ~850 are folded into pear-shaped heads, which contain the catalytic sites involved in harnessing ATP cleavage to movement. Following proline 850 nearly all of the remaining 1088 residues form an α-helical coiled-coil rod of dimensions ~160 x 2 nm (Fig. 19-10) in which the two chains coil around each other. The two heavy chains are parallel, each having its N terminus in one of the two heads and its C terminus bound in the shaft of the thick filament.

Myosins II from other sources have similar structures. For example, analysis of the DNA sequence for a heavy chain gene from the nematode *Caenorhabditis* showed that the protein contains 1966 residues, 1095 of which contain an amino acid sequence appropriate for a 160-nm long coiled coil.[123] There are no prolines within this sequence, which lies between Pro 850 and Pro 1944. Although there are many bands containing positively and negatively charged side chains along the myosin rod, the interactions between the two coiled helices are largely nonpolar. In *Drosophila* 15 different heavy-chain isoforms are created by splicing of a single mRNA.[123a]

While the C-terminal portions of the two parallel myosin heavy chains form a rod, the N-terminal portions fold into two separate heads. Each head also contains two smaller 16- to 21-kDa peptide chains which belong to the calmodulin family. One of these, the **essential light chain**, is tightly bound to the heavy chain. The second, the **regulatory light chain**, is able to bind Ca^{2+} and is less tightly bound to the rest of the head. A short treatment with trypsin or papain cuts the myosin molecule into two pieces. The tail end gives rise to **light meromyosin (LMM)**, a molecule ~90 nm in length. The remainder of the molecule including the heads is designated **heavy meromysin (HMM)**. A longer trypsin treatment leads to cleavage of HMM into one ~62-kDa **S2** fragment 40 nm long, and two ~130-kDa **S1** fragments, each of the latter representing one of the two heads (Fig. 19-10).

The junction of the head and tail portions of myosin appears rigid in Fig. 19-10A. However, there must be considerable conformational flexibility and perhaps some uncoiling of the helices to allow the two heads to interact with a single thin filament as is observed by electron microscopy.[126,128] There also appears to be a hinge between the S2 and LMM segments (Figs. 19-10A and 19-14).

The thick filaments. Dissociated myosin molecules can be induced to aggregate into rods similar to the thick filaments of muscle.[129] Since the filaments



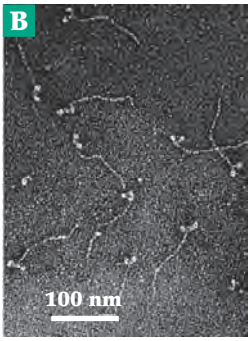


Figure 19-10 (A) An approximate scale drawing of the myosin molecule. The "hinge" is a region that is rapidly attacked by trypsin to yield the light and heavy meromyosins (LMM and HMM). Total length ~160 nm, molecular mass, 470 kDa; two ~200-kDa heavy chains; two pairs of 16- to 21-kDa light chains; heads: ~15 x 4 x 3 nm. (B) Electron micrograph of rabbit myosin monomers that became dissociated from thick filaments in the presence of ATP, fixed and shadowed with platinum.[127] Courtesy of Tsuyoshi Katoh.

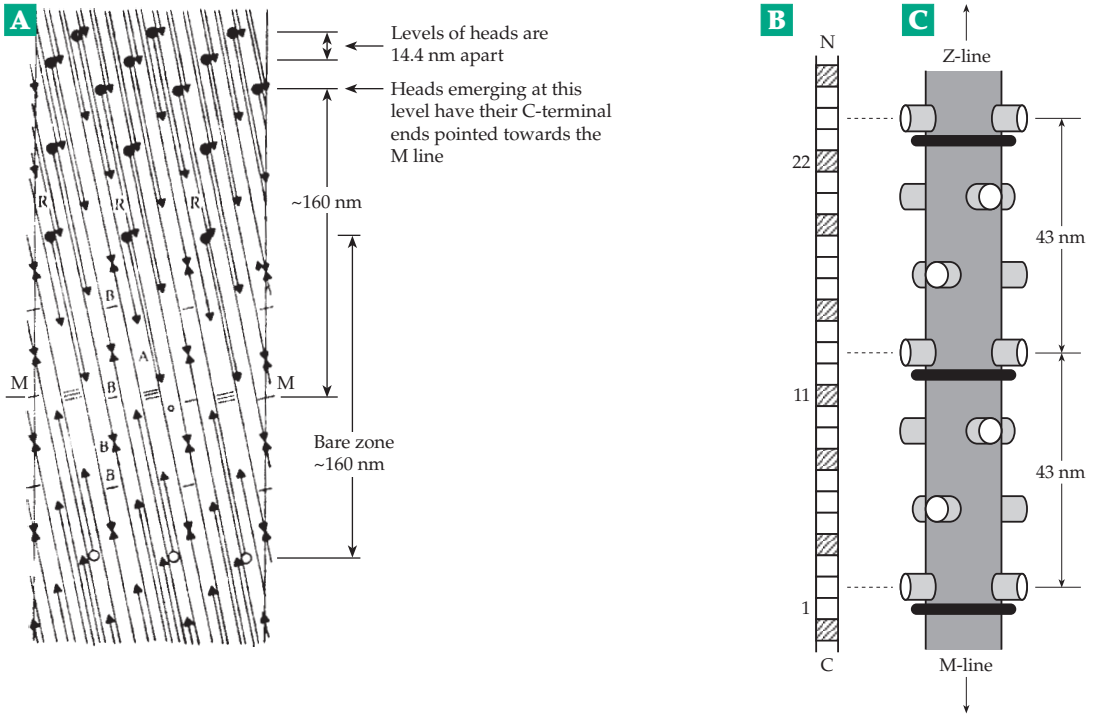

Figure 19-11 (A) Radial projection illustrating packing of myosin rods as suggested by Squire[130] for thick filaments of vertebrate skeletal muscle. The region of the bare zone at the M-line is shown. The filled circles represent the head ends of the myosin molecules and the arrowheads represent the other end of the rod, i.e., the end of the LMM portion. Antiparallel molecules interacting with overlaps of 43 and 130 nm are shown joined by single and triple cross-lines, respectively. Positions where two arrowheads meet are positions of end-to-end butting. O is an "up" molecule (thin lines) and A a "down" molecule (thick lines). The molecules move from the core at the C-terminal end to the filament surface at the head end. The levels marked B may be the levels of attachment of M-bridge material to the myosin filament. The level M-M is the center of the M-line and of the whole filament. The lateral scale is exaggerated more than threefold. (B) A segment of titin showing the 43-nm 11-domain super-repeat. (C) Model of a segment of a thick filament showing the 43-nm repeat, the C-protein, also bound at 43 nm intervals.[99] (B) and (C) Courtesy of John Trinick.

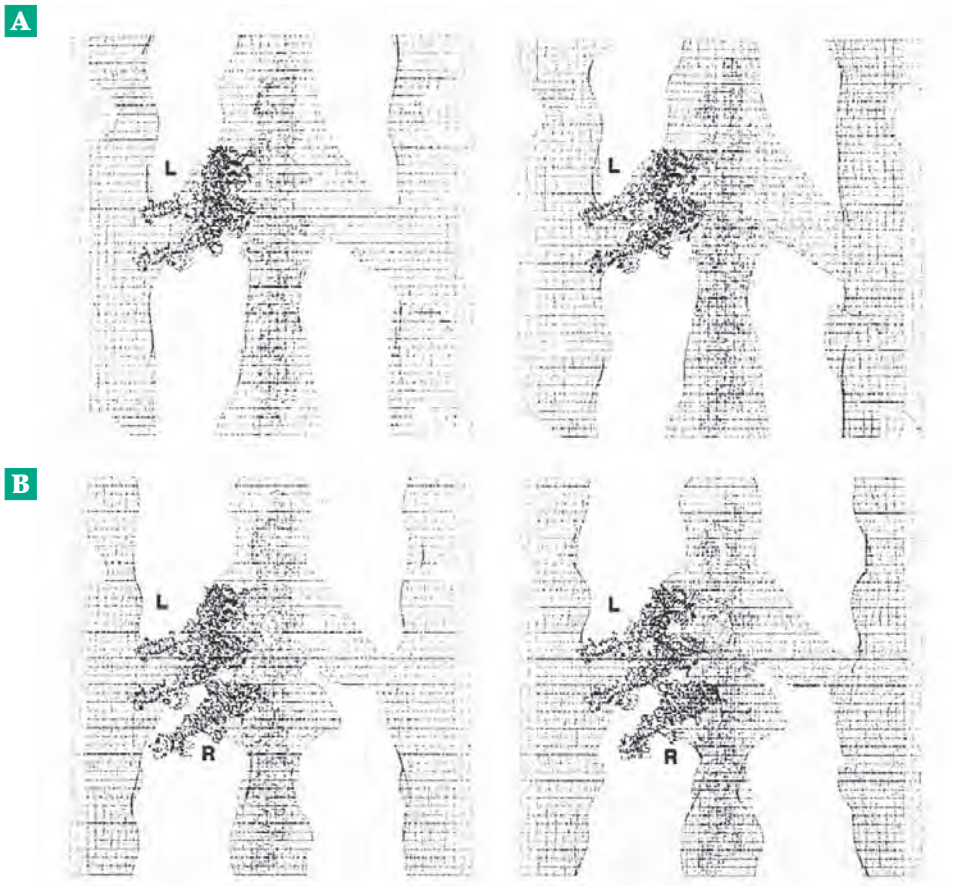

Figure 19-12 (A) Stereoscopic views of computer-assisted reconstructions of images of myosin heads attached to an F-actin filament centered between two thick filaments. Atomic structures of actin (Fig. 7-10) and of myosin heads (Fig. 19-15) have been built into the reconstructed images obtained by electron microscopy. (A) With the nonhydrolyzable ATP analog ATPPNP bound in the active sites. (B) Rigor. Two myosin heads are apparently bound to a single actin filament in (A). If they belong to the same myosin molecule the two C-terminal ends must be pulled together from the location shown here. In (B) a third head is attached, presumably from another myosin rod. This configuration is often seen in rigor. From Winkler *et al.*[134] Courtesy of K. A. Taylor.

have a diameter of ~14 to 20 nm, a large number of the thin 2-nm myosin molecules must be packed together. Electron microscopy reveals the presence of the heads projecting from the thick filaments at intervals of ~43.5 nm. However, there is a bare zone centered on the M-line, a fact that suggests tail-to-tail aggregation of the myosin monomers at the M-line in the centers of the thick filaments (see magnified section of Fig. 19-6, A). A helical packing arrangement involving about 300 myosin molecules (up to 30 rods in a single cross section) in close packing with a small central open core has been proposed for skeletal muscle myosin[130,131] and is illustrated in Fig. 19-11A,B. There are approximately three heads per turn of the helix, each group of three heads spaced 14.3 nm from the preceding one along the thick filament. It is apparently the zones of positive and negative charge, which are especially prevalent in the LMM segment toward the C termini, that lock the successive myosin molecules into this 14.3-nm spacing.[116,132] Titin also binds to the LMM segment of the myosin rod,[99,133] and its 11-domain super repeat of IgG-like and fibronectin-like modules are also 43 nm in length.[98,101] There are typically 47–49 of these super repeats in titin, and if each fits to a turn of the helix, as shown in Fig. 19-11B, there would be 147 myosin molecules in one-half of the thick filament.

Not all muscles have the thick filament structure of Fig. 19-11. In the tarantula muscle, which has a particularly well-ordered structure, there are four myosins per turn.[135,135a] Figure 19-13 shows a reconstruction of scallop myosin which has a 7-fold rotational symmetry. The thick filaments often contain

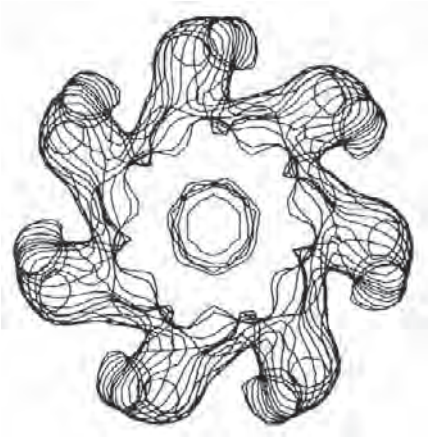

Figure 19-13 Superimposed sections for the 14 nm thickness of a computer-assisted reconstruction of the myosin filaments of the scallop adductor muscle. From Vibert and Craig.[137]

other proteins in addition to myosin. Thus, skeletal muscle contains the C-protein in a series of helical bands along the thick rod.[135b,c] In nematodes, molluscs, and insects the thick filament has a cylindrical core of **paramyosin**, another protein with a structure resembling that of the myosin rod. A minor component of *Drosophila* myosin, the **myosin rod protein**, lacks heads but is transcribed from the myosin heavy chain gene.[136]

3. Actomyosin and Muscle Contraction

That actin and myosin are jointly responsible for contraction was demonstrated long before the fine structure of the myofibril became known. In about 1929, ATP was recognized as the energy source for muscle contraction, but it was not until 10 years later that Engelhardt and Ljubimowa showed that isolated myosin preparations catalyzed the hydrolysis of ATP.[138] Szent-Györgi[139,140] showed that a combination of the two proteins actin (discovered by F. Straub[141]) and myosin was required for Mg^{2+}-stimulated ATP hydrolysis (ATPase activity). He called this combination **actomyosin**.

Under the electron microscope the myosin heads can sometimes be seen to be attached to the nearby thin actin filaments as **crossbridges**. When skeletal muscle is relaxed (not activated by a nerve impulse), the crossbridges are not attached, and the muscle can be stretched readily. The thin filaments are free to move past the thick filaments, and the muscle has some of the properties of a weak rubber band. However, when the muscle is activated and under tension, the crossbridges form more frequently. When ATP is exhausted (e.g., after death) muscle enters the state of **rigor** in which the crossbridges can be seen by electron microscopy to be almost all attached to thin filaments, accounting for the complete immobility of muscle in rigor (Figs. 19-12, 14).[134]

In rigor the crossbridges are almost all firmly attached to the thin actin filaments, making an approximately 45° angle to the actin filaments.[142–144] However, the addition of ATP causes their instantaneous release and the relaxation of the muscle fiber. In contrast, activation by a nerve impulse, with associated release of calcium ions (Section B,4), causes the thin filaments to slide between the thick filaments with shortening of the muscle. An activated muscle shortens if a low tension is applied to the muscle, but at a higher tension it maintains a constant length. Because the maximum tension developed is proportional to the length of overlap between the thick and thin filaments, it was natural to identify the individual crossbridges as the active centers for generation of the force needed for contraction.

The rowing hypothesis. H. E. Huxley[145,146] and A. F. Huxley and R. M. Simmons[147] independently proposed that during contraction the myosin heads attach themslves to the thin actin filaments. The hydrolysis of ATP is then coupled to the generation of a tension that causes the thick and thin filaments to be pulled past each other. The heads then release themselves and become attached at new locations on the actin filament. Repetition of this process leads to the sliding motion of the filaments (Fig. 19-14). The evidence in favor of this "rowing" or "swinging bridge" hypothesis was initially based largely on electron microscopy. For example, contracting muscle was frozen rapidly and fixed for microscopy in the frozen state.[148] Relaxed muscle shows no attached crossbridges, but contracting muscle has many. However,

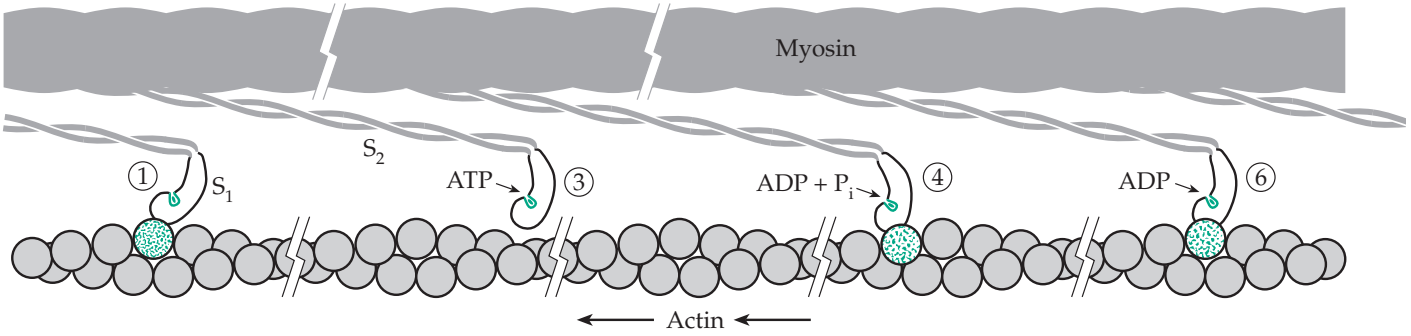

Figure 19-14 A model for the coupling of ATP hydrolysis to force production in muscle based on proposals of H. E. Huxley, and A. F. Huxley and Simmons. The power stroke is depicted here as a rotation of the crossbridge from a 90° to a 45° configuration. Four representative stages are shown: (1) the rigor complex, (3) the dissociated myosin ATP complex, (4) the actomyosin ADP pre-power stroke state in which the actin–myosin band has reformed but with a different actin subunit, which may be distant from that in (1), and (6) the actomyosin ADP post-power stroke state. Force production and contraction result from crossbridges passing cyclically through the steps depicted from left to right. Numbering of the stages corresponds approximately to that in Fig. 19-18. After H. Huxley.[146]

their appearance was distinct from that seen in rigor. The model was also supported by indirect physical methods.

An impressive demonstration that myosin heads do move along the actin filaments was provided by Sheetz and Spudich, who found that myosin-coated fluorescent beads ~0.7 μm in diameter will move along actin filaments from cells of the alga *Nitella* in an ATP-dependent fashion at velocities similar to those required in muscle.[149] The myosin heads literally glide along the thick cables of parallel actin filaments present in these algae.

Why two heads? The actin filament is a two-start helix, and it is natural to ask whether the two myosin heads bind to just one or simultaneously to both of the actin strands. Most evidence supports a 1:1 interaction of a single head with just one strand of actin. However, the other actin strand may associate with heads from a different thick filament. Another question concerns the role of the pairs of myosin heads. Could the two heads bind sequentially to the actin and exert their pull in a fixed sequence? In the reconstruction of the actomyosin complex in rigor (Fig. 19-12B) two different images are seen for the crossbridges. This suggests the existence of two different conformations for the attached myosin heads. Similar images for smooth muscle heavy meromyosin in its inactive (resting) dephosphorylated state (see p. 1116) show the two heads in very different orientations with one binding to the other of the pair and blocking its movement.[121b] Perhaps one head is tightly bound at the end of the power stroke while the other is at a different stage of the catalytic cycle. Nevertheless, single-headed myosin from *Acanthamoeba* will propell organelles along actin filaments,[150] and actin filaments will slide across a surface coated with single-headed myosin formed by controlled proteolysis.[151] The additional interactions seen in rigor may be peculiar to that state.

Structure of the myosin heads. Myosin and myosin fragments can be isolated in large quantities, but they have been difficult to crystallize. However, Rayment and coworkers purified S1 heads cleaved from chicken myosin by papain and subjected them to reductive methylation (using a dimethylamine–borane complex; see also Eq. 3-34). With most of the lysine side chain amino groups converted to dimethylamine groups, high-quality crystals were obtained, and a structure was determined by X-ray diffraction.[152] Since that time various forms of both modified and unmodified myosin heads from several species have been studied by X-ray crystallography.[153–160] Especially clear results were obtained with unmodified myosin from the ameba *Dictyostelium discoideum*. The head structure, shown in Fig. 19-11, includes a 95-kDa piece of the heavy chain and both light chains. A clearer picture of the neck region containing the light chains was provided by the structure of the "regulatory domain" of scallop myosin.[161] Unlike mammalian or avian myosins, molluscan myosins are regulated by binding of Ca^{2+} to a site in the essential light chain, but the structures are similar to those in Figs. 19-10 and 19-15.

Cleavage of the ~850-residue S1 heads with trypsin yields mainly three large fragments that correspond to structural domains of the intact protein as shown in Fig. 19-15. They are known as the 25-kDa (N-terminal), 50-kDa, and 20-kDa fragments, and for myosin from *D. discoideum* correspond to residues 1 to 204, 216 to 626, and 647 to 843, respectively. The ATP-binding site is in a deep cleft between the 20-kDa and 50-kDa

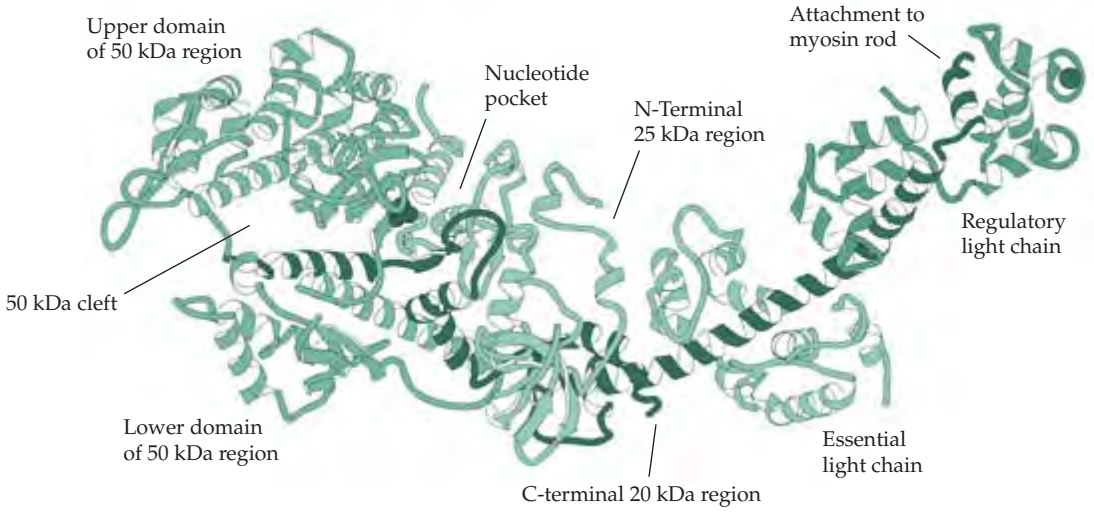

Figure 19-15 Ribbon representation of chicken skeletal myosin subfragment-1 showing the major domains and tryptic fragments. Prepared with the program MolScript. From Rayment.[157]

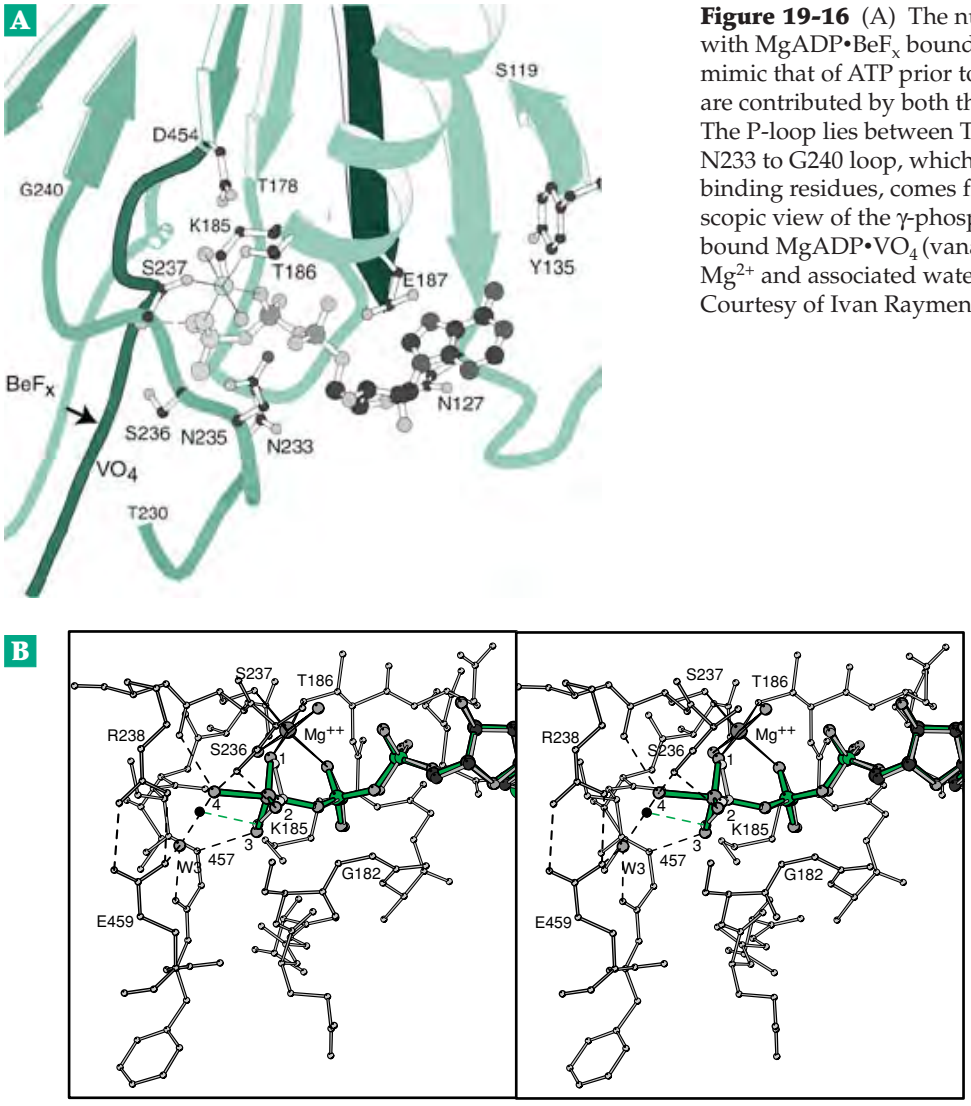

Figure 19-16 (A) The nucleotide binding site of myosin with MgADP•BeF_x bound in a conformation thought to mimic that of ATP prior to hydrolysis. The β-sheet strands are contributed by both the 25-kDa and 50-kDa domains. The P-loop lies between T178 and E187. The conserved N233 to G240 loop, which also contributes important ATP-binding residues, comes from the 50-kDa region. (B) Stereoscopic view of the γ-phospho group binding pocket with the bound MgADP•VO_4 (vanadate) complex. The coordinated Mg^{2+} and associated water molecules are seen clearly. Courtesy of Ivan Rayment.[157]

regions. Figure 19-16 illustrates the binding of an ATP analog, the beryllium fluoride complex of MgADP, in the active site. As can be seen, the ATP binds to loops at the C termini of the β strands of the 8-stranded β sheet from the 25-kDa domain. The conserved P-loop (Chapter 12, E), which lies between T178 and E187, curls around the α and β phospho groups, and has the sequence G(179)ESGAGKT. A second conserved loop N(233)SNSSR-G(240) from the 50-kDa domain contributes to the binding of ATP.

The actin-binding region of the myosin head is formed largely by the 50-kDa segment, which is split by a deep cleft into two separate domains (Fig. 19-15), both of which are thought to participate in binding to actin. A surface loop (loop 1) near the ATP-binding site at the junction of the 25- and 50-kDa regions affects the kinetic properties of myosin, probably by influencing product release. A second loop (loop 2, residues 626–647) at the junction of the 50- and 20-kDa regions interact with actin. Loop 2 contains a GKK sequence whose positive charges may interact with negative charges in the N-terminal part of actin.[162–164]

The C-terminal fragment of myosin contains a globular domain that interacts with both the 20-kDa and 50-kDa regions and contains an α-helical neck that connects to the helix of the coiled-coil myosin rod. This helical region is surrounded by the two myosin light chains (Fig. 19-15).[157] A pair of reactive thiol groups (from C697 and C707) in the globular domain are near the active site. Crosslinking of these cysteines by an –S–S– bridge has been utilized to trap nucleotide analogs in the active site.[165]

How does actin bind? The actin monomer consists of four subdomains, 1, 2, 3, and 4 numbered from the N terminus (Fig. 7-10). The negatively charged N-terminal region of actin contains the sequence

$$\overset{4}{\text{D}}\text{-E-D-}\overset{24}{\text{E}}\text{----D-}\overset{25}{\text{D}}.$$

It may interact with loop 1 of myosin, which contains five lysines. However, to form a strong interaction with the myosin head a conformational change must occur in the myosin. A change may also occur in actin. Modeling suggests that a large nonpolar contact region involves actin residues A144, I341, I345, L349, and F352 and myosin residues P529, M530, I535, M541, F542, and P543. A conformational change in actin, which might involve largely the highly conserved actin subdomain 2, may also be required for tight interaction.[142,166–168]

Kinesins and other molecular motors. Before considering further how the myosin motor may work, we should look briefly at the **kinesins**, a different group of motor molecules,[168a] which transport various cellular materials along microtubule "rails." They also participate in organization of the mitotic spindle and other microtubule-dependent activities.[168a,b,c] See Section C,2 for further discussion. More than 90 members of the family have been identified. Kinesin heads have much shorter necks than do the myosin heads. A myosin head is made up of ~850 residues, but the motor domain of a kinesin contains only ~345. Like myosin, the 950- to 980-residue kinesins have a long coiled-coil C- terminal region that forms a "neck" of ~50 residues, a "stalk" of ~190 and ~330 residue segments with a Pro / Gly-rich hinge between them, and an ~45 residue "tail."[169–171]

Figure 19-17 Ribbon drawing of human kinesin with bound Mg•ADP. From Gulick *et al.*[174] Courtesy of Ivan Rayment and Andy Gulick.

Crystal structures are known for motor domains of human kinesin[172] and of a kinesin from rat brain.[169,173] The structures of one of six yeast kinesins,[174] a protein called **Kar3**, and also of a *Drosophila* motor molecule designated **Ncd** have also been determined.[175] The last was identified through study of a *Drosophila* mutant called non-claret disjunctional (Ncd). The motor domains of various members of the kinesin family show ~40% sequence identity and very close structural identity (Fig. 19-17).[174] Although the sequences are different from those of the myosin heads or of G proteins, the folding pattern in the core structures is similar in all cases. An 8-stranded β sheet is flanked by three α helices on each side and a P-loop crosses over the ATP-binding site as in Fig. 19-16. Further similarity is found in the active site structures, which, for a monomeric kinesin KIF1A,[174a] have been determined both with bound ADP and with a nonhydrolyzable analog of ATP.[174b,174c] Although there is little similarity in amino acid sequences the structures in the catalytic core are clearly related to each other, to those of dimeric kinesins,[174d] to those of myosins, and to those of the GTP-hydrolyzing G proteins.

A puzzling discovery was that the motor domain of kinesin, which binds primarily to the β subunits of tubulin (Fig. 7-34) and moves toward the fast growing *plus* end of the microtubule,[176] is located at the N terminus of the kinesin molecule, just as is myosin. However, the Ncd and Kar3 motor domains are at the C-terminal ends of their peptide chains and move their "cargos" toward the *minus* ends of microtubules.[174] Nevertheless, the structures of all the kinesin heads are conserved as are the basic chemical mechanisms. The differences in directional preference are determined by a short length of peptide chain between the motor domain and the neck, which allows quite different geometric arrangements when bound to microtubules.[173,177] Like Ncd, myosin VI motor domains also move "backwards" toward the pointed (minus) ends of actin filaments.[178–179a]

Other major differences between kinesins and myosin II heads involve kinetics[180,181] and processivity.[173] Dimeric kinesin is a **processive** molecule. It moves rapidly along microtubules in 8-nm steps but remains attached.[182,182a] Myosins V and VI are also processive[183–183e] but myosin II is not. It binds, pulls on actin, and then releases it. The many myosin heads interacting with each actin filament accomplish muscle contraction with a high velocity in spite of the short time of attachment. Ncd and Kar3 are also nonprocessive and slower than the *plus* end-oriented kinesins.[184]

The ATPase cycles of actomyosin and of the kinesins. The properties of the protein assemblies found in muscle have been described in elegant details, but the most important question has not been fully answered. How can the muscle machinery use the Gibbs energy of hydrolysis of ATP to do mechanical work? Some insight has been obtained by studying the ATPase activity of isolated myosin heads (S1) alone or together with actin. Results of numerous studies of ATP binding, hydrolysis, and release of products using fast reaction techniques[185–191] and cryoenzymology[191a] are summarized in Fig. 19-18. In resting muscle the myosin heads swing freely in the ~20-nm space between the thick and thin filaments. However, in activated muscle some heads are bound tightly to actin as if in rigor (complex A•M in Fig. 19-18). When ATP is added MgATP binds into the active site of the myosin (Fig. 19-18, step *a*) inducing a conformational change to form A•M*•ATP in which the bond between actin and myosin is weakened greatly, while that between myosin and ATP is strengthened. The complex dissociates (step *b*) to give free actin and (M*•ATP), which accumulates at −15°C. However, at higher temperatures the bound ATP is hydrolyzed rapidly (step *c*) to a form M**•ADP•P_i in which the ATP has been cleaved to ADP + P_i but in which the split products remain bound at the active site.[116,192,192a,b] All of these reactions are reversible. That is, the split products can recombine to form ATP. This fact suggests that most of the Gibbs energy of hydrolysis of the ATP must be stored, possibly through a conformational change in the myosin head or through tighter bonding to ATP. As long as calcium ions are absent, there is only a slow release of the bound ADP and P_i and replacement with fresh ATP takes place. Thus, myosin alone shows a very weak ATPase activity.

On the other hand, in activated muscle the head with the split ATP products will bind to actin (step *d*), probably at a new position. The crossbridges that form appear to be attached almost at right angles to the thin filaments. In step *e*, P_i is released following a conformational alteration that is thought to open a "back door" to allow escape of the phosphate ion.[193] In the final two steps (*f* and *g*) the stored energy in the myosin head (or in the actin) is used to bring about another conformational change that alters the angle of attachment of myosin head to the thin filament from ~90° to ~45°. At least some indication of such a change can be observed directly by electron microscopy.[144] Such a change in angle is sufficient to cause the actin filament to move ~10 nm with respect to the thick filaments to complete the movement cycle (Fig. 19-18), if the head is hinged at the correct place. However, the existence of at least four different conformational states suggests a more complex sequence.[193a,193b] Examination of the three-dimensional structures available also suggest a complex sequence of alterations in structure and geometry. X-ray crystallographic structures of myosin heads, in states thought to correspond to states 1 and 3 of Figs. 19-14 and 19-18, are also in agreement on an ~10 (5–12) nm movement of the lever arm.[194,195] Six states of the actomyosin complex are depicted in Fig. 19-18, but a complete kinetic analysis requires at least eight and possibly 12 states.[196,197]

Observing single molecules. A major advance in the study of molecular motors has been the development of ways to observe and study single macromolecules. The methods make use of **optical traps** (optical "tweezers") that can hold a very small (~1 μm diameter) polystyrene or silica bead near the waist of a laser beam focused through a microscope objective.[198–202] In one experimental design an F-actin filament is stretched between two beads, held in a pair of optical traps. The filament is pulled taut and lowered onto a stationary silica bead to which a few myosin HMM fragments have been attached (Fig. 19-19). If ATP is present, short transient movements along the filament are detected by observation of displacements of one of the beads when the actin filament contacts HMM heads. An average lateral displacement of 11 nm was observed. Each HMM head exerted a force of 3–4 pN, a value consistent with expectations for the swinging bridge model.[200] From the duration of a single displacement (≤7 ms) and an estimated k_{cat} for ATP hydrolysis of 10 s^{-1}, the fraction of time that the head was attached during one catalytic cycle of the head was therefore only 0.07. This ratio, which is called the **duty ratio**, is low for actomyosin. However, many myosin heads bind to each actin filament in a muscle. Each head exerts its pull for a short time. but the actin is never totally unattached.[203] Similar measurements with smooth muscle revealed similar displacements but with a 10-fold slower sliding velocity and a 4-fold increase in the duty ratio. This may perhaps account for an observed 3-fold increase in force as compared with skeletal muscle.[204,204a]

Other single molecule techniques involve direct observation of motor molecules or of S1 myosin fragments tagged with highly fluorescent labels.[205,206] All measurements of single molecule movement are subject to many errors. Brownian motion of the beads makes measurements difficult.[207] Not all results are in agreement, and some are difficult to understand.[207a] Most investigators agree that there is a step size of ~4–10 nm. Kitamura *et al.* found 5.3 nm as the average.[206] However, they also reported the puzzling observation that some single S1 molecules moved 11–30 nm in two to five rapid successive steps during the time of hydrolysis of a single molecule at ATP. They suggested that some of the energy of ATP hydrolysis may be stored in S1 or in the actin filament and be released in multiple steps. Veigel *et al.*[208] observed that a brush border myosin I from chicks produced ~ 6 nm

movements, each of which was followed by an additional ~ 5.5 nm step within ~5 ms. They attribute these steps to two stages in the power stroke, e.g., to steps *f* and *g* of Fig. 19-18. A value of ~10nm was reported recently by Piazzesi *et al*.[208a] Myosin V moves along actin filaments with very large 36-nm steps.[208b]

Motion of kinesin heads has been observed by movement of microtubules over biotinylated kinesin fixed to a steptavidin-coated surface,[209] by direct observation of fluorescent kinesin moving along microtubules,[171] and by optical trap interferometry.[210] Kinesin heads move by 8-nm steps, evidently the exact length

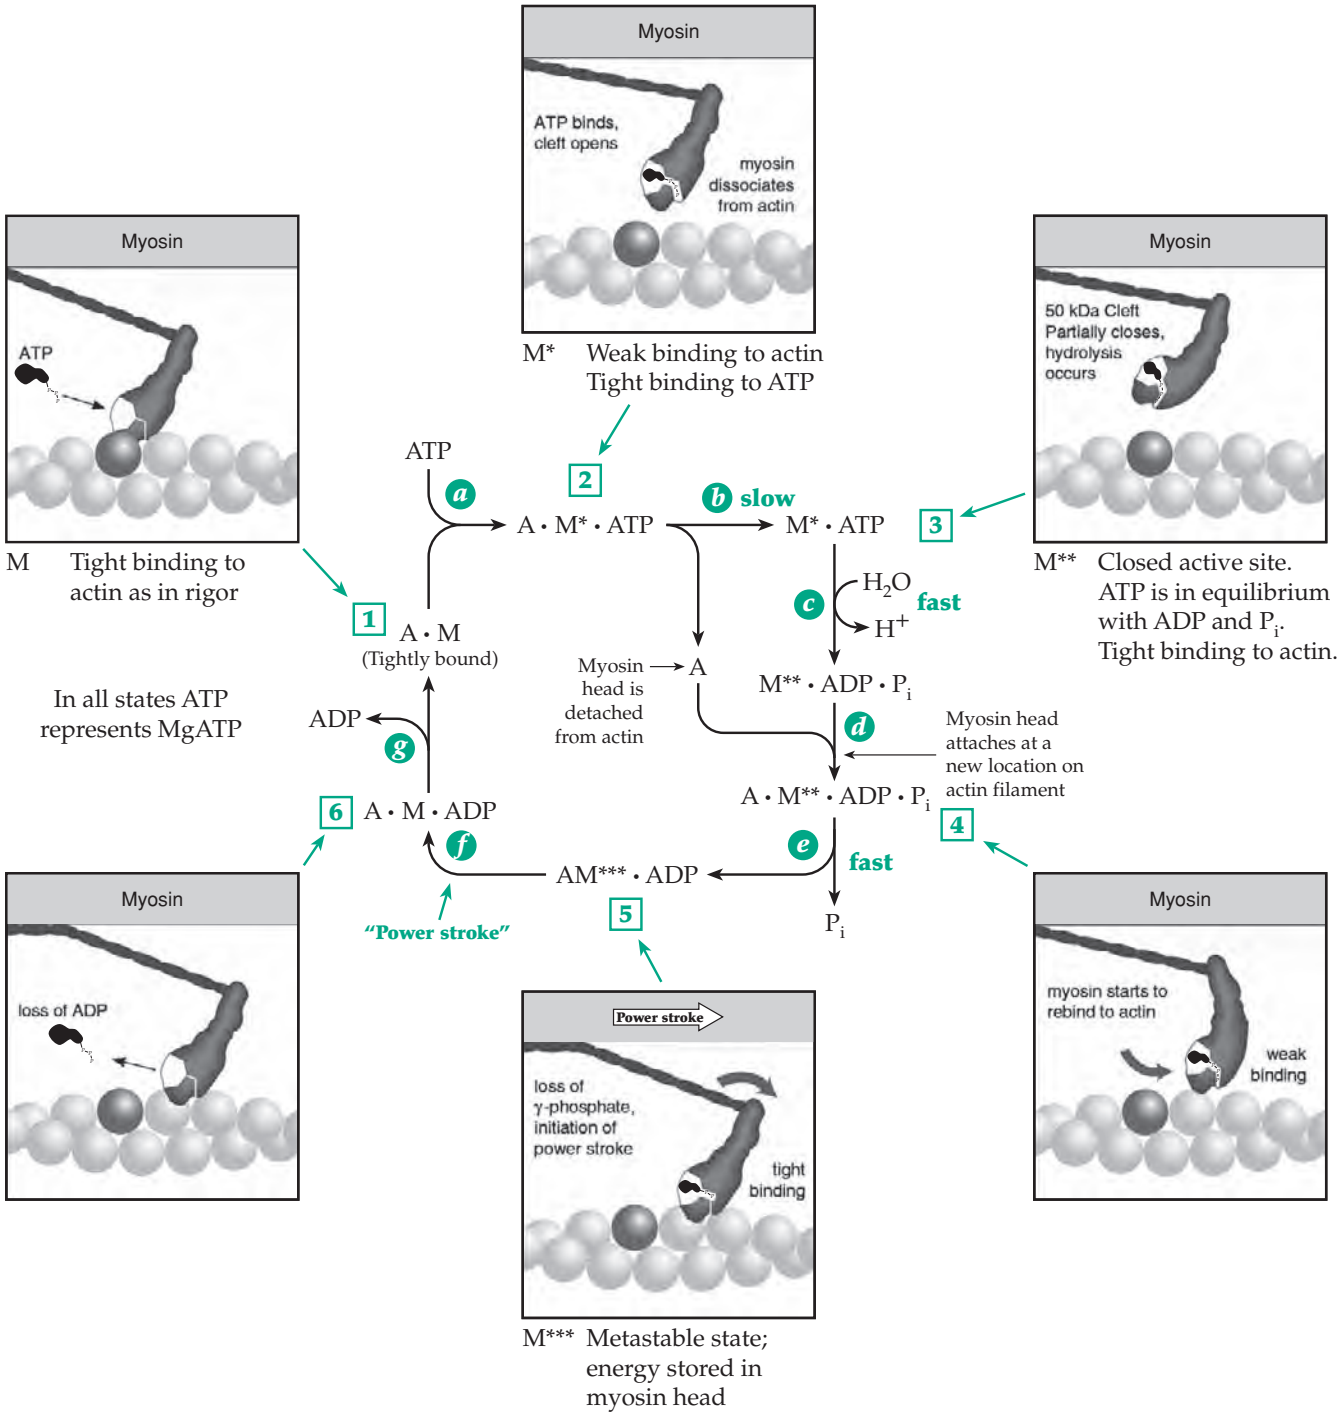

Figure 19-18 Simplified view of the ATP hydrolysis cycle for actomyosin. A similar cycle can be written for kinesins and dyneins. Here A stands for fibrous actin and M, M*, M**, and M*** for four different conformations of the myosin heads. As indicated by the numbers in squares, four of the six states of actomyosin shown here can also be correlated with those in Fig. 19-14.

of an αβ tubulin dimer in the microtubule structure (Fig. 7-33). One ATP is apparently hydrolyzed for each 8-nm step. However, shorter steps of ~5 nm have sometimes been seen.[211,212]

The movement is processive, kinesin motors typically taking 100 steps before dissociating from the microtubule.[201,212a] Kinesin is bound to the microtubule continuously. Its duty ratio is nearly 1.0 (the same is true for the bacterial flagellar motor; Fig. 19-4).[212b] However, single kinesin heads, which lack the coiled-coil neck region, have a duty ratio of <0.45. The movement is nonprocessive.[213] The Ncd motor is also nonprocessive.[214–216] As mentioned previously, the Ncd and kinesin motor domains are at opposite ends of the peptide chain, and the motors move in opposite directions along microtubules.[217,218] The critical difference between the two motor molecules was found in the neck domains, which gave rise to differing symmetrics in the two heads.[219] The latter are shown in Fig. 19-20, in which they have been docked onto the tubulin protofilament structure. One head, both of ncd and of kinesin, occupies a similar position on the microtubule, but the other head points toward the microtubular plus end for kinesin but toward the minus end for Ncd. Cryoelectron microscopy also supports this interpretation.[220]

Still not fully understood is the processive action of kinesin.[221–224] It is often assumed that this protein moves in a hand-over-hand fashion with the two heads binding alternatively to the microtubule. Some substantial reorganization of the peptide chain in the hinge region at the end of the neck is presumably involved.[173] An alternative "inchworm" mechanism has been suggested.[220a]

Thinking about chemical mechanisms. We have now examined the active sites of kinases that cleave ATP (Chapter 12), ATPases that pump ions by cleaving ATP, ATP synthases that form ATP from ADP and P_i (Chapter 18), and GTP hydrolyzing enzymes that cause movement and shape changes that control metabolic processes (Chapter 11). It is striking that the active site regions where the ATP or GTP bind have such a highly conserved structure.[225] This suggests that the secret of movement can be found in the very strong interactions of the nucleotides and their split products with the proteins. In every case there is at least one tight binding or closed conformation in which a large number of hydrogen bonds and ionic interactions bind the nucleotide. This is shown for a kinase in Fig. 12-32 and for myosin in Fig. 19-16. During the actomyosin reaction several conformational changes must occur. Not only does the affinity for the bound nucleotide vary, but also the binding of actin to myosin can be strong, as in the nucleotide-free state or

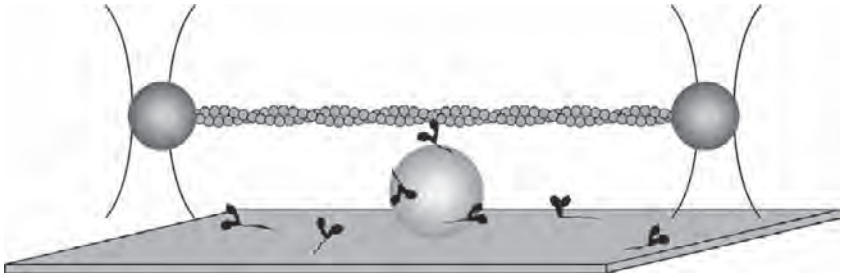

Figure 19-19 Schematic drawing (not to scale) illustrating the use of two optical traps that are focused on beads attached to a single actin filament. The filament is lowered onto a stationary silica bead sparsely coated with HMM fragments of myosin. In the presence of ATP the myosin heads bind transiently for a few milliseconds to the actin, moving it in one direction and displacing the beads from their positions in the optical traps. An image of one of the beads is projected onto photodiode detectors capable of measuring small displacements. The displacing force can also be recorded. For details of the experiments and of the optical traps and measuring devices see Finer *et al.*[200] Courtesy of J. A. Spudich.

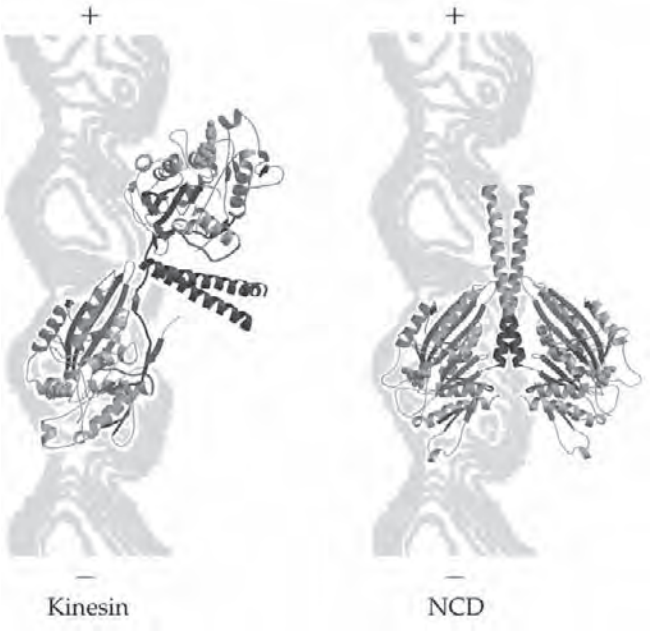

Figure 19-20 Model showing the ncd and kinesin dimer structures docked onto a tubulin protofilament. The bound ncd and kinesin heads are positioned similarly. Because of the distinct architectures of the kinesin and ncd necks, the unbound kinesin head points toward the plus end, whereas the unbound ncd head is tilted toward the minus end of the protofilament. From Sablin *et al.*[219] Courtesy of Ronald Vale.

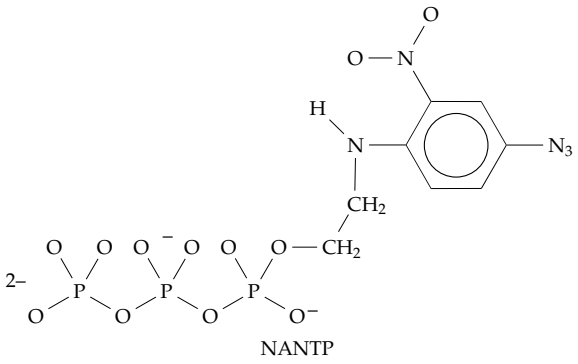
in the presence of bound ADP. Binding is weak when ATP or the split product ADP + P_i are in the active site.

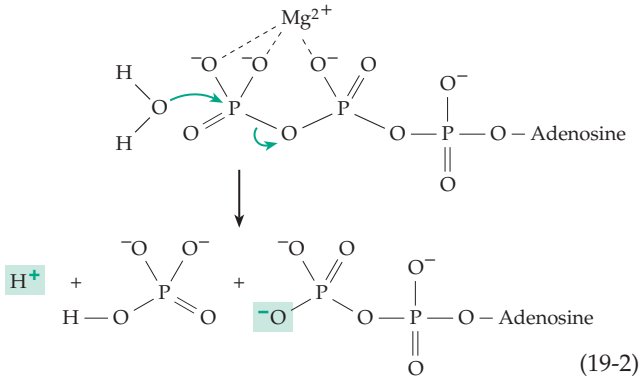
To understand these differences we should look at the structure of ATP itself. The triphosphate group has many negative charges repelling each other. What must happen to allow the binding of ATP to myosin to break the actin-myosin bond? The electrostatic attraction of these phospho groups for active site groups is doubtless one cause of the observed conformational changes. Could it be that electrostatic repulsion, via a proton shuttle mechanism, is also induced at the right point in the actin–myosin interface? Many studies with analogs of ATP have contributed to our understanding. Neither the purine nor the ribose ring of ATP is absolutely essential. The compound 2-[(4-azido-2-nitrophenyl) amino] diphosphate (NANDP) and related nonnucleotide analogs[165,196,226] support muscle contraction and relaxation in the same



way as does ATP. An analog with a rigid five-membered ring, 2',3'-dideoxydidehydro-ATP, is also active.[227] A comparison of kinetic data and X-ray structural data supports the proposal that the ATP must be bound in the conformation shown for MgADP•BeF_x in Fig. 19-16A.[196] When the two SH groups of C697 and C707 of the myosin head are crosslinked by various reagents,[227a] this NANDP analog can be trapped at the active site. Because of the presence of its azide ($-N_3$) group the trapped compound can serve as a photoaffinity label, attaching itself to a tryptophan side chain upon activation with visible light (Eq. 23-27).

How can cleavage of ATP to bound ADP + P_i create a metastable high-energy state of the myosin head ready to hold onto and pull the actin chain? This may be compared with the inverse problem of generating ATP in oxidative phosphorylation, in which ADP and P_i coexist in equilibrium with ATP in a closed active site (Fig. 18-14). Comparison should also be made with the GTP-hydrolyzing G proteins (Fig. 11-7).[227b,c] During hydrolysis of GTP by the Ras protein binding to the protein induces a shift of negative charge from the γ- to β-oxygens of GTP facilitating bond cleavage as in Eq. 19-2. G proteins also couple substrate hydrolysis to mechanical motion. We should also think about the fact that when ATP is cleaved within myosin there will necessarily be a flow of electrical charge from the water to the ADP (Eq. 19-2). This will be followed by some accomodation of the protein to the new charge constellation. As we have seen previously, movement of protons is often the key to conformational changes. In this case, the initial change must be to create a high-energy state of myosin which, following loss of the orthophosphate ion, can cause the major conformational change that swings the lever arm of the myosin. The conformational changes may occur in several steps in which the packing of groups within the myosin head is always tight in some places and rather loose in others. Movement within the head is being observed not only by X-ray crystallography but by **fluorescence resonance energy transfer** (FRET; Chapter 23)[227d] and by the newer **luminescence resonance energy transfer** (LRET). For example, a terbium chelate of azide-ATP was photochemically bound in the active site, and a fluorescent dye was attached to Cys 108 in the regulatory light chain. The terbium ion was irradiated, and fluorescence of the dye was observed. Distance changes, measured in the absence and presence of ATP, were consistent with the swinging arm model.[228] Dyes have been attached to –SH groups engineered into various locations in the myosin molecule to permit other distance measurements.[229,230] In another elegant application of the FRET technique the **green fluorescent protein** of *Aequoria* (Box 23-A) was fused to the C terminus of the motor domain of myosin giving a fluorescent lever arm. Energy transfer to blue fluorescent protein fused to the N terminus of the S1 head was measured. The distance between these was estimated by the FRET technique and was also consistent with expectations for the "rowing model."[231]

The "rowing model" is generally accepted, but other quite different processes have been proposed to account for the elementary cycle of muscle contraction. Muscle contracts nearly *isovolumetrically*; thus, anything that expands the sarcomere will cause a contraction. It has been suggested that the hydrolysis of ATP deposits negatively charged phospho groups on the actin filaments, and that the electrostatic repulsion is responsible for



(19-2)

BOX 19-A HEREDITARY DISEASES OF MUSCLE

Considering the numerous specialized proteins in muscle it is not surprising that many rare hereditary muscle diseases are known. The most frequent and most studied of these is **Duchenne muscular dystrophy**. An X-linked disease of boys, it may not be recognized until two to three years of age, but victims are usually in a wheelchair by age 12 and die around age 20. Individual muscle fibers disintegrate, die, and are replaced by fibrous or fatty tissue.[a–d] The disease strikes about 1 out of 3500 boys born. The less serious **Becker muscular dystrophy** arises from defects in the same gene but affects only 1 in 30,000 males, some of whom have a normal life span. Because of its frequency and the knowledge that the gene must lie in the X-chromosome, an intensive search for the gene was made. It was found in 1986 after a five-year search.[a,e] This was the first attempt to find a faulty gene whose protein product was totally unknown. The project, which relied upon finding restriction fragment polymorphisms (Chapter 26) that could serve as markers in the genome, made use of the DNA from patients with a range of related diseases. The very rare female patients in whom the faulty gene had been translocated from the X-chromosome to an autosome also provided markers. DNA probes obtained from a young man with a large X-chromosome deletion that included genes related to retinitis pigmentosa and several other diseases provided additional markers. The result was a triumph of "reverse genetics" which has since been applied to the location of many other disease genes.[e]

The muscular dystrophy gene may be the largest human gene. It consists of 2.3 million base pairs, which include 79 exons which encode a huge 427 kDa protein named **dystrophin**. The protein consists of four main domains.[a,f,g] The N-terminal domain binds to actin and is homologous to β-actinin. The central domain is an elongated rod resembling spectrin. It contains repetitive coiled-coil segments and four hinge regions. The third domain is rich in cysteine and binds Ca^{2+}, while the fourth domain has a structure that is shared by several other proteins of the dystrophin family. Dystrophin is quantitatively a minor protein of muscle. It forms part of the cytoskeleton, lying adjacent to the sarcolemma (cell membrane) along with β-spectrin and vinculin (see Fig. 8-16).

While one end of the dystrophin molecule binds to actin filaments, the C-terminal domain associates with several additional proteins to form a **dystrophin–glycoprotein complex** (see figure).[f,h–k] Dystrophin is linked directly to the membrane-spanning protein **β-dystroglycan,** which in the outer membrane surfaces associates with a glycoprotein **α-dystroglycan**. The latter binds to laminin-2 (Fig. 8-33), a protein that binds the cell to the basal lamina. Four other membrane-spanning proteins, α-, β-, γ-, and δ-**sarcoglycans**, are among additional members of the complex.[k–m]

Patients with Duchenne muscular dystrophy are deficient not only in dystrophin but also in the dystroglycan and sarcoglycan proteins.[f,n] Evidently, dystrophin is needed for formation of the complex which plays an essential role in muscle. In both types of X-linked muscular dystrophy there are individuals with a wide range of point mutations, frame-shift mutations, and deletions in the dystrophin gene.[d] The essential function of dystrophin and associated proteins is uncertain but may be related to the linkage from actin filaments through the membrane to laminin. Individuals with Becker muscular dystrophy also have defects in dystrophin, but the protein is partially functional. Some other muscular dystrophies are caused by defects in the autosomal genes of any of the four sarcoglycan subunits.[j,k,o] or in that of laminin α1 chain.[p,q] The arrows in the accompanying drawing indicate chromosome locations of the sarcoglycan subunits, which are sites for mutations causing **limb girdle muscular dystrophy**.[k]

Dystrophin, shorter isoforms, and related proteins are found in many tissues including the brain.[s] One related protein, **utrophin** (dystrophin-related

BOX 19-A (continued)

protein 1), is present in the neuromuscular junction of adult skeletal muscle. One approach to therapy of Duchenne muscular dystrophy is to stimulate a higher level of expression of the utrophin gene.[t] Because the dystrophin gene is so large treatment by gene transfer is not practical, but transfer of parts of the gene may be. Myoblast transfer has not been successful, but new approaches will be devised.[d]

Myotonic dystrophy is a generalized adult-onset disorder with muscular spasms, weakness, and many other symptoms.[u–y] It is one of the **triple-repeat diseases** (Table 26-4). The affected gene encodes a protein kinase of unknown function. The corresponding mRNA transcript has ~2400 nucleotides. The gene has a CTG repeat $(CTG)_n$ near the 3'-end with $n < 30$ normally. For persons with the mildest cases of myotonic dystrophy n may be over 50 while in severe cases it may be as high as 2000. As in other triple-repeat diseases the repeat number tends to increase in successive generations of people as does the severity of the disease.[x]

For some individuals, muscular dystrophy causes no obvious damage to skeletal muscle but affects the heart producing a severe **cardiomyopathy,** and persons with Duchenne muscular dystrophy often die from heart failure. Heart failure from other causes, some hereditary, is a major medical problem, especially among older persons. Hereditary forms are often autosomal dominant traits that may cause sudden death in young persons. At least seven genes for cardiac sarcomeric proteins including actin,[z] myosin, both heavy and light chains,[aa–dd] three subunits of troponin,[ee] tropomyosin, and protein C (p. 1104) may all carry mutations that cause cardiomyopathy.

A hereditary disease common in Japan results from a defect in migration of neurons and is associated with brain malformation as well as muscular dystrophy.[ff] In **nemaline myopathy** a defect in nebulin leads to progressive weakness and often to death in infancy. A characteristic is the appearance of "nemaline bodies" or thickened Z-discs containing Z-disc proteins.[gg] Some hereditary diseases involve nonmuscle myosins. Among these is **Usher syndrome**, the commonest cause of deaf-blindness. The disease, which results from a defect in the myosin VIA gene, typically causes impairment of hearing and retinitis pigmentosa (Chapter 23).[hh]

lateral expansion of the sarcomere.[232] Still other ideas have been advanced.[233,234]

4. Control of Muscle Contraction

Skeletal muscle must be able to rest without excessive cleavage of ATP but able to act rapidly with a high expenditure of energy upon nervous excitation. Even a simple physical activity requires that a person's muscles individually contract and relax in rapid response to nerve impulses from the brain. To allow for this control the endoplasmic reticulum (**sarcoplasmic reticulum, SR**) of striated muscle fibers is organized in a striking regular manner.[235–237] Interconnecting tubules run longitudinally through the fibers among the bundles of contractile elements. At regular intervals they come in close contact with infoldings of the outer cell membrane (the **T system** of membranes, Fig. 19-21; see also Fig. 19-7A). A nerve impulse enters the muscle fiber through the neuromuscular junctions and travels along the sarcolemma and into the T tubules. At the points of close contact the signal is transmitted to the longitudinal tubules of the sarcoplasmic reticulum, which contain a high concentration of calcium ions.

Calcium ions in muscle. A nerve signal arriving at a muscle causes a sudden release of the calcium ions into the cytoplasm from cisternae of the sarcoplasmic reticulum (SR) that are located adjacent to the T-tubules. Diffusion of the Ca^{2+} into the myofibrils initiates contraction. In smooth muscle the signals do not come directly from the nervous system but involve hormonal regulation.[238] Again, calcium ions play a major role, which is also discussed in Chapter 6, Section E, and in Box 6-D. Muscle contains a large store of readily available Ca^{2+} in lateral cisternae of the SR. The free intracellular Ca^{2+} concentration is kept low by a very active ATP-dependent calcium ion pump (Fig. 8-26), which is embedded in the membranes of the SR.[238a] Within the vesicles Ca^{2+} is held loosely by the ~63-kDa protein **calsequestrin,** which binds as many as 50 calcium ions per molecule. When the cytoplasmic concentration of free Ca^{2+} falls below ~10^{-6} M, contraction ceases. In fast-contracting skeletal muscles the Ca^{2+}-binding protein **parvalbumin** (Fig. 6-7) may

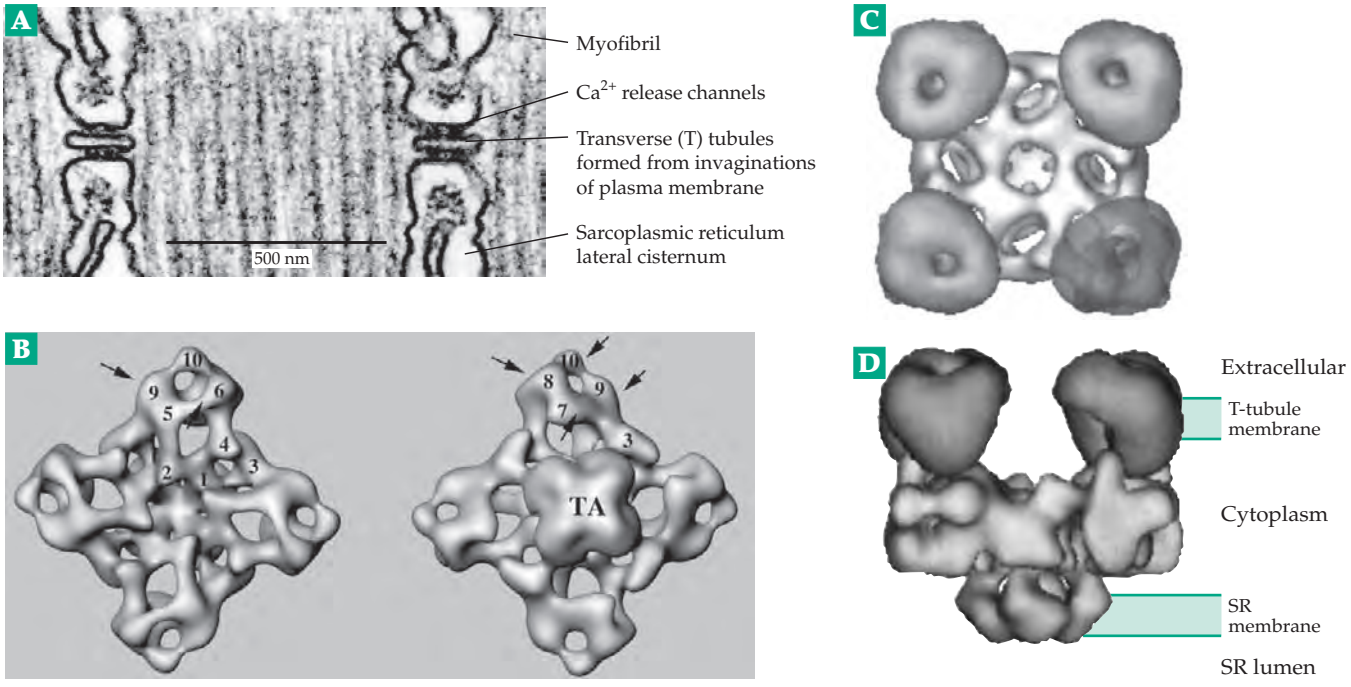

Figure 19-21 (A) Electron micrograph showing two transverse tubules (T-tubules) that are formed by infolding of the plasma membrane. They wrap around a skeletal muscle fiber and carry nerve impulses to all parts of the fiber. From Alberts *et al.*[237] Courtesy of Clara Franzini-Armstrong. (B) Three-dimensional surface representation of the calcium release channels known as ryanodine receptors, type RyR1 based on cryoelectron microscopy and image reconstruction at a resolution of 4.1 nm. The image to the left shows the surface that would face the cytoplasm while that to the right shows the surface that would interact with the sarcoplasmic reticulum, TA representing the transmembrane portion. Notice the fourfold symmetry of the particle, which is composed of four 565-kDa subunits. From Sharma *et al.*[239] Courtesy of Manjuli Rani Sharma. (C), (D) Model showing proposed arrangement of ryanodine receptors and dihydropyridine receptors (round) in the T tubule and SR membranes. From Serysheva *et al.*[245a]

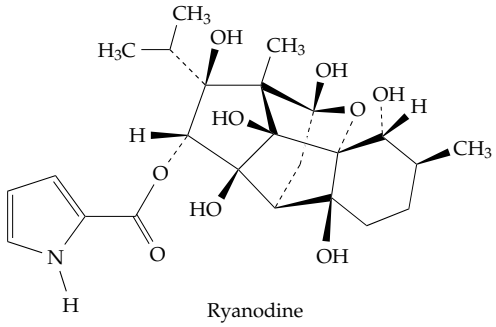
assist in rapid removal of free Ca^{2+} from the cytoplasm. Contraction is activated when Ca^{2+} is released from the SR through the **calcium release channels**,[240–244] which are often called **ryanodine receptors**. The name arises from their sensitivity to the insecticidal plant alkaloid ryanodine, which at low concentration (≤60 μM) causes the channels to open, but a high concentration closes the channels.[243] These calcium release channels consist of tetramers of ~5000-residue proteins. The bulk of the 565-kDa polypeptides are on the cytosolic surface of the SR membranes, where they form a complex "foot" structure (Fig. 19-21B) that spans the ~12 nm gap between the SR vesicles and the T-tubule membrane.[239,240] Ryanodine receptor function is modulated by NO, which apparently binds to –SH groups within the Ca^{2+} channel.[243a,243b] Some ryanodine receptors are activated by cyclic ADP-ribose (cADPR, p. 564).[243c] Some have an oxidoreductase-like structural domain.[243d]

The release channels open in response to an incompletely characterized linkage to the **voltage sensor** that is present in the T-tubule membrane and is known as the **dihydropyridine receptor**.[240,245] This too, is a Ca^{2+} channel, which opens in response to arrival of an **action potential** (nerve impulse; see Chapter 30) that move along the T-tubule membrane. Because the



Ryanodine

action potential arrives almost simultaneously throughout the T-tubules of the muscles, the dihydropyridine receptors all open together. It isn't clear whether the linkage to the calcium channels is via stimulation from released Ca^{2+} passing from the dihydropyridine receptor to the surfaces of the feet of the release channels, or is a result of depolarization of the T-tubule membrane, or involves direct mechanically linked conformational changes.[240,245] The close cooperation of the Ca^{2+} release channel and the voltage sensor is reflected in their close proximity. In the sarcoplasmic reticulum every second release channel is adjacent to a voltage sensor in the opposing T-tubule membrane.[240,245a] The essential nature of the voltage

BOX 19-B MALIGNANT HYPERTHERMIA AND STRESS-PRONE PIGS

Very rarely during surgery the temperature of a patient suddenly starts to rise uncontrollably. Even when heroic measures are taken, sudden death may follow within minutes. This **malignant hyperthermia syndrome** is often associated with administration of halogenated anesthetics such as a widely used mixture of halothane (2-bromo-2-chloro-1,1,1-trifluoroethane) and succinylcholine.[a–d] There is often no warning that the patient is abnormally sensitive to anesthetic. However, development of an antidote together with increased alertness to the problem has greatly decreased the death rate. Nevertheless, severe damage to nerves and kidneys may still occur.[c] Biochemical investigation of the hyperthermia syndrome has been facilitated by the discovery of a similar condition that is prevalent among certain breeds of pigs. Such "stress-prone" pigs are likely to die suddenly of hyperthermia induced by some stress such as shipment to market. The sharp rise in temperature with muscles going into a state of rigor is accompanied by a dramatic lowering of the ATP content of the muscles.

The problem, both in pigs and in humans susceptible to malignant hyperthermia, was found in the Ca^{2+} release channels (ryanodine receptors). Study of inheritance in human families together with genetic studies in pigs led to the finding that the stress-prone pigs have cysteine replacing arginine 615 in the Ca^{2+} channel protein. This modification appears to facilitate opening of the channels but to inhibit their closing.[e] A similar mutation has been found in some human families in which the condition has been recognized. However, there is probably more than one site of mutation in humans.[c,f] Similar mutations in the nematode *C. elegans* are being investigated with the hope of shedding light both on the problem of hyperthermia and on the functioning of the Ca^{2+} release channels.[g]

sensor is revealed by a lethal mutation (**muscular disgenesis**) in mice. Animals with this autosomal recessive trait generate normal action potentials in the sarcolemma but Ca^{2+} is not released and no muscular contraction occurs. They lack a 170-kDa dihydropyridine-binding subunit of the sensor.[246]

Some aspects of regulation by calcium ions are poorly understood. The frequent observations of oscillations in [Ca^{2+}] in cells is described in Box 6-D. Another phenomenom is the observation of Ca^{2+} "sparks," detected with fluorescent dyes and observation by confocal microscopy.[247] These small puffs of Ca^{2+} have been seen in cardiac muscle[247] and in a somewhat different form in smooth muscle.[248] They may represent the release of Ca^{2+} from a single release channel or a small cluster of channels. When the calcium release channels open, Ca^{2+} ions flow from the cisternae of the SR into the cytoplasm, where they activate both the troponin–tropomyosin system and also the Ca^{2+}-calmodulin-dependent **light chain protein kinase,** which acts on the light chains of the myosin head. These light chains resemble calmodulin in their Ca^{2+}-binding properties. The function of light chain phosphorylation of skeletal muscle myosin is uncertain but it is very important in smooth muscle.[248a]

The regulatory complex of tropomyosin and troponin is attached to the actin filaments as indicated in Fig. 19-8D and also in Fig. 19-9. The latter shows a model at near atomic resolution but without side chains on the tropomyosin and without the troponin components. When the regulatory proteins are completely removed from the fibrils, contraction occurs until the ATP is exhausted. However, in the presence of the regulatory proteins and in the absence of calcium, both contraction and hydrolysis of ATP are blocked. Tropomyosin (Tm) is a helical coiled-coil dimer, a 40-nm rigid rod, in which the two 284-residue 33-kDa monomers have a parallel orientation (Fig. 19-9)[249] as in the myosin tail. However, an 8– to 9– residue overlap at the ends may permit end-to-end association of the Tm molecules bound to the actin filament. As with other muscle proteins there are several isoforms,[250,251] whose distribution differs in skeletal and smooth muscle and in platelets. The elongated Tm rods appear to fit into the grooves between the two strands of actin monomers in the actin filament.[252–254] In resting muscle the Tm is thought to bind to actin near the site at which the S1 portion of the myosin binds. As a consequence, the Tm rod may block the attachment of the myosin heads to actin and prevent actin-stimulated hydrolysis of ATP. The 40-nm Tm rod can contact about seven actin subunits at once (Fig. 19-9). Thus, one Tm–troponin complex controls seven actin subunits synchronously.

Troponin (Tn) consists of three polypeptides (TnC, TnI, TnT) that range in mass from 18 to 37 kDa. The complex binds both to Tm and to actin.[255,256] Peptide TnT binds tightly to Tm and is thought to link the TnI•TnC complex to Tm.[256,257] TnI interacts with actin and inhibits ATPase activity in the absence of Ca^{2+}.[258–261] It may work with the other two peptides to keep the Tm in the proper position to inhibit ATP hydrolysis. TnC binds calcium ions. This ~160-residue protein has a folding pattern almost identical to that of calmodulin (Fig. 6-8) with four Ca^{2+}-binding domains arranged in two pairs at the ends of a long 9-turn helix. When Ca^{2+} binds to TnC, a conformational change occurs[258,259,262-265] (p. 313). This induces changes in the troponin•tropomyosin•actin complex, releases the inhibition of actomyosin ATPase, and allows contraction to occur.[265a] In the heart additional effects are exerted by β-adrenergic stimulation, which induces phosphorylation of two sites on TnI by the action of the cAMP-dependent protein kinase PKA. Dephosphorylation by protein phosphatase 2A completes a regulatory cycle in which the doubly phosphorylated TnI has a decreased sensitivity to calcium ions.[266] Cardiac muscle also contains a specialized protein called **phospholamban**. An oligomer of 52-residue subunits, it controls the calcium ion pump in response to β-adrenergic stimulation. Unphosphorylated phospholamban inhibits the Ca ATPase, keeping [Ca^{2+}] high in the cytoplasm. Phosphorylation of phospholamban by cAMP and/or calmodulin-dependent protein kinase activates the Ca^{2+} pump,[267–268a] removing Ca^{2+} and ending contraction.

X-ray diffraction and electron microscopy in the 1970s suggested that when calcium binds to troponin the tropomyosin moves through an angle of ~ 20° away from S1, uncovering the active site for the myosin–ATP–actin interactions.[252,253] Tropomyosin could be envisioned as rolling along the surface of the actin, uncovering sites on seven actin molecules at once. Side-chain knobs protruding from the tropomyosin like teeth on a submicroscopic gear might engage complementary holes in the actin. At the same time a set of magnesium ion bridges between zones of negative charge on tropomyosin and actin could hold the two proteins together. This proposal has been difficult to test. Although the older image reconstruction is regarded as unreliable, recent work still supports this **steric blocking** model.[255,269-270c] Image reconstruction from electron micrographs of thin filaments shows that, in the presence of Ca^{2+}, the tropomyosin does move 25° away from the position in low [Ca^{2+}]. However, instead of two states of the thin filament, "on" and "off," there may be at least three, which have been called "blocked," "closed," and "open."[255,269,271,271a] The closed state may be attained in rigor.[269] In addition, the possibility that changes in the conformation of actin as well as of myosin occur during the contraction cycle must be considered.[255]

Smooth muscle. The primary regulation of smooth muscle contraction occurs via phosphorylation of the Ser 19 –OH group in the 20-kDa regulatory light chains of each myosin head.[121b,160,272–274] The phosphorylated form is active, participating in the contraction process. Removal of Ca^{2+} by the calcium pump and dephosphorylation of the light chains by a protein phosphatase[275] restores the muscle to a resting state. The N-terminal part of the myosin light chain kinase binds to actin, while the catalytic domain is in the center of the protein. The C-terminal part binds to myosin, and this binding also has an activating effect.[276]

Another protein, **caldesmon**, binds to smooth muscle actin and blocks actomyosin ATPase.[271,277–278a] It is present in smooth muscle in a ratio of actin:tropomyosin:caldesmon of ~14:2:1. Inhibition can be reversed by Ca^{2+}, but there is no agreement on the function of caldesmon.[277] It is an elongated ~756-residue protein with N-terminal domain, which binds to myosin, and a C-terminal domain, which binds to actin, separated by a long helix.[278] Caldesmon may be a substitute for troponin in a tropomyosin-type regulatory system, or it may promote actomyosin assembly. Another possibility is that it functions in a **latch state**, an energy-economic state of smooth muscle at low levels of ATP hydrolysis.[278,279] In molluscan muscles Ca^{2+} binds to a myosin light chain and activates contraction directly. Some molluscan smooth muscles (**catch muscles**) also have a latch state, which enables these animals to maintain muscular tension for long periods of time, e.g., holding their shells tightly closed, with little expenditure of energy.[279a] Catch muscles contain myosin plus a second protein, **catchin**, which is formed as a result of alternative mRNA splicing. Catchin contains an N-terminal sequence that may undergo phosphorylation as part of a regulatory mechanism.[280] However, recent experiments indicate that twitchin (see next paragraph), rather than catchin, is essential to the catch state and is regulated by phosphorylation.[280a] Regulation of the large groups of unconventional myosins is poorly understood. Phosphorylation of groups on the myosin heavy chains is involved in ameba myosins and others.[281]

An unexpected aspect of regulation was discovered from study of the 40 or more genes of *Caenorhabditis elegans* needed for assembly and function of muscle. The mutants designated *unc-22* showed a constant twitch arising from the muscles in the nematode's body. The gene was cloned using transposon tagging (Chapter 27) and was found to encode a mammoth 753-kDa 6839-residue protein which has been named **twitchin**.[282–285] Twitchin resembles titin (Fig. 19-8) and like titin has a protein kinase domain, which is normally inhibited by the end of its peptide chain, which folds over the active site of the kinase. Perhaps the protein kinase activities of twitchin, titin, and related proteins[285] are required in assembly of the sarcomere.

5. The Phosphagens

ATP provides the immediate source of energy for muscles but its concentration is only ~5 mM. As discussed in Chapter 6, Section D, **phosphagens**, such as **creatine phosphate**, are also present and may

$$\text{Creatine-}P + \text{ADP} \longrightarrow \text{Creatine} + \text{ATP}$$

attain a concentration of 20 mM in mammalian muscle. This provides a reserve of high-energy phospho groups and keeps the adenylate system buffered at a high phosphorylation state ratio[286] (see Eq. 6-67).

The concentration of both ATP and creatine phosphate as well as their rates of interconversion can be monitored by ^{31}P NMR within living muscles (Figs. 6-4 and 19-22). Phospho groups were observed to be

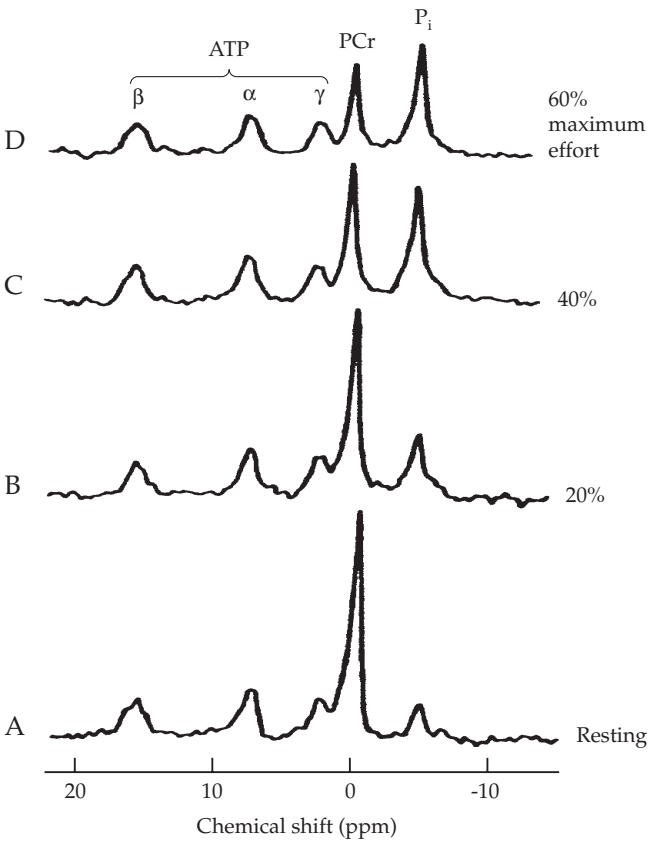

Figure 19-22 Phosphorus-31 magnetic resonance spectra of wrist flexor muscles of the forearm of a trained long-distance runner at rest and during contraction at three different levels of exercise. Ergometer measurements indicating the percent of initial maximum strength (% max) were recorded over each 6-min period. Spectra were obtained during the last 3 min of each period. Times of spectral data collection: A, resting; B, 4–6 min; C, 10–12 min; and D, 16–18 min. The pH ranged from 6.9 to 7.0. From Park *et al.*[288]

transferred from creatine phosphate to ADP to form ATP with a flux of 13 mmol $kg^{-1}s^{-1}$ in rat legs.[287] The reverse reaction must occur at about the same rate because little cleavage of ATP to P_i was observed in the anaesthetized rats. Use of surface coils has permitted direct observation of the operation of this shuttle system in human muscle (Fig. 19-22)[288] as well as in animal hearts (see Chapter 6). Only a fraction of the total creatine present within cells participates in the shuttle, however.[289]

C. Motion in Nonmuscle Cells

At one time actin and myosin were thought to be present only in muscles, but we know now that both actin proteins of the myosin family are present in all eukaryotic cells. Ameboid movement, the motion of cilia and flagella, and movement of materials along microtubules within cells also depend upon proteins of this group.

1. Actin-Based Motility

Ameboid movements of protozoa and of cells from higher organisms, the ruffling movements of cell membranes, phagocystosis, and the cytoplasmic streaming characteristic of many plant cells[289a] have all been traced to actin filaments or actin cables rather

TABLE 19-1
Some Actin-Binding Proteins

Function	Name	Function	Name
Bind and stabilize monomeric actin	Profilin[a,b,c,d,e,f,g,h]	Crosslink actin filaments or monomers	
	ADF/Cofilin[i,j,h,k]	Tight bundles	Villin[c,z,aa]
	Thymosin[f,l]	Loose bundles	α-Actinin[bb]
Cap actin filament ends	CapZ[m,n]		Spectrin[bb]
barbed end	Fragmin[o,p]		Fascin[cc]
pointed end	β-Actin[q]		MARCKS[a]
	Tropomodulin[r]	Network	Filamin[bb,c]
	Arp2/3, a complex of seven polypeptides		Gelactins
Sever or dissociate actin filament	Gelsolin[s,t,u,v,w]	Bind actin filaments to membrane	Talin[dd]

than to microtubules.[289b] Actin is one of the most abundant proteins in all eukaryotes. Its network of filaments is especially dense in the lamellipodia of cell edges, in microvilli, and in the specialized stereocilia and acrosomal processes (see also pp. 369-370).[289c] Actin filaments and cables are often formed rapidly and dissolve quickly. When actin filaments grow, the monomeric subunits with bound ATP are added most rapidly at the "barbed end" and dissociate from the filament at the "pointed end" (see Section B,2).[94,290] The rate of growth may be ~20–200 nm / s, which requires the addition of 10–100 subunits / s.[291] Various actin-binding proteins control the growth and stability of the filaments. The actin-related proteins **Arp2** and **Arp3**, as a complex Arp2/3, together with recently recognized **formins**.[291a], provide nuclei for rapid growth of new actin filaments as branches near the barbed ends.[290,292–293c]

Growth of the barbed ends of actin filaments is stimulated by phosphoinositides and by members of the Rho family of G proteins (p. 559)[293d] through interaction with proteins of the **WASp** group.[293b,d,e] The name WAS comes from the immune deficiency disorder Wiskott–Aldrich Syndrome. Yet another family, the **Ena/VASP** proteins, are also implicated in actin dynamics. They tend to localize at focal adhesions and edges of lamellipodia.[293e,f] Profilin (Table 19-1) stabilizes a pool of monomeric actin when the barbed ends of actin filaments are capped. However, it catalyzes both the addition of actin monomers to uncapped barbed ends and rapid dissociation of subunits from pointed ends, leading to increased **treadmilling**.[294,295] Actin-severing proteins such as the **actin depolymerizing factor** (**ADF** or **cofilin**, Table 19-1) promote breakdown of the filaments.[296–297a] Treadmilling in the actin filaments of the lamellipods of crawling cells or pseudopods of amebas provides a motive force for many cells[291,298–299] ranging from those of *Dictyostelium* to human leukocytes. A series of proteins known as the **ezrin**, **radixin**, **moesin** (**ERM**) group attach actin to integral membrane proteins (Fig. 8-17)[292,300,301] and may interact directly with membrane lipids.[301a,b] Bound ATP in the actin subunits is essential for polymerization, and excess ATP together with crosslinking proteins stabilize the filaments. However, when the bound ATP near the pointed ends is hydrolyzed to ADP the filaments become unstable and treadmilling is enhanced. Thus, as in skeletal muscle, ATP provides the energy for movement.

Bacteria also contain filamentous proteins that resemble F-actin and which may be utilized for cell-shape determination.[301c] Actin-based motility is used by some bacteria and other pathogens during invasion of host cells (Box 19-C). It is employed by sperm cells of *Ascaris* and of *C. elegans*, which crawl by an ameboid movement that utilizes treadmilling of filaments formed from a motile sperm protein, which does not resemble actin.[302,302a] Cells are propelled on a glass surface at rates up to ~1 μm / s.

Various nonmuscle forms of myosin also interact with actin without formation of the myofibrils of muscle.[299] In most higher organisms nonmuscle myosins often consist of two ~200-kDa subunits plus two pairs of light chains of ~17 and 24 kDa each. These may form bipolar aggregates, which may bind to pairs of actin filaments to cause relative movement of two parts of a cell.[303] Movement depending upon the cytoskeleton is complicated by the presence of a bewildering array of actin-binding proteins, some of which are listed in Table 19-1.

2. Transport along Microtubules by Kinesin and Dynein

Many materials are carried out from the cell bodies of neurons along microtubules in the axons, which in the human body may be as long as 1 m. The rates of this **fast axonal transport** in neurons may be as high as 5 μm / s or 0.43 m / day. The system depends upon ATP and kinesin (Fig. 19-17) and permits small vesicles to be moved along single microtubules.[304–305b] Movement is from the minus end toward the plus end of the microtubule as defined in Figs. 7-33, 7-34. Slower **retrograde axonal transport** carries vesicles from the synapses at the ends of the axons (Fig. 30-8) back toward the cell body. This retrograde transport depends upon the complex motor molecule **cytoplasmic dynein** which moves materials from the plus end of the microtubule toward the minus end.[305,305c] In addition to these movements, as mentioned in Chapter 7, microtubules often grow in length rapidly or dissociate into their tubulin subunits. Growth occurs at one end by addition of tubulin subunits with their bound GTP. The fast growing *plus*-ends of the microtubules are usually oriented toward the cell periphery, while the *minus*-ends are embedded in the **centrosome** or **microtubule-organizing center** (p. 372).[306] Just as with actin, in which bound ATP is hydrolyzed to ADP, the bound GTP in the β-tubulin subunits of microtubules is hydrolyzed to GDP[307–310] decreasing the stability of the microtubules, a phenomenon described as **dynamic instability**. Various **microtubule-associated proteins** (MAPs) have strong effects on this phenomenon.[311] The MAPs are often regulated by phosphorylation–dephosphorylation cycles involving serine / threonine kinases. Microtubules also undergo posttranslational alterations not seen in other proteins. These include addition or removal of tyrosine at the C terminus.[312] Polyglycyl groups containing 3–34 glycine residues may be bound covalently to γ-carboxyl groups of glutamate side chains in both α- and β-tubulins.[312,313] This stabilizes the microtubules and is important to the long-lived microtubules of the axonomes of flagella and

BOX 19-C ACTIN-BASED MOTILITY AND BACTERIAL INVASION

Listeria monocytogenes is a dangerous food-borne bacterium that has become a major problem in the United States. This is one of the best understood *intracellular* pathogens. It is able to enter cells, escape from phagocytic vesicles, spread from cell to cell, and cross intestinal, blood–brain, and placental barriers.[a–c] Within cells these bacteria move using actin-based motility. Actin subunits polymerize at one end of a bacterium leaving a "comet tail" of crosslinked fibrous actin behind (see micrographs). Actin polymerization occurs directly behind the bacteria with subunits of monomeric actin adding to the fast growing "barbed end" (see Section B,2) of the actin strands. Growth has been described as a "Brownian ratchet."[c,d] Continual Brownian movement opens up spaces behind the bacteria, spaces that are immediately filled by new actin subunits. This provides a propulsive force adequate to move the bacteria ahead at velocities of about 0.3 μm / s.

Polymerization of actin is induced by interaction of a dimer of a 610-residue bacterial protein **ActA** with proteins of the host cell.[a,e–h] ActA is a composite protein with an N-terminal region that protrudes from the bacterial cell, a central region of proline-rich repeats that appear to be essential for recognition by host cells, and a C-terminal hydrophobic membrane anchor. There are also regions of close sequence similarity to the human actin-binding proteins vinculin and zyxin. The number of host proteins needed in addition to monomeric actin are:[i,j] the two actin-related proteins, **Arp2** and **Arp3**, which stimulate actin polymerization and branching;[h] **ADF/ cofilin**, which increases the rates, both of growth at the barbed ends and dissociation from the pointed ends of the filaments; and **Cap Z**, which caps barbed ends (Table 19-1). The need for ADF/ cofilin and Cap Z seems paradoxical. Cap Z may cap mostly older and slower growing filaments, restricting rapid filament assembly to the region closest to the bacterium. The need for ADF/ cofilin is unclear.[i] Growth rates are also enhanced by the human protein called **VASP** (vasodilator-stimulated phosphoprotein). The proline-rich region of the bacterial ActA may bind to VASP to initiate polymerization.[g] Both profilin (Table 19-1) and the crosslinking protein α-actinin also stimulate comet tail growth. Myosin does not participate in actin-based motility, but the hydrolysis of ATP drives the process through its link to actin polymerization.[i]

Although *Listeria* has been studied most, actin-based motility is employed by other pathogens as well, e.g., *Shigella flexneri* (the dysentery bacterium),[k] *Rickettsia*,[l] and vaccinia virus.[l] Although enteropathogenic *E. coli* do not use this method of movement, they induce accumulation of actin beneath the bacteria. They also promote formation of actin-rich adherent pseudopods and highly organized cytoskeletal structures that presumably assist the bacteria in entering a cell.[m]

cilia. Polyglutamyl groups of 6–7 glutamates are also often added.[314]

Both dynein and several kinesins act as motors for formation of the spindle and for movement of chromosomes toward the minus ends of spindle microtubules during mitosis and meiosis (Fig. 26-11).[314a] In the genome of *Saccharomyces cerevisiae* there is only one dynein gene, but genes for six different kinesin-type motor molecules are present.[315] In higher organisms there may be even more genes for kinesins but there is apparently only one dynein in most species.[316]

Axonemal dyneins drive the motion of eukaryotic flagella and cilia. As with the cytoplasmic dyneins a complete molecule consists of two or three heavy chains with molecular mass ~520 kDa, some localized in the dynein tail, and several lighter chains.[305a,317–321] Like myosin dynein is an ATPase.

3. Eukaryotic Cilia and Flagella

The motion of eukaryotic flagella (Fig. 1-8) involves a sliding of the microtubular filaments somewhat analogous to the sliding of muscle filaments.[305,322–325] Sliding between the outer doublet microtubules (Fig. 19-23) via their inner and outer arms (dynein compounds) is thought to provide the characteristic bending waves.[325a,b] The movement is powered by dynein and ATP hydrolysis. Force and displacement measurements made by optical trapping nanometry suggest that the characteristic rhythmic beating of flagella results from an oscillatory property of the dynein.[326] The extremely complex structure of flagella is illustrated in Fig. 19-23. About 250 individual axonemal proteins have been detected in flagella of the alga *Chlamydomonas* (Fig. 1-11),[327] and a large number of mutants with various defects in their flagella have been isolated. The radial spokes (Fig. 19-23) alone contain 17 different proteins. These spokes protrude at ~29-nm intervals while the dynein molecules lie between pairs of the outer microtubule doublets at ~24-nm intervals. The dynein "arms" protrude from the "A" microtubule of each outer doublet and make contact with the incomplete "B" microtubule of the next doublet (Fig. 19-12). Although the shapes of the molecules are quite different, the basic chemistry of the ATPase activity of the dynein–microtubule system resembles that of actomyosin. However, the complexity of the dynein arms,[328]

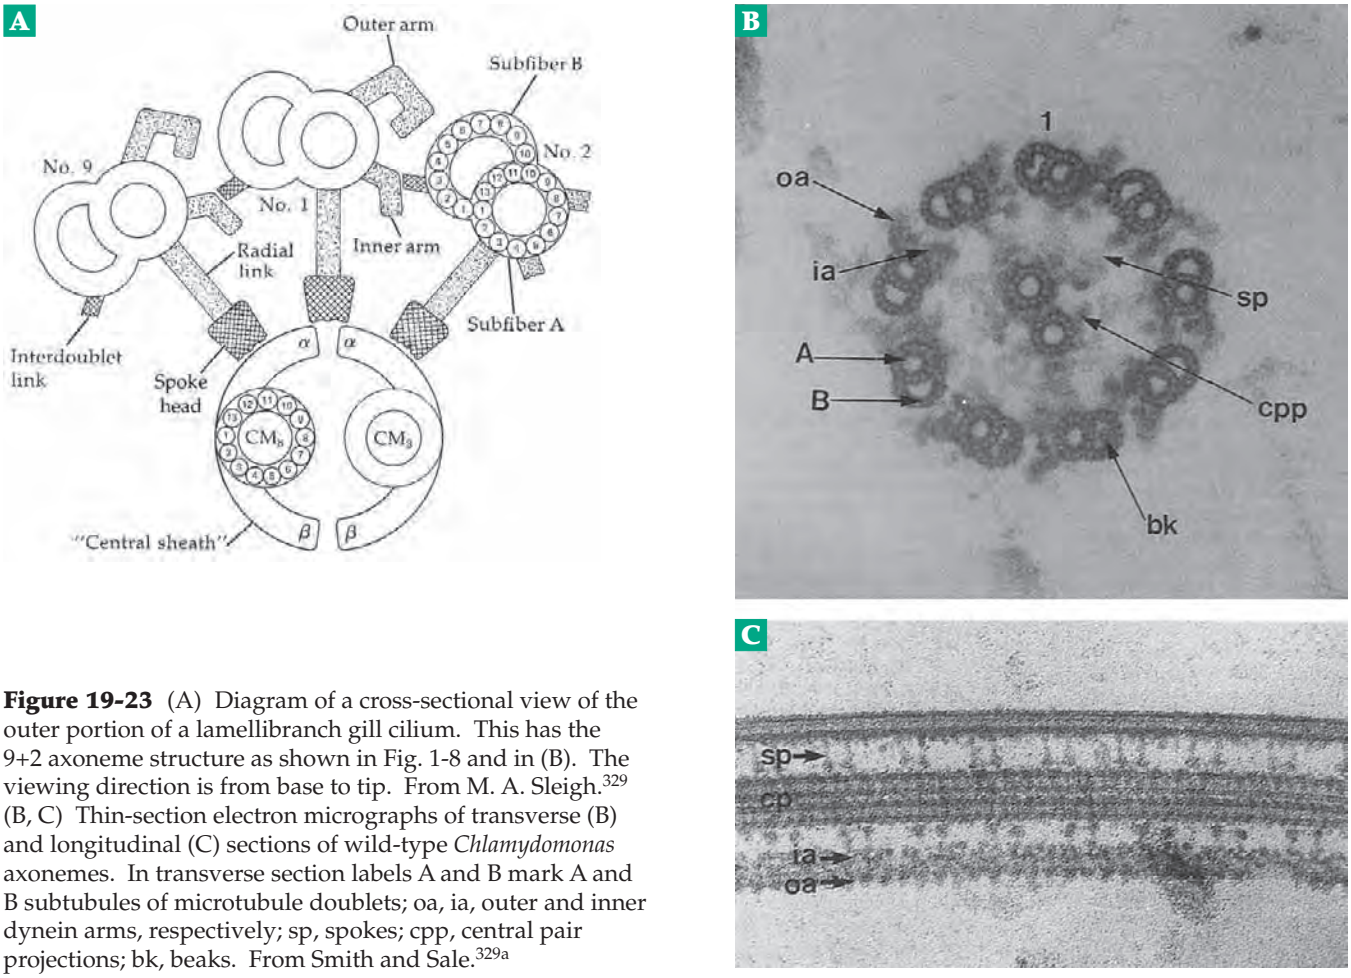

Figure 19-23 (A) Diagram of a cross-sectional view of the outer portion of a lamellibranch gill cilium. This has the 9+2 axoneme structure as shown in Fig. 1-8 and in (B). The viewing direction is from base to tip. From M. A. Sleigh.[329] (B, C) Thin-section electron micrographs of transverse (B) and longitudinal (C) sections of wild-type *Chlamydomonas* axonemes. In transverse section labels A and B mark A and B subtubules of microtubule doublets; oa, ia, outer and inner dynein arms, respectively; sp, spokes; cpp, central pair projections; bk, beaks. From Smith and Sale.[329a]

which exist in two types, inner and outer, suggests a complex contraction cycle.

4. Chemotaxis

As described in Box 11-C, the ameboid cells of the slime mold *Dictyostelium discoideum* are attracted to nutrients such as folic acid during their growth stage. Later, as the cells undergo developmental changes they become attracted by pulses of cyclic AMP.[330] Occupancy of 7-helix receptors for cAMP on the outer plasma membrane appears to induce methylation of both proteins and phospholipids and a rise in cytosolic Ca^{2+} and changes in the cytoskeleton that result in preferential extension of the actin-rich pseudopods toward the chemoattractant.[331]

In a similar manner, human ameboid leukocytes are attracted to sites of inflammation by various **chemotactic factors**.[332] These include the 74-residue cleavage product C5a formed from the fifth component of complement (Chapter 31),[333] various **lymphokines** (Chapter 31) secreted by lymphocytes, and peptides such as VGSE and AGSE, as well as larger peptides released by mast cells, basophils, or stimulated monocytes[334] and oxoicosenoids.[335] Polymorphonuclear leukocytes, upon engulfing sodium urate crystals in gouty joints, release an 8.4-kDa chemotactic protein which may cause a damaging response in this arthritic condition. Leukotriene B is a potent chemotactic agent as are a series of specific bacterial products, formylated peptides such as *N*-formyl-MLF.[332,336]

Neutrophils, monocytes, macrophages, eosinophils, basophils, and polymorphonuclear leukocytes are all affected by several or all of these factors. Binding to specific receptors results in a variety of changes in the cells. These include alterations in membrane potential, cyclic nucleotide levels, and ion fluxes (Na^+, K^+, Ca^{2+}) as well as increased methylation of specific proteins. A reorganization of microtubules and actin fibrils occurs, probably in response to an altered gradient of Ca^{2+}. The morphology of the cells changes, and they begin immediately to crawl toward the chemoattractants. It appears that these ameboid cells detect a gradient of attractant concentration between one end of the cell and the other, even though the anticipated difference may amount to only 0.1% of the total.[337,338]

5. Other Forms of Movement

Movement is characteristic of life and is caused not only by motor proteins but by various springs and ratchets which may be energized in a number of ways.[339] A striking example, which any one with a microscope and some fresh pond water can observe, is contraction of the stalk of protozoa of the genus *Vorticella*. Apparently first reported in 1676 by Leeuwenhoek the organism's 2–3 mm-long stalk contracts into a coiled spring (see p. 1 and also p. 281) when the animal is disturbed. Application of calcium ions causes contraction within a few milliseconds to ~40% of the original length. The process reverses slowly after a few seconds. Contraction is caused by a spring-like organ the **spasmoneme**, which is a bundle of short 2 nm-diameter fibrils inside the stalk. The fibrils are thought to be weakly crosslinked and held in the extended state by electrostatic repulsion between the negatively charged rods. Addition of Ca^{2+} neutralizes the charges permitting an entropy-driven collapse of the fibers.[339]

Another remarkable example is extension of the acrosomal process from a sperm cell of the horseshoe crab *Limulus polyphemus* at fertilization. A bundle of actin filaments in a crystalline state lies coiled around the base of the nucleus. At fertilization the bundle uncoils and slides through a tunnel in the nucleus to form a 60 µm-long acrosomal process within a few seconds. The uncoiled bundle is also crystalline. The coiled bundle is apparently overtwisted and an actin crosslinking protein **scruin** mediates the conformational alteration that takes place.[339] A somewhat related process may be involved in contraction of bacteriophage tails (pp. 363, 364)

Some bacteria glide with a twitching movement induced by rapid retraction of pili.[340] Another type of movement involves the pinching off of vesicles, e.g., of clathrin-coated pits (Fig. 8-27). This is a GTP-driven process that requires a mechanoenzyme called **dynamin**.[341,342]

Study Questions

1. Describe briefly major aspects of the structure, properties, locations, and functions of each of the following proteins of skeletal muscle.

Actin	Tropomyosin
Myosin	Troponin
Titin	Myomesin
Nebulin	Desmin
α-Actinin	Vimentin
C-protein	

2. Describe the generally accepted sliding filament model of muscle contraction. List some uncertainties in this description.

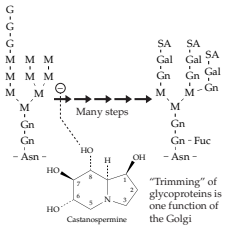
3. Compare mechanisms that regulate contraction in skeletal muscle and in smooth muscle.

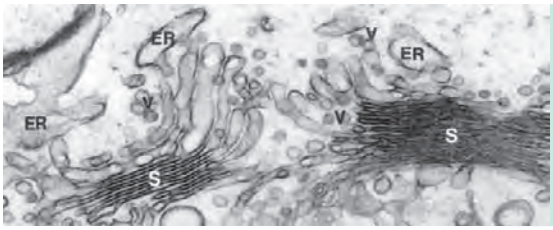
4. Compare myosin with kinesins and dyneins. What features do they have in common? What differences can you describe?

5. Compare the properties of actin in skeletal muscle and in nonmuscle cells. What is meant by "treadmilling?" What is "actin-based motility?"

6. The human genome contains more than 100 genes for proteins of the kinesin superfamily. Why?

7. Describe some of the major diseases that involve muscle proteins.



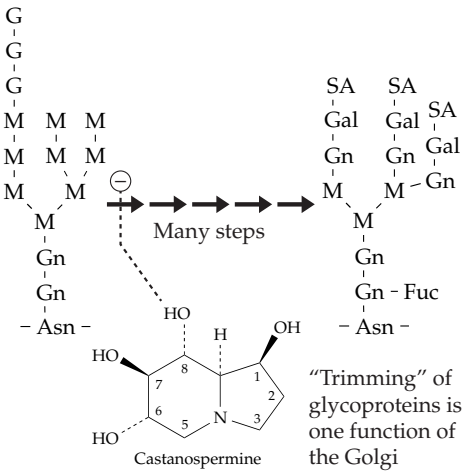


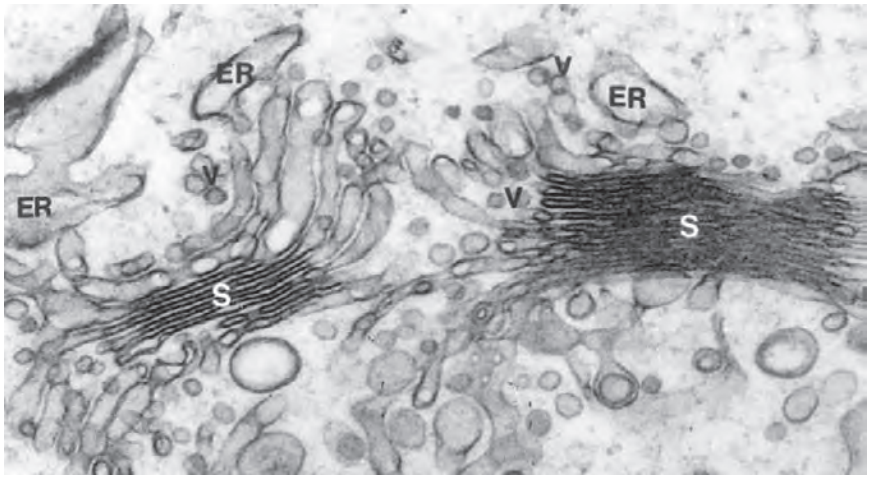
The branched oligosaccharides of glycoprotein surfaces are formed on asparagine side chains of selected cell surface proteins. The oligosaccharide at the left is formed in the ER and is transferred intact (Fig. 20-6) to an acceptor asparagine. It is then trimmed by removal of glucose and mannose units and residues of glucosamine, galactose, and fucose are added as in Fig. 20-7. These reactions begin in the ER and continue in the Golgi apparatus (right). See also Fig. 20-8.

Contents

Some Pathways of Carbohydrate Metabolism

20

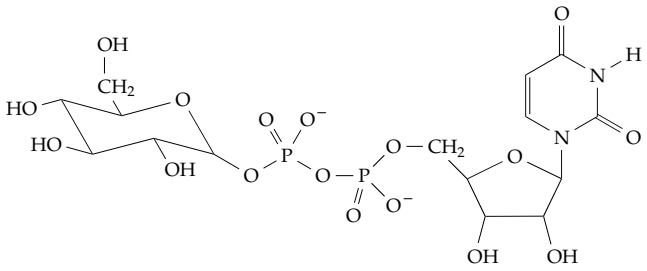




The general principles of biosynthesis, as well as the pathways of formation of major carbohydrate and lipid precursors, are considered in Chapter 17. Also described are the processes of gluconeogenesis, the synthesis of glucose 6-phosphate and fructose 6-phosphate from free glucose, and typical polymerization pathways for formation of polysaccharides. In this chapter, additional aspects of the metabolism of monosaccharides, oligosaccharides, polysaccharides, glycoproteins, and glycolipids are considered. These are metabolic transformations that affect the physical properties of cell surfaces and body fluids. They are essential to signaling between cells, to establishment of the immunological identity of individuals, and to the development of strong cell wall materials. Some of the differences in carbohydrates found in bacteria, fungi, green plants, and mammals are considered.

A. Interconversions of Monosaccharides

Chemical interconversions between compounds are easiest at the level of oxidation of carbohydrates. Consequently, many reactions by which one sugar can be changed into another are known. Most of the transformations take place in the "sugar nucleotide derivatives" (see also Eq. 17-56). The first of this group of compounds to be recognized was **uridine diphosphate glucose** (UDPG), which was discovered around 1950 by L. F. Leloir[1,2] during his investigation of the metabolism of galactose 1-*P*. The fact that interconversions of hexoses take place largely at the sugar nucleotide level was unknown at the time. Leloir's studies led to the characterization of both UDP-glucose and UDP-galactose.



Uridine diphosphate D-glucose

Figure 20-1 summarizes pathways by which glucose 6-phosphate or fructose 6-phosphate can be converted into many of the other sugars found in living things. Galactose and mannose can also be interconverted with the other sugars. A kinase forms **mannose 6-phosphate** which equilibrates with fructose 6-phosphate. Galactokinase converts free galactose to **galactose 1-phosphate**, which can be isomerized to glucose 1-phosphate by the reactions of Eq. 20-1. Fructose, an important human dietary constituent[3] derived largely by hydrolysis of sucrose, can also be formed in tissues via the **sorbitol pathway**[4] (Box 20-A). Fructose can be phosphorylated to fructose 1-phosphate by liver **fructokinase**. We have no mutase able to convert fructose 1-*P* to fructose 6-*P*, but a special aldolase cleaves fructose 1-*P* to dihydroxyacetone phosphate and free glyceraldehyde. Lack of this aldolase leads to occasionally observed cases of fructose intolerance.[5,6] The glyceraldehyde formed from fructose can be metabolized by reduction to glycerol followed by phosphorylation (glycerol kinase) and reoxidation to dihydroxyacetone phosphate. Some phosphorylation of fructose 1-*P* to fructose 1,6-P_2 apparently also occurs.[7] Interconversion of ribose 5-*P* and other sugar phosphates

is a central part of the pentose phosphate pathway (Fig. 17-8). Free ribose can be phosphorylated by a **ribokinase**.[8]

Oxidation of UDP-glucose in two steps[9,9a] by NAD^+ yields **UDP-glucuronic** acid, which can be epimerized to **UDP-galacturonic** acid. Likewise (see bottom of Fig. 20-1), **guanosine disphosphate-mannose** (GDP-mannose) is oxidized to **GDP-mannuronic acid**, which undergoes 4-epimerization to **GDP-guluronic acid**. Looking again at the top of the scheme, notice that UDP-D-glucuronic acid may be epimerized at the 5 position to **UDP-L-iduronic acid**. However, the iduronic acid residues in dermatan sulfate arise by inversion at C-5 of D-glucuronic acid residues in the polymer.[10] The mechanism of these reactions, like that of the decarboxylation of UDP-glucuronic acid to UDP-xylose (near the top of Fig. 20-1), apparently have not been well investigated.

Notice that glucuronic acid is abbreviated GlcA, in accord with IUB recommendations. However, many authors use GlcUA, ManUA, etc., for the uronic acids.

1. The Metabolism of Galactose

The reactions of galactose have attracted biochemists' interest because of the occurrence of the rare (30 cases / million births) hereditary disorder **galactosemia**. When this defect is present, the body cannot transform galactose into glucose metabolites but reduces it to the sugar alcohol **galactitol** or oxidizes it to **galactonate**, both products being excreted in the urine. Unfortunately, severe gastrointestinal troubles often appear within a few days or weeks of birth. Growth is slow and cataracts develop in the eyes, probably as a result of the accumulating galactitol. Death may come quickly from liver damage. Fortunately, galactose-free diets can be prepared for young infants, and if the disease is diagnosed promptly the most serious damage can be avoided. However, it has not been possible to prevent long-term effects that include speech difficulties, learning disabilities, and ovarian dysfunction.[1,11]

In some less seriously affected galactosemic patients **galactokinase** (Eq. 20-1, step *a*) is absent, but it is more often **galactose-1-phosphate uridyltransferase** (Eq. 20-1, step *b*) that is missing or inactive.[12–15a] This enzyme transforms galactose 1-*P* to UDP-galactose by displacing glucose 1-*P* from UDP-glucose. The UDP-galactose is then isomerized by the NAD^+-dependent

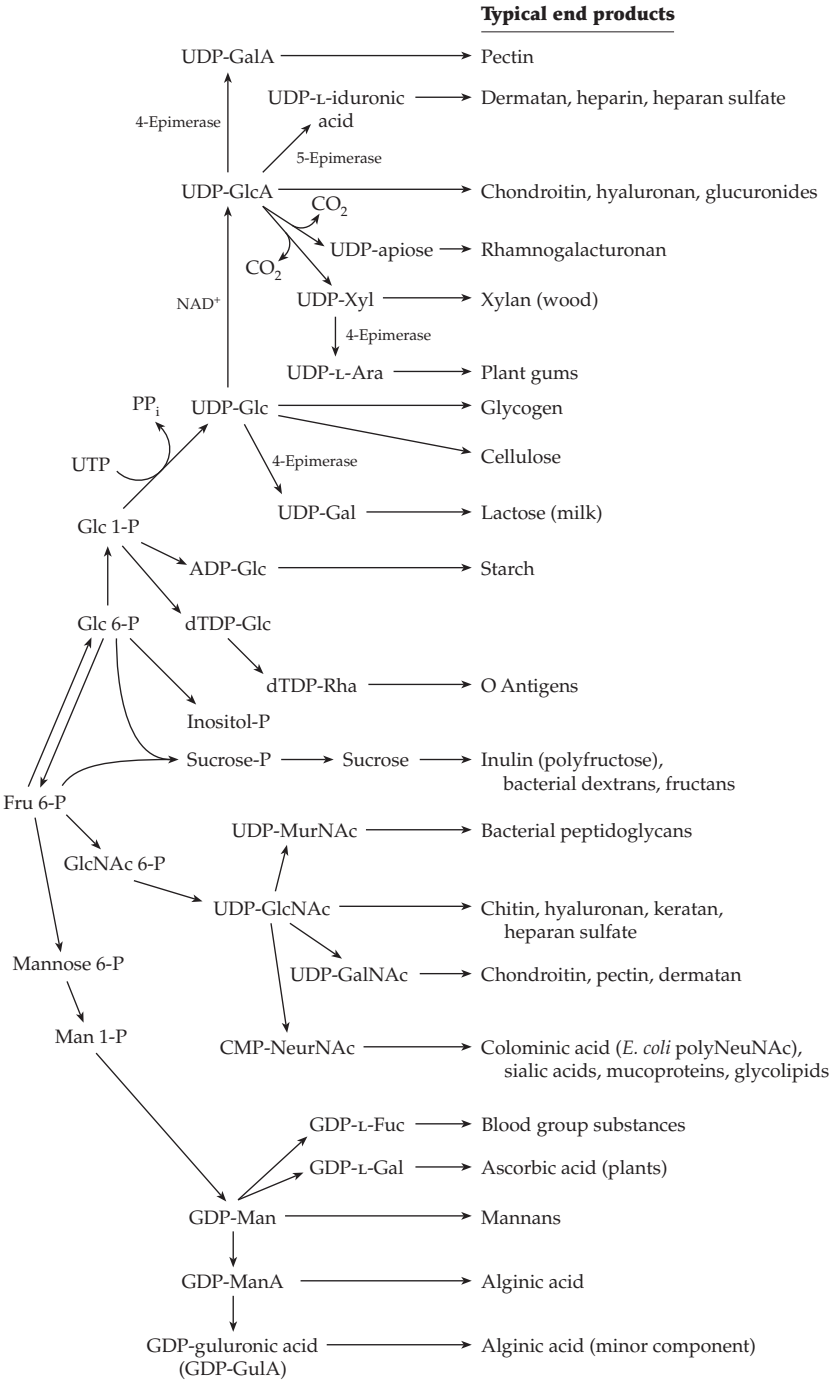


Figure 20-1 Some routes of interconversion of monosaccharides and of polymerization of the activated glycosyl units.

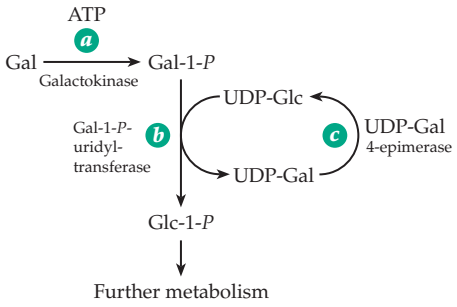


(20-1)

UDP-Gal 4-**epimerase**[16–16b] (Eq. 20-1, step *c*; see also Eq. 15-13 and accompanying discussion). Absence of this enzyme also causes galactosemia.[11] The overall effect of the reactions of Eq. 20-1 is to transform galactose into glucose 1-*P*. At the same time, the 4-epimerase can operate in the reverse direction to convert UDP-glucose to UDP-galactose, when the latter is needed for biosynthesis (Fig. 20-1).

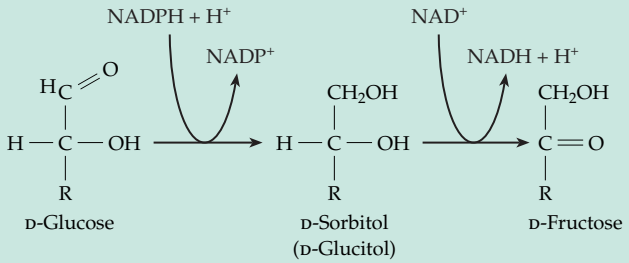
Another enzyme important to galactose metabolism, at least in *E. coli*, is **galactose mutarotase**.[17] Cleavage of lactose by β-galactosidase produces β-D-galactose which must be converted to the α-anomer by the mutarotase before it can be acted upon by galactokinase. Galactose is present in most glycoproteins and glycolipids in the pyranose ring form. However, in bacterial O-antigens, in cell walls of mycobacteria and fungi, and in some protozoa glactose occurs in the furanose form. The precursor is UDP-Gal*f*, which is formed from UDP-Gal*p* by **UDP-Gal*p* mutase**.[17a]

2. Inositol

Related to the monosaccharides is the hexahydroxycyclohexane ***myo*-inositol** (Eq. 20-2). This **cyclitol**, which is apparently present universally within cells (Fig. 11-9), can be formed from glucose-6-*P* according to Eq. 20-2 using a synthase that contains bound

BOX 20-A FRUCTOSE FOR SPERM CELLS VIA THE POLYOL PATHWAY

An interesting example of the way in which the high [NADPH]/[NADP$^+$] and [NAD$^+$]/[NADH] ratios in cells can be used to advantage is found in the metabolism of sperm cells. Whereas D-glucose is the commonest sugar used as an energy source by mammalian cells, spermatozoa use principally D-fructose, a sugar that is not readily metabolized by cells of surrounding tissues.[a–c] Fructose, which is present in human semen at a concentration of 12 mM, is made from glucose by cells of the seminal vesicle by reduction with NADPH to the sugar alcohol D-sorbitol, which in turn is oxidized in the 2 position by NAD$^+$. The combination of high [NADPH]/[NADP$^+$] and high [NAD$^+$]/[NADH] ratio is sufficient to shift the equilibrium far toward fructose formation.[d]



The polyol pathway is an active bypass of the dominant glycolysis pathway in many organisms.[e] Sorbitol and other polyols such as glycerol, erythritol, threitol, and ribitol serve as cryoprotectants in plants, insects, and other organisms.[f] Sorbitol is also an important osmolyte in some organisms (see Box 20-C). On the other hand, accumulation of sorbitol in lenses of diabetic individuals has often been blamed for development of cataract. However, doubts have been raised about this conclusion. The polyol pathway is more active than normal in diabetes, and there is evidence that the increased flow in this pathway may lead to an increase in oxidative damage to the lens. This may result, in part, from the depletion of NADPH needed for reduction of oxidized glutathione in the antioxidant system.[g] Aldose reductase inhibitors, which reduce the rate of sorbitol formation, decrease cataract formation. However, the reason for this is not yet clear.[h]

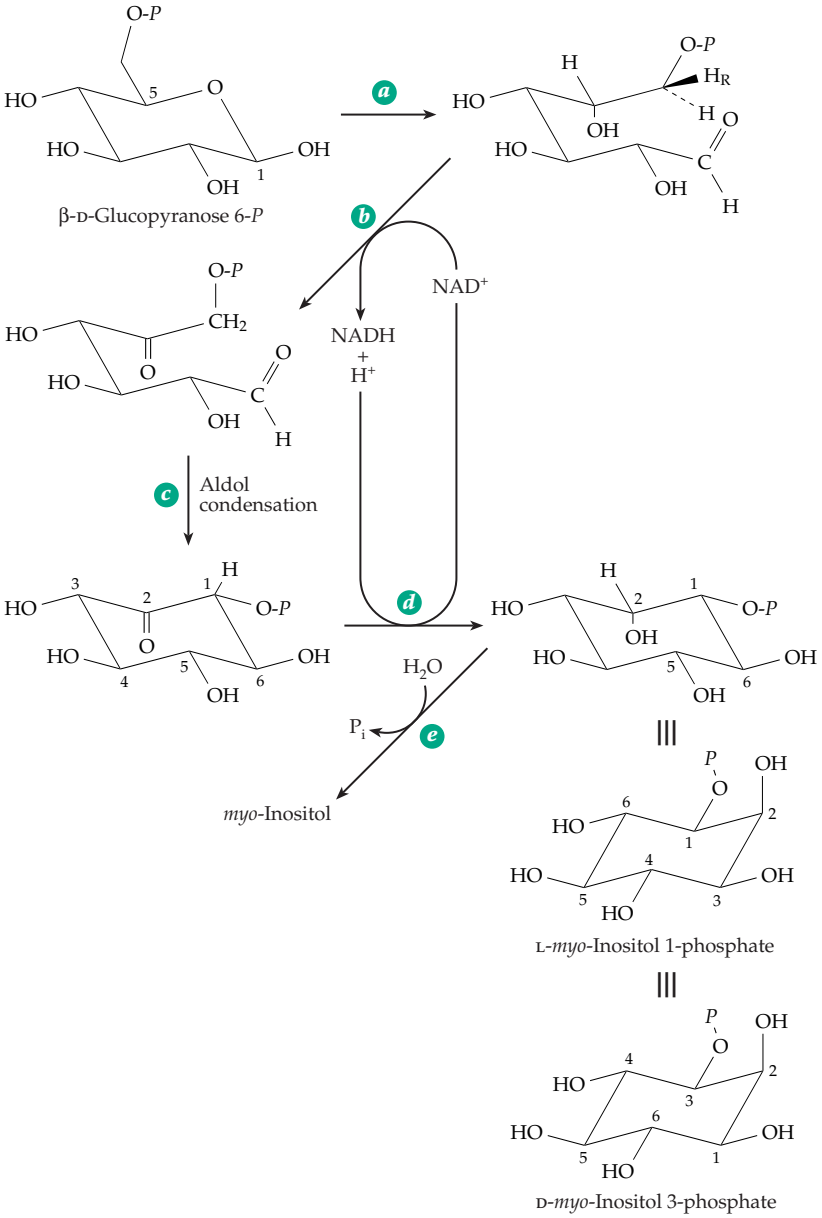
NAD^+. In addition to the two redox steps (Eq. 20-2, *b* and *d*), this enzyme catalyzes both the conversion of the β anomer of glucose 6-*P* to the open-chain aldehyde form and the internal aldol condensation of Eq. 20-2, step *c*.[18-19b] The pro-*R* hydrogen at C-6 of glucose 1-*P* is lost in step *b* while the pro-*S* hydrogen is retained.[20] The ring numbering system is different for glucose and for the inositols, C-5 of glucose 1-*P* becoming C-2 of L-*myo*-inositol. Since *myo*-inositol contains a plane of symmetry D- and L- forms are identical. However, they are numbered differently (Eq. 20-2). The phosphoinositides and inositol polyphosphates are customarily numbered as derivatives of D-*myo*-inositol.

Synthesis of inositol by animals is limited and *myo*-inositol is sometimes classified as a vitamin. Mice grow poorly and lose some of their hair if deprived of dietary inositol. Various phosphate esters of inositol occur in nature. For example, large amounts of the hexaphosphate (**phytic acid**) are present in grains, usually as the calcium or mixed Ca^{2+}–Mg^{2+} salts known as **phytin**. The two apical cells of the 28-cell larvae of mesozoa (Fig. 1-12A) contain enough magnesium phytate in granular form to account for up to half of the weight of the larvae.[21] Inositol pentaphosphate is an allosteric activator for hemoglobin in birds and turtles (p. 358). Di-*myo*-inositol-1,1'-phosphate is an osmolyte in some hypothermophilic archaea.[19a] Inositol is a component of **galactinol**, the β glycoside of D-galactose with inositol (Eq. 20-15). Galactinol, as well as free inositol, circulates in human blood and in plants and may be a precursor of cell wall polysaccharides. However, in our own bodies the greatest importance for inositol doubtless lies in the inositol-containing phospholipids known as **phosphoinositides** (Figs. 8-2, 11-9, 21-5). Their function in generation of "second messengers" for various hormones is dealt with in Chapters 11 and 21.

A person typically ingests daily about one gram of inositol, some in the free form, some as phosphoinositides, and some as phytin. As much as four grams of inositol per day may be synthesized in the kidneys.[22] Breast milk is rich in inositol and dietary supplementation with inositol has increased survival of premature infants with respiratory distress syndrome.[22] The action of insulin is reported to be improved by administration of D-*chiro*-inositol (p. 998) to women with polycystic ovary syndrome.[22a]



(20-2)

3. D-Glucuronic Acid, Ascorbic Acid, and Xylitol

In bacteria, as well as in animal kidneys,[23] inositol may be converted to D-glucuronic acid (Fig. 20-1) with the aid of an oxygenase. Free glucuronic acid may also be formed by animals from glucose or from UDP-glucose (Fig. 20-2). Within the animal body glucuronic acid can be reduced with NADH (Fig. 20-2, step *a*) to yield **L-gulonic acid**, an aldonic acid that could also be formed by oxidation at the aldehyde end of the sugar **gulose**. Because C-6 of the glucuronic acid has become C-1 of gulonic acid, the latter belongs to the L family of

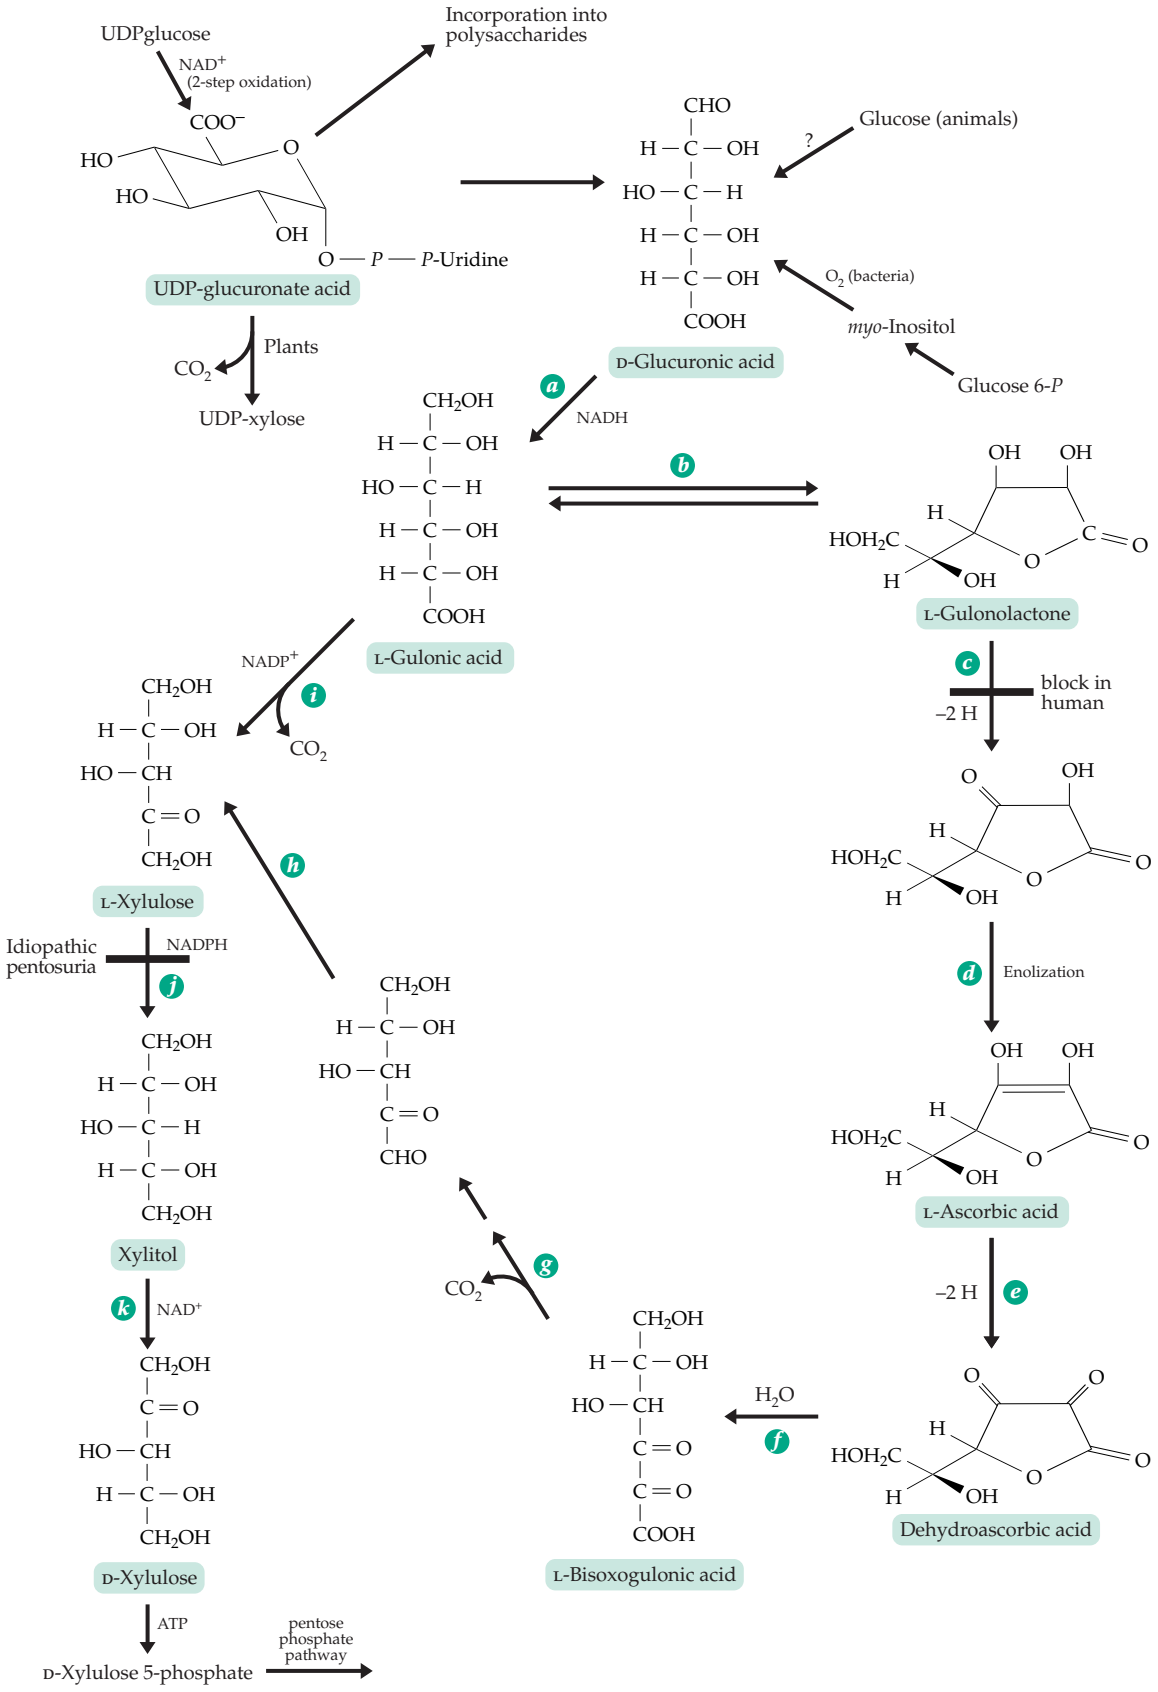


Figure 20-2 Some pathways of metabolism of D-glucuronic acid and of ascorbic acid, vitamin C.

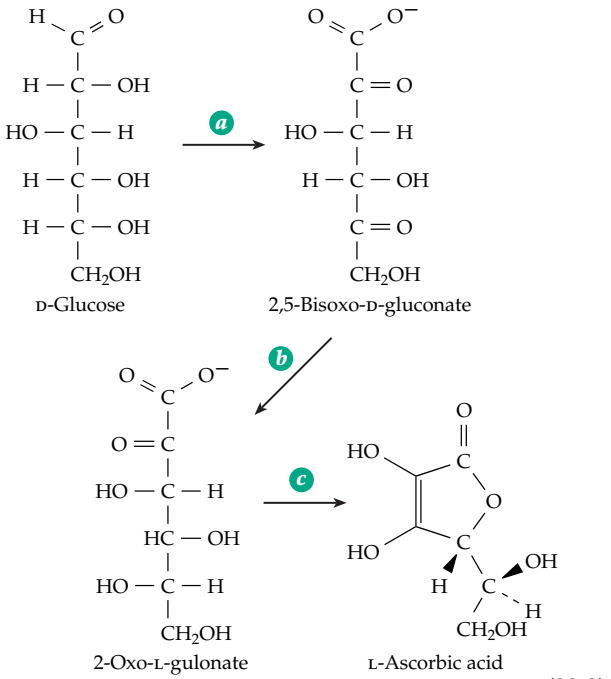
sugars. Gulonic acid can be converted to a cyclic lactone (step *b*) which, in a two-step process involving dehydrogenation and enolization (steps *c* and *d*), is converted to **L-ascorbic acid**. This occurs in most higher animals.[24] However, the dehydrogenation step is lacking in human beings and other primates, in the guinea pig, and in a few other species. One might say that we and the guinea pig have a genetic defect at this point which obliges us to eat relatively large quantities of plant materials to satisfy our bodily needs for ascorbic acid (see Box 18-D). Gulonolactone oxidase is one of the enzymes containing covalently bound 8α-(N^1-histidyl)riboflavin.[25] The defective human gene for this enzyme has been identified, isolated, and sequenced. It is found to have accumulated a large number of mutations, which have rendered it inactive and now only a pseudogene.[26] Mice with an inactivated gulonolactone oxidase have a dietary requirement for vitamin C similar to that of humans. They suffer severe vascular damage on diets marginal in ascorbic acid.[26a] Even in rodents Na^+-dependent ascorbic acid transporters are present in metabolically active tissues to bring the vitamin from the blood into cells.[26b]

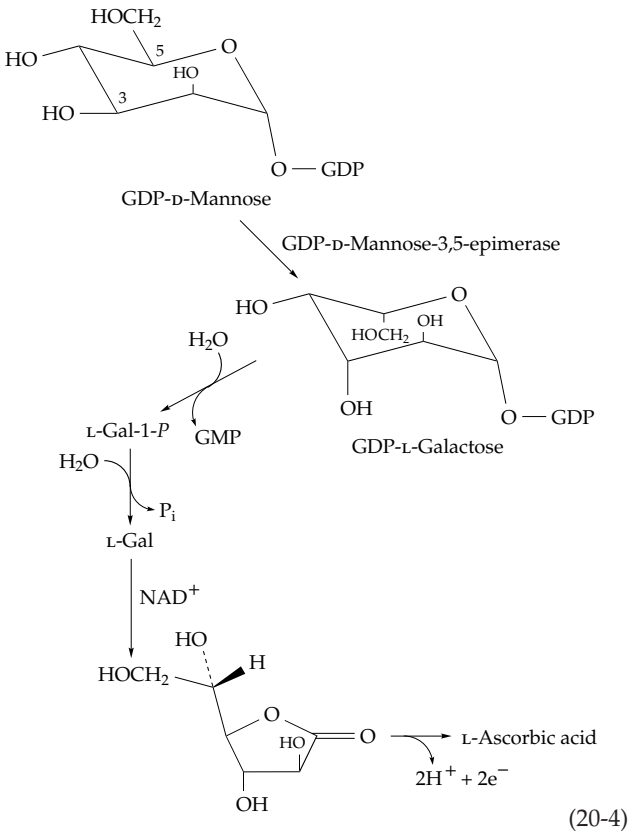
A clever bit of genetic engineering has permitted the conversion of D-glucose to 2-oxo-L-gulonate in the enzymatic sequence of Eq. 20-3, *a*, *b*.



(20-3)

The bacterium *Erwinia herbicola* naturally has the ability to oxidize glucose to 2,5-bisoxo-D-gluconate (Eq. 20-3, step *a*) but cannot carry out the next step, the stereospecific reduction to 2-oxo-L-gulonate. However, a gene encoding a suitable reductase was isolated from a genomic library from *Corynebacterium*. The cloned gene was fused to an *E. coli trp* promoter (see Chapter 28) and was introduced in a multicopy plasmid into *E. herbicola*. The resultant organism can carry out both steps *a* and *b* of Eq. 20-3 leaving only step *c*, a nonenzymatic acid-catalyzed reaction, to complete an efficient synthesis of vitamin C from glucose.[27]

Higher plants make large amounts of L-ascorbate, which in leaves may account for 10% of the soluble carbohydrate content.[28] However, the pathway of synthesis differs from that in Fig. 20-2. Both D-mannose and L-galactose are efficient precursors. The pathway in Eq. 20-4, which starts with GDP-D-mannose and utilizes known enzymatic processes, has been suggested.[28,29] The GDP-D-mannose-3, 5-epimerase is a well documented but poorly understood enzyme. Multistep mechanisms related to that of UDP-glucose 4-epimerase (Eqs. 20-1, 15-14) can be envisioned.

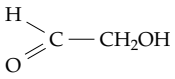


(20-4)

Ascorbic acid is readily oxidized to dehydroascorbic acid (Box 18-D; Fig. 20-2, step *e*), which may be hydrolyzed to L-bisoxogulonic acid (step *f*). The latter, after decarboxylation and reduction, is converted to L-xylulose (steps *g* and *h*), a compound that can also be formed by a standard oxidation and decarboxylation sequence on L-gulonic acid (step *i*). Reduction of xylulose to xylitol and oxidation of the latter with NAD^+ (steps *j* and *k*) produces D-xylulose, which can

be phosphorylated with ATP and enter the pentose phosphate pathways. A metabolic variation produces a condition called **idiopathic pentosuria**. Affected individuals cannot reduce xylulose to xylitol and, hence, excrete large amounts of the pentose into the urine, especially if the diet is rich in glucuronic acid. The "defect" seems to be harmless, but the sugar in the urine can cause the condition to be mistaken for diabetes mellitus.[30]

Xylitol is as sweet as sucrose and has been used as a food additive. Because it does not induce formation of dental plaque, it is used as a replacement for sucrose in chewing gum. It appeared to be an ideal sugar substitute for diabetics. However, despite the fact that it is already naturally present in the body, ingestion of large amounts of xylitol causes bladder tumors as well as oxalate stones in rats and mice. Its use has, therefore, been largely discontinued. A possible source of the problem may lie in the conversion by fructokinase of some of the xylitol to D-xylulose 1-*P*, which can be cleaved by the xylulose 1-*P* aldolase to dihydroxyacetone *P* and glycolaldehyde.

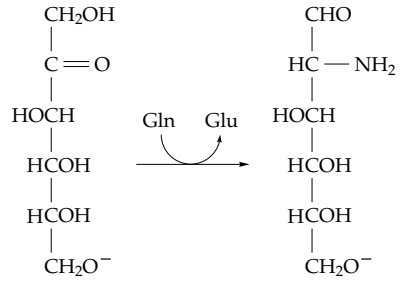


Glycolaldehyde

The latter can be oxidized to oxalate and may also be carcinogenic. As indicated in the upper left corner of Fig. 20-2, UDP-glucuronate can be decarboxylated to UDP-xylose.

4. Transformations of Fructose 6-Phosphate

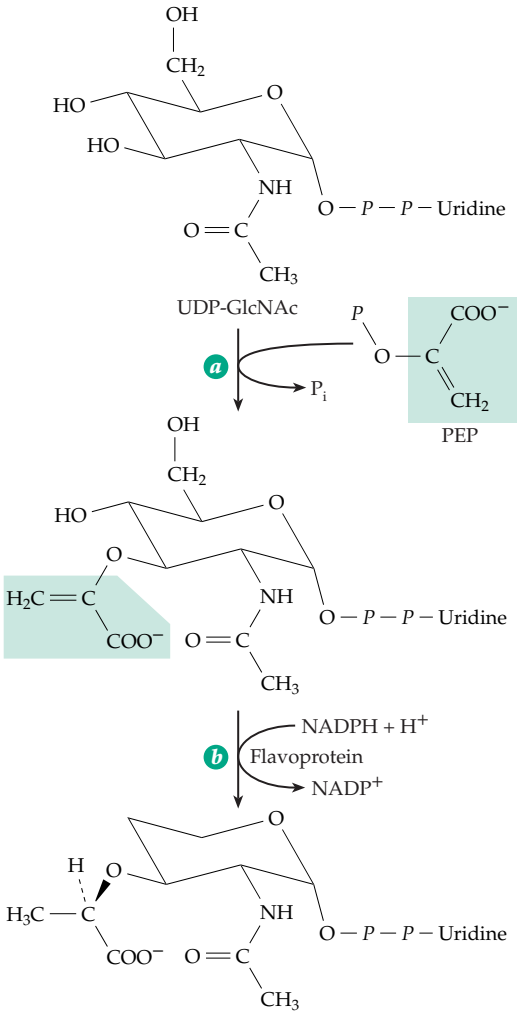
Biosynthesis of **D-glucosamine 6-phosphate** is accomplished by reaction of fructose 6-*P* with glutamine (Eq. 20-5):



Fructose 6-*P* D-Glucosamine 6-*P* (20-5)

Glutamine is one of the principal combined forms of ammonia that is transported throughout the body (Chapter 24). Glucosamine 6-phosphate synthase, which catalyzes the reaction of Eq. 20-5, is an amidotransferase of the N-terminal nucleophile hydrolase superfamily (Chapter 12).[31] It hydrolyzes the amide linkage of glutamine. The released ammonia presumably reacts with the carbonyl group of fructose 6-*P* to form an imine,[32–34a] which then undergoes a reaction analogous to that catalyzed by sugar isomerases.[35] The resulting D-glucosamine 6-*P* is acetylated on its amino group by transfer of an acetyl group,[36] and a mutase moves the phospho group to form *N*-acetylglucosamine 1-*P*. In *E. coli* acetylation occurs on GlcN 1-*P* and is catalyzed by a bifunctional enzyme that also has mutase activity.[37-37b] The resulting *N*-acetylglucosamine 1-*P* is converted to UDP-*N*-acetylglucosamine (UDP-GlcNAc) with cleavage of UTP to inorganic pyrophosphate as in the synthesis of UDP-glucose (Eq. 17-56). Cells of *E. coli* are also able to catabolize glucosamine 6-phosphate. A **deaminase,** with many properties similar to those of GlcN 6-*P* synthase, catalyzes a reaction resembling the reverse of Eq. 20-5 but releasing NH_3.[38,39]

One of the compounds formed from UDP-GlcNAc is **UDP-*N*-acetylmuramic acid**. The initial step in its synthesis is an unusual type of displacement reaction on the α-carbon of PEP by the 3-hydroxyl group of the sugar (Eq. 20-6, step *a*).[40-41c] Inorganic phosphate is



UDP-*N*-acetylmuramic acid (UDP-MurNAc) (20-6)

displaced with formation of an enolpyruvyl derivative of UDP-GlcNAc. This derivative is then reduced by NADPH (Eq. 20-6, step *b*).[42-43a] A second sugar nucleotide formed from UDP-GlcNAc is **UDP-*N*-acetylgalactosamine** (UDP-GalNAc), which may be created by the same 4-epimerase that generates UDP-Gal (Eq. 20-1).[44] Some animal tissues such as kidney and liver also have a **GalNAc kinase** that may salvage, for reuse, GalNAc that arises from the degradation of complex polysaccharides.[44] Bacteria may dehydrogenate UDP-GalNAc to UDP-*N*-acetylgalactosaminuric acid (UDP-GalNAcA).[44a]

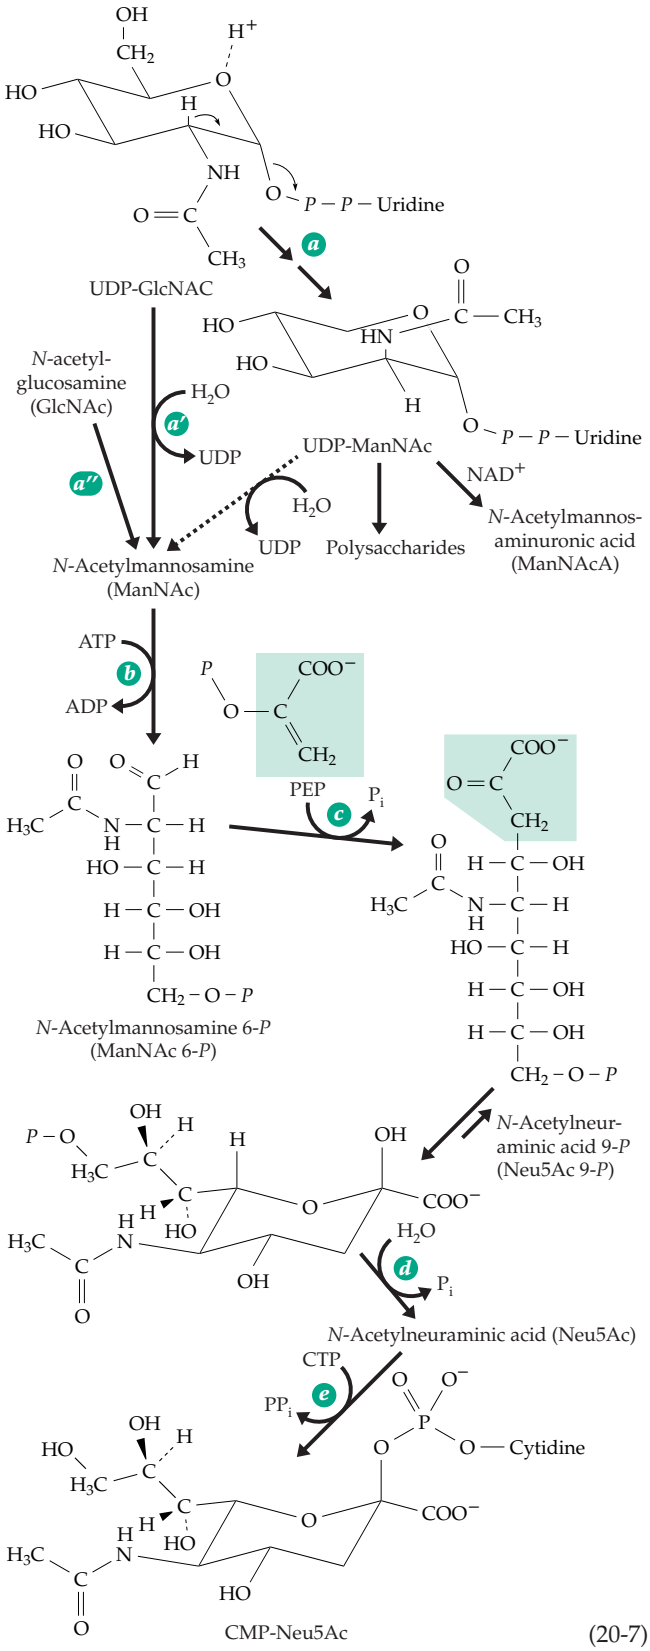
UDP-GlcNAc can be converted to UDP-*N*-acetylmannosamine (UDP-ManNAc) with concurrent elimination of UDP (Eq. 20-7).[45–47b] This unusual epimerization occurs without creation of an adjacent carbonyl group that would activate the 2-H for removal as a proton. As indicated by the small arrows in Eq. 20-7, step *a*′, the UDP is evidently eliminated. In a bacterial enzyme it remains in the E–S complex and is returned after a conformational change involving the acetamido group. This allows the transient C1–C2 double bond to be protonated from the opposite side (Eq. 20-7, step *a*).[47] In bacteria the UDP-ManNAc may be dehydrogenated to UDP-*N*-acetylmannos-aminuronic acid (ManNAcA). Both ManNAc and ManNAcA are components of bacterial capsules.[47]

In mammals the epimerase (Eq. 20-7, step *a*′) probably utilizes a similar chemical mechanism but eliminates UDP and replaces it with HO^- to give free *N*-acetylmannosamine, which is then phosphorylated on the 6-hydroxyl (Eq. 20-7, step *b*). ManNAc may also be formed from free GlcNAc by another 2-epimerase (step a″).[47c,d]

5. Extending a Sugar Chain with Phosphoenolpyruvate (PEP)

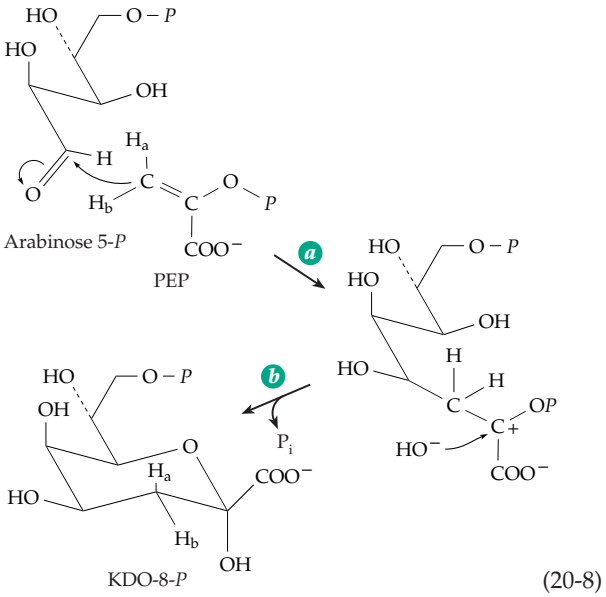
The six-carbon chain of ManNAc 6-*P* can be extended by three carbon atoms using an aldol-type condensation with a three-carbon fragment from PEP (Eq. 20-7, step *c*) to give ***N*-acetylneuraminic acid** (sialic acid).[48] The nine-carbon chain of this molecule can cyclize to form a pair of anomers with 6-membered rings as shown in Eq. 20-7. In a similar manner, arabinose 5-*P* is converted to the 8-carbon **3-deoxy-D-*manno*-octulosonic acid** (**KDO**) (Fig. 4-15), a component of the lipopolysaccharide of gram-negative bacteria (Fig. 8-30), and D-Erythrose 4-*P* is converted to 3-deoxy-D-*arabino*-heptulosonate 7-*P*, the first metabolite in the shikimate pathway of aromatic synthesis (Fig. 25-1).[48a] The arabinose-*P* used for KDO synthesis is formed by isomerization of D-ribulose 5-*P* from the pentose phosphate pathway, and erythrose 4-*P* arises from the same pathway.

The mechanism of the aldol condenstion that



(20-7)

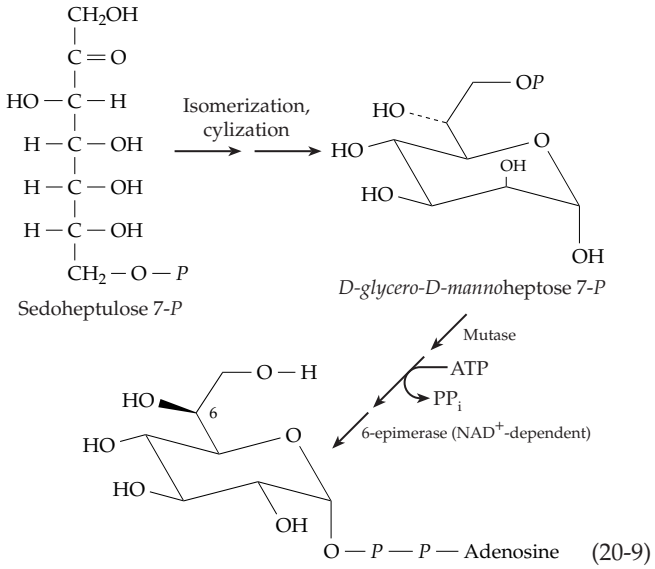
forms these sugars is somewhat unexpected. A reactive enolate anion can be formed from PEP by hydrolytic attack on the phospho group with cleavage of the O–P bond. However, in reactions such as step *a* of



(20-8)

Eq. 20-6, step *c* of Eq. 20-7,and also in EPSP synthase (Eq. 25-4) the initial condensation does not involve O–P cleavage. NMR studies of the action of KDO synthase reveal that the C–O bond of PEP is cleaved as is indicated in Eq. 20-8.[49-52b] The *si* face of PEP faces the *re* face of the carbonyl group of the sugar phosphate. A carbanionic center is generated at C-3 of PEP with possible participation of the phosphate oxygen as well as electrostatic stabilization of the carbocation formed in step *a*. Ring closure (step *b*) occurs with loss of P_i. The immediate product of the aldol condensation, in Eq. 20-7, is *N*-acetylneuraminic acid 9-phosphate, which is cleaved through phosphatase action (step *d*) and is activated to the CMP derivative by reaction with CTP (Eq. 20-7,step *e*).[52c] Further alterations may occur. For example, CMP-Neu5Ac is hydroxylated to form CMP-*N*-glycolylneuraminic acid.[53] Furthermore, an additional type of sialic acid, 2-oxo-3-deoxy-D-*glycero*-D-*galacto*-nononic acid (**KDN**), has been found in human developmentally regulated glycoproteins and also in many other organisms.[54-55a] It has an –OH group in the 5-position rather than the acetamido group of the other sialic acids. Like NeuNAc it is activated by reaction with CTP forming CMP-KDN. These activated monosaccharides differ from most others in being derivatives of a CMP rather than of CDP. More than 40 different naturally occuring variations of sialic acid have been identified.[55b]

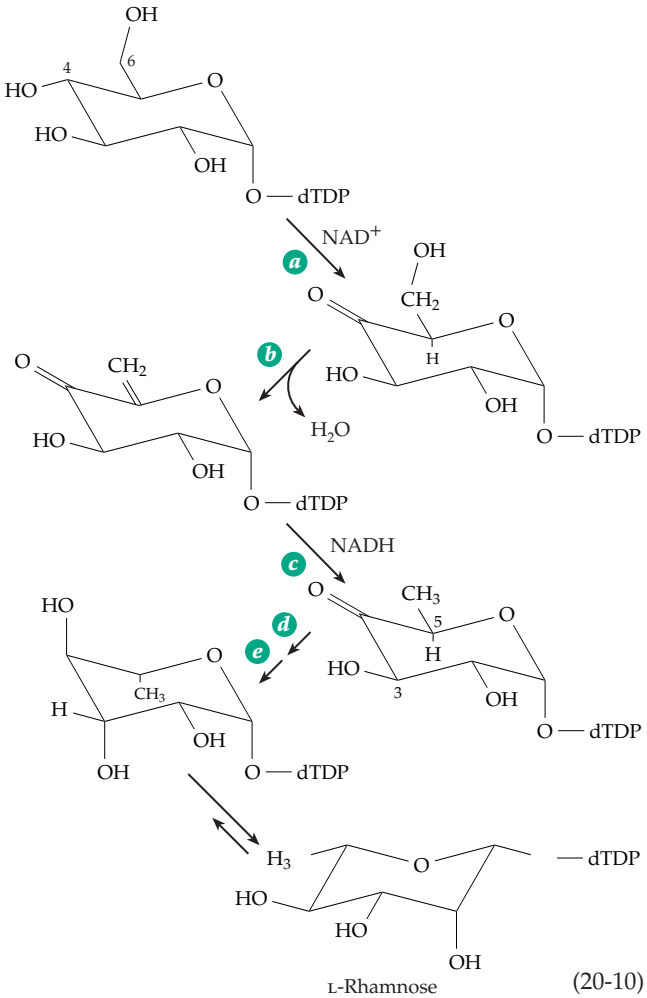
In a similar fashion, KDO is converted to the β-linked **CMP-KDO**,[56-56b] which is incorporated into lipid A as shown in Fig. 20-10. The ADP derivative of the **L-*glycero*-D-*manno*-heptose** (Fig. 4-15), which is also present in the lipopolysaccharide of gram-negative bacteria, is formed from sedoheptulose 7-*P* in a five-step process (Eq. 20-9).[57-58b]



(20-9)

6. Synthesis of Deoxy Sugars

Metabolism of sugars often involves dehydration to α,β-unsaturated carbonyl compounds. An example is the formation of 2-oxo-3-deoxy derivatives of sugar acids (Eq. 14-36). Sometimes a carbonyl group is



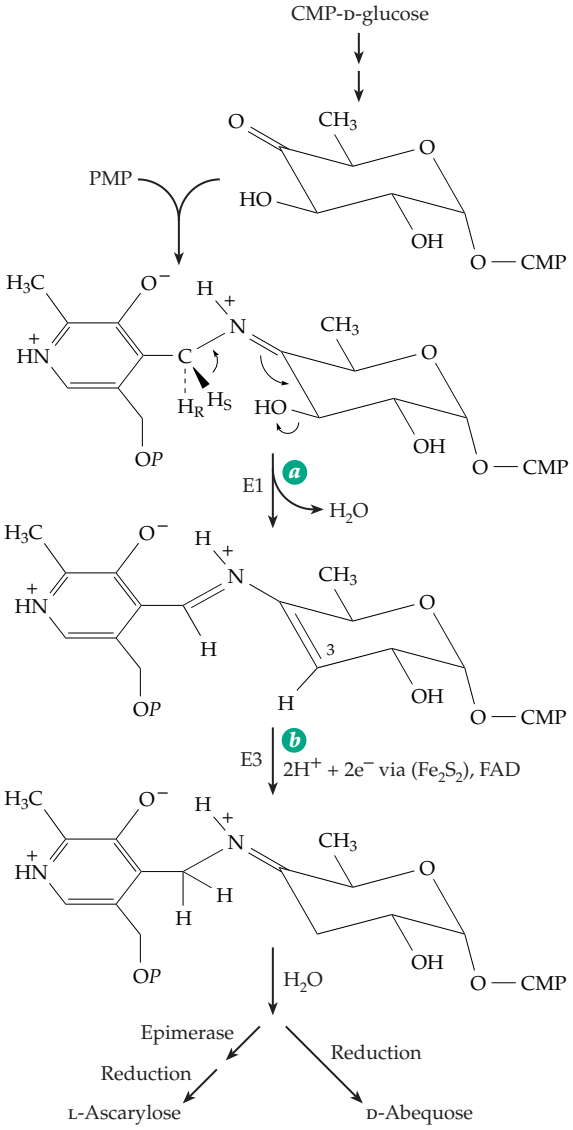
(20-10)

created by oxidation of an –OH group, apparently for the sole purpose of promoting dehydration. For example, the biosynthesis of L-rhamnose from D-glucose is a multistep process (Eq. 20-10) that takes place while the sugars are attached to deoxythymidine diphosphate.[59,59a,b] Introduction of the carbonyl group by dehydrogenation with tightly bound NAD^+ (Eq. 20-10, step *a*) is followed by dehydration (step *b*).[59c,d] To complete the sequence, the double bond formed by dehydration is reduced (step *c*) by the NADH produced in step *a*. A separate enzyme, a 3,5-epimerase catalyzes inversion at both C-3 and C-5 (step *d*).[59e] Finally, a third enzyme is needed for a second reduction (step *e*) using NADPH.[59f] The biosynthesis of **GDP-L-fucose** from GDP-D-mannose occurs by a parallel sequence.[60-61b]

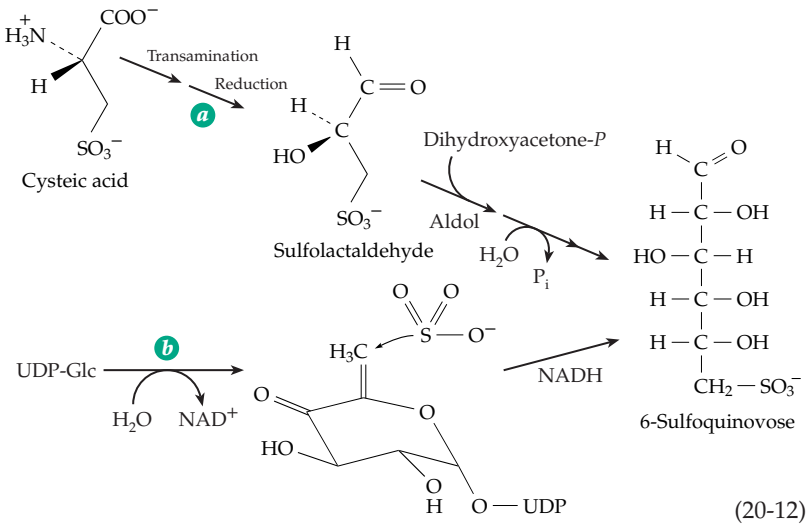
The metabolism of free L-fucose (6-deoxy-L-galactose), which is present in the diet and is also generated by degradation of glycoproteins, resembles the Entner–Doudoroff pathway of glucose metabolism (Eq. 17-18). Similar degradative pathways act on D-arabinose and L-galactose.[60]

Bacterial surface polysaccharides contain a variety of dideoxy sugars. The four 3,6-dideoxy sugars **D-paratose** (3,6-dideoxy-D-glucose), **D-abequose** (3,6-dideoxy-D-galactose), **D-tyvelose** (3,6-dideoxy-D-mannose), and **L-ascarylose** (3,6-dideoxy-L-mannose), whose structures are shown in Fig. 4-15, arise from CDP-glucose.[60a] This substrate is first converted, in reactions parallel to the first three steps of Eq. 20-10, to 4-oxo-6-deoxy-CDP-glucose which reacts in two steps with pyridoxamine 5'-phosphate (PMP) and NADH (Eq. 20-11). This unusual reaction[62–65] is catalyzed by a two-enzyme complex. The first component, E1, catalyzes the formation of a Schiff base of the substrate with PMP and a transamination, which also accomplishes dehydration, to give an unsaturated sugar ring (Eq. 20-11, step *a*). The protein also contains an Fe_2S_2 center suggesting a possible one-electron transfer. The second component, E_3, contains both an Fe_2S_2 plant type ferredoxin center and bound FAD.[65] Observation by EPR spectroscopy revealed accumulation of an organic free radical[64] that may be an intermediate in step *b* of Eq. 20-11. Hydrolysis, epimerization at C-5, and reduction yields L-ascarylose. A similar reaction sequence without the last epimerization would yield D-abequose. CDP-D-tyvelose arises by C-2 epimerization of CDP-D-paratose.[65a] Other unusual sugars[66–68] are formed from intermediates in Eq. 20-11. One is a **3-amino-3,4,6-trideoxyhexose** in which the amino group has been provided by transamination[67] (see also Box 20-B).

The unusual sulfur-containing sugar **6-sulfoquinovose** is present in

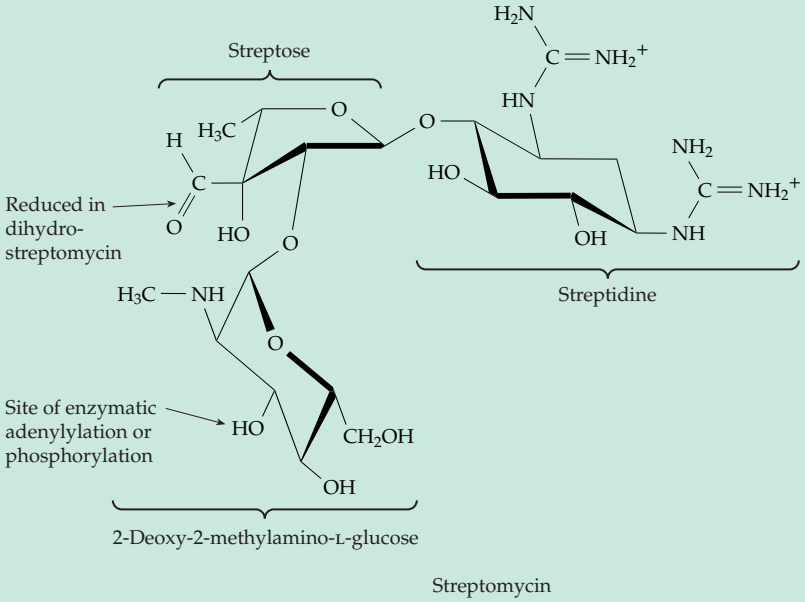


(20-11)

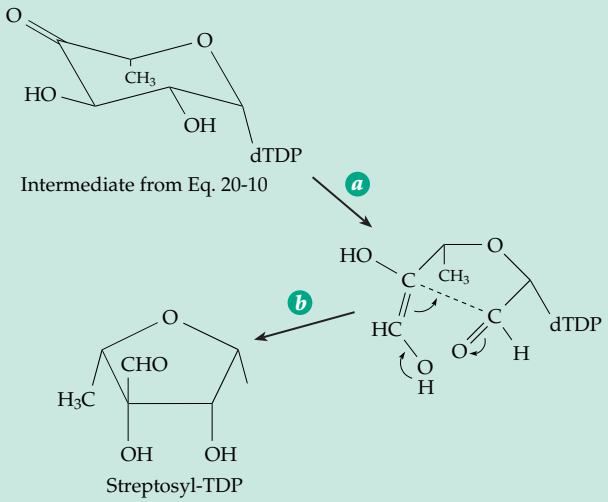


(20-12)

BOX 20-B THE BIOSYNTHESIS OF STREPTOMYCIN

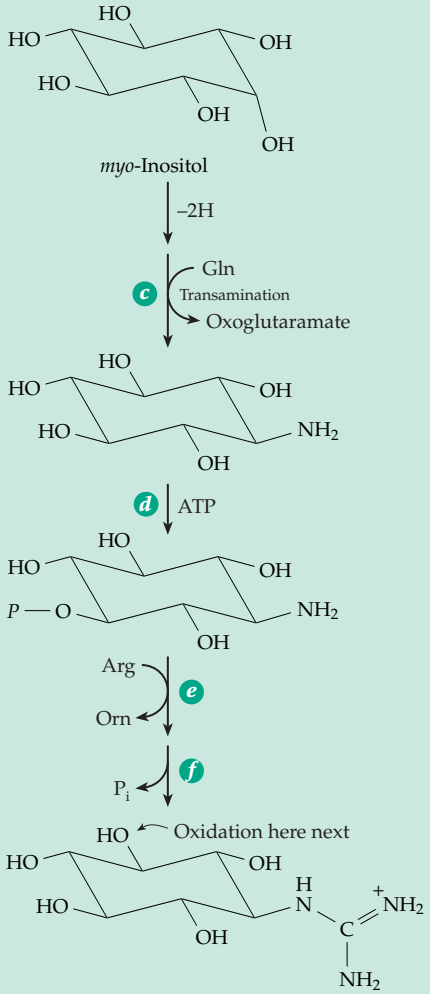


Streptomycin, the kanamycins, neomycins, and gentamycins form a family of medically important **aminoglycoside antibiotics**.[a] They are all water-soluble basic carbohydrates containing three or four unusual sugar rings. D-Glucose is a precursor of streptomycin, all three rings being derived from it. While the route of biosynthesis of 2-deoxy-2-methylamino-L-glucose is not entirely clear, the pathways to L-streptose and streptidine, the other two rings, have been characterized.[b–d] The starting material for streptidine synthesis is a nucleoside diphosphate sugar, which is an intermediate in the synthesis of L-rhamnose (Eq. 20-10). The carbon–carbon chain undergoes an aldol cleavage as shown in step *a* of the following equation:



The ring-open product is written here as an enediol, which is able to recyclize in an aldol condensation (step *b*) to form a five-membered ring with a branch at C-3. The L-streptosyl nucleoside diphosphate formed in this way serves as the donor of streptose to streptomycin.

The basic cyclitol streptidine is derived from *myo*-inositol, which has been formed from glucose 6-*P* (Eq. 20-2). The guanidino groups are introduced by oxidation of the appropriate hydroxyl group to a carbonyl group followed by transamination from a specific amino donor. In the first step, illustrated by the following equation, glutamine is the amino donor for the transamination, the oxoacid product being α-oxoglutaramic acid.



BOX 20-B THE BIOSYNTHESIS OF STREPTOMYCIN (continued)

The amino group on the ring now receives an amidine group, which is transferred from arginine by nucleophilic displacement[e] in a reaction resembling that in the synthesis of urea (see Fig. 24-10, step *h*). However, there is first a phosphorylation at the 2 position. After the amidine transfer has occurred to form the guanidino group, the phospho group is hydrolyzed off by a phosphatase. This is another phosphorylation–dephosphorylation sequence (p. 977) designed to drive the reaction to completion in the desired direction. The second guanidino group is introduced in an analogous way by oxidation at the 3 position followed by transamination, this time with the amino group being donated by alanine. Again, a phosphorylation is followed by transfer of an amidine group from arginine. The final hydrolytic removal of the phospho group (which this time is added at C-6) does not occur until the two other sugar rings have been transferred on from nucleoside diphosphate precursors to form streptomycin phosphate.

As with other antibiotics,[f–i] streptomycin is subject to inactivation by enzymes encoded by genetic resistance factors (Chapter 26). Among these are enzymes that transfer phospho groups or adenylyl groups onto streptomycin at the site indicated by the arrow in the structure.[j,k] Thus, dephosphorylation at one site generates the active antibiotic as the final step in the biosynthesis, while phosphorylation at another site inactives the antibiotic.

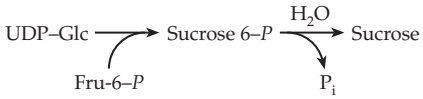
the sulfolipid of chloroplasts (p. 387).[69] A possible biosynthetic sequence begins with transamination of cysteic acid to 3-sulfopyruvate, reduction of the latter to sulfolactaldehyde, and aldol condensation with dihydroxyacetone-*P* as indicated in Eq. 20-12a.[70] See also Eq. 24-47 and Fig. 4-4. However, biosynthesis in chloroplasts appears to start with action of a 4,6-dehydratase on UDP-glucose followed by addition of sulfite and reduction (Eq. 20-12*b*).[70a,b] The sulfite is formed by reduction of sulfate via adenylyl sulfate (Fig. 24-25). However, biosynthesis in chloroplasts appears to start with action of a 4,6-dehydratase on UDP-glucose followed by addition of sulfite and reduction (Eq. 20-12*b*).[70a,b] The sulfite is formed by reduction of sulfate via adenylyl sulfate (Fig. 24-25).

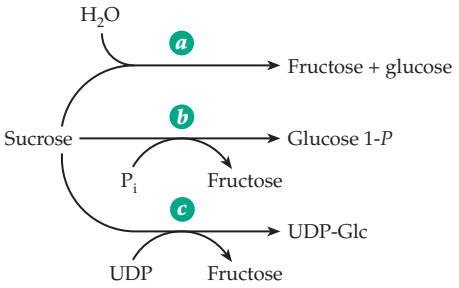
B. Synthesis and Utilization of Oligosaccharides

Our most common food sugar **sucrose** is formed in all green plants and nowhere else. It is made both in the chloroplasts and in the vicinity of other starch deposits. It serves both as a transport sugar and, dissolved within vacuoles, as an energy store. Sucrose is very soluble in water and is chemically inert because the hemiacetal groups of both sugar rings are blocked. However, sucrose is thermodynamically reactive, the glucosyl group having a group transfer potential of 29.3 kJ mol^{-1}. It is extremely sensitive toward hydrolysis catalyzed by acid. Transport of sugar in the form of a disaccharide provides an advantage to plants in that the disaccharide has a lower osmotic pressure than would the same amount of sugar in monosaccharide form.

Biosynthesis of sucrose[71,71a] utilizes both UDP-glucose and fructose 6-*P* (Eq. 20-13). Reaction of UDP-glucose with fructose can also occur to give sucrose directly.[72] Because this reaction is reversible, sucrose serves as a source of UDP-glucose for synthesis of cellulose and other polysaccharides in plants. Metabolism of sucrose in the animal body begins with the action of **sucrase** (invertase), which hydrolyzes the disaccharide to fructose and glucose (Eq. 20-14, step *a*). The same enzyme is also found in higher plants and fungi. Mammalian sucrase is one of several carbohydrases that are anchored to the external surfaces of the microvilli of the small intestines. Sucrose is bound



(20-13)



(20-14)

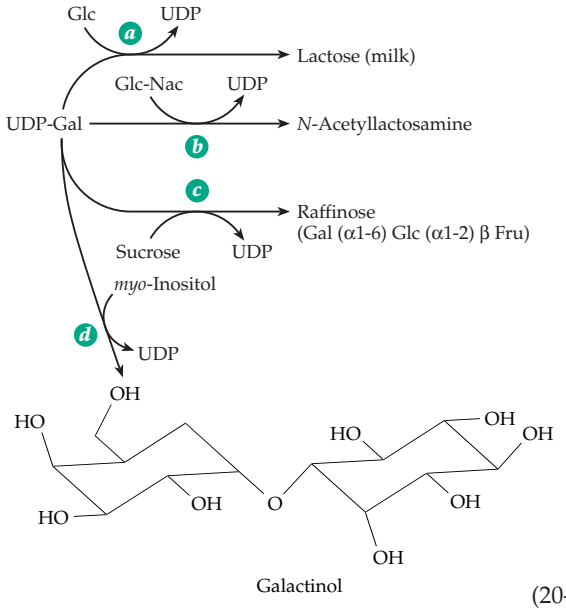
tightly but noncovalently to **isomaltase,** which hydrolyzes the α-1,6-linked isomaltose and related oligosaccharides. A nonpolar N-terminal segment of the isomaltase anchors the pair of enzymes to the microvillus membrane. The two-protein complex arises naturally because the two enzymes are synthesized as a single polypeptide, which is cleaved by intestinal proteases.[73,74]

Because of the relatively high group transfer potential of either the glucosyl or fructosyl parts, sucrose is a substrate for glucosyltransferases such as sucrose phosphorylase (Eq. 20-14, step *b*; see also Eq. 12-7 and associated discussion). In certain bacteria this reaction makes available the activated glucose 1-*P* which may enter catabolic pathways directly. Cleavage of sucrose for biosynthetic purposes can occur by reaction 20-14, step *c*, which yields UDP-glucose in a single step.

A disaccharide with many of the same properties as sucrose is **trehalose,** which consists of two α-glucopyranose units in 1,1 linkage (p. 168). The biosynthetic pathway from UDP-glucose and glucose 6-*P* parallels that for synthesis of sucrose (Eq. 20-13).[75,76] In *E. coli* the genes for the needed glucosyltransferase and phosphatase are part of a single operon. Its transcription is controlled in part by glucose-mediated catabolite repression (Chapter 28) and also by a repressor of the Lac family.[76,76a,77] The repressor is allosterically activated by trehalose 6-*P*, the intermediate in the synthesis. Trehalose formation in bacteria, fungi, plants, and microscopic animals is strongly induced during conditions of high osmolality (see Box 20-C).[77] Both trehalose and maltose can also be taken up via an ABC type transporter (p. 417).[77a,b]

Lactose, the characteristic sugar of milk, is formed by transfer of a galactosyl unit from UDP-galactose directly to glucose (Eq. 20-15, reaction *a*). The similar transfer of a galactosyl unit to *N*-acetylglucosamine to form *N*-acetyllactosamine (Eq. 20-15, reaction *b*) occurs in many animal tissues. An interesting regulatory mechanism is involved. The transferase catalyzing Eq. 20-15, reaction *b*, forms a complex with **α-lactalbumin** to become **lactose synthase**,[78–80b] the enzyme that catalyzes reaction *a*. Lactalbumin was identified as a milk constituent long before its role as a regulatory protein was recognized.

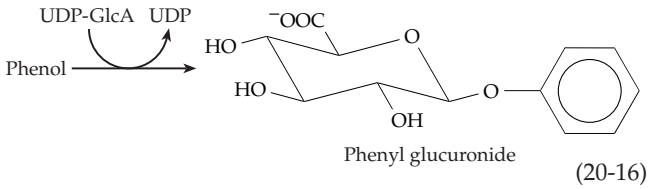
A very common biochemical problem is intolerance to lactose.[81] This results from the inability of the intestinal mucosa to make enough **lactase** to hydrolyze the sugar to its monosaccharide components galactose and glucose. Among most of the peoples of the earth only infants have a high lactase level, and the use of milk as a food for adults often leads to a severe diarrhea. The same is true for most animals. In fact, baby seals and walruses, which drink lactose-free milk, become very ill if fed cow's milk.



(20-15)

The plant trisaccharide **raffinose** arises from UDP-galactose by transfer of a galactosyl unit onto the 6-hydroxyl of the glucose ring of sucrose (Eq. 20-15, reaction *c*). Transfer of a galactosyl unit onto *myo*-inositol (Eq. 20-15, reaction *d*) produces **galactinol**, whose occurrence is widespread within the plant kingdom. Galactinol, in turn, can serve as a donor of activated galactosyl groups. Thus, many plants contain **stachyose** and higher homologs, all of which are formed by transfer of additional α-D-galactosyl units onto the 6-hydroxyl of the galactose unit of raffinose. These sugars appear to serve as antifreeze agents in the plants. The concentration of stachyose in soy beans can be as high as that of sucrose. Some seeds, e.g., those of maize, are coated with a glassy sugar mixture of sucrose and raffinose in a ratio of ~3:1.[81a]

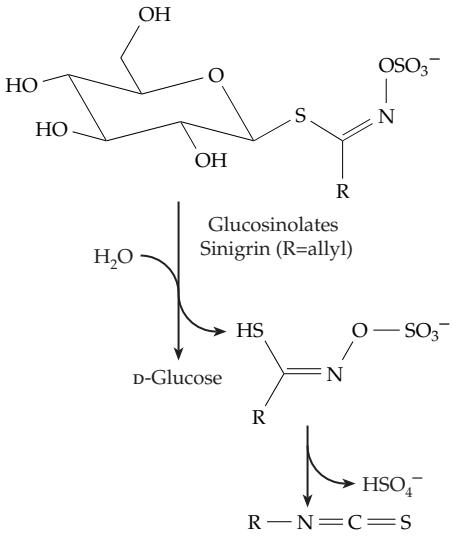
Besides the oligosaccharides, living organisms form a great variety of glycosides that contain nonsugar components. Among these are the **glucuronides** (glucosiduronides), excretion products found in urine and derived by displacement of UDP from UDP-glucuronic acid by such compounds as phenol, benzoic acid, and sterols.[81b,c] Phenol is converted to phenyl glucuronide (Eq. 20-16), while benzoic acid (also excreted in part as hippuric acid, Box 10-A) yields an ester by the same type of displacement reaction. Many other aromatic or aliphatic compounds containing –OH, –SH, $-NH_2$, or $-COO^-$ groups also form glucuronides.[82]



Phenyl glucuronide (20-16)

Among these is bilirubin (Fig. 24-24). UDP-glucuronosyltransferases responsible for their synthesis are present in liver microsomes.

Among the many glycosides and glycosylamines made by plants are the anthocyanin and flavonoid pigments of flowers (Box 21-E), cyanogenic glycosides such as amygdalin (Box 25-B), and antibiotics (e.g., see Box 20-B).[83,84] Some are characteristic of certain families of plants. For example, more than 100 β-thioglucosides known as **glucosinolides** are found in the Cruciferae (cabbages, mustard, rapeseed). The compounds impart the distinctive flavors and aromas of the plants. However, some are toxic and may cause goiter or liver damage. The enzyme **myrosinase** hydrolyzes these compounds releasing isothiocyanates, thiocyanates, and nitriles (Eq. 20-17).[85-86a] L-Ascorbate acts as a cofactor for this enzyme, evidently providing a catalytic base.[86a]



(20-17)

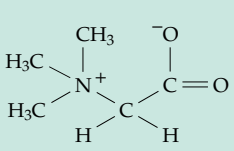
BOX 20-C OSMOTIC ADAPTATION

Bacteria, plants of many kinds, and a variety of other organisms are forced to adapt to conditions of variable osmotic pressure.[a,b] For example, plants must resist drought, and some must adapt to increased salinity. Some organisms live in saturated brine ~6 M in NaCl.[c] The **osmotic pressure** Π in dilute aqueous solutions is proportional to the total molar concentration of solute particles, c_s, as follows.

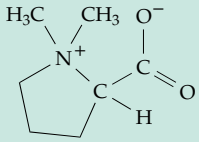
$\Pi = RTc_s$ where R is the gas constant and T the Kelvin temperature

At higher solute concentrations c_s must be replaced by the "effective molar concentration," which is called **osmolarity** (OsM) and has units of molarity (see Record *et al.* for discussion).[b] An osmolarity difference across a membrane of 0.04 OsM results in a turgor pressure of ~ 1 atmosphere. To adapt to changes in the environmental osmolarity organisms must alter their internal solute concentrations.

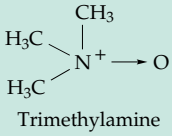
Cells of *E. coli* can adapt to at least 100-fold changes in osmolarity. Because of the porosity of the bacterial outer membrane the osmolarity of the periplasmic space is normally the same as that of the external medium. However, the inner membrane is freely permeable only to water and a few solutes such as glycerol.[b] The bacterial cells avoid loss of water when the external osmolarity is high by accumulating K^+ together with anions such as glutamate⁻ and nonionic **osmoprotectants** such as trehalose, sucrose, and oligosaccharides. *E. coli* cells will also take up other osmoprotectants such as **glycine betaine**, dimethylglycine, choline, proline, and proline betaine. Some methanogens accumulate N^{ε}-acetyl-β-lysine as well as glycine betaine.[d]



Betaine (glycine betaine)



Proline betaine



Trimethylamine *N*-oxide

Functioning in a somewhat different way in *E. coli* are 6- to 12-residue **periplasmic membrane-derived oligosaccharides**. These are β-1,2- and β-1,6-linked glucans covalently linked to *sn*-1-phosphoglycerol, phosphoethanolamine, or succinate (see Fig. 8-28).[b,e,f] They accumulate in the periplasm when cells are placed in a medium of low osmolarity. The resulting increased turgor in the periplasm is thought to buffer the cytoplasm against the loss of external osmolarity and to protect the periplasmic space from being eliminated by expansion of the plasma membrane. Related cyclic glucans, which are attached to *sn*-1-phosphoglycerol or *O*-succinyl ester residues, are accumulated by rhizobia.[g]

C. Synthesis and Degradation of Polysaccharides

Polysaccharides are all formed by transfer of glycosyl groups onto initiating molecules or onto growing polymer chains. The initiating molecule is usually a glycoprotein. However, let us direct our attention first to the growth of polysaccharide chains. The glycosyl are transferred by the action of glycosyltransferases from substrates such as UDP-glucose, other sugar nucleotides, and sometimes sucrose. The glycosyltransferases act by mechanisms discussed in Chapter 12 and are usually specific with respect both to substrate structure and to the type of linkage formed.

1. Glycogen and Starch

The bushlike glycogen molecules grow at their numerous nonreducing ends by the transfer of glucosyl units from UDP-glucose (Eq. 17-56)[87,87a] or in bacteria from ADP-glucose.[88–90] Utilization of glycogen by the cell involves removal of glucose units as glucose 1-*P* by the action of glycogen phosphorylase. The combination of growth and degradation from the same chain ends provides a means of rapidly storing and utilizing glucose units. The synthesis and breakdown of glycogen in mammalian muscle (Fig. 11-4) involves one of the first studied[91] and best known metabolic control systems. Various aspects have been discussed in Chapters 11, 12, and 17. The mechanism[92] and regulatory features[93–96b] have been described. An important recent development is the observation of glycogen concentrations in human muscles *in vivo* with ^{13}C NMR. This can be coupled with observation of glucose 6-*P* by ^{31}P NMR. The concentration of the latter is ~ 1 mM but increases after intense exercise.[94]

Glycogen phosphorylase and glycogen synthase alone are insufficient to synthesize and degrade glycogen. Synthesis also requires the action of the **branching enzyme** amylo-(1,4 → 1,6-transglycosylase,[97]

BOX 20-C (continued)

Fungi, green algae, and higher plants more often accumulate glycerol,[h,i] sorbitol, sucrose,[j] trehalose,[k] or proline.[a,l,m] These compounds are all "compatible solutes" which tend not to disrupt cellular structure.[n] Betaines and proline are especially widely used by a variety or organisms. How is it then that some desert rodents, some fishes, and other creatures accumulate **urea**, a well-known protein denaturant? The answer is that they also accumulate methylamine or trimethylamine *N*-oxide in an approximately 2:1 ratio of urea to amine. The mixture of compounds is compatible, the stabilizing effects of the amines offsetting the destabilizing effect of urea.[c,o]

Adaptation to changes in osmotic pressure involves sensing and signaling pathways that have been partially elucidated for *E. coli*[p] and yeasts.[i,q] Major changes in structure and metabolism may result. For example, in *E. coli* the outer membrane porin OmpF (Fig. 8-20) is replaced by OmpC (osmoporin), which has a smaller pore.[r]

A "resurrection plant" that normally contains an unusual 2-octulose converts this sugar almost entirely into sucrose when desiccated. This is one of a small group of plants that are able to withstand severe desiccation but can, within a few hours, reverse the changes when rehydrated.[j]

an enzyme with dual specificity. After the chain ends attain a length of about ten glucose units, the branching enzyme attacks a 1,4-glycosidic linkage somewhere in the chain. Acting much as does a hydrolase, it forms a glycosyl enzyme or a stabilized carbocation intermediate. The enzyme does not release the severed chain fragment but transfers it to another nearby site on the glycogen molecule. There the enzyme rejoins the bound oligosaccharide chain that it carries to a free 6-hydroxyl group of the glycogen creating a new branch attached in α-1,6-linkage. Degradation of glycogen requires **debranching** after the long nonreducing ends of the polysaccharide have been shortened until only four glycosyl residues remain at each branch point. This is accomplished by **amylo-1,6-glucosidase / 4- α-glucanotransferase**. This 165-kDa bifunctional enzyme transfers a trisaccharide unit from each branch end to the main chain and also removes hydrolytically the last glucosyl residue at each branch point.[98-99a]

How are new glycogen molecules made? There is some evidence that a 37-kDa protein primer **glycogenin** is needed to initiate their formation.[100-101a] Thus, glycogen synthesis may be analogous to that of the glycosaminoglycans considered in Section D,1. Muscle glycogenin is a self-glycosylating protein, which catalyzes attachment of ~7 to 11 glucose units in α–1,4 linkage to the hydroxyl group of Tyr 194. The glucose units are added one at a time and when the chain is long enough it becomes a substrate for glycogen synthase.[100,102] The role of glycogenin in liver has been harder to demonstrate,[103] but a second glycogenin gene, which is expressed in liver, has been identified.[104] Genes for several glycogenins or glycogenin-like proteins have been identified in yeast, *Caenorhabditis elegans*, and *Arabidopsis*.[101a,105]

In contrast to animals, bacteria such as *E. coli* synthesize glycogen via ADP-glucose rather than UDP-glucose.[88] ADP-glucose is also the glucosyl donor for synthesis of starch in plants. The first step in the biosynthesis (Eq. 20-18) is catalyzed by the enzyme ADP-glucose pyrophosphorylase (named for the reverse reaction).

$$\text{Glucose 1-}P + \text{ATP} \rightarrow \text{ADP-glucose} + \text{PP}_i \qquad (20\text{-}18)$$

In bacteria this enzyme is usually inhibited by AMP and ADP and activated by glycolytic intermediates such as fructose 1,6-P_2, fructose 6-P, or pyruvate. In higher plants, green algae, and cyanobacteria the enzyme is usually activated by 3-phosphoglycerate, a product of photosynthetic CO_2 fixation, and is inhibited by inorganic phosphate (P_i).[106–108].

In eukaryotic plants starch is deposited within chloroplasts or in the cytoplasm as granules (Fig. 4-6) in a specifically differentiated and physically fragile plastid, the **amyloplast**.[108–110] Within the granules the starch is deposited in layers ~ 9 nm in thickness. About two-thirds of the thickness consists of nearly crystalline arrays, probably of double helical amylopectin side chains (Figs. 4-7, 4-8, 20-3) with "amorphous" segments between the layers.[111–114] In maize there are at least five starch synthases, one of which forms the straight chain amylose.[115–117] There are also at least three branching enzymes[118] and two or three debranching enzymes.[119,120] As in the synthesis of glycogen the molecules of amylopectin may grow at the many nonreducing ends. A current model, which is related to the broom-like cluster model of French (Fig. 4-7), is shown in Fig. 20-3. The branches are thought to arise, in part, by transglycosylation within the double helical strands. After branching the two chains remain in a double helix but the cut chain can now grow. Only double helical parts of strands pack well in the crystalline layer. A recent suggestion is that debranching enzymes then trim the molecule, removing single-stranded regions.[112]

The location (within the granule) of amylose, which makes up 15–30% by weight of many starches,[121] is uncertain. It may fill in the amorphous layers. It may be cut and provide primer pieces for new amylopectin molecules.[122,122a] Another possibility is that it grows by an insertion mechanism such as that portrayed for cellulose in Fig. 20-5 and is extruded inward from the membrane of the amyloplast. This mechanism might explain a puzzling question about starch. The branched amylopectin presumably grows in much the same way as does glycogen. A branching enzyme transfers part of the growing glycan chain to the $-CH_2-OH$ group of

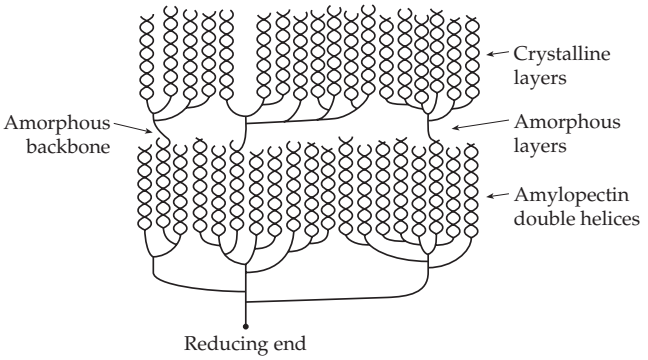

Figure 20-3 Proposed structure of a molecule of amylopectin in a starch granule. The highly branched molecule lies within 9 nm thick layers, about 2 / 3 of which contains parallel double helices of the kind shown in Fig. 4-8 in a semicrystalline array. The branches are concentrated in the amorphous region.[113,114,121] Some starch granules contain no amylose, but it may constitute up to 30% by weight of the starch. It may be found in part in the amorphous bands and in part intertwined with the amylopectin.[122]

BOX 20-D GENETIC DISEASES OF GLYCOGEN METABOLISM

In 1951, B. McArdle described a patient who developed pain and stiffness in muscles after moderate exericse.[a] Surprisingly, this person completely lacked muscle glycogen phosphorylase. Since that time several hundred others have been found with the same defect. Glycogen accumulates in muscle tissue in this disease, one of the several types of **glycogen storage disease**.[b] Severe exercise is damaging, but steady moderate exercise can be tolerated. Until the time of McArdle's discovery, it was assumed that glycogen was synthesized by reversal of the phosphorylase reaction. No hint of the UDP-glucose pathway had appeared, and it was, therefore, not obvious how glycogen could accumulate in the muscles of these patients. Leloir's discovery of UDP-glucose at about the same time provided the answer. Persons with McArdle syndrome are greatly benefitted by a high-protein diet, presumably because amino acids such as alanine and glutamine are converted efficiently to glucose and because branched-chain amino acids may serve as a direct source of muscle energy.[c,d]

Several other rare heritable diseases also lead to accumulation of glycogen because of some block in its breakdown through the glycolysis pathway. The enzyme deficiencies include those of muscle phosphofructokinase,[e] liver phosphorylase kinase, liver phosphorylase, and liver glucose-6-phosphatase. In the last case, glycogen accumulates because the liver stores cannot be released to the blood as free glucose.[b,f,g] This is a dangerous disease because blood glucose concentrations may fall too low at night. The prognosis improved greatly when methods were devised for providing the body with a continuous supply of glucose. The simplest treatment is ingestion of uncooked cornstarch which is digested slowly.[b,h] In one of the storage diseases the branching enzyme of glycogen synthesis is lacking, and glycogen is formed with unusually long outer branches. In another the debranching enzyme is lacking, and only the outer branches of glycogen can be removed readily.[i]

The most serious of the storage diseases involve none of the enzymes mentioned above. Pompe disease is a fatal generalized glycogen storage disease in which a lysosomal α-1,4-glucosidase is lacking. This observation suggested the existence of a new and essential pathway of degradation of glycogen to free glucose in the lysosomes. A few cases of glycogen synthase deficiency have been reported. Little or no glycogen is stored in muscle or liver, and patients must eat at regular intervals to prevent hypoglycemia. Severe diseases in which glycogen synthesis is impaired include deficiencies of the gluconeogenic enzymes pyruvate carboxylase and PEP carboxykinase.

The following tabulation includes deficiencies of glycogen metabolism, glycolysis, and gluconeogenesis.[a] Glycogen storage diseases are often designated as Types I–V and these terms are included.

Deficiency	Organ	Severity
Glycogen phosphorylase (Type V), McArdle disease	Muscle	Moderate, late onset
Glycogen phosphorylase	Liver	Very mild
Phosphorylase kinase	Liver	Very mild
Debranching enzyme (Type III)	Liver	Mild
Lysosomal α-glucosidase (Type II)		Lethal, infant and adult form
Phosphofructokinase	Muscle	Moderate, late onset
Phosphoglycerate mutase[j]	Muscle	Moderate
Pyruvate carboxylase		Lethal
PEP carboxykinase		Lethal
Fructose-1,6-bisphosphatase	Muscle	Severe
Glycogen synthase	Liver	Mild
Branching enzyme (Type IV)		Lethal, liver transplantation
Glucose-6-phosphatase (Type I)		Severe if untreated

a glucose unit in an adjacent polysaccharide chain that lies parallel to the first, possibly in a double helix. Since amylose and amylopectin are intimately intermixed in the starch granules, it seems strange that the branching enzyme never transfers a branch to molecules of the straight-chain amylose. However, if the linear amylose chains are oriented in the opposite direction from the amylopectin chains, the nonreducing ends of the amylose molecules would be located toward the center of the starch granule. Growth could occur by an insertion mechanism at the reducing ends and the ends could move out continually with the amyloplast membrane as the granule grows.[123] Recent evidence from ^{14}C labeling indicates that both amylose and amylopectin too may grow by insertion at the reducing end of glucose units from ADP-glucose.[123a,b] Branching could occur to give the structure of Fig. 20-3. Starch synthesis in leaves occurs by day but at night the starch is degraded by amylases, α-glucosidases, and starch phosphorylase. Both the starch synthases and catabolic enzymes are present within the amyloplasts where they may be associated with regulatory proteins of the 14-3-3 class.[122a]

Digestion of dietary glycogen and starch in the human body begins with the salivary and pancreatic amylases, which cleave α-1,4 linkages at random. It continues with a **glucoamylase** found in the brush border membranes of the small intestine where it occurs as a complex with **maltase**.[74] Carbohydrases are discussed in Chapter 12, Section B.

2. Cellulose, Chitin, and Related Glycans

Cellulose synthases transfer glucosyl units from UDP-glucose, while chitin synthases utilize UDP-*N*-acetylglucosamine. Not only green plants but some fungi and a few bacteria form cellulose. The ameba *Dictyostelium discoideum* also coats its spores with cellulose.[124] Electron microscopic investigations suggest that both in bacteria[125] and in plants[126] multienzyme aggregates located at the plasma membrane synthesize many polymer chains side by side to generate hydrogen-bonded microfibrils which are extruded through the membrane. Both green plants and fungi also form important β-1,3-linked glycans.

The bacterial cellulose synthase from *Acetobacter xylinum* can be solubilized with detergents, and the resulting enzyme generates characteristic 1.7 nm cellulose fibrils (Fig. 20-4) from UDP-glucose.[125,127–129] These are similar, but not identical, to the fibrils of cellulose I produced by intact bacteria.[125,130] Each native fibril appears as a left-handed helix which may contain about nine parallel chains in a crystalline array. Three of these helices appear to coil together (Fig. 20-4) to form a larger 3.7-nm left-handed helical fibril. Similar fibrils are formed by plants. In both

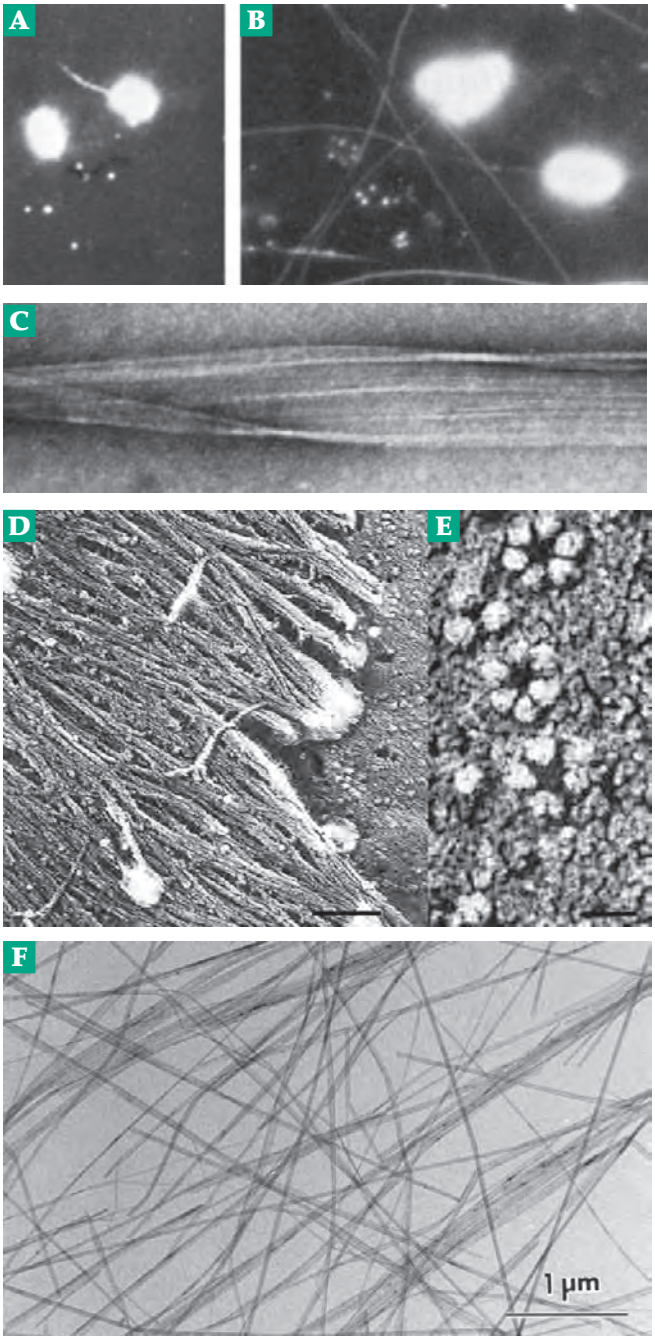

Figure 20-4 Cellulose microfibrils being formed by *Acetobacter xylinum*.[127] (A) Dark-field light micrograph after five minutes of cellulose production (x 1250). (B) After 15 minutes a pellicle of cellulose fibers is forming (x 2000) (C) Negatively stained cellulose ribbon. At the right the subdivision into microfibrils is visible. Courtesy of R. Malcolm Brown, Jr. (D) Cellulose microfibrils overlaying the plasma membrane in the secondary cell wall of a tracheary element of *Zinnia elegans*. Bar = 100 nm. (E) Rosettes in the plasma membrane underlying the cellulose-rich secondary cell wall thickening in *A. elegans*. Bar = 30 nm. (D) and (E) from Haigler and Blanton.[132] Courtesy of Candace H. Haigler. (F) Chitin microfibrils purified from protective tubes of the tube-worm *Lamellibrachia satsuma*.[137] Courtesy of Junji Sugiyama.

bacteria and plants the cellulose I fibrils that are formed are highly crystalline, contain parallel polysaccharide chains (Fig. 4-5), and have the tensile strength of steel. Electron micrographs show that the cell envelope of *A. xylinum* contains 5–80 pores, through which the cellulose is extruded, lying along the long axis of the cell.[129] The biosynthetic enzymes are probably bound to the plasma membrane. Similar, but more labile, cellulose synthases are present in green plants.[131] In *Arabidopsis* there are ten genes. The encoded cellulose synthases appear to be organized as rosettes on some cell surfaces (Fig. 20-4E).[131a-133a] The rosettes may be assembled to provide parallel synthesis of ~36 individual cellulose chains needed to form a fibril.[131a]

Because of the insolubility of cellulose fibrils it has been difficult to determine whether they grow from the reducing ends or the nonreducing ends of the chains. From silver staining of reducing ends and micro electron diffraction of cellulose fibrils attached to bacteria,[134] Koyama *et al.* concluded that the reducing ends are extruded from cells. New glucosyl rings would be added at the *nonreducing ends*, which remain attached noncovalently to the cells.[134] From amino acid sequence similarities it was also concluded that the same is true for *Arabidopsis*.[131,133] A single cellulose chain has a twofold screw axis, each residue being rotated 180° from the preceding residue (Fig. 4-5). It was postulated that two synthases act cooperatively to add cellobiose units. Another suggestion is that sitosterol β-glucoside acts in some fashion as a primer for cellulose synthesis in plants.[133b]

An insertion mechanism for synthesis of cellulose. Using ^{14}C "pulse and chase" labeling Han and Robyt found that new glucosyl units are added at the *reducing ends* of cellulose chains formed by cell membrane preparations from *A. xylinum*.[135] This conclusion is in accord with the generalization that extracellular polysaccharides made by bacteria usually grow from the reducing end by an insertion mechanism that depends upon a polyprenyl alcohol present in the cell membrane.[136] This lipid alcohol, often the C_{55}

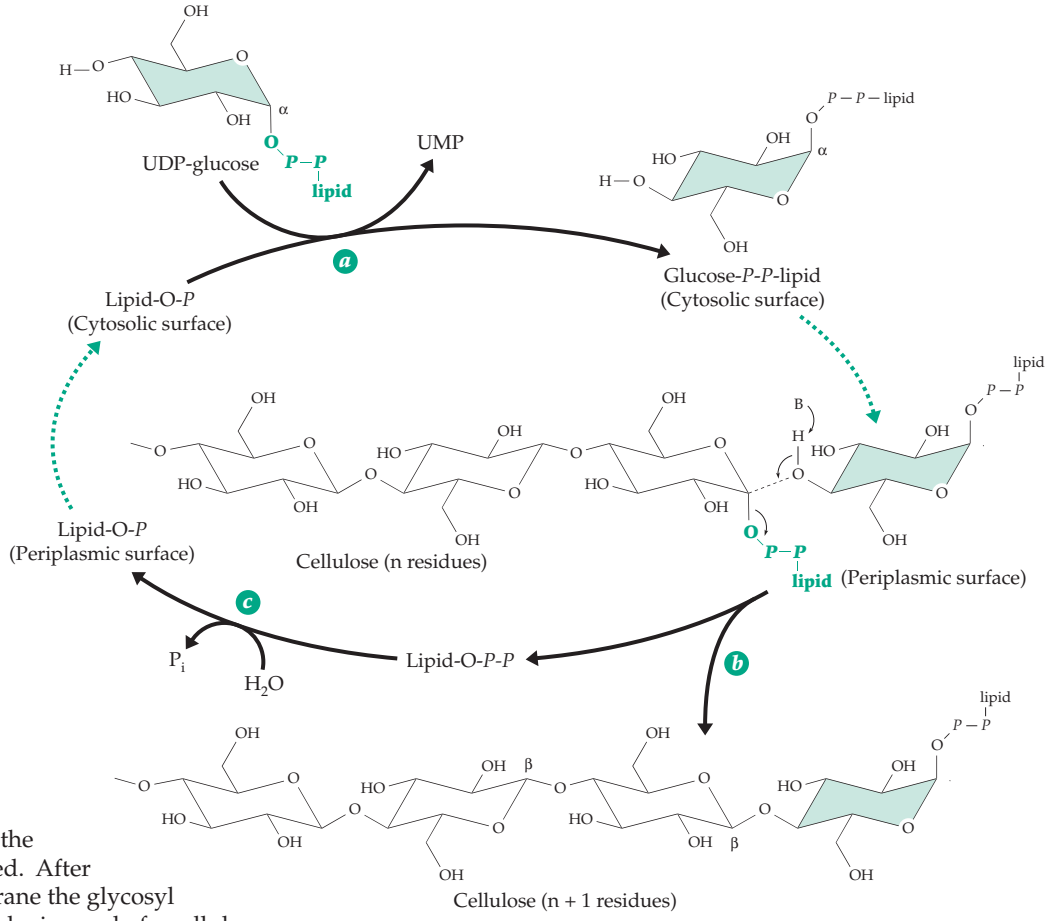

Figure 20-5 Proposed insertion mechanism for biosynthesis of cellulose. Three enzymatic steps are involved: a nucleophilic displacement reaction of a lipid phosphate on UDP-glucose yields a glucosyl diphosphate lipid in which the α-glycosyl linkage is retained. After passage through the membrane the glycosyl group is inserted into the reducing end of a cellulose chain, which is covalently attached by a pyrophosphate linkage to another lipid. The first lipid diphosphate is released and is hydrolyzed (step *c*) to the monophosphate, which crosses the membrane to complete the cycle. After Han and Robyt.[135] As throughout this book *P* represents the phospho group $-PO_3H$. The H may be replaced by groups which may contain oxygen atoms. This explains why an O is included in Lipid-O-*P* but no O is shown between the *P*'s in -O-*P*-*P*.

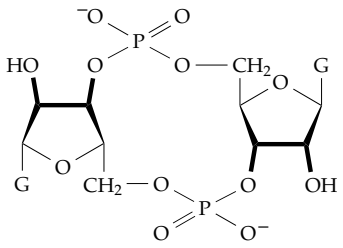
bactoprenol, reacts with UDP-glucose (or other glycosyl donor) to give a lipopyrophospho-glucose (step *a*, Fig. 20-5). The α linkage of the UDP-glucose is retained in this compound. The growing cellulose chain is attached at the reducing end by a similar linkage to a second lipid molecule. Then, in a displacement on the anomeric carbon of the first glucosyl residue of the cellulose chain, the new glucosyl unit is inserted with inversion of the α linkage to β. In step *c* the pyrophosphate linkage of the lipid diphosphate is hydrolyzed to regenerate the lipid monophosphate and to drive the reaction toward completion. Two of the steps in the cycle involve transport across the bacterial membrane. The first involves the lipid –O-*P*-*P*-glucose and the second the lipid monophosphate. This type of insertion mechanism is a common feature of polyprenol phosphate-dependent synthetic cycles for extracellular polysaccharides (Figs. 20-6, 20-9 and Eq. 20-20). However, further verification is needed for cellulose synthesis.

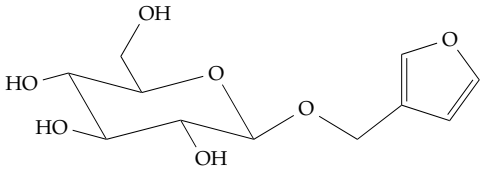
Regulation of cellulose synthesis in bacteria depends on allosteric activator of cellulose synthase, **cyclic diguanylate** (c-di-GMP), and a Ca^{2+}-activated phosphodiesterase that degrades the activator.[129,138–139a] Sucrose is the major transport form of glucose in plants. Synthesis of both cellulose and starch is reduced in mutant forms of maize deficient in sucrose synthase (Eq. 20-13). This synthase, acting in the reverse direction, forms UDP-Glc from sucrose.[140,141] The enzymatic degradation of cellulose is an important biological reaction, which is limited to certain bacteria, to fungi, and to organisms such as termites that obtain cellulases from symbiotic bacteria or by ingesting fungi.[142] These enzymes are discussed in Chapter 12, Section B,6. Genetic engineering methods now offer the prospect of designing efficient cellulose-digesting yeasts[143] that may be used to produce useful fermentation products from cellulose wastes.



Cyclic diguanylate

Callose and other β-1,3-linked glycans.

Attempts to produce cellulose from UDP-Glc using enzymes of isolated plasma membranes from higher plants have usually yielded the β-1,3-linked glucan (callose) instead. This is a characteristic polysaccharide of plant wounds which, as healing occurs, is degraded and replaced by cellulose.[140,144] Callose formation is induced by a specific activator β-furfuryl-β-glucoside, and callose synthase is virtually inactive unless both the activator and Ca^{2+} are present.[144]



β-Furfuryl-β-glucoside

Beta-1,3-linked glycans are major components of the complex layered cell wall of yeasts and other fungi. In the fission yeast *Saccharomyces pombe* ~55% of the cell wall carbohydrate consists of β-1,3-linked glucan with some β-1,4-linked branches, ~ 28% is α-1,3-linked glucan, ~6% is α-1,6-linked glucan, and ~0.5% is chitin. There are two carbohydrate layers, the outer one appearing amorphous. The inner layer contains interwoven fibrils of both α-1,3-linked and α-1,4-linked glucans and holds the shape of the cell. The β-1,3 glucan synthase is localized on the inner side of the cell membrane and is activated by GTP and a small subunit of the Rho family of G proteins.[145]

Plants synthesize 1,3-β-glucanases that hydrolyze the glycans of fungal cell walls. Synthesis is induced by wounding as a defense reaction (see Box 20-E). These glycanases also function in the removal of callose.[146]

Chitin. Like cellulose synthase, fungal chitin synthases are present in the plasma membrane and extrude microfibrils of chitin to the outside.[147–150] In the fungus *Mucor* the majority of the chitin synthesized later has its *N*-acetyl groups removed hydrolytically to form the deacetylated polymer **chitosan**.[151,152] Chitin is also a major component of insect exoskeletons. For this reason, chitin synthase is an appropriate target enzyme for design of synthetic insecticides.[153]

Chitin hydrolyzing enzymes are formed by fungi and in marine bacteria.[154] Chitinases are also present in plant vacuoles, where they participate in defense against fungi and other pathogens[155] (Box 20-E). More recently a chitinase has been identified in human activated macrophages.[156] Another unanticipated discovery was that a developmental gene designated *DG*42, from *Xenopus*, has a sequence similar to that of the *NodC* gene. The latter encodes a synthase for chitin oligosaccharides (Nod factors) that serve as nodulation factors in *Rhizobia* (Chapter 24). The enzyme is synthesized for only a short time during early embryonic development.[157] The significance of this discovery is not yet clear. Synthesis of both the bacterial Nod factors and chitin oligosaccharides in zebrafish embryos occurs by transfer of GlcNAc residues from UDP-GlcNAc at the *nonreducing ends* of the

chains.[158] Whether the same is true of chitin in fungi or arthropods remains uncertain.

Cell walls of plants. The thick walls of higher plant cells (Figs. 1-7, 4-14, and 20-4D) provide strength and rigidity to plants and, at the same time, allow rapid elongation during periods of growth.[159–163a] Northcote[164] likened the wall structure to glass fiber-reinforced plastic (fiber glass). Thus, the cell wall contains microfibrils of cellulose and other polysaccharides embedded in a matrix, also largely polysaccharide. The **primary cell wall** laid down in green plants during early stages of growth contains loosely interwoven cellulose fibrils ~10 nm in diameter and with an ~4 nm crystalline center. The cellulose in these fibrils has a degree of polymerization of 8000–12,000 glucose units. As the plant cell matures, a secondary cell wall is laid down on the inside of the primary wall. This contains many layers of closely packed microfibrils, alternate layers often being laid down at different angles to one another (Fig. 20-4D). The microfibrils in green plants are most often cellulose but may contain other polysaccharides as well. Some algae are rich in fibrils of xylan and mannan.

The materials present in the matrix phase vary with the growth period of the plant. During initial phases **pectin** (polygalacturonic acid derivatives) predominate but later xylans and a variety of other polysaccharides known as **crosslinking glycans** (or hemicelluloses) appear. Primary cell wall constituents of dicotyledons include **xyloglucans** (linear glucan chains with xylose, galactose, and fucose units in

BOX 20-E OLIGOSACCHARIDES IN DEFENSIVE AND OTHER RESPONSES OF PLANTS

Plants that are attacked by bacteria, fungi, or arthropods respond by synthesizing broad-spectrum antibiotics called **phytoalexins**,[a,b] by strengthening their cell walls with lignin and hydroxyproline-rich proteins called **extensins**,[c] and by making **protease inhibitors** and other proteins that help to block the chemical attack.[d] These plant responses seem to be initiated by the release from an invading organism of **elicitors**, which are often small oligosaccharide fragments, sometimes called **oligosaccharins**.[e] These include β-1,6-linked glucans that carry β-1,3-linked branches as well as chitin and chitosan oligomers, derived from fungal cell walls.[f] Other elicitors include galacturonic acid oligomers released from damaged plant cell walls,[g] metabolites such as arachidonic acid and glutathione,[h] and bacterial toxins.[i] Any of these may serve as signals to plants to take defensive measures.

Phytoalexins are often isoflavonoid derivatives (Box 21-E). Their synthesis, like that of lignin, occur via 4-coumarate (4-hydroxycinnamate, Fig. 25-8). The ligase which forms the thioester of 4-coumarate with coenzyme A is one of the **pathogenesis-related proteins** whose synthesis is induced.[j] A second induced enzyme is chalcone synthase, which condenses three acetyl units onto 4-coumaroyl-CoA as shown in Box 21-E. Its induction by elicitors acting on bean cells requires only five minutes.[h] Another rapidly induced gene is that of cinnamoyl alcohol dehydrogenase,[k] essential to lignin synthesis. Other proteins formed in response to infections include **chitinases** that are able to attack invading fungi[l,m] as well as the protease inhibitors. Their synthesis is induced via derivatives of **jasmonate**, a product of the octadecenoic acid pathway (Eq. 21-18).[a] As yet, little is known about the mechanism by which elicitors induce the defensive responses, but the presence of receptors, of phosphorylation, and of release of second messengers have been suggested.[d]

Lipooligosaccharides known as Nod factors (p. 1365) are another group of signaling molecules. These chitin-related *N*-acylated oligomers of *N*-acetylglucosamine (GlcNAc) do not defend against infection but invite infection of roots of legumes by appropriate species of *Rhizobia*[n–p] leading to formation of nitrogen-fixing root nodules.

branches),[164a] other crosslinking glycans, and galacturonic acid-rich pectic materials.[163a] The xyloglycans, which comprise 20% of the cell wall in some plants, have a backbone of α-1,4-linked glucose units with numerous α-1,6-linked xylose rings, some of which carry attached L-arabinose, galactose, or fucose. The structures, which vary from species to species, are organized as repeating blocks with a continuous glucan backbone. Another crosslinking glycan is **glucuronoarabinoxylan**. The backbone is β-1,4-linked xylose. Less abundant glucomannans, galactomannans, and galactoglucomannans, with β-1,4-linked mannan backbone structures, are also present in most angiosperms.[163a]

Pectins form a porous gel on the inside surface of plant cell walls.[163a,164a] A major component is a **homogalacturonan**, which consists of α-1,4-linked galacturonic acid (GalA). A second is rhamnogalacturonan I, an alternating polymer of (2-L-Rhaα1 → 4GalAα →) units. The most interesting pectin component is **rhamnogalacturonan II**, one of the less abundant constuents of pectin. It is obtained by hydrolytic cleavage of pectin by a polygalacturonidase. Before such release it forms parts (hairy regions) of pectin molecules that are largely homogalacturonans (in smooth regions). A rhamnogalacturonan II segment consists of 11 different monomer units.[164b–f] Attached to the polygalacturonic acid backbone are four oligosaccharides, consisting of rhamnose, galactose and fucose as well as some unusual sugars (see structure in Box 20-E). This polysaccharide is apparently present in all higher plants and is unusually stable, accumulating, for example, in red wine.[164e] It contains two residues of the branched chain sugar **apiose**, one of which is a site of crosslinking by boron (Box 20-F). A borate diol ester linkage binds two molecules of the pectin together as a dimer, perhaps controlling the porosity of the pectin gel. All of the complex cell wall polysaccharides bind, probably through multiple hydrogen bonds, to the cellulose microfibrils (Fig. 4-14). The resulting structures are illustrated in drawings of Carpita and McCann,[163a] which are more current than is Fig. 4-14. The cellulose plus crosslinking glycans form one network in the cell wall. The pectic substances form a second independent network. Some covalent crosslinking occurs, but most interactions are noncovalent.[163a] The site of biosynthesis of pectins and hemicelluloses is probably Golgi vesicles which pass to the outside via exocytosis. However, the cellulose fibrils as well as the chitin in fungi are apparently extruded from the plasma membrane.

Although the principal cell wall components of plants are carbohydrates, proteins account for 5–10% of the mass.[165] Predominant among these are glycoprotein **extensins**. Like collagen, they are rich in 4-hydroxyproline which is glycosylated with arabinose oligosaccharides and galactose (p. 181). Other hydroxyproline-containing proteins with the characteristic sequence $(\text{hydroxyproline})_4$-Ser are also found, e.g., in soybean cell walls.[166] Some plant cell walls contain glycine-rich structural proteins. One in the petunia consists of 67% glycine residues.[167] During advanced stages of formation, as the walls harden into wood, large amounts of **lignins** are laid down in some plant cells. These chemically resistant phenylpropanoid polymers contain many crosslinked aromatic rings (Fig. 25-9).[163a]

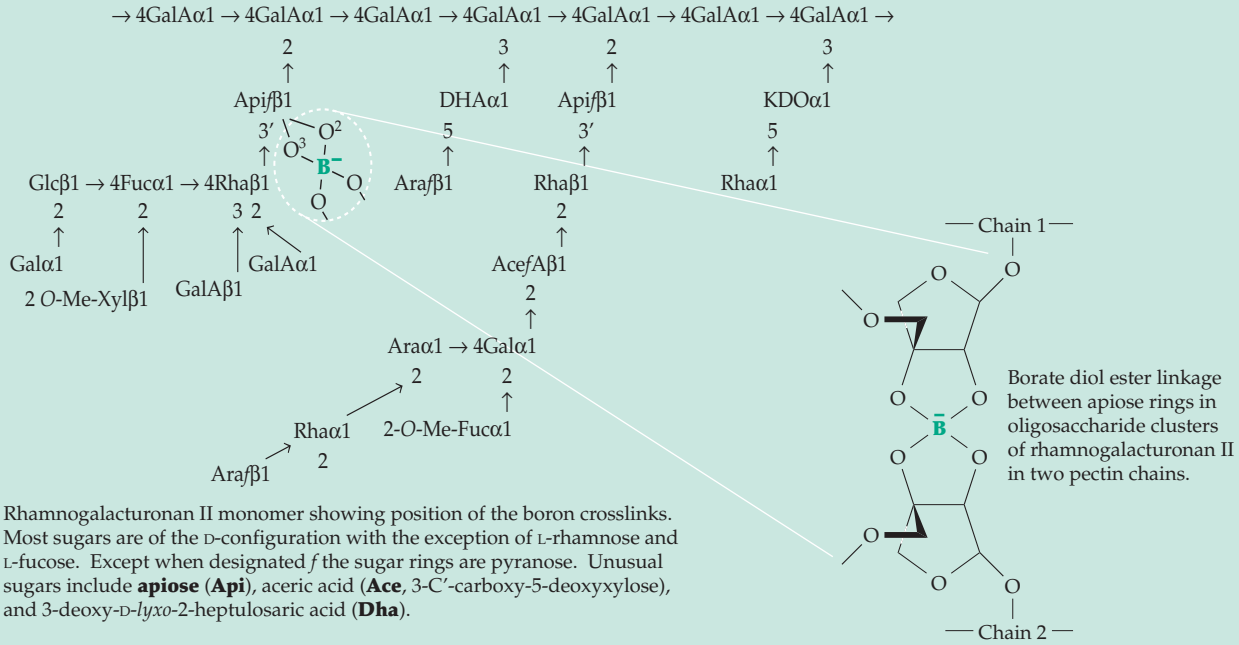
A remarkable aspect of primary plant cell walls is their ability to be elongated extremely rapidly during growth. While the driving force for cell expansion is thought to be the development of pressure within the cell, the manner in which the wall expands is closely regulated. After a certain point in development, elongation occurs in one direction only and under the influence of plant hormones. Most striking is the effect of the **gibberellins** (Eq. 22-5), which cause very rapid elongation. Elongation of plant cell walls may depend to some extent upon chemical cleavage and reforming of crosslinking polysaccharides. However, the cellulose fibrils probably remain intact and slide past each other.[161] A curious effect, which is mediated by proteins called **expansins**,[133a,168] is the ability of plant tissues to extend rapidly when incubated in a mildly acidic buffer of pH <5.5. Expansins are also involved in ripening of fruit. They may disrupt noncovalent bonding between cellulose fibrils and the hemicelluloses.[169,170] The β-expansins of grasses are allergens found in grass pollens.[133a,168] The borate diol ester linkages in the pectin may also facilitate expansion.

3. Patterns in Polysaccharide Structures

How can the many complex polysaccharides found in nature be synthesized? Are there genetically determined patterns? How are these controlled? The answer can be found in the *specificities* of the hundreds of known *glycosyltransferases*[171,172] and in the *patterns of expression of the genes* for transferases and other proteins. As a consequence, a great variety of structurally varied polysaccharide structures arise, especially on cell surfaces. The structures are not random but depend upon the assortment of glycosyltransferases available at the particular stage of development in a tissue. The numerous possibilities can account for much of the variation observed between species, between tissues, and also among individuals.

The simplest pattern is the growth of straight-chain homopolysaccharides such as amylose, cellulose, and chitin. The glycosyltransferases must recognize both the glycosyl donor, e.g., ADP-glucose, UDP-glucose, and also the correct end of the growing polymer, always adding the same monomer unit.

BOX 20-F WHAT DOES BORON DO?



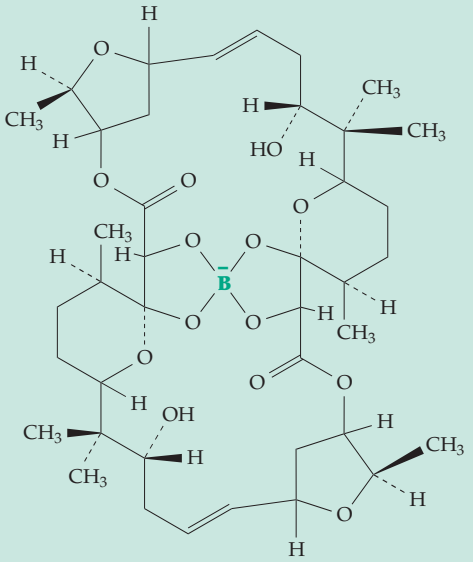
Rhamnogalacturonan II monomer showing position of the boron crosslinks. Most sugars are of the D-configuration with the exception of L-rhamnose and L-fucose. Except when designated *f* the sugar rings are pyranose. Unusual sugars include **apiose** (**Api**), aceric acid (**Ace**, 3-C′-carboxy-5-deoxyxylose), and 3-deoxy-D-*lyxo*-2-heptulosaric acid (**Dha**).

Borate diol ester linkage between apiose rings in oligosaccharide clusters of rhamnogalacturonan II in two pectin chains.

For 75 years or more it has been known that boron is essential for growth of green plants.[a,b] In its absence root tips fail to elongate normally, and synthesis of DNA and RNA is inhibited. Boron in the form of boric acid, $B(OH)_3$, is absorbed from soil. Although deficiency is rare it causes disintegration of tissues in such diseases as "heart rot" of beets and "drought spot" of apples. The biochemical role has been obscure, but is usually thought to involve formation of borate esters with sugar rings or other molecules with adjacent pairs of –OH groups (as in the accompanying structures). A regulatory role involving the plant hormones auxin, gibberelic acid, and cytokinin has also been suggested.

Diatoms also require boron, which is incorporated into the silicon-rich cell walls.[a] Some strains of *Streptomyces griseus* produce boron-containing macrolide antibiotics such as **aplasmomycin** (right).[c] Recently a function in plant cell walls has been identified (see also main text) as crosslinking of rhamnogalacturonan portions of pectin chains by borate diol ester linkages as illustrated.

It was long thought that boron was not required by human beings, but more recent studies suggest that we may need ~30 µg / day.[d] The possible functions are uncertain. Animals deprived of boron show effects on bone, kidney, and brain as well as a relationship to the metabolism of calcium, copper, and nitrogen. Nielson proposed a signaling function, perhaps via phosphoinositides, in animals.[b]



Aplasmomycin, a boron-containing antibiotic

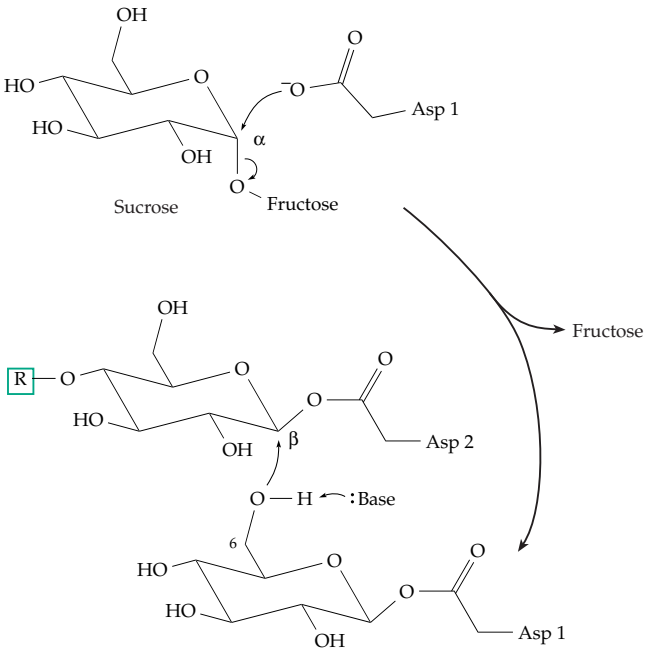
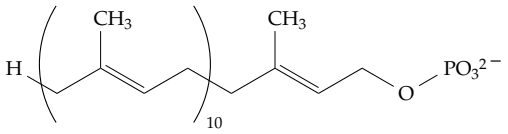
In contrast, hyaluronan and the polysaccharide chains of **glycosaminoglycans** (Fig. 4-11) have an alternating pattern. For a hyaluronan chain growing at the reducing end, one active site of hyaluronan synthase must be specific for UDP-GlcNAc and transfer the sugar unit only to the end of a glucuronic acid ring. A second active site must be specific for UDP-glucuronic acid but attach it only to the end of an acetylglucosamine unit.[172a,172b] There is still uncertainty about the direction of growth of hyaluronan.[173–175] Some hyaluronan synthases are lipid-dependent and their mechanism may resemble that proposed for cellulose synthesis (Fig. 20-5).

Dextrans. Some polysaccharides, such as the bacterial dextrans, are synthesized outside of cells by the action of secreted enzymes. An enzyme of this type, **dextran sucrase** of *Leuconostoc* and *Streptococcus*, adds glucosyl units at the *reducing* ends of the dextran chains (p. 174). Sucrose is the direct donor of the glucosyl groups, which are added by an insertion mechanism.[121,176–178] However, it is not dependent upon a membrane lipid as is that of Fig. 20-5. The glucosyl groups are transferred from sucrose to one of a pair of carboxylate groups of aspartate side chains in the active site.[179,180] If both carboxylates are glucosylated, a dextran chain can be initiated by insertion of one glucosyl group into the second (Eq. 20-19). The dextran grows alternating binding sites between the two carboxylates. Chain growth can be terminated by reaction with a sugar or oligosaccharide that fits into the active site and acts in place of the glucosyl group attached to Asp 1 as pictured in Eq. 20-19. The α-1,3-linked branches can be formed when a 3-OH group of a second dextran chain enters the catalytic site, serving as the glycosyl acceptor. See Robyt for a detailed discussion of synthesis of dextrans and related polysaccharides such as **alternan** and the α-1,3-linked **mutan** (p. 175).[121,176] Some bacteria form β-2,6-linked **fructans** by a similar mechanism, with glucose being released by displacement on C2 of sucrose.[181] Fructans are also formed in green plants, apparently from reaction of two molecules of sucrose with release of glucose to form the trisaccharide Fru*f*β2 → 1Fru*f*β2–1α-Glc*p*, which then transfers a fructosyl group to the growing chain.



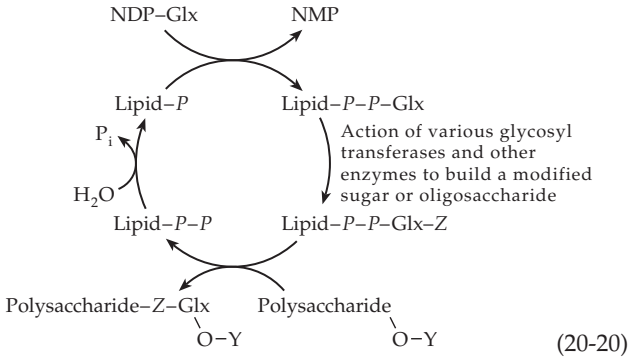
(20-19)

Lipid-dependent synthesis of polysaccharides. Insertion of monomer units at the base of a chain is a major mechanism of polymerization that is utilized for synthesis not only of polysaccharides but also of proteins (Chapter 29). For most carbohydrates the synthesis is dependent upon a polyprenyl lipid alcohol. In bacteria this is often the 55-carbon **undecaprenol** or **bactoprenol**,[136] which functions as a phosphate ester:



Undecaprenol phosphate

It serves as a membrane anchor for the growing polysaccharide. We have already discussed one example in the hypothetical cellulose synthase mechanism of Fig. 20-5. For some polysaccharides the mechanism is better established. The synthetic cycles all resemble that of Fig. 20-5 and can be generalized as in Eq. 20-20. Here NDP-Glx is a suitable nucleotide disphosphate derivative of sugar Glx, and Z-Glx is the repeating unit of the polysaccharide formed by the action of glycosyltransferases and other enzymes.



(20-20)

For example, the biosynthesis of alginate involves GDP-mannuronic acid (GDP-ManA) as NDP-Glx, bactoprenol as the lipid, and a glycosyltransferase that inserts a second mannuronate residue (as Z).

An additional transferase that uses acetyl-CoA as a substrate sometimes acetylates one mannuronate unit. The disaccharide units are then inserted into the growing chain. An additional modification, which occurs after polymerization, is random C5 epimerization of unacetylated D-mannuronate residues to L-guluronate.[136,182] Formation of alginate is of medical interest because infections by alginate-forming bacteria are a major cause of respiratory problems in cystic fibrosis.[182]

Sometimes an oligosaccharide assembled on the polyprenol phosphate represents a substantial block in assembly of a repeating polymer. For example, the xanthan gum (p. 179) produced by the bacterium *Xanthomonas campestris* is formed by several successive glycosyl transfers to bactoprenol-*P*-*P*-Glc. A second glucose is transferred onto the first from UDP-Glc, forming a pair of glucosyl groups in β-1,4 linkage. Mannose is then transferred from GDP-Man and joined in an α-1,3 linkage to the first GDP-Man to form a branch point. A glucuronate residue is then transferred from UDP-GlcA and another mannose from GDP-Man. The last mannose is modified by reaction with PEP to form a ketal (Eq. 4-9). The product of this assembly is the following lipid-bound oligosaccharide block.

$$\begin{array}{lcc} & \text{Acetyl} & \text{Glc}\beta 1 \\ \text{Pyruvate} & \downarrow & \downarrow \\ \| & 6 & 4 \end{array}$$
$$\text{Man}\beta 1 \rightarrow 4\,\text{GlcA}\beta 1 \rightarrow 2\,\text{Man}\alpha 1 \rightarrow 3\,\text{Glc}\beta 1 \rightarrow \text{O-}P\text{-}P\text{-lipid}$$

This is inserted into the growing polysaccharide using the free 4-OH on the second glucose to link the units in a cellulose type chain. The twelve separate genes needed for synthesis of xanthan gum are contained in a 16-kb segment of the *X. campestris* genome.[136] Lipid-bound intermediates are also involved in synthesis of peptidoglycans (Fig. 20-9) and in the assembly of bacterial O-antigens (Fig. 8-30). Both of these also yield "block polymers."

D. Proteoglycans and Glycoproteins

The glycoproteins contain oligosaccharides attached to the protein either through *O*-glycosidic linkages with hydroxyl groups of side chains of serine, threonine, hydroxyproline, or hydroxylysine (*O*-linked) or via glycosylaminyl linkages to asparagine side chains (*N*-linked). The "core proteins" of the proteoglycans carry long polysaccharide chains, which are usually *O*-linked and are usually described as glycosaminoglycans.

1. Glycosaminoglycans

Synthesis of the alternating polysaccharide hyaluronan has been discussed in Section C,3 and may occur by an insertion mechanism. However, other glycosaminoglycans (sulfate esters of **chondroitin**, **dermatan**, **keratan**, **heparan**, and **heparin**) grow at their nonreducing ends.[183,184] Their synthesis is usually initiated by the hydroxyl group of serine or threonine side chains at special locations within several secreted proteins.[185] These proteins are synthesized in the rough ER and then move to the Golgi. Addition of the first sugar ring begins in the ER with transfer of single xylosyl residues to the initiating –OH groups.[186–190b] This reaction is catalyzed by the first of a group of special glycosyltransferases of high specificity that form the special terminal units (Chapter 4, Section D,1), that anchor the alternating polysaccharide represented here as $(X–Y)_n$:

$$(X \rightarrow Y)_n \rightarrow 4\,\text{GlcA}\beta 1 \rightarrow 3\,\text{Gal}\beta 1 \rightarrow 3\,\text{Gal}\beta 1 \rightarrow 4\,\text{Xyl}\beta 1 \rightarrow \text{O-Ser / Thr}$$

After transfer of the xylosyl residue from UDP-xylose to the –OH group in the protein,[190a] a second enzyme with proper specificity transfers a galactosyl group from UDP-galactose, joining it in β-1,4 linkage. A third enzyme transfers another galactosyl group onto the first one in β-1,3 linkage. A fourth enzyme, with a specificity different from that used in creating the main chain, then transfers a glucuronosyl group from UDP-glucuronic acid onto the chain terminus to complete the terminal unit.[190c] Then two more enzymes transfer the alternating units in sequence to form the repeating polymer with lengths of up to 100 or more monosaccharide residues. The sequence $(X–Y)_n$ in the preceding formula is:

$$(\rightarrow 4\,\text{GlcA}\beta 1 \rightarrow 3\,\text{GalNAc}\beta 1 \rightarrow)_n$$
for chondroitin[172a,191,192]

$$(\rightarrow 4\,\text{GlcA}\beta 1 \rightarrow 4\,\text{GlcNAc}\alpha 1 \rightarrow)_n$$
for heparan sulfate and heparin

$$(\rightarrow 3\,\text{Gal}\beta 1 \rightarrow 4\,\text{GlcNAc}\beta 1 \rightarrow)_n$$
for dermatan sulfate

Subsequent modifications of the polymers involve extensive formation of *O*-sulfate esters,[190a,193–197] *N*-deacetylation and *N*-sulfation,[198,199] and epimerization at C5.[10] In some tissues almost all GluA is epimerized.[200] The modifications are especially extensive in dermatan, heparan sulfates, and heparin (see also p. 177).[196,201–203b] The modifications are not random and follow a defined order. *N*-Deacetylation must precede *N*-sulfation, and *O*-sulfation is initiated only after *N*-sulfation of the entire chain is complete. The modifications occur within the Golgi (see Fig. 20-7) but not all

of the glycosyltransferases, PAPS (3'-phosphoadenosine 5'-phosphosulfate)-dependent sulfotransferases, and epimerases are present within a single compartment. Nevertheless, an entire glycosaminoglycan chain can be synthesized within 1–3 min.[189]

The completed polymers are modified uniformly. There are clusters of sulfo groups with unusual structures in chondroitin from squid and shark cartilages[204,205] and fucosylated chondroitin from echinoderms.[206] Similar modifications are present less extensively in vertebrates. One of the best known modifications forms the unique pentasaccharide sequence shown in Fig. 4-13, which is essential to the anticoagulant activity of heparin. This sequence has been synthesized in the laboratory as have related longer heparin chains. A sequence about 17 residues in length containing an improved synthetic version of the unique pentasaccharide binds tightly to both thrombin and antithrombin (Chapter 12, Section C,9).[207,208] This opens the door to the development of improved substitutes for the medically important heparin. Heparan sulfate chains are found on proteoglycans throughout the body, but the highly modified heparin does not circulate in the blood. It is largely sequestered in cytoplasmic granules within mast cells and is released as needed.[208a] Heparin binds to many different proteins (p. 177). Among them is the glycoprotein selenoprotein P (p. 824), which may impart antioxidant properties to the extracellular matrix.[208b]

Although glycosaminoglycans are most often attached to *O*-linked terminal units, chondroitin sulfate chains can also be synthesized with *N*-linked oligosaccharides attached to various glycoproteins serving as initiators.[209] At least one form of keratan sulfate, found in the cornea, is linked to its initiator protein via GlcNAc-Man to *N*-linked oligosaccharides of the type present in many glycoproteins (Section D).

At least 25 different proteins that are secreted into the extracellular spaces of the mammalian body carry glycosaminoglycan chains.[183,210,211] Most of these proteins can be described as (1) **small leucine-rich proteoglycans** with 36- to 42-kDa protein cores and (2) **large modular proteoglycans** whose protein cores have molecular masses of 40 to 500 kDa.[210] The most studied of the second group is **aggrecan**, a major component of cartilage. This 220-kDa protein carries ~100 chondroitin chains, each averaging about 100 monosaccharide residues and ~100 negative charges from the carboxylate and sulfate groups. Aggrecan has three highly conserved globular domains near the N and C termini.[212–213a] The G1 domain near the N terminus is a **lectin** (p. 186), which, together with a small link protein that is structurally similar to the G1 domain, binds to a decasaccharide unit of hyaluronan. One hyaluronan molecule of 500- to1000-kDa mass (~2500–5000 residues) may bind 100 aggrecan and link molecules to form an ~200,000-kDa particle such as that shown in Fig. 4-16. These enormous highly negatively charged molecules, together with associated counterions, draw in water and preserve osmotic balance. It is these molecules that keep our joints mobile and which deteriorate by proteolytic degradation in the common **osteoarthritis**.[214,215] The keratan sulfate content of cartilage varies with age, and the level in serum and in synovial fluid is increased in osteoarthritis.[215] Keratan sulfate is also found in the cornea and the brain. Its content is dramatically decreased in the cerebral cortex of patients with Alzheimer disease.[216]

Other modular core proteins[210] include **versican** of blood vessels and skin,[210,213a,217,217a] **neurocam** and **brevican** of brain, **perlecan** of basement membranes,[218] **agrin** of neuromuscular junctions, and **testican** of seminal fluid. However, several of these have a broader distribution than is indicated in the foregoing description. The sizes vary from 44 kDa for testican to greater than 400 kDa for perlecan. The numbers of glycosaminoglycan chains are smaller than for aggrecan, varying from 1 to 30. Another of the chondroitin sulfate-bearing core protein is **appican**, a protein found in brain and one of the splicing variants of the amyloid precursor protein that gives rise to amyloid deposits in Alzheimer disease (Chapter 30).[217a,b]

The core proteins of the leucine-rich proteoglycans have characteristic horseshoe shapes and are constructed from ~28-residue repeats, each containing a β turn and an α helix. The three-dimensional structures are doubtless similar to that of a ribonuclease inhibitor of known structure which contains 15 tandem repeats.[219,220] A major function of these proteoglycans seems to be to interact with collagen fibrils, which have distinct proteoglyan-binding sites,[221] and also with fibronectin.[222] The small leucine-rich proteoglycans have names such as **biglycan**, **decorin**,[222a] **fibromodulin**, **lumican**, **keratoglycan**, **chondroadherin**, **osteoglycin**, and **osteoadherin**.[219,223–223c] The distribution varies with the tissue and the stage of development. For example, biglycan may function in early bone formation; decorin, which has a high affinity for type I collagen, disappears from bone tissue as mineralization takes place. Osteoadherin is found in mature osteoblasts.[223] **Phosphocan**, another brain proteoglycan, has an unusually high content (about one residue per mole) of L-isoaspartyl residues (see Box 12-A).[224]

Proteoglycans bind to a variety of different proteins and polysaccharides. For example, the large extracellular matrix protein **tenascin**, which is important to adhesion, cell migration, and proliferation, binds to chondroitin sulfate proteoglycans such as neurocan.[225] **Syndecan**, a transmembrane proteoglycan, carries both chondroitin and heparan sulfate chains, enabling it to interact with a variety of proteins that mediate cell–matrix adhesion.[185]

The ability of dissociated cells of sponges to aggregate with cells only of a like type (p. 29) depends upon large extracellular proteoglycans. That of *Microciona prolifera* appears to be an aggregate of about three hundred 35-kDa core protein molecules with equal masses of attached carbohydrate. This **aggregation factor** has a total mass of ~2 x 10^4 kDa.[226,227] It apparently interacts specifically, in the presence of Ca^{2+} ions, with a 210-kDa cell matrix protein to hold cells of the same species together.[227]

2. *O*-Linked Oligosaccharides

A variety of different oligosaccharides are attached to hydroxyl groups on appropriate residues of serine, threonine, hydroxylysine, and hydroxyproline in many different proteins (Chapter 4). Such oligosaccharides are present on external cell surfaces, on secreted proteins, and on some proteins of the cytosol and the nucleus.[228–231b] The rules that determine which –OH groups are to become glycosylated are not yet clear.[232] Glycosylation occurs in the ER, and, just as during synthesis of the long carbohydrate chains of proteoglycans, the sugar rings are added directly to an –OH group, either of the protein or of the growing oligosaccharide. The first glycosyl group transferred is most often **GalNAc** for external and secreted proteins[233] but more often **GlcNAc** for cytosolic and nuclear proteins.[228,231,233a–c] Glycosylation of protein –OH groups can occur on either the luminal or cytosolic faces of the ER membranes.[234] The external *O*-linked glycoproteins often have large clusters of oligosaccharides attached to –OH groups of serine or threonine, but cytosolic proteins may carry only a small number of small oligosaccharides.

Of great importance are the **blood group determinants** which are discussed in Box 4-C. The ABO determinants are found at the nonreducing ends of *O*-linked oligosaccharides. Conserved Ser/Thr sites in the epidermal growth factor domains (Table 7-3) of various proteins carry ***O*-linked fucose**.[235]

The secreted **mucins** are unique in having clusters of large numbers of oligosaccharides linked by ***N*-acetylgalactosamine** to serine or threonine of the polypeptide.[236] The following core structures predominate.[237] These may be lengthened or further branched by the particular variety of glycosyltransferases present in a tissue and by their specificities.[233] The human genome contains at least nine mucin genes.[238] The large apomucins contain central domains with tandem repeats rich in Ser, Thr, Gly, and Ala and flanked at the ends by cysteine-rich domains.[239] For example, porcine submaxillary mucins are encoded by a gene with at least three alleles that encode 90, 125, or 133 repeats. The polypeptide may contain as many as 13,288 residues. N-terminal cysteine-rich regions are involved in dimer formation.[240]

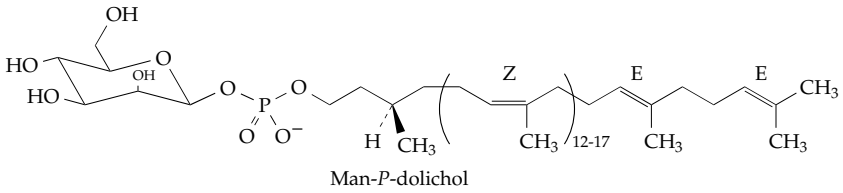
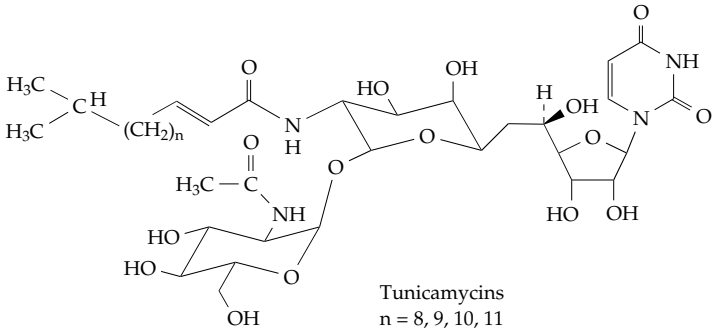
3. Assembly of *N*-Linked Oligosaccharides on Glycosyl Carrier Lipids

In eukaryotes the biosynthesis of the *N*-linked oligosaccharides of glycoproteins depends upon the polyprenyl alcohols known as **dolichols**, which are present in membranes of the endoplasmic reticulum. They contain 16–20 prenyl units, of which the one bearing the OH group is completely saturated as a result of the action of an NADPH-dependent reductase on the unsaturated precursor.[241] The predominant dolichol in mammalian cells contains 19 prenyl units. The structure of its mannosyl phosphate ester, one of the intermediates in the oligosaccharide synthesis, is illustrated below. The fully extended 95-carbon dolichol has a length of almost 10 nm, four times greater than that of oleic acid and twice the thickness of the nonpolar membrane bilayer core. The need for this great length is not clear nor is it clear why the first prenyl unit must be saturated for good acceptor activity.

The assembly of the oligosaccharides that will become linked to Asn residues in proteins occurs on the phosphate head of dolichol-*P*. The process begins on the cytoplasmic face of the membrane and within the lumen of the rough or smooth ER and continues within cisternae of the Golgi apparatus.[234,242–245] The initial transfer of GlcNAc-*P* to dolichol-*P* (Fig. 20-6, step *a*) appears to occur on the cytoplasmic face of the ER and is specifically inhibited by **tunicamycin**.[246,247] As the first "committed reaction" of *N*-glycosylation, it is regulated by a variety of hormonal and other factors.[248,249] The reaction takes place cotranslationally as the still unfolded peptide chain leaves the ribosome.[242] The oligosaccharide, still attached to the dolichol, continues to grow on the cytosolic surface of the ER membrane by transfer of GlcNAc and five residues of mannose from their sugar nucleotide forms (Fig. 20-6, steps *b* and *c*).[249a] The intermediate Dol-*P*-*P*-$GlcNAc_2Man_5$ crosses the membrane bilayer (Fig. 20-6, step *d*), after which mannosyl and glucosyl units are added (steps *e* and *f*). These sugars are carried across the membrane while attached to dolichol.



Man-*P*-dolichol



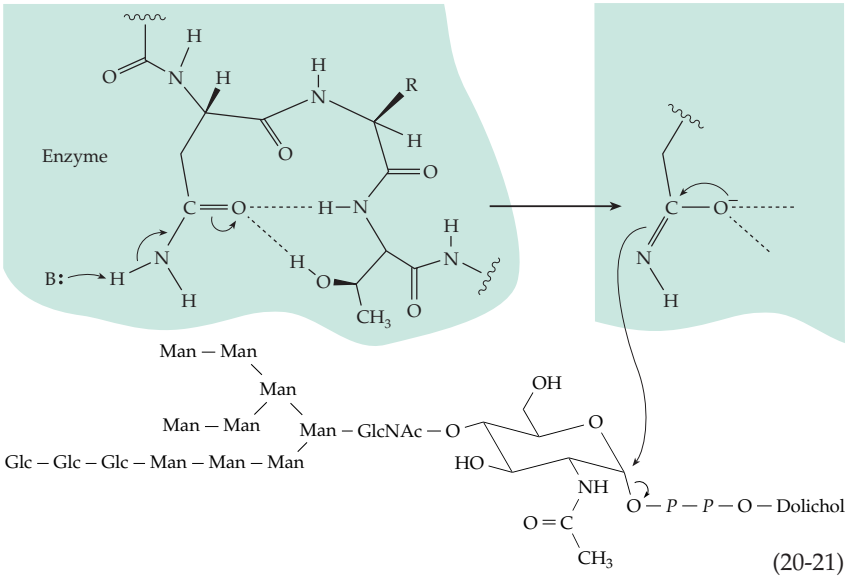
Tunicamycins
n = 8, 9, 10, 11

The completed 14-residue branched oligosaccharide $Glc_3Man_9GlcNAc_2$, with the structure indicated in Fig. 20-6, is then transferred to a suitable asparagine side chain (step *g*). This may be on a newly synthesized protein or on a still-growing polypeptide chain that is being extruded through the membrane into the lumenal space of the rough ER (Eq. 20-21; Fig. 20-6). The glycosylation site is often at the sequence Asn-X-Ser(Thr), which is likely to be present at a beta bend in the folded protein. Bends of the type illustrated in Eq. 20-21 and stabilized by the asparagine side chain are apparently favored.[250] In such a bend the –OH of the serine or threonine helps to polarize the amide group of the Asn side chain, perhaps enolizing it and generating a nucleophilic center that can participate in a displacement reaction[250,251] as indicated in Eq. 20-21. The **oligosaccharyltransferase** that catalyzes the reaction is a multisubunit protein. As many as eight different subunits have been reported for the enzyme in yeast. Genes for at least five of these are essential.[250–252b] One subunit serves to recognize suitable glycosylation sites.

Trimming of glycoprotein oligosaccharides. After transfer to glycoproteins the newly synthesized oligosaccharides undergo trimming, the hydrolytic removal of some of the sugar units, followed by addition of new sugar units to create the finished glycoproteins. The initial glycosylation process ensures that the glycoproteins remain in the lumen of the ER or within vesicles or cisternae separated from the cytoplasm. The subsequent processing appears to allow the cell to **sort** the proteins. Some remain attached to membranes and take up residence within ER, Golgi, or plasma membrane. Others are passed outward into transfer vesicles, Golgi, and secretion vesicles. A third group enter **lysosomes**. A series of specific inhibitors of trimming reactions, some of whose structures are shown in Fig. 20-7, has provided important insights.[253–255] Use of these inhibitors, together with immunochemical methods and study of yeast mutants,[250,252,256] is enabling us to learn many details of glycoprotein biosynthesis.

Whereas the formation of dolichol-linked oligosaccharides occurs in an identical manner in virtually all eukaryotic cells, trimming is highly variable as is the addition of new monosaccharide units.[257–257b] The major pathway for mammalian glycoproteins is shown in Fig. 20-7. Specific hydrolases in the ER remove all of the glucosyl units and one to three mannosyl units.[258] Removal of additional mannosyl residues occurs in the cis Golgi, to give the pentasaccharide core $Man_3GlcNAc_2$ which is common to all of the complex N-linked oligosaccharides. However, partial trimming without additional glycosylation produces some "high mannose" oligosaccharides.[258a] Removal of glucose may be necessary to permit some glycoproteins to leave the ER.

Sulfate groups and in some cases fatty acyl groups[259] may also be added. The exact composition of the oligosaccharides may depend upon the condition of the cell and may be altered in response to external influences.[257] Oligosaccharides attached to proteins that remain in the ER membranes may undergo



(20-21)

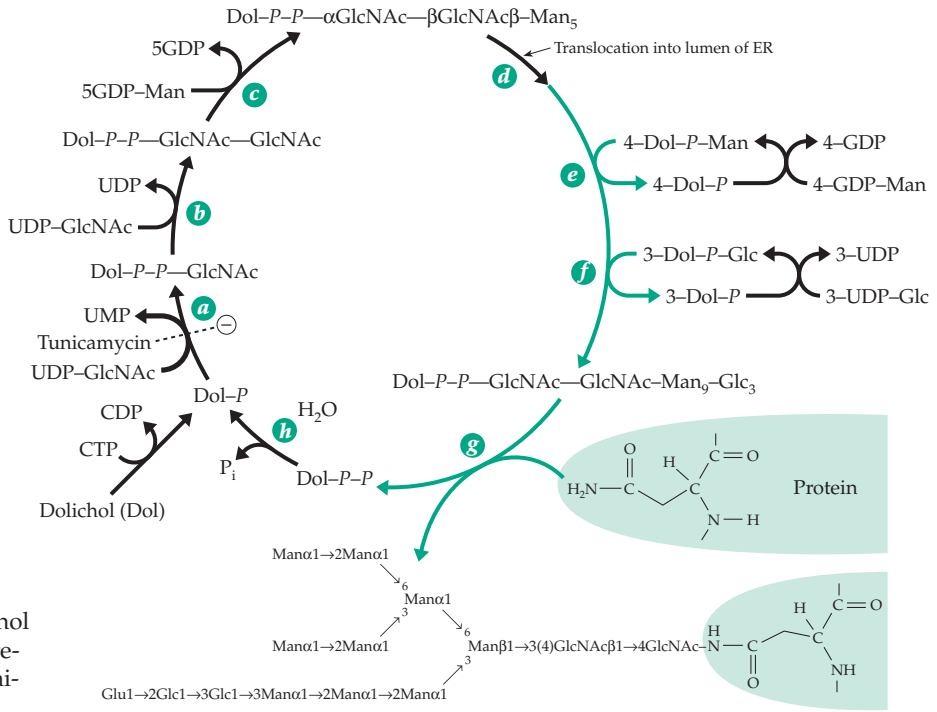


Figure 20-6 Biosynthesis of the dolichol diphosphate-linked oligosaccharide precursor to glycoproteins. The site of inhibition by tunicamycin is indicated.

very little trimming. However, the three glucosyl residues are usually removed by the glucosidases present in the rough ER. Some plant glycoproteins of the high-mannose type undergo no further processing.

Extensions and terminal elaborations. Even before trimming is completed, addition of new residues begins within the medial cisternae.[260] In mammalian Golgi, *N*-acetylglucosamine is added first. Galactose, sialic acid, and often fucose are then transferred from their activated forms to create such elaborate oligosaccharides as that shown in Fig. 4-17. As many as 500 glycosyltransferases, having different specificities for glycosyl donor and glucosyl acceptor, may be involved.[245] Extensions of the basic oligosaccharide structure often contain polylactosamine chains, branches with fucosyl residues, and sulfate groups.[245,261] More than 14 sialyltransferases place sialic acid residues, often in terminal positions, on these cell surface oligosaccharides.[262,263]

The cell wall of the yeast *Saccharomyces* is rich in **mannoproteins** that contain 50–90% mannose.[264] The ~250-residue mannan chains consist of an α-1,6-linked backbone with mono-, di-, and tri-mannosyl branches. These are attached to the same core structure as that of mammalian oligosaccharides. All of the core structures are formed in a similar way.[258,265] The mannoproteins may serve as a "filler" to occupy spaces in a cell wall constructed from β-1,3- and β-1,6-linked glycans and chitin. All of the four components, including the mannoproteins, are covalently linked together.[266] As was emphasized in Chapter 4 (pp. 186–188) glycoproteins serve many needs in biological recognition. The N-linked oligosaccharides play a major role in both animals and plants.[266a–c] Use of mass spectrometry, new automated methods of oligosaccharide synthesis,[266d] and development of new synthetic inhibitors[266c] are all contributing to current studies of what is commonly called "glycobiology."

The perplexing Golgi apparatus. First observed by Camillo Golgi[267,268] in 1898, the stacked membranes, now referred to simply as Golgi, remain somewhat mysterious.[268–271] There are at least three functionally distinct sets of Golgi cisternae, the **cis** (nearest the nucleus), **medial**, and **trans**. An additional series of tubules referred to as the **trans Golgi network** lies between the Golgi and the cell surface and may be the site at which lysosomal enzymes are sorted from proteins to be secreted.[260,272] Immunochemical staining directed toward specific glycosidases and glycosyl transferases suggested that the trimming reactions of glycoproteins start in the ER and continue as the proteins pass outward successively from one compartment of the Golgi to the next (Fig. 20-8). This has been the conventional view since the 1970s. The movement of the glycoproteins between compartments is thought to take place in small vesicles using a rather elaborate system of specialized proteins. Some of these coat the vesicles[273,274] while others target the vesicles to specific locations, e.g., the lysosomes[275] or the plasma membranes where they may be secreted.[273,277] A host of regulatory G-proteins assist these complex processes and drive them via hydolysis of GTP.[271,278]

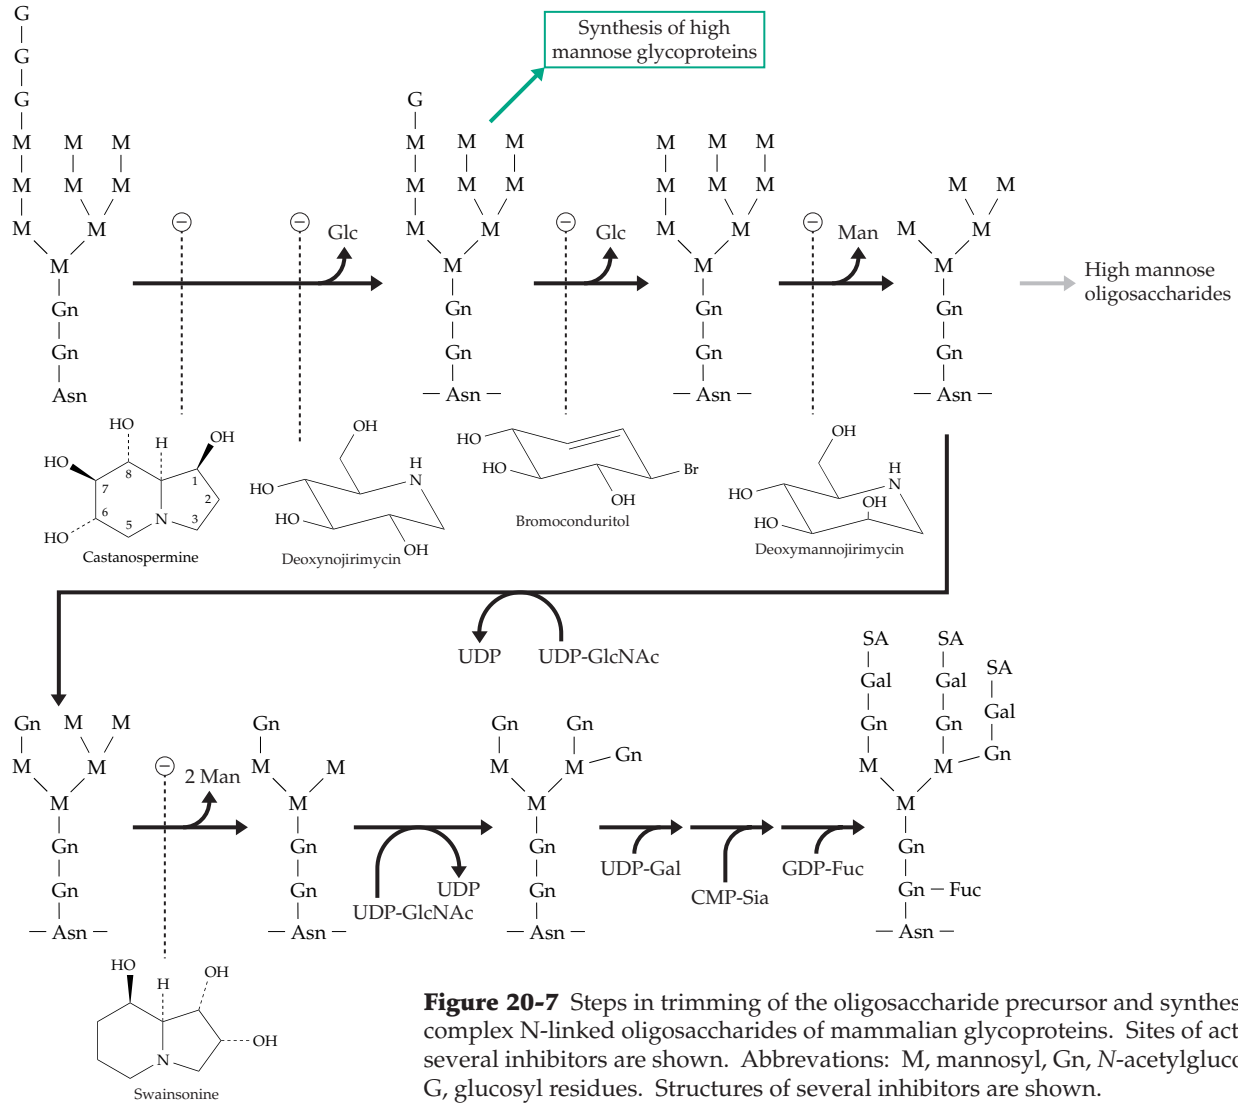

Figure 20-7 Steps in trimming of the oligosaccharide precursor and synthesis of complex N-linked oligosaccharides of mammalian glycoproteins. Sites of action of several inhibitors are shown. Abbrevations: M, mannosyl, Gn, *N*-acetylglucosaminyl, G, glucosyl residues. Structures of several inhibitors are shown.

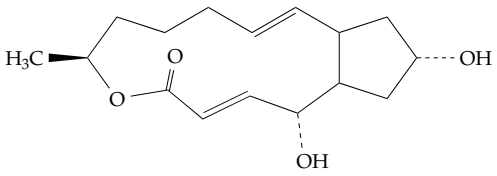
(B) Scheme showing functions of endoplasmic reticulum, transfer vesicles, Golgi apparatus, and secretion vesicles in the metabolism of glycoproteins.

While most proteins synthesized in the ER follow the exocytotic pathway through the Golgi, some are retained in the ER and some that pass on through the Golgi are returned to the ER.[279] In fact, such **retrograde transport** can carry some proteins taken up by endocytosis through the plasma membrane and through the Golgi to the ER where they undergo *N*-glycosylation. Retrograde transport is essential for recycling of plasma membrane proteins and lipids. The forward flow of glycoproteins and membrane components from the ER to the Golgi can be blocked by the fungal macrocyclic lactone **brefeldin A**. In cells treated with this drug, which inactivates a small



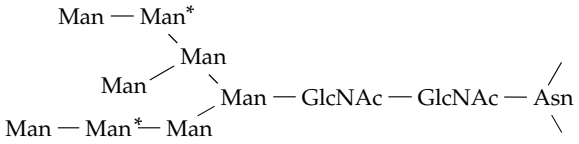
Brefeldin A

CTP-binding protein,[280] the Golgi apparatus is almost completely resorbed into the ER by retrograde transport. Proteins remaining in the ER undergo increased *O*-glycosylation as well as unusual types of *N*-glycosylation.

Although the conventional view of flow through the Golgi is generally accepted, it is difficult to distinguish it from an alternative explanation: *The Golgi compartments may move outward continuously while retrograde transport occurs via the observed vesicles*.[268,272] Some evidence for this **cisternal maturation model** has been known for many years but was widely regarded as reflecting unusual exceptions to the conventional model. In fact, both views could be partially correct; vesicular transport may function in both directions.[280a] High-resolution tomographic images are also altering our view of the Golgi.[280b]

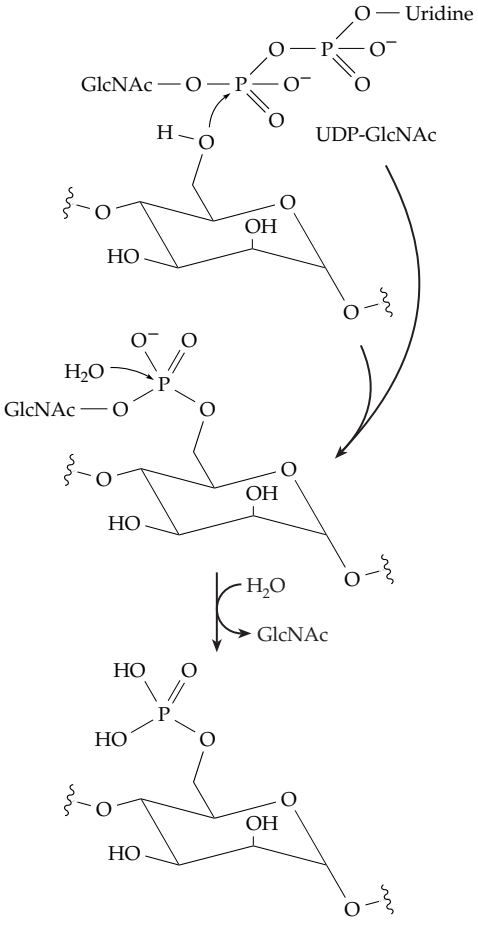
The proteins of Golgi membranes are largely integral membrane proteins and peripheral proteins associated with the cytosolic face. Some of the integral membrane proteins are the oligosaccharide-modifying enzymes, which protrude into the Golgi lumen.[280c,280d] Many other proteins participate in transport,[280d–f] docking, membrane fusion,[280g,h] and acidification of Golgi compartments.[280i] Many of the first studies of vesicular transport were conducted with synaptic vesicles and are considered in Chapter 30 (see Fig. 30-20). Other aspects of membrane fusion and transport are discussed in Chapter 8. A group of specialized Golgi proteins, the **golgins**, are also present. They are designated golgin-84, -95, -160, -245, and -376 (giantin or macrogolgin) and were identified initially as human **autoantigens** (Chapter 31), appearing in the blood of persons with autoimmune disorders such as Sjögren's syndrome.[281,282] Another protein of molecular mass ~130 kDa, and which appears to be specific to the trans-Golgi network, has been found in human serum of patients with renal vasculitis.[283]

Lysosomal enzymes. Various **sorting signals** are encoded within proteins. These include the previously mentioned C-terminal KDEL (mammals) or HDEL (yeast) amino acid sequence, which serves as a retrieval signal for return of proteins from the Golgi to the ER (p. 521).[279,284] Other sorting signals are provided by the varied structures of the oligosaccharides attached to glycoproteins. These sugar clusters convey important biological information, which is "decoded" in the animal body by interaction with various **lectins** that serve as receptors.[285] This often leads to endocytosis of the glycoprotein. An example is provided by the more than 50 proteins that are destined to become lysosomal enzymes and which undergo phosphorylation of 6-OH groups of the mannosyl residue marked by asterisks on the following structure. This is an *N*-linked oligosaccharide that has been partially trimmed. The phosphorylation is accomplished in



two steps by enzymes present in the cis Golgi compartment (Eq. 20-22) An ***N*-acetylglucosaminyl-phosphotransferase** transfers phospho-GlcNAc units from UDP-GlcNAc onto the 6-OH groups of mannosyl residues. These must be recognized by the phosphotransferase as appropriate.[286,287] Then a hydrolase cleaves off GlcNAc.

The proteins carrying the mannose 6-phosphate groups bind to one of two different **mannose 6-*P* receptors** present in the Golgi membranes and are subsequently transported in clathrin-coated vesicles to endosomes where the low pH causes the proteins to dissociate from the receptors, which may be recycled.[288–290a] The hydrolytic enzymes are repackaged in lysosomes. The same mannose 6-*P* receptors also appear on the external surface of the plasma membrane allowing many types of cells to take up lysosomal enzymes that have "escaped" from the cell. These proteins, too, are transported to the lysosomes. The mannose 6-*P* receptors have a dual function, for they also remove insulinlike growth factor from the circulation, carrying it to the lysosomes for degradation.[287,290] Most Man 6-*P* groups are removed from proteins once they reach the lysosomes but this may not always be true.[291] Not all lysosomal proteins are recruited by the mannose 6-*P* receptors. Some lysosomal membrane proteins are sorted by other mechanisms.[292]

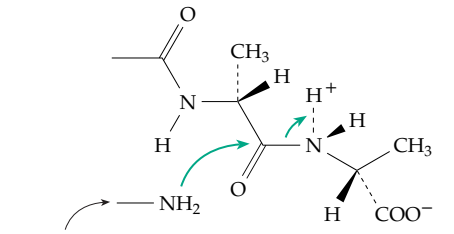


(20-22)

The hepatic asialoglycoprotein (Gal) receptor. A variety of proteins are taken out of circulation in the blood by the hepatocytes of the liver. Serum glycoproteins bearing sialic acid at the ends of their oligosaccharides (see Fig. 20-7) have relatively long lives, but if the sialic acid is removed by hydrolysis, the exposed galactosyl residues are recognized by the multisubunit **asialoglycoprotein receptor**.[293–295] The bound proteins are then internalized rapidly via the coated pit pathway and are degraded in the lysosomes. Other receptors, including those that recognize transferrin, low-density lipoprotein, α_2 macroglobulin, and T lymphocyte antigens, also depend upon interaction with oligosaccharides.[296]

E. Biosynthesis of Bacterial Cell Walls

The outer surfaces of bacteria are rich in specialized polysaccharides. These are often synthesized while attached to lipid membrane anchors as indicated in a general way in Eq. 20-20.[136,296a] One of the specific biosynthetic cycles (Fig. 20-9) that depends upon undecaprenol phosphate is the formation of the **peptidoglycan** (murein) layer (Fig. 8-29) of both gram-negative and gram-positive bacterial cell walls. Synthesis begins with attachment of L-alanine to the OH of the lactyl group of UDP-*N*-acetylmuramic acid in a typical ATP-requiring process (Fig. 20-9, step *a*).[297] Next D-glutamic acid, *meso*-diaminopimelate (Fig. 8-29), or L-lysine, and D-alanyl-D-alanine are joined in sequence, each in another ATP-requiring step.[298–301d] The entire unit assembled in this way is transferred to undecaprenol phosphate with creation of a pyrophosphate linkage (step *e*). An *N*-acetylglucosamine unit is added by action of another transferase (step *f*), and in an ATP-requiring process ammonia is sometimes added to cap the free α-carboxyl group of the D-glutamyl residue (step *g*). In *Staphylococcus aureus* and related gram-positive bacteria five glycyl units are also added, each from a molecule of glycyl-tRNA (green arrows in Fig. 20-9). The completely assembled repeating unit, together with the connecting peptide chain needed in the crosslinking reaction, is transferred onto the growing chain (step *h*). As in formation of dextrans, growth is by insertion of the repeating unit at the reducing end of the chain. The polyprenyl diphosphate is released, and the cycle is completed by the action of a pyrophosphatase (step *i*). This step is blocked by **bacitracin**, an antibiotic which forms an unreactive complex with the polyprenyl diphosphate carrier. Completion of the peptidoglycan requires crosslinking. This is accomplished by displacement of the terminal D-alanine of the pentapeptide by attack by the $-NH_2$ group of the diaminopimelate or lysine or other diamino acid (see also Fig. 8-29).[301e]



Because the peptidoglycan layer must resist swelling of the bacteria in media of low osmolarity, it must be strong and must enclose the entire bacterium. At the same time the bacterium must be able to grow in size and also to divide. For these reasons bacteria must continuously not only synthesize peptidoglycan but also degrade it.[302,303] The latter is accomplished by hydrolytic cleavage using cell wall enzymes to the ***N*-acetylglucosamine-anhydro-*N*-acetylmuramate-tripeptide** (GlcNAc-1,6-anhydro-MurNAc-L-Ala-D-Glu-A_2pm) fragment.[304,305] A hydrolase cuts the peptide bridge.[305a] This process is probably essential to formation of new growing points for expansion of the murein layer. Most of the peptide fragments that are released in the periplasm are transported back into the cytosol.

The anhydroMurNAc is removed, and new UDP-MurNAc and D-Ala-D-Ala units are added salvaging the tripeptide unit. The repaired UDP-MurNA-pentapeptide can then reenter the biosynthetic pathway (Fig. 20-9).

The O-antigens and lipid A. A cluster of sugar units of specific structure makes up the repeating unit of the "O-antigen" of *Salmonella*. The many structural variations in this surface polysaccharide account for the over two thousand serotypes of *Salmonella* (p. 180).[121,306] As is illustrated in Fig. 8-30, the O-antigen is a repeating block polymer that is attached to a complex lipopolysaccharide "core" and a hydrophobic membrane anchor known as lipid A (Figs. 8-28 and 8-30).[307–308a] Lipid A and the attached core and O-antigen are synthesized inside the bacterial cell by enzymes found in the cytoplasmic membrane.[309] The complete lipopolysaccharide units are then translocated from the inner membrane to the outer membrane of the bacteria. The synthesis of the O-antigen is understood best. Consider the following group E3 antigen, where Abe is abequose (Fig. 4-15) and Rha is rhamnose:

$$\begin{array}{l}\text{Abe}\alpha 1\\ \quad\downarrow\\ \quad 4\\ (\rightarrow 6\,\text{Gal}\beta 1\rightarrow 6\,\text{Man}1\rightarrow 4\,\text{Rha}1\rightarrow)_n\end{array}$$

Assembly of this repeating unit begins with the transfer of a *phosphogalactosyl* unit from UDP-Gal to the phospho group of the lipid carrier undecaprenol phosphate. The basic reaction cycle is much like that in Fig. 20-9 for assembly of a peptidoglycan.

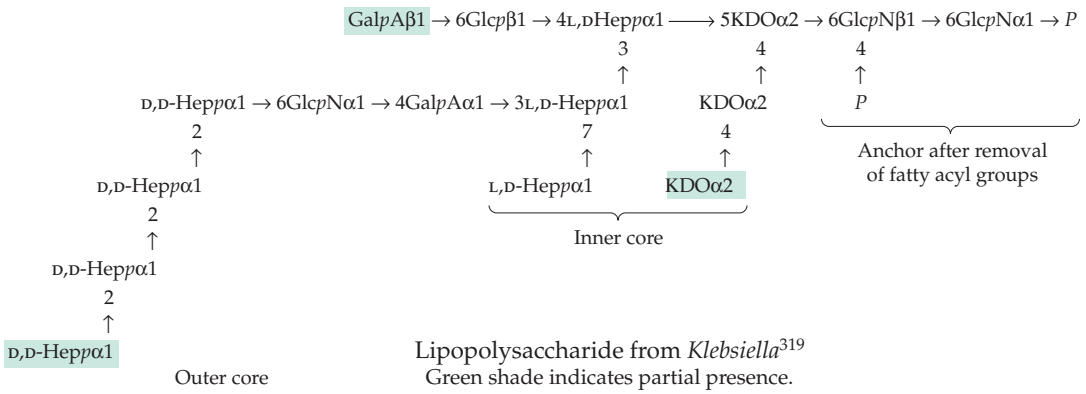
The oligosaccharide repeating unit of the O-antigen is constructed by the consecutive transferring action of three more transferases. For the antigen shown above, one enzyme transfers a rhamnosyl unit, another a mannosyl unit, and another an abequosyl unit from the appropriate sugar nucleotides. Then the entire growing O-antigen chain, which is attached to a second molecule of undecaprenol diphosphate, is transferred onto the end of the newly assembled oligosaccharide unit. In effect, the newly formed oligosaccharide is inserted at the reducing end of the growing chain just as in Fig. 20-9. Elongation continues by the transfer of the entire chain onto yet another tetrasaccharide unit. As each oligosaccharide unit is added, an undecaprenol diphosphate unit is released and a phosphatase cleaves off the terminal phospho group to regenerate the original undecaprenol phosphate carrier. When the O-antigen is long enough, it is attached to the rest of the lipopolysaccharide.

The lipid A anchor is also based on a carbohydrate skeleton. Its assembly in *E. coli*,[307] which requires nine enzymes, is depicted in Fig. 20-10. *N*-Acetylglucosamine 6-*P* is acylated at the 3-position[310] and after deacetylation[311] at the 2-position. As shown in this figure, acylation is accomplished by transfer of hydroxymyristoyl groups from acyl carrier protein (ACP). Two molecules of the resulting UDP-2,3-diacyl-GlcN are then joined via the reactions shown to give the acylated disaccharide precursor to lipid A. Stepwise transfer of KDO, L-*glycero*-D-*manno*-heptose, and other monosaccharide units from the appropriate sugar nucleotides and further acylation follows (Fig. 20-10). The assembled O-antigen chain is transferred from undecaprenol diphosphate onto the lipopolysaccharide core. This apparently occurs on the periplasmic surface of the plasma membrane. If so, the core lipid domain must be flipped across the plasma membrane before the O-antigen chain is attached.[312] Less is known about the transport of the completed lipopolysaccharide across the periplasmic space and into the outer membrane.

The core structures of the lipopolysaccharides vary from one species to another or even from one strain of bacteria to another. All three domains (lipid A, core, and O-antigen) contribute to the antigenic properties of the bacterial surface[313] and to the virulence of the organism.[313,314] Nitrogen-fixing strains of *Rhizobium* require their own peculiar lipopolysaccharides for successful symbiosis with a host plant.[315] However, there are some features common to most lipopolysaccharides. Two to three residues of KDO are usually attached to the acylated diglucosamine anchor, and these are often followed by 3 – 4 heptose rings.[316–318]

The structure of the inner core regions of a typical lipopolysaccharide from *E. coli* is indicated in Fig. 8-30. The complete structure of the lipopolysaccharide from a strain of *Klebsiella* is shown at the top of the next page.[319] Here L, D-Hep*p* is D-*manno*-heptopyranose and D, D-Hep*p* is D-*glycero*-D-*manno*-heptose. As in this case, the outer core often contains several different hexoses. The lipopolysaccharide of *Neisseria meningititis* has sialic acid at the outer end.[320] However, the major virulence factor for this organism, which is a leading cause of bacterial meningitis in young children, is a capsule of poly(ribosyl)ribitol phosphate that surrounds the cell.[321] *Haemophilus influenzae*, a common cause of ear infections and meningitis in children, has no *O*-antigen but a more highly branched core oligosaccharide than is present in *E. coli*.[321a] *Legionella* has its own variations.[321b]

Gram-positive bacteria. Although their outer coatings are extremely varied, all gram-positive bacteria have a peptidoglycan similar to that of gram-negative bacteria but often containing the intercalated pentaglycine bridge indicated in Fig. 8-29. However, the peptidoglycan of gram-positive bacteria is 20–50 nm thick, as much as ten times thicker than that of *E. coli*. Furthermore, the peptidoglycan is intertwined with the anionic polymers known as teichoic acids and



Lipopolysaccharide from *Klebsiella*[319]

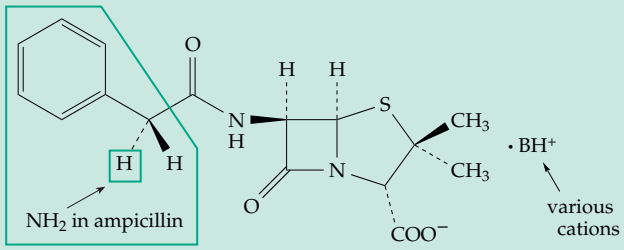
BOX 20-G PENICILLINS AND RELATED ANTIBIOTICS



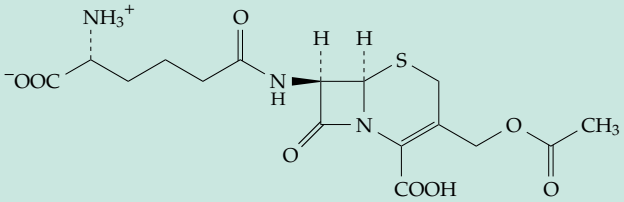
Penicillin G
(Benzylpenicillin)

Many organisms produce chemical substances that are toxic to other organisms. Some plants secrete from their roots or leaves compounds that block the growth of other plants. More familiar to us are the medicinal antibiotics produced by fungi and bacteria. The growth inhibition of one kind of organism upon another was well known in the last century, e.g., as reported by Tyndall[a,b] in 1876. The beginning of modern interest in the phenomenon is usually attributed to Alexander Fleming, who, in 1928, noticed the inhibition of growth of staphylococci by *Penicillium notatum*. His observation led directly to the isolation of penicillin, which was first used on a human patient in 1930. The early history as well as the subsequent purification, characterization, synthesis, and development as the first major antibiotic has been recorded in numerous books and articles.[c–i] During the same time period, Rene Dubos isolated the peptide antibiotics **gramicidin** and **tyrocidine**.[j] A few years later **actinomycin** (Box 28-A) and **streptomycin** (Box 20-B) were isolated from soil actinomycetes (streptomyces) by Waksman, who coined the name **antibiotic** for these compounds. Streptomycin was effective against tuberculosis, a finding that helped to stimulate an intensive search for additional antibacterial substances. Since that time, new antibiotics have been discovered at the rate of more than 50 a year. More than 100 are in commercial production.

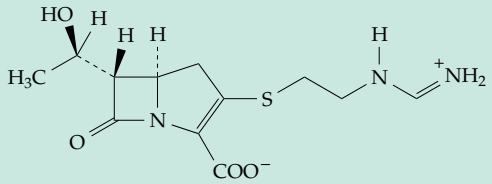
Major classes of antibiotics include more than 200 peptides such as the gramicidins, bacitracin, tyrocidines and valinomycin (Fig. 8-22)[k]; more than 150 **penicillins, cephalosporins,** and related compounds; **tetracyclines** (Fig. 21-10); the **macrolides**, large ring lactones such as the **erythromycins** (Fig. 21-11); and the **polyene** antibiotics (Fig. 21-10).

Penicillin was the first antibiotic to find practical use in medicine. Commercial production began in the early 1940s and benzylpenicillin (penicillin G), one of several natural penicillins that differ in the R group boxed in the structure above, became one of the most important of all drugs. Most effective against gram-positive bacteria, at higher concentrations it also attacks gram-negative bacteria including *E. coli*. The widely used semisynthetic penicillin **ampicillin** (R = D-α-aminobenzyl) attacks both gram-negative and gram-positive organisms. It shares with penicillin extremely low toxicity but some danger of allergic reactions. Other semisynthetic penicillins are resistant to β-lactamases, enzymes produced by penicillin-resistant bacteria which cleave the four-membered β-lactam ring of natural penicillins and inactivate them.

Closely related to penicillin is the antibiotic **cephalosporin C**. It contains a D-α-aminoadipoyl side chain, which can be replaced to form various semisynthetic cephalosporins. **Carbapenems** have similar structures but with CH_2 replacing S and often a different chirality in the lactam ring.



Cephalosporin C



Imipenem, a carbapenem antibiotic of last resort

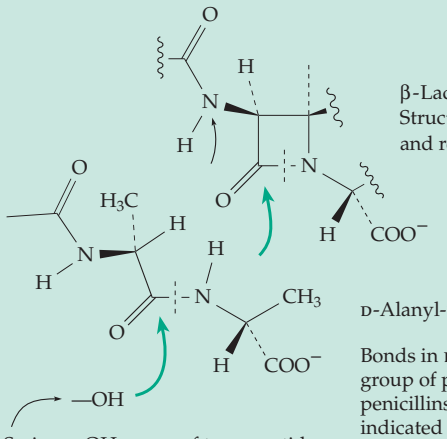
These and other related β-lactams are medically important antibacterial drugs whose numbers are increasing as a result of new isolations, synthetic modifications, and utilization of purified biosynthetic enzymes.[c,l,m]

How do antibiotics act? Some, like penicillin, block specific enzymes. Peptide antibiotics often form complexes with metal ions (Fig. 8-22) and disrupt the control of ion permeability in bacterial membranes. Polyene antibiotics interfere with proton and ion transport in fungal membranes. Tetracyclines and many other antibiotics interfere directly with protein synthesis (Box 29-B). Others intercalate into DNA molecules (Fig. 5-23; Box 28-A). There is no single mode of action. The search for suitable antibiotics for human use consists in finding compounds highly toxic to infective organisms but with low toxicity to human cells.

Penicillin kills only growing bacteria by preventing proper crosslinking of the peptidoglycan

BOX 20-G (continued)

layer of their cell walls. An amino group from a diamino acid in one peptide chain of the peptidoglycan displaces a D-alanine group in a transpeptidation (acyltransferase) reaction. The transpeptidase is also a hydrolase, a DD-carboxypeptidase. Penicillins are structural analogs of D-alanyl-D-alanine and bind to the active site of the transpeptidase.[l,n–p] The β-lactam ring of penicillins is unstable, making penicillins powerful acylating agents. The transpeptidase apparently acts by a double displacement mechanism, and the initial attack of a nucleophilic serine hydroxyl group of the enzyme on penicillin bound at the active site leads to formation of an inactivated, penicillinoylated enzyme.[q,r] More than one protein in a bacterium is derivatized by penicillin.[s] Therefore, more than one site of action may be involved in the killing of bacterial cells.



Several classes of **β-lactamases**, often encoded in transmissible plasmids, have spread worldwide rapidly among bacteria, seriously decreasing the effectivenss of penicillins and other β-lactam antibiotics.[t–y] Most β-lactamases (classes A and C) contain an active site serine and are thought to have evolved from the DD transpeptidases, but the B type[y] has a catalytic Zn^{2+}. The latter, as well as a recently discovered type A enzyme,[z] hydrolyze imipenem, currently one of the antibiotics of last resort used to treat infections by penicillin-resistant bacteria. Some β-lactam antibiotics are also powerful inhibitors of β-lactamases.[u,aa,bb] These antibiotics may also have uses in inhibition of serine proteases[cc,dd] such as elastase. Some antibiotic-resistant staphylococci produce an extra penicillin-binding protein that protects them from beta lactams.[ee] Because of antibiotic resistance the isolation of antibiotics from mixed populations of microbes from soil, swamps, and lakes continues. Renewed efforts are being made to find new targets for antibacterial drugs and to synthesize new compounds in what will evidently be a never-ending battle. We also need better antibiotics against fungi and protozoa.

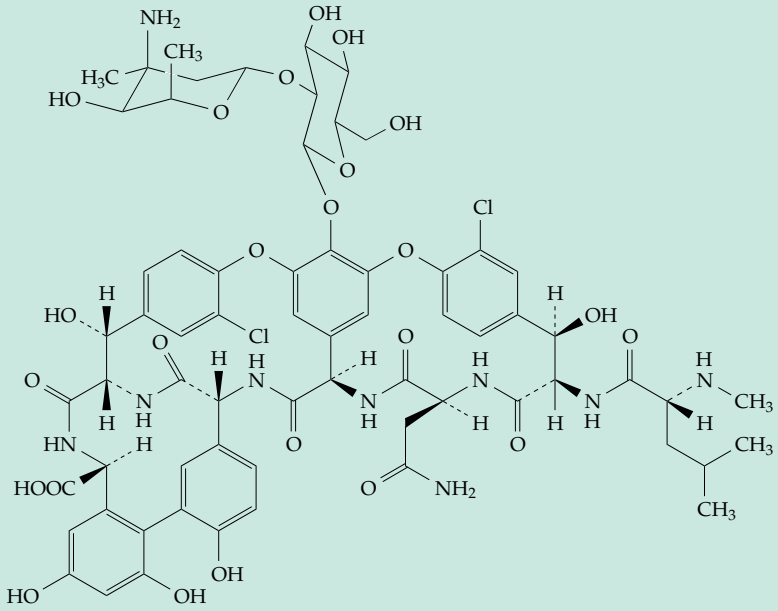
BOX 20-H ANTIBIOTIC RESISTANCE AND VANCOMYCIN



Vancomycin

As antibiotics came into widespread use, an unanticipated problem arose in the rapid development of resistance by bacteria. The problem was made acute by the fact that resistance genes are easily transferred from one bacterium to another by the infectious R-factor plasmids.[a–d] Since resistance genes for many different antibiotics may be carried on the same plasmid, "super bacteria," resistant to a large variety of antibiotics, have developed, often in hospitals.

The problem has reached the crisis stage, perhaps most acutely for tuberculosis. Drug-resistant *Mycobacteria tuberculosis* have emerged, especially, in patients being treated for HIV infection (see Box 21-C). Mechanisms of resistance often involve inactivation of the antibiotics. Aminoglycosides such as streptomycin, spectinomycin, and kanamycin (Box 20-B) are inactivated by en-zymes catalyzing phosphorylation or adenylylation of hydroxyl groups on the sugar rings.[e–g] Penicillin and related antibiotics are inactivated by β-lactamases (Box 20-G). Chloramphenicol (Fig. 25-10) is inactivated by acylation on one or both of the hydroxyl groups.

What is the origin of the drug resistance factors? Why do genes for inactivation of such unusual molecules as the antibiotics exist widely in nature? Apparently the precursor to drug resistance genes fulfill normal biosynthetic roles in nature. An antibiotic-containing environment, such as is found naturally in soil, leads to selection of mutants of such genes with drug-inactivating properties. Never-theless, it is not entirely clear why drug resistance factors have appeared so promptly in the population. Overuse of antibiotics in treating minor infections is one apparent cause.[h,i] Another is probably the widespread use on farms.[j] A nationwide effort to decrease the use of erythromycin in Finland had a very favorable effect in decreasing the incidence of erythromycin-resistant group A streptocci.[h]

Because of the rapid development of resistance, continuous efforts are made to alter antibiotics by semisynthesis (see Box 20-G) and to identify new targets for antibiotics or for synthetic antibacterial compounds.[d] An example is provided by the discovery of vancomycin. Like the penicillins, this antibiotic interferes with bacterial cell wall

teichuronic acids (p. 431). Both proteins and neutral polysaccharides, sometimes covalently bound, may also be present.[303] Like peptidoglycans, teichoic and teichuronic acids are assembled on undecaprenyl phosphates[303] or on molecules of diacylglycerol.[322] Either may serve as an anchor. A "linkage unit" may be formed by transfer of several glycosyl rings onto an anchor unit. For example, in synthesis of ribitol teichoic acid sugar rings are transferred from UDP-GlcNAc, UDP-ManNAC, and CDP-Gal to form the following linkage unit:

$$\text{Lipid}-P-P-\text{GlcNAc}-\text{ManNAc}-(P\text{-Gal})_{2,3}$$

Then many ribitol phosphate units are added by transfer from CDP-ribitol. Finally, the chain is capped by transfer of a glucose from UDP-Glc. Lipoteichoic acids often carry covalently linked D-alanine in ester linkage, altering the net electrical charge on the cell surface.[322a] The completed teichoic acid may then be transferred to a peptidoglycan, releasing the lipid phosphate for reuse.[303] Glycerol teichoic acid may be formed in a similar fashion.[322] Teichuronic acids arise by alternate transfers of *P*-GalNAc from UDP-GalNAc and of GlcA from UDP-GlcA.[303]

Gram-positive bacteria often carry surface proteins that interact with host tissues in establishing human infections. Protein A of *Staphylococcus* is a well-known

BOX 20-H (continued)

synthesis but does so by binding tightly to the D-alanyl-D-alanine termini of peptidoglycans that are involved in crosslinking (Fig. 8-29, Fig. 20-9).[k,l] Like penicillin, vancomycin prevents crosslinking but is unaffected by β-lactamases. Initially bacteria seemed unable to develop resistance to vancomycin, and this antibiotic was for 25 years the drug of choice for β-lactam resistant streptococci or staphylococci. However, during this period bacteria carrying a plasmid with nine genes on the transposon Tn1546 (see Fig. 27-30) developed resistance to vancomycin and were spread worldwide.[l] Vancomycin-resistant bacteria are able to sense the presence of the antibiotic and to synthesize an altered **D-alanine:D-alanine ligase**, the enzyme that joins two D-alanine molecules in an ATP-dependent reaction to form the D-alanyl-D-alanine needed to permit peptidoglycan crosslinking (Fig. 20-9, step *c'*). The altered enzyme adds D-lactate rather than D-alanine providing an –OH terminus in place of $-NH_3^+$. This prevents the binding of vancomycin[l,m] and allows crosslinking of the peptidoglycan via depsipeptide bonds. Another gene in the transposon encodes an oxoacid reductase which supplies the D-lactate.[l] A different resistant strain synthesizes a D-Ala-D-Ser ligase.[n] High-level vancomycin resistance is not attained unless the bacteria also synthesize a D-alanyl-D-alanine dipeptidase.[o]

The D-Ala-D-Ala ligase does provide yet another attractive target for drug design.[p,q] Still another is the D-Ala-D-Ala adding enzyme (Fig. 20-8, step *d*; encoded by the *E. coli MurF* gene).[r,s] Strategies for combatting vancomycin resistance include synthesis of new analogs of the antibiotic[t,u] and simultaneous administration of small molecules that catalyze cleavage of the D-Ala-D-lactate bond formed in cell wall precursors of resistant bacteria.[v]

Another possibility is to use **bacteriophages** directly as antibacterial medicines. This approach was introduced as early as 1919 and has enjoyed considerable success. It is now regarded as a promising alternative to the use of antibiotics in many instances.[w]

example. After synthesis in the cytoplasm, it enters the secretory pathway. An N-terminal hydrophobic leader sequence and a 35-residue C-terminal sorting signal guide it to the correct destination. There a free amino group of an unlinked pentaglycyl group of the peptidoglycan carries out a transamidation reaction with an LPXTG sequence in the proteins, cutting the chain between the threonine and glycine residues, and anchoring the protein A to the peptidoglycan.[323]

Group A streptococci, which are serious human pathogens, form α-helical coiled-coil threads whose C termini are anchored in the cell membrane. They protrude through the peptidoglycan layers and provide a hairlike layer around the bacteria. A variable region at the N termini provides many antigens, some of which escape the host's immune system allowing infection to develop.[324] Group B streptococci form carbohydrate antigens linked to teichoic acid.[325] Streptococci, which are normally present in the mouth, utilize their carbohydrate surfaces as receptors for adhesion, allowing them to participate in formation of dental plaque.[326]

Cell walls of mycobacteria are composed of a peptidoglycan with covalently attached galactan chains. Branched chains of **arabinan**, a polymer of the furanose ring form of arabinose with covalently attached **mycolic acids**, are glycosidically linked to the galactan.[327] Shorter **glycopeptidolipids**, containing

modified glucose and rhamnose rings as well as fatty acids, contribute to the complexity of mycobacterial surfaces.[328]

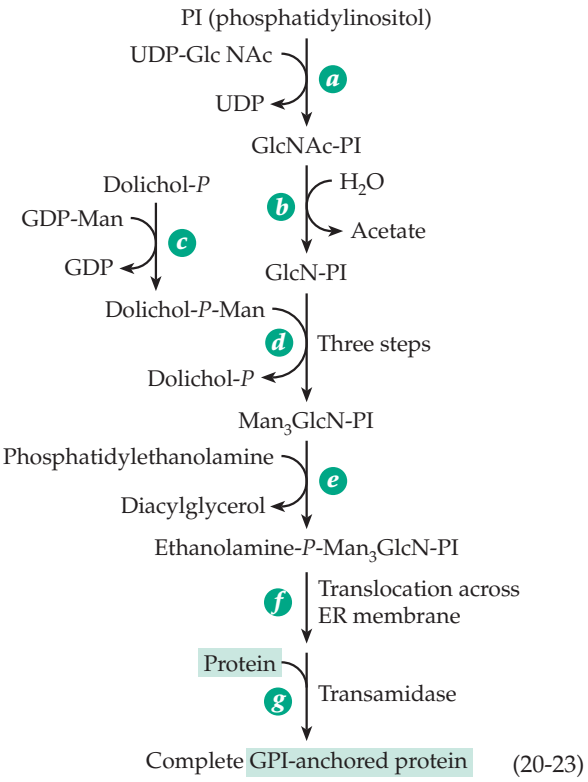
These examples describe only a small sample of the great diversity of cell coats found in the prokaryotic world. Some bacteria also provide themselves with additional protection in the form of external sheaths of crystalline arrays of proteins known as S-layers.[329]

F. Biosynthesis of Eukaryotic Glycolipids

Glycolipids may be thought of as membrane lipids bearing external oligosaccharides. In this sense, they are similar to glycoproteins both in location and in biological significance. Like the glycoproteins, glycolipids are synthesized in the ER, then transported into the Golgi apparatus and eventually outward to join the outer surface of the plasma membrane. Some glycolipids are attached to proteins by covalent linkage.

1. Glycophosphatidylinositol (GPI) Anchors

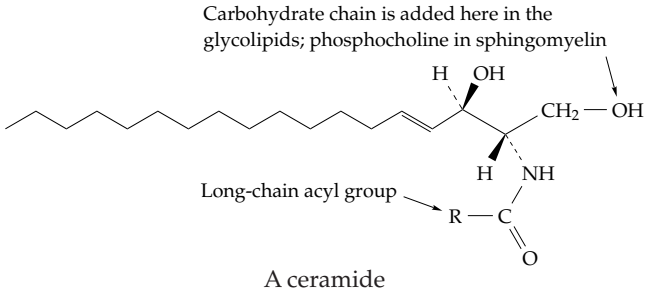
More than 100 different human proteins are attached to phosphatidylinositol anchors of the type shown in Fig. 8-13.[329a] Similar anchors are prevalent in yeast and in protozoa including *Leishmania* and *Trypanosoma*,[330–334b] and *Plasmodium* [334c] where they often bind major surface proteins to the plasma membrane.[335] They are also found in mycobacteria.[336] The structures of the hydrophobic anchor ends are all similar.[337] Two or three fatty acyl groups hold the molecule to the bilayer. Variations are found in the attached glycan portion, both in the number of sugar rings and in the structures of the covalently attached phosphoethanol-amine groups.[337–339] A typical assembly pathway is shown in Eq. 20-23. The first step (step *a* in Eq. 20-23), the transfer of an *N*-acetylglucosamine residue to phosphatidylinositol, is surprisingly complex, requiring at least three proteins.[340] The hydrolytic deacetylation (step *b*) helps to drive the synthetic process. Step *c* provides dolichol-*P*-mannose for the GPI anchors as well as for glycoproteins. The phosphoethanolamine part of the structure is added from phosphatidylethanolamine, apparently via direct nucleophilic displacement.[333] In this way the C terminus of the protein forms an amide linkage with the $-NH_2$ group of ethanolamine in the GPI anchor. Another unexpected finding was that this completed anchor unit undergoes "remodeling" during which the fatty acyl chains of the original phosphatidylinositol are replaced by other fatty acids.[339,339a]



(20-23)

2. Cerebrosides and Gangliosides

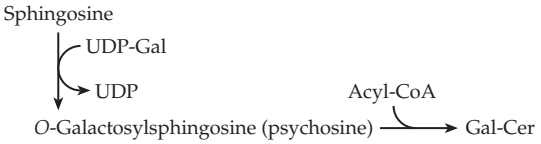
These two groups of glycolipids are derived from the *N*-acylated sphingolipids known as **ceramides**. Some biosynthetic pathways from sphingosine to these substances are indicated in Fig. 20-11. Acyl, glycosyl, and sulfo groups are transferred from appropriate derivatives of CoA, CDP, UDP, CMP, and from PAPS to form more than 40 different gangliosides.[341,342] The biosynthesis of a sphingomyelin is also shown in this scheme but is discussed in Chapter 21.



A ceramide

Each biosynthetic step in Fig. 20-11 is catalyzed by a specific transferase. Most of these enzymes are present in membranes of the ER and the Golgi.[343–346] Furthermore, the sequence by which the transferases act may not always be fixed, and a complete biosynthetic scheme would be far more complex than is shown in the figure. For example, one alternative

sequence is the synthesis of galactosyl ceramide by transfer of galactose to sphingosine followed by acylation (Eq. 20-24). However, the pathway shown in Fig. 20-11 is probably more important.



(20-24)

G. The Intracellular Breakdown of Polysaccharides and Glycolipids

The attention of biochemists has been drawn to the importance of pathways of degradation of complex polysaccharides through the existence of at least 35 inherited **lysosomal storage diseases**.[347–351] In many of these diseases one of the 40-odd lysosomal hydrolases is defective or absent.

1. Mucopolysaccharidoses

There are at least seven mucopolysaccharidoses (Table 20-1) in which glycosaminoglycans such as hyaluronic acid accumulate to abnormal levels in tissues and may be excreted in the urine. The diseases cause severe skeletal defects; varying degrees of mental retardation; and early death from liver, kidney, or cardiovascular problems. As in other lysosomal diseases, undegraded material is stored in intracellular inclusions lined by a single membrane. Various tissues are affected to different degrees, and the diseases tend to progress with time.

First described in 1919 by Hurler, **mucopolysaccharidosis I** (MPS I, the **Hurler syndrome**) leads to accumulation of partially degraded dermatan and heparan sulfates (Fig. 4-11).[347,352,353] A standard procedure in the study of diseases of this type is to culture fibroblasts from a skin biopsy. Such cells cultured from patients with the Hurler syndrome accumulate the polysaccharide, but when fibroblasts from a normal person are cultured in the same vessel the defect is "corrected." It was shown that a protein secreted by the normal fibroblasts is taken up by the defective fibroblasts, permitting them to complete the degradation of the stored polysaccharide. This "Hurler corrective factor" was identified as an **α-L-iduronidase**. In the **Hunter syndrome** (MPS II) dermatan sulfate and heparan sulfate accumulate. The missing enzyme is a **sulfatase** for 2-sulfated iduronate residues.[354,355] The diagram at the bottom of the page illustrates the need for both of these enzymes as well as three others in the degradation of dermatan.[352,356,357]

The **Sanfilippo disease** type A (MPS III) corrective factor is a heparan *N*-sulfatase. However, as is true for many other metabolic diseases, the same symptoms

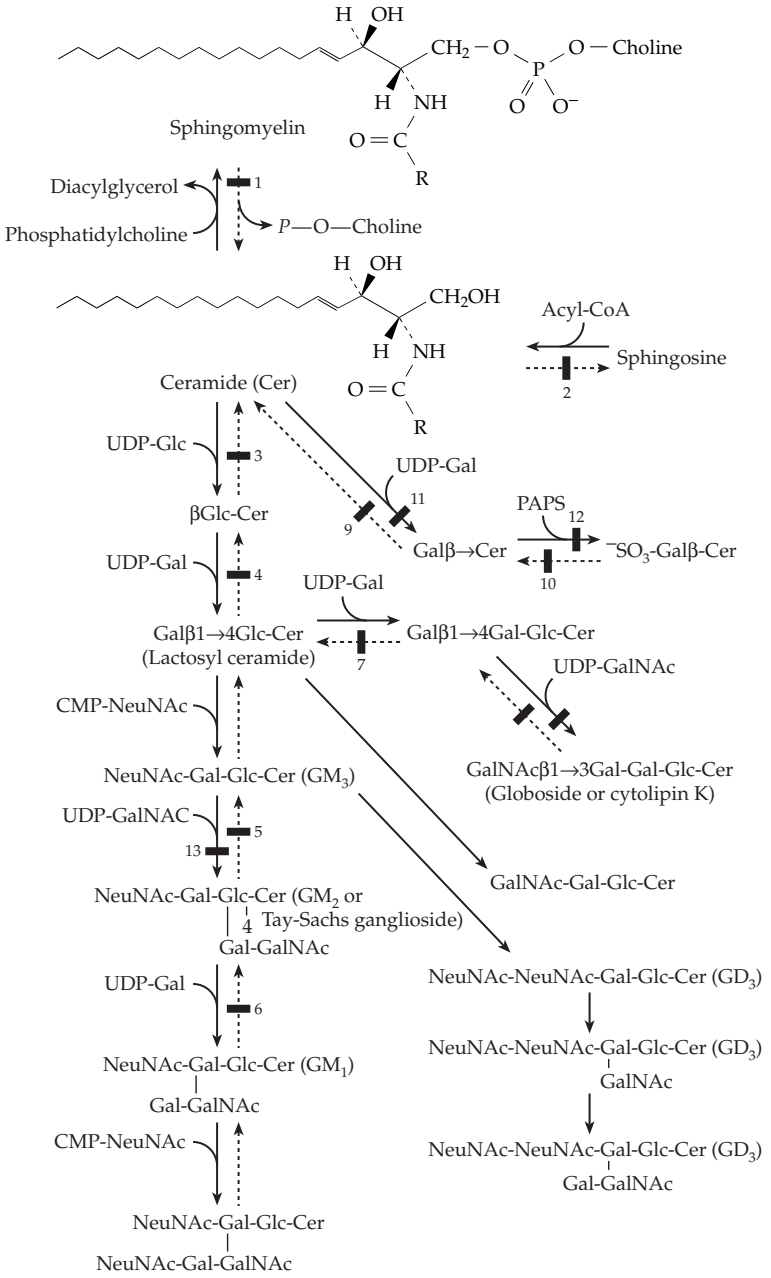


Figure 20-11 Biosynthesis and catabolism of glycosphingolipids. The heavy bars indicate metabolic blocks in known diseases.

may arise from several causes. Thus, Sanfilippo diseases B and D arise from lack of an *N*-acetylglucosaminidase and of a sulfatase for GlcNac-6-sulfate, respectively.[354] In Sanfilippo disease C the missing or defective enzyme is an acetyl transferase that transfers an acetyl group from acetyl-CoA onto the amino groups of glucosamine residues in heparan sulfate fragments. All four of these enzymes are needed to degrade the glucosamine-uronic acid pairs of heparan. The *N*-sulfate groups must be removed by the *N*-sulfatase. The free amino groups formed must then be acetylated before the *N*-acetylglucosaminidase can cut off the GlcNac groups. Remov-al of the 6-sulfate groups requires the fourth enzyme. Completion of the degradation also requires both β-glucuronidase and α-L-iduronidase. Another lysosomal enzyme deficiency, which is most prevalent in Finland, is the absence of **aspartylglucosaminidase**, an N-terminal nucleophile hydrolase (Chapter 12, Section C,3) that cleaves glucosamine from aspartate side chains to which oligosaccharides were attached in glycoproteins.[358–360]

Some hereditary diseases are characterized by lack of two or more lysosomal enzymes. In **I-cell disease** (mucolipidosis II), which resembles the Hurler syndrome, at least ten enzymes are absent or are present at much reduced levels.[350,361] The biochemical defect is the absence from the Golgi cisternae of the *N*-acetylglucosaminyl phosphotransferase that transfers *P*-GlcNAc units from UDP-GlcNAc onto mannose residues (Eq. 20-22) of glycoproteins marked for use in lysosomes.

2. Sphingolipidoses

There are at least ten lysosomal storage diseases, known as sphingolipidoses, that involve the metabolism of the glycolipids. Their biochemical bases are indicated in Fig. 20-11 and in Table 20-1. **Gaucher disease**[362–365] is a result of an autosomal recessive trait that permits glucosyl ceramide to accumulate in macrophages. The liver and spleen are seriously damaged, the latter becoming enlarged to four or five times normal size in the adult form of the disease. In the more severe juvenile form mental retardation occurs. By 1965, it was established that cerebroside is synthesized at a normal rate in the individuals affected, but that a lysosomal hydrolase was missing. This blocked the catabolic pathway indicated by dashed arrows in Fig. 20-11 (block No. 3 in the figure). In many patients a single base change causing a Leu → Pro substitution accounts for the defect. In **Fabry disease** an X-linked gene that provides for removal of galactosyl residues from cerebrosides is defective.[350] This leads to accumulation of the triglycosylceramide whose degradation is blocked at point 7 in Fig. 20-11.

The best known and the commonest sphingolipidosis is **Tay–Sachs disease**.[366–368] Several hundred cases have been reported since it was first described in 1881. A terrible disease, it is accompanied by mental deterioration, blindness, paralysis, dementia, and death by the age of three. About 15 children a year are born in North America with this condition, and the world figure must be 5–7 times this. The defect is in the α subunit of the β-hexosaminidase A (point 7 in Fig. 20-10)[366,366a] with accumulation of ganglioside G_{M2}. Somewhat less severe forms of the disease are caused by different mutations in the same gene[369] or in a protein activator. **Sandhoff disease**, which resembles Tay–Sachs disease, is caused by a defect in the β subunit, which is present in both β-hexosaminidases A and B.[368] Mutant "knockout" mice that produce only ganglioside GM_3 as the major ganglioside in their central nervous system die suddenly from seizures if they hear a loud sound. This provides further evidence of the essential nature of these components of nerve membranes.[369a]

3. Causes of Lysosomal Diseases

The descriptions given here have been simplified. For many lysosomal diseases there are mild and severe forms and infantile or juvenile forms to be contrasted with adult forms. Some of the enzymes exist as multiple isozymes. An enzyme may be completely lacking or

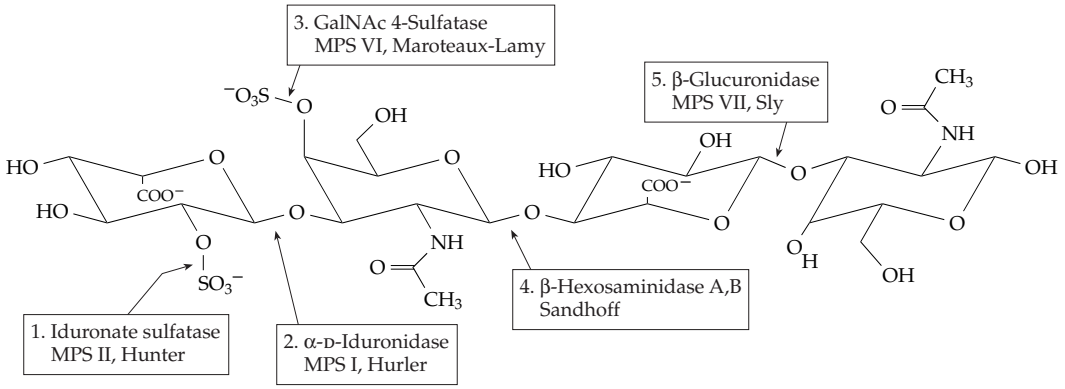

TABLE 20-1
Lysosomal Storage Diseases: Sphingolipidoses and Mucopolysaccharidoses[a]

No. in Fig. 20-11	Name	Defective enzyme

may be low in concentration. The causes of the deficiencies may include total absence of the gene, absence of the appropriate mRNA, impaired conversion of a proenzyme to active enzyme, rapid degradation of a precursor or of the enzyme itself, incorrect transport of the enzyme precursor to its proper destination, presence of mutations that inactivate the enzyme, or absence of protective proteins. Several lysosomal hydrolases require auxiliary **activator proteins** that allow them to react with membrane-bound substrates.[350,351,365,370]

4. Can Lysosomal Diseases Be Treated?

There has been some success in using enzyme replacement therapy for lysosomal deficiency diseases.[347,371-371b] One approach makes use of the fact that the mannose-6-*P* receptors of the plasma membrane take up suitably marked proteins and transfer them into lysosomes (Section C,2). The missing enzyme might simply be injected into the patient's bloodstream from which it could be taken up into the lysosomes.[372] This carries a risk of allergic reaction, and it may be safer to attempt microencapsulation of the enzyme, perhaps in ghosts from the patient's own erythrocytes.[347] A second approach, which has had limited success, is transplantation of an organ[371] or of bone marrow[373] from a donor with a normal gene for the missing enzyme. This is dangerous and is little used at present. However, new hope is offered by the possibility of transferring a gene for the missing enzyme into some of the patient's cells. For example, the cloned gene for the transferase missing in Gaucher disease has been transferred into cultured cells from Gaucher disease patients with apparent correction of the defect.[374] Long-term correction of the Hurler syndrome in bone marrow cells also provides hope for an effective therapy involving gene transfer into a patient's own bone marrow cells[375] or transplantation of selected hematopoietic cells.[375a]

In the cases of Gaucher disease and Fabry disease, it is hoped that treatment of infants and young children may prevent brain damage. However, in Tay–Sachs disease the primary sites of accumulation of the ganglioside GM_2 are the ganglion and glial cells of the brain. Because of the "blood–brain barrier" and the severity of the damage it seems less likely that the disease can be treated successfully.

The approach presently used most often consists of identifying carriers of highly undesirable genetic traits and offering genetic counseling. For example, if both parents are carriers the risk of bearing a child with Tay–Sachs disease is one in four. Women who have borne a previous child with the disease usually have the genetic status of the fetus checked by **amniocentesis**. A sample of the amniotic fluid surrounding the fetus is withdrawn during the 16th to 18th week of pregnancy. The fluid contains fibroblasts that have become detached from the surface of the fetus. These cells are cultured for 2–3 weeks to provide enough cells for a reliable assay of the appropriate enzymes. Such tests for a variety of defects are becoming faster and more sensitive as new techniques are applied.[376] In the case of Tay–Sachs disease, most women who have one child with the disease choose abortion if a subsequent fetus has the disease.

The diseases considered here affect only a small fraction of the problems in the catabolism of body constituents. On the other hand, fewer cases are on record of deficiencies in biosynthetic pathways. These are more often absolutely lethal and lead to early spontaneous abortion. However, blockages in the biosynthesis of cerebrosides are known in the special strains of mice known as Jimpy, Quaking, and msd (myelin synthesis deficient).[377,378] The transferases (points 11 and 12 of Fig. 20-11) are not absent but are of low activity. The mice have distinct neurological defects and poor myelination of nerves in the brain. A human ailment involving impaired conversion of GM_3 to GM_2 (with accumulation of the former; point 13 of Fig. 20-11) has been reported. Excessive synthesis of sialic acid causes the rare human **sialuria.**[379] This is apparently a result of a failure in proper feedback inhibition.

Animals suffer many of the same metabolic diseases as humans. Among these are a large number of lysosomal deficiency diseases.[380] Their availability means that new methods of treating the diseases may, in many cases, be tried first on animals. For example, enzyme replacement therapy for the Hurler syndrome is being tested in dogs.[381] Bone marrow transplantation for human **α-mannosidosis** is being tested in cats with a similar disease.[382] Mice with a hereditary deficiency of β-glucuronidase are being treated by gene transfer from normal humans.[357]

Study Questions

1. Constitution of cell surface oligosaccharides or polysaccharides includes the following:
   - D-Glucose
   - D-Mannose
   - D-Galactose
   - L-Arabinose
   - L-Fucose
   - D-Glucuronic acid
   - D-Neuraminic acid

   Outline pathways for biosynthesis of these compounds from glucose.

2. Decarboxylation steps are required for synthesis of UDP-xylulose and UDP-apiose (Fig. 21-1). Propose chemical mechanisms for these reactions.

3. How do animals and plants differ with respect to transport and storage of glucose?

4. Comment on unresolved questions about the biosynthesis of cellulose, amylose, and amylopectin. What glycosyl carrier groups are required?

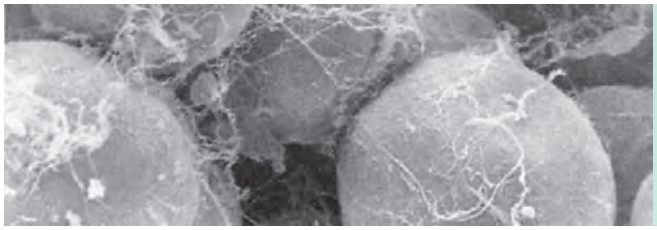
5. Most 5- and 6-membered sugars are found in nature as pyranose ring forms. Why is ribose in RNA in the furanose ring form?

6. If the ratio $[NAD^+]/[NADH]$ in a cell were 500 and the ratio $[NADP^+]/[NADPH]$ were 0.002, what concentrations of fructose and sorbitol would be in equilibrium with 0.1 mM glucose? See Box 20-A and Table 6-4.

7. Write a balanced equation for reaction of boric acid (H_3BO_3) with two sugar rings to give a borate diol ester linkage (Box 20-E).

8. Describe in general terms the process by which *N*-linked oligosaccharides are synthesized and attached to proteins. What are the functions of the ER and the Golgi?

9. What, if any, restrictions do you think should be applied to the use of antibiotics on farms?



Two large fat-filled adipose cells are seen in the foreground of this scanning electron micrograph. They are part of a larger cluster of cells from rat tissue. Delicate strands of connective tissue fibers intertwine the cells and hold them together. While most of the connective tissue substance has been washed away during preparation of the specimen, the remnants give a realistic impression of the soft, loose nature of the intercellular material. Specific Aspects of Lipid Metabolism

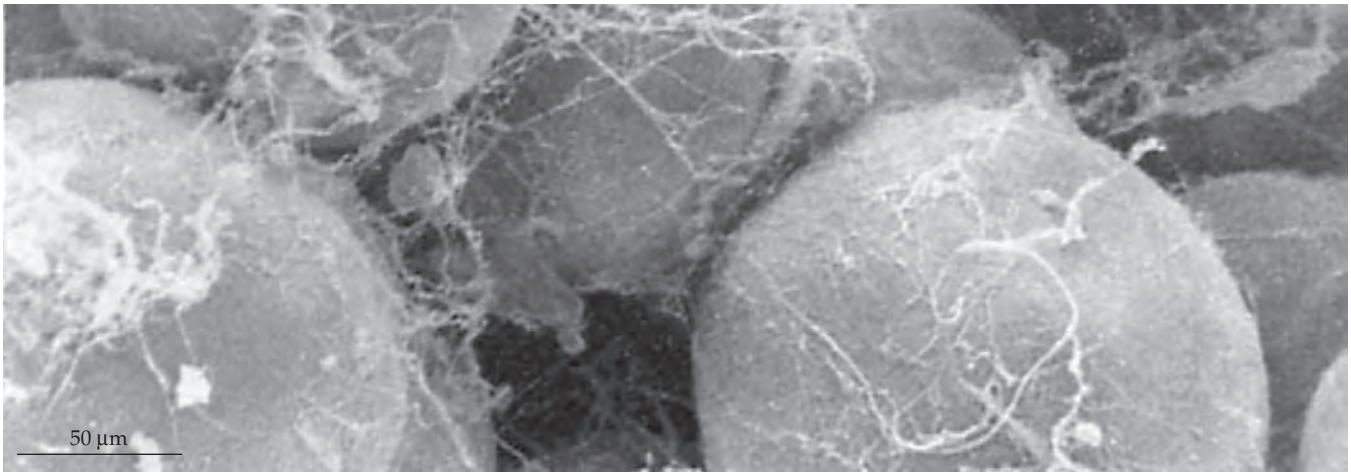
21



The basic pathways for both synthesis of fatty acids and for their β-oxidation (Fig. 17-1) have been described in Chapter 17. However, there are many variations to these pathways, and additional sets of enzymes are needed to synthesize the complex array of lipids present in most organisms. We will consider these details in this chapter. Like most other organisms, human beings are able to synthesize triacylglycerols (triglycerides), phospholipids, and glycolipids needed for cell membranes. Glucose can serve as the starting material. However, dietary lipids are also a major source. For this reason, we will start with a discussion of the digestion and uptake of lipids and of the distribution by way of the bloodstream of ingested lipids and of lipids synthesized in the liver or in other tissues.

A. Digestion, Synthesis, and Distribution of Triacylglycerols in the Human Body

Digestion of triglycerides begins in the stomach with emulsification and partial digestion by gastric lipase. Within the small intestine the ~100-residue protein called **colipase**[1–2a] binds to the surface of the fat droplets and provides an attachment site for the 449-residue **pancreatic lipase**. This Ca^{2+}-dependent serine esterase cleaves each triglyceride to two molecules of fatty acid and one of a 2-monoacylglycerol.[3–5] These products are emulsified by bile salts (Fig. 22-10) and are then taken up by the cells of the intestinal lining. The fatty acids are converted to acyl-CoA esters which transfer their acyl groups to the monoacylglycerols to resynthesize the triacylglycerols.[6] The latter are incorporated into the very large lipoprotein particles called **chylomicrons** (Table 21-1) and enter the bloodstream via the lymphatic system (Fig. 21-1).[7] Free fatty acids are also transported as complexes with serum albumin.

Synthesis of lipids from carbohydrates is an efficient process, which occurs largely in the liver and also in intestinal epithelial cells.[6] The newly synthesized triacylglycerols, together with smaller amounts of phospholipids and cholesterol, combine with specific **apolipoproteins**, which are also synthesized in the liver, to form **very low density lipoprotein (VLDL)** particles which are secreted into the blood stream. They transport the newly formed triacylglycerols from the liver to other body cells including the adipocytes, which store excess fat (Fig. 21-1).

1. Plasma Lipoproteins

The small particles of plasma lipoprotein, which carry triacylglycerols, can be separated according to their buoyant densities by centrifugation. They have been classified into five groups of increasing density but smaller size as **chylomicrons,** very low density lipoproteins **(VLDL)**, intermediate density lipoproteins (**IDL**), low density **(LDL),** and high density lipoproteins **(HDL)** (Table 21-1 and Fig. 21-2). Each lipoprotein particle contains one or more apolipoproteins (Table 21-2), whose sizes vary from the enormous 4536-residue apoB-100 to apoC-II and apoC-III, each of which contains just 79 residues[7a] and the 57-residue apoC-I.[7b]

The larger lipoproteins are spherical micelles containing a core of triacylglycerols and esters of cholesterol surrounded by a 2- to 3-nm-thick layer

consisting of phospholipid, free cholesterol, and the apolipoprotein components.[8] The size of the lipoprotein particles also varies from a 200- to 500-nm diameter for chylomicrons to as little as 5 nm for the smallest HDL particles. The difference in volume is more impressive. If, as has been estimated,[9] a 22-nm diameter LDL particle contains about 2000 cholesterol and cholesteryl ester molecules and 800 phospholipids, a small HDL particle of 7-nm diameter will have room for only about 60 molecules of cholesterol and 90 of phospholipid, while a chylomicron may carry 10 million molecules of triacylglycerol. HDL particles are quite heterogeneous. As is indicated in Table 21-1, they are sometimes dividing into HDL2 and HDL3 density groups. In addition, there is a pre-HDL with lower phospholipid content and discoid forms low in cholesterol. Models of a reconstituted lipoprotein disc contain two molecules of apoA-I and ~160 phosphatidylcholines that form a bilayer core.[10–10b]

Each apolipoprotein has one or more distinct functions. The apoB proteins probably stabilize the lipoprotein micelles. In addition, apoB-100 is essential to recognition of LDL by its receptors. The 79-residue apoC-II has a specific function of activating the lipoprotein lipase that hydrolyses the triacylglycerols of chylomicrons and VLDL. Lack of either C-II or the lipase results in a very high level of triacylglycerols in the blood.[11]

The large apolipoprotein B-100 is synthesized in the liver and is a principal component of VLDL, IDL, and LDL. It is the sole protein in LDL, accounting for nearly 20% of the mass of LDL particles. Partly because of its insolubility in water, its detailed structure is uncertain. If it were all coiled into an α helix, it would be 680 nm long and could encircle the LDL particle nearly 10 times! While the true structure of apoB-100 is unknown, it is thought to be extended and to span at least a hemisphere of the LDL surface.[12] It consists of at least five domains. Sixteen cysteines are present in the first 25 residues at the N terminus, forming a crosslinked high-cysteine region. There are also 16 *N*-glycosylated sites. Domain IV (residues 3071–4011) is thought to contain the site that binds to its specific receptor, the LDL receptor.[12] Heterogeneity in the amide I band of the infrared absorption spectrum (Fig. 23-3) suggests that about 24% is α helix, 23% β sheet, and that a large fraction consists of turns, and unordered and extended peptide structures.[13]

In intestinal epithelial cells the same apoB gene that is used to synthesize apoB-100 in the liver is used to make the shorter **apoB-48** (48%) protein. This is accomplished in an unusual way that involves "editing" of the mRNA that is formed. Codon 2153 in the mRNA for the protein is CAA, encoding glutamine. However, the cytosine of the triplet is acted on by a deaminase, an editing enzyme, to form UAA, a chain termination codon.[14,15] A third form of apoB is found in **lipoprotein(a)** (Lpa). This LDL-like particle contains apoB-100 to which is covalently attached by a single disulfide linkage (probably to Cys 3734 of apoB-100) a second protein, **apo(a)**. The latter consists largely of a chain of from 11 to over 50 kringle domains resembling the 78-residue kringle-4 of plasminogen (see Fig. 7-30C)[16–19a] as well as a protease domain.[20] This additional chain may cause tighter binding to LDL receptors and may cause lipoprotein(a) to displace plasminogen from cell surface receptors.[21] The amount of Lp(a) varies over 1000-fold among individuals and is genetically determined. The number of kringle domains also varies.[17] Although the presence of high Lp(a) is associated with a high risk of atherosclerosis and stroke,[21a] many healthy 100-year olds also have high serum Lp(a).[22]

Apolipoprotein A-I is the primary protein component of HDL.[23–25b] Most of the 243 residues consist of a nearly continuous amphipathic α helix with kinks at regularly spaced proline residues.[26–28] Two disulfide-linked ApoA-I molecules may form a belt that encircles the discoid lipoprotein.[25b] ApoA-II is the second major HDL protein, but no clearly specialized function has been identified.[29,30] ApoA-I, II, and IV, apoC-I, II, and III, and apoE all have multiple repeats of 22 amino acids with sequences that suggest amphipathic helices. The 391-residue ApoA-IV has 13 tandem 22-residue repeats. Proline and glycine are present in intervening hinge regions.[23] This may enable these proteins to spread over and penetrate the surfaces of the lipoprotein micelles. Most of these proteins are encoded by a related multigene family.[7,30a]

The 299-residue apolipoprotein E plays a key role in metabolism of both triacylglycerols and cholesterol. Like apoB-100 it binds to cell surface receptors.[31–33a] Absence of functional apoE leads to elevated plasma triacylglycerol and cholesterol, a problem that is considered in Chapter 22, Section D. The N-terminal domain, from residues 23 to 164, forms a 6.5 nm-long four-helix bundle, which binds to the LDL receptors.[32] There are three common isoforms of alipoprotein E (apoE2, apoE3, and apoE4). ApoE3 is most common.[33b] The presence of apoE4 is associated with an increased risk of Alzheimer disease (Chapter 30).

The major lipoproteins of insect hemolymph, the **lipophorins**, transport diacylglycerols. The apolipophorins have molecular masses of ~250, 80, and sometimes 18 kDa.[34–37a] The three-dimensional structure of a small 166-residue lipophorin (apolipophorin-III) is that of a four-helix bundle. It has been suggested that it may partially unfold into an extended form, whose amphipathic helices may bind to a phospholipid surface of the lipid micelle of the lipophorin.[35] A similar behavior may be involved in binding of mammalian apolipoproteins. Four-helix lipid-binding proteins have also been isolated from plants.[38] See also Box 21-A. Specialized lipoproteins known as **lipovitellins**

TABLE 21-1
Classes of Lipoprotein Particles

Class	Diameter (nm)	Density (g/ml)	Composition (weight percent)[a]				
			Surface components			Core lipids	
			Protein	Phospholipid	Cholesterol	Cholesteryl esters	Triacylglycerol
Chylomicrons	75–1200	0.93	2	7	2	3	86
VLDL	30–80	0.93–1.006	8	18	7	12	55
IDL	25–35	1.006–1.019	19	19	9	29	23
LDL	18–25	1.019–1.063	22	22	8	42	6
HDL2	9–12	1.063–1.125	40	33	5	17	5
HDL3	5–9	1.125–1.21	45	35	4	13	3

These are averages and there is considerable variation.

TABLE 21-2
Properties of Major Plasma Apolipoproteins

Designation	No. residues	Mass (kDa)	Source	Function
A-I	243	29		Major HDL protein
A-II	—	17.4	Liver and intestine	
A-IV	376	44.5		
B-100	4536	513	Liver	VLDL formation; ligand for LDL receptor
B-48	2152	241	Intestine	Chylomicron formation ligand for liver chylomicron receptor
C-I	57	6.6		
C-II	79	8.9	Liver	Cofactor for lipoprotein lipase
C-III	79	8.8		
D	—	31	Many tissues	A lipocalin
E	299	34	Liver, VLDL	Ligand for LDL receptor
(a)	Variable			Ligand for liver chylomicron receptor

store phospholipid in eggs whether from nematodes, frogs, or chickens.[39] There is some sequence similarity to that of human apolipoprotein B-100.

2. Movement of Lipid Materials Between Cells

After the synthesis and release of chylomicrons into the lymphatic circulation, various exchange processes occur by which apolipoproteins, as well as enzymes and other proteins, may be added or removed. These very complex and incompletely understood phenomena are presented in simplified form in Fig. 21-1. Chylomicrons donate apolipoproteins of the A and C families to HDL particles which, in turn, donate apoE and may also return some apoC protein to the chylomicrons.

Both chylomicrons and VLDL particles undergo similar processes in the capillary blood vessels, where their triacylglycerols are hydrolyzed to glycerol and free fatty acids by **lipoprotein lipase**.[40–42a] This enzyme requires for its activity the apolipoprotein C-II which is present in the chylomicrons and VLDL particles. Lipoprotein lipase is also known as the "clearing

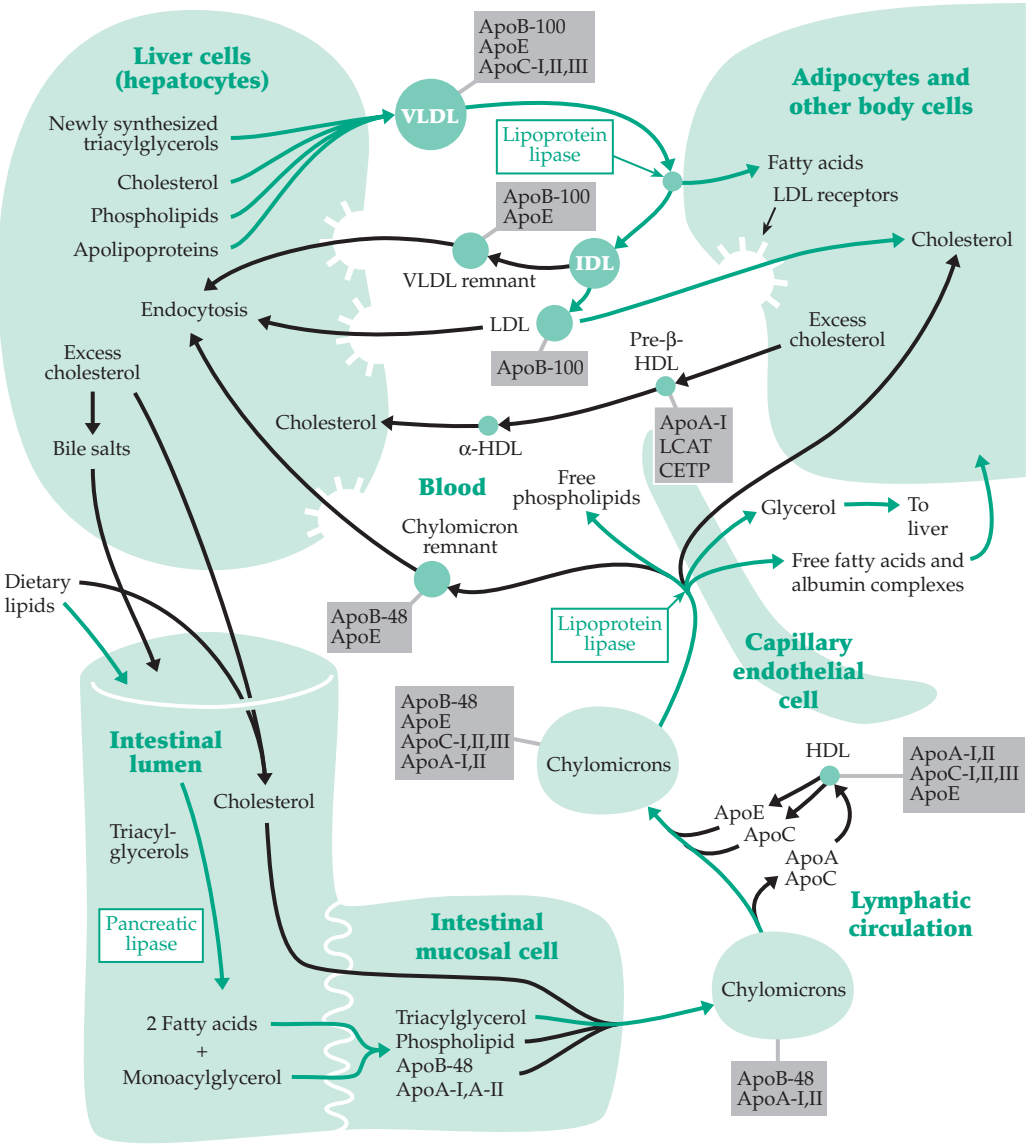

Figure 21-1 Movement of triacylglycerols from liver and intestine to body cells and lipid carriers of blood. VLDL; very low density lipoprotein which contains triacylglycerols, phospholipids, cholesterol, and apolipoproteins B, and C. IDL; intermediate density lipoproteins found in human plasma. LDL; low density lipoproteins which have lost most of their triacylglycerols. ApoB-100, etc., are apolipoproteins listed in Table 21-2. LCAT, lecithin: cholesterol acyltransferase; CETP, cholesteryl ester transfer protein (see Chapter 22).

factor" because it clears the milky chylomicron-containing lymph. It is secreted by adipocytes and other cells and becomes attached to heparan sulfate proteglycans on surfaces of capillary endothelial cells, a major site of its action.[43] Hereditary absence of functional lipoprotein lipase causes **chylomicronemia**, a massive buildup of chylomicrons in plasma.[41,44] The condition does not cause atherosclerosis but may lead to pancreatitis if not treated. Restriction of dietary fat to 20 g / day or less usually prevents problems. Naturally occurring mutations of lipoprotein lipase involving both the aspartate of the catalytic triad (p. 635)[45] and the flexible loop that covers the active site[46] have been discovered.

Both lipoprotein lipase and the less well understood **hepatic lipase** are related structurally to pancreatic lipase.[42,42b] In addition to hydrolysis of the triacylglycerols, the uptake of materials from lipoproteins probably involves shedding of intact phospholipids, perhaps as liposome-like particles.[40]

The free fatty acids and glycerol are taken up by mammalian tissue cells leaving the cholesterol and some of the phospholipids of the VLDL particles as LDL. In humans **intermediate density lipoproteins** (IDL) are formed initially, but some are converted to LDL later. Both LDL particles and the shrunken **chylomicron remnants** and **VLDL remnants** are taken up by endocytosis in coated pits and are degraded by body cells, principally of the liver.[47,48] The best known of these receptors is the 839-residue **LDL receptor,** which has a specific affinity for ApoB-100. The related **VLDL receptor** (apoE receptor) has a higher affinity for apoE[48–50] and may function in uptake of both VLDL and chylomicron remnants. The **LDL receptor-related protein** functions as a third lipoprotein receptor.[51] In addition, a series of **scavenger receptors**, found in abundance in macrophages, take up oxidized lipoproteins and other materials.[51,52] Scavenger receptor B1 (SR-B1), which is also found in liver cells, is involved in uptake of cholesterol from HDL particles by hepatocytes [53] (see also Chapter 22). Liver cells, and other cells as well, contain **lipocalins** and **fatty acid binding proteins** (Box 21-A) that help to carry these relatively insoluble acids to their destinations within the cells. Serum albumin (Box 2-A) is also a major carrier of free fatty acids.[53a] Within the adipocytes the fatty acids are reconverted to triacylglycerols. The low density (LDL) and high density (HDL) lipoproteins are involved primarily in transporting cholesterol to and from cells, a topic that is discussed in Chapter 22, Section D,2.

Fatty acids are carried to tissues for use in synthesis of triacylglycerols, phospholipids, and other membrane lipids. The mobilization of fatty acids from triacylglycerol stores and from cholesterol esters depends upon **hormone-sensitive lipase** (p. 635).[53b, 53c] This enzyme is activated by cAMP-dependent phosphorylation and moves from the cytoplasm to the surfaces of lipid droplets in response to catecholamines and other lipolytic hormones. Fatty acids are a major fuel for aerobic cells. Their conversion to acyl-CoA derivative and oxidation to CO_2 by beta oxidation (Fig. 17-1) and other pathways are discussed in Chapter 17 (pp. 939 – 950).

B. The Biosynthesis of Fatty Acids and Their Esters

The synthesis of fatty acids two carbon atoms at a time from acetyl-CoA has been considered in Chapter 17 and is outlined in Fig. 17-12. In this pathway, which resembles the β oxidation sequence in reverse, the products are saturated fatty acids with an even number of carbon atoms as shown in Fig. 21-2. In this section, we will consider some of the factors that lead to variations in the chain lengths and types of fatty acids.

1. Fatty Acid Synthases

Both bacteria and plants have separate enzymes that catalyze the individual steps in the biosynthetic sequence (Fig. 17-12). The fatty acyl group grows while attached to the small acyl carrier protein (ACP).[54–58] Control of the process is provided, in part, by the existence of isoenzyme forms. For example, in *E. coli* there are three different β-oxoacyl-ACP synthases. They carry out the transfer of any acyl primer from ACP to the enzyme, decarboxylate malonyl-ACP, and carry out the Claisen condensation (steps *b*, *e*, and *f* in Eq. 17-12)[58a – e] One of the isoenzymes is specialized for the initial elongation of acetyl-ACP and also provides feedback regulation.[58c] The other two function specifically in synthesis of unsaturated fatty acids.

In a few bacteria and protozoa and in higher animals the fatty acid synthase consists of only one or two multifunctional proteins. That from animal tissues contains six enzymes and an acyl carrier protein (ACP) domain as well. The human enzyme contains 2504 amino acid residues organized as a series of functional domains.[59–59b] Pairs of the 272-kDa chains associate to form 544-kDa dimers. The complex protein may have arisen via an evolutionary process involving fusion of formerly separate genes.[60] The enzyme contains an ACP-like site with a bound 4'-phosphopantetheine near the C terminus as well as a cysteine side chain near the N terminus in the second acylation site. Since the two –SH groups can be crosslinked by dibromopropanone,[61,62] an antiparallel linear arrangement of the two chains was proposed.[63–65] Locations of the six enzymatic activities in each chain are indicated on page 1187. According to this picture,

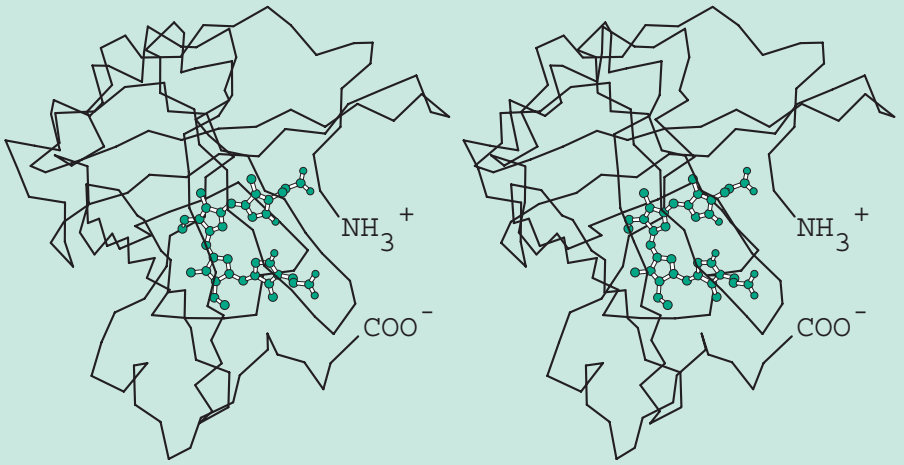
BOX 21-A LIPOCALINS, FATTY ACID-BINDING PROTEINS, AND LIPOPHORINS

Small hydrophobic molecules, which might easily bind in biologically undesirable ways, are chaperoned in animals, plants, and bacteria by binding proteins that provide hydrophobic cavities or crevices appropriate for holding these molecules in readily releasable forms. The **lipocalins**, most of which are extracellular proteins, have a conserved structural motif consisting of an 8-stranded β barrel arranged as two stacked orthogonal sheets with a C-terminal α helix that blocks one end. The other end is able to open and allow a small hydrophobic molecule to bind in the internal cavity[a–c] (see figure). Only three short amino acid sequences are conserved within a large family of lipocalins[b,d] which includes **plasma retinol-binding protein**,[e] mammalian **odorant-binding proteins**,[f] **α-lactalbumin**, **apolipoprotein D**,[a] and the blue biliverdin-binding protein **insecticyanin** of insect hemolymph.[g,h] Most lipocalins are soluble, but some such as the plasma **α1-microglobulin**,[i] which plays a role in the immune system (Chapter 31), have additional functions that require them to bind to other proteins or to cell surfaces.[j] The **gelatinase-associated lipocalin** of human neutrophils binds bacterially derived *N*-formylpeptides that act as chemotactic agents (Chapter 19) and induces release of materials from intracellular granules.[c] A few lipocalins have enzymatic activity. For example, **prostaglandin D synthase** is both an enzyme and a carrier of bile pigments and thyroid hormones.[k] Most lipocalins have been found in higher animals, but at least a few bacterial proteins belong to the family.[d] One is the 77-residue *E. coli* outer membrane lipoprotein.[a]

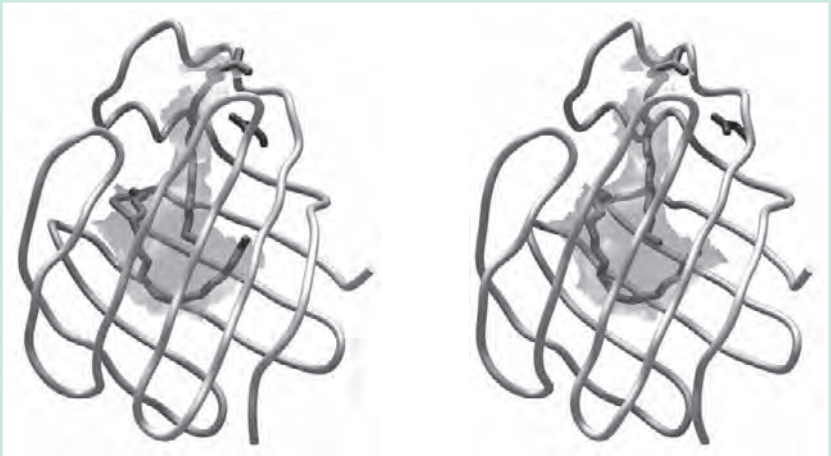
A related family of proteins are represented by **fatty acid-binding proteins**[l–o] and by the intracellular **retinol-** and **retinoic acid-binding proteins** (see also Box 22-A).[p] These are 10-stranded antiparallel β-barrels with two helices blocking an end (see Figure).

A third group of lipid-binding proteins have a four-helix bundle structure. They include the insect **lipophorins**, which transport diacylglycerols in the hemolymph (see main text), and nonspecific lipid carriers of green plants.[q] An 87-residue four-helix protein with a more open structure binds acyl-coenzyme A molecules in liver.[r]

A small 98-residue sterol-binding protein from



Stereoscopic view of an α-carbon model of an insecticyanin subunit with the bound biliverdin. The N and C termini are labeled NH_3^+ and COO^-, respectively. The positions of several amino acid residues are indicated. From Holden *et al.*[g] Courtesy of Hazel Holden.



Structure of a crystalline fatty acid-binding protein from liver with two molecules of bound oleate (dark rods). The lower molecule is more deeply embedded in the protein and more tightly bound than the second molecule, which is closer to the outer surface of the protein. Semitransparent grey marks the solvent-accessible surface of the binding cavity. An unknown molecule, perhaps butanoic acid (as modeled), binds also at top of the protein. See Thompson *et al.*[n] Courtesy of Leonard Banaszak.

BOX 21-A (continued)

the fungus *Phytophthora*, an agriculturally important plant pathogen, has a very different folding pattern. The sterol binds into a cavity formed by six helices and two loops. The protein is not only a sterol carrier but an **elicitin**, which induces a defensive response in the invaded plant. The function of the protein for the invader may be to acquire sterols for the fungus, which is unable to synthesize them.[s]

Many larger lipid carrier proteins are known. The 476-residue plasma cholesteryl ester transfer protein is discussed briefly in Chapter 22. Plasma phospholipid transfer proteins are of similar size.[t,u] A 456-residue human phospholipid-binding protein interacts with the lipopolysaccharide of the surfaces of gram-negative bacteria (Fig. 8-30) and participates in the immune response to the bacteria. It has an elongated boomerang shape with two cavities, both of which bind a molecule of phosphatidylcholine. Other plasma lipid transfer proteins may have similar structures.[v]

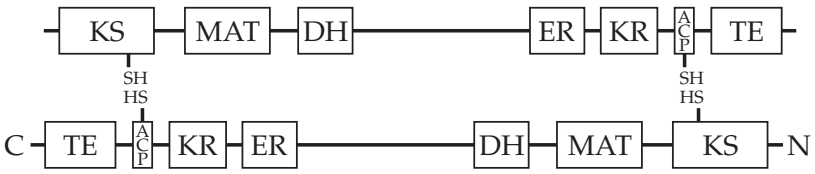
the ACP domain of one chain would cooperate with the β-oxacyl synthase (KS) domain of the second chain. However, more recent studies indicate greater flexibility with the ACP, MAS, and KS domains of a single chain also being able to function together.[58,62] Animal fatty acid synthases produce free fatty acids, principally the C_{16} palmitate. The final step is cleavage of the acyl-CoA by a thioesterase, one of the six enzymatic activities of the synthase.



Abbreviation	Enzymatic activity	Residue numbers
KS	β-Oxoacyl (ketoacyl) synthase	1 – 406
MAT	Malonyl and acetyl transferase	428 – 815
DH	Dehydratase	829 – 969
Central region	Structural core (?)	970 – 1629
ER	Enoyl reductase	1630 – 1850
KR	β-Oxoacyl (ketoacyl) reductase	1870 – 2100
ACP	Acyl carrier protein	2114 – 2190
TE	Thioesterase	2200 – 2505

Organization of eukaryotic fatty acid synthase. From Joshi *et al.*[61]

Yeast fatty acid synthase[66,67] has an $\alpha_6\beta_6$ structure where the 208-kDa α subunit contains the ACP-like site, the active site –SH, and three catalytic activities. The 220-kDa β subunit has five catalytic activities. The yeast enzyme contains the FMN thought to act as $FMNH_2$ in the second reduction step. As in bacteria, the products of the complex are molecules of acyl-CoA of chain lengths C_{14}, C_{16}, and C_{18}.[68]

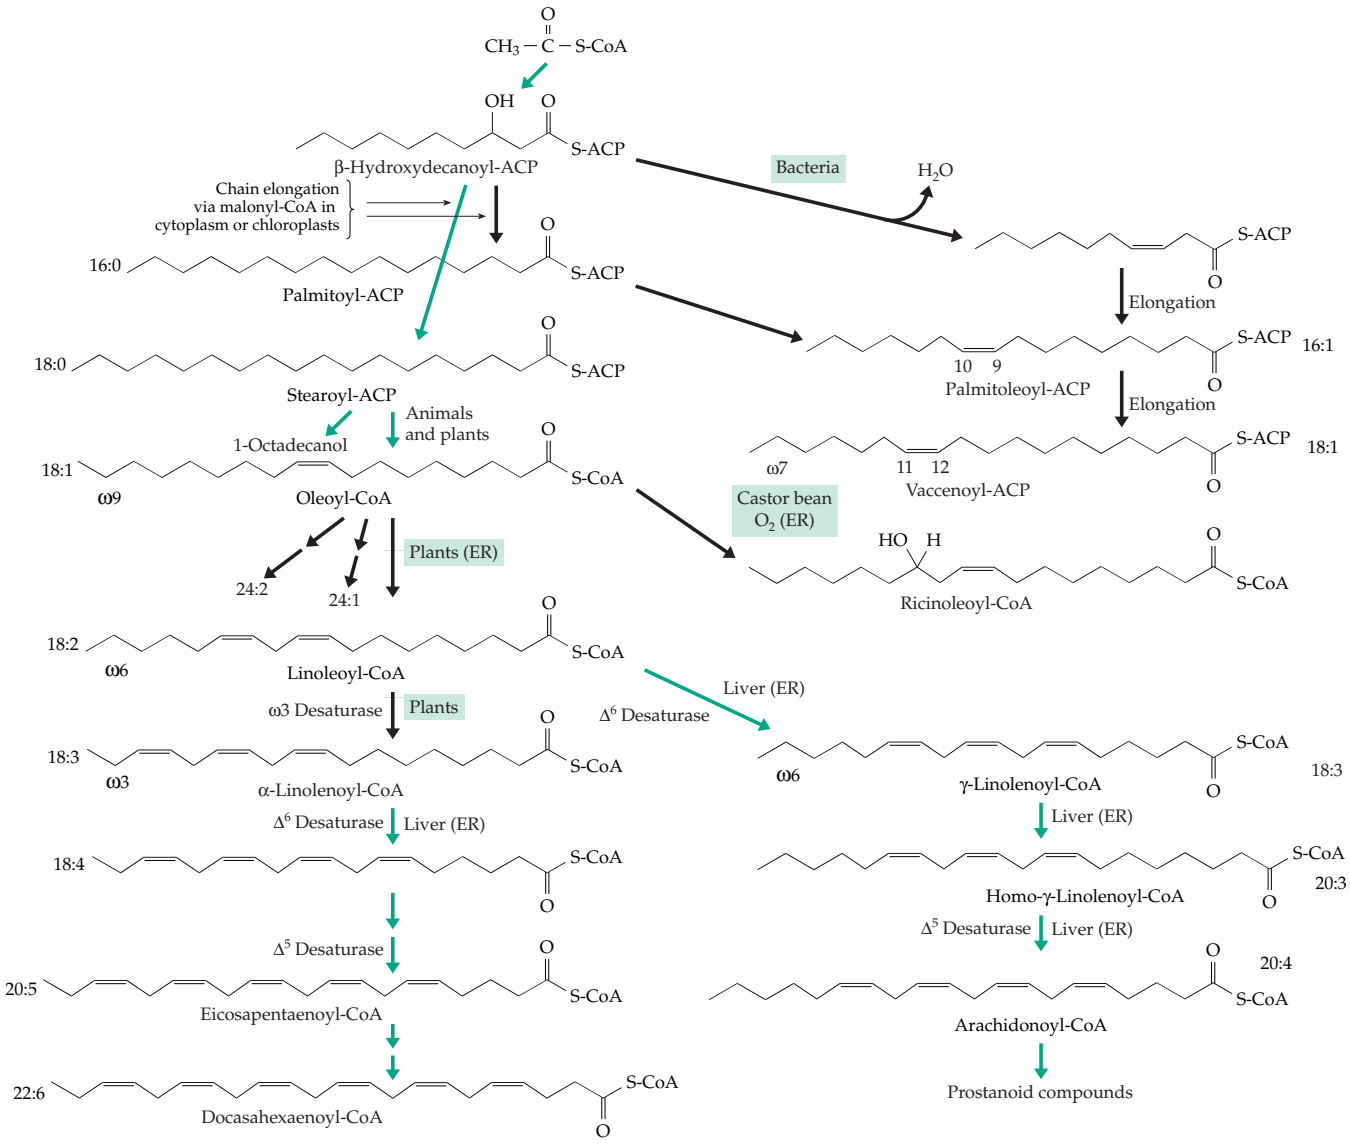


Figure 21-2 Some biosynthetic reactions of fatty acids. Green arrows indicate transformations carried out by the human body.

2. Control of Chain Length

The length of fatty acid chains is controlled largely by the enzymatic activity that releases the fatty acyl-CoA molecules or the free fatty acids from the synthase complex. In the animal enzymes the thioesterase, which is built into the synthase molecule, favors the release primarily of the 16-carbon saturated (16:0) palmitic acid. However, in mammary glands and in the uropygial glands (preen glands) of waterfowl shorter chain fatty acids predominate. These are released from the synthase by reaction with a second thioesterase, a 29-kDa protein[69,70] that catalyzes the otherwise premature release of shorter fatty acids. Cow's milk contains significant amounts of C_4-C_{14} acids as well as those with longer chains, whereas rabbit's milk contains largely C_8 to C_{10} fatty acids.[71]

In plants most biosynthesis occurs in the chloroplasts or in the protoplastids of seeds.[72–75] There are two different synthase systems in chloroplasts, one that forms primarily the 16:0 palmitoyl-ACP and the other the 18:0 stearoyl-ACP. Hydrolysis of the palmitoyl-ACP releases palmitate, one major product of chloroplasts. However, the stearoyl-ACP is desaturated to oleoyl-ACP[75a] before hydrolysis to free oleate or conversion to oleoyl-CoA. In many species oleic acid is almost the sole fatty acid exported by the chloroplasts. However, it undergoes a variety of modification reactions in the plant cytosol.

Plants, animals, and fungi all have fatty acid elon-

gation systems in the endoplasmic reticulum. Using malonyl-CoA and NADPH,[76,77] chain lengths of fatty acids may be increased to C_{20} to C_{26}. Elongation of fatty acids can also occur in mitochondria by reactions that are essentially the reverse of β oxidation. The only deviation from an exact reversal of oxidation is the use of NADPH as the reductant for enoyl-CoA reductase. Elongation of fatty acids in the *outer* membrane of mitochondria, followed by transport of the elongated chains into the mitochondria, may even constitute another shuttle for transport of reducing equivalents from NADH into mitochondria (Chapter 18, Section D).[78] Elongation reactions may also occur in peroxisomes.[78a]

3. Starter Pieces and Branches

Acetyl-CoA is most often the primer or starter piece for fatty acid synthesis, but butyryl-CoA is a better primer for rabbits. Butyryl-CoA arises from acetyl-CoA by a reversal of β oxidation, the necessary enzymes occurring in significant amounts in the cytosol.[79] If either acetyl-CoA or butyryl-CoA is the starter piece, chain elongation via malonyl-CoA (Fig. 18-12) leads to fatty acids with an even number of carbon atoms. However, degradation of the branched chain amino acids valine, isoleucine, and leucine creates a series of branched starter pieces (Table 21-3), whose utilization leads to formation of branched fatty acids of the iso and anteiso series. These are found in bacteria, in the lipids of tobacco and wool, in the "sound lens" of echo-locating porpoises,[80] and in many other materials.[81] Propionyl-CoA serves as an intermediate for introduction (via methylmalonyl-CoA) of branches at various other points in a fatty acid chain.[82] For example, 2*R*- and 4*R*-methylhexanoic acids, 2,4,6,8-tetramethyldecanoic acid, and a variety of other branched chain acids are esterified with long- chain alcohols (mainly 1-octadecanol) to form the waxes of the preen glands of ducks and geese.[83] The C_{32} **mycocerosic acid** of *Mycobacterium tuberculosis* is also formed using both malonyl-CoA and methylmalonyl-CoA for chain elongation.[84] This acid is present in mycobacterial cell walls esterified with long-chain diols (Box 21-C).[85]

TABLE 21-3
Starter Pieces for Biosynthesis of Fatty Acids

Starter piece	Fatty acid products
 Acetyl-CoA	Acid with even number of carbon atoms
 Propionyl-CoA	Acid with odd number of carbon atoms
 Isobutyryl-CoA	Iso series (even)
 Isovaleryl-CoA	Iso series (odd)
	Anteiso series (odd)

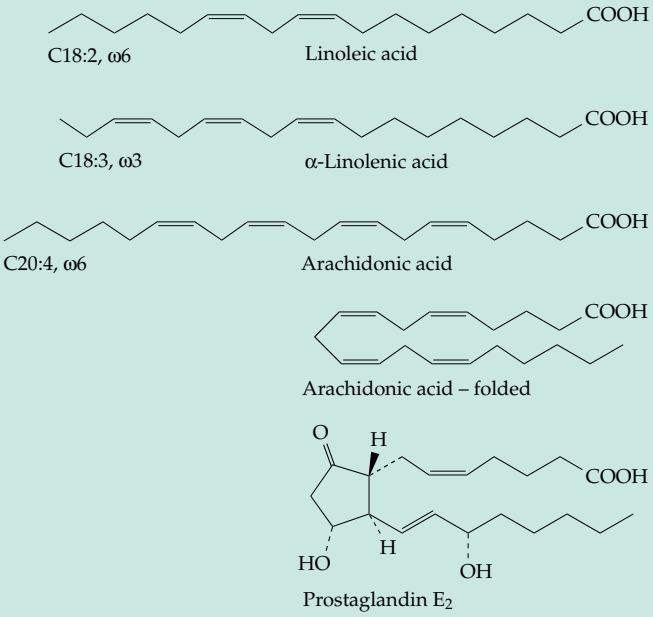
4. Synthesis by the Oxoacid Chain Elongation Process

The carbon skeleton of leucine is derived from that of valine by elongation of the corresponding oxoacid by a single carbon atom that is derived from acetyl-CoA (Fig. 17-18). At least in plants some branched-chain fatty acids of medium length are formed via the same oxoacid elongation process, which extends the chain one carbon atom at a time using 2-oxobutyrate as a starting compound. The same process can be used to form medium length straight-chain fatty acids (up to ~C_{12}) with either an odd or an even number of carbon atoms.[86]

2-Oxoglutarate can also serve as a starter piece for elongation by the oxoacid pathway. Extension by three carbon atoms yields 2-**oxosuberate** (Eq. 21-1). This dicarboxylate is converted by reactions shown in Eq. 24-39 into biotin and in archaebacteria into the coenzyme 7-mercaptoheptanoylthreonine phosphate (HTP), Eq. 21-1.[87] Lipoic acid is also synthesized from a fatty acid, the eight-carbon octanoate.[88,89] A fatty acid synthase system that utilizes a mitochondrial ACP may have as its primary function the synthesis of octanoate for lipoic acid formation.[90] The mechanism of insertion of the two sulfur atoms to form lipoate (Chapter 15) is uncertain. It requires an iron–sulfur protein[91,91a,b] and is probably similar to the corresponding process in the synthesis of biotin (Eq. 24-39)[92-93a] and in formation of HTP (Eq. 21-1). One component of the archaebacterial cofactor **methanofuran** (Chapter 15) is a tetracarboxylic acid that is formed from 2-oxoglutarate by successive condensations with two malonic acid units as in fatty acid synthesis.[94]

BOX 21-B THE ESSENTIAL FATTY ACIDS

In 1930, George and Mildred Burr reported that the C18:2 ($\Delta^{9,12}$) **linoleic acid**, a fatty acid of exclusively plant origin, cured a disease condition observed in rats raised on a highly purified fat-free diet.[a,b] These animals grew poorly, developed a scaly dermatitis, and suffered kidney damage and impaired fertility. The symptoms could be prevented if 1% of the dietary energy was provided by linoleic acid. This C18:2 fatty acid can be converted in animals into a series of other fatty acids by chain elongation and desaturation. All of this series have a double bond six carbon atoms from the $-CH_3$ terminus and form an ω6 (or n-6) family.[c]



ω6: C18:2 → C18:3 → C20:3 → C20:4 → C22:4 → C22:5

Arachidonate

↓ ↓

PGE_1, $PGF_{1\alpha}$ PGE_2, $PGF_{2\alpha}$

The major known essential function of linoleic acid is conversion to the C20:4 ($\Delta^{5,8,11,14}$) **arachidonic acid**, the major precursor to prostaglandins and other prostanoid compounds (Section D). This conversion occurs in infants as well as adults,[d] but the rate may not always be adequate, and arachidonic acid is usually classified as an essential fatty acid. It is not clear whether linoleic acid has any essential role of its own. However, while arachidonic acid can be converted into the prostaglandins designated PGE_2 and $PGF_{2\alpha}$, linoleic acid can also give rise, via the C20:30 **dihomolinolenic acid**, to PGE_1 and $PGF_{1\alpha}$ (see Eq. 21-16). The C18:3 ($\Delta^{9,12,15}$) **α-linolenic acid**, another plant acid, can partially replace linoleic acid and can be converted into PGE_3 and $PGF_{3\alpha}$.

ω3: C18:3 → C18:4 → C20:4 → C20:5 → C22:5 → C22:6

↓ ↓ ↓

PGE_3, $PGE_{3\alpha}$ PG_4 PG_5

Thus, it is not surprising that the three acids are not completely equivalent.[e–g]

Recent interest has focused on the C20:5 **eicosapentaenoic acid** (EPA) and the C22:6 **docosahexaenoic acids** (DHA). These ω3 (or n-3) polyunsaturated acids are formed from linolenic acid by marine algae and are found in fish oils.[h] The C22:5 and C22:6 acids can be converted to prostaglandins of the PG_4 and PG_5 series. DHA together with the ω6 C22:4 acid constitutes over 30% of the fatty acids in brain phospholipids. In the retina DHA accounts for over 60% of the total in the rod outer segments (Fig. 23-40). DHA may be formed in the human body from α-linolenic acid obtained from plant sources (Fig. 21-2). However, the rate of synthesis may be inadequate especially in infants and in persons of old age.[i–m] Deficiency of either EPA or DHA may lead to poor brain development during prenatal and infant life. Formation of new synapses between neurons as well as growth of new neurons in some areas of the brain is associated with thinking and with memory formation (Chapter 30). Therefore, a lack of the essential ω3 and ω6 fatty acids may contribute to mental deterioration in older adults. Eskimo populations, which consume large amounts of fish, have a very low incidence of coronary heart disease. An inverse relation between fish consumption and heart disease has also been demonstrated in other populations.[n] Inclusion of fish oils to 20–30% of total caloric intake in the diet causes a marked decrease in plasma triacylglycerols and very low density lipoproteins (VLDL).[o] This effect has been attributed to the altered composition of the prostanoid compounds known as thromboxanes and prostacyclins (PGI). For similar reasons the ω3 acids may have an antiinflammatory effect.[p,q] Administration of fish oil to patients with kidney disease has proved beneficial[r] and may decrease risk of some cancers.[s] However, a diet high in ω3 fatty acids has also been reported to increase cancer risk.[f] Long-chain ω3 fatty acids may protect against sudden death from heart disease.[t] They may promote lateral phase separation within membranes to form regions low in cholesterol (see references 95a and 119d).

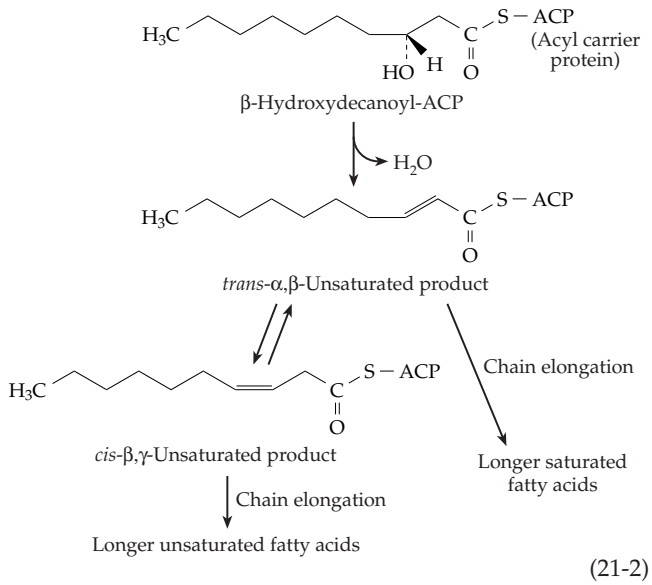
(21-1)

5. Unsaturated Fatty Acids

Fatty acids containing one or more double bonds provide necessary fluidity to cell membranes[95,95a] and serve as precursors to other components of cells. Significant differences in the methods of introduction of double bonds into fatty acids are observed among various organisms. Bacteria such as *E. coli* that can live anaerobically often form **vaccenic acid** as the principal unsaturated fatty acid. It is formed by chain elongation after introduction of a cis double bond at the C_{10} stage of synthesis. The bacteria possess a **β-hydroxydecanoyl thioester dehydratase,** which catalyzes elimination of a β-hydroxyl group to yield primarily the *cis*-β,γ rather than the *trans*-α,β-unsaturated product (Eq. 21-2).[96] The mechanism may resem-



(21-2)

ble that of enoyl hydratase (Eq. 13-7), the indicated *trans*-α,β-unsaturated intermediate (enzyme bound) being isomerized to the *cis*-β,γ-unsaturated product through an allylic rearrangement. The product can then be elongated to the C_{16} **palmitoleoyl-ACP** and C_{18} **vaccenoyl-ACP** derivatives (Fig. 21-2, right side). However, dehydration of β-hydroxydecanoyl-ACP lies at a branch point in the biosynthetic sequences. The *trans*-α,β-unsaturated fatty acyl compound lies on the usual route of chain elongation to palmitoyl-CoA (left side, Fig. 21-2).

In higher plants, animals, protozoa, and fungi, saturated fatty acids are acted upon by **desaturases** to introduce double bonds, usually of the cis (Z) configuration. The substrates may be fatty acyl-ACP, fatty acyl-CoA molecules, membrane phospholipids,[97] or glycolipids.[98] The Δ^9 desaturase, isolated from liver or from yeast, converts stearoyl-CoA to oleoyl-CoA (Eq. 21-3).[99–102] This membrane-associated enzyme system utilizes NADH as a reductant, passing electrons via cytochrome b_5 reductase and cytochrome b_5 itself to the desaturase.[103,104] The pro-*R* hydrogens are removed at both C-9 and C-10.

$$O_2 + 2\ H^+ + 2\ e^- + \text{stearoyl-CoA} \rightarrow \text{oleoyl-CoA} + 2\ H_2O \quad (21\text{-}3)$$

In plants a similar enzyme catalyzes formation of the first double bond in a fatty acyl group converting stearoyl-ACP into oleoyl-ACP in the chloroplasts.[72,75a,105–108] The soluble Δ^9 stearoyl-ACP desaturase has a diiron-oxo active site (Fig. 16-20, B, C).[109,110] Electrons are donated from light-generated reduced ferredoxin (see Chapter 23). In addition to the Δ^9 desaturase both plants and cyanobacteria usually desaturate C_{18} acids also at the Δ^{12} and Δ^{15} positions and C_{16} acids at the Δ^7, Δ^{10}, and Δ^{13} (ω3) positions.[111,112] Desaturation of oleate occurs primari-

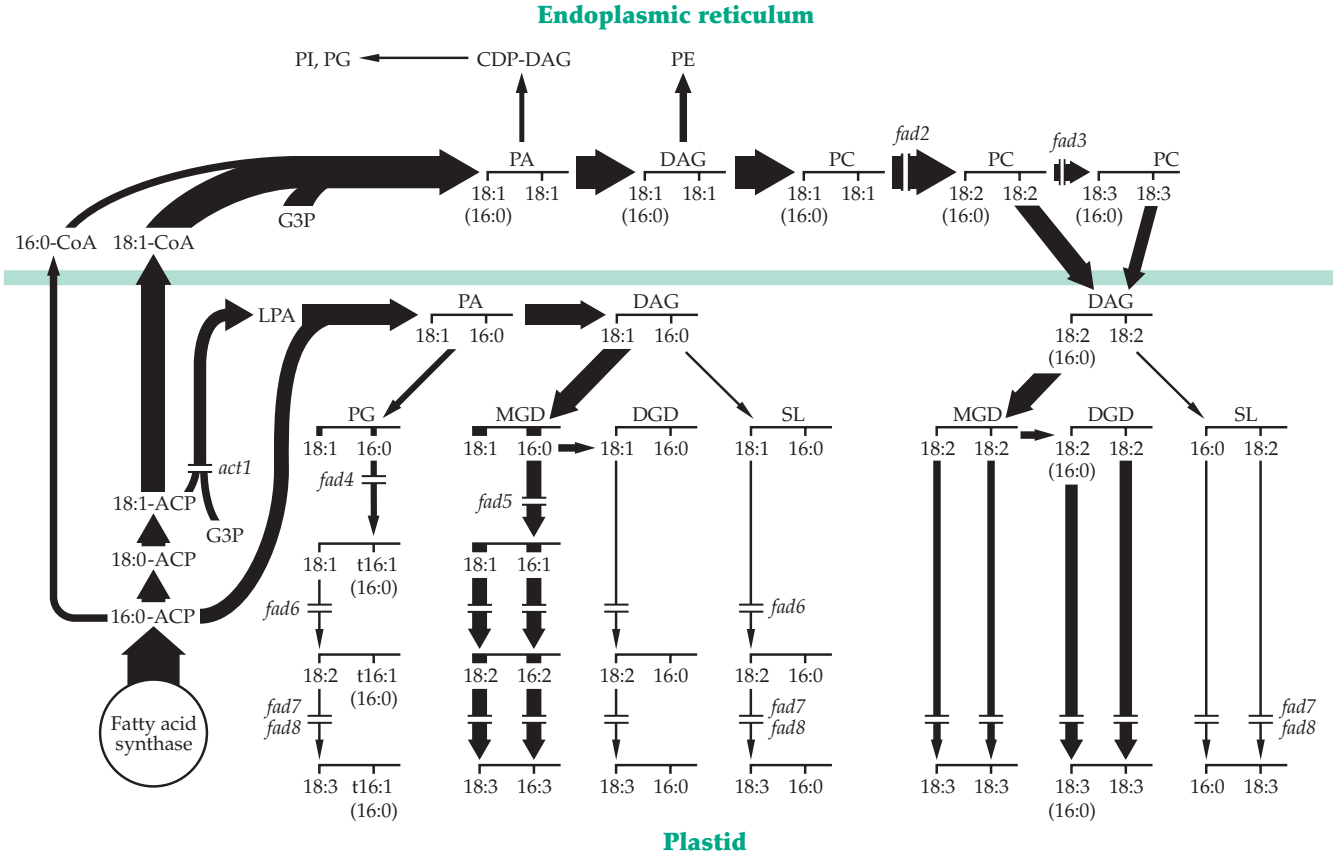


Figure 21-3 Major pathways of synthesis of fatty acids and glycerolipids in the green plant *Arabidopsis*. The major site of fatty acid synthesis is chloroplasts. Most is exported to the cytosol as oleic acid (18:1). After conversion to its coenzyme A derivative it is converted to phosphatidic acid (PA), diacylglycerol (DAG), and the phospholipids: phosphatidylcholine (PC), phosphatidylinositol (PI), phosphatidylglycerol (PG), and phosphatidylethanolamine (PE). Desaturation also occurs, and some linoleic and linolenic acids are returned to the chloroplasts. See text also. From Sommerville and Browse.[106] See also Figs. 21-4 and 21-5. Other abbreviations: monogalactosyldiacylglycerol (MGD), digalactosyldiacylglycerol (DGD), sulfolipid (SL), glycerol 3-phosphate (G3P), lysophosphatidic acid (LPA), acyl carrier protein (ACP), cytidine diphosphate-DAG (CDP-DAG).

ly in the ER after conversion of the free acid to its coenzyme A derivative or to phosphatidylcholine. Consecutive introduction of two double bonds forms linoleoyl-CoA (18:2, $\Delta^{9,12}$) and linolenoyl-CoA (18:3, $\Delta^{9,12,15}$; see Fig. 21-3).[108] All double bonds are cis. The membrane lipids of chloroplasts contain both linoleic and linolenic acids, which have apparently been returned to the chloroplasts from the cytosol[72] as indicated in Fig. 21-3. Plants grown at colder temperatures have a higher content of these trienoic acids than those grown at higher temperature.[72a]

The origin of ricinoleic acid, an abundant constituent of castor beans, is also shown in Fig. 21-2. It is formed by an **oleate hydroxylase** that has an amino acid sequence similar to those of oleate desaturases.[113] Both hydroxylation and desaturation are reactions catalyzed by diiron centers.[114] Other fatty acid hydroxylases act on the alpha[115] and the omega positions. The latter are members of the cytochrome P450 family.[116,117]

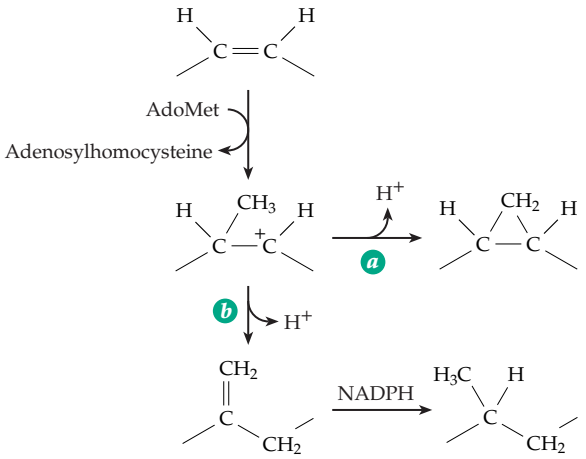
The conversion of oleoyl-CoA to linoleoyl-CoA is accomplished by some insects[118] but does not take place in most animals. As a result of this biosynthetic deficiency, polyunsaturated fatty acids such as linoleic, linolenic, and the C_{20} arachidonic acid are necessary in the diet (Box 21-B). One essential function of linoleic acid is to serve as a precursor of **prostaglandins** and related **prostanoids** (Section D). Dietary linoleate is converted to its CoA derivative and then by sequential Δ^6 desaturation,[119] elongation, and then Δ^5 desaturation, to the 20:4 ($\Delta^{5,8,11,14}$) arachidonoyl-CoA (Fig. 21-2, lower right). These acids are referred to as ω6 because of the position of the last double bond. Linolenic acid can be converted in an analogous fashion to the CoA derivative of the 20:5 ($\Delta^{5,8,11,14,17}$ ω6) eicosapentaenoic acid (**EPA**). The 22:6 docasahexaenoic acid (**DHA**; Fig. 21-2) is apparently formed by elongation of the 22:5 acyl-CoA to 24:5, desaturation, transfer to a peroxisome or mitochondrion, and β oxidation to shorten the chain.[95a]

These acids are very important in human nutrition.[119a–d] (See also Box 21-B.) In the absence of adequate essential fatty acids oleate is desaturated and elongated in a similar sequence to the unusual 20:3 ($\Delta^{5,8,11}$ ω9) acid. Vertebrate tissues also carry out desaturation at the Δ^4 and Δ^3 positions.[111] Lepidoptera, which synthesize a great diversity of pheromones, are rich in unusual desaturases such as the gland-specific acyl-CoA Δ^{11} desaturase of cabbage looper moths.[120]

Polyunsaturated fatty acids, containing 4, 5, or 6 double bonds and chain lengths of up to C_{36}, are found in phosphatidylcholine of vertebrate retinas.[121] Although the double bonds are rarely in conjugated positions in food fats and in animal bodies, some plants convert oleic or linoleic acid into fatty acids with as many as three or four conjugated double bonds.[121a] **Conjugated linoleic acid** (9*c*, 11*t* 18:2) can be formed from 11-*trans*-octadecenoate in the human body.[121b] This compound is also found in meat and dairy products. It has been reported to have anticancer properties[121c] and may be another beneficial dietary constituent. An isomerase isolated from red algae converts polyunsaturated acids into forms with conjugated double bonds. For example, arachidonic acid (5*Z*, 8*Z*, 11*A*, 14*Z*) is converted to (5*Z*, 7*E*, 9*E*, 14*Z*)-eicosatetraenoic acid.[122,123]

6. Cyclopropane Fatty Acids and Mycolic Acids

Fatty acids containing one or more cyclopropane rings are present in many bacteria (p. 381).[124,125] The extra carbon of the cyclopropane ring is added from *S*-adenosylmethionine (AdoMet) at the site of a cis double bond in a fatty acyl group of a phosphatidylethanolamine molecule in a membrane (Eq. 21-4).[126,126a] The same type of intermediate carbocation can yield either a cyclopropane fatty acid (Eq. 21-4, step *a*) or a methenyl fatty acid (Eq. 21-4, step *b*). The latter can be reduced to a branched fatty acid. This is an alternative way of introducing methyl branches that is used by some bacteria.[127]



(21-4)

Mycobacteria are rich in cyclopropane-containing fatty acids. These **mycolic acids** are major components of the cell walls and may account for 30% of the dry weight of the cells.[128] The most abundant mycolic acid of *M. tuberculosis* consists of C_{52} fatty acid containing two cyclopropane rings joined via a Claisen-type condensation with a C_{26} carboxylate fatty acid (Eq. 21-5). A similar mycolic acid formed by *M. smegmatis* has double bonds instead of cyclopropane rings as indicated below Eq. 21-5.[128,129] There are other variations. In place of a double bond or cyclopropane group there may be –OH, $-OCH_3$, C=O, epoxide, or CH_3[127]

Cyclopropane fatty acids are catabolized via β oxidation,[130] which is modified as in Eq. 21-6 when the chain degradation reaches the cyclopropane ring. The

BOX 21-C TUBERCULOSIS

As many as one-third of the inhabitants of the earth are infected by *Mycobacterium tuberculosis*. For most the infection is dormant, but in some the slow-growing bacteria cause a progressive and deadly destruction of the lungs. There are still about three million deaths annually, and *M. tuberculosis* now, as in the past, kills more people then any other pathogen.[a,b] The development of drug-resistant strains of the bacterium and the threat of a world-wide resurgence of tuberculosis[c,d] has spurred new efforts to understand the unusual metabolism of mycobacteria and to develop new drugs. The complete 4.4 million base-pair sequence of the circular genome is known.[c] An unusually large fraction of the genes encode enzymes involved in synthesis and breakdown of lipids, including the synthesis of **mycolic acids** (Eq. 21-5) which are characteristic of mycobacteria.

The mycobacterial cell wall, discussed in Chapter 8, contains mycolic acids bound covalently at the nonreducing ends of arabinogalactans that are attached to the inner peptidoglycan layer,[e] as well as phosphatidylinositol-anchored lipoarabinomannans. Other unusual lipids that are also present and account for some of the difficulty of treatment with antibiotics include esters of **mycocerosic acid** with long-chain diols known as phenolphthiocerols and phthiocerols.[f,fg]

Streptomycin (Boxes 20-B, 20-H) was introduced into clinical use against tuberculosis in about 1943. However, resistant mutants always survived until newer drugs were developed. Isonicotinylhydrazide (**isoniazid**) is especially effective in combinations with suitable antibiotics and other drugs.[g] The four-drug combination isoniazid, rifampicin (Box 28-A), pyrazinamide, and ethambutol is often used. Nevertheless, bacteria resistant to all of these have developed.

Although isoniazid has been in use for about 45 years, the enzyme that it inhibits has been recognized only recently. It is a specific NADH-dependent **enoyl reductase** involved in synthesis of mycolic acids.[h,i] The isoniazid must be activated by action of a bacterial catalase-peroxidase.[j,k] This enzyme may convert the drug to a reactive radical that combines with a NADH-derived radical to form an adduct in the active site of the enzymes. One possible reaction sequence follows.[h] However, the mechanisms are not clear.

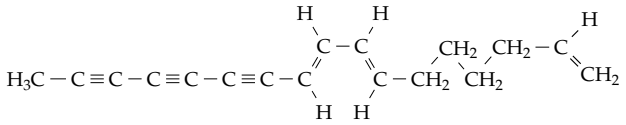
(21-6)

ring opening of the cyclopropanol derivatives occurs readily, even with mild nonenzymatic acid–base catalysis.

Another alteration of unsaturated fatty acids is the formation of acetylenic groups (–C≡C–). This apparently occurs by dehydrogenation of –CH=CH–. Examples of naturally occurring acetylenes are **crepenynic acid** (p. 381), **alloxanthin** (p. 1240), and the following remarkable hydrocarbon from the common cornflower *Centaurea cyanus*[131]:



7. The Lipids of Skin and Other Surfaces

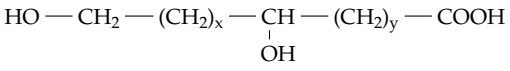
Special fatty materials are often secreted to form external surfaces of organisms.[81,132] An example already mentioned is the secretion of the uropygial glands (preen glands) of water fowl. In the goose 90% of this material is a wax consisting of monoesters of various acids with predominantly **1-octadecanol** as the long-chain fatty alcohol.[81] The latter is formed by reduction of stearoyl-CoA as indicated in Fig. 21-2. Waxes are also important constituents of marine environments, where they are not limited to surfaces. For example, copepods, which constitute a major component of marine zooplankton, may contain up to 70% of their dry weight as wax esters. Some marine animals, such as sperm whales, accumulate the same esters in major amounts as energy stores.[133]

Among the compounds present in the lipids of human skin are a variety of branched fatty acids, both free and combined. They may play a role in maintaining the ecological balance among microorganisms of the skin, and they also impart to each individual a

distinct odor or "chemical fingerprint."[132] Some of the skin lipids are incorporated into the cornified outer skin surface (Box 8-F).[134] See also Section C, 3.

Surface lipids of plants. The thick cuticle (Fig. 1-6) that covers the outer surfaces of green plants consists largely of waxes and other lipids but also contains a complex polymeric matrix of **cutin** (stems and leaves) or **suberin** (roots and wound surfaces).[135,135a] Plant waxes commonly have $C_{10} - C_{30}$ chains in both acid and alcohol components. Methyl branches are frequently present. A major function of the waxes is to inhibit evaporation of water and to protect the outer cell layer. In addition, the methyl branched components may inhibit enzymatic breakdown by microbes. Free fatty acids, free alcohols, aldehydes, ketones, β-diketones, and alkanes are also present in plant surface waxes. Chain lengths are usually $C_{20} - C_{35}$.[136] Hydrocarbon formation can occur in other parts of a plant as well as in the cuticle. Thus, normal **heptane** constitutes up to 98% of the volatile portion of the turpentine of *Pinus jeffreyi*.[81]

Cutin is largely a polyester with a high content of ω-hydroxypalmitic acid and related fatty acids, which are also hydroxylated at a second position:



Cutin monomers. C_{16} acids in which y = 8, 7, 6, or 5 and x + y = 13

This allows branching of the polymer. Monomers of other chain lengths as well as aromatic components related to lignin are also present and polymerized into a high molecular mass branched structure. Suberin is a more complex ligninlike polymer with a high content of phenolic constituents[135] such as vanillin (Fig. 25-8).

Formation of hydrocarbons. Alkanes and alkenes occur in plants, in preen gland secretions, and in insects. The alkanes of plant cuticle are thought to be formed by elongation of a C_{16} acid followed by loss of the carboxyl group. The mechanisms are not obvious. However, these hydrocarbons are often two carbon atoms shorter than the starting fatty acid. The pathway between them might begin by α-oxidation to form an α-peroxy acid which would decarboxylate to form an aldehyde, a reaction similar to that of Eq. 15-36. Alternatively, a long-chain acyl-CoA may be reduced directly to an aldehyde. In fact, when suitable inhibitors are present aldehydes do accumulate in tissues that are forming hydrocarbons.[137] Conversion of an aldehyde intermediate to an alkane may occur by **decarbonylation** (loss of CO). This has been demonstrated in pea (*Pisum sativum*) leaves,[138] in uropygial glands,[139] in flies, and in a colonial green alga, *Botyrococcus braunii*.[138] In the last case 32% of the dry weight of the cells is C_{27}, C_{29}, and C_{31} hydrocarbons. They appear to be formed by action of a decarbonylase that apparently contains a cobalt porphyrin.[137] Plants require cobalt for growth, but an enzymatic function has not previously been established.

In contrast, the sex pheromone of the female housefly is (Z)-9-tricosene, a hydrocarbon apparently formed by an oxidative decarboxylative process from a precursor aldehyde by an enzyme that requires NADPH and O_2 and is apparently a cytochrome P450.[140] Oxidative deformylation by a cytochrome P450 converts aldehydes to alkenes, presumably via a peroxo intermediate.[117] Formation of an alkene by decarboxylation has also been proposed,[141] but a mechanism is not obvious.

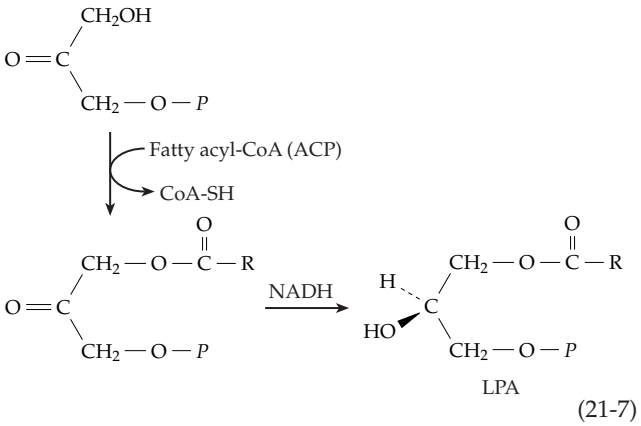
Insect waxes, hydrocarbons, and pheromones. Surface lipids of many insects contain esters of long-chain (as long as 66 carbon atoms) alcohols and long-chain acids.[142] On the other hand, waxes of the tobacco hornworm consist largely of 11- and 12-oxo derivatives of a C_{28} alcohol, which may be esterified to short-chain acids.[142] A major hydrocarbon of cockroaches is 6,9-heptacosadiene.[81]

Insects communicate through the use of a great variety of volatile pheromones. As mentioned in Chapter 8, Section A,1, some moths utilize acetate esters of various isomers of Δ^7 and Δ^{11} unsaturated C_{14} fatty acids as sex pheromones. Some other moths convert the *trans*-11-tetradecenyl acetate into the corresponding C_{14} aldehyde or alcohol, while others use similar compounds of shorter ($C_{11} - C_{12}$) chain length.[143] Some ants use ketones, such as 4-methyl-3-heptanone, as well as various isoprenoid compounds and pyrazines as volatile signaling compounds.[144] Other insects also utilize isoprenoids,[145] alkaloids,[146] and aromatic substances as pheromones.

C. Synthesis of Triacylglycerols, Glycolipids, and Phospholipids

Reduction of dihydroxyacetone phosphate yields *sn*-glycerol 3-phosphate, the starting compound for formation of the glycerol-containing lipids (Fig. 21-4 step *a*).[146a,b] Transfer of two acyl groups from ACP or CoA to the hydroxyl groups of this compound (steps *b* and *c*) yields 1,2-diacylglycerol 3-phosphate (phosphatidic acid). Two different acyltransferases are required.[147] Unsaturated fatty acids are incorporated preferentially into the 2-position. The intermediate 1-acyl-*sn*-glycero-3-phosphate, often called **lysophosphatidic acid** (LPA), is formed in excess in activated platelets and has a variety of signaling activities.[148,149] LPA for signaling is derived by turnover of existing phospholipids. An alternative route of LPA formation in liver is the transfer of one acyl group onto dihy-

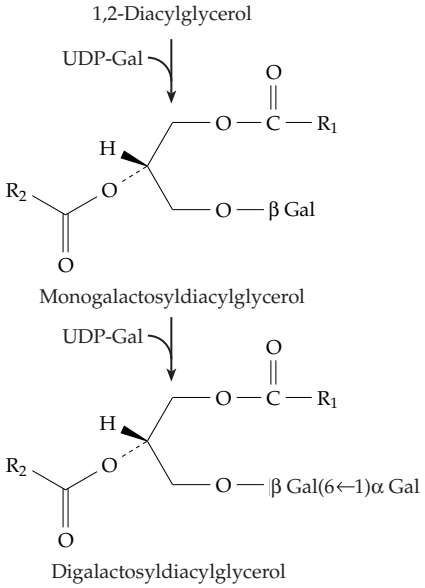
droxyacetone phosphate and reduction prior to addition of the second acyl group (Eq. 21-7).



(21-7)

Phosphatidic acid lies at a metabolic branch point. On the one hand, the phospho group can be removed by a specific phosphatase (step *d*)[150] and another acyl group (most often an unsaturated acyl group) may be transferred onto the resulting diacylglycerol (DAG, diglyceride, step *e*)[150a,b] to form a **triacylglycerol** (triglyceride). Alternatively, the phosphatidic acid may be converted to a **CDP-diacylglycerol** (step *g*), a key intermediate in phospholipid synthesis both in eukaryotes and in bacteria.[151] Not only can phosphatidic acid be hydrolyzed to 1,2-diacylglycerols, but the reverse process can occur by action of a kinase. This presumably permits recycling of the diacylglycerol formed by turnover of membrane phospholipids.[152]

Diacylglycerols can also be converted to a variety of glycolipids such as the **galactolipids** of chloroplasts (Eq. 21-8). See also Chapter 8. These are the major lipids of photosynthetic membranes.[98,153–155] Some bacteria, e.g., the mycoplasma *Acholeplasma laidlawii*, contain both monoglucosyl- and diglucosyl-DAG. Changes in the ratio of these two membrane components may regulate the phase equilibrium between bilayer and nonbilayer forms.[156] 1,2-Diacylglycerol can also react with UDP-sulfoquinovose (Eq. 20-12) to form the characteristic sulfolipid of chloroplasts.[154]



(21-8)

In animals a principal regulatory point for lipid synthesis is in the activation of acetyl-CoA carboxylase by citrate (Fig. 17-20).[156a,b] Beyond that, a complex hormonal control is exerted on both biosynthesis and the catabolism of triglycerides stored in liver and adipose tissues.[157] For example, adrenaline and glucagon, by stimulating production of cAMP, stimulate acetyl-CoA carboxylase,[158] activate lipases that cleave triacylglycerols, and mobilize depot fats.[159] Insulin, on the other hand, promotes lipid storage. It increases the activity of the enzymes of lipogenesis from the ATP-dependent citrate cleavage enzyme (Eq. 13-39) and inhibits cAMP production, thus blocking lipolysis within cells. At the transcriptional level sterols bind to activator proteins (**sterol regulatory element binding proteins,** SREBPs) and activate genes for acetyl-CoA carboxylase[158] and for stearoyl-CoA desaturases.[160] Fatty acid synthases, which play a central role in lipid formation, are controlled by both hormonal and nutritional factors at the transcriptional[161] and translational[162] levels. Environmental factors also have indirect effects. For example, the Δ^9 fatty acid desaturase activity of poikilothermic (cold-blooded) animals is increased at low temperatures. The resulting increased synthesis of unsaturated fats leads to increased fluidity of the membrane bilayer.[163] As mentioned on p. 1193; the same is true for green plants.

1. Phospholipids

Bacterial and also some eukaryotic phospholipids are formed following conversion (Fig. 21-4, step *g*) of phosphatidic acids to CDP-diacylglycerols, which are able to react with a variety of nucleophiles with displacement of CMP.[164–166] Reaction with L-serine (step *h*)[167] leads to **phosphatidylserine,** and reaction with glycerol 3-phosphate (step *i*),[168] which enters cells via a special transporter,[168a] produces **phosphatidylglycerol 3-*P*.** The enzyme catalyzing the formation of phosphatidylserine appears to occur naturally as an integral membrane protein of the ER. Some is also bound to ribosomes and to mitochondria.[169,169a] In contrast, most of the other enzymes of phospholipid formation are closely associated with or embedded in the cytoplasmic membrane. One of these, a pyruvoyl group dependent enzyme (Chapter 14, Section F), catalyzes decarboxylation of phosphatidylserine to **phosphatidylethanolamine** (PE, step *j*, Fig. 21-4).[170] This reaction had been thought unimportant in animals, but

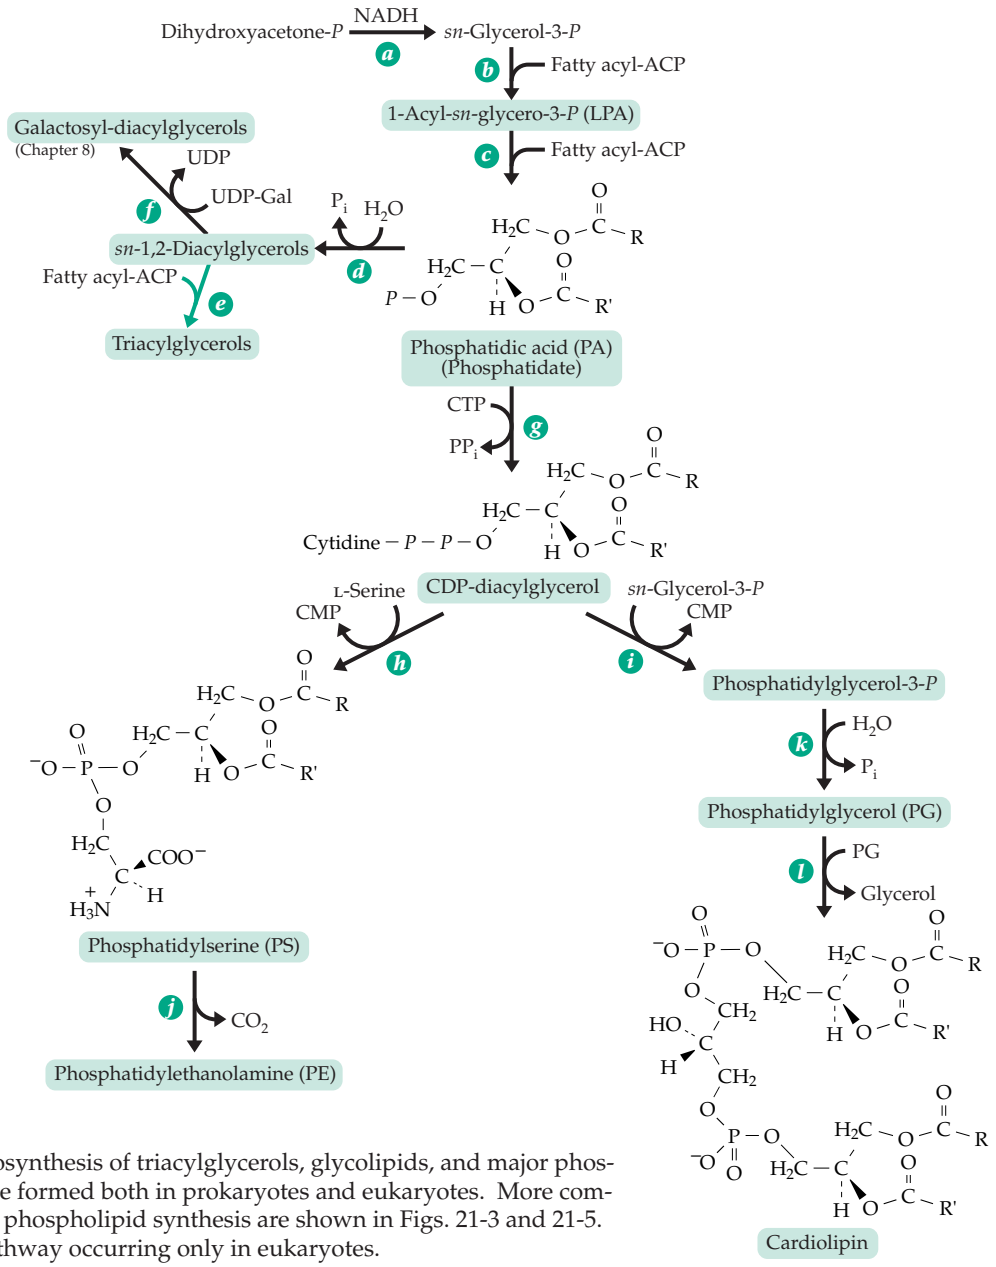


Figure 21-4 Biosynthesis of triacylglycerols, glycolipids, and major phospholipids that are formed both in prokaryotes and eukaryotes. More complete schemes of phospholipid synthesis are shown in Figs. 21-3 and 21-5. Green arrow: pathway occurring only in eukaryotes.

results with cultured cells show that decarboxylation of phosphatidylserine is often the major route of formation of phosphatidylethanolamine in mammalian cells.[171,172] This phospholipid also accounts for 75% of total phospholipid of the *E. coli* cell envelope. It is synthesized on the cytosolic side of the inner membrane, but it is also translocated to the outer membrane, where it is a major constituent of the inner bilayer leaflet.[173] PE is essential for viability of *E. coli* cells.[174] It provides dipolar ionic head groups and apparently serves as a chaperone for folding of some membrane proteins.[175]

After removal of a phosphate from phosphatidylglycerol 3-*P*, the resulting phosphatidylglycerol can be converted to **diphosphatidylglycerol** (known as **cardiolipin**). One manner in which this is accomplished in bacteria is indicated by step *l* of Fig. 21-4. One molecule of glycerol is displaced as two molecules of phosphatidylglycerol are coupled. The alternative pathway of Eq. 21-9 is followed in eukaryotic mitochondria and perhaps in some bacteria. The entire phosphatidic acid group is transferred from CDP-diacylglycerol to phosphatidylglycerol with displacement of CMP.[176–178] Gram-negative bacteria also synthesize a second set of membrane phospholipids, compounds such as **lipid A** (Figs. 8-30, 20-10) that are based on acylated glucosamine.[165]

Phosphatidylcholine, which is rarely present in bacteria, is formed in eukaryotes from phosphatidylethanolamine by three consecutive steps of methylation

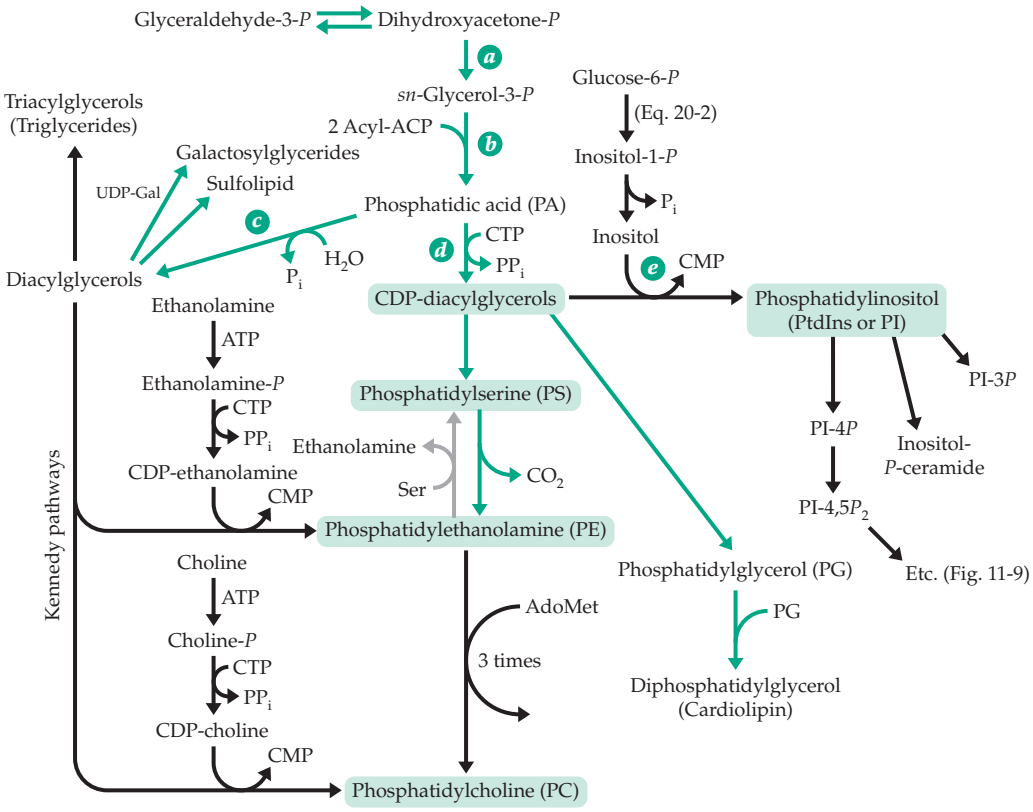

Figure 21-5 A more complete outline of the biosynthesis of triacylglycerols, glycolipids, and phospholipids including characteristic eukaryotic pathways. Green lines indicate pathways utilized by both bacteria and eukaryotes. Structures of some of the compounds are shown in Fig. 21-4. The gray arrows show the formation of phosphatidylserine by exchange with ethanolamine (Eq. 21-10).

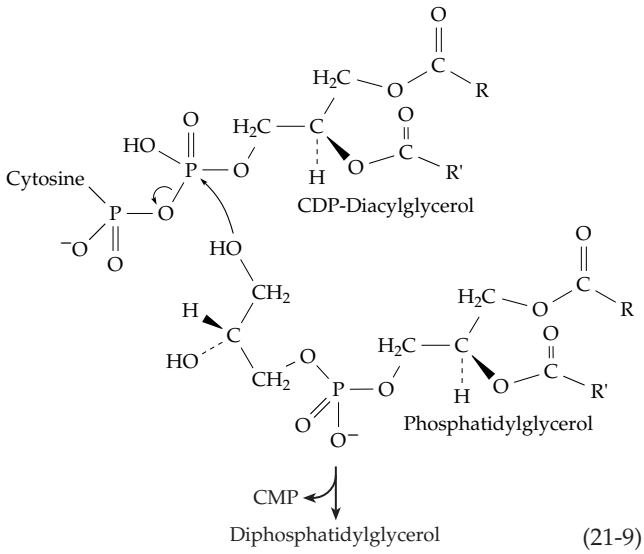
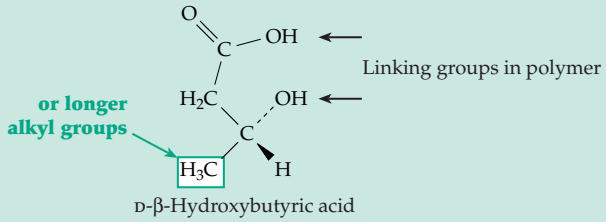


(21-9)

by *S*-adenosylmethionine (Fig. 21-5). This pathway is of major importance in eukaryotic cells.[179,180] However, alternative pathways (the Kennedy pathways),[166] which are represented by black lines on the left side of Fig. 21-5, are also used for formation of both phosphatidylcholine and phosphatidylethanolamine. In both cases, the free base, choline, or ethanolamine[180a,b] is phosphorylated with ATP. Choline phosphate formed in this manner is then converted by reaction with CTP to CDP-choline (Eq. 17-58).[181] Phosphatidylcholine is formed from this intermediate[181a,b] while CDP-ethanolamine is used to form phosphatidylethanolamine (Fig. 21-5). These synthetic reactions occur within cell nuclei as well as on surfaces of cytoplasmic membranes.[181c]

The formation of phosphatidylserine and possibly other phospholipids in animal tissues may also be accomplished by exchange reactions (Eq. 21-10, step *a*).[182,183] At the same time, decarboxylation of phosphatidylserine back to phosphatidylethanolamine (Eq. 21-10, step *b*) also takes place, the net effect being a catalytic cycle for decarboxylation of serine to ethanolamine. The latter can react with CTP to initiate synthesis of new phospholipid molecules or can be converted to phosphatidylcholine (step *c*). However, unless there is an excess of methionine and folate in the diet, choline is an essential human nutrient.[184]

BOX 21-D POLY-β-HYDROXYBUTYRATE AND BIODEGRADABLE PLASTICS



D-β-Hydroxybutyric acid

The important bacterial storage material polyhydroxybutyric acid is related metabolically and structurally to the lipids. This highly reduced polymer is made up of D-β-hydroxybutyric acid units in ester linkage, about 1500 residues being present per chain. The structure is that of a compact right-handed coil with a twofold screw axis and a pitch of 0.60 nm.[a] Within bacteria it often occurs in thin lamellae ~5.0 nm thick. Since a chain of 1500 residues stretches to 440 nm, there must be ~88 folds in a single chain. Present in both cytoplasmic granules and in membranes,[b] polyhydroxybutyrate can account for as much as 50% of the total carbon of some bacteria.[c] In *E. coli* and many other bacteria polyhydroxybutyrate is present in a lower molecular mass form bound to calcium polyphosphates, proteins, or other macromolecules.[d,e] It has also been extracted from bovine serum albumin and may be ubiquitous in both eukaryotes and prokaryotes.[d,e] The polymer may function in formation of Ca^{2+} channels in membranes.[b,d]

Biosynthesis occurs from 3-hydroxybutyryl-CoA. Some bacteria incorporate other β-hydroxyacids into the polymer.[f] Apparently various hydroxyacyl-CoAs can be diverted from the β oxidation pathway to polymer synthesis,[g] and synthases that will accept a variety of β-hydroxyacyl-CoA substrates have been isolated.[h,i] More than 80 different hydroxyacyl groups can be incorporated into the polymer.[i] A bacterially produced copolymer of β-hydroxybutyrate and β-hydroxyvalerate resembles polypropylene but is biodegradeable. It not only can be used for sutures and other medical implants[j] but also could compete with petroleum-derived plastics[h] and be derived from renewable sources. To this end the synthase genes have been cloned, engineered, and transferred into other microorganisms and plants.[k–n] Transgenic cotton plants incorporate polyhydroxybutyrate granules into the cotton fibers altering the properties of the fibers.[m] The polyhydroxybutyrate synthases apper to be related mechanistically to bacterial lipases.[o]

(21-10)

Apparently the synthesis via serine and phosphatidylserine cannot provide an adequate amount of choline, which is present in the body not only in phosphatidylcholine but in plasmalogens, sphingomyelins, and the neurotransmitter **acetylcholine**.[185]

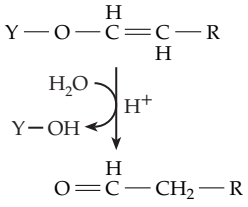
Phosphatidylinositol (PI), a major component of membrane lipids, is formed by displacement of CMP from CMD-dialylglycerol by *myo*-inositol.[186] It is also converted into a variety of less abundant phosphorylated derivatives that engage in signaling activities (see Fig. 11-9). In addition, PI is a component of the glycosylphosphatidylinositol (GPI) membrane anchors for suface proteins (Fig. 8-13). Free GPI anchors, lacking bound proteins, are also present in membranes.

They are especially abundant in many parasitic protozoa and may carry additional glycosyl groups.[186a]

Regulation of phospholipid synthesis, which has been studied in detail in yeast,[187–191] is complex but highly coordinated. The committed step in the synthesis of PE and PC is the hydrolysis of phosphatidate (PA) by a phosphatase to generate diacylglycerols (Fig. 21-5, step *c*). Reaction of PA with CTP (step *d*) also affects synthesis of the other major phospholipids. Much of the coordinate regulation arises at the transcriptional level. For example, genes for the synthesis of PC or PI are repressed by inositol alone and in combination with choline.[187,188] Regulation of CTP synthetase controls the formation of CDP-diacylglycerols.[190] In mammalian cells PC synthesis appears to occur only during the S-phase of the cell cycle (Fig. 11-15).[191] The CTP: phosphocholine cytidyltransferase that catalyzes CDP-choline formation is controlled by storage in a resevoir in the nucleus from which it is transferred to ER membranes.[181b]

2. The Ether-Linked Lipids

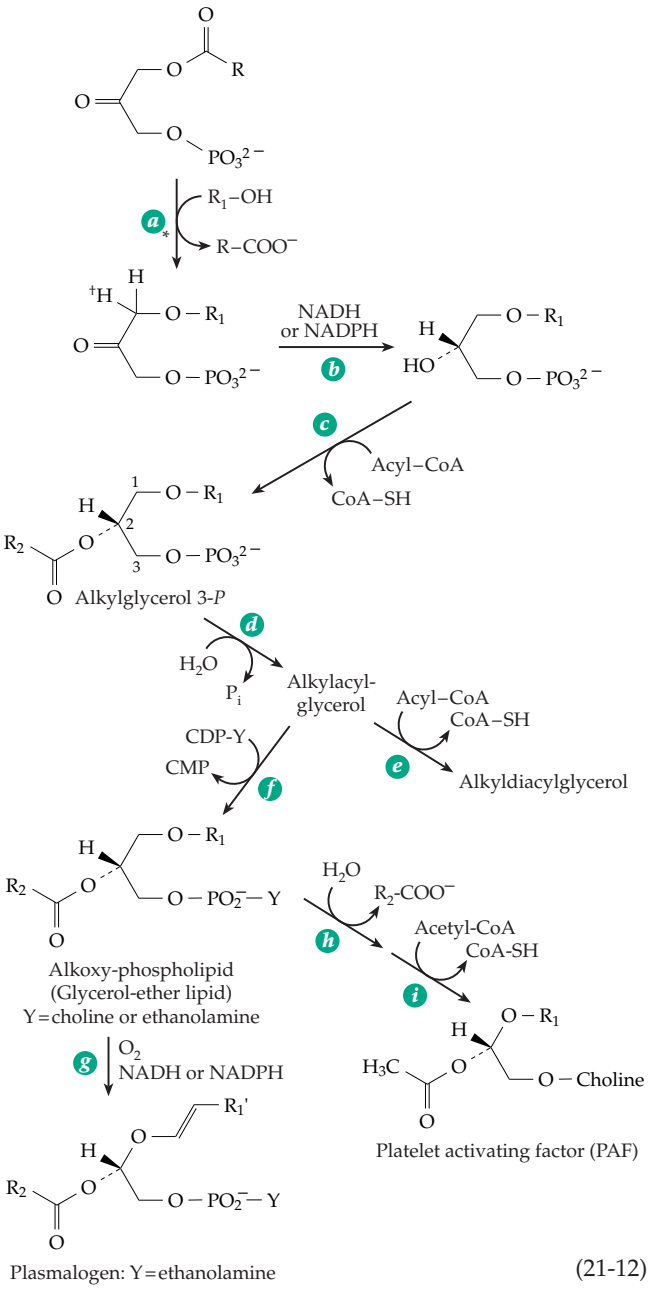
Closely related to both the triacylglycerols and phospholipids, the ether-linked lipids contain in place of one ester group an *alkoxy* (–OR) or *alkenyl* (–O–CH=CH–R) group.[192] Phospholipids containing the alk-1-enyl group, the **plasmalogens**, were first recognized in 1924 by Feulgen and Voit, who were developing histological staining procedures. They observed that treatment of tissue slices with acid resulted in the liberation of aldehydes, which were later shown to be formed by breakdown of the alkenyl lipids (Eq. 21-11). Over 10% of the lipid in the human central nervous system is plasmalogen and about 1% is alkoxy lipid. Among the latter is the **platelet activating factor** (Box 8-A).[193-194a] In many mammalian cells the ethanolamine plasmalogen **plasmenylethanolamine** represents the major storage depot of arachidonic acid.[195]



(21-11)

Ether-linked lipids constitute up to 35% of the total phospholipid in molluscs. Although they are usually regarded as animal constituents, small amounts of ether-linked lipids have been identified in plants. The major phospholipids of archaebacterial membranes are ether-linked derivatives of the polyprenyl phytanyl group and of the dimeric biphytanyl group (Chapter 8).[196–198]

Biosynthesis of ether lipids begins with formation of fatty acyl derivatives of dihydroxyacetone phosphate. The acyl group is then displaced, along with the oxygen atom to which it is attached, by an alkoxy group of a long-chain fatty alcohol (Eq. 21-12, step *a*), which is formed by reduction of the corresponding acyl-CoA.[199] The oxygen of the alcohol (designated by an asterisk) is retained in the product.[200,201] The reaction differs significantly from displacements discussed in Chapter 12. The pro-*R* hydrogen atom (marked by the dagger, †) at C-1 exchanges with the medium during the reaction suggesting that enolization of the dihydroxyacetone phosphate takes place. A possible mechanism would be to add the incoming R–O⁻, generated as in serine proteases, to the double bond of



(21-12)

the enol at C-1. This would generate a transient carbanion on C-2. It could then eliminate the carboxylate containing the original C-1 acyl group, and the enol could then ketonize.

Once an alkoxy derivative of dihydroxyacetone is formed, reduction to the 2-OH form, further acylation, and conversion to various alkyl phospholipids and neutral lipids can occur. The pathways (Eq. 21-12, steps *b–f*) are closely akin to those of Fig. 21-4. The conversion of alkoxy lipids to plasmalogens occurs by oxidative desaturation (Eq. 21-12, step *f*).[202] The initial steps in the synthesis of ether-linked lipids take place principally in the peroxisomes. Enzymes catalyzing both the acylation of dihydroxyacetone phosphate and the synthesis of alkyl-dihydroxyacetone-*P* (step *a*, Eq. 21-12) are found in high amounts in animal peroxisomes. In the rare autosomal recessive disorder known as the **Zellweger syndrome** peroxisomes are completely lacking.[203] Both the synthesis of ether-linked lipids[204] and the β oxidation of very-long-chain fatty acids are depressed. These acids, principally C26:0 and C26:1, accumulate in tissues[205,206] of patients with this severe disease, which is usually fatal during the first four months of life.

The platelet activating factor (PAF, Box 8-A) is formed in neutrophils and macrophages from alkylacyl-*sn*-glycero-3-phosphocholine by the action of phospholipase A_2. This enzyme removes the C2 acyl group, which is then replaced by an *acetyl group* transferred from acetyl-CoA to form PAF. Alternatively, a phosphocholine group may be transferred onto 1-alkyl-2-acyl-*sn*-glycerol from CDP-choline as in the formation of phosphatidylcholine (Fig. 21-5). PAF can undergo hydrolytic removal of its acetyl group in tissues but can also transfer it to such acceptors as lysoplasmalogens or sphingosine.[194] Hydrolytic loss of the acetyl group from PAF destroys biological activities including induction of allergic and inflammatory responses.[194a] The various signaling activities of PAF arise from binding to G-protein linked receptors in many cells and tissues.[207]

3. Sphingolipids

Sphinoglipids are phospholipids and glycolipids derived from **sphingosine** and other "long-chain bases."[208] At least 60 bases of this type have been identified.[209] They vary in chain length from C_{14} to C_{26} and include members of the iso and anteiso series. Up to two double bonds may be present. The C_{18} compound, usually called sphingosine, is derived from condensation of palmitoyl-CoA with serine.[209a] Carbon dioxide is lost from the serine during the condensation reaction (Fig. 21-6, step *a*; Chapter 14), and the resulting ketone is reduced with NADPH (step *b*) to form **sphinganine**, a common component of animal sphingolipids. It may be hydroxylated to phytosphingosine in plants and fungi (step *c*).[210,211] Sphinganine is converted to long-chain amides by acyl transfer from acyl-CoA (step *d*) and then undergoes desaturation (step *e*)[212–213a] to form **ceramides**, the precursors to more than 100 gangliosides (Fig. 20-11),[214,215] to the phospholipid **sphingomyelins** (Fig. 21-6, step *g*), and also to free sphingosine (step *h*). This last reaction is degradative and on the pathway of breakdown of gangliosides (Fig. 20-11). Further catabolism of sphingosine is thought to take place by a PLP-mediated chain cleavage to palmitaldehyde.[216]

The essential functions of sphingolipids, including the complex gangliosides, are only now being clarified.[215,217,218] The latter are abundant in brain and are thought to function in cell–cell recognition. On blood cell surfaces they carry blood group antigens (Box 4-C). They play an essential role in spermatogenesis[218] and may function in various signaling processes.[218a] In the outer cornified layers of skin, ceramides with very long chain (C_{28}–C_{36}) fatty acyl groups undergo ω hydroxylation (Fig. 21-6) and become esterified to glutamate side chains of specific skin proteins called **involucrins**. The long hydrocarbon chains are thought to pass entirely through the lipid bilayer to form rigid lamellae of a water-impermeable outer skin barrier.[134] An important hypothesis is that sphingolipids associate with cholesterol to form "lipid rafts," which float in a sea of glycerolipids and serve as bases for various signaling processes. The long hydrophobic acyl chains of the sphingolipids pack well with cholesterol to form a rigid lipid structure of high melting temperature.[218b,c]

4. Complex Lipids in Signaling

While pathways of synthesis of complex lipids have been described, we are far from understanding the dynamics of the synthesis and turnover of the membranous structures built from them. The fact that the lipid bilayer of a cell membrane is so thin means that any sudden changes in composition at a particular location will cause changes in physical properties and a wave of diffusion that will travel along the membrane. The membrane seems to be ideally structured to receive and propagate messages from outer surface or internal receptors, or messages sent along the bilayer.

One of the most studied examples of signaling with membrane lipids is provided by the **phosphoinositide cascade**, which is pictured in Fig. 11-9. Six or more phosphate esters of phosphatidylinositol (PI) are generated by the action of kinases.[219,220] More than 100 extracellular signaling molecules activate specific isozyme forms of **phospholipase C**,[221–224] releasing 20 or more different inositol phosphates from these

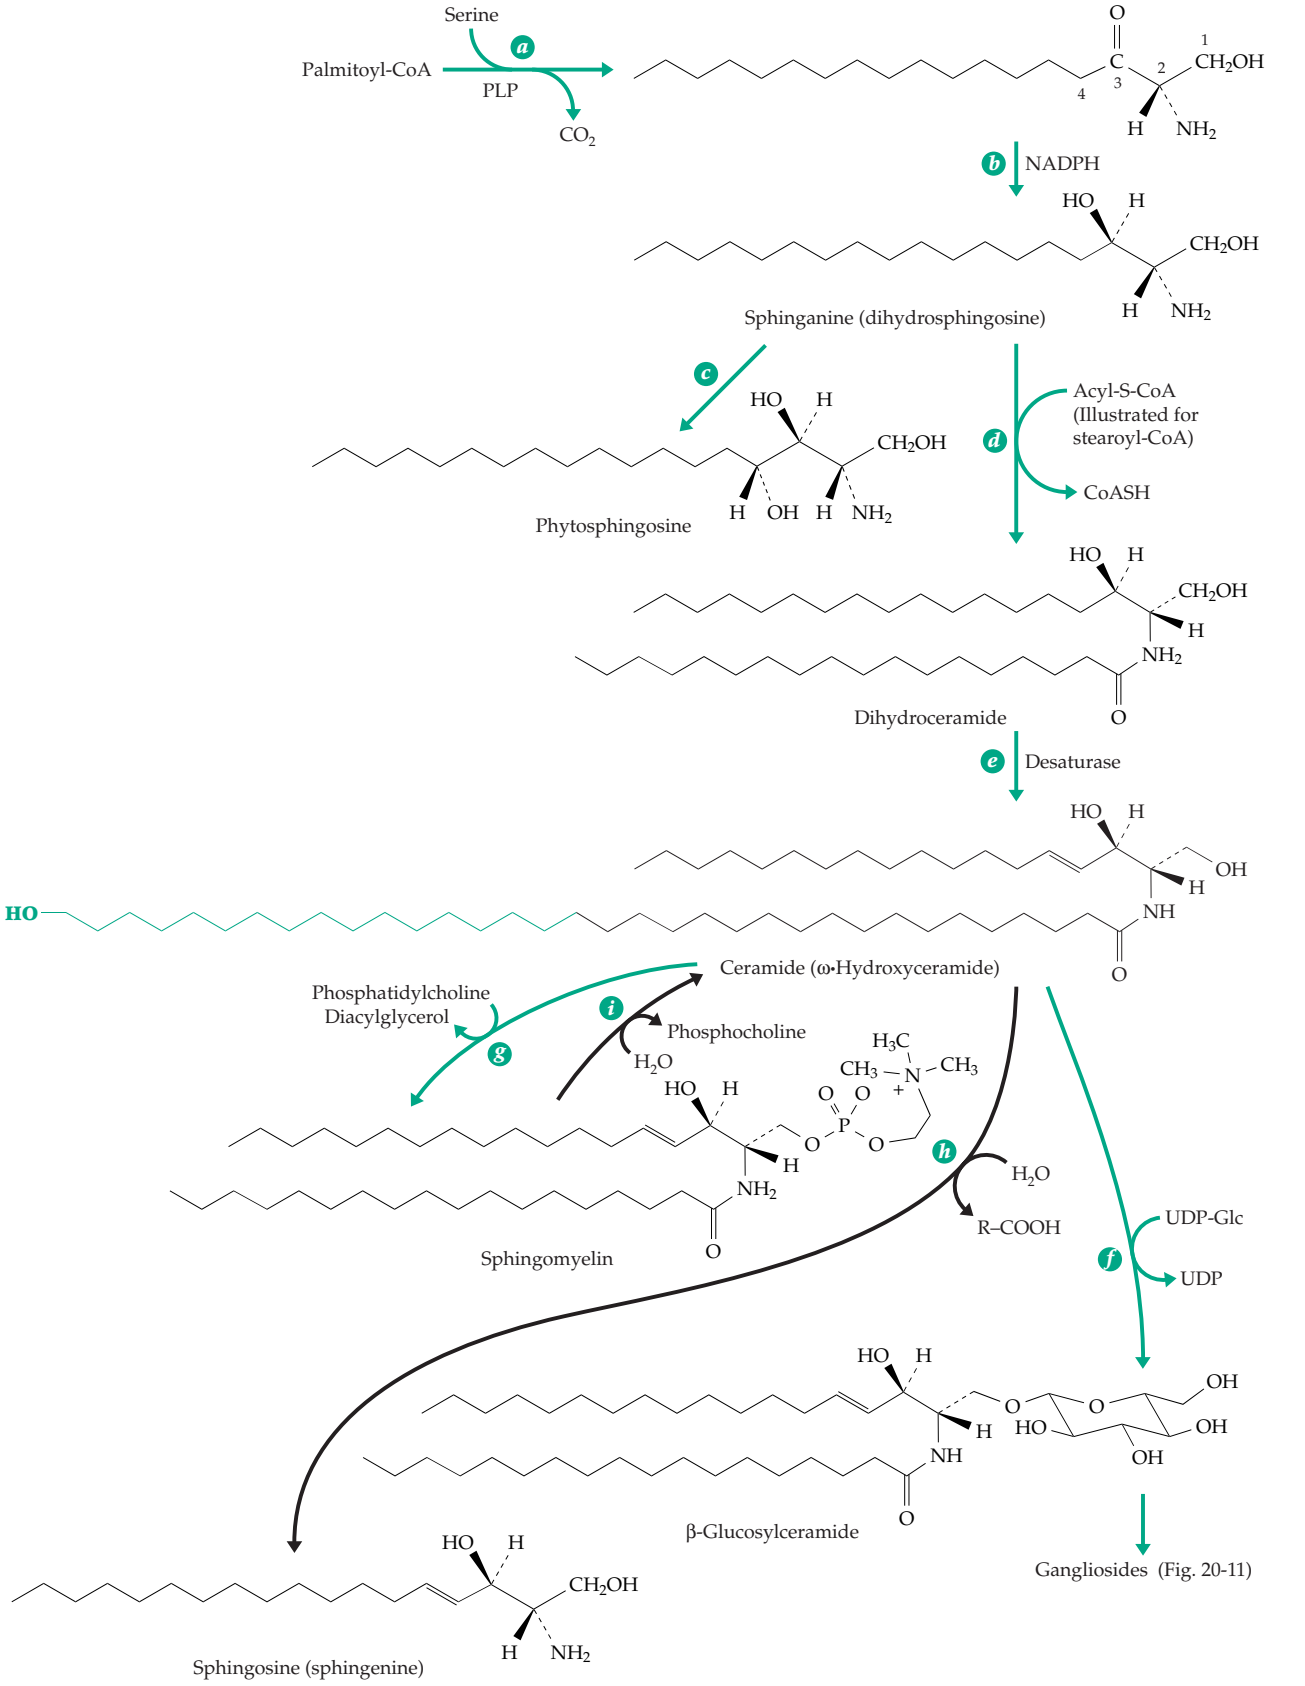


Figure 21-6 Pathways of synthesis and metabolism of sphingolipids. Gray arrows indicate catabolic pathways. See also Fig. 20-11. The green extension on the ceramide structure is that of a long-chain ω-hydroxyceramide that is covalently bound to protein in human skin.

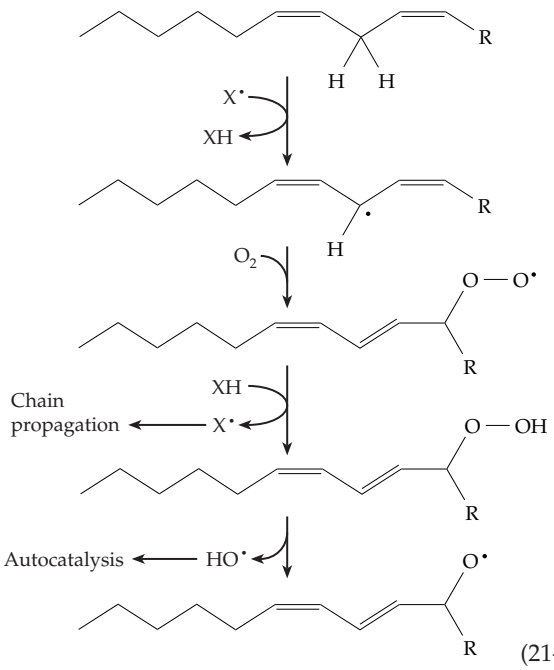
phosphoinositide esters. The released inositol phosphates, which act as water-soluble messengers, are further modified by the action of several phosphatases (Fig. 11-9).[225] At the same time, **diacylglycerols** are left in the membrane. With loss of the negative charges of the PI phosphates there will be immediate electrostatic effects in the membrane, which may alter the ionic environment, open ion channels, etc. The diacylglycerols, which diffuse within the membrane, may lose arachidonic acid from the *sn*-2 position to supply substrate for the arachidonate cascades described in Section D (Eq. 21-16). Diacylglycerols also activate the 11 isozyme forms of **protein kinase C**.[226–228] Some of these enzymes not only are activated by diacylglycerols, but also require **phosphatidylserine** for activity.

Other lipid-based signaling cascades arise from reactions that modify phosphatidylcholine molecules. Unsaturated fatty acids in the *sn*-2 position are readily oxidized by free radicals with cleavage of the hydrocarbon chains to form alcohols, aldehydes, and carboxylic acids. These mimic PAF in their biological activities.[194a,228a] Phosphatidate molecules with saturated or monounsaturated fatty acids in the *sn*-2 position arise from breakdown of phosphatidylcholine catalyzed by **phospholipase D**.[229] Phosphatidate may also be formed by a family of lipid **diacylglycerol kinases**.[230,230a] Phosphatidates containing saturated or monounsaturated fatty acids also have a variety of signaling activities.[230a] An arachidonoyl-diacylglycerol kinase is thought to function in many processes. An example is a PI-mediated cycle in invertebrate vision.[231] Sphingomyelin breakdown (black arrows in Fig. 21-6) releases diffusible ceramides that have been implicated as signaling molecules in cell proliferation, differentiation, growth arrest, and apoptosis.[232–237a] Sphingosine and sphingosine 1-*P* also have signaling functions.[211,237b-e]

Phospholipids have been shown to exchange between different membranes, e.g., of mitochondria and the ER. Exchanges of phosphatidylcholine, phosphatidylinositol, and sphingomyelin are catalyzed by specific **exchange proteins** (Box 21-A).[238,238a] These proteins may also participate in signaling, but their major function may be to transport the phospholipids from their sites of synthesis to the various membranes of the cell.

5. Peroxidation of Lipids and Rancidity

Storage of fats and oils leads to **rancidity**, a largely oxidative deterioration that causes development of unpleasant tastes, odors, and toxic compounds.[239] Similar chemical changes account for the "drying" of oil-based paints and varnishes. These reactions occur most readily with polyunsaturated fatty acids, whether free or in ester linkage within triacylglycerols. The reactions are initiated by free radicals, which may be generated by oxidative enzymes within or outside of cells, or by nonenzymatic reactions catalyzed by traces of transition metals or by environmental pollutants. Characteristic of rancidity is an autocatalytic chain reaction (Eq. 21-13).[239–241]



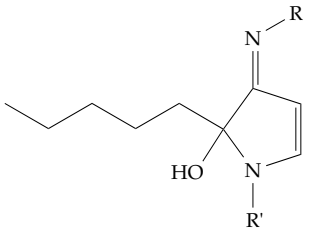
(21-13)

Radical X•, which initiates the reaction, is regenerated in a chain propagation sequence that, at the same time, produces an organic peroxide. The latter can be cleaved to form two additional radicals, which can also react with the unsaturated fatty acids to set up the autocatalytic process. Isomerization, chain cleavages, and radical coupling reactions also occur, especially with polyunsaturated fatty acids. For example, reactive unsaturated aldehydes can be formed (Eq. 21-14).

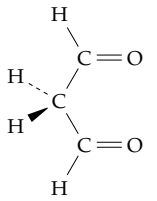
$$\mathrm{R{-}CH{=}CH{-}\overset{\bullet O}{\overset{|}{C}}H{-}R' \rightarrow R{-}CH{=}CH{-}CHO + {}^{\bullet}R'}$$

(21-14)

An intermediate in Eq. 21-13 may be converted to **4-hydroxy-2-nonenal**, a prominent product of the peroxidation of arachidonic or linoleic acids (Eq. 21-15).[242–243a] However, other biosynthetic pathways to this compound are possible.[244,244a] 4-Hydroxy-2-nonenal can react with side chains of lysine, cysteine, and histidine[245] to form fluorescent products such as the following cyclic compound generated by an oxidative reaction.[246]



Polyenoic acids also give rise to malondialdehyde, a reactive mutagenic compound, which can be reduced



Malondialdehyde

and dehydrated to acrolein, a toxic compound which also reacts with both lysine and serine to

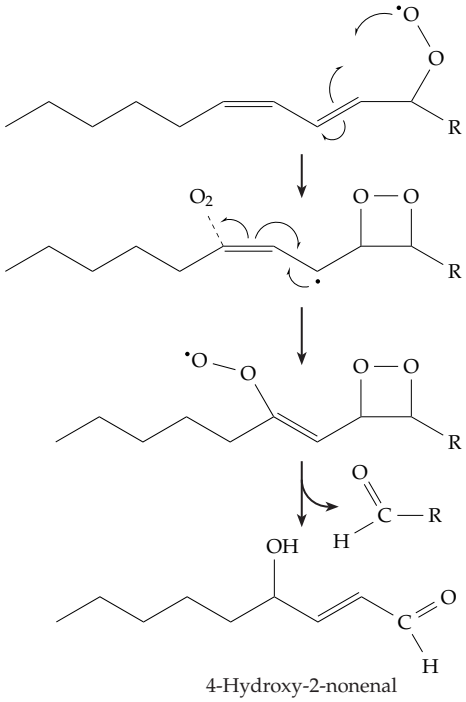
CH_2=CH–CHO

Acrolein

produce products excreted in the urine.[247,248] More dangerous are similar reactions of these aldehydes with proteins of the body in conditions such as diabetes or renal insufficiency.[242] The bifunctional malondialdehyde forms Schiff bases with protein amino groups and acts as a crosslinking agent.[249] **Age pigments** (also called **lipofuscin**), which tend to accumulate within neurons and other cells, are thought to represent precipitated lipid-protein complexes resulting from such reactions.[250] The reactions are similar to those of proteins with the products of sugar breakdown (glycation; p. 69).[250a] Organisms have developed multiple enzymatic mechanisms for detoxification of products of both glycation and oxidative degradation.[243a]

The oxidative degradation represented by the foregoing reactions is referred to as peroxidation. Peroxidation can lead to rapid development of rancidity in fats and oils. However, the presence of a small amount of tocopherol inhibits this decomposition, presumably by trapping the intermediate radicals in the form of the more stable tocopherol radicals (Eq. 15-54), which may dimerize or react with other radicals to terminate the chain.

Catalytic hydrogenation of vegetable oils is widely used to form harder fats and to decrease the content of polyunsaturated fatty acyl groups. The products have a greatly increased resistance to rancidity. However, they also contain fats with trans double bonds as well as isomers with double bonds in unusual positions.[251–253] Such compounds may interfere with normal fatty acid metabolism and also appear to affect serum lipoprotein levels adversely. Trans fatty acids are present in some foods. One hundred grams of butter contain 4–8 g, but hydrogenated fats often contain much more. It has been estimated that in the United States trans fatty acids account for 6–8% of total dietary fat.[253]



4-Hydroxy-2-nonenal (21-15)

6. Some Nutritional Questions

While many of the poorer people on earth starve to death the problems of atherosclerosis and obesity affect many in wealthier societies.[253a–c] The fat content of foods is often blamed, and, as discussed in Boxes 21-B and 22-B, the quality of fatty acids in the diet is very important. However, like fatty acids, carbohydrates are also metabolized via acetyl-CoA and can readily be converted to both fatty acids and cholesterol.[253d] Obesity is largely a problem of excessive total caloric intake.

Why do some people stay slim while others become obese? What are the regulatory mechanisms that affect appetite and body composition? The human body weight tends to be stable or to increase slowly during adult life.[253e] Is there a natural set point for each individual? No, an apparent set point is just a result of action of a multitude of factors including genetic variations[253f] and psychological factors that affect exercise levels, eating habits, etc.[253g] It is worthwhile to recognize that the basal metabolic rate, which is also affected by many factors, accounts for a very high fraction of a person's energy expenditure (p. 283).

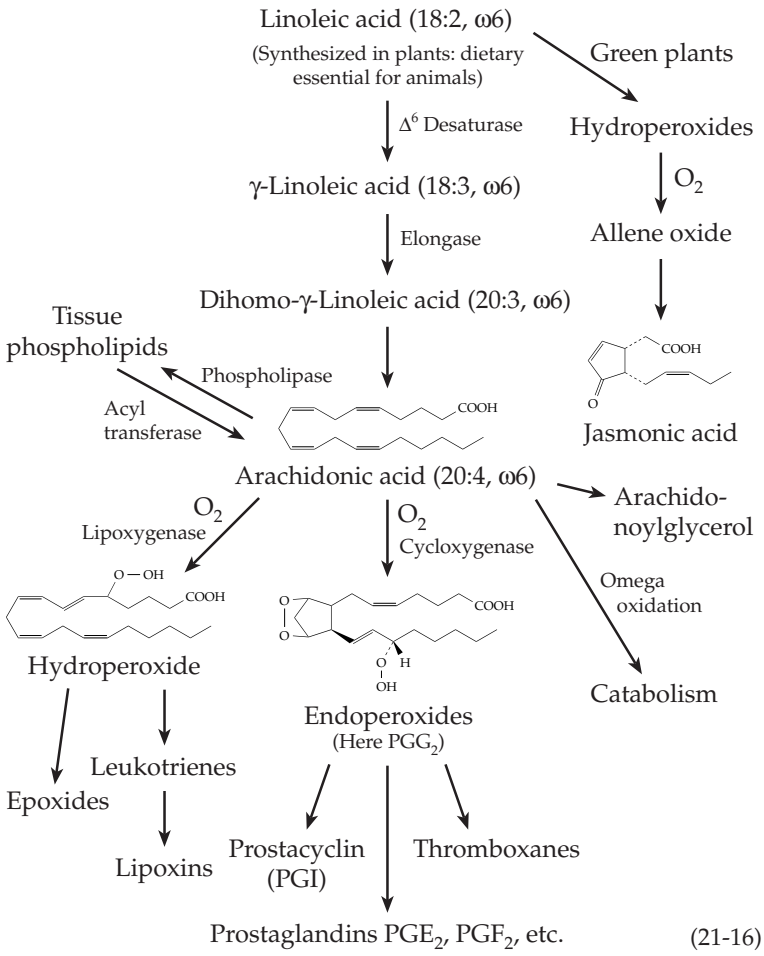
The following are among specific biochemical

factors that act on the energy balance: the activity of acetyl-CoA carboxylase and the associated level of malonyl-CoA[253h,i]; the activity of mitochondrial uncoupling proteins (Box 18-C)[253j,k]; actions of the hormone leptin[253l] (which have been hard to interpret)[253m,n]; and other hormones including cholecystokinins and neuropeptide Y (Chapter 30).

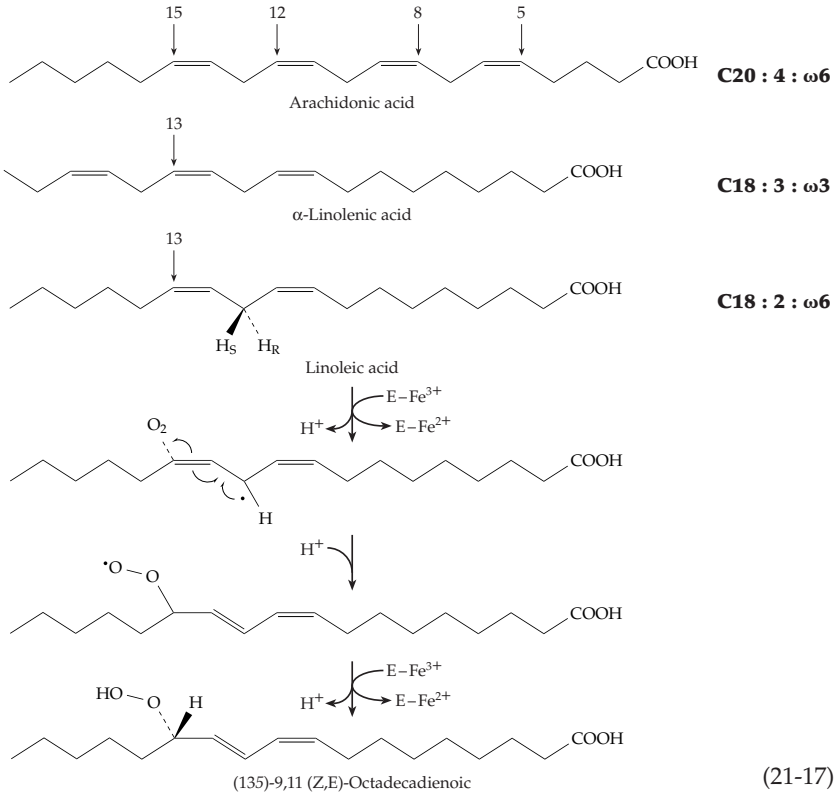
D. Prostaglandins and Related Prostanoid Compounds

Lipid peroxidation has often been regarded simply as an undesirable side reaction, but it is also a normal part of metabolism. Initiated by enzymatically generated radicals, peroxidation occurs as specific metabolic pathways, such as the **arachidonate cascade**, which leads to a variety of local hormones and other substances (Eq. 21-16).[254–256a]

As early as 1930, it was recognized that seminal fluid contains materials that promote contraction of uterine muscles. The active compounds, the **prostaglandins**, were isolated and crystallized in 1960 and were identified shortly thereafter.[257,258] As many as 14 closely related compounds are found in human seminal fluid, one of the richest known sources. Prostaglandins are present in seminal fluid at a total concentration of ~1 mM, but their action on smooth muscles has been observed at a concentration as low as 10^{-9} M. The structures and biosynthetic pathways of several of the prostaglandins are indicated in Fig. 21-7. Prostaglandins are usually abbreviated PG with an additional letter and numerical subscript added to indicate the type. The E type are β-hydroxyketones, the F type 1,3-diols, and the A type α, β-unsaturated ketones. Series 2 prostaglandins arise from arachidonic acid, while series 1 and 3 arise from fatty acids containing one fewer or one more double bond, respectively (Fig. 21-7). Additional forms are known.[257,259]



(21-16)



(21-17)

1. Metabolism of the Prostaglandins

Prostaglandins are not stored by cells but are synthesized in response to external stimuli. Arachidonic acid and other polyenoic acids are present in relatively small amounts (e.g., ~1% of total plasma fatty acids), but they are concentrated in the 2-position of phospholipids. This is in part a result of phospholipid "remodeling." Acyl groups are hydrolyzed from the *sn*-2 position by action of phospholipase A_2. An acyltransferase with a preference for arachidonoyl groups then transfers esterified arachidonic acid from

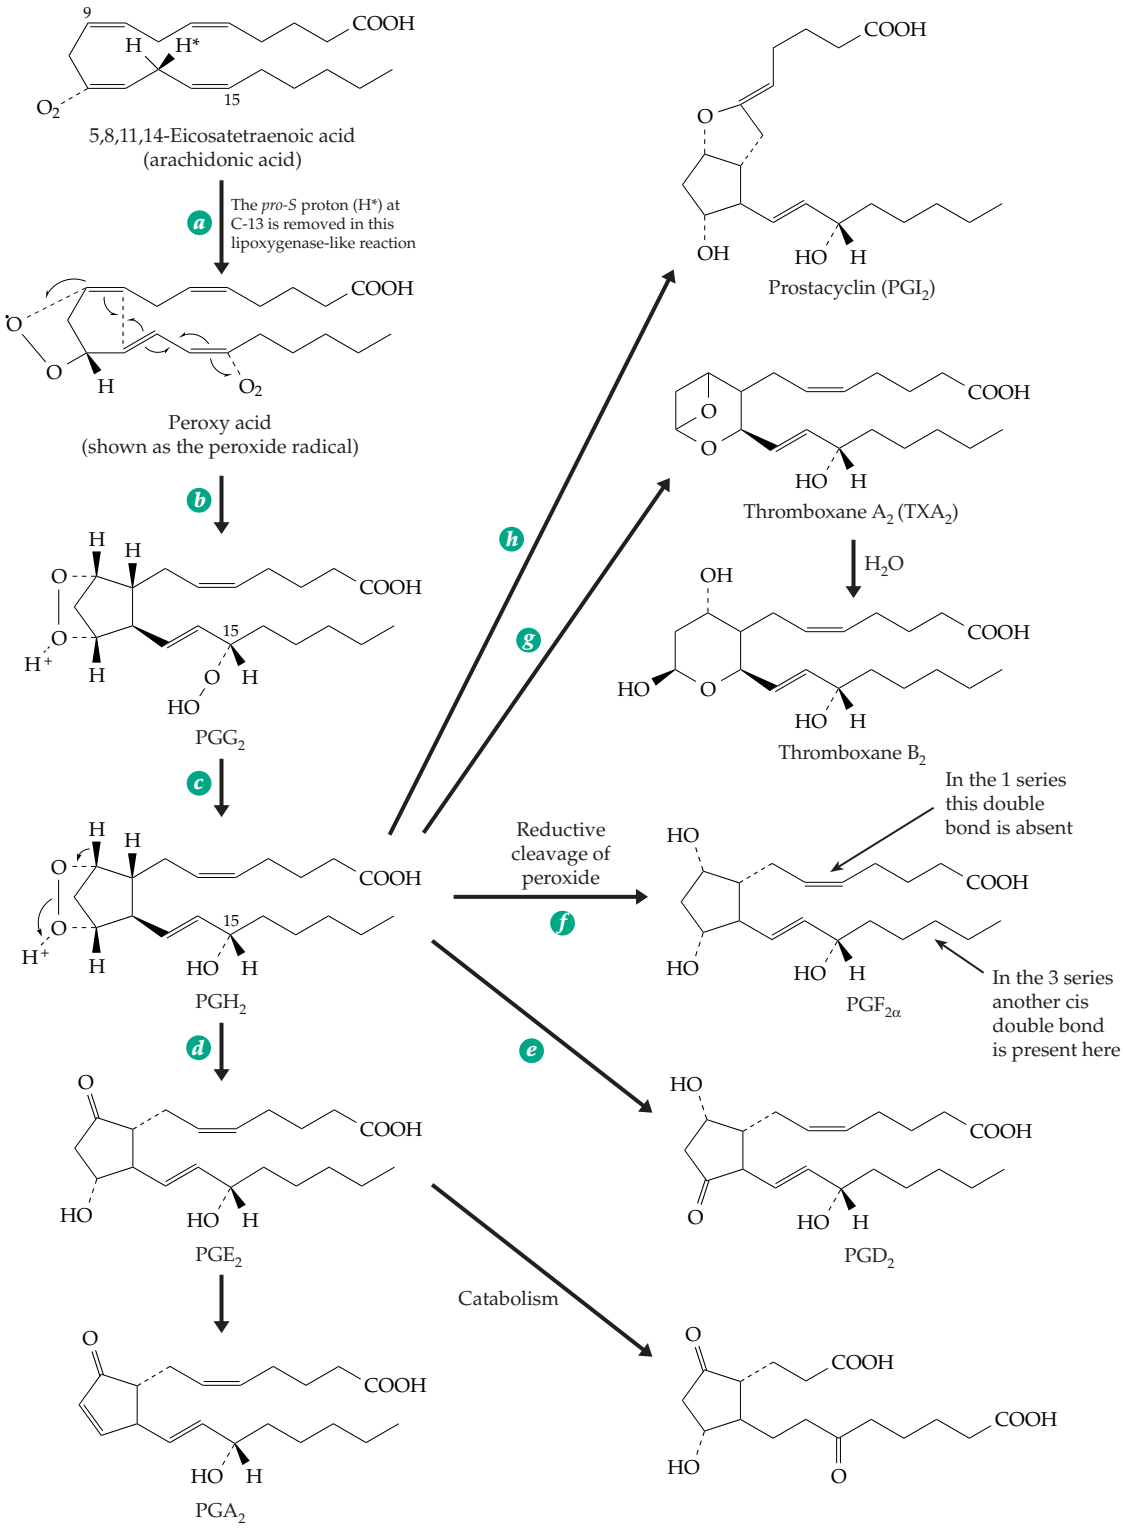


Figure 21-7 Pathway of synthesis and catabolism of the prostaglandins.

phosphatidylcholine and other phospholipids to the lyso forms of the phospholipids, which lack a 2-acyl group. The enzyme has a strong preference for the lyso-ethanolamine plasmalogens. As a consequence, in the plasmenylethanolamine of platelets arachidonoyl groups account for 66% of the acyl residues at the 2-position.[260] An arachidonate-specific acyl-CoA synthetase rapidly reconverts any free arachidonate that is not used for prostanoid synthesis back into phospholipids.[261]

The synthesis of prostaglandins, which was elucidated by Samuelsson,[258–260] begins with the release of arachidonate and other polyenoic acid precursors from phospholipids through the action of phospholipase A_2. The released arachidonate is then acted upon by **prostaglandin H synthases,** which catalyze two consecutive reactions at adjacent but distinct sites in a single protein.[262–262d] The first, **cyclooxygenase** or prostaglandin endoperoxide synthase reaction, forms PGG_2 from arachidonate and the second, a **peroxidase** reaction, generates PGH_2. There are two major mammalian isozymes of prostaglandin synthase, which are often called cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2). From studies of stereospecifically synthesized ^3H-containing fatty acid precursors, it was established that the first step in cyclooxygenase action involves removal of the *pro*-S proton at C-13 of the fatty acid (step *a*, Fig. 21-7). The O_2-requiring cyclooxygenase resembles lipoxygenase (Eq. 21-17).[181] The product is a peroxy acid, possibly in the form of the peroxide radical shown in Fig. 21-7. This radical (or peroxide anion) undergoes cyclization with synchronous attack by a separate O_2 molecule at C-15 (Fig. 21-7, step *b*) to give the endoperoxide PGG. Reduction of the latter to an OH group by the NADPH-dependent peroxidase (step *c*) yields PGH. The entire sequence is catalyzed by the single 70-kDa PGH synthase, which contains a single heme prosthetic group.[263] During the cyclooxygenase reaction the enzyme appears to accept electrons from cytochrome b_5. During the peroxidase step the heme group undergoes formation of the characteristic peroxidase intermediate compounds I and II[263] (Fig. 16-14). It has been suggested that a tyrosyl radical is generated in the peroxidase active site (on Y385 of COX-1) and is used to form an arachidonate radical that reacts with O_2 in the cyclooxygenase reaction.[264–266b] Alternatively, a carbocation mechanism is also possible.[267]

PGH can break down in three ways to give the E and F series of prostaglandins.[268] In one the proton at C-9 is eliminated (step *d*) as indicated by the small arrows by the PGH_2 structure of Fig. 21-7. An alternative isomerization (step *e*) gives PGD_2. The F prostaglandins are formed by reductive cleavage of the endoperoxide (step *f*). The A series and other prostaglandins arise by secondary reactions, one of which is shown in Fig. 21-7.

A biochemical characteristic of the prostaglandins is rapid catabolism. The product shown in Fig. 21-7 (lower right) arises by oxidation of the 15-OH to a carbonyl group, permitting reduction of the adjacent trans double bond. Two steps of β oxidation as well as ω oxidation are also required[269] to produce the dicarboxylic acid product shown. However, a series of products appears, and the distribution varies among species. Catabolism of prostaglandins is especially active in the lungs, and any prostaglandins entering the bloodstream are removed by a single pass through the lungs. This observation has led to the conclusion that prostaglandins are not hormones in the classical sense but act on a more local basis.

2. Thromboxanes and Prostacyclins

In blood platelets and in some other tissues PGG is also transformed to another series of compounds, the **thromboxanes**,[270] which were identified in 1975. Labile hemiacetals, the thromboxanes A (TXA, Fig. 21-7), are derived by rearrangement of PGH (step *g*). Thromboxane synthase,[271–273] which catalyzes the reaction, has characteristics of a cytochrome P450. Cytochromes P450 are known to react with peroxides as well as with O_2, and the endoperoxide of PGH may be opened by the synthase prior to rearrangement to TXA.[273] Thromboxane A_2 is so unstable that its half-life at 37°C in water is ~36 s. It is spontaneously converted to TXB_2 (Fig. 21-7), which contains an –OH group at C-15. The thromboxanes B are much more stable than TXA but are not very active physiologically.

By 1976, Vane and associates had identified another prostanoid compound, **prostacyclin** (or PGI_2).[274–275a] This compound also arises from PGH_2 by action of a cytochrome P450-like prostacyclin synthase (Fig. 21-7).[273,275,276] It is thought to be an important vasoprotective molecule. As with the thromboxanes, prostacyclin undergoes rapid inactivation[277] by hydrolysis to the physiologically inactive 6-oxo-$PGF_1\alpha$.

3. Lipoxygenases

Lipoxygenases, of which the enzyme from soy beans has been studied the most, also catalyze oxidation of polyunsaturated fatty acids in lipids as indicated in Eq. 21-17. Formation of the hydroperoxide product is accompanied by a shift of the double bond and conversion from cis to trans configuration. Soybean lipoxygenase is a member of a family of related lipoxygenases that are found in all eukaryotes. All

appear to have similar iron- or manganese-containing active sites and to act by similar mechanisms.[278–280e] The major substrate in animals is arachidonic acid (probably as the arachidonate ion). As marked on the structures above Eq. 21-17, there are 5-, 8-, 12-, and 15-lipoxygenases, which catalyze reaction with dioxygen at the indicated places.[281,282] Linoleic and linolenic acids are the primary substrates in plants. Soybean lipoxygenase acts on the 13-position of linoleic acid as shown in Eq. 21-17. However, this enzyme is often referred to as a *15-lipoxygenase* because it acts on arachidonate at C15. The 100-kDa enzyme from

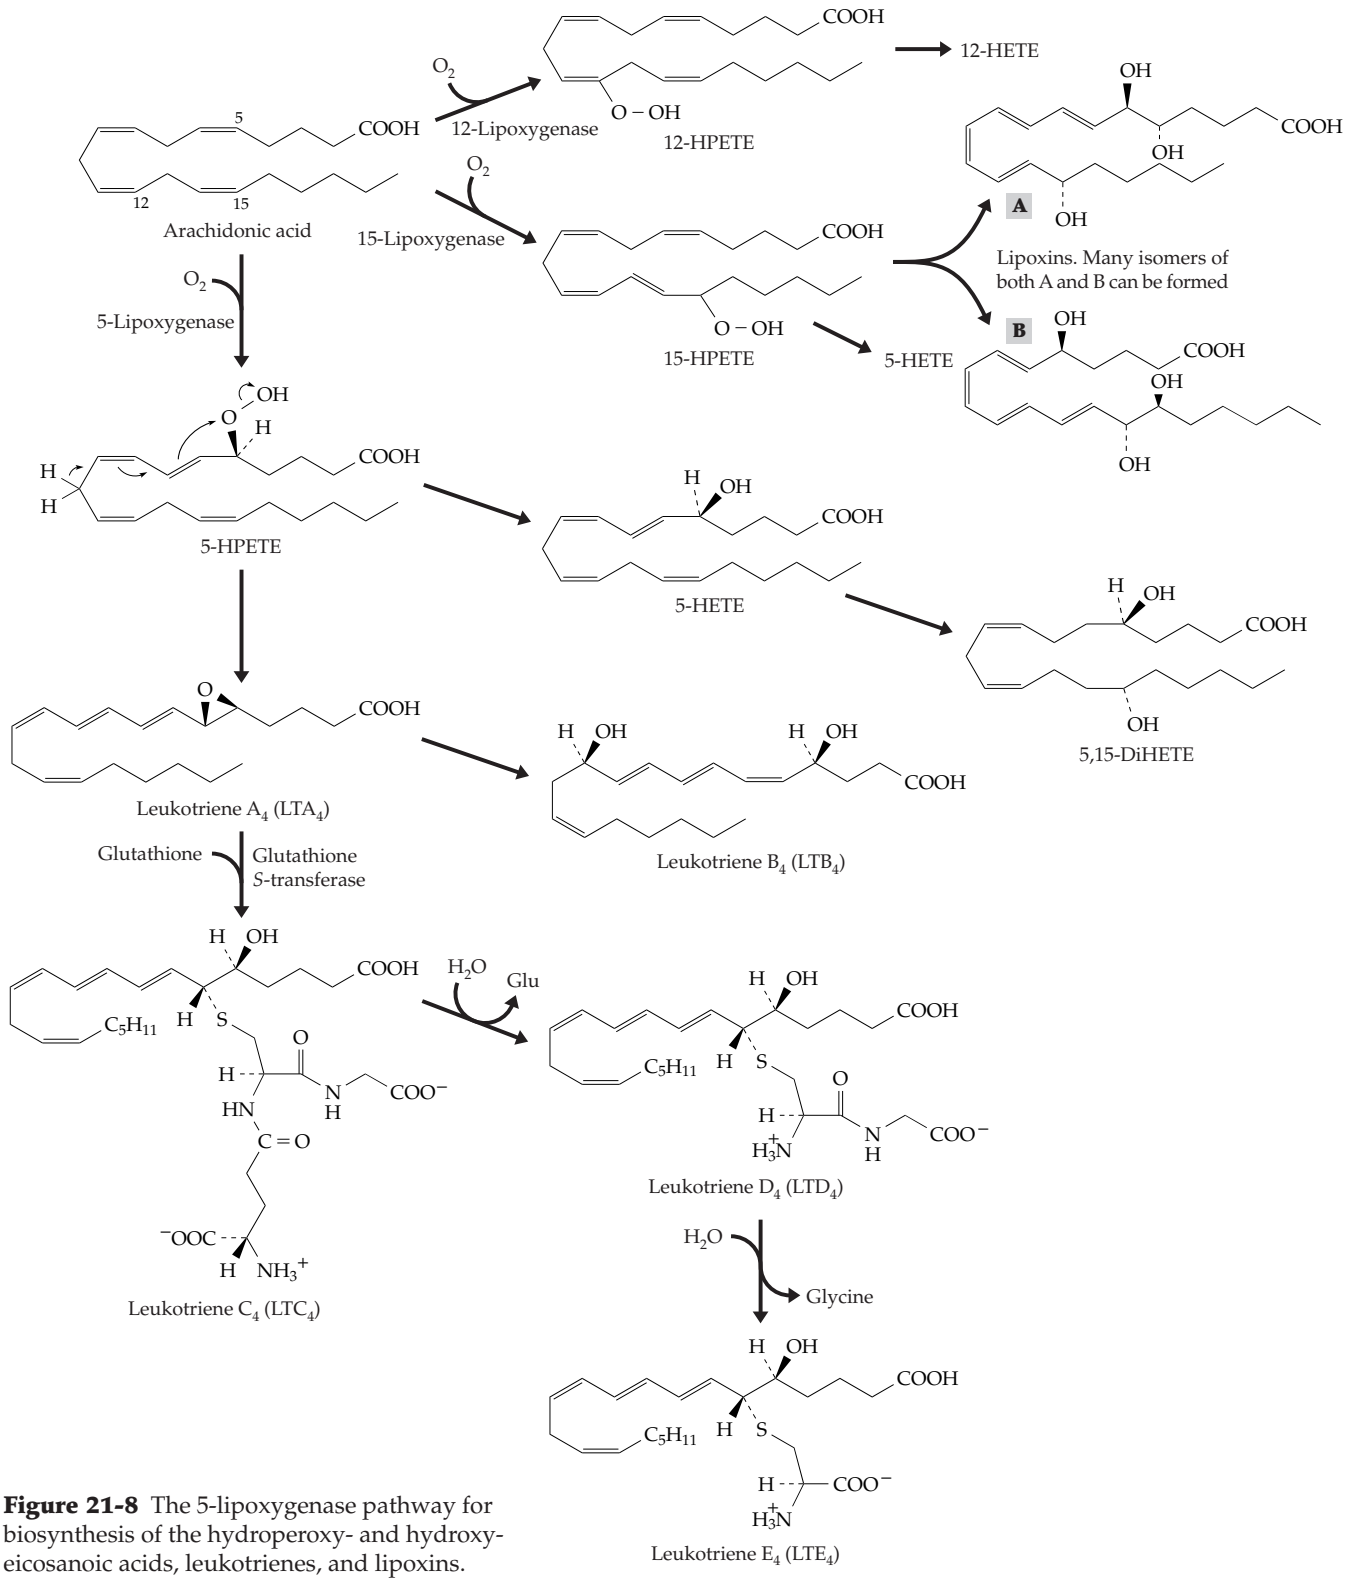

Figure 21-8 The 5-lipoxygenase pathway for biosynthesis of the hydroperoxy- and hydroxyeicosanoic acids, leukotrienes, and lipoxins.

soybeans contains one atom of Fe(II), which is bound by a cluster of His and Tyr side chains.[283] It must be oxidized to the Fe(III) state before becoming active.[279,284] The initial reaction with O_2 may occur via an intermediate radical.

4. Leukotrienes, Lipoxins, and Related Compounds

Yet another series of products results from the action on arachidonate of tissue lipoxygenases, which compete with the prostaglandin-forming cyclooxygenases. The 5-lipoxygenase (Fig. 21-8) produces the unstable peroxide **5-hydroperoxy 6,8,11,14-eicosatetraenoic acid** (usually abbreviated **5-HPETE**). This enzyme requires ATP and Ca^{2+} and appears to be regulated by a series of other metabolites.[285] The 12- and 15-lipoxygenases, whose distribution varies among different mammalian organs and tissues, form the corresponding 12- and 15-HPETES as well as 5, 15-, 8,15-, 14,15-diHPETEs.[255,286] Some of these peroxides have physiological effects of their own, but they are largely transformed by peroxidases to more stable compounds such as the corresponding alcohols (hydroxy-icosatetraenoic acids or HETEs; Fig. 21-8).

The **leukotrienes** are formed from 5-HPETE (Fig. 21-8).[287,288] Dehydration of HPETE produces the unstable epoxide **leukotriene A_4** (LTA_4), which can be hydrolyzed enzymatically by leukocytes to the diol **leukotriene B_4** (LTB_4).[289,290] Alternatively leukotriene synthase, present in many cells, catalyzes the addition of glutathione (Box 11-B) to the LTA. This is a ring-opening reaction of the epoxide that can be visualized as a nucleophilic displacement by the thiolate anion of glutathione at C-6 (Fig. 21-8). The product is **leukotriene C_4** (LTC_4),[291] which can undergo consecutive removal of glutamate and glycine to form **leukotrienes D** and **E** (LTD_4, LTE_4), respectively. Removal of the glutamate occurs by the action of γ-glutamyl transpeptidase (Box 11-B), whereas removal of the glycine is hydrolytic. LTC_4 and the more potent LTD_4 have been identified as the **slow-reacting substance of anaphylaxis** (SRS-A), a long-sought mediator of bronchial asthma.[292,293] Leukotrienes can be formed from polyunsaturated acids other than arachidonic acid. Thus, eicosapentaenoic acid yields LTC_5 and LTD_5.[294] A lipoxygenase-derived product from the C18:2 linoleic acid is 13-hydroxylinoleic acid, which is made principally by endothelial cells that line blood vessels. It may contribute to resistance to blood clotting.[294]

Products of the 15-lipoxygenase pathway include a group of trihydroxytetraenes formed by leukocytes.[295] Several routes of biosynthesis, which may involve epoxide intermediates, are known.[296,297] The structures of two of these compounds, **lipoxin A** and **lipoxin B,** are shown in Fig. 21-8. Several stereoisomers and cis–trans isomers can be formed. These compounds can all arise from 15-HPETE, either by enzyme action or nonenzymatically. In fact, the entire series of prostanoid compounds arise by reactions related to but more specific than those that occur during nonenzymatic autoxidation of arachidonate.[255,298] Cytochrome P450-catalyzed reaction with O_2 can convert arachidonic acid into four different **epoxytrienoic acids** (**EETs**), which may also exist as stereoisomers. They are vasodilators which affect a variety of signaling pathways.[298a,b]

5. Physiological Effects of the Prostanoids

The release of arachidonate and initiation of the arachidonate cascade is induced by hormones, various inflammatory and immunological stimuli, and even mechanical agitation. Tissues do not all behave the same in response to the arachidonate cascade.[299] Blood platelets form largely thromboxane A_2, whereas tissues of the aorta form prostacyclin. Prostaglandin D_2 is a major prostanoid in the central nervous system.[300] Biological functions of prostanoids are also varied.[256a,301] The **primary prostaglandins** PGE and PGF were first recognized as mediators of inflammation. However, PGE_2 and PGF_2 sometimes have opposite effects. The unstable precursors PGG_2 and PGH_2, which have half-lives of only a few minutes, are much more powerful than the more stable PGEs and PGFs. Prostaglandin D_2, which is released in lungs during attacks of asthma, is thought to be a major bronchoconstrictor, but it may also serve as a neurotransmitter.[300] Thromboxanes released from platelets cause smooth muscle contraction and aggregation of the platelets, the first step in blood clot formation. Thromboxanes have half life-times of only seconds but are extremely potent not only in inducing platelet aggregation but also in causing contraction of blood vessels. Prostacyclin has the opposite effect, being a potent vasodilator that causes relaxation of smooth muscle. Upon release from blood vessel walls it acts to prevent clot formation.

The lipoxygenase pathway (Fig. 21-8) leading to the leukotrienes, lipoxins, and other products is especially active in leukocytes and in mast cells.[302] The leukotrienes promote inflammation, but lipoxins A_4 and B_4 are antiinflammatory.[303] The release of leukotrienes LTC_4, LTD_4, and LTE_4 in lung tissue is correlated with the long-lasting contractions of smooth muscle of the bronchi that are characteristic of asthma.[304] Leukotriene LTC_4 is ~1000 times more powerful than histamine in inducing such contraction. Leukotrienes have also been found in the central nervous system.[305]

Some effects of prostaglandins are mediated through cell surface G-protein coupled receptors (see Chapter 11).[306] Some other prostanoids bind to and activate nuclear peroxisome proliferator-activated receptors.[306] PGJ_2 may inhibit fatty acid synthesis and fat deposition in adipose tissue through these receptors. Some of the prostanoid derivatives enter membranes and may become incorporated into phospholipids and exert their effects there.

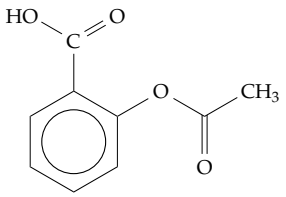
A number of medical uses of prostaglandins have been discovered and more will probably be developed. While prostaglandins may be required for conception, small amounts of PGE_2 or $PGF_{2\alpha}$ induce abortion. $PGF_{2\alpha}$ is also used to induce labor. Prostaglandins are widely employed to control breeding of farm animals, to synchronize their estrus cycles, and to improve the efficiency of artificial insemination.[307]

6. Inflammation

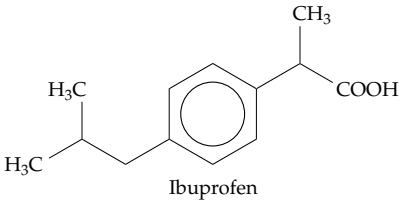
Special interest in the prostaglandins has focused on pain of inflammation and allergic responses. The medical significance is easy to see. Five million Americans have **rheumatoid arthritis**, an inflammatory disease. Bronchial asthma and other allergic diseases are equally important. Our most common medicine is **aspirin**, an anti-inflammatory drug. Both the inflammatory response and the immune response are normal parts of the defense mechanisms of the body, but both are potentially harmful, and it is their regulation that is probably faulty in rheumatoid arthritis and asthma. Overproduction of prostaglandins may be a cause of menstrual cramps.[308]

Prostaglandins have been implicated both in the induction of inflammation and in its relief. In inflammation small blood vessels become dilated, and fluid and proteins leak into the interstitial spaces to produce the characteristic swelling (edema). Many polymorphonuclear leukocytes attracted by chemotactic factors that include LTB_4[309] (Chapter 19) migrate into the inflamed area, engulfing dead tissue and bacteria. In this process lysosomes of the leukocytes release phospholipase A, which hydrolyzes phospholipids and initiates the arachidonate cascade. The leukotrienes that are formed promote the inflammatory response. However, cAMP can suppress inflammation, and PGE_2 has a similar effect. Indeed, E prostaglandins, when inhaled in small amounts, relieve asthma.

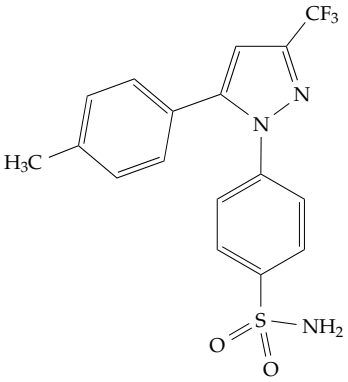
The synthesis of prostaglandins is inhibited by aspirin[310] and many other analgesic drugs. Aspirin is an acetylating reagent, and the inhibition has been traced to acetylation of the side chain –OH group of a single serine residue, Ser 530 of COX-1 or Ser 516 of COX-2 in the arachidonate binding channel.[311–313] Other nonsteroidal antiinflammatory drugs (NSAIDs),



Aspirin (acetylsalicylic acid)



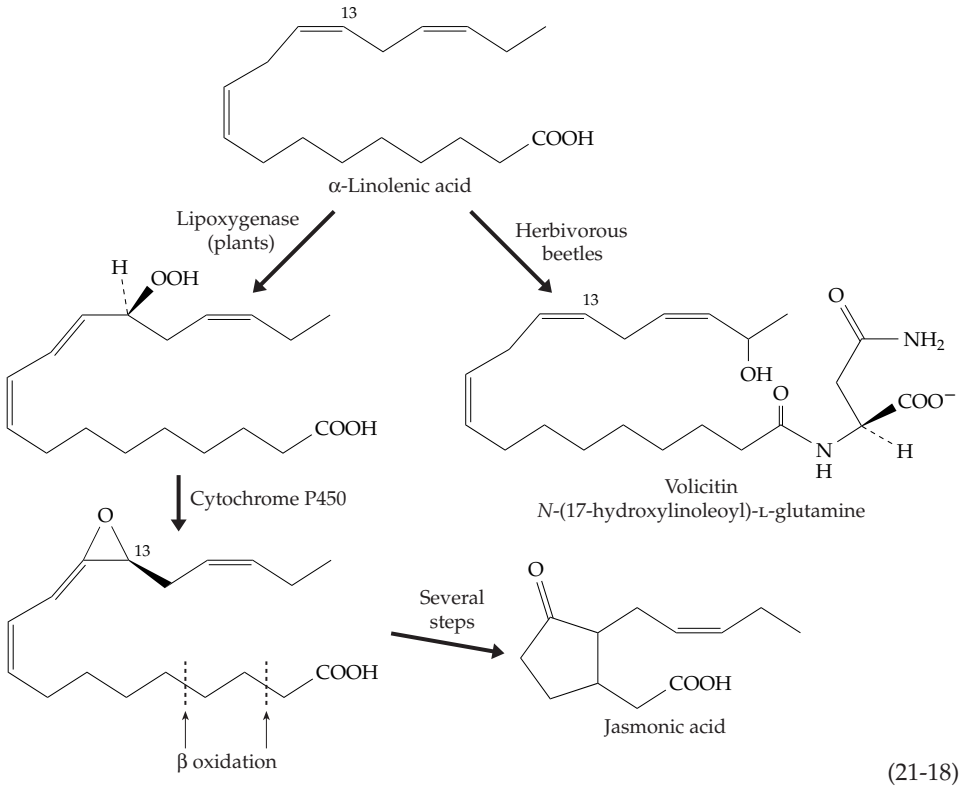
Ibuprofen



Celecoxib, a new COX-2 inhibitor

e.g., ibuprofen, are competitive inhibitors of the cyclooxygenases.[314] COX-3, a variant form of COX-1, may be the target for acetaminohen (Box 18-E).[314a] However, the same drugs also inhibit activation of neutrophils and may thus exercise their anti-inflammatory action in more than one way.[315] Since PGE_1 is a potent **pyrogen** (fever-inducing agent), a relationship to the ability of aspirin to reduce fever is also suggested. Unfortunately, all of these drugs inhibit COX-1 of platelets. Small regular doses of aspirin may be useful in preventing blood clots in persons with arterial disease, but they can be disastrous. Thousands of people die annually of hemorrhage caused by aspirin.[316,317]

Recently it was recognized that COX-1 provides eicosinoids for homeostatic purposes, while it is COX-2 that is inducible and generates prostoglandins for production of leukotrienes and induction of the inflammatory response. Now there is a major effort, with the first drugs already in use, to develop specific inhibitors for COX-2, which do not inhibit COX-1. It is hoped that these will be safer than aspirin.[256a,266a,311,317,317a-c] However, these drugs can also cause dangerous side effects.[317d] COX-2 of macrophages is also inhibited by γ-tocopherol, a major form of vitamin E.[317e]



(21-18)

7. Plant Lipoxygenases and Jasmonic Acid

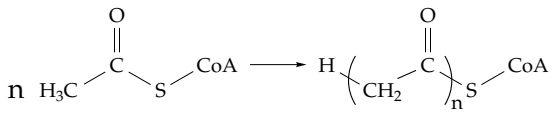
An octadecenoid signaling pathway (Eq. 21-18), which resembles the arachidonate cascade in some respects, plays an important role in green plants.[318–320] Alpha-linolenic acid is acted upon by a lipoxgenase in plastids to form a 13-hydroperoxy derivative. This is dehydrated and cyclized by allene oxide synthase. Although this doesn't appear to be an oxidation–reduction process, the enzyme seems to be a cytochrome P450 and to initiate the cyclization to the unstable epoxide **allene oxide** by homolytic cleavage of the peroxy group.[321,321a] Allene oxide synthase and the cyclase that acts in the next step may be cytosolic, while the β oxidation that shortens the chain occurs in plants exclusively in peroxisomes or glyoxysomes.[319]

Jasmonic acid is a plant growth regulator that affects many aspects of plant development as well as responses to environmental signals. A very important function is mobilization of plant defenses in response to damage by herbivores, by bacterial or fungal pathogens, or by ultraviolet light.[322,323] The synthesis of protease inhibitors as well as phytoalexins is induced. A curious variant of the jasmonate pathway is the acquisition of α-linoleic acid from plants by chewing caterpillars. The linoleic acid is hydroxylated by the insect, and conjugated with glutamine to form **volicitin** (*N*-(17-hydroxylinoleoyl)-L-glutamine; Eq. 21-18). Some of this compound reenters the plant from material regurgitated into wounds by the caterpillars. Volicitin induces the plant to release volatile terpenes and other compounds. The value to the caterpillars is not clear, but not only does volicitin induce defensive reactions in plants but also the released volatile compounds attract wasps that parasitize the caterpillars.[324,325] Plants also form a group of **isoprostanes** E_1 from α-linolenic acid.[326]

Allene oxides are unusual biological products. However, they are formed from arachidonic acid by some corals and are evidently precursors to prostaglandin esters, which may be present in high concentrations.[327] Allene oxides are also present in starfish oocytes.[321,328]

E. The Polyketides

In 1907, Collie proposed that polymers of ketene ($CH_2=C=O$) might be precursors of such compounds as **orsellinic** acid, a common constituent of lichens. The hypothesis was modernized in 1953 by Birch and Donovan, who proposed that several molecules of acetyl-CoA are condensed (Eq. 21-19) but *without the two reduction steps required in biosynthesis of fatty acids* (Fig. 17-12).[329] As we now know they were correct in assuming that the condensation occurs via malonyl-CoA and an acyl carrier group of an enzyme. The resulting **β-polyketone** can react in various ways to give the large group of compounds known as polyketides.



Acetyl-CoA β-Polyketone (21-19)

β-Polyketones can be stabilized by ring formation through ester or aldol condensations. Remaining carbonyl groups can be reduced (prior to or after cyclization) to hydroxyl groups, and the latter can be eliminated as water to form benzene or other aromatic rings. Figure 21-9 illustrates two ways in which cyclization can occur. One involves a Claisen ester condensation during which the enzyme and its SH group are eliminated. Enolization of the product gives a trihydroxy-acetophenone. The second cyclization reaction is the aldol condensation. Following the condensation water is eliminated, and the product is hydrolyzed and enolized to form orsellinic acid. Another product of fungal metabolism is **6-methylsalicylic acid,** which lacks one OH group of orsellinic acid. This synthesis can be explained by assuming that the carbonyl group at C-5 of the original β-polyketone was reduced to an OH group at some point during the biosynthesis. Elimination of two molecules of water together with enolization of the remaining ring carbonyl gives the product (Fig. 21-9).[330]

By allowing a few variations in the basic polyketone structure, the biosynthesis of a large number of unusual compounds can be explained. Extra oxygen atoms can be added by hydroxylation, and methyl groups may be transferred from *S*-adenosylmethionine to form methoxyl groups.[331] Occasionally a methyl group may be transferred directly to the carbon chain. Glycosyl groups may also be attached.[332,333] Many starter pieces other than acetyl-CoA may initiate polyketide synthesis. These include the branched-chain acids of Table 21-3, nicotinic and benzoic acids, 4-coumaroyl-CoA, and a 14:1 Δ^9-ACP. The last of these starter pieces is formed by desaturation of the corresponding 14:0-ACP and is converted via polyketide synthesis to one of a family of **anacardic acids,** which provide pest resistance to a variety of dicotyledenous plants (Fig. 21-10, bottom).[334] The CoA derivative of malonic acid amide is the starter piece for synthesis of the antibiotic **tetracycline** as indicated in Fig. 21-10).[335] Polyketide origins of some other antibiotics are also indicated in this figure.

The cloning and sequencing of genes for enzymes involved in synthesis of polyketides of fungi and actinomycetes has shown that these enzymes are closely related to the fatty acid synthases and, like the latter, have a multidomain structure (Fig. 21-11). The possibilities of engineering these genes, together with the urgent need for new antibiotics, has led to an

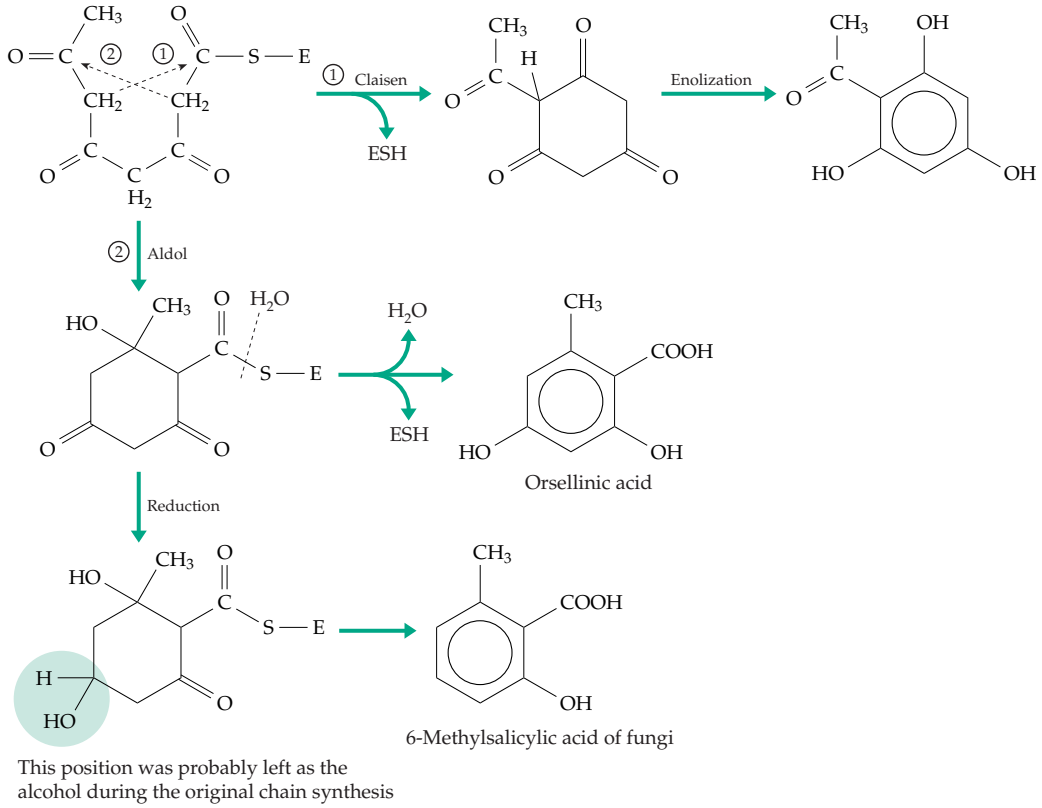


Figure 21-9 Postulated origin of orsellinic acid and other polyketides.

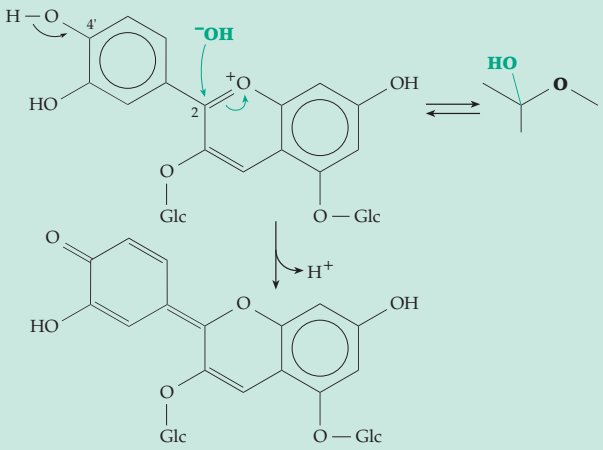
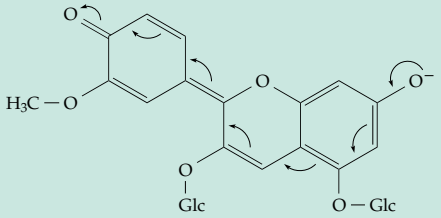
BOX 21-E HOW THE FLOWERS MAKE THEIR COLORS

Most of the pigments of flowers arise from a single polyketide precursor. Phenylalanine is converted to ***trans*-cinnamic acid** (Eq. 14-45) and then to cinnamoyl-CoA. The latter acts as the starter piece for chain elongation via malonyl-CoA (step *a* in the accompanying scheme). The resulting β-polyketone derivative can cyclize in two ways. The aldol condensation (step *b*) leads to **stilbenecarboxylic acid** and to such compounds as **pinosylvin** of pine trees. The Claisen condensation (step *c*) produces **chalcones**, **flavonones**, and **flavones**. These, in turn, can be converted to the yellow **flavonol pigments** and to the red, purple, and blue **anthocyanidins**.[a–c]

At the bottom of the synthetic scheme on the next page the structures and names of three common anthocyanidins are shown. The names are derived from those of flowers from which they have been isolated. The colors depend upon the number of hydroxyl groups and on the presence or absence of methylation and glycosylation. In addition to the three pigments indicated in the diagram, three other common anthocyanidins are formed by methylation. **Peonidin** is 3'-methylcyanidine. Methylation of delphinidin at position 3' yields **petunidin**, while methylation at both the 3' and 5' positions gives **malvidin**. There are many other anthocyanidins of more limited distribution. Anthocyanidins are nearly insoluble, but they exist in plants principally as glycosides known as **anthocyanins**. The number of different glycosides among the many species of flowering plants is large. Both the 3 and 5 –OH groups may be glycosylated with Glc, Gal, Rha, Ara, and by a large variety of oligosaccharides. The colors of the anthocyanins vary from red to violet and blue and are pH dependent. For example, **cyanin** (diglucosyl cyanidin) is red in acid solution and becomes violet upon dissociation of the 4'-hydroxyl group:

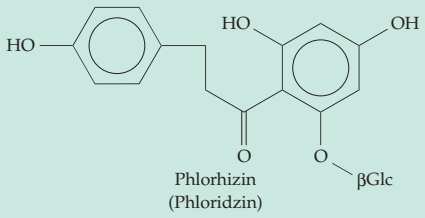


Dissociation of the 7–OH generates an anion with an extended conjugated π electron system, which will favor absorption of long-wavelength light (Chapter 23) and a blue color. Notice that a large number of resonance structures can be drawn for both the anthocyanin and the dissociated forms. Formation of complexes of Mg^{2+} or other metal ions with the 4' $-O^-$ and adjacent OH groups may also stabilize blue colored forms.[d]

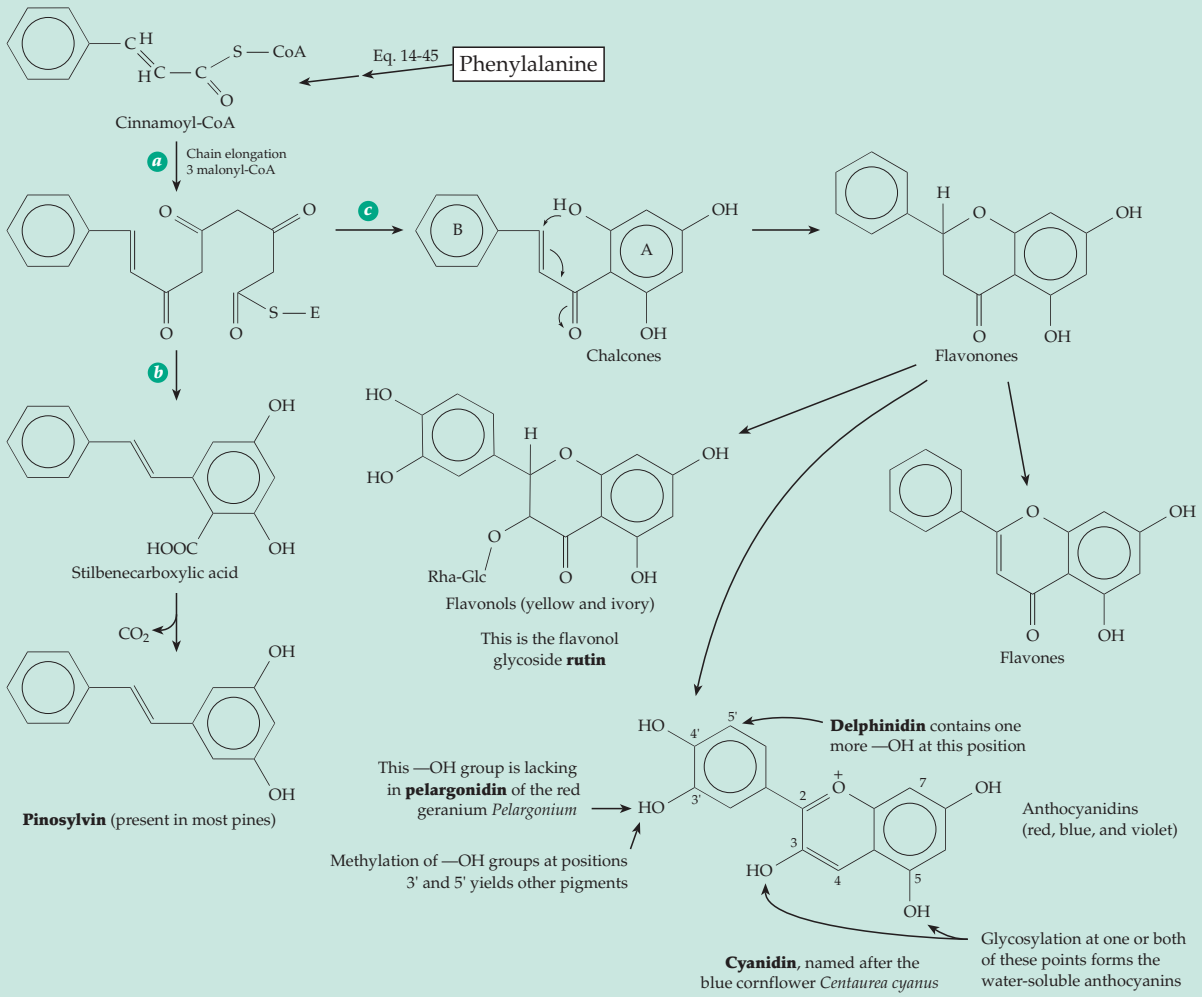


Most blue flower pigments are based on delphinidin,[b] but the "heavenly blue" of the morning glory is a peonidin with a complex caffeoylglucose-containing glycosyl group on the 3-position. Its blue color has been attributed to the relatively high pH of ~7.7 in vacuoles.[e] The aromatic rings within the glycosyl group of this and other complex anthocyanins may fold over the primary chromophore and stabilize the colored forms. A competing reaction, which is indicated in green on the first structure in this box, is the addition of a hydroxyl ion at C-2 to give a nearly colorless adduct.[f]

The yellow pigments of flowers are usually flavonols. The most common of all is **rutin**, the 3α-rhamnosyl-D-glucosyl derivative of **quercitin** (see diagram). An extraordinary number of other flavonols, flavones, and related compounds are found throughout the plant kingdom.[g] One of these is **phlorhizin**, a dihydrochalcone found in the root bark of pears, apples, and other plants of the rose family. Phlorhizin specifically blocks resorption of glucose by kidney tubules. As a result, the drug induces a strong glucosuria. The biochemical basis is uncertain, but the action on kidney tubules may be related to inhibition of mutarotase.[h]



BOX 21-E (continued)



The flavone glycoside **hesperidin** makes up 80% of the dry weight of orange peels. It has been claimed (but not proved) that this compound, also known as **vitamin P** and **citrus bioflavonoid**, is essential to good health. Another flavone, **maysin**, is a resistance factor for the corn earworm and is present in silks of resistant strains of *Zea mays*.[i]

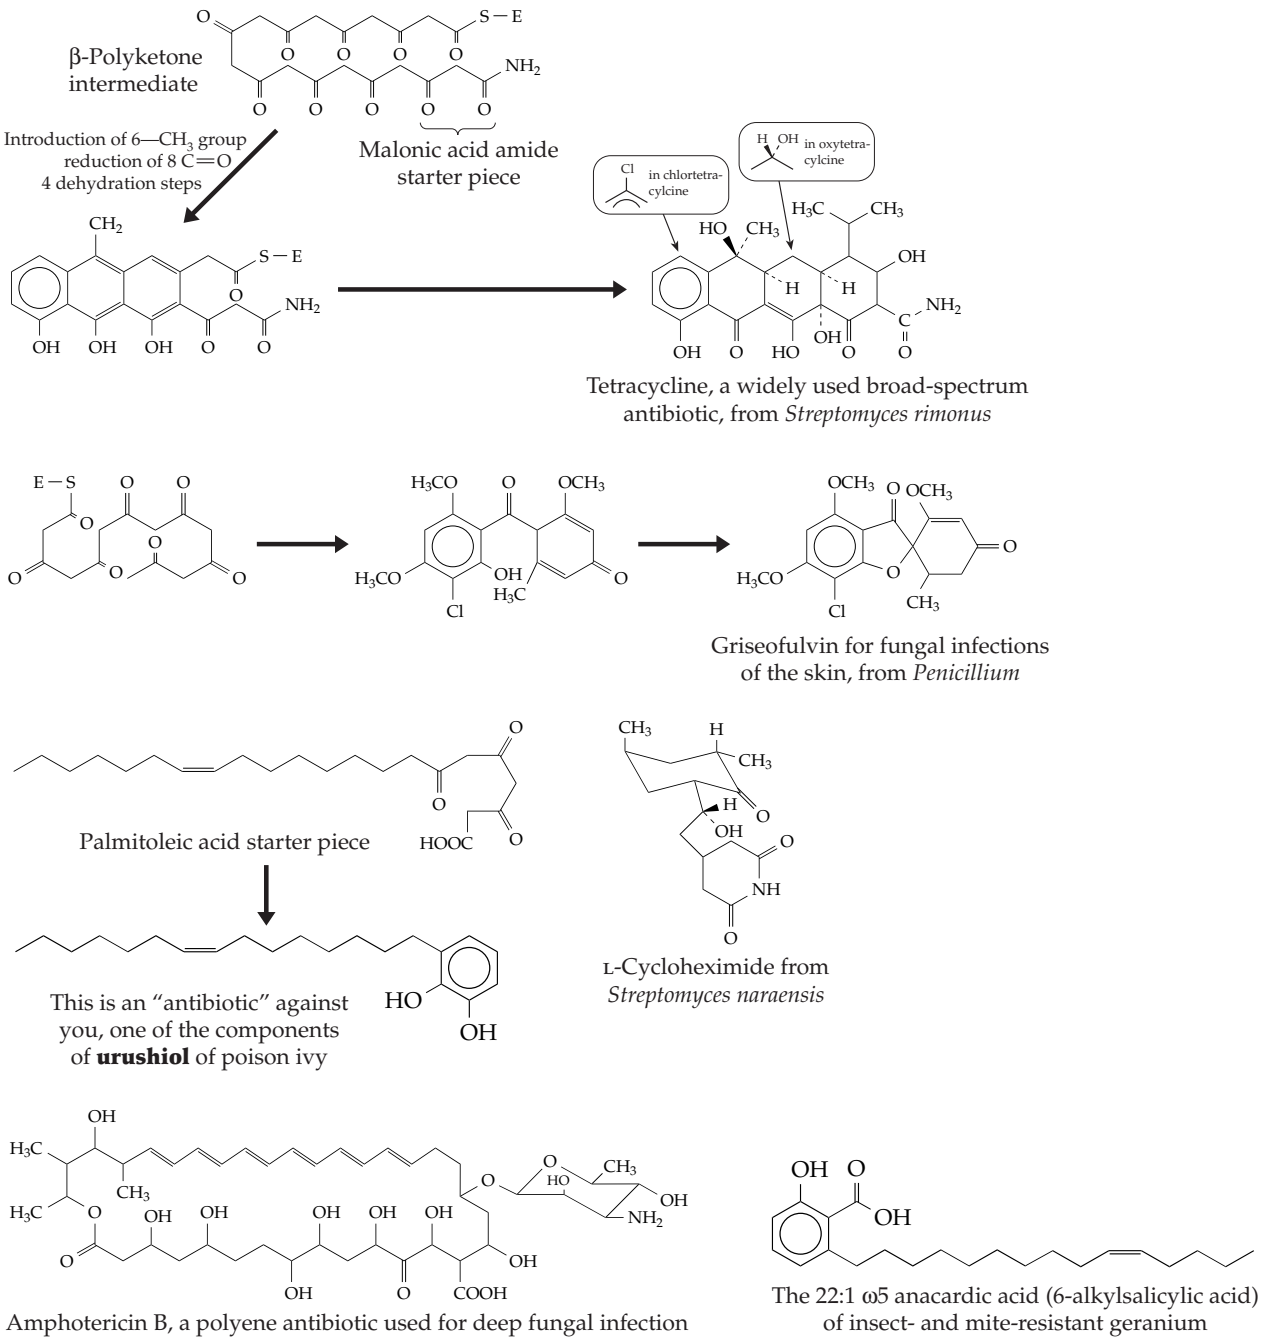

Figure 21-10 Some important polyketide antibiotics and plant defensive compounds.

explosion of information about polyketide synthases.[336,336a–c]

A 26-kb gene cluster encoding enzymes for synthesis of the blue antibiotic **actinorhodin** by *Streptomyces coelicolor* has been cloned and sequenced.[332,337] The three large ~10-kb genes required for formation of the broad-spectrum antibiotic **erythromycin** by *Saccharopolyspora erythraea* have also been cloned and sequenced.[337–339] In both cases, the genes encode large proteins with structures resembling those of the eukaryotic fatty acid synthases (Section B,1). However, a new feature is evident. As shown in Fig. 21-11, each of the three polypeptides of the deoxyerythronolide synthase, which synthesizes the aglycone of erythromycin, consists of two multidomain modules, each able to catalyze one round of reaction with a new molecule of malonyl-CoA. When reduction of an oxo group or dehydration and

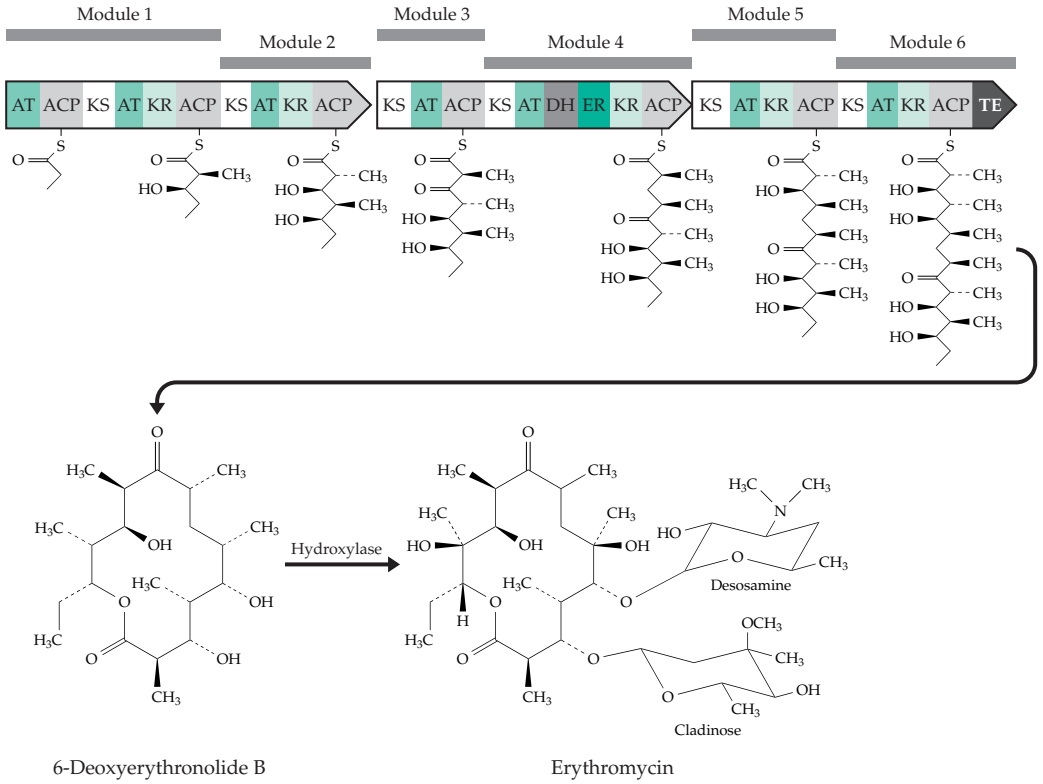

Figure 21-11 Catalytic domains within three polypeptide chains of the modular polyketide synthase that forms 6-deoxyerythronolide B, the aglycone of the widely used antibiotic erythromycin. The domains are labeled as for fatty acid synthases; AT, acyltransferase; ACP, acyl carrier protein; KS, β-ketoacyl-ACP synthase; KR, ketoreductase; DH, dehydrase; ER, enoylreductase; TE, thioesterase. After Pieper *et al.*[338] Courtesy of Chaitan Khosla.

reduction of an enoyl-CoA are not needed in a round, the KR, DH, and ER domains are absent (as in module 3 of Fig. 21-11). A final domain contains a thioesterase that releases and cyclizes the product. The "assembly line" sequence of synthetic steps, beginning with a propionyl group from propionyl-CoA, is pictured in Fig. 21-11. Two hydroxylation steps[340] and transfer of two unusual glycosyl groups complete the synthesis of the antibiotic.

Other medically important polyketides include the antibiotics **doxorubicin** (14-hydroxydaunomycin; Fig. 5-23),[341] rifamycin (Box 28-A),[342] and the antifungal **pimaricin**,[343] **griseofulvin**, and **amphotericin** (Fig. 21-10), the HMG-CoA reductase inhibitor **lovastatin**,[344] the 2-butanyl-4-methylthreonine of cyclosporin A (Box 9-F),[345] and other immunosuppressants such as **rapamycin**.[346] Many characteristic plant products, including **stilbenes**[347] and **chalcones**[348,348a] (Box 21-E), are polyketides. A variety of different polyketides serve as phytoalexins.[349] Some such as **aflatoxin**[350] are dangerous toxins. Ants and ladybird beetles make toxic polyamine alkaloids using a polyketide pathway.[350a]

Avermectin (Fig. 30–25), a widely used antibiotic against canine heartworms, is formed by a polyketide synthase with an unusually broad specificity for starter units. More than 40 alternative carboxylic acids are accepted. By grafting the first multidomain module of the erythromycin-forming synthase (of Fig. 21-11) onto the wide-specificity loading module of the avermectin-forming synthase, a whole new series of antibiotics have been created.[351] This is only one of many steps being taken to create new aliphatic and aromatic, linear and macrocyclic polyketides by genetic engineering.[336,352,353] Combinatorial biosynthesis (see Chapter 3) is also being developed[336,354] and has even been discovered in nature.[355]

Study Questions

1. Outline possible pathways of metabolism of dietary fats. Consider digestion, transport of fatty acids, storage, conversion to prostaglandins, steroids, etc. Will any of the fat be converted into glucose?

2. What are the functions in the human body of the following?

   Pancreatic lipase
   Lipocalins
   Lipoprotein lipase
   Very low density lipoprotein (VLDL)
   Hormone-sensitive lipase
   Chylomicrons
   Apolipoproteins

3. Describe two different types of fatty acid synthase. Compare the basic chemical reactions that are involved. Also, compare these with the reactions of fatty acid oxidation.

4. Discuss the different types of fatty acids found in the human body and the synthetic pathways by which they are formed.

5. What mechanisms are utilized for incorporation of double bonds into fatty acids? Propose a mechanism that makes use of polyketide synthase domains (Fig. 21-11) in the synthesis of polyunsaturated fatty acids. See Metz *et al.*[356]

6. In what locations would you expect to find the following?

   Tripalmitin
   Mycolic acids
   Arachidonic acid
   Propionic acid
   Docosahexaenoic acid

7. Substitution of a small percentage of ω6 fatty acids in the diet of insulin-resistant rodents with ω3 unsaturated fatty acids normalized insulin action.[357] Can you suggest possible mechanisms? Is this result significant to human nutrition?

8. Formation of the 3-hydroxymyristoyl groups of lipid A (Fig. 8-30) requires O_2. Comparisons of amino acid sequences suggest that an Fe^{2+}/2-oxoglutarate-dependent oxygenase is involved.[358] Write a balanced equation for this reaction.

9. Phosphatidylcholine can be formed by two pathways as described on pp. 1198–1199. A third pathway, used by some bacteria, involves a direct one-step reaction of choline with CDP-diacylglycerol.[359] Write a reasonable chemical mechanism.

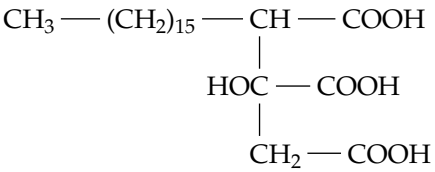
Study Questions

10. ^{14}C-Carboxyl labeled palmitic acid is fed to a fasted rat. There is no increase in liver glycogen, but the glucose units of the glycogen contain ^{14}C.
    a) Outline, using appropriate equations, the reaction sequence by which the carbon atoms of glucose become labeled.
    b) Explain why there is no net synthesis of glycogen from the fatty acid.

11. a) Write the reactions that most *dietary* tripalmitin will undergo in the body of an adult human in order to be deposited in adipose tissue as tripalmitin.
    b) What is the minimum amount of ATP (high energy bonds) normally required to deposit the one mole of dietary tripalmitin in adipose tissue? Count only ATP involved in tripalmitin metabolism and consider the source of glycerol in the adipose tissue.

12. Describe the biochemical effects on lipid metabolism of injecting into a normal animal
    a) insulin
    b) glucagon
    c) epinephrine

13. Suggest a biosynthetic pathway for formation of the fungal metabolite **agaricic acid**:



14. The ketone **palmiton** $CH_3(CH_2)14 - *CO - (CH_2)_{14}CH_3$ is formed by mycobacteria. The carbon marked by an asterisk was found to be labeled after feeding of [1-^{14}C]palmitic acid. Suggest a biosynthetic pathway.

15. The following reaction occurs in the biosynthesis of fatty acids.

    Crotonyl-ACP + NADPH + H^+ $\rightarrow$ butyryl-ACP + $NADP^+$

    The reduction half-reactions for crotonyl-ACP and NADPH are

    Crotonyl-ACP + 2 H^+ + 2 e^- $\rightarrow$ butyryl-ACP
    $E^{o'} = -0.015$ V
    $NADP + 2\ H^+ + 2\ e^- \rightarrow NADPH + H$
    $E^{o'} = -0.320$ V

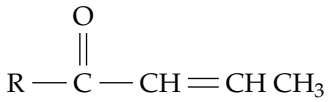
    What is $\Delta G^{o'}$ for this reaction? What is the equilibrium constant for the reaction?

16. How does the inhibition of citrate synthase affect fatty acid synthesis?

17. Malonyl CoA is an allosteric effector of carnitine acyl transferase. What kind of effector is it, i.e., activator or inhibitor, and what is the logic behind the interaction?

18. Compound II is formed in a series of enzymatic reactions from compound I. Propose a mechanistically realistic sequence, showing by name any cofactors required.

I

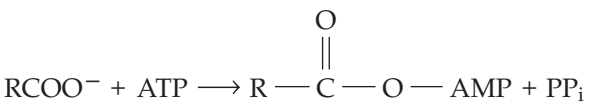


II

19. Fatty acid biosynthesis requires NADPH. Where does the NADPH come from?

20. An individual has been found who is missing malic enzyme in his cytoplasm. He has instead an enzyme that converts the oxalacetate made from the citrate lyase reaction directly to pyruvate and CO_2. Discuss this patient in terms of the likely effect of these changes on his ability to synthesize fatty acids.

21. The $\Delta G^{o'}$ values for the hydrolysis of any P – O – P bond of ATP, inorganic pyrophosphate, or any acyl CoA thiolester are all about –34 kJ/mole, while the corresponding figure for the hydrolysis of a mixed carboxylic phosphate anhydride is about –55 kJ/mole. Calculate the value of $\Delta G^{o'}$ for the following reaction describing the activation of fatty acids to the fatty acyl adenylate.



Study Questions

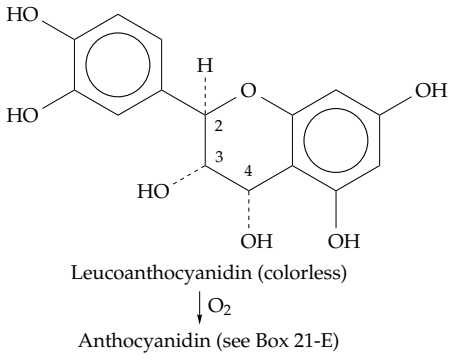
22. Fatty acid biosynthesis is made irreversible by the specific input of energy. Name the reactions or give equations for those steps in the pathway that require ATP. It is important that you consider both the mitochondrial and cytosolic components of the pathway.

23. The fatty acid biosynthesis pathway communicates with at least three other metabolic pathways either by sharing common intermediates or by regulatory mechanisms. Fill in the table below. List four molecules that have this function. You should name the additional pathway where each of these is found and briefly describe what it does in this second pathway. Do **not** use a redox cofactor as one of your choices.

Molecule	Other Pathway	Role in Second Pathway

24. The endogenous cannabinoid 2-arachidonoylglycerol is thought to play important roles both in the brain (Chapter 30) and in the immune system (Chapter 31). Leukocyte 12-oxygenase acts on this compound.[360] What products would be expected?

25. In the synthesis of anthocyanidins (Box 21-E) another Fe^{2+}/2-oxoglutarate-dependent oxygenase acts on the colorless leukoanthrocyanidin, which is then converted to the colored anthocyanidin:

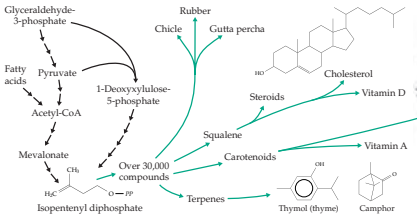


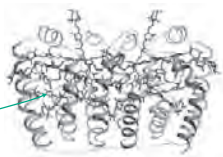
Propose a reasonable sequence for this reaction. See Nakajima *et al*.[361]

26. Why does a dietary deficiency of choline in humans induce a fatty liver, i.e., a liver in which the hepatocytes contain excess triglycerides?

27. Name two important functions of citrate in the conversion of acetate to palmitate by adipose tissues.

28. Outline the steps by which linoleic acid can be converted to prostaglandins in the human body.





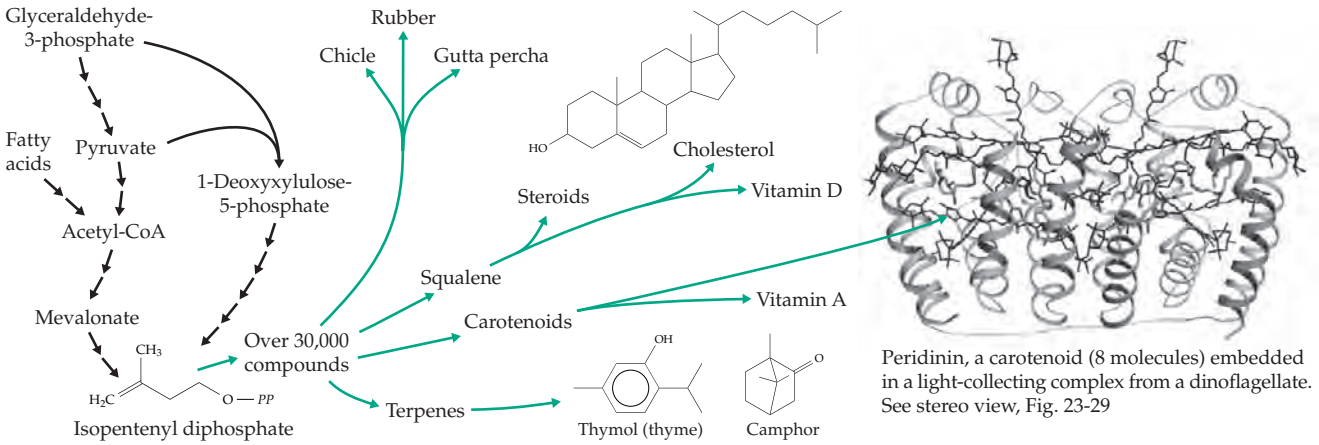
Peridinin, a carotenoid (8 molecules) embedded in a light-collecting complex from a dinoflagellate. See stereo view, Fig. 23-29

Starting with the simple compounds acetyl-CoA, glyceraldehyde-3-phosphate, and pyruvate, which arise via the central pathways of metabolism, the key intermediate **isopentenyl diphosphate** is formed by two independent routes. It is then converted by bacteria, fungi, plants, and animals into thousands of different naturally occurring products. These include high polymers, such as rubber, as well as vitamins, sterols, carotenoids, and over 30,000 different terpenes and related compounds. Many of the latter are found only in specific plants where they may function as defensive compounds or pheromones.

Contents

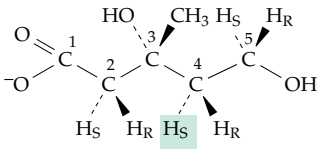
Polyprenyl (Isoprenoid) Compounds

22

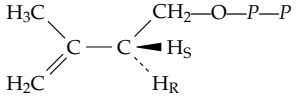


Peridinin, a carotenoid (8 molecules) embedded in a light-collecting complex from a dinoflagellate. See stereo view, Fig. 23-29

The **terpenes**, **carotenoids**, **steroids**, and many other compounds arise in a direct way from the prenyl group of **isopentenyl diphosphate** (Fig. 22-1).[1–6a] Biosynthesis of this five-carbon branched unit from **mevalonate** has been discussed previously (Chapter 17, Fig. 17-19) and is briefly recapitulated in Fig. 22-1. Distinct isoenzymes of 3-hydroxy-3-methylglutaryl-CoA synthase (HMG-CoA synthase) in the liver produce HMG-CoA destined for formation of ketone bodies (Eq. 17-5) or mevalonate.[7,8] A similar cytosolic enzyme is active in plants which, collectively, make more than 30,000 different isoprenoid compounds.[9,10] However, many of these are formed by an alternative pathway that does not utilize mevalonate but starts with a thiamin diphosphate-dependent condensation of glyceraldehyde 3-phosphate with pyruvate (Figs. 22-1, 22-2).



3(*R*) Mevalonate



Isopentenyl diphosphate

The two-step reduction of HMG-CoA to mevalonate (Fig. 22-1, step *a*)[11–15] is highly controlled, a major factor in regulating cholesterol synthesis in the human liver.[12,16,17] The N-terminal portion of the 97-kDa 888-residue mammalian HMG-CoA reductase is thought to be embedded in membranes of the ER, while the C-terminal portion is exposed in the cytoplasm.[16] The enzyme is sensitive to feedback inhibition by cholesterol (see Section D, 2). The regulatory mechanisms include a phosphorylation–dephosphorylation cycle and control of both the rates of synthesis and of proteolytic degradation of this key enzyme.[14,15,18–20]

A. Isopentenyl Diphosphate and Polyprenyl Synthases

In animals all isoprenoid compounds are apparently synthesized from mevalonate, which is converted by the consecutive action of two kinases[21–23] into mevalonate 5-diphosphate (Fig. 22-1, step *b*). Mevalonate kinase is found predominantly in peroxisomes, which are also active in other aspects of steroid synthesis in humans.[21,24] A deficiency of this enzyme is associated with mevalonic aciduria, a serious hereditary disease in which both blood and urine contain very high concentrations of mevalonate.[23] Mevalonate diphosphate kinase, which is also a decarboxylase, catalyzes phosphorylation of the 3-OH group of mevalonate (step *c*, Fig. 22-1) and decarboxylative elimination of phosphate (step *d*)[25] to form isopentenyl diphosphate.

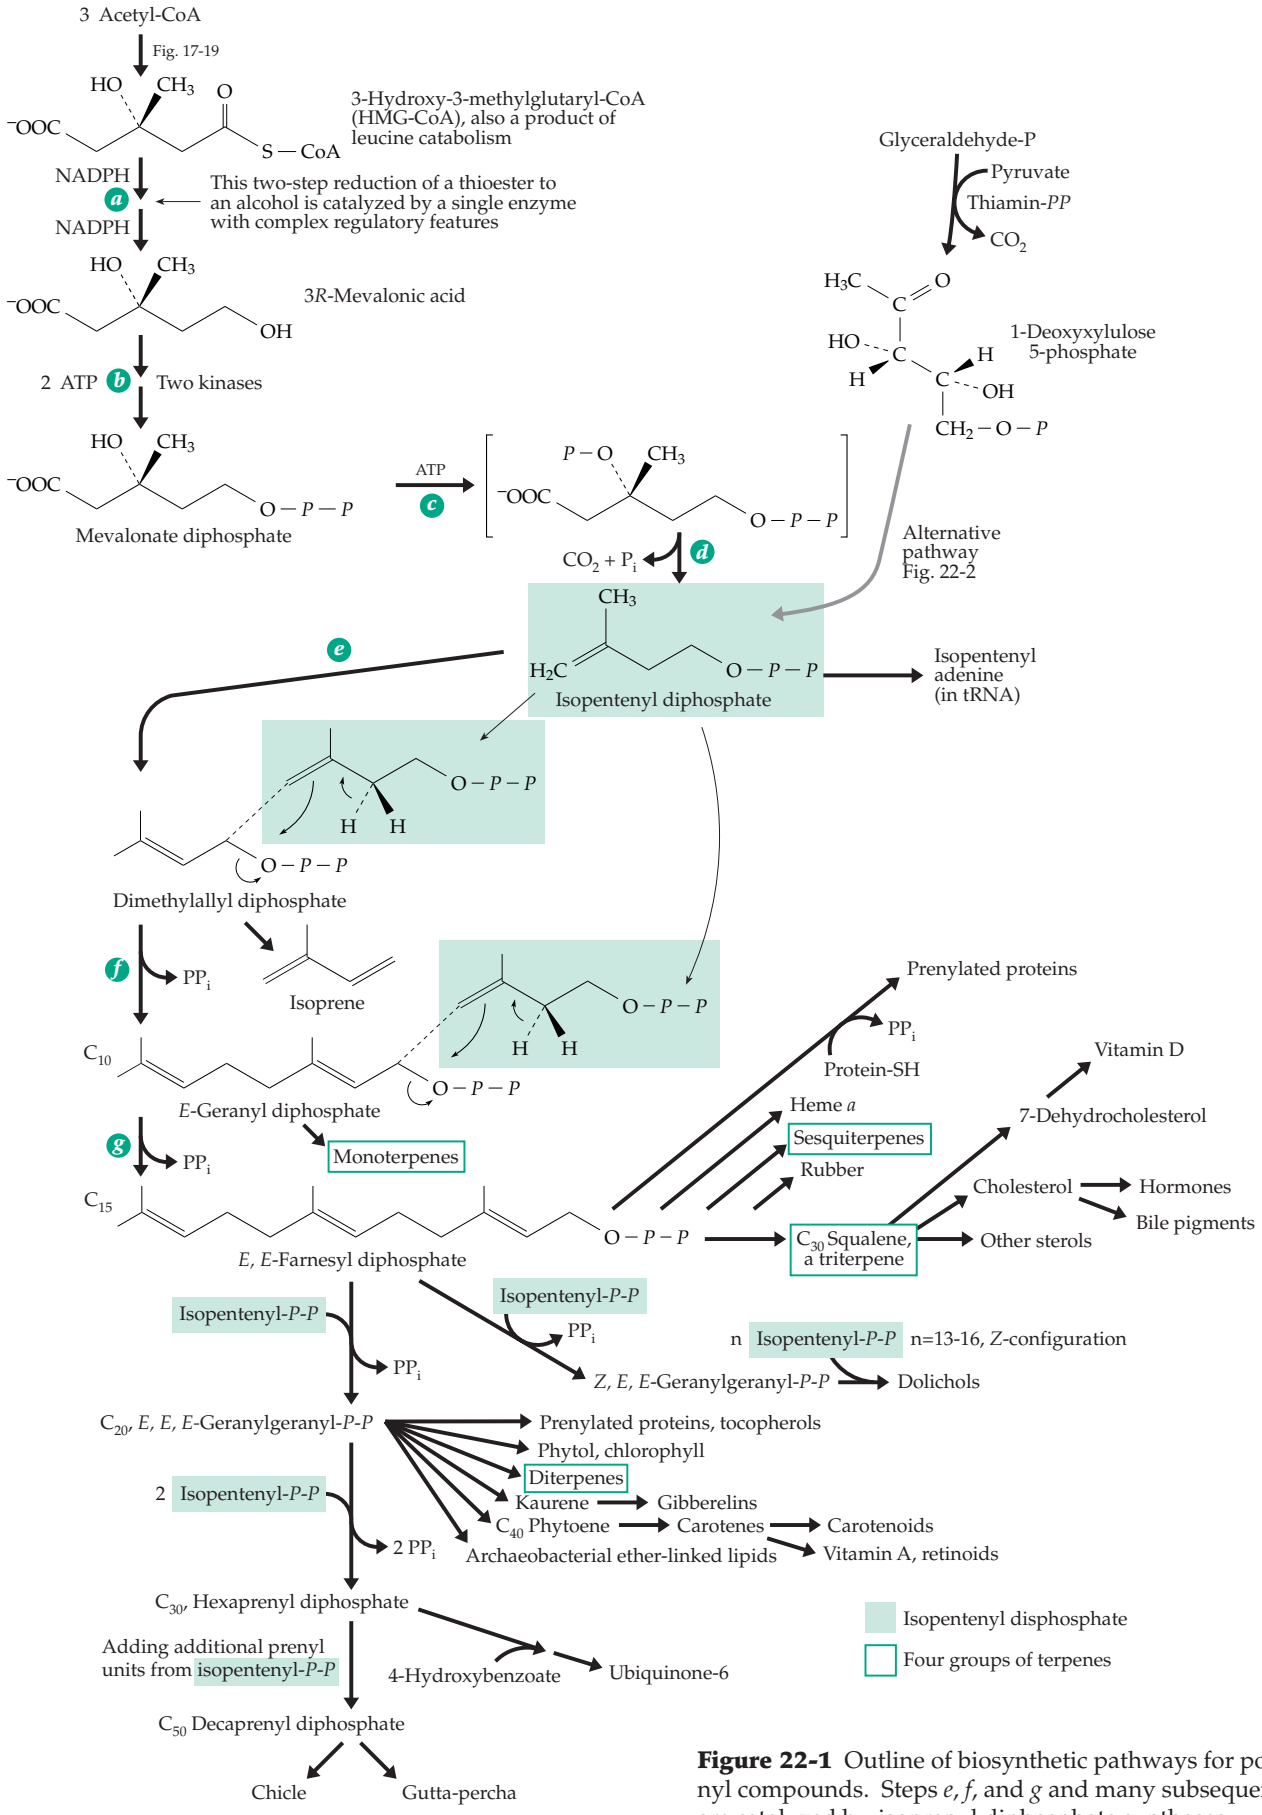


Figure 22-1 Outline of biosynthetic pathways for polyprenyl compounds. Steps *e*, *f*, and *g* and many subsequent steps are catalyzed by isoprenyl diphosphate synthases.

1. An Alternative Pathway for Isoprenoid Synthesis

It is generally agreed that mevalonate is the precursor to sterols in higher plants as well as in animals and is also the precursor to plant carotenoids. However, it is poorly incorporated into monoterpenes and into some diterpenes such as those of the taxane group.[26,27] The alternative **glyceraldehyde 3-phosphate:pyruvate pathway** explains this result. The pathway also operates in some bacteria and apparently is the sole source of isoprenoid compounds for the unicellular alga *Scenedesmus*.[28] The pathway is outlined in Fig. 22-2. Pyruvate is decarboxylated by a thiamin diphosphate-dependent enzyme,[29] and the resulting enamine is condensed with D-glyceraldehyde 3-phosphate to form 1-deoxyxylulose 5-phosphate.[28,30–31a] The latter undergoes an isomeroreductase rearrange-

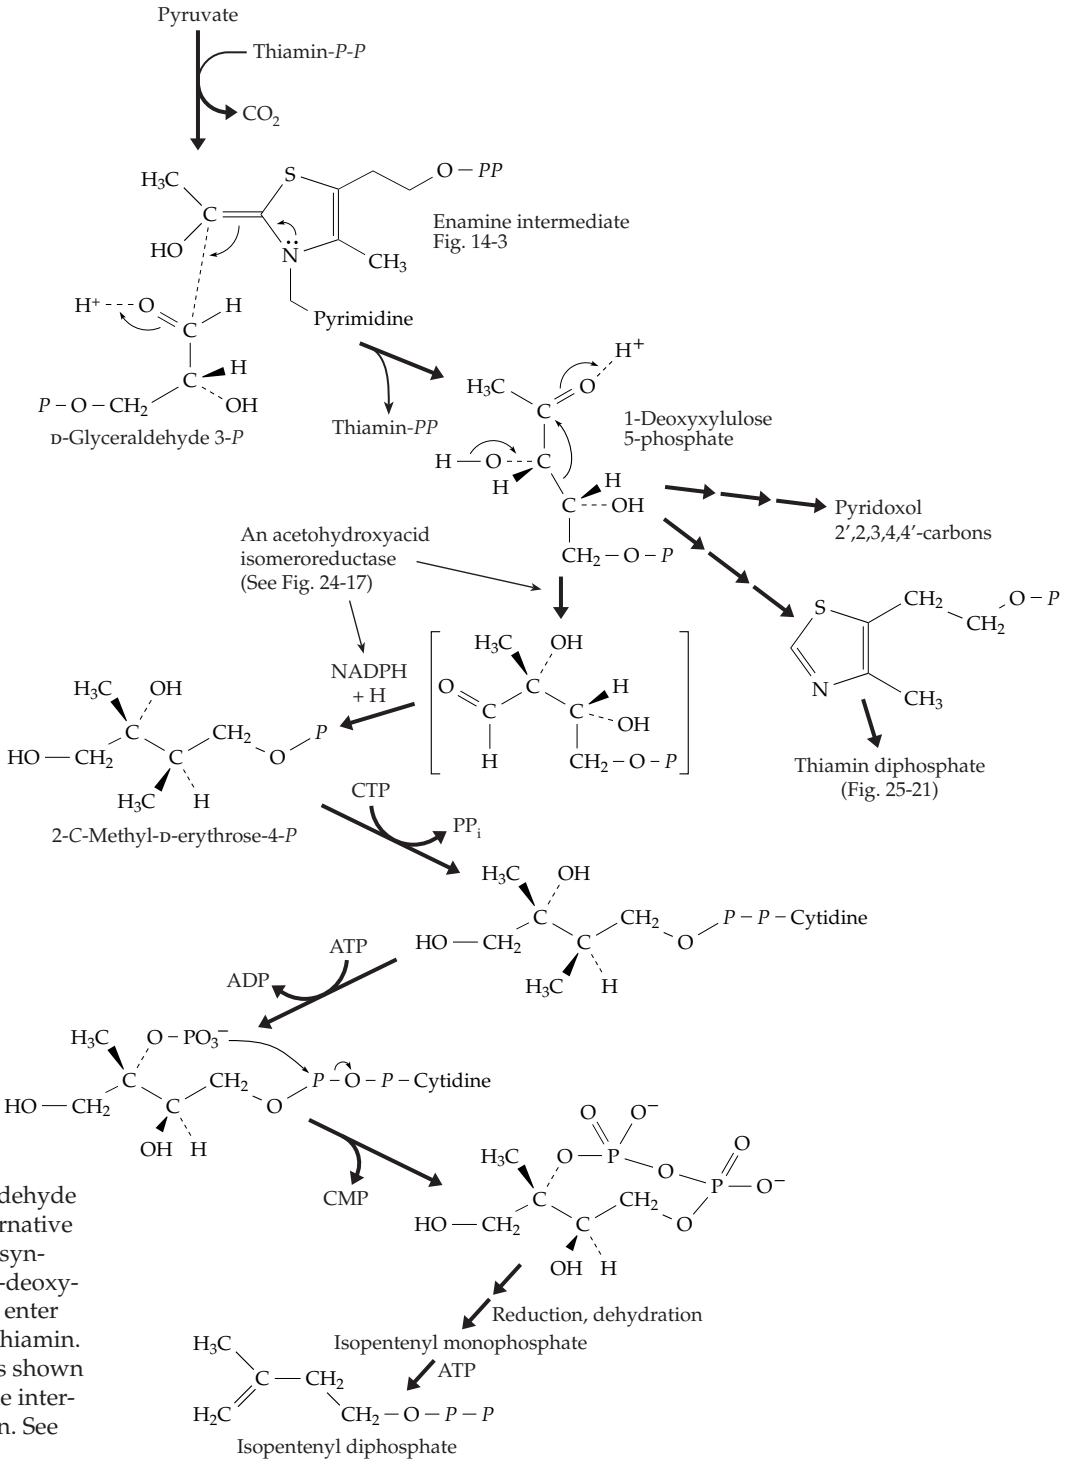

Figure 22-2 The glyceraldehyde 3-phosphate:pyruvate alternative pathway of isoprenoid biosynthesis. The intermediate 1-deoxyxylulose 5-phosphate may enter terpenes, vitamin B_6, and thiamin. Isopentenyl diphosphate is shown as the final product, but the intermediate steps are uncertain. See Lange *et al*.[32g]

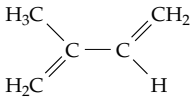
ment of the type that occurs in the biosynthesis of valine and isoleucine (Fig. 24-17),[32] but the additional steps on to isopentenyl diphosphate are not obvious. However, some intermediate compounds have been identified as is indicated in Fig. 22-2.[32a–g] 1-Deoxyxylulose 5-phosphate has also been identified as an intermediate in the biosynthesis of vitamin B_6 in *E. coli*.[32a,h,33] It gives rise to the 2', 2, 3, 4, and 4' carbon atoms of pyridoxine and also to the pyrimidine ring of thiamin. See Chapter 25.

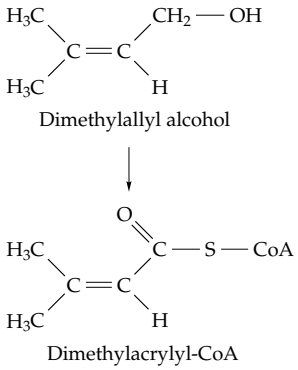
2. Isomerization and Isoprene Formation

Before polymer formation begins, one molecule of isopentenyl diphosphate must be isomerized to **dimethylallyl diphosphate** (Fig. 22-1, step *e*, Eq. 13-56).[10,33a,b] In this process the hydrogen that was in the 4-*pro-S* position of mevalonic acid (the *pro-R* position of isopentenyl pyrophosphate) is lost. Dimethylallyl diphosphate is unstable and can undergo acid-catalyzed elimination of PP_i to form isoprene, apparently by a carbocation mechanism.



Isoprene

This evidently accounts for the presence of isoprene in the breath.[34] Isoprene is also formed by many plants and is released into the atmosphere in large amounts, which contribute to photochemical formation of haze. A Mg^{2+}-dependent enzyme catalyzes the elimination of pyrophosphate.[35] Isoprene emissions rise with increasing temperature, and it has been suggested that the isoprene may dissolve in chloroplast membranes and in some way confer increased heat resistance.[36,37] Hydrolytic dephosphorylation can lead to dimethylallyl alcohol, which is oxidized in the liver to dimethylacrylyl-CoA (Eq. 22-1).



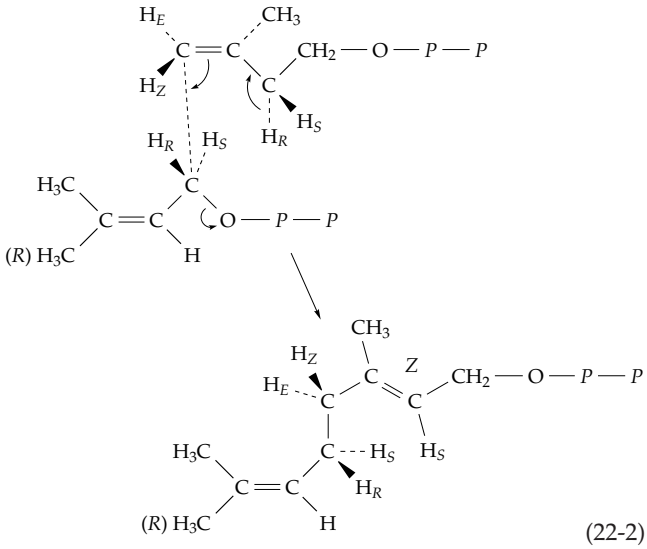
Dimethylallyl alcohol

Dimethylacrylyl-CoA (22-1)

The latter is also a catabolite of leucine and can be converted back to HMG-CoA via a biotin-dependent carboxylation (see Fig. 24-18). This provides a means of recycling the dimethylallyl alcohol back to the polyprenyl pathway.[38]

3. Polyprenyl Compounds

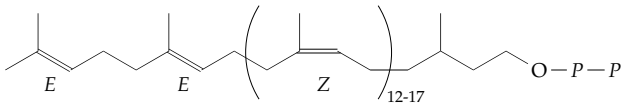
Dimethylallyl diphosphate serves as the starter piece for most polyprenyl compounds. Additional prenyl units are added, with elimination of pyrophosphate, by the action of **polyprenyl diphosphate synthases** as indicated in Fig. 22-1. Many of the products have all-trans (*E*) double bonds. A substantial number of these synthases are known and are distinguished by their chain length specificity and stereochemical properties.[39–46b] The most studied is farnesyl diphosphate synthase. The three-dimensional structure of an avian form is known.[47,47a] It catalyzes steps *f* and *g* of Fig. 22-1, joining three prenyl groups with the *E,E* (trans, trans) configuration. This protein, which consists almost entirely of packed α helices, has a large central cavity with conserved lysines and two aspartate-rich sequences (DDXXD) along its walls. These polar groups, together with magnesium ions, probably bind the pyrophosphate groups of the substrates.[48] Aspartates 224 and 225 of a bacterial form of the enzyme appear to be essential for catalytic activity.[49] The reaction is thought to be initiated by elimination of PP_i to form a carbocation to which the second prenyl unit adds as in Eq. 22-2.[50,51] For each prenyl unit a hydrogen atom that was originally the 4-*pro-S* hydrogen of mevalonic acid is lost as a proton.[52,53] Addition of another prenyl unit gives *E,E,E* geranylgeranyl diphosphate.[46a]



(22-2)

The chain length of the polyprenyl compounds appears to be determined by the protein structure of

the synthase.[45,54,54a,b] Polymerization of prenyl units can continue with the formation of high molecular weight polyprenyl alcohols such as the **dolichols** and bacterial decaprenols (Chapter 20) or of the high polymers **rubber** (all *Z* configuration), chicle, and **gutta-percha**.[6a] Dolichols, which function in the biosynthesis of glycoproteins, consist of 16–21 prenyl units and are synthesized in the endoplasmic reticulum as the diphosphates.[55–57] Farnesyl diphosphate is elongated to *Z*,*E*,*E* geranylgeranyl diphosphate, and polymerization continues with addition of 13–18 more units, all with the *Z* (cis) configuration.[46b,57a,b] However, after dephosphorylation[58] the double bond of the last unit added becomes saturated.[59] Partial absence of the required reductase causes a serious human deficiency disease involving faulty glycoprotein synthesis.[60]



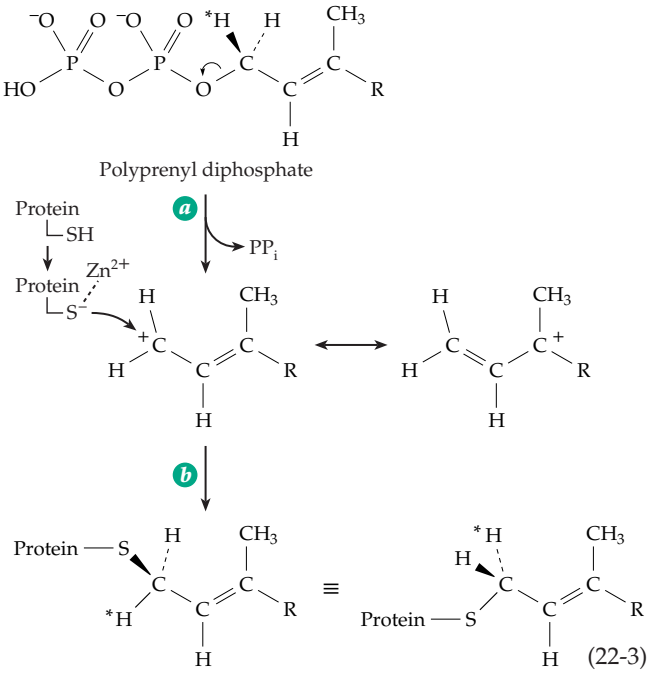
A fully extended 19-unit dolichol (dolichol-19) would have a length of about 10 nm, twice that of the bilayer in which it is dissolved. It has been suggested that the central part of the molecule has a helical structure, while the ends are more flexible. Dolichols also appear to increase the fluidity of membrane bilayers.[61] Bacterial undecaprenyl diphosphate, which has a similar function, contains only one *E* and ten *Z* double bonds[62–63a] (see p. 1152).

Rubber also contains almost entirely *Z* double bonds. Consistent with this fact is the finding that the prenyltransferases catalyzing formation of rubber promote loss of the *pro-R* proton rather than the *pro-S* proton of mevalonic acid (see Eq. 22-2). There appear to be two types of prenyltransferase in animal mitochondria giving rise to *E* and *Z* double bonds, respectively.[64] In contrast, the rubber tree contains a 137-residue protein, the **rubber elongation factor**. This small protein binds to *E* prenyltransferases causing them to form *Z* double bonds.[65] The bacterium *Micrococcus luteus* synthesizes all *E* polyprenyl alcohol diphosphates up to the C_{45} nonaprenyl compound **solanesyl diphosphate**.[66]

Chain elongation during polymerization of prenyl units can be terminated in one of a number of ways. The pyrophosphate group may be hydrolyzed to a monophosphate or to a free alcohol. Alternatively, two polyprenyl compounds may join "head to head" to form a symmetric dimer. The C_{30} terpene **squalene**, the precursor to cholesterol, arises in this way from two molecules of farnesyl diphosphate as does **phytoene**, precursor of the C_{40} carotenoids, from *E*,*E*,*E* geranylgeranyl diphosphate. The phytanyl groups of archaebacterial lipids (p. 385) arise rather directly from geranylgeranyl diphosphate by transfer of the polyprenyl group to the $-CH_2OH$ group of *sn*-glycerol 3-phosphate.[67,67a] This is followed by hydrogenation of the double bonds. Formation of diphytanyl group (p. 388) must involve additional crosslinking reactions.

4. Prenylation of Proteins and Other Compounds

Polyprenyl groups are often transferred onto thiolate ions of cysteine side chains of certain proteins that bind to membranes (p. 559).[68,69] We have previously considered the Ras family (Chapter 11). Recoverin, an important protein in the visual cycle (Fig. 23-43), is another example of a prenylated protein. Both **farnesyltransferases**[70–76f] and **geranylgeranyltransferases**[72,77–78b] have been characterized, and the three- dimensional structure of the former has been established.[73,75–76] The two-domain protein contains a seven-helix crescent-shaped hairpin domain and an α,α-barrel similar to that in Fig. 2-29. A bound zinc ion in the active site may bind the $-S^-$ group of the substrate protein after the farnesyl diphosphate has been bound into the active site.[76,79] These enzymes are thought to function by a carbocation mechanism as shown in Eq. 22-3 and with the indicated inversion of configuration.[71]



Inhibition of these prenyltransferases blocks growth of tumor cells. Many prenyltransferase inhibitors are apparently nontoxic to normal cells and are undergoing human clinical trials as anticancer drugs.[76a, 79a,b] Among other important polyprenyl

compounds are the side chains of vitamin K, the ubiquinones, plastoquinones, tocopherols, and the phytyl group of chlorophyll. In all cases, a diphosphate of a polyprenyl alcohol serves as an alkyl group donor. Introduction of the polyprenyl chain into aromatic groups, such as those of the quinones (Fig. 15-24), occurs at a position ortho to a hydroxyl group in the reduced quinone (hydroquinone). The reader should be able to propose a reasonable prenyltransferase mechanism involving participation of the hydroxy group. The monoprenyl compound dimethylallyl diphosphate prenylates the N^6 position of adenine in a specific site in many tRNA molecules (Fig. 5-33)[80] as well as the C-4 position of L-tryptophan in the synthesis of ergot alkaloids.[81]

B. Terpenes

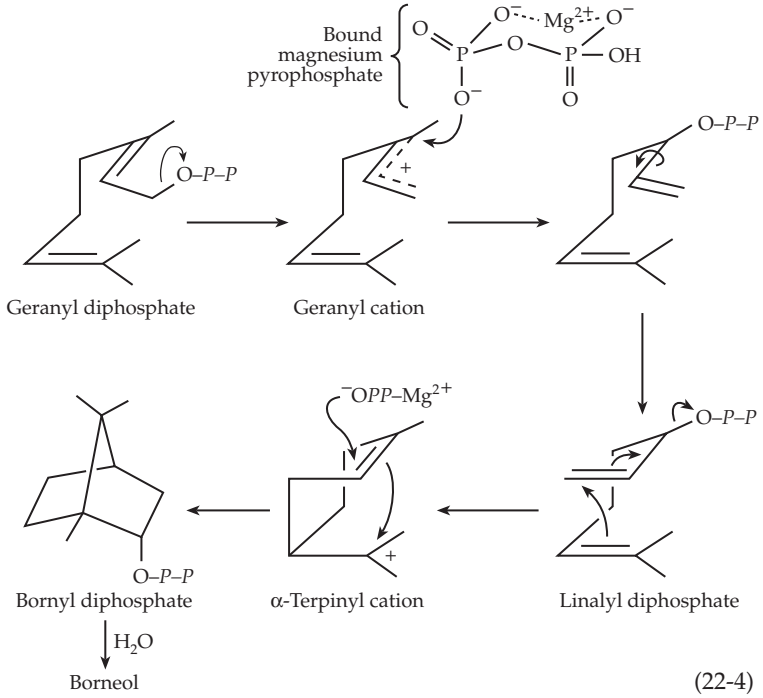
The number of small compounds that arise from isopentenyl diphosphate and are found in plants, animals, and bacteria is staggering. Just a few of these "terpenes" are shown in Figs. 22-3 and 22-4. The biosynthetic pathways have been worked out by "feeding" radioactively labeled acetate to plants and studying the characteristic labeling patterns in the terpenes. Many of the enzymes involved have been identified and studied. A given plant usually contains a large number of different terpenes, which are often concentrated in specialized "oil glands" or resinous duct tissues. Lesser amounts, often as glycosides of terpene alcohols, may be present within cells. Some terpenes occur in truly enormous amounts. For example, turpentine may contain 64% of **α-pinene** and juniper oil 65% **α-terpineol**.[82] The large quantities of α-pinene released into the air from pine trees are a major cause of photochemical smog.[83]

Terpenes have a variety of functions. Plant terpenes may deter herbivores and attract pollinators. They may participate in competition among plants and may act as antibiotics, called **phytoalexins**, to protect plants from bacteria and fungi.[84] In invertebrate animals terpenes serve as hormones, pheromones, and defensive repellants (Figs. 22-3, 22-4). The terpene squalene is the precursor to sterols. Some terpenes are toxic. For example, thujone (Fig. 22-3), which is present in the liqueur absinthe, causes serious chronic poisoning.[84]

1. Biosynthesis of Monoterpenes

The compounds of Figure 22-3 each contain ten carbon atoms and are called monoterpenes. They occur largely in plants, but some function in arthropods as pheromones. As with chain elongation, the cyclization of geranyl diphosphate to the various monoterpenes appears to occur through loss of pyrophosphate (as PP_i) with formation of an intermediate carbocation such as that depicted in Equation 22-3.[85–88a] Similar mechanisms initiate cyclization of sesquiterpenes and diterpenes. Numerous terpene cyclases have been isolated, and several have been studied carefully. A stereochemical view of the formation of borneol is illustrated in Eq. 22-4. Both linalyl-*PP* and bornyl-*PP* are intermediates. Croteau and associates suggested that a tight ion pair between carbocation and magnesium pyrophosphate is maintained at each stage.[86,89]

As is indicated in Fig. 22-3, the same intermediate cation can yield a variety of end products. For example, pure geranyl diphosphate: pinene cyclase catalyzes formation of several other terpenes in addition to α-pinene.[89] Another aspect of terpene synthesis is that insects may convert a plant terpene into new compounds for their own use. For example, **myrcene**, which is present in pine trees, is converted by bark beetles to **ipsenol** (Fig. 22-3), a compound that acts as an aggregation pheromone.[90]



(22-4)

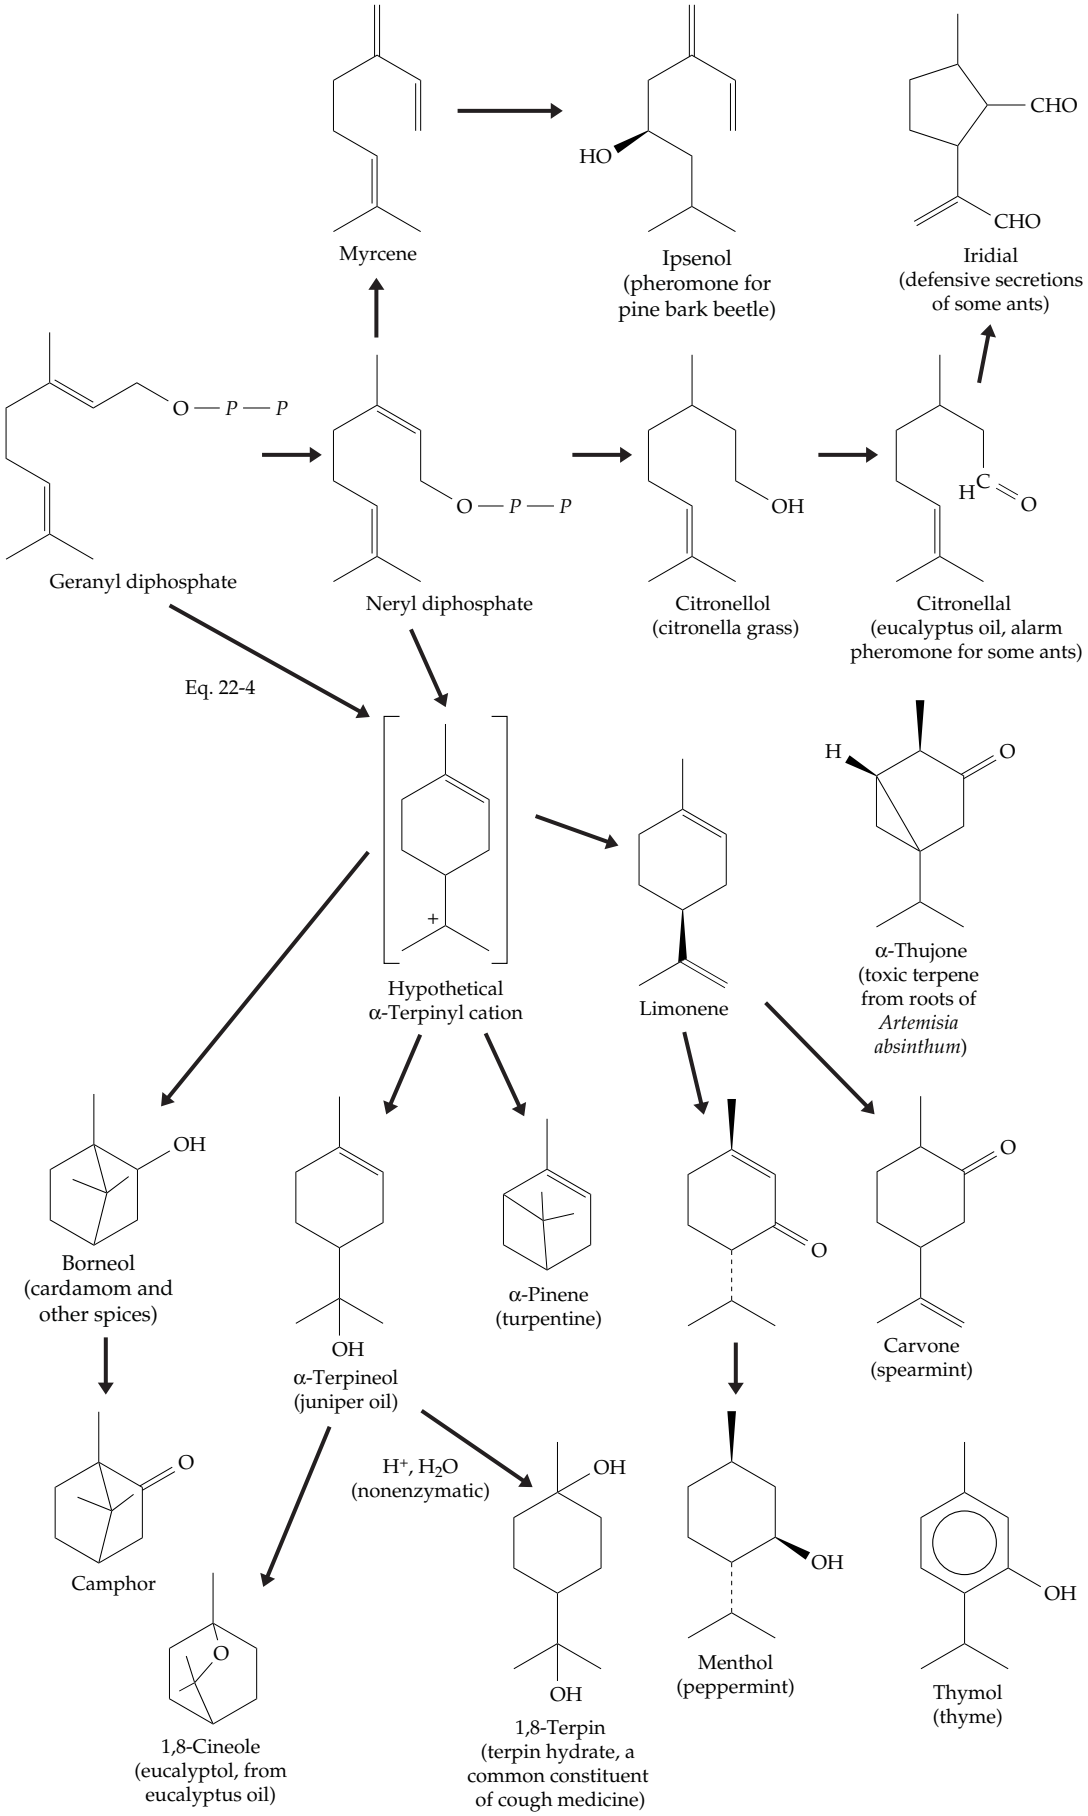


Figure 22-3 Probable biosynthetic pathways of some monoterpenes and related substances. Some of the natural sources are indicated.

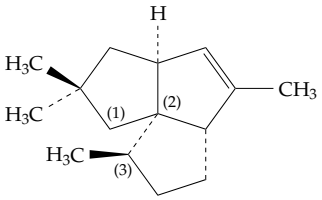
2. Sesquiterpenes and Diterpenes

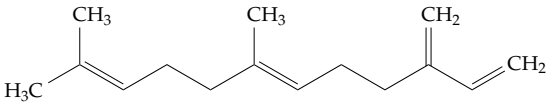
Most of the compounds shown in Figure 22-4 are derived from the C_{15} farnesyl diphosphate. There are more than 300 known cyclic structures among these **sesquiterpenes,** and many sesquiterpene synthases have been characterized.[91,91a] **Aristolochene** is formed by the action of a 38-kDa cyclase that has been isolated from species of *Penicillium* and *Aspergillus*.[92–94] Notice that the synthesis must involve two cyclization steps and migration of a methyl group. Three-dimensional structures are known for at least two terpene synthases,[95,96] and comparison of gene sequences suggests that many others have similar structures. The **5-epi-aristolochene synthase** of tobacco makes the 5-epimer of aristolochene (Fig. 22-4). It binds the diphosphate group within a central cavity using two Mg^{2+} ions held by carboxylates, some of which are in the DDXXD sequence found also in polyprenyl diphosphate synthases. The enzyme active sites of both the epi-aristolochene synthase and a **pentalenene synthase** from *Streptomyces*[96] are rich in polar groups that form hydrogen-bonded networks and which participate in proton abstraction and donation during the rearrangement reactions that must occur.



Pentalenene

Aromatic groups that are also present may assist in stabilizing intermediate carbocationic species. Deprotonation by an aspartate side chain in the epi-aristolochene synthase has been proposed to assist the cyclization; subsequent reprotonation by an Asp•Tyr•Asp triad would generate a new carbocation and promote the necessary methyl group migration. A detailed step-by-step mechanism has been proposed.[95] The fungal pentalenene synthase has an active site histidine, which is proposed to serve as proton acceptor and donor for the several steps of the reaction of farnesyl diphosphate.[96] The carbon atoms originating from C1 to C3 of the precursor have been marked on the pentalenene structure as well as on the aristolochene structure in Fig. 22-4. We now see how synthases can guide the terpene cyclase reactions to give specific products.

Another sesquiterpene synthase forms **trichodiene**, the parent compound for a family of mycotoxins and antibiotics.[97,97a,b] A different sesquiterpene synthase, present in peppermint and also in a wide range of other plants and animals, forms the acyclic **(E)-β-farnesene**.[98] It serves as alarm pheromone for aphids, has a variety of signaling functions in other insects, and is a urinary pheromone in mice.[98]



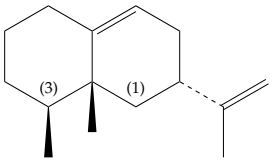
(*E*)-β-Farnesene

Abscisic acid, one of five known types of plant hormone of general distribution throughout higher plants, is not regarded as a true terpene because it arises by degradation of a carotenoid.[99–99b] However, its structure (Fig. 22-4) is that of a sesquiterpene.

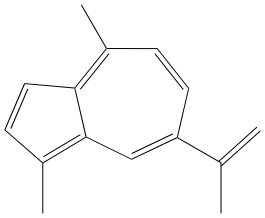
The C_{20} **diterpenes** are derived from geranylgeranyl-*PP*. Among the best known members are another group of plant hormones, the **gibberellins**.[100–102a] The first gibberellin was isolated as a product of plants infected with a *Fusarium* fungus. The rice plants grew in an abnormally tall, weak form. Subsequently, this multimembered class of over 50 highly modified diterpenes have been shown to have a variety of regulatory functions in all higher plants. For example, gibberellins are essential for stem elongation.

Equation 22-5 gives an abbreviated biosynthetic sequence for gibberellin A_1. The ring closure of step *a*, Eq. 22-5, may be initiated by protonation of the double bond at the left of the first structural formula. The resultant carbocation could initiate the consecutive closure of the two rings and the loss of a proton from a methyl group (step *b*) to yield copalyl-*PP*. Steps *c* and *d*, Eq. 22-5, each represent several reactions. In step *c*, pyrophosphate is eliminated, and the methyl group that becomes a methylene in *ent*-kaurene (enantiotopic kaurene) undergoes migration.[102b] Step *d* involves several hydroxylation and oxidation steps as well as a ring contraction through which one of the original methylene groups ends up as a carboxyl group in the final product.[102,103,103a] Deactivation of the hormone is initiated by a 2-oxoglutarate-dependent dioxygenase.[103b]

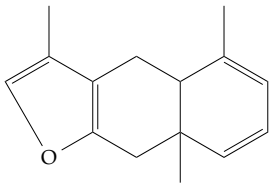
The **juvenile hormone** of insects (Fig. 22-4) is also of polyprenyl origin.[104,105] However, two of the methyl groups have been converted to (or replaced by) ethyl groups. The isolation and identification of the structure of the juvenile hormone was a difficult task. After its completion it was a surprise to researchers to discover that a large variety of synthetic compounds, sometimes with only a small amount of apparent structural similarity, also serve as juvenile hormones, keeping insects in the larval stage or preventing insect eggs from hatching. Furthermore, a number of plant products such as **juvebione** (Fig. 22-4),[106] which was originally isolated from paper, have the same effect. Thus, in nature products of plant metabolism have a profound effect upon the development of insects that



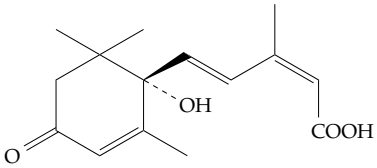
Aristolochene, parent hydrocarbon of many fungal toxins



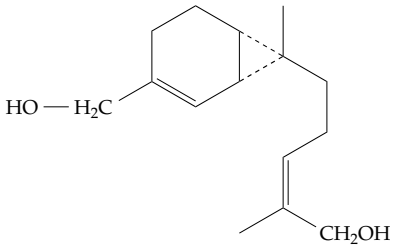
Lactarazulene, dye from the mushroom *Lactarius deliciosus*



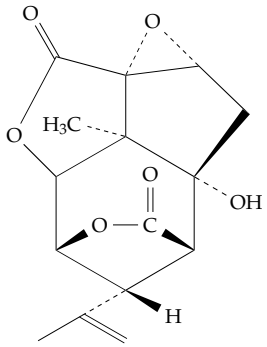
Furanoeudesma-1,3-diene, a sesquiterpene from myrrh with analgesic properties



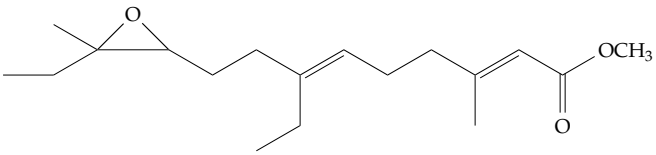
Abscisic acid, an important hormone of green plants



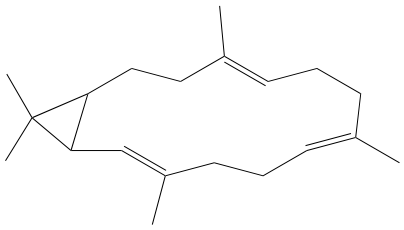
Sirenin, a sperm attractant produced by female gametes of the phycomycete *Allomyces*



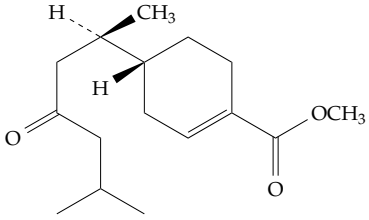
Picrotoxin, a plant toxin sometimes used to kill fish



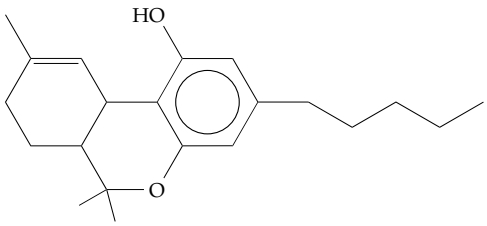
Juvenile hormone, a substance acting to maintain the larval stage of insects



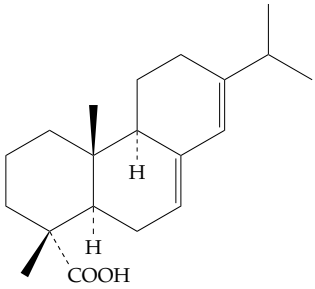
Casbene, a macrocyclic phytoalexin



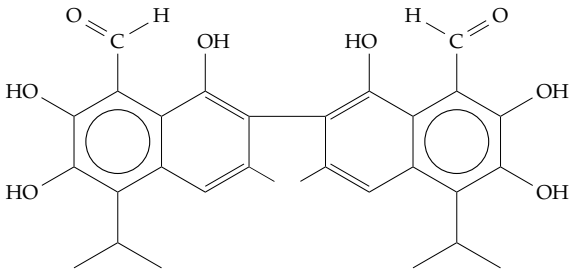
Juvebione, a product of the balsam fir with juvenile hormone activity



Δ'-3,4-*trans*-Tetrahydrocannabinol (Δ'-THC) a psychotropic component of marijuana

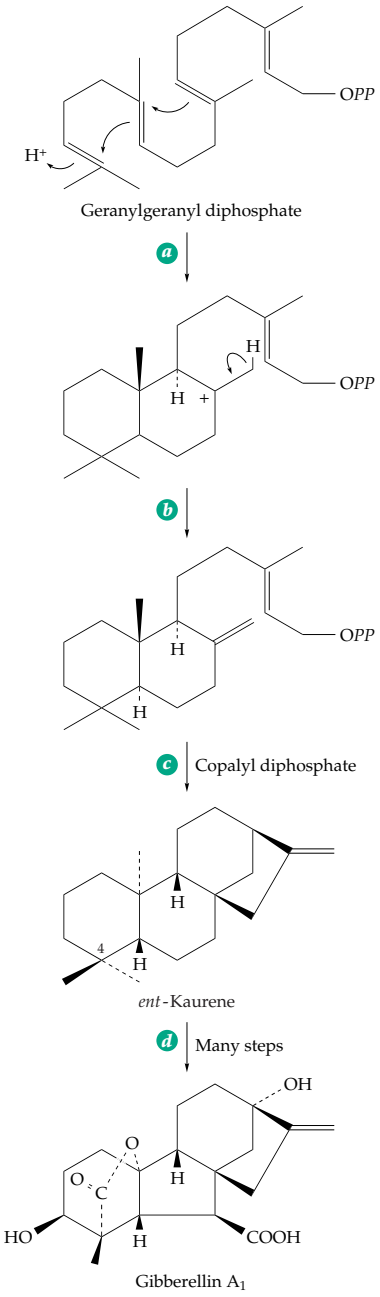


Abietic acid, a component of rosin, from conifers



Gossypol, toxic, dimeric sesquiterpene from cottonseed

Figure 22-4 More terpenes and related substances. The numbers in parentheses on the aristolochene structure are those of atoms in the precursor farnesyl diphosphate.



(22-5)

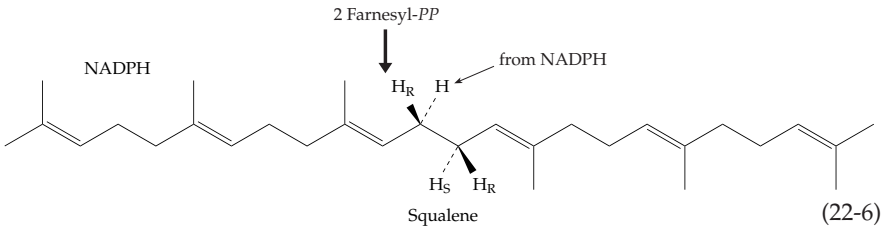
eat the plants. There is interest in the possible use of juvenile hormone, or of synthetic compounds mimicking its action, as insecticides.

Many conifers secrete **oleoresin** (pitch) in response to attack by bark beetles. The oleoresin contains approximately equal amounts of turpentine (a mixture of monoterpenes and sesquiterpenes) and diterpenoid rosin including **abietic acid** (Fig. 22-4).[91,107,107a] The oleoresin is toxic to beetles and, after evaporation of the turpentine, forms a hard rosin seal over the wounds. **Casbene** (Fig. 22-4) is a diterpene produced by castor beans as a phytoalexin (Chapter 31), an antifungal antibiotic.[108] The synthesis of the anticancer compound taxol (Box 7-D) from geranylgeranyl diphosphate involves extensive oxidative and other modification.[109]

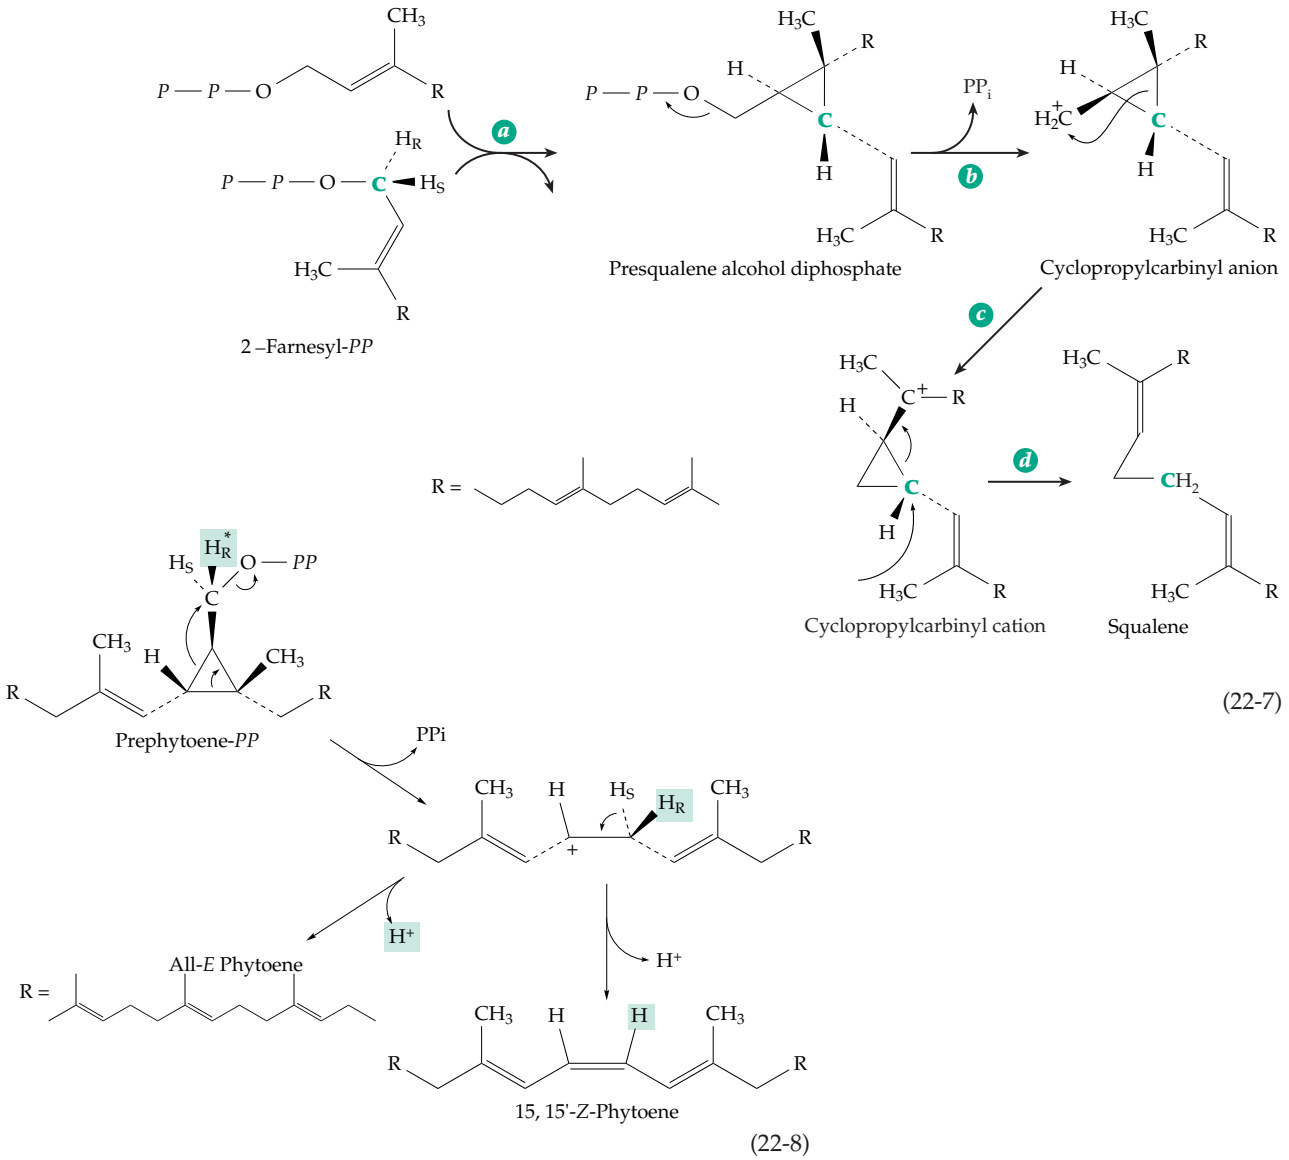
3. Formation of the Symmetric Terpenes, Squalene and Phytoene

Two molecules of the C_{15} farnesyl diphosphate can be joined "head to head" to form the C_{30} squalene (Eq. 22-6). Similarly, two C_{20} **geranylgeranyl-*PP*** molecules can be joined to form the C_{40} phytoene (Fig. 22-5), a precursor of carotenoid pigments of plants.[110] In the synthesis of squalene both pyrophosphate groups are eliminated from the precursor molecules, and one proton from C-1 of one of the molecules of farnesyl-*PP* is lost. The other three C-1 hydrogens are retained. At the same time, one proton is introduced from the *pro-S* position of NADPH. Squalene synthase has been difficult to obtain,[111,112] and its mechanism has been uncertain. However, there is strong evidence in favor of carbocationic intermediates.[113–114b] The first step (Eq. 22-7, step *a*) involves reaction of the initial carbocation with the double bond of the second farnesyl-*PP* to form the cyclopropane derivative **presqualene alcohol-*PP***, which was first isolated from yeast as the free alcohol by Rilling and associates.[115] The loss of the second pyrophosphate (Eq. 22-7, step *b*) generates a cyclopropylcarbinyl cation, which can rearrange (step *c*) to a more stable tertiary cation.[112,113] The latter is reduced by NADPH with opening of the cyclopropane ring (Eq. 22-7, step *d*). Once formed squalene diffuses within and between membranes with the help of cytosolic protein carriers.[116]

Phytoene (Fig. 22-5) is apparently formed from geranylgeranyl-*PP* via **prephytoene-*PP*,** whose structure is entirely analogous to that of presqualene-*PP*.[44,117] However, no reduction by NADH is required (Eq. 22-8). It is known that the 5-*pro-R* hydrogen atoms of mevalonate are retained in the phytoene as indicated by a shaded box in Eq. 22-8. Elimination of the other (*pro-S*) hydrogen yields 15,15'–*Z* phytoene (*cis*-phytoene), while elimination of the *pro-R* hydrogen yields all-*E* (trans) phytoene. Higher plants and fungi form mostly *cis*-phytoene, but some bacteria produce the all-*E* isomer.[118]



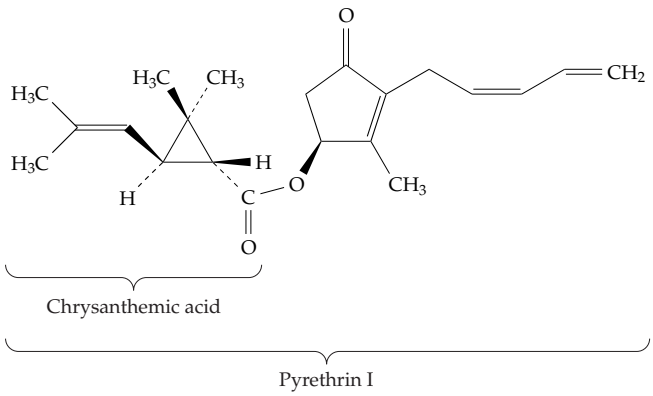
(22-6)



(22-7)

(22-8)

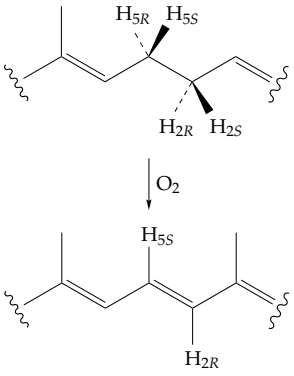
Another polyprenyl compound formed by a head to head condensation is **chrysanthemic acid**. This monoterpene component of the pyrethrum insecticides is formed by chrysanthemums from two molecules of dimethyallyl-*PP* via an intermediate analogous to presqualene alcohol-*PP*.[118a]



A quite different "tail to tail" condensation, whose chemistry is still obscure,[118b] must occur in archaebacteria whose lipids contain the C_{40} diphytanyl alcohol. An example is the diglyceryltetraether,[119,120] whose structure is shown on p. 388.

C. Carotenes and Their Derivatives

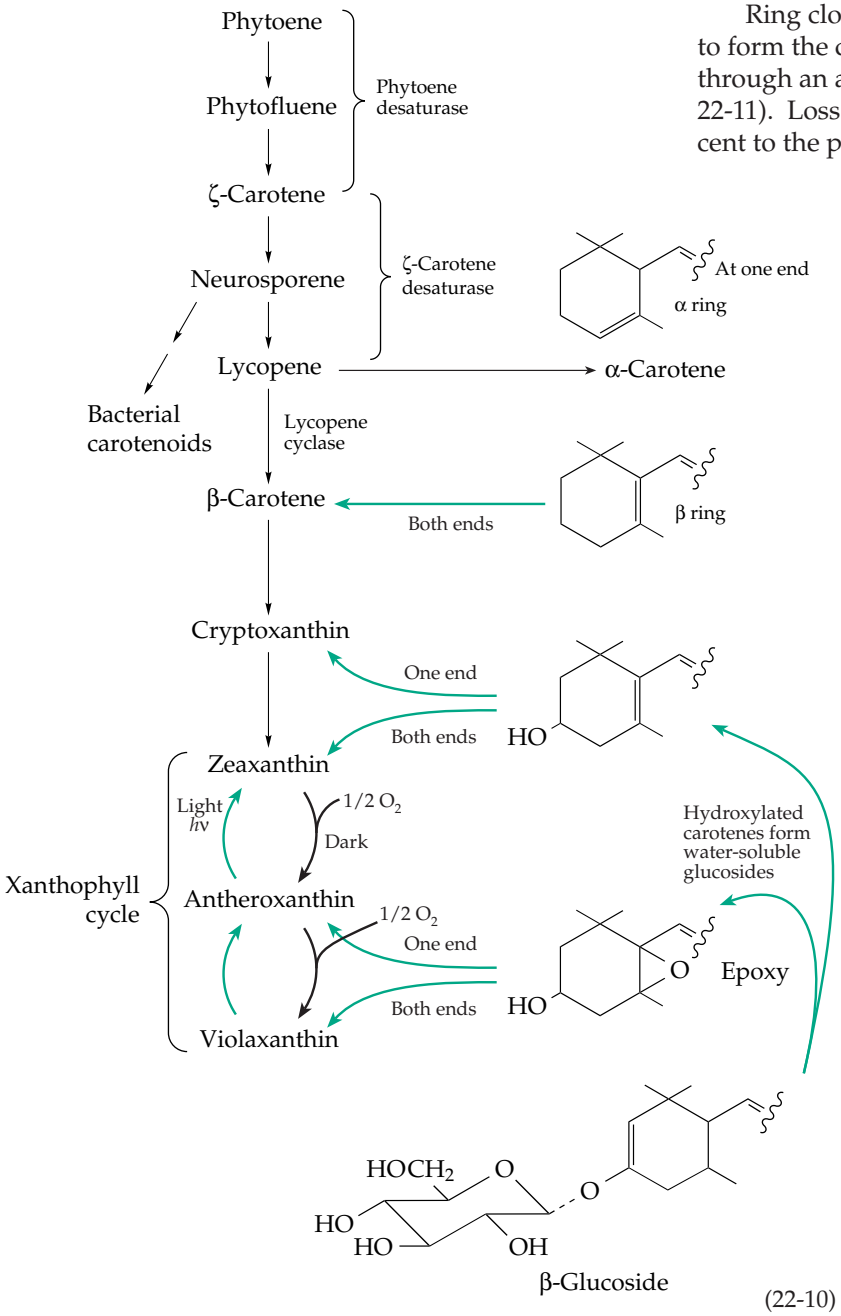
Phytoene can be converted to the carotenes by pathways indicated in part in Fig. 22-5 and Eq. 22-10. One of the first products is **lycopene**, the red pigment of tomatoes and watermelons, which is an all-trans compound. If 15-*Z* phytoene is formed, it must, at some point, be isomerized to an all-*E* isomer, and four additional double bonds must be introduced. The isomerization *may* be nonenzymatic. The double bonds are created by an oxygen-dependent **desaturation,** which occurs through the trans loss of hydrogen atoms.



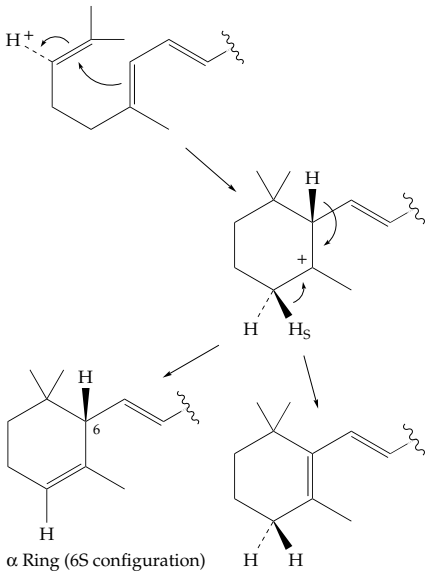
(22-9)

Desaturation takes place in a stepwise fashion, and many intermediate compounds with fewer double bonds are known (Eq. 22-10).[118,121–123] The enzymes required have not been characterized well until recently. Plant enzymes are present in small amounts, and isolation has been difficult. However, the genes for carotenoid biosynthesis in such bacteria as the purple photosynthetic *Rhodobacter*,[118,124] *Rhodospirillum*,[125] and *Rubrivarax*,[126] the cyanobacterium *Synechococcus*,[127] and the nonphotosynthetic *Erwinia*[44,118] have been cloned, sequenced, and used to produce enzymes in quantities that can be studied. Matching genes from higher plants have also been cloned and expressed in bacteria.[123]

Ring closure at the ends of the lycopene molecule to form the carotenes can be formulated most readily through an acid-catalyzed carbocation mechanism (Eq. 22-11). Loss of one or the other of two protons adjacent to the positive charge leads to the β ring of β-carotene or to the α ring of α-carotene.[110,123a] Compounds with only one ring may also be formed.[123b] In many bacteria



(22-10)



(22-11)

these rings are not formed at all, but the open-chain (acyclic) cartenoids may be modified in ways similar to those of higher plants.[118,124,125]

A genetic engineering success is the transfer of genes for synthesis of β-carotene into rice. The resulting "golden rice" contains enough carotene in its endosperm to make a significant contribution to the vitamin A needs of people for whom

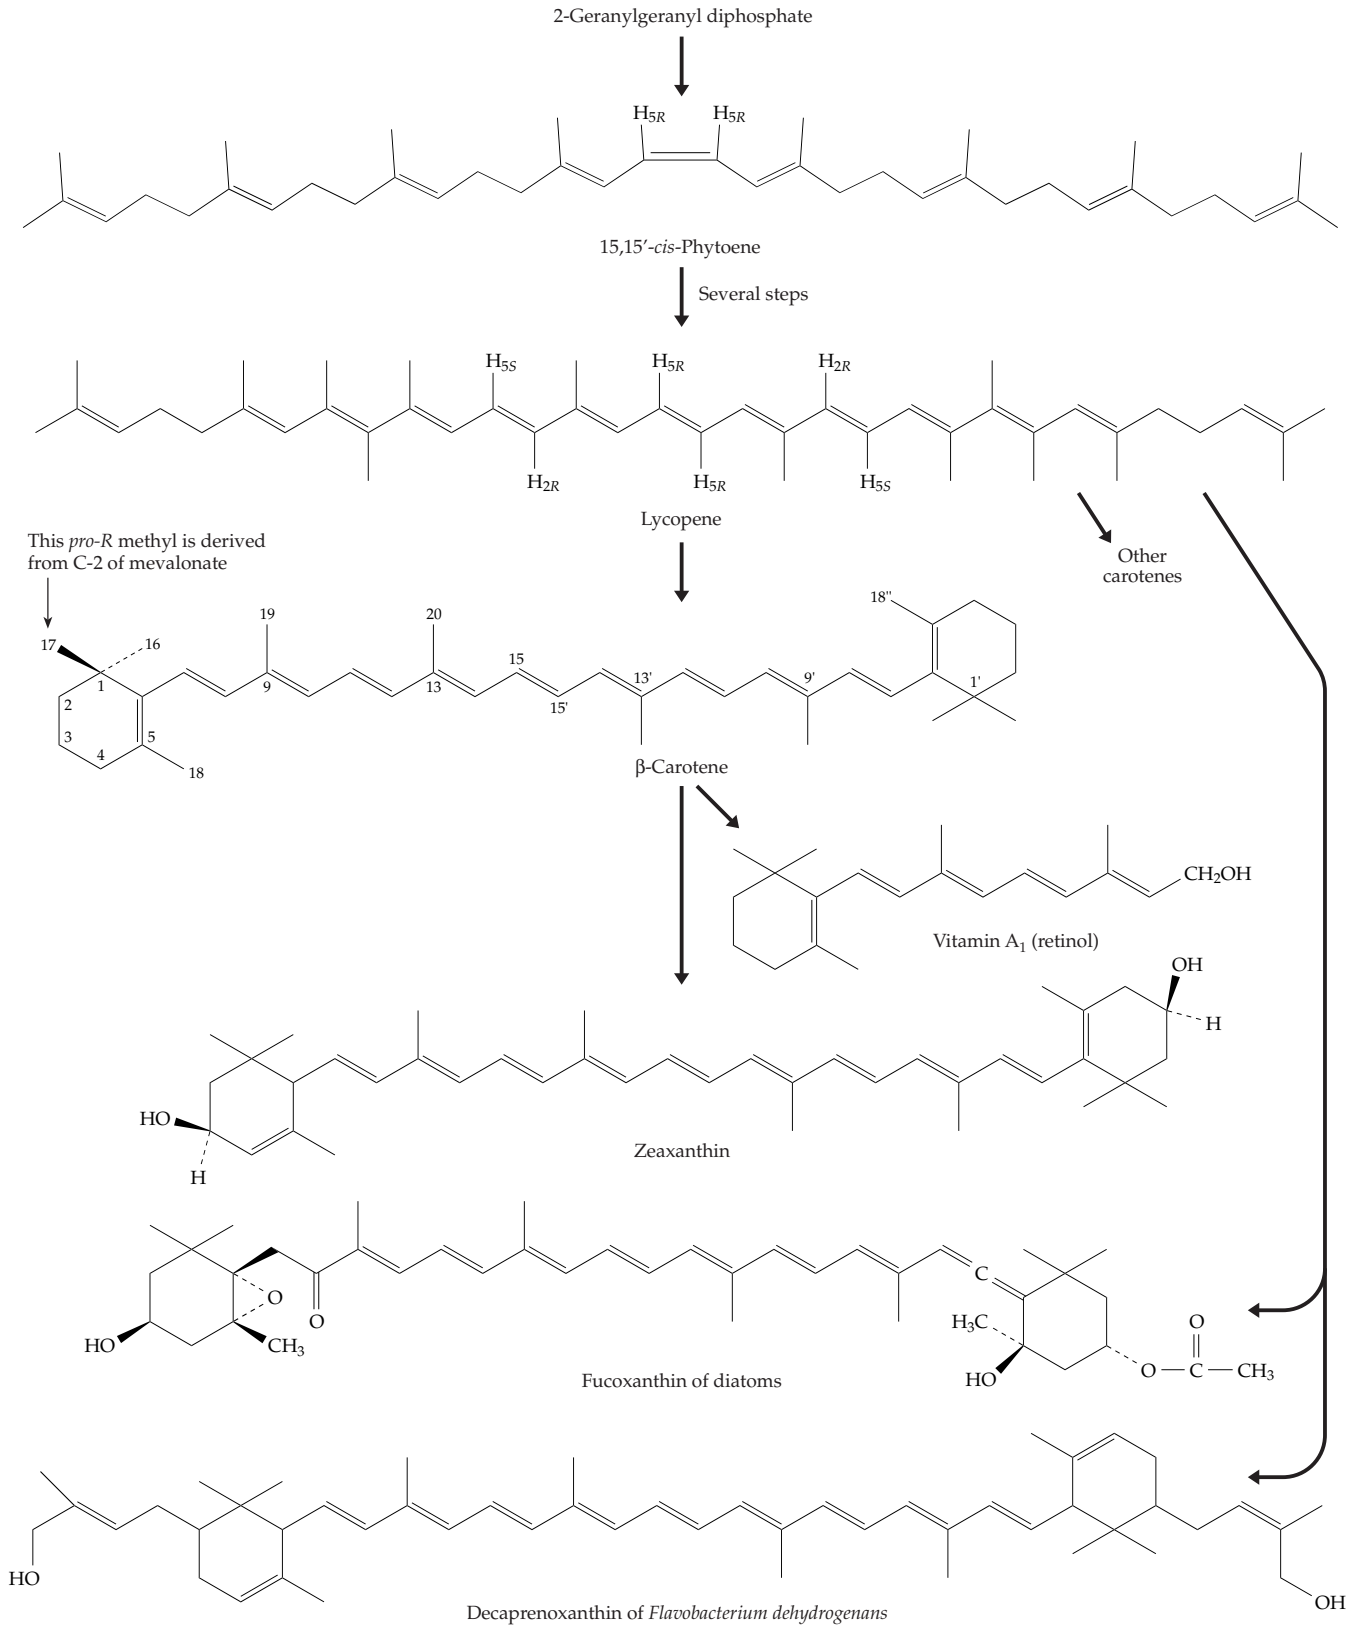


Figure 22-5 Structures and partial biosynthetic pathways for a few of the more than 600 known carotenoid compounds. The origin of some hydrogen atoms from mevalonate is shown, using the numbering for mevalonate. The numbering system for C_{40} carotenoids is also indicated.

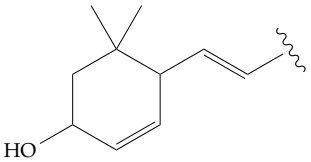
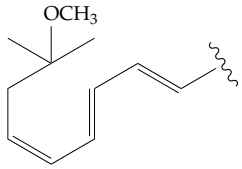
rice is a major food. There are estimated to be over 100 million vitamin A-deficient children in the world. As many as one-quarter of a million of these go blind each year.[127a] It is hoped that the golden rice will help to alleviate the problem. At the same time, an ongoing program is supplying vitamin A, which is stored in the liver, at regular intervals of time to many children.[127b]

1. Xanthophylls and Other Oxidized Carotenes

Carotenes can be hydroxylated and otherwise modified in a number of ways.[110,128–131] The structure of zeaxanthin, one of the resulting **xanthophylls**, is indicated in Fig. 22-5. Some other xanthophylls are shown in Eq. 22-10. Lutein resembles zeaxanthin, but the ring at one end of the chain has been isomerized by a shift in double bond position to the accompanying structure. The photosynthetic bacterium *Rhodospirillum rubrum* has its own special carotenoid spirilloxanthin, which has the accompanying structure at both ends of the chain.



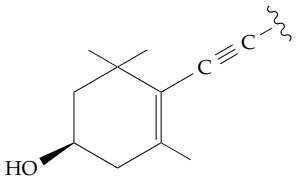
Lutein (structure at one end of molecule)



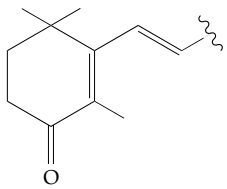
Spirilloxanthin

Fucoxanthin (Fig. 22-5) is the characteristic brown pigment of diatoms. One end of the molecule has an epoxide, also formed by the action of O_2, while the other end contains an **allene** structure rare in nature. Even so, fucoxanthin may be the most abundant carotenoid of all. The structure of the allene-containing end of the fucoxanthin molecule (turned over from that shown in Fig. 22-5) is also given in Eq. 22-12. Figure 22-5 does not indicate the stereochemistry of the allene group correctly; the carotenoid chain protrudes behind the ring as drawn in the equation. **Violaxanthin** contains epoxide groups in the rings at both ends of the molecule (Eq. 22-12). An isomerase in algae converts violaxanthin into **neoxanthin** (Eq. 22-12), which contains the allene structure at one end. Subsequent acetylation yields fucoxanthin.

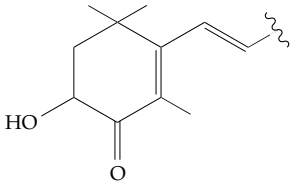
Other algal carotenoids contain acetylenic triple bonds. For example, **alloxanthin** has the following structure at both ends of the symmetric molecule. The symmetric carotenoids **canthaxanthin** and **astaxanthin** have oxo groups at both ends:



Alloxanthin



Canthaxanthin



Astaxanthin

These carotenoids have a limited distribution and occur as complexes, perhaps in Schiff base linkage, with proteins. Astaxanthin–protein complexes with absorption maxima ranging from 410 nm to 625 nm or more provide the color to the lobster's exoskeleton.[130,132] Whereas most naturally occurring carotenoids have all-*E* double bonds, mono-*Z* isomers of canthaxanthin are found in the colored carotenoproteins of the brine shrimp *Artemesia*.[133]

Some bacteria synthesize C_{50} carotenoids such as decaprenoxanthin (Fig. 22-5), the extra carbon atoms at each end being donated from additional prenyl groups, apparently at the stage of cyclization of lycopene.[134] Thus, a carbocation derived by elimination of pyrophosphate from dimethylallyl-*PP* could replace the H^+ shown in the first step of Eq. 22-11. The foregoing descriptions deal with only a few of the many known structural modifications of carotenoids.[2,135,136]

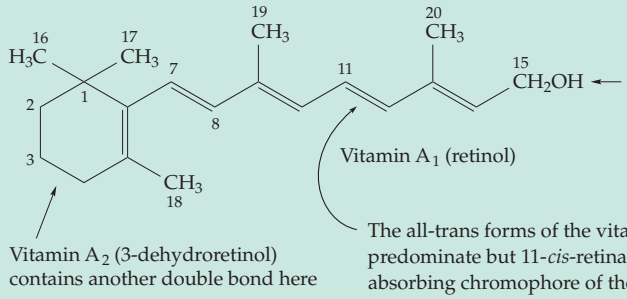
BOX 22-A VITAMIN A



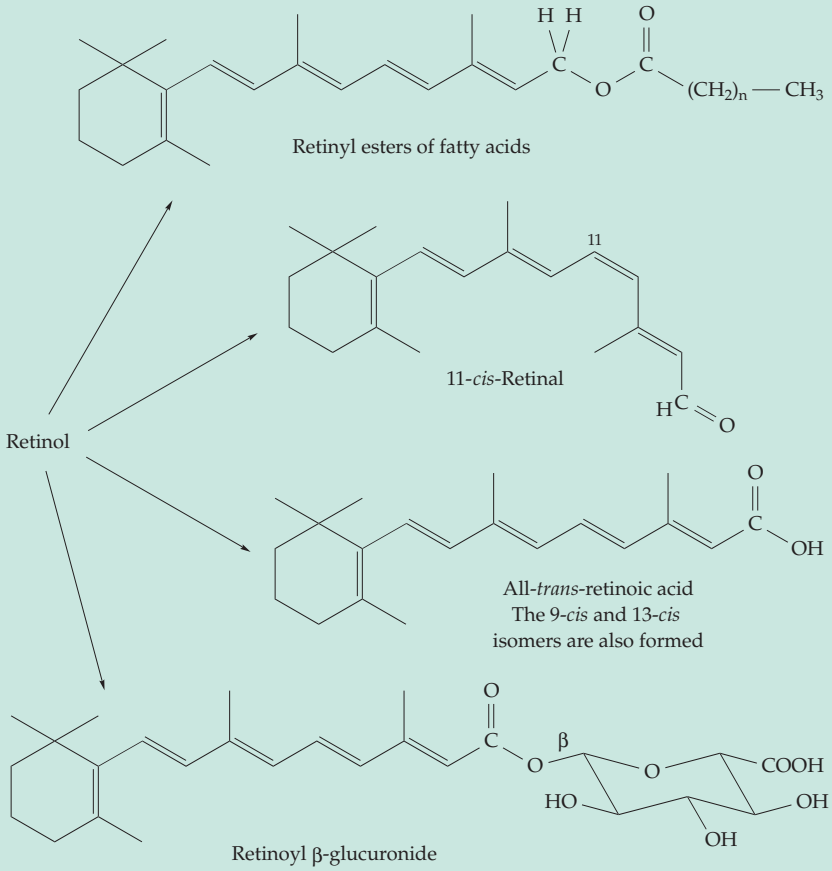
The recognition in 1913 of vitamin A (Box 14-A) was soon followed by its isolation from fish liver oils.[a–c] Both vitamin A_1 (**retinol**) and vitamin A_2 are 20-carbon polyprenyl alcohols. They are formed by cleavage of the 40-carbon β-carotene (Fig. 22-5) or other carotenoids containing a β-ionone ring. While the carotenes are plant products, vitamin A is produced only in animals, primarily within cells of the intestinal mucosa.[d–f] The carotene chains are cleaved in the center, and to some extent in other positions,[g] by oxygenases; β-carotene yields as many as two molecules of the vitamin A aldehyde **retinal**.[h–i] The retinal is reduced by NADH to retinol which is immediately esterified, usually with saturated fatty acids, by transfer of an acyl group from a fatty acyl-CoA or from phosphatidylcholine. The resulting retinyl esters are transported in chylomicrons. They remain in the chylomicron remnants (see Fig. 21-1), which are taken up by the liver where both hydrolysis and reesterification occur.[j] Vitamin A is one of the few vitamins that can be stored in animals in relatively large quantities. It accumulates in the liver, mainly as retinyl palmitate, in special storage cells termed stellate cells.[f] The human body usually contains enough vitamin A to last for several months.

Free retinol is released from the liver as a 1:1 complex of retinol with the 21-kDa **retinol-binding protein**.[k,l] This protein is normally almost saturated with retinol and is bound to another serum protein, the 127-residue **transthyretin** (prealbumin).[m,n] Some of the retinol is oxidized to **retinoic acid**. Both all-*trans* and 13-*cis*-retinoic acids as well as 5,6-epoxyretinoic acid are found in tissue.[f,o,p,pq]

Another metabolite, which may be very important, is **retinoyl β-glucuronide**.[q,r,rs]

Cell surfaces of body tissues appear to contain receptors for the retinol-binding protein. Many cells also contain cytoplasmic retinol-binding proteins[s–u] as well as proteins that bind retinoic acid.[u–y] These proteins are members of the large superfamily of hydrophobic transporter molecules described in Box 21-A. This includes the milk protein **β-lactoglobulin,** which also forms a complex with retinol.[z,aa]

A strikingly early symptom of vitamin A deficiency is **night blindness**. A variety of other symptoms include dry skin and hair, conjunctivitis of the eyes, retardation of growth, and low resistance to infection. The skin symptoms are particularly noticeable in the internal respiratory passages and alimentary canal lining. About 0.7 mg/day of vitamin A is required by an adult. The content of vitamin A in foods is often expressed in terms of international units: 1.0 mg of retinol equals 3333 I.U.



BOX 22-A VITAMIN A (continued)

Vitamin A, as retinal, has a clearly established role in vision (Chapter 23) and apparently has a specialized function in reproduction. In vitamin A deficiency no sperm cells are formed in males, and fetal resorption occurs in females. Rats deprived of vitamin A but fed retinoic acid become blind and sterile but otherwise appear healthy.[e,bb] Evidently either the alcohol or the aldehyde has an essential function in reproduction, whereas bone growth and maintenance of mucous secretions requires only retinoic acid. Indeed, retinoic acid is 100 to 1000 times more active than other forms of vitamin A in these differentiation functions.[r]

In vitamin A deficiency the internal epithelial surfaces of lungs and other tissues, which are usually rich in mucous secreting cells and in ciliated cells, develop thick layers of keratinizing squamous cells similar to those on the external surface of the body. The synthesis of some mannose- and glucosamine-containing glycoproteins consequently decreases.[cc] The major effects of retinoic acid is evidently through regulation of transcription (Chapter 28). In developing lungs retinoic acid promotes the transformation of undifferentiated epithelial cells into mucus-secreting cells.[dd]

Do we know all of the special chemistry of vitamin A that is involved in its functions? Retinal could form Schiff bases with protein groups as it does in the visual pigments. Redox reactions could occur. Conjugative elimination of water from retinol to form **anhydroretinol** is catalyzed nonenzymatically by HCl. Anhydroretinol occurs in nature and

Anhydroretinol

may serve as an inhibitor of the action of 14-hydroxy-*retro*-retinol in lymphocyte differentiation.[ee,ff]

Much recent interest has been aroused by the fact that retinoid compounds, including both retinol and retinoic acid, reduce the incidence of experimentally induced cancer. In addition, 13-*cis*-retinoic acid taken orally is remarkably effective in treatment of severe cystic acne.[gg] However, both vitamin A and retinoic acid in large doses are **teratogenic**, i.e., they cause fetal abnormalities. The use of 13-*cis*-retinoic acid during early phases of pregnancy led to a high incidence of major malformations in infants born.[hh]

2. Properties and Functions of Carotenes

The most characteristic property of carotenoids is the striking color, most often yellow to red, which is used by birds as a sexual attractant and by plants to attract pollinators.[137,138] The associated light absorption fits these compounds for a role in photosynthetic light-harvesting,[139] in photoprotection, and in photoreception,[140] matters that are dealt with in Chapter 23. One aspect of photoprotection, which involves the **xanthophyll cycle,** is also indicated in Eq. 22-10. The cycle allows green plants to adjust to varying light intensity by altering the amount of zeaxanthin available for quenching excessive amounts of photoexcited chlorophyll (Chapter 23). Zeaxanthin undergoes epoxidation by O_2 to form antheroxanthin and violaxanthin as shown in Eq. 22-10. The process requires NADPH and reduced ferredoxin.[131] When light intensity is high the process is reversed by an ascorbate-dependent violaxanthin **de-epoxidase**.[99,128,141]

Violaxanthin also functions as a precursor to the plant hormone abscisic acid. Compare the structure of the latter (Fig. 22-4) with those of carotenoids. Oxidative cleavage of violaxanthin or related epoxy-carotenoids initiates the pathway of synthesis of this hormone.[142,143]

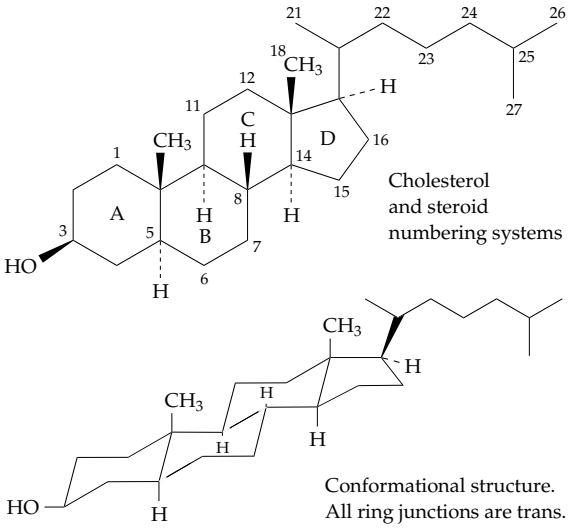
The system of conjugated double bonds responsible for carotenoid colors also helps to impart specific shapes to these largely hydrophobic molecules and ensures that they occupy the appropriate niches in the macromolecular complexes with which they associate. Information on stereochemistry is provided in a short review by Britton.[138]

β-Carotene, which can serve as an antioxidant at low oxygen pressures and can quench singlet oxygen,[144,145] has been associated with a reduced incidence of lung cancer.[137,146] While most animals do not synthesize carotenoids, they use them to make vitamin A and related retinoids and also as colorants. Yellow and red pigments of bird feathers[147] and the colors of tissues of salmon and of lobsters and other invertebrates are derived from dietary carotenoids, which are often modified further by the new host. The lobster accumulates astaxanthin, as a blue protein complex,[148] and the flamingo uses the astaxanthin of shrimp to color its feathers.[130]

Dietary carotenes and carotenoids are absorbed and transported in the plasma of humans and animals by lipoproteins.[149] The conversion of carotenes to vitamin A (Box 22-A) provides the aldehyde **retinal** for synthesis of visual pigments (Chapter 23) and **retinoic acid**, an important regulator of gene transcription and development (Chapter 32).[150–152c] See also Section E,5.

D. Steroid Compounds

The large class of **steroids** contains a characteristic four-ring nucleus consisting of three fused six-membered rings and one five-membered ring.[153] **Cholestanol** (dihydrocholesterol) may be taken as a representative steroid alcohol or **sterol**. Most sterols, including cholestanol, contain an 8- to 10-carbon side chain at position 17. The polyprenyl origin of the side chain is suggested by the structure. Steroid compounds usually contain an oxygen atom at C-3. This atom is present in an –OH group in the sterols and

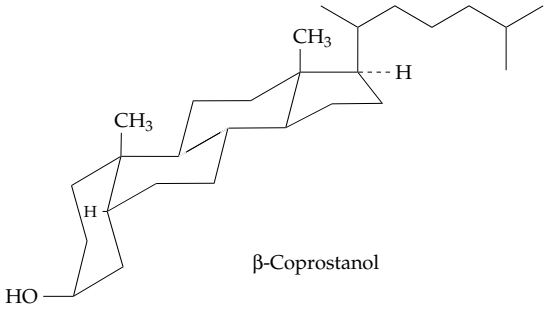


frequently in a carbonyl group in other steroids. Most steroids contain two axially oriented methyl groups, the "angular methyl groups,"which are attached to the ring system and numbered C-18 and C-19. In the customary projection formulas they are to be thought of as extending forward toward the viewer. In the same manner, the equatorially oriented 3-OH group of cholestanol and the side chain at C-17 also project forward toward the viewer in the projection formula.

The angular methyl groups, the 3-OH groups, and the side chain of cholestanol are all on the same side of the steroid ring in the projection formula and are all said to have a **β orientation**. Substituents projecting from the opposite side of the ring system are **α oriented**. While the methyl groups (C-18 and C-19) almost always have the β orientation, the 3-OH group has the α orientation in some sterols. Dashed lines are customarily used to connect α-oriented substituents, and solid lines are used for β-oriented substituents in structural formulas. Cholesterol is chiral and its enantiomer does not support life for *C. elegans* and presumably for other organisms.[153a]

In cholestanol the ring fusions between rings A and B, B and C, and C and D are all trans; that is, the hydrogen atoms or methyl groups attached to the

bridgehead carbon atoms project on opposite sides of the ring system. This permits all three of the six-membered rings to assume relatively unstrained chair conformations. However, the introduction of a double bond alters the shape of the molecule significantly. Thus, in cholesterol the double bond between C-5 and C-6 (Δ^5) distorts both the A and B rings from the chair conformation. In some steroid compounds the junction between rings A and B is cis. This greatly alters the overall shape of the steroid from the relatively flat one of cholestanol to one that is distinctly bent. An example is **β-coprostanol**, a product of bacterial action on cholesterol and a compound occurring in large amounts in the feces. In some sterols, notably the estrogenic hormones, ring A is completely aromatic and the methyl group at C-19 is absent.



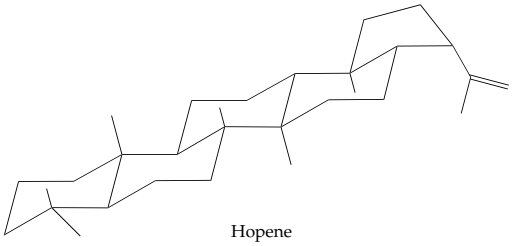
β-Coprostanol

1. Biosynthesis of Sterols

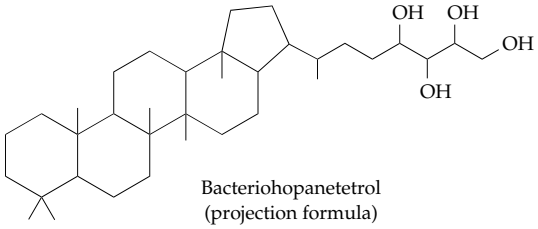
Most animal steroids arise from cholesterol, which in turn is derived from squalene. This C_{30} triterpene, whose biosynthesis is described in Section B, is named after the dogfish *Squalus* in whose liver it accumulates as a result of blockage in oxidation to cholesterol. Squalene is also a prominent constituent of human skin lipids. Its conversion to **cholesterol**, which takes place in most animal tissues,[117,154–156] is initiated by a microsomal enzyme system that utilized O_2 and NADPH to form **squalene 2,3-oxide** (Fig. 22-6, step *a*). The subsequent cyclization reaction, which probably takes place through a carbocation created by attack of a proton on the oxygen atom of the epoxide ring (Fig. 22-6, step *b*), is catalyzed by the large 70- to 80-kDa **oxidosqualene cyclase**.[157–159] The enzyme from rat liver consists of 733 residues and contains a highly conserved sequence with two consecutive aspartates that are thought to be at the active site. The sequence is somewhat similar to that of prenyltransferases and sesquiterpene cyclases.[157] The cyclization step appears to require that the enzyme hold the substrate in a rigid conformation as indicated in Fig. 22-6. The flow of electrons effects the closure of all four rings. The carbocation created at C-2 of squalene (C-4 of the sterol ring that is formed) by opening of the epoxide ring reacts with electrons from the 6,7 double bond to close ring A leaving a carbocation at C-6. This in turn reacts with the 10,11 double bond leaving a carbocation at C-10, etc. At the end of this cascade a carbocation is left on C-19 of squalene, which is numbered C-20 in the incipient sterol. The closures of rings A and B both follow the Markovnikov rule by generating relatively stable tertiary carbocations. Thus, the natural chemical reactivities of the substrates are followed in these enzymatic reaction steps. However, this is not the case in the closure of ring C to form a 6-membered ring instead of a 5-membered ring. This presumably happens because the enzyme imposes the correct geometry for a 6-membered ring on the squalene and the correct stereochemistry on the ring closure.[160]

The rearrangement of this initially created C-20 carbocation to **lanosterol** (Fig. 22-6, step *c*) is also a remarkable reaction that requires the shift of a hydride ion and of two methyl groups, as indicated by the arrows in the figure. In addition, a hydrogen at C-9 (sterol numbering) is lost as a proton. Lanosterol is named for its occurrence in lanolin, the waxy fat in wool. Although the principal component of lanolin is cholesterol, lanosterol is its precursor both in sheep and in all other animals. Cholesterol is in turn the precursor to other animal sterols. The cholesterol biosynthetic pathway also provides cells with a variety of important signaling molecules.[160a]

In green plants, which contain little or no cholesterol, **cycloartenol** is the key intermediate in sterol biosynthesis.[161–162a] As indicated in Fig. 22-6, step *c*′, cycloartenol can be formed if the proton at C-9 is shifted (as a hydride ion) to displace the methyl group from C-8. A proton is lost from the adjacent methyl group to close the cyclopropane ring. There are still other ways in which squalene is cyclized,[162,163,163a] including some that incorporate nitrogen atoms and form alkaloids.[163b] One pathway leads to the **hopanoids**. These triterpene derivatives function in bacterial membranes, probably much as cholesterol does in our membranes. The three-dimensional structure of a bacterial hopene synthase is known.[164,164a] Like glucoamylase (Fig. 2-29) and farnesyl transferase, the enzyme has an $(\alpha,\alpha)_6$-barrel structure in one domain and a somewhat similar barrel in a second domain. The active site lies in a large interior cavity. The properties of the hopene synthase are similar to those of oxidosqualene synthase, and it appears to function by a similar mechanism, which resembles that of Fig. 22-6 but does not depend upon O_2. Hopene lacks polar groups, but these are provided in the hopanoids by a polyol side chain. One of these compounds, **bacteriohopanetetrol**, may be one of the most abundant compounds on earth.[160,165,166] Hopanoids appear to originate from mevalonate synthesized via the 1-deoxyxylulose pathway (Fig. 22-2). The polyol side chain is probably formed from ribose.[166]



Hopene



Bacteriohopanetetrol
(projection formula)

Formation of cholesterol. The conversion of lanosterol to cholesterol requires at least 19 steps,[167,168] which are catalyzed by enzymes bound to membranes of the ER. The removal of the three methyl groups of lanosterol, the migration of the double bond within the B ring, and the saturation of the double bond in the side chain may occur in more than one sequence, two of which are indicated in Fig. 22-7. The predominant pathway in many organisms including humans is the oxidative demethylation at the C / D ring junction (C-14) by a cytochrome P450 called **lanosterol 14α-demethylase**. This single enzyme catalyzes three consecutive O_2 and NADPH-dependent reactions that convert the methyl group to hydroxymethyl, formyl, and then free formate (right side of Fig. 22-8).[169–172b] Steps *a* and *b* are typical cytochrome P450 oxygenation reactions. In step *b* a geminal diol is formed and is dehydrated to the formyl derivative. The third step is atypical. Shyadehi *et al.* proposed the sequence depicted in steps *c-f* in which an Fe(III) peroxo intermediate reacts as shown.[172] This mechanism is supported by the fact that both ^{18}O present in the formyl group and ^{18}O from $^{18}O_2$ appear in the liberated formate.

The corresponding reactions of the methyl groups at C-4 on the A ring[167,168,173] are depicted on the left side of Fig. 22-8. The 4α methyl group is first hydroxylated by a microsomal (ER) system similar to cytochrome P450 but able to accept electrons from NADH and cytochrome b_5 rather than NADPH.[173] The two-step oxidation of the resulting alcohol to a carboxylic acid is catalyzed by the same enzyme. A second enzyme catalyzes the dehydrogenation of the 3-OH group to a ketone allowing for efficient β-decarboxylation (Fig. 22-8, steps *j* and *k*).[173a] Inversion of configuration at C-4, assisted by the 3-carbonyl group (step *l*), places the second 4-methyl group in the α orientation. After reduction of the 3-carbonyl by a third enzyme the sequence is repeated on this second methyl group.

In addition to the enzymes that are embedded in the membranes of the ER, conversion of lanosterol to cholesterol depends upon soluble cytoplasmic carrier proteins.[174] See also Box 21-A. Other sterols formed in

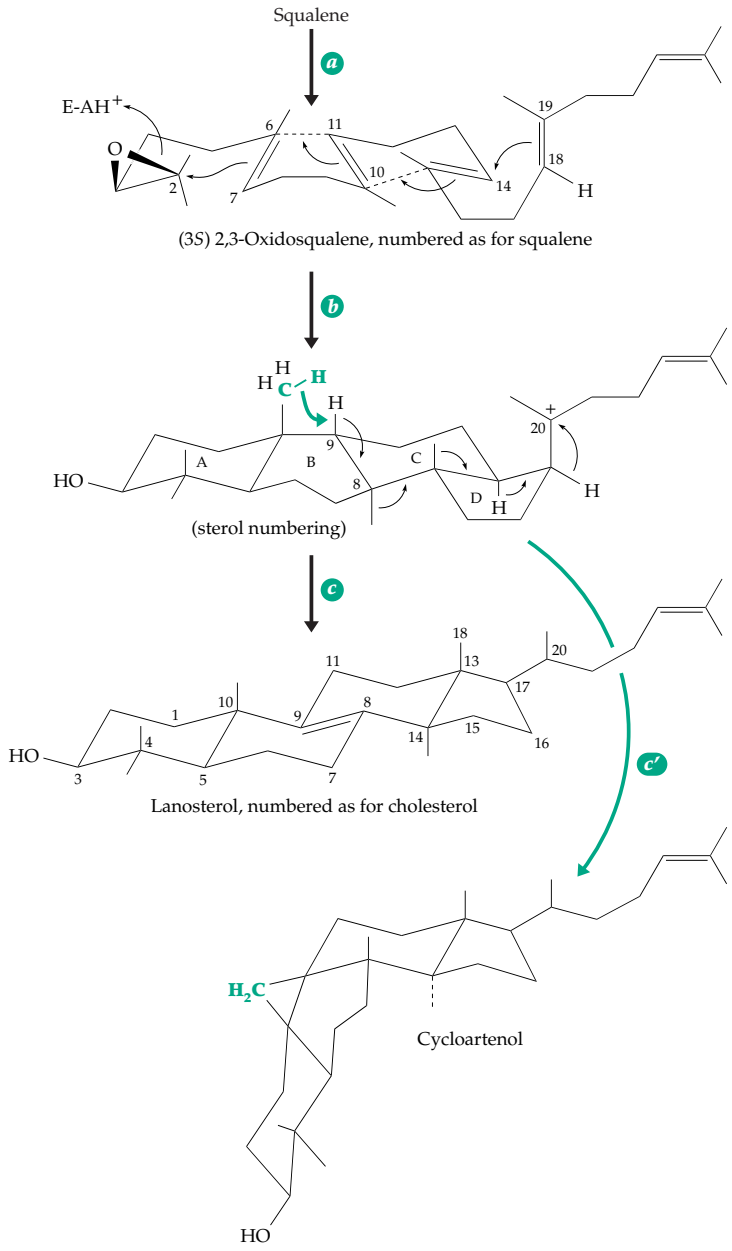


Figure 22-6 The cyclization of all-*trans* squalene to lanosterol and cycloartenol.

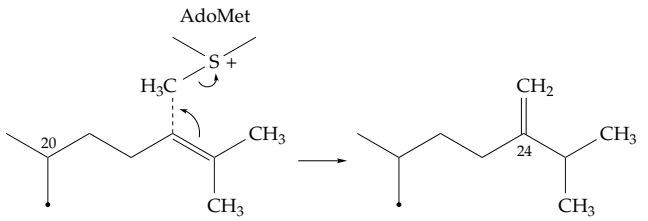
the animal body are **7-dehydrocholesterol**, prominent in skin and a precursor of vitamin D. Both β-cholestanol and its isomer β-coprostanol are formed by bacteria in the intestinal tract, and small amounts of cholesterol are converted to cholestanol within tissues. **Ergosterol**, the most common sterol in fungi, contains the $\Delta^{5,7}$ ring system of 7-dehydrocholesterol as well as an extra double bond in the side chain. It arises from zymosterol (Fig. 22-7).[173,174a]

As indicated previously, plant sterols are thought to be formed in most cases through cycloartenol which is often converted to **24-methylenecycloartenol**, a substance present in grapefruit peel and in many other plants. The methylene carbon is donated by *S*-adenosylmethionine (AdoMet) as shown in Eq. 22-13, which implies a transient intermediate carbocation. Saturation of the side chain and oxidative demethylation similar to that shown in Fig. 22-8[175] and introduction of a double bond[176] leads to **campesterol** (Fig. 22-9). It has the Δ^5-unsaturated ring of cholesterol but, like many other plant sterols, the side chain has one additional methyl group, which is also donated from *S*-adenosylmethionine.[161,177,178] Several more steps are



Side chain of cycloartenol — 24-Methylenecycloartenol

(22-13)

required to convert campesterol into the plant steroid hormone **brassinolide**.[179–180] Among higher plants, **sitosterol** and **stigmasterol** are the most common sterols. Each contains an extra ethyl group in the side chain. Sitosterol is formed by the methylation (by AdoMet) of ergosterol. For the guinea pig stigmasterol is a vitamin, the"antistiffness factor" necessary to prevent stiffening of the joints. Some other plant steroids arise without addition of the extra carbons at C-23 or C-24 but usually via a different cyclization of squalene. Of these, the cucurbitacins (Fig. 22-9) are among the bitterest substances known.[181]

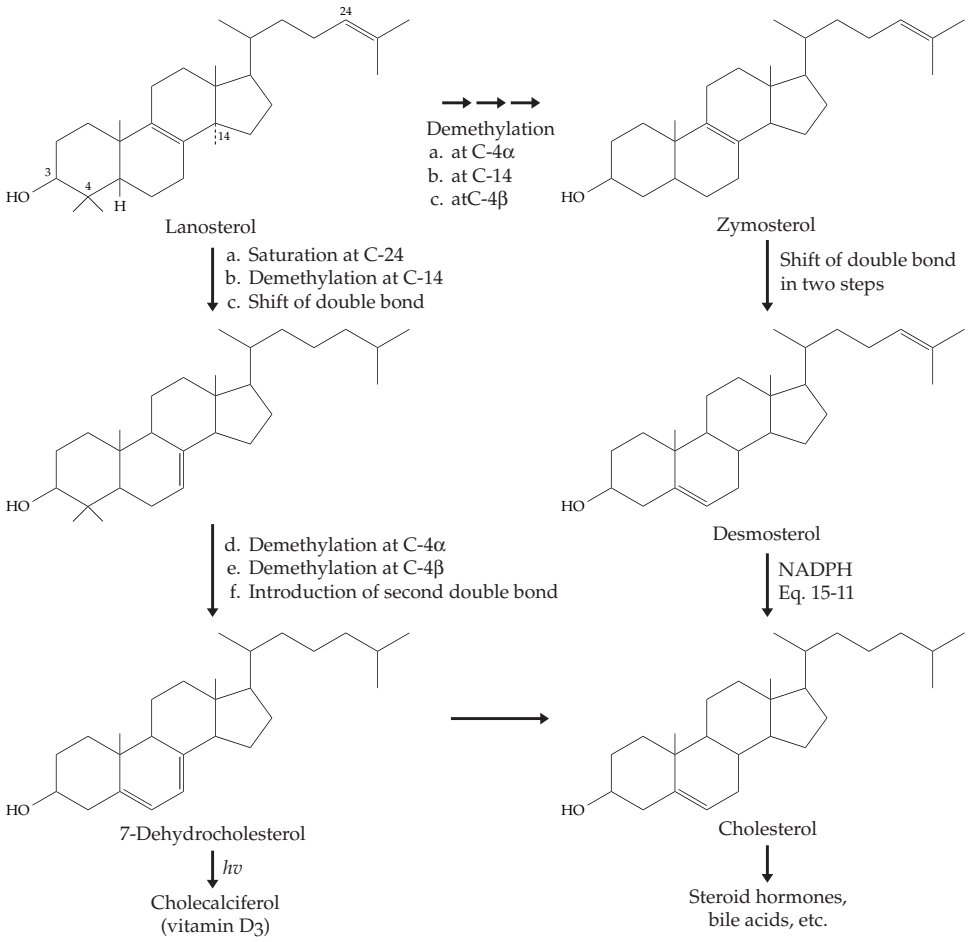


Figure 22-7 Conversion of lanosterol to cholesterol. Two of many possible sequences are shown.

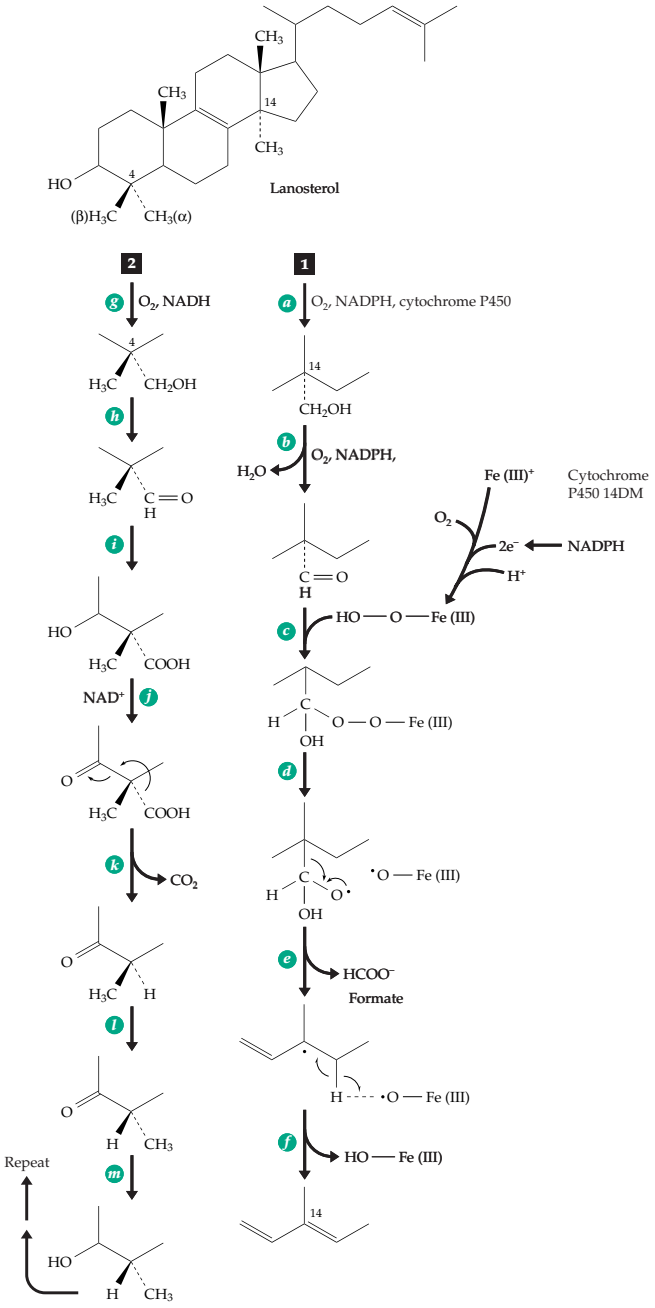

Figure 22-8 Steps in the demethylation of lanosterol. The most frequent sequence, labeled [1], begins with demethylation at C-14 by the action of a cytochrome P450 and is followed [2] by the successive demethylation of the α-CH_3 and β-CH_3 at C-4 by an NADH-dependent oxygenase.

2. Metabolism of Cholesterol in the Human Body

Cholesterol is both absorbed from the intestinal tract and synthesized from acetate via squalene, principally in the liver. The quantities produced are substantial. Daily biosynthesis is ~600 mg, and dietary uptake may supply another 300 mg.[182] Not only is there a large amount of cholesterol in the brain and other nervous tissues but also about 1.7 g of cholesterol per liter is present in blood plasma, about two-thirds of it being esterified principally to unsaturated fatty acids. The cholesterol content of plasma varies greatly with diet, age, and sex. By age 55 it averages 2.5 g / liter and may be considerably higher. Women up to the age of menopause have distinctly lower blood cholesterol than do men. Cholesterol regulates its own abundance by a variety of feedback mechanisms.[183,184] These include inhibition of the synthesis by means of reduced activities (step *a* of Fig. 22-1) of HMG-CoA reductase, farnesyl diphosphate synthase (step *g* of Fig. 22-1), and squalene synthase. All of these reactions are essential steps in cholesterol synthesis.[16,185] On the other hand, cholesterol induces an increase in acyl-CoA:cholesterol acyltransferase.

Dietary cholesterol, together with triacylglycerols, is absorbed from the intestinal tract and enters the large lipoprotein chylomicrons (see Fig. 21-1). Absorption of cholesterol is incomplete, usually amounting to less than 40% of that in the diet. Absorption requires bile salts and is influenced by other factors.[186] As it is needed cholesterol is taken from the plasma lipoproteins into cells by endocytosis. Much of the newly absorbed cholesterol is taken up by the liver. The liver also secretes cholesterol, in the form of esters with fatty acids, into the bloodstream.

Cholesterol is synthesized in the ER and other internal membranes by most cells of the body.[187,188] Newly formed cholesterol is sorted from the ER into the various membranes of the cell, the greatest abundance being in plasma membranes where cholesterol plays an essential role in decreasing fluidity. Cholesterol also aggregates with sphingolipids to form rigid lipid "rafts" floating in the plasma membrane. These rafts are thought to have important functions in signaling, in distribution of lipid materials,[188a] and in influencing protein translocation.[188b] Caveolae in cell surfaces may also arise from cholesterol-rich rafts.[188c] However, cholesterol must also be able to move out of the internal membranes back into the interior ER of the cell to provide for homeostasis and to allow formation of cholesteryl esters for transport, bile acids for excretion by liver, and the steroid hormones.[183,184,189] Movement between organelles occurs with the aid of sterol carrier proteins.[190–190c]

Liver and some intestinal cells export cholesterol into the bloodstream, together with triacylglycerols and phospholipids in the form of VLDL particles, for uptake by other tissues (see Fig. 21-1). Cholesteryl esters are formed in the ER by **lecithin:cholesterol acyltransferase** (LCAT), an enzyme that transfers the central acyl group from phosphatidylcholine to the hydroxyl group of cholesterol.[191,191a] This enzyme is also secreted by the liver and acts on free cholesterol in lipoproteins.[192] Tissue acyltransferases also form cholesteryl esters from fatty acyl-CoAs.[192a]

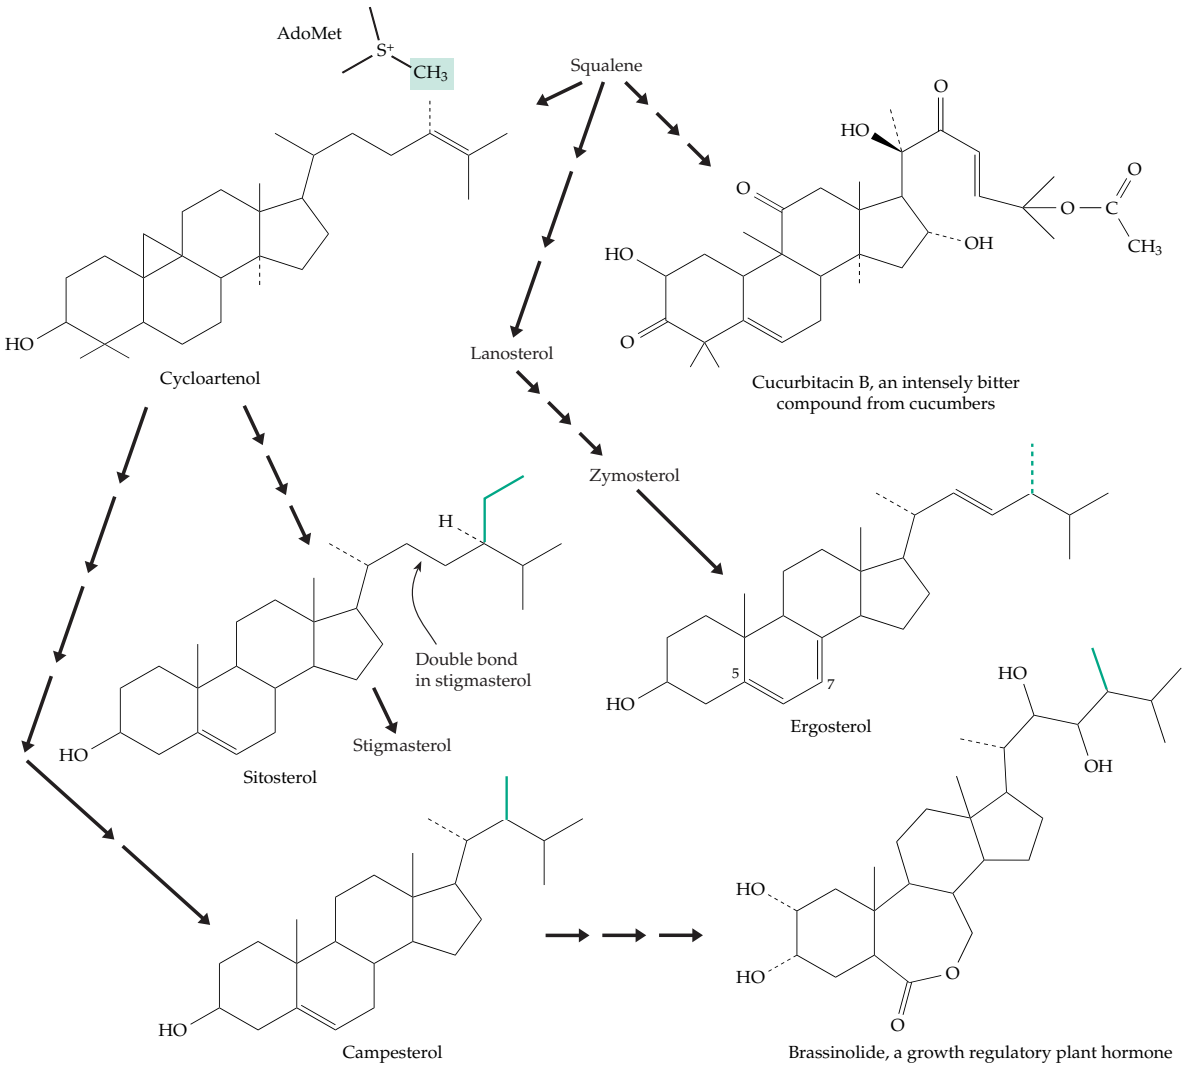

Figure 22-9 Structures and routes of biosynthesis for a few plant steroids.

In the brain a complex of cholesterol with apolipoprotein E (Table 21-2) promotes the formation of new synapses (Chapter 30). Synthesis of cholesterol for this purpose appears to occur within glial cells.[192b,c]

Serum cholesterol. Most cholesterol is carried in the blood by low density lipoprotein (LDL, Tables 21-1, 21-2), which delivers the cholesteryl esters directly to cells that need cholesterol. Both a 74-kDa **cholesteryl ester transfer protein**[193–195a] and a **phospholipid transfer protein**[196,196a] are also involved in this process. **Cholesterol esterases**, which release free cholesterol, may act both on lipoproteins and on pancreatic secretions.[197–199]

The LDL–cholesterol complex binds to LDL receptors on the cell surfaces.[167,168,200–202] These receptors are specific for apolipoprotein B-100 present in the LDL. The occupied LDL–receptor complexes are taken up by endocytosis through coated pits; the apolipoproteins are degraded in lysosomes, while the cholesteryl esters are released and cleaved by a specific **lysosomal acid lipase**[203,204] to form free cholesterol.

While the primary role of LDL appears to be the transport of esterified cholesterol to tissues, the high density lipoproteins (HDL) carry excess cholesterol away from most tissues to the liver.[205–207] The apoA-I present in the HDL particle not only binds lipid but activates LCAT, which catalyzes formation of cholesteryl esters which migrate into the interior of the HDL and are carried to the liver.

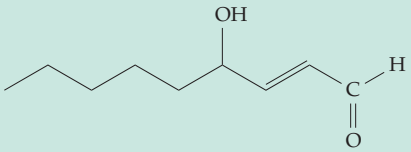
Unlike other lipoproteins, HDL particles are assembled outside of cells from lipids and proteins, some of which may be donated from chylomicrons (see Fig. 21-1) or other lipoprotein particles. HDL has a higher protein content than other lipoproteins and is more heterogeneous. The major HDL protein is apolipoprotein A-I, but many HDL particles also contain A-II,[205,208–210] and apolipoproteins A-IV, D, and E may also be present. A low plasma level of HDL cholesterol is associated with a high risk of atherosclerosis.[205,207]

BOX 22-B ATHEROSCLEROSIS

Our most common lethal disease is atherosclerosis, which causes constriction and blockage of arteries of the heart, brain, and other organs. In the United States, Europe, and Japan half of all deaths can be attributed to this ailment.[a,b] There seems to be a variety of causes. However, there is agreement that the disease begins with injury to the endothelial cells that form the inner lining of the arteries.[a,c,d] This is followed by the aggregation of blood platelets at the sites of injury and infiltration of smooth muscle cells, which may be attracted by 12-hydroxyeicosotetraenoic acid and other chemoattractants formed by activated platelets.[c] **"Foam cells"** laden with cholesterol and other lipids appear, and the lesions enlarge to become the characteristic plaques (**atheromas**).

The best understood cause of atherosclerosis is the genetic defect **familial hypercholesterolemia**, an autosomal dominant trait carried by one person in 500 all over the world.[e] Males with the defective gene tend to develop atherosclerosis when they are 35–50 years of age. The approximately one in a million persons *homozygous* for the trait develop coronary heart disease in their teens or earlier. Cultured fibroblasts from these patients have 40- to 60-fold higher levels of HMG-CoA reductase (Eq. 15-9) than are present normally, and the rate of cholesterol synthesis is increased greatly. The LDL level is very high and, as shown by Brown and Goldstein,[f–i] the LDL receptor gene is defective. Genetic defects associated with a low HDL level are also associated with atherosclerosis[b,j–l] as is a genetic variant of the metalloproteinase **stromelysin**.[m]

Other factors favoring development of atherosclerosis include hypertension and smoking. Chickens infected with a herpes virus (Marek disease virus) develop the disease after infection, and it is possible that artery damage in humans can also be caused by viruses[n] or bacterial infections.[o] In recent years it has been established that oxidative modification of the phospholipids in LDL induces the uptake of LDL by scavenger receptors of macrophages. This appears to trigger the development of foam cells and atherosclerotic plaques.[c,p,q] The initial damage is thought to be caused by lipid peroxides in the diet or generated by lipoxygenases in platelets and other cells.[c,p,r] Unsaturated fatty acids in lipoproteins can undergo oxidation (Chapter 21), especially in the presence of Cu^{2+} ions,[s,t] to yield malondialdehyde, 4-hydroxynonenal (Eq. 21-15), and other reactive compounds, which may damage the lipoproteins and cause them to have too high an affinity for their receptors in the smooth muscle cells of artery walls.[p,u] The 17β-hydroperoxy derivative of cholesterol has also been found in atherosclerotic lesions and may account for some of the toxicity of oxidized LDL.[r] Ascorbic acid may help to prevent formation of these oxidation products.[p,q,v] Chlorinated sterols may also be produced by the myeloperoxidase of the phagocytic macrophages that are abundant in atherosclerotic plaque.[w] Trans fatty acids, which are abundant in some margarines, and other hydrogenated fats raise both cholesterol and LDL levels.[x] Another cause of artery disease may be the presence of excessive homocysteine,[y,z] which can accumulate as a result of marginal deficiencies of folate, vitamin B_6, or vitamin B_{12}.



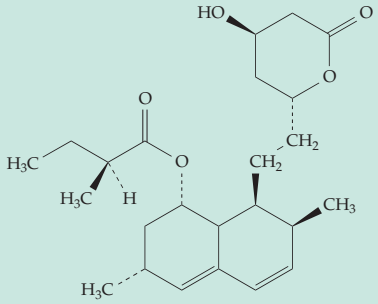
4-Hydroxy-2-nonenal

What can be done to prevent atherosclerosis? For persons with a high LDL level there is little doubt that a decreased dietary intake of cholesterol and a decrease in caloric intake are helpful. While such dietary restriction may be beneficial to the entire population, controlled studies of the effect of dietary modification on atherosclerosis have been disappointing and confusing.[aa] A diet that is unhealthy for some may be healthy for others. For example, an 88-year old man who ate 25 eggs a day for many years had a normal plasma cholesterol level of 150–200 mg / deciliter (3.9–5.2 mM)![bb] Comparisons of diets rich in unsaturated fatty acids, palmitic acid, or stearic acid have also been confusing.[cc,cd,dd] Can it be true that palmitic acid from tropical oils and other plant sources promotes atherogenesis, but that both unsaturated fatty acids and stearic acid from animal fats are less dangerous?

One of the best therapeutic approaches may be to prevent absorption of cholesterol from the intestines by inclusion of a higher fiber content in the diet.[ee] Supplementation with a cholesterol-binding resin may provide additional protection. Plant sterols also interfere with cholesterol absorption. Incorporation of esters of **sitostanol** into margarine provides an easy method of administration.[ff] Supplemental vitamin E may also be of value.[q] Another effective approach is to decrease the rate of cholesterol synthesis by administration of drugs that inhibit the synthesis of cholesterol. Inhibitors of HMG-CoA reductase,[gg,hh] (e.g., vaLostatin) isopentenyl-*PP* isomerase, squalene synthase (e.g.,

BOX 22-B ATHEROSCLEROSIS (continued)

squalestatin S1),[ii] and other enzymes in the biosynthetic pathway are targets for drug treatment.



Lovastatin
(Mevinolin)

Questions of possible long-term toxicity remain. Since 1976 there has been a greater than 25% decrease in the incidence of ischemic heart disease in the United States.[jj] Increased exercise, a decreased severity of influenza epidemics, and fluoridation of water[kk] have been suggested as explanations.

The LDL and related receptors. The LDL receptor gene extends over 50 kb of DNA and appears to be a mosaic of exons shared by several other genes that seem to have nothing to do with cholesterol metabolism.[201,211] The 839-residue receptor protein consists of five structural domains. The N-terminal domain that binds the LDL consists of seven repeated ~40-residue cysteine-rich modules.[212,213] This is followed by a large domain that is homologous to a precursor of the epidermal growth factor, a 48-residue domain containing many *O*-glycosylated serine and threonine residues, a 27-residue hydrophobic region that spans the membrane, and a 50-residue C-terminal cytoplasmic domain.[200,214–216] Synthesis of LDL receptors is regu-

lated by a feedback mechanism, the cholesterol released within cells inhibiting the synthesis of new receptors.

As mentioned in Chapter 21, there are several related receptors with similar structures. Two of them have a specificity for apolipoprotein E and can accept remnants of VLDL particles and chylomicrons.[216–220] The LDL receptor-related protein is a longer-chain receptor.[216,221] LDL particles, especially when present in excess or when they contain oxidized lipoproteins, may be taken up by endocytosis into macrophages with the aid of the quite different **scavenger receptors**.[221–225] The uptake of oxidized lipoproteins by these receptors may be a major factor in promoting development of atherosclerosis (Box 22-B). On the other hand, **scavenger receptor SR-B1**, which is also present in liver cells, was recently identified as the receptor for HDL and essential to the "reverse cholesterol transport" that removes excess cholesterol for excretion in the bile.[213,213a]

Abnormalities of cholesterol metabolism. A variety of genetic problems have been identified, many of them being associated with atherosclerosis (Box 22-B).[218,226–230] In the commonest form of **familial hypercholesterolemia** a mutation in the LDL receptor protein prevents normal synthesis, binding, clustering into coated pits, or uptake of LDL and its cholesteryl esters. Over 600 mutations have been identified.[229,229a] Some of these are present in a Ca^{2+}-binding region of the 5th cysteine-rich module.[230] Other disorders that raise the plasma LDL level include a defective apoB-100 protein (see p. 1182)[230a] and deficiency of a protein that seems to be involved in incorportation of LDL receptors into clathrin-coated pits during endocytosis or in receptor recycling.[229a] In a **cholesteryl ester storage disease** the lysosomal lipase is lacking. Absence of lecithin:cholesterol acyltransferase from plasma causes corneal opacity and often kidney failure.[231]

In the very rare and fatal **Niemann–Pick C1** disease lysosomes in cells of the central nervous system and the viscera accumulate LDL-derived cholesterol. Study of the DNA of patients led to discovery of a 1278-residue integral membrane protein, which may be required for the Golgi-mediated transport of unesterified cholesterol from lysosomes to the ER.[189,232–234c]

Some people with elevated lipoprotein levels have VLDL that migrates on electrophoresis in the β band rather than the pre-β band (see Box 2-A). The presence of the β-VLDL is associated with a high incidence of artery disease,[218] which is most likely to develop in persons homozygous for a genetic variant of apolipoprotein E. The problem may arise because apo-E is required for receptor-mediated uptake of VLDL, which interacts both with tissue LDL receptors and with hepatic apo-E receptors. Genes for many of the apolipoproteins are polymorphic, and numerous alleles are present in a normal population.[218,235] In the rare **Tangier disease** apolipoprotein A-I is catabolized too rapidly, and the HDL level is depressed, resulting in accumulation of cholesterol esters in macrophages, Schwann cells, and smooth muscles. Orange-yellow enlarged tonsils are characteristic of the disease.[236] An ABC type transporter that allows cholesterol to leave cells is defective.[236a,b,c] The faulty component is known as the **cholesterol-efflux regulatory protein**. Another ABC transporter, apparently encoded by a pair of genes, which are expressed predominantly in liver and intestinal cells, prevents excessive accumulation of plant sterols such as sitosterol (Fig. 22-9).[236d,e]

Bile acids. Among the metabolites of cholesterol the bile acids (Fig. 22-10)[182,237,238] are quantitatively the most important (100–400 mg / day). These powerful emulsifying agents are formed in the liver and flow into the bile duct and the small intestine. A large fraction is later reabsorbed in the duodenum and is returned to the liver for reuse.[238a] Formation of the bile acids involves the removal of the double bond of cholesterol, inversion at C-3 to give a 3α-hydroxyl group, followed by hydroxylation and oxidation of the side chain.[238b–f] The principal human bile acids are **cholic acid** and **chenodeoxycholic acid** (Fig. 22-10). The free bile acids are then converted to CoA derivatives and conjugated with glycine and taurine to form **bile salts**, such as **glycocholic** and **taurocholic acids**.[238d] Several rare lipid-storage diseases are associated with defective bile acid formation.[239–241] In one of these, **cerebrotendinous xanthomatosis**, cholestanol is deposited both in tendons throughout the body and in the brain. Oxidation of the cholesterol side chain is incomplete with excretion, as glucuronides, of large amounts of bile alcohols (precursors to the bile acids). The synthesis of bile acids is regulated by feedback inhibition by the bile acids, but in this disease the inhibition is absent and the rates of both cholesterol biosynthesis and oxidation are increased. The problem is not one of storage of cholesterol but of the cholestanol that arises as a minor product of the pathway. A proper ratio of bile salt, phosphatidylcholine, and cholesterol in the bile is important to prevention of **cholesterol gallstones**.[207]

A variety of other oxidative modifications of cholesterol take place in tissues to give small amounts of diols.[242] Hydroperoxides of cholesterol may also be formed.[243] Some of the products are probably toxic, but others may be essential. One of these is 26-hydroxycholesterol, a minor component of plasma but a major neonatal excretion product.[244]

The body contains sulfate esters of cholesterol and other sterols,[245] sometimes in quite high concentrations relative to those of unesterified steroids. These esters are presumably soluble transport forms. They

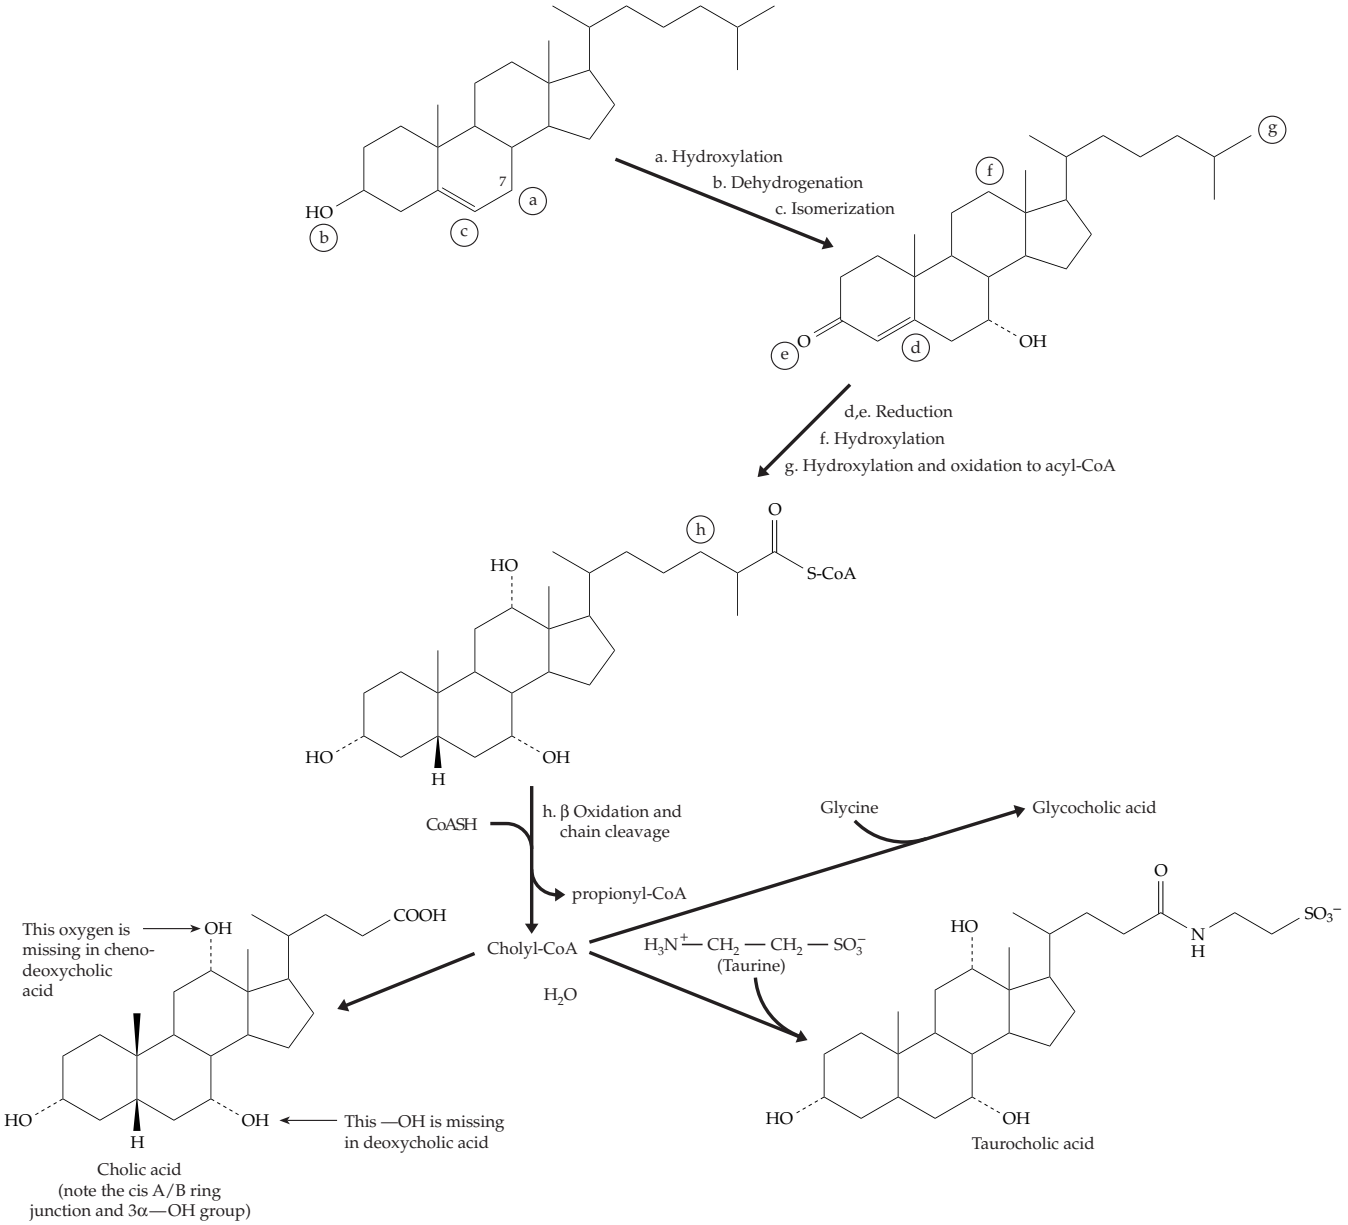

Figure 22-10 Formation of the bile acids.

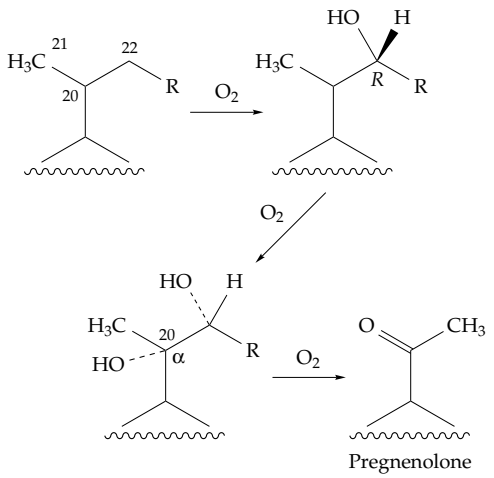
are hydrolyzed by a steroid sulfatase present within cells and whose absence causes **X-linked ichthyosis**, one of the commoner forms of scaly skin. The defect may also lead to corneal opacity but appears not to cause any other problems.[246] Glucuronides of sterols are another group of water-soluble metabolites.[247] We tend to think of cholesterol as an inert structural component of cell membranes. However, it has been found in ester linkage to a signaling protein of the "hedgehog" family, important in embryo development.[248]

E. The Steroid Hormones

In the animal body three important groups of hormones are formed by the metabolism of cholesterol: the **progestins**, the **sex hormones**, and the **adrenal cortical hormones**.[249] Their synthesis occurs principally in mitochondria of the adrenal cortex and the gonads. Steroid hormone synthesis is regulated by hormones, such as **corticotropin** (ACTH), from the anterior pituitary[250] (see Chapter 30) and is also dependent upon the recently discovered **steroidogenic acute regulatory protein,** which in some way promotes the movement of stored cholesterol into mitochondrial membranes.[251,252] Some major pathways of

biosynthesis are outlined in Fig. 22-11. The side chain is shortened to two carbon atoms through hydroxylation and oxidative cleavage to give the key intermediate **pregnenolone**. The reaction is initiated by the mitochondrial **cytochrome P450$_{ssc}$**, which receives electrons from NADPH and adrenodoxin (Chapter 16).[253] Hydroxylation occurs sequentially on C-22 and C-20 (Eq. 22-14). The chain cleavage is catalyzed by the same enzyme, an overall 6-electron oxidation occurring in three O_2-dependent steps. Dehydrogenation of the 3-OH group of pregnenolone to C=O is followed by a shift in the double bond, the oxosteroid isomerase reaction (Eq. 13-30, step *b*). In bacteria these two steps are catalyzed by different proteins, but a single human 3β-hydroxysteroid / Δ^5-Δ^4 isomerase catalyzes both reactions.[254,255] The product is the α,β-unsaturated ketone **progesterone**.

Most steroid hormones exist in part as sulfate esters and may also become esterified with fatty acids.[256] The fatty acid esters may have relatively long lives within tissues.[256] A special sex hormone-binding globulin transports sex hormones in the blood and regulates their access to target cells.[256a,b]

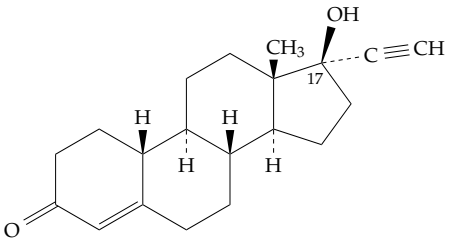


(22-14)

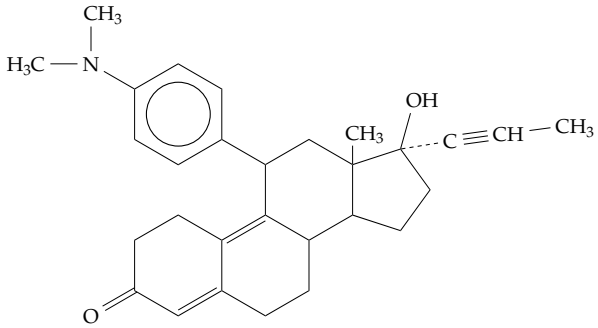
1. Progestins

Progesterone is the principal hormone of the **corpus luteum**, the endocrine gland that develops in the ovarian follicle after release of an ovum. Progesterone is also formed in the adrenals, testes, and placenta. It is metabolized rapidly, largely by reduction to alcohols, which may then be conjugated and excreted as glucuronides (see Eq. 20-16).[247] Reduction of the double bond within the A ring of progesterone leads to complete loss of activity, an indication that the α,β-unsaturated ketone group may play an essential role in the action of the hormone. Progesterone has a special role in the maintenance of pregnancy, and together with the estrogenic hormones it regulates the menstrual cycle. It is also essential for reproduction in lower animals such as birds and amphibians.[257,258]

The synthetic progesterone agonist **norethindrone** is widely used as one component of contraceptive pills. Having an opposite effect is **mifepristone** (also known as RU 486), a powerful antagonist of both progesterone and glucocorticoids. It is capable of inducing abortion and has other medical uses.[258–260] It is an effective emergency contraceptive agent that prevents implantation of an embryo.[261,262]



Norethindrone
(19-Nor-17α-ethynyltestosterone)



Mifepristone (RU 486)

2. Adrenal Cortical Steroids

Within the adrenal cortex (the outer portion of the adrenal glands) progesterone is converted into two groups of hormones of which **cortisol** and **aldosterone** are representative.[263] Two different cytochrome P450 hydroxylases, found in the ER and specific for C-21 and C-17α, respectively, together with a mitochondrial cytochrome P450 specific for C-11β (Eq. 18-55) participate in formation of cortisol.[264] Two of the same enzymes together with additional hydroxylases are required to form aldosterone.

Absence of the C-21 hydroxylase is one of the commonest of hereditary metabolic defects and is one of several enzymatic deficiencies that lead to **congenital adrenal hyperplasia**.[265–269] Cortisol, the synthesis of which is controlled by ACTH, is secreted by the adrenals in amounts of 15–30 mg daily in an adult. The hormone, which is essential to life, circulates in the blood, largely bound to the plasma protein **transcortin**. Cortisol, in turn, exerts feedback inhibi-

tion on ACTH production, and it is this feedback loop that fails when the C-21 hydroxylase is missing. Normally the circulating cortisol binds to receptors in both the pituitary and the hypothalamus of the brain to inhibit release of both ACTH and its hypothalamic releasing hormone (corticotropin-releasing hormone, CRF; see also Chapter 30). Girls are especially seriously affected by adrenal hyperplasia because, as ACTH production increases, the adrenal glands swell and produce an excessive amount of androgens. This occurs during the prenatal period of androgen release that initiates sexual differentiation. Girls with this deficiency are born with a masculine appearance of their external genitalia and continue to develop a masculine appearance. For reasons that are not clear the gene for the 21-hydroxylase is located within the HLA region (Chapter 31) of human chromosome 6.

Cortisol is a glucocorticoid which promotes gluconeogenesis and the accumulation of glycogen in the liver (Chapter 17). While it induces increased protein synthesis in the liver, it inhibits protein synthesis in muscle and many other tissues and leads to breakdown of fats to free fatty acids in adipose tissue.

Cortisol and its close relative **cortisone**, which was discovered by Kendall and Reichstein in the late 1940s, are probably best known for their anti-inflammatory effect in the body.[268,270] The effect depends upon several factors including inhibition of protein synthesis by fibroblasts, neutrophils, and antibody-forming cells. Migration of neutrophils into the inflamed area is also suppressed. Because of this action cortisone and synthetic analogs such as prednisolone and dexamethasone are among the modern "wonder drugs." They are used in controlling acute attacks of arthritis and of serious inflammations of the eyes and other organs. However, prolonged therapy can have serious side effects including decreased resistance to infections, wasting of muscle, and resorption of bone. The last results from a specific inhibition of calcium absorption from the gastrointestinal tract, glucocorticoids being antagonistic to the action of vitamin D (Box 22-C).

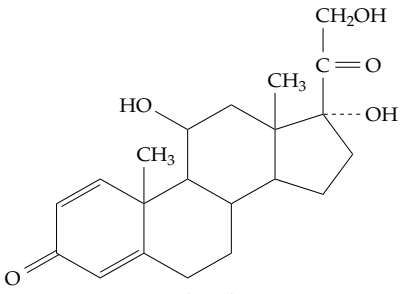
Aldosterone, which is classified as a **mineralocorticoid**, is produced under the control of the **renin–angiotensin** hormone system (Box 22-D), which is stimulated when sodium ion receptors in the kidneys detect an imbalance. It is synthesized in vascular cells of the body as well as in the adrenal cortex.[271] Aldosterone promotes the resorption of sodium ions in the kidney tubules and thus regulates water and electrolyte metabolism.[267,268] Glucocorticoids also have weak mineralocorticoid activity, and most patients with adrenocortical insufficiency (**Addison's disease**) can be maintained with glucocorticoids alone if their salt intake is adequate. Addison's disease develops when the adrenals are destroyed, most often by autoimmune disease or by tuberculosis.

3. Androgens

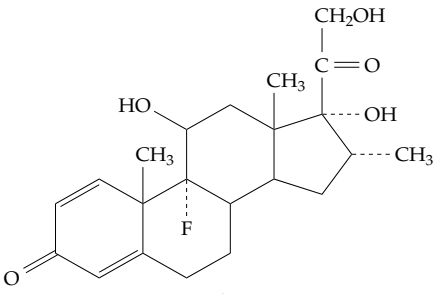
The principal **androgenic** or male sex hormone is **testosterone** formed from pregnenolone through removal of the side chain at C-17. The first step in the conversion is 17α-hydroxylation by a cytochrome P450 which may also mediate the further oxidative cleavage to **Δ^4-androstenedione** (Fig. 22-11). Reduction of the 17-carbonyl group forms testosterone. About 6–10 mg are produced daily in men, and smaller amounts (~0.4 mg) are synthesized in women. Testosterone is carried in the blood as a complex with a β-globulin and affects a variety of target tissues including the reproductive organs. Another striking effect is stimulation of the growth of the beard. Testosterone also causes premature death of follicles of head hair in genetically susceptible individuals. However, a bald man can usually grow a full beard, and follicles of the beard type, when transplanted to the head, remain immune to the action of androgen. No one knows what regulatory differences explain this fact. Baldness might be cured by use of suitable antagonists of the androgenic hormones, but the beard might fall out and sexual interest could be lost.

Androgen synthesis in the human male fetus begins at the age of about 70 days when the testes enlarge and go through an important period of activity that begins the conversion of the infant body to a male type. Other bursts of testosterone synthesis occur during infancy, but there is little further synthesis until the onset of puberty.[268,272]

Within many target tissues testosterone is converted by an NADPH-dependent 5α-reductase into **5α-dihydrotestosterone**. That this transformation is important is shown by the fact that absence of one of the two 5α-reductase isomers causes a form of **pseudohermaphroditism** in which male children are often mistaken as female and raised as girls. However, at puberty they become unmistakably male.[268,273–275] Many other metabolites of testosterone are known. These include the

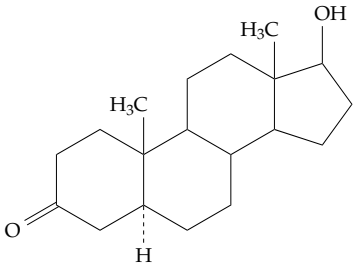


Prednisolone

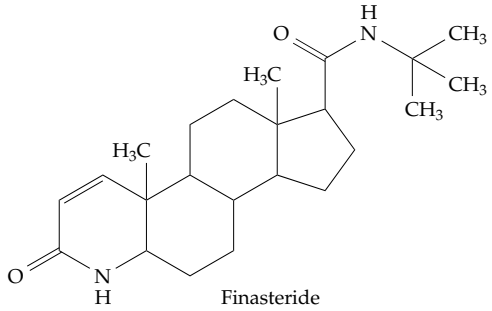


Dexamethasone

isomeric 5β-dihydrotestosterone and 5α-androstane-3β, 17β-diol which arises by reduction of the carbonyl group of 5α-dihydrotestosterone. Testosterone and dihydroxytestosterone have distinct roles in the body.



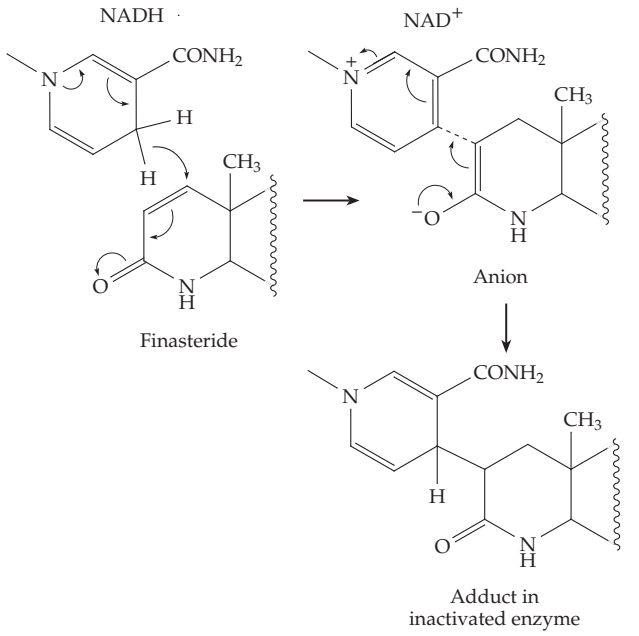
5α-Dihydrotestosterone



Finasteride

For example, testostosterone is required for sperm cell formation, voice deepening, and growth of pubic hair while dihydroxytestosterone stimulates development of the prostate gland and male pattern hair growth.[276]

Males with deficiency of the 5α-reductase isoenzyme do not develop acne, male pattern baldness, or enlarged prostates.[274] The last fact was some of the impetus for development of the steroid 5α-reductase inhibitor **finasteride,** which is widely used to treat benign prostate enlargement.[274,277,278] It is an enzyme-activated inhibitor in which the NADH reduces the C=C bond in the A ring, which is not in the same position as in the substrate. The resulting anion cannot become protonated but instead adds to the NAD^+ as shown in Eq. 22-15.



(22-15)

A number of other androgens are present in the body. The adrenal glands make **dehydroepiandrosterone** (DHEA; Fig. 22–11), which circulates in human blood as its sulfate ester in higher concentration than that of any other androgen.[279–283] However, this steroid is absent from most species. DHEA can be taken up by tissues and converted to testosterone, estrogens, or other steroids (Fig. 22–11).[280] Recent attention has been focused on this hormone because it reaches a peak plasma concentration at age 20–25 years and by age 70 has fallen to 1/5 this value or less.[283] Should older men supplement their circulating DHEA by oral ingestion of 25–50 mg per day of DHEA sulfate? The hormone depresses blood cholesterol and lowers blood glucose in diabetic individuals.[280,282] It seems to promote increased energy metabolism.[281] It may fight obesity and atherosclerosis,[282] increase levels of estrogen and other steroid hormones in the brain,[284] and enhance memory and immune function.[285–285c] However, the hormone may be metabolized differently in different tissues, and its pathway of biosynthesis in the brain is uncertain.[279,286] Will men synthesize more testosterone from DHEA or make more estrogens in their adipose tissues? Young women should not take DHEA. It may increase the testosterone and dihydrotestosterone levels in the blood manyfold, and the women may become hirsute and masculinized.[280] However, most DHEA is converted to estrogen which may be of value to older women.[285a]

In addition to their role in sexual development androgens have a generalized "anabolic" effect causing increased protein synthesis, especially in muscles.[287–289] They promote bone growth, and the adolescent growth spurt in both males and females is believed to result from androgens. The greater height attained by men results in part from the higher concentration of androgen than is present in women. Many synthetic steroids have been made in an attempt to find "anabolic hormones" with little or no androgenic activity. The effort has been at least partially successful, and the use of anabolic hormones by athletes has become both widespread and controversial.

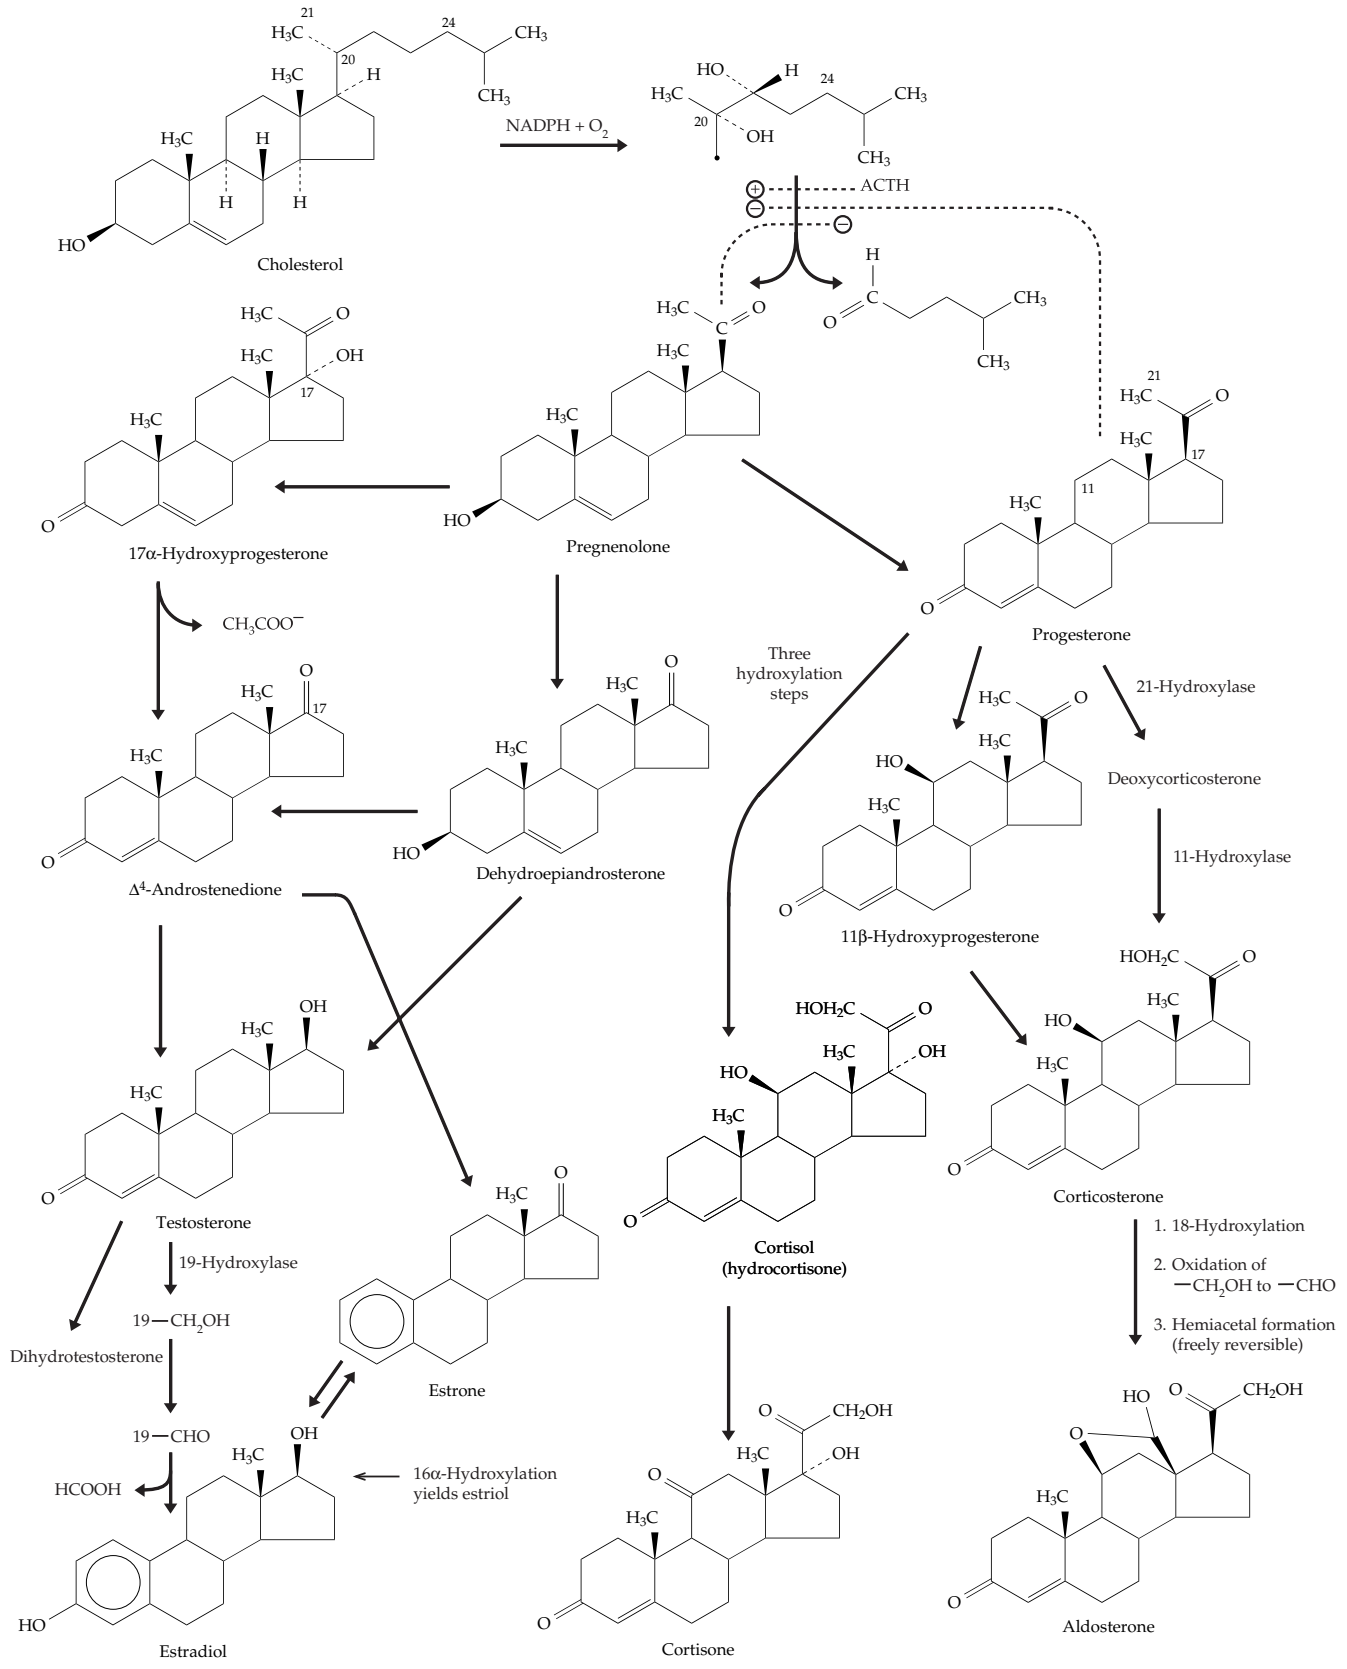


Figure 22-11 Biosynthesis of some steroid hormones.

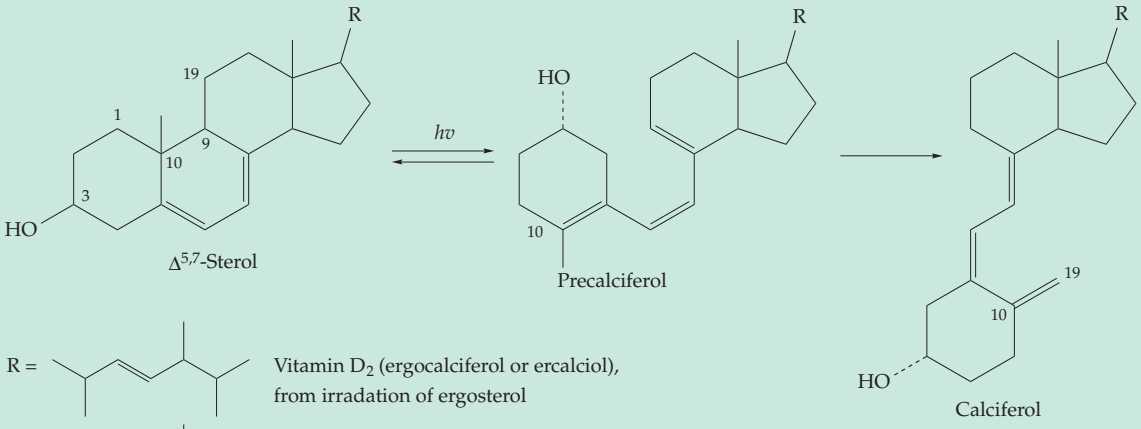
BOX 22-C VITAMIN D

A lack of vitamin D causes **rickets**, a disease of humans and other animals in which the bones are soft, deformed, and poorly calcified. Rickets was recognized by some persons to result from a dietary deficiency well over a hundred years ago, and the use of cod liver oil to prevent the disease was introduced in about 1870. By 1890 an association of rickets with a lack of sunlight had been made.

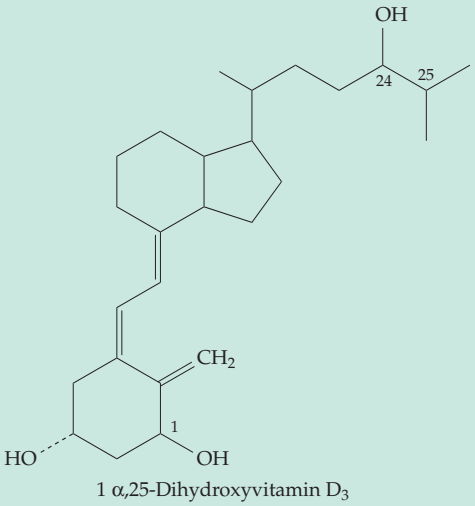


However, it was not until 1924, when Steenbock and Hess showed that irradiation of certain foods generated protective activity against the disease, that vitamin D (**calciferol**) was recognized as a second lipid-soluble vitamin. Vitamin D is a family of compounds formed by the irradiation of $\Delta^{5,7}$-unsaturated sterols such as ergosterol and 7-dehydrocholesterol.[a–e] The former yields **ergocalciferol** (vitamin D_2) and the latter **cholecalciferol** (vitamin D_3).

At low temperature the intermediate **precalciferol** can be isolated. Irradiation sets up a photochemical steady-state equilibrium between the $\Delta^{5,7}$-sterol and the precalciferol. At higher temperatures the latter is converted to calciferol.[f] Other products, including toxic ones, are produced in slower photochemical side reactions. Therefore, the irradiation of ergosterol for food fortification must be done with care.

With normal exposure to sunlight enough 7-dehydrocholesterol is converted to cholecalciferol in the skin that it was concluded that no dietary vitamin D is required by most adults except during pregnancy. However, recently it has been recognized that old and sick adults probably need 400–600 I.U. per day to maintain calcium absorption and to prevent osteoporesis and fractures.[g,gh] It is usually recommended that children receive ~20 μg (400 I.U.) of ergocalciferol per day in their diet. Larger amounts are undesirable, and at a tenfold higher level vitamin D is seriously toxic.[h]

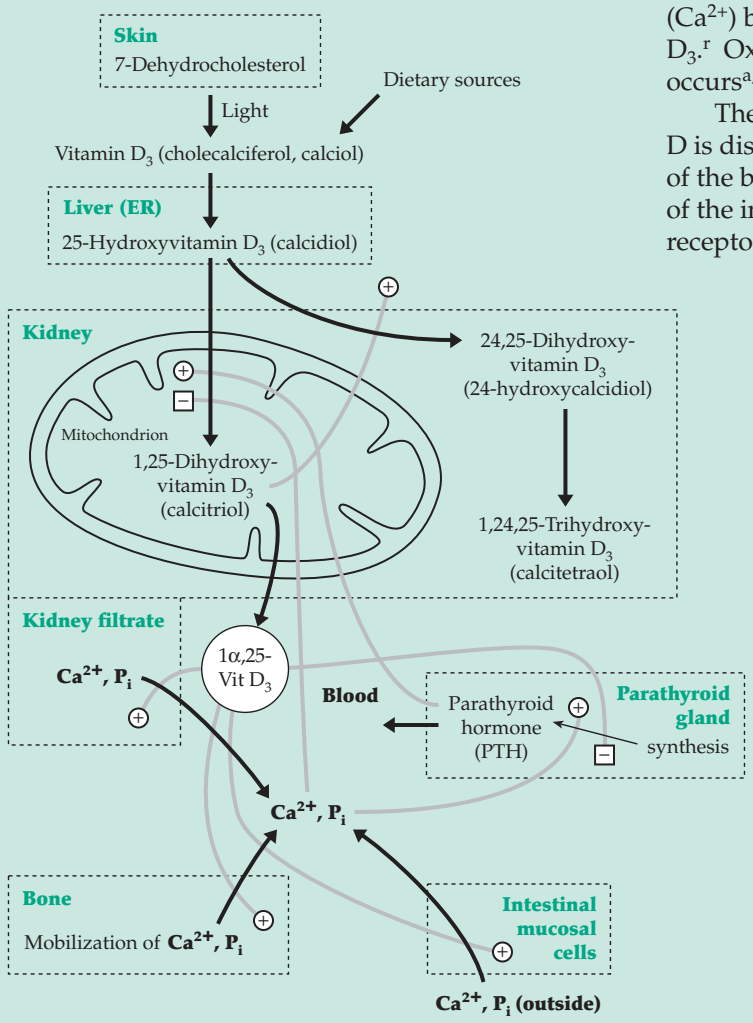
The principal function of vitamin D is in the control of calcium metabolism. This is accomplished through the mediation of polar, hydroxylated metabolites, the most important of which is **1α,25-dihydroxyvitamin D3** (1,25-dihydroxycholecalciferol or calcitriol).[a,i,j] This compound may be properly described as a steroid hormone and vitamin D itself as a hormone precursor formed in the skin. The major hydroxylation reactions of



vitamin D are summarized in the accompanying scheme. The first hydroxylation to 25-hydroxyvitamin D_3 occurs largely in the liver,[jk] but the subse-

BOX 22-C VITAMIN D (continued)

quent cytochrome P450 catalyzed 1α-hydroxylation takes place almost entirely in the kidneys.[k,l] Since it is 1,25-dihydroxy derivative that is essential for control of calcium ion metabolism, human patients



with damaged kidneys often suffer severe demineralization of their bones (renal osteodystrophy). Administration of synthetic 1α,25-dihydroxyvitamin D_3 provides an effective treatment for these persons and also for children with an inherited defect in production of this hormone.[a,m] However, large doses, tested as an antileukemia drug, caused a severe hypercalcinemia limiting its use.[n]

A second major vitamin D metabolite is 24*R*,25-dihydroxyvitamin D_3, a compound that circulates in the blood at a concentration 10 times higher than that of the 1,25-isomer.[a,b] However, no biological function has been discovered, and like a series of other polar metabolites (>30) it is probably on a pathway of inactivation and degradation of vitamin D. 1α,25-Dihydroxyvitamin D is also hydroxylated at C-24.[o] Additional hydroxylations occur at the 23- and 26-positions.[p,q] The 24-OH is often converted to an oxo group. Oxidation at C-26 together with cyclization yields 26,23 lactol and lactone species. The 25-hydroxy-26,23-lactone suppresses serum (Ca^{2+}) by competing with 1,25-dihydroxyvitamin D_3.[r] Oxidative cleavage of the side chains also occurs[a,s] as in the metabolism of cholesterol.

The hormonally active 1α,25-dihydroxyvitamin D is distributed through the bloodstream to all parts of the body. It is taken up rapidly by nuclei of cells of the intestinal lining where it binds to a 55-kDa receptor protein. In response, the cells synthesize **calbindins** (Chapter 6), Ca^{2+}-binding proteins which facilitate the uptake of calcium ions by the body.[t–v] (see also Fig. 6-7).

Other target organs for the action of 1,25-dihydroxyvitamin D include the kidneys, bone, muscle,[vw] and skin. The hormone promotes reabsorption of both Ca^{2+} and inorganic phosphate by kidney tubules. In bone it binds to a specific receptor where it promotes the mobilization of calcium ions. This effect may result in part from stimulation of calcium-activated ATPase of the outer membrane of bone cells. Dissolution of bone also requires the presence of **parathyroid hormone** (**PTH**), the 83-residue hormone secreted by the parathyroid gland. In women past the age of menopause and in elderly men the production of 1,25-dihydroxyvitamin D decreases.[w] This may be a cause of the serious bone loss (**osteoporosis**) frequently observed. Treatment with 1,25-dihydroxyvitamin D_3 or a synthetic analog seems to be helpful to such individuals.[x,xy] See also Chapter 30, Section A,5.

There is another important member of the Ca^{2+} homeostatic system. While vitamin D and PTH act together to increase the calcium level of the blood, **calcitonin**, a hormone of the thyroid gland, lowers the level of Ca^{2+} by promoting deposition of calcium in bone by the osteoblasts. The overall effect is to hold the concentration of Ca^{2+} in the blood at 2.2–2.6 mM in most animals with bones serving as a mobile reserve. Another role for vitamin D is suggested by the observation that 1,25-dihydroxyvitamin D_3 inhibits the growth promoting effect of interleukin-2 on mitogen-activated lymphocytes (Chapter 31).

BOX 22-C (continued)

Like other steroid hormones 1,25-dihydroxyvitamin D_3 acts to regulate gene transcription. It binds to a specific receptor, a member of the v-*erb*-A superfamily of ligand-activated transcription factors and a relative of the steroid receptor family.[a,j,y] Like other hormone receptors this vitamin D_3 receptor (VDR) has some rapid "nongenomic" actions such as causing an increase in intracellular [Ca^{2+}] as well as slower effects on transcription.[y–bb] Like the steroid receptors it is found in both cytoplasm and nucleus.[y] When occupied by 1,25-dihydroxyvitamin D, the receptor binds tightly to specific dihydroxyvitamin D_3 response elements in the DNA. These are found in promoter sequences for genes such as that of bone protein **osteocalcin**.[cc] In some promoters the response element binds heterodimers of VDR with another receptor, e.g., the retinoid X receptor (Table 22-1).[cc,dd] One effect of this response element is to activate the gene for the 24-hydroxylase involved in degradation of 1,25-dihydroxyvitamin D.[dd] Heterodimers of VDR with the thyroid hormone receptor activate the transcription of genes for calbindins D_{28K} and D_{9K}.[u] VDR also binds to repressor sequences, e.g., in the parathyroid gland.[ee] See also Chapter 28 and Table 22-1.

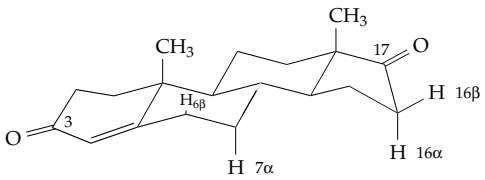
Norandrolone phenyl propionate, a synthetic drug having a five times higher ratio of anabolic to androgenic activities as does testosterone

Several sex-dependent differences have been observed in the action of cytochrome P450 isoenzymes on steroid hormones.[290,290a] Thus, androstenedione is hydroxylated by rat liver enzymes specific for the 6β, 7α, 16α, and 16β positions.[291] Of these the 16 hydroxylase is synthesized only in males, and synthesis of the 6 hydroxylase is also largely suppressed in females.



Δ4-Androstenedione

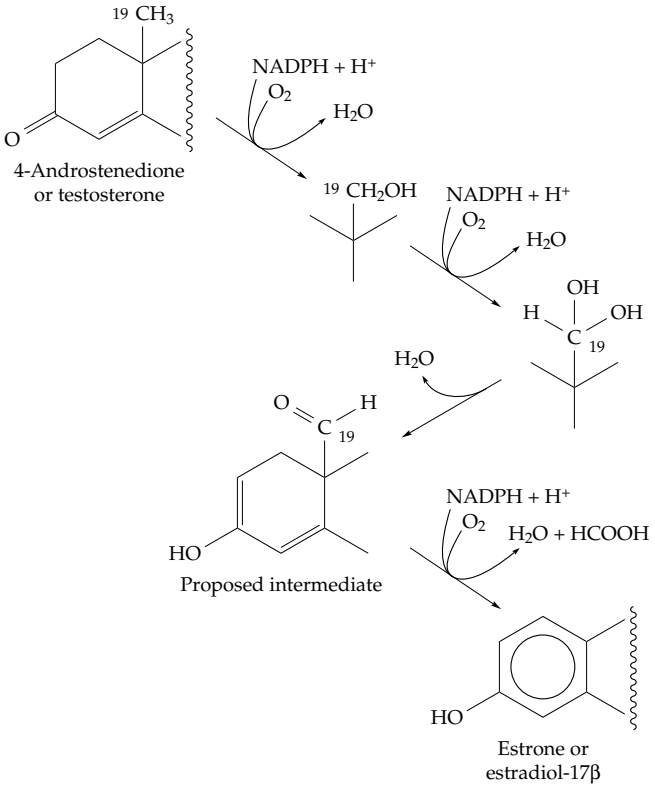
A female-specific 15β hydroxylase acts on steroid sulfates such as corticosterone sulfate and forms the major urinary excretion product of that hormone in female rats.[292] These sex-specific differences in enzymes are thought to be related to secretions of growth hormone that are in turn controlled by the "programming" of the hypothalamus by androgen during the neonatal period in rats[272] or during human fetal development.

4. Estrogens

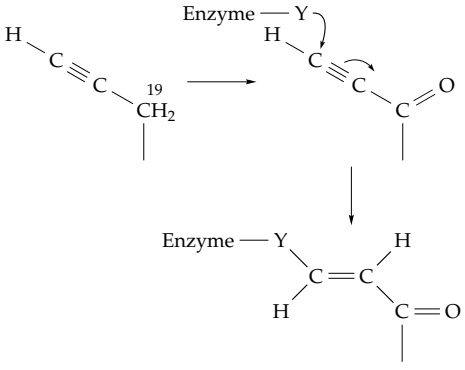
The principal **estrogenic** or female hormone is estradiol-17β. It is formed by oxidative removal of C-19 of testosterone followed by aromatization of the A ring.[268,293–295] All of the estrogenic hormones have this aromatic ring. Its formation involves three steps of hydroxylation followed by elimination of formate (Eq. 22-16). This **aromatase** appears to be a unique cytochrome P450, which catalyzes all of the steps of Eq. 22-16. It accepts electrons from NADPH via the flavoprotein NADH-cytochrome P450 reductase, which serves as the intermediate electron carrier.[296] It probably acts by a mechanism related to that illustrated for lanosterol 14α-demethylase on the right-hand side of Fig. 22-8.[294] This enzyme is the target for synthetic enzyme-activated inhibitors.[293] One of these is an androstenedione derivative with an acetylenic group attached to C-19. Passage through the first two steps of Eq. 22-16 generates a conjugated ketone to which a nucleophilic group of the enzyme can add irreversibly to inactivate the enzyme (Eq. 22-17). The C-17 acetylenic progesterone antagonist (norethyndrone) is also an enzyme activated inhibitor of the aromatase.

Estrogens are formed largely in the ovary and during pregnancy in the placenta. Estrogens are also synthesized in the testes, and the estrogen content of the horse testis is the highest of any endocrine organ. Target tissues for estrogens include the mammary glands, the uterus, and many other tissues throughout the body. Estrogens act on the growing ends of the long bones to stop growth and are therefore responsible, in part, for the shorter stature of females as compared to males. They are responsible for the overall higher fat content of the female body and for the smoother skin of the female. Recent attention has been focused on the effects of estrogens on brain neurons. Estrogens stimulate sprouting of axons and dendrites in neurons in cell cultures, and there is preliminary evidence that the hormone improves memory in healthy women and in those with Alzheimer disease.[285]

The cooperative action of progesterone and estradiol regulate the menstrual cycle. At the beginning of the cycle the levels of both estrogen and progesterone are low. Estrogen synthesis increases as a result of release of **follicle-stimulating hormone** (FSH) from the anterior pituitary. This hormone stimulates growth of the graafian follicles of the ovary which in turn produce estrogen. At about the midpoint of the cycle, as a result of the action of the pituitary **luteinizing hormone** (LH), an ovum is released and progesterone secretion begins. The latter is essential to maintenance of pregnancy. If a blastocyst is not implanted, hormone production decreases and menstruation occurs.



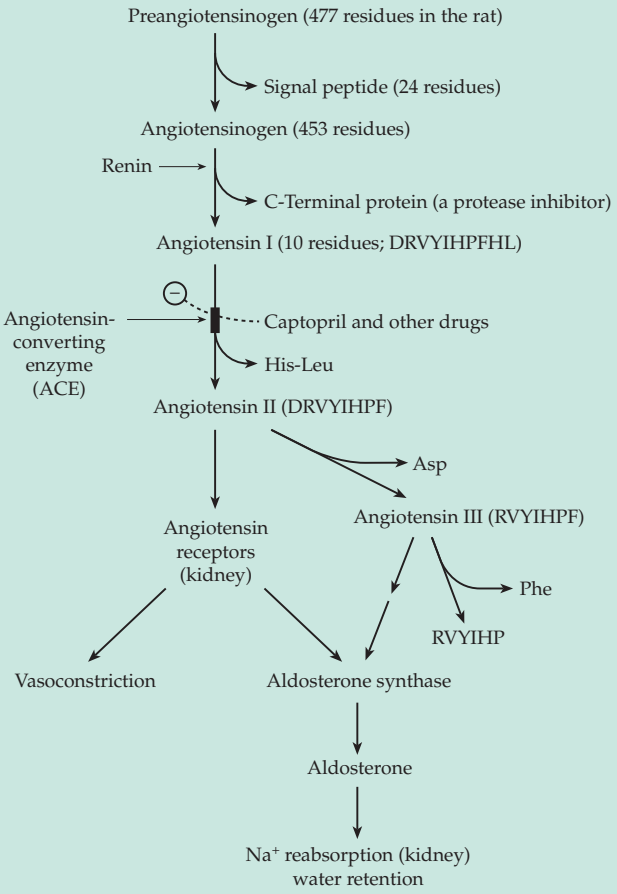
(22-16)



(22-17)

BOX 22-D THE RENIN–ANGIOTENSIN–ALDOSTERONE SYSTEM AND THE REGULATION OF BLOOD PRESSURE

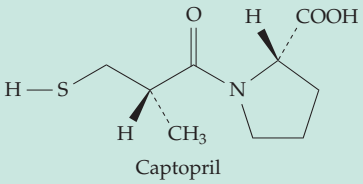
The mineralocorticoid **aldosterone** was isolated and identified in 1953. Although the function of adrenal cortical hormones in regulation of electrolytes had been known for many years, the special role of aldosterone had been overlooked.[a] Aldosterone works in concert with the aspartate protease **renin** and the octapeptide **angiotensin II** to regulate blood pressure. Angiotensin II, which is the most potent pressor substance known, is formed in the liver from the 477-residue (in the rat) **preangiotensinogen** as shown in the following cascade:



This **renin–angiotensin system** is a peptide hormone-generating system that operates in blood plasma rather than within tissues.[b,c]

Angiotensinogen, which is secreted by the liver and circulates in the blood, is converted to the physiologically inactive decapeptide angiotensin I by cleavage of a Leu-Leu peptide bond by the 328-residue renin.[d–f] Its precursor **preprorenin** is produced in the kidneys by the juxtaglomerular cells as well as in some other tissues and undergoes several steps of processing before the active enzyme is formed.[g–j] Active renin is released from the kidney cells into the bloodstream in response to various stimuli which include low arterial pressure resulting from constriction of the renal arteries or loss of blood.[k] Parathyroid hormone, glucagon, other adrenergic agonists, cAMP, some prostaglandins, low levels of aldosterone or Na^+, or high K^+ all induce secretion of renin. High blood pressure, α-adrenergic agonists, some prostaglandins, angiotensin, vasopressin, high Na^+, or low K^+ concentration decrease secretion of renin. It has been suggested that these diverse effects may be modified by a rise or fall in the Ca^{2+} concentration, high Ca^{2+} inhibiting secretion of renin, and low Ca^{2+} favoring secretion.

The only known physiological substrate for renin is angiotensinogen,[e] but it may also act on related proteins in the brain and other organs.[g] The inactive angiotensin I is converted to angiotensin II by the metal-containing carboxydipeptidase known as **angiotensin-converting enzyme**.[l,m] This enzyme is a target for drugs such as captopril, which is used to control high blood pressure (hypertension).[i] A zinc-dependent aminopeptidase may cut off the



Captopril

N-terminal aspartate to form angiotension III,[n] and degradation of angiotensions II and III can be initiated by removal of the C-terminal phenylalanine by a prolylcarboxypeptidase.[o]

Angiotensin II has a variety of effects. By constricting blood vessels it raises blood pressure, and by stimulating thirst centers in the brain it increases blood volume. Both angiotensins II and III also act on the adrenal gland to promote the synthesis and release of aldosterone. Most of the effects of angiotension II are mediated by 359-residue seven-helix G-protein linked receptors which activate phospholipase C.[p,q,qr] Like other steroid hormones aldosterone acts,via mineralocorticoid receptors, to control transcription of a certain set of proteins. The end effect is to increase the transport of Na^+ across the renal tubules and back into the blood. Thus, aldosterone acts to decrease the loss of Na^+ from the body. It promotes retention of water and raises

BOX 22-D THE RENIN–ANGIOTENSIN–ALDOSTERONE SYSTEM AND THE REGULATION OF BLOOD PRESSURE (continued)

blood pressure.[c,r,s] Its primary function is to provide adequate Na^+ to cells.[s] Dietary sodium appears to have little or no effect on blood pressure.[t]

The control of blood pressure is considerably more complex than it is described here. Another hormone system involving the peptide **bradykinin** and prostaglandins acts to lower blood pressure. Bradykin is also cleaved by the angiotensin-converting enzyme but is *inactivated* by the cleavage.[u,v] At least ten human genes have been shown to affect blood pressure.[c] One of these is the structural gene for angiotensin-converting enzyme, which has been linked to hypertension in both rats and humans.[w,x]

While several antagonists of angiotensin-converting enzyme are widely used to treat hypertension, they are not free of harmful side effects.[u,y,z] One alternative approach is to inhibit renin.[v,y]

While the angiotensins promote release of aldosterone, the **atrial natriuretic hormone**[r,aa–cc] inhibits release. This group of 21- to 33-residue polypeptides, secreted by cells of the atria (auricles) of the heart, also inhibits release of renin and promotes secretion of both Na^+ and water. Thus, they antagonize the action of aldosterone, which promotes Na^+ retention. However, there is uncertainty as to the significance of these peptides. The following metabolite of γ-tocopherol (Fig. 15-24) has been isolated from urine and is proposed as a new endogenous natriuretic factor.[dd]

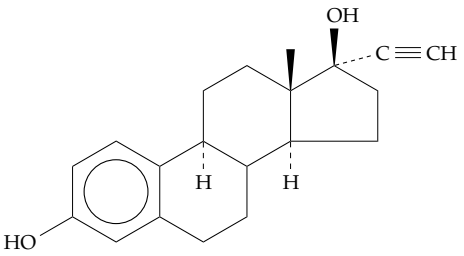
Administration of estrogens and progestins inhibits FSH and LH secretion from the pituitary (feedback inhibition) and hence ovulation. This effect is the action of contraceptive pills. A small amount of the synthetic estrogen 17-ethynylestradiol may be taken daily for 10–15 days followed by a combination of estrogen plus a progestin such as norethindrone for 0–15 days. Alternatively, a progestin alone may be

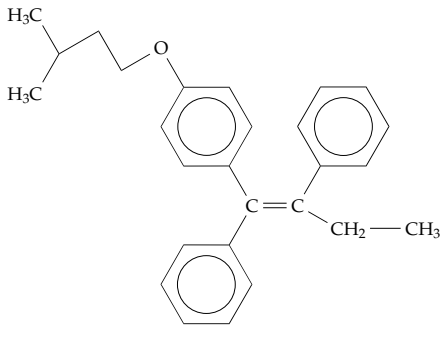


17-Ethynylestradiol

ingested over the entire period. Another synthetic compound with estrogenic activity is diethylstilbestrol. Its once widespread use in promoting growth of cattle and other animals has been discontinued because of carcinogenic action in rats fed large amounts of the compound.

Human cancers of the breast and endometrium are stimulated by estrogen. However, the mechanism is unknown.[297,298] It has usually been assumed that the proliferation of cells induced by estrogens leads to mutations and cancer. However, estrogens can form adducts with DNA after oxidation to 2- and 4-hydroxy derivatives and further oxidation to quinones.[297,298] In a similar manner prostate cancer is promoted by androgens. It has also been observed that in the United States the incidence of cancers of the ovary and endometrium has declined substantially during the past 35 years, perhaps as a result of the anti-estrogenic activity of the progestin in the widely used oral contraceptives.[299] This observation led to the idea of **hormonal chemoprevention**, the deliberate use of hormone antagonists to slow cancer formation.[299a] This may be especially attractive to persons carrying known cancer-susceptibility genes. The synthetic antiestrogen **tamoxifen** is being evaluated as a chemopreventive agent for breast cancer.[299,299b] However, a planned large-scale trial was postponed because of uncertainities about safety.[300]

In addition to steroids there are plant flavonoids (Box 21-E) that have estrogenic activity. These labile compounds are among the **"environmental estrogens."** In addition, there are many much more stable compounds, including the insecticides atrazine and DDT, PCBs, and phenolic softeners for plastics, that have weak estrogenic activity. Alarm has been sounded



trans-Tamoxifen

by some who maintain that these **xenoestrogens** are contributing to breast cancer, to reproductive difficulties in animals, and to low sperm counts in men.[301] It seems surprising that such small amounts of weakly estrogenic compounds could have such large effects. Some experiments suggest that two weak xenoestrogens may cooperate to give larger effects,[302,303] but this concept needs further evaluation.

Although estrogens are usually regarded as female hormones, they are present in small amounts in male blood and in high concentration in semen. Male reproductive tissues contain estrogen receptors, and mice deficient in these receptors are sterile and their testes degenerate.[304] Furthermore, as in females estrogen stops growth of long bones in late puberty. A few men lacking estrogen or estrogen receptors have grown very tall (>2.1 m and still growing).[305]

5. The Steroid Receptor Family

The principal mode of action of steroid hormones is to stimulate transcription of specific sets of genes. The plasma concentrations of these hormones are low, typically ~10^{-9} M, but they have a high affinity for their protein receptors, some of which are located initially in the cytosol but are found largely in the nucleus. The earliest identification of steroid receptors was accomplished with radioactive ^{3}H-labeled progesterone, estrogens, and glucocorticoids.[306,307] Autoradiographs of thin sections of tissue made after the uptake of the hormones revealed that the radioactivity was concentrated in the nuclei. The protein receptors were then isolated and were found to bind both to the hormone and to specific sequences in DNA, the hormone **response elements**.[308] The progesterone, estrogen, and glucocorticoid receptors are multidomain proteins with two of the domains having highly conserved sequences and structures. One of these domains binds to DNA and the other to the steroid hormone. Their amino acid sequences are also related to those of the v-*erb-A* oncogene (Table 11-3).[309] With this knowledge available and through use of methods of "reverse genetics," receptors for the other steroid hormones and also for vitamin D, retinoic acid, and thyroid hormone were identified as members of the family as were several "orphan" receptors of as yet unknown function (Table 22-1). Invertebrates have similar receptors. At least eight are present in *Drosophila*,[307] and the family is present in the nematode *Caenorhabditis*.[310]

Because of their hydrophobic character the steroid hormones or other nonpolar ligands diffuse through membranes into cells. There they may encounter a variety of binding proteins that affect their access to a receptor.[307,311] Some receptors, including glucocorticoid receptors, are found in the cytosol. After a hor-

TABLE 22-1
Known Members of the Steroid Receptor Family[a]

Glucocorticoid[b–d]	Thyroid α, β_1, β_2[r]
Mineralocorticoid[e,f]	Retinoic acid α, β, γ[s]
Progesterone[g,h]	Retinoid-X α,β[t–w]
Androgen[i,j,k]	Peroxisome proliferators[x,y]
Estrogen[l–o]	Farnesoid X: bile acids[z,aa]
Vitamin D_3[p,q]	Orphan receptors, 8 or more

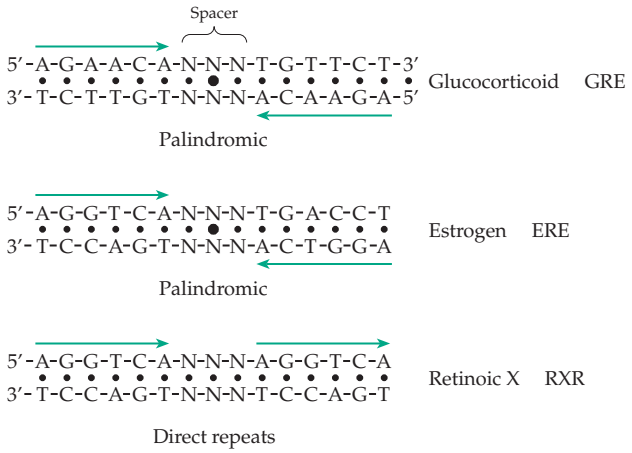
mone binds to a cytosolic receptor, the complex apparently undergoes time and temperature dependent alterations that activate the receptor before it diffuses into the nucleus and binds to its proper response element in the DNA.[312] This process has been observed directly for glucocorticoid receptors labeled by fusion with green fluorescent protein (Box 23-A).[313]

The conserved 68-residue DNA binding domain of the glucocorticoid receptor contains two Zn^{2+} ions, each coordinated by four cysteine $-CH_2-S^-$ groups with tetrahedral geometry. These two consecutive motifs form structures somewhat similar to those of the "zinc fingers" shown in Fig. 5-38.[314–316] However, the overall folding pattern is different from those considered in Chapter 5. The two zinc-binding sites lie at the N termini of a pair of helices that cross at right angles near their centers. One of these is a DNA-recognition helix that fits into the major groove of DNA thereby allowing interaction of its amino acid side chains with the bases of the DNA response elements.

The response elements for glucocorticoids and estrogen receptors contain short palindromic sequences with various three-nucleotide "spacer" sequences in the center as follows.[308,314,316–318] Two receptor proteins bind to the palindromic DNA forming a homodimeric receptor pair. For the 9-*cis* retinoic acid receptor RXR-α the response element contains a pair of direct repeats of a 6-base consensus sequence with a two-base pair spacer:



The RXR-α receptor binds differently and tends to form *heterodimeric* pairs with other receptors.[319,320] All of these receptors undergo conformational changes when agonists or antagonists bind.[320,321] Estrogens can also bind to androgen receptors, perhaps in playing their essential role in male reproductive physiology.[322] There are more than one type of receptor for each group of steroid hormones, and these may interact differently with the various response elements in DNA[323] making the effects of hormones complex and hard to analyze. Interactions with additional proteins

also affect the response of a cell to hormones.[324] Furthermore, steroid hormones have **transcription-independent effects**. For example, progesterone binds to oxytocin receptors[325] as well as to other steroid receptors, which affect a broad range of biochemical processes.[326]

F. Other Steroids

The **saponins** are a series of steroid glycosides with detergent properties that are widespread among higher plants.[327] Some are toxic, and among these toxic materials are compounds of extraordinary medical importance. Best known are the steroid glycosides of *Digitalis*, among them **digitonin** (Fig. 22-12). The particular arrangement of sugar units in this molecule imparts a specificity toward heart muscle. The compound is extremely toxic; in small amounts it acts to increase the tone of heart muscle and is widely used in treatment of congestive heart failure.[328] The maintenance dose is only 0.1 mg / day. Another toxic glycoside and heart stimulant is **ouabain** (Fig. 22-12). Ouabain is a specific inhibitor of the membrane-bound $(Na^+ + K^+)$-ATPase believed to be the ion pump that keeps intracellular K^+ concentrations high and Na^+ concentrations low (Chapter 8). Similar glycosides account for the extreme toxicity of the leaves of the oleander and the roots of the lily of the valley. A steroid glycoside from red squill is used as a rat poison. A number of alkaloids (nitrogenous bases) are derived from steroids. An example is **solanidine** (Fig. 22-12), which is present in the skins and sprouts of potatoes, making both quite toxic.

Some animals also contain toxic steroids. **Batrachotoxin** of the Columbian poison arrow frog (Fig. 22-12) is present in amounts of only 50 μg per frog.[329,330]

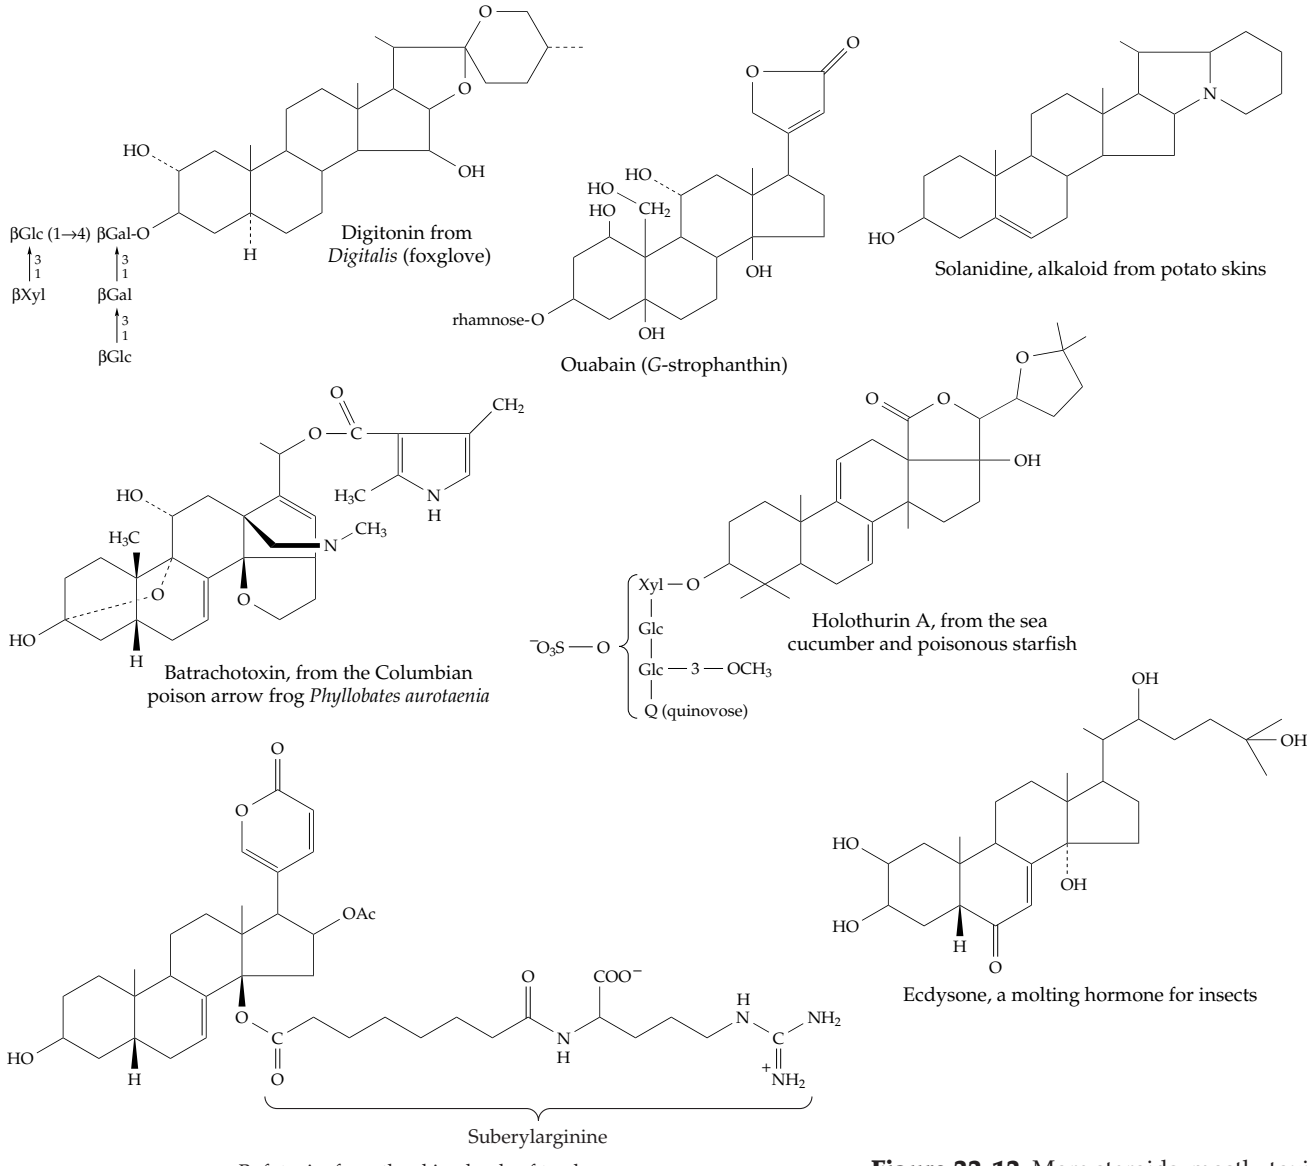


Figure 22-12 More steroids, mostly toxic.

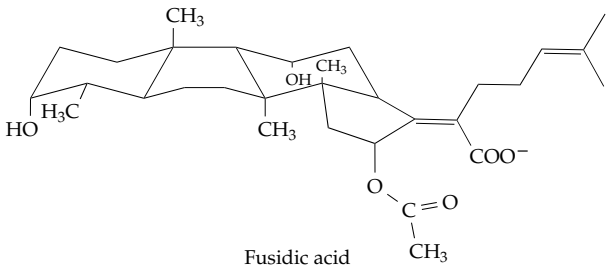
The toxin acts on nerves to block transmissions to the muscle by increasing the permeability of membranes to sodium ions. It is specifically antagonized by **tetrodotoxin** (Fig. 30-16). Batrachotoxin alkaloids are present also in certain birds.[330a] Some echinoderms make powerful steroid toxins such as **holothurin A** (Fig. 22-12), a surface active agent that causes irreversible destruction of the excitability of neuromuscular tissues. The common toad produces in its skin steroid toxins such as **bufotoxin** (Fig. 22-12), which are sufficiently powerful to teach a dog to leave toads alone.

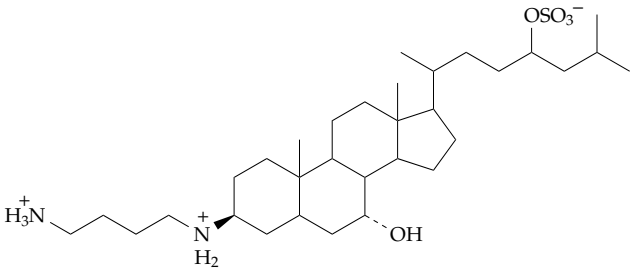
Ecdysone, a highly hydroxylated steroid (Fig. 22-12), is a molting hormone for insects.[331,332] Several molecules with ecdysone activity are known, and some of these are produced by certain plants. Although ecdysones are needed by insects for larval molting, they are toxic in excess. Perhaps plants protect themselves from insects by synthesizing these substances.

Among the antibiotics **fusidic acid** is a steroid. An inhibitor of chloramphenicol acetyltransferase[333] it is highly inhibitory to staphyococci but almost noninhibitory to *E. coli*. Note the boat conformation of the B ring.



Fusidic acid

Another steroid antibiotic, **squalamine**,[334] was isolated from the stomachs of sharks. It is effective against gram-positive and gram-negative bacteria, and some fungi as well.[335]



Squalamine

Study Questions

1. Outline the sequence and chemical mechanisms of the reactions involved in the conversion of acetyl-CoA into mevalonate.

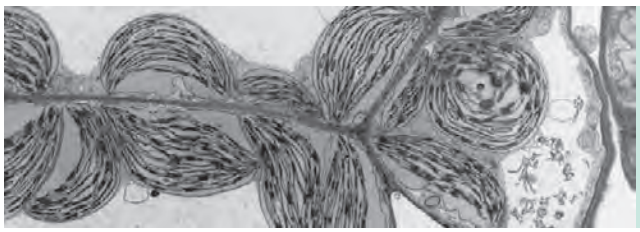
2. a) Show the structures of the reactants for the hydroxymethylglutaryl CoA synthase reaction.
   b) Free coenzyme A is liberated in the above reaction. From which molecule did it come? Explain the metabolic purpose behind the liberation of free CoA.

3. List as many substances as you can that are of polyprenyl origin and are present
   a) in foods
   b) in various commercial products

4. What distinctly different functions do 3-hydroxy-3-methylglutaryl-CoA synthases serve in the cytosol and in mitochondria of the liver?

5. Outline the functions of mitochondrial enzymes in the conversion of fructose into cholesterol in the liver.

6. How do you think that hydroxycitrate, an inhibitor of ATP citrate lyase, would affect the ability of liver to convert dietary fructose into bile acids?



Chloroplasts fill most of the cytoplasm around the junction of three cells of *Arabidopsis thaliana* seen in this micrograph. Both grana stacks and stroma lamellae (pictured in more detail in Fig. 23-19) can be seen. Also present are several small mitochondria. Portions of the large vacuoles, characteristic of plant cells, are seen at top, right, and bottom. Micrograph courtesy of Kenneth Moore.

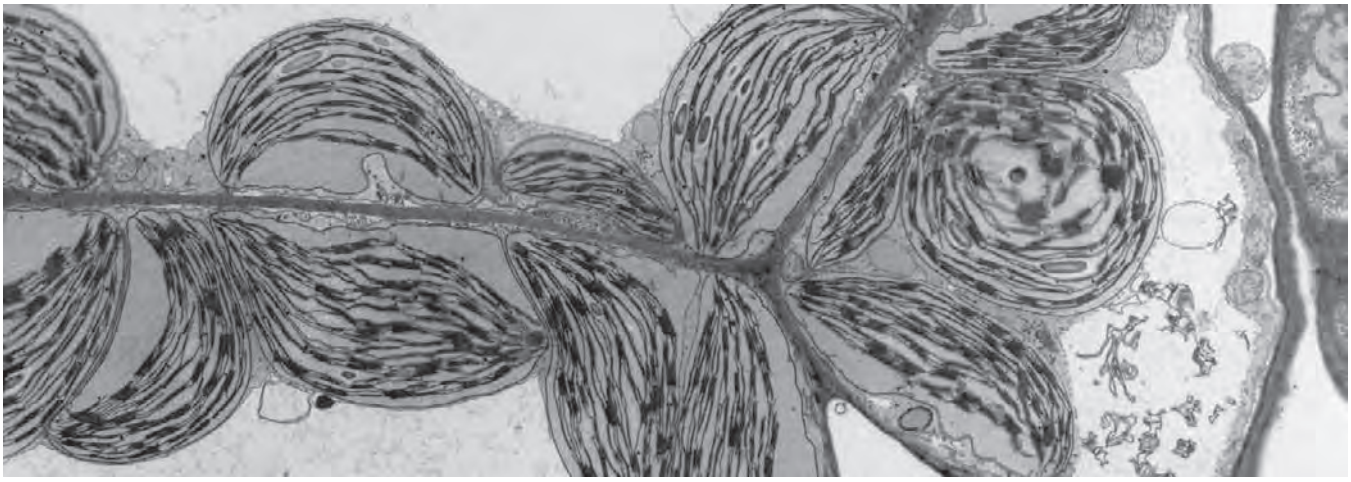
23 Light and Life



Light plays a pervasive role in human life. The earth is bathed in light from the sun, and from this light comes not only warmth but also energy for all living organisms. Of the 3×10^4 kJ m^{-2} of light energy falling on the earth each day,[1,2] ~30 kJ m^{-2} are captured by photosynthesis.[3] Light penetrating the atmosphere allows us to see and provides color to our environment. It controls the flowering of plants, the germination of seeds and spores, the greening of seedlings, and the daily cycles of many organisms. High in the stratosphere ultraviolet light reacts with oxygen to create a protective blanket of ozone. The ultraviolet light that is not screened out by the ozone layer kills bacteria, tans our skin, and often mutates our DNA, inducing many cancers.[4,5] Organisms, from bacteria to higher plants, display **phototaxis**, the ability to move toward a source of light or to orient themselves with respect to a source of light. In plants the chloroplasts assume an orientation that maximizes efficiency of light absorption. Plants grow toward light (**phototropism**), and some organisms avoid light. Many organisms emit light.

Many of our most important experimental techniques involve the use of light or of other forms of electromagnetic radiation of a wide range of energies. X-rays, ultraviolet light, infrared light, and microwaves all serve in the study of biomolecules.

A. Properties of Light

Light is a form of electromagnetic radiation and possesses characteristics of both waves and particles (**photons**). The energy of a photon is usually measured by the frequency (or by the wavelength in a vacuum to which it is inversely related, Table 23-1). A portion of the electromagnetic spectrum is shown on a logarithmic scale in Fig. 23-1.[1] At the high-energy end (off the scale of the figure to the right) are cosmic rays and gamma rays, while at the low-energy end radio waves extend to wavelengths of many kilometers. The narrow range of wavelengths from about 100 nm to a few micrometers, which is the subject of this chapter, includes the ultraviolet, visible, and near infrared

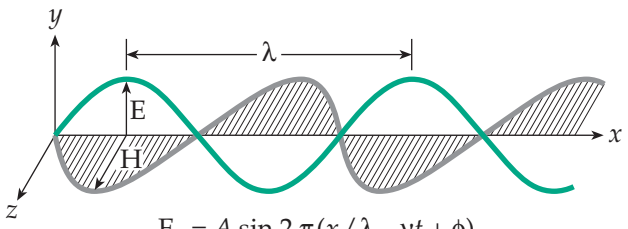
TABLE 23-1
Some Properties of Light

Velocity of light in a vacuum	$c = 2.998 \times 10^8$ m s^{-1}
Velocity of light in a medium	$c' = c/n$ where n = refractive index
Wave number (in nm)	$\bar{\nu} = 1/\lambda$; $\bar{\nu}$ (in cm^{-1}) $= 10^7/\lambda$
Frequency	$\nu = c/\lambda = c\bar{\nu}$ ν (in hertz) $= 2.998 \times 10^{10}\,\bar{\nu}$ (cm^{-1}) in a vacuum
Energy of quantum	$E = h\nu = hc\bar{\nu}$ E (joules) $= 1.986 \times 10^{-23}\,\bar{\nu}$ (cm^{-1}) E (eV) $= 1.240 \times 10^{-4}\,\bar{\nu}$ (cm^{-1})
Energy of einstein	$E = Nh\nu = Nhc\bar{\nu}$ $= 6.023 \times 10^{23}\,hc\bar{\nu}$ E (joules) $= 11.961\,\bar{\nu}$ (cm^{-1}) E (kcal) $= 2.859 \times 10^{-3}\,\bar{\nu}$ (cm^{-1})

ranges. The second line of Fig. 23-1 shows this region expanded. Note that the range of light reaching the earth's surface is narrow, largely being confined to wavelengths of 320–1100 nm. The human eye responds to an even more limited range of 380–760 nm, in which all of the colors of the rainbow can be found. The aromatic rings of proteins and nucleic acids absorb maximally at 280 and 260 nm, respectively. Even though these wavelengths are largely screened out by the ozone layer of the stratosphere, enough light penetrates to cause mutations and to damage the skin of the unwary sunbather.

The energy of a quantum of light is proportional to the **wave number** or **frequency**. The wave number $\bar{\nu}$ is the reciprocal of wavelength and is customarily given in units of cm^{-1} (**reciprocal centimeters**). Most of the absorption spectra in this book are plotted against wave number in cm^{-1}. The frequency ν in **hertz** is equal to $c'\nu$, where c' is the velocity of light in a medium. (The velocity of light in a vacuum is designated c and is equal to 3.00×10^8 m s^{-1}.) The energy of a quantum of light E is equal to $h\nu$, where h is Planck's constant, 6.626×10^{-34} J s^{-1}. From a chemical viewpoint, we are more interested in the energy of one **einstein**, i.e., one "mole" of light (6.023×10^{23} quanta). The energy in kJ per einstein is 11,960 $\bar{\nu}$ (in cm^{-1}, vacuum). Energy relationships are summarized in Table 23-1. The lower three scales of Fig. 23-1 also show the relationships of $\bar{\nu}$, ν, and E to wavelength.

The light wave is characterized by oscillating electrical and magnetic fields.[2,3,6] For propagation of light in the x direction the electric field vector **E**, which is customarily plotted in the y direction, is a function of the wavelength λ and the time (Eq. 23-1).



$$E_y = A \sin 2\pi(x/\lambda - \nu t + \phi) \qquad (23\text{-}1)$$

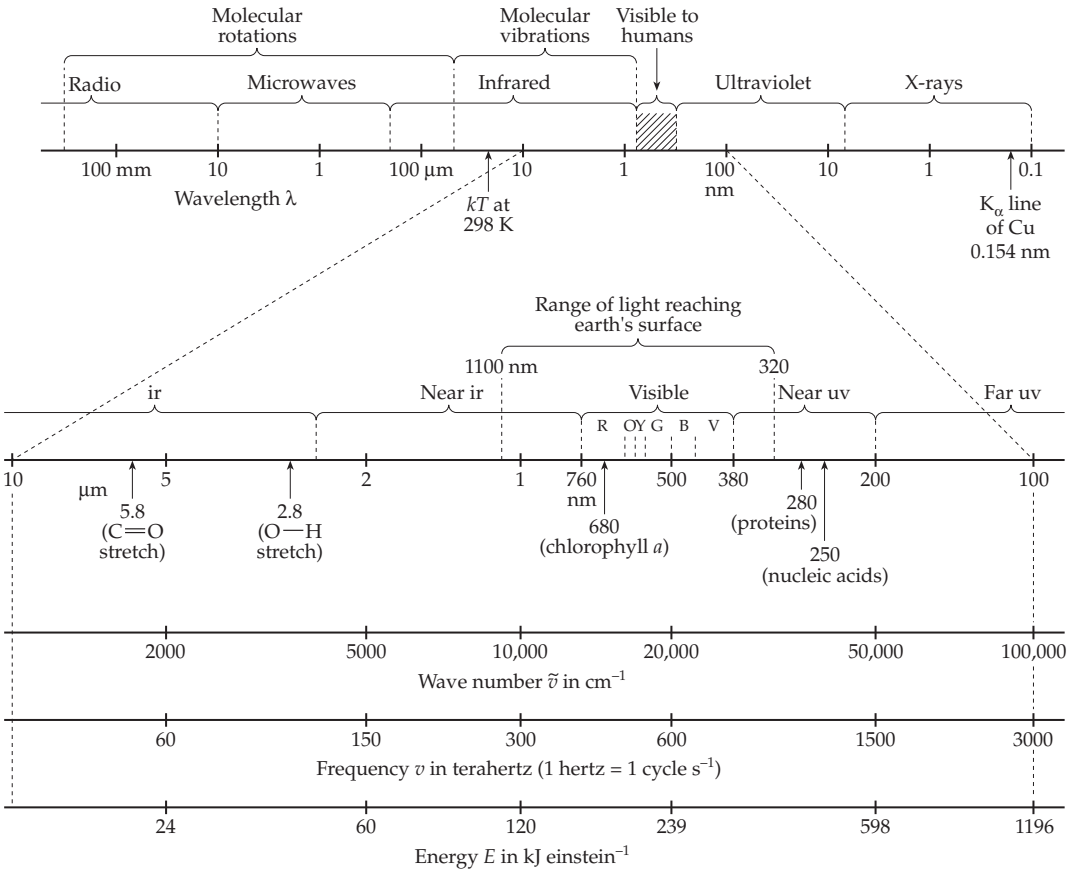


Figure 23-1 A part of the electromagnetic spectrum. The letters V, B, G, Y, O, R over the visible part of the spectrum refer to the colors of the light. The position marked "K_a line of Cu" is the wavelength of X-rays and most widely employed in X-ray diffraction studies of proteins and other organic materials.

The magnetic vector H is at right angles to the electric vector and is given by Eq. 23-2.

$$H_z = (\varepsilon / \mu)^{-} A \sin 2\pi(x/\lambda - \upsilon t + \phi) \qquad (23\text{-}2)$$

The velocity of propagation of light in a medium, c' (Eq. 23-3), depends upon both ε, the **dielectric constant** of the medium, and μ, the **magnetic permeability**.

$$\text{Velocity in a medium: } c' = c/(\varepsilon/\mu)^{-} = c/n \qquad (23\text{-}3)$$

The **refractive index** of a medium relative to a vacuum is given the symbol n. It is the factor by which the velocity of light in a vacuum is diminished in a medium. It is a function of wavelength. For the 589 nm sodium line n is 1.00029 for air and 1.33 for water at 25°C.

The term ϕ in Eqs. 23-1 and 23-2 is a **phase factor**. Most light is called **incoherent** because ϕ varies for the many photons making up the beam. **Coherent light** produced by **lasers** contains photons all with the same phase relationship. If the electric vectors of all the photons in a beam of light are in the same plane (as will be the case for light emerging after passage through certain kinds of crystals), the light is called **plane polarized**. The direction of polarization is that of the electric vector E. **Circularly polarized light**, in which the electric vector rotates and traces out either a left-handed or right-handed helix, can also be generated. A beam of left-handed circularly polarized light, together with a comparable beam polarized in the right-handed direction, is equivalent to a beam of plane polarized light. Conversely, plane polarized light can be resolved mathematically into right- and left-handed circularly polarized components.

B. Absorption of Light

Absorption of light is fundamental to all aspects of photochemistry and provides the basis for absorption spectroscopy.[3,5–11] Light absorption is always **quantized**. It can take place only when the energy $h\nu$ of a quantum is equal to the difference in energy between two energy levels of the absorbing molecule (Eq. 23-4).

$$E_2 - E_1 = h\nu \qquad (23\text{-}4)$$

Not only must the difference $E_2 - E_1$ be correct for absorption but also there must always be a change in the dipole moment of the molecule in going from one energy level to another. Only when this is true can the electric field of the light wave interact with the molecule. A further limitation comes from the symmetry properties of the wave functions associated with each energy level. Quantum mechanical considerations show that transitions between certain energy levels are allowed, while others are forbidden. Consideration of such matters is beyond the scope of this book, but the student should be aware that the quantum mechanical selection rules that express this fact are an important determinant of light absorption.

Many types of light source are used in chemical measurements. Of great importance is the recent development of lasers that deliver very short pulses of light. Pulses as short as five femtoseconds (5 fs)[11a,11b] and even less[11c] are being utilized for very rapid spectroscopy and excitation of fluorescence. Structures are being determined by ultrafast electron diffraction[11d] or X-ray diffraction.[11e,11f] It takes 200 fs or more for a chemical bond to stretch and break during a reaction. The cleavage and formation of bonds during this time can be observed using 5-fs pulses. Lasers with pulses in the attosecond range may soon be used to observe movements of electrons.[11g]

1. Quantitative Measurement of Light Absorption, Spectroscopy

An absorption spectrum is a plot of some measure of the intensity of absorption as a function of wavelength or wave number. The **transmittance** of a sample held in a **cell** (or **cuvette**) is the fraction of incident light that is transmitted, i.e., transmittance = I/I_o where I_o is the intensity of light entering the sample and I is that of the emerging light. The transmittance is usually defined for a single wavelength, i.e., for **monochromatic** light. The absorbance (or optical density) is defined by Eq. 23-5, which also states the **Beer–Lambert law**. The length (in centimeters) of the

$$\text{Absorbance} = A = \log_{10}(I_o/I) = \varepsilon c l \qquad (23\text{-}5)$$

light path through the sample is l, c is the concentration in moles per liter, and ε is the **molar extinction coefficient** (molar absorptivity or molar absorption coefficient), whose units are liter mol^{-1} cm^{-1} (or $\mathbf{M^{-1}\,cm^{-1}}$). The reader can derive Eq. 23-5 by assuming that in a thin layer of thickness dx the number of light quanta absorbed is proportional to the number of absorbing molecules in the layer. Integration from x = 0 to l gives the Beer–Lambert law. Equation 23-5 generally holds very well for solutions containing single ionic or molecular forms. However, it is usually valid only for monochromatic light. Furthermore, making precise measurements of absorbance is not easy. At A=1 only 10% of the incident light is transmitted, and the utmost care is required to obtain a value of A good to within ±0.05. At A=2 only 1% of incident light is transmitted, and the value of A will be much less reliable. Very low absorbances are also difficult to measure. In view of the importance that

spectrometry has played in biochemistry, it may seem surprising that the first reliable commercial laboratory ultraviolet–visible spectrophotometers became available in 1940 and the first commercial infrared spectrometer in 1942.[12]

2. The Energy Levels of Molecules

The energy of molecules consists of **kinetic** (translational), **rotational**, **vibrational**, and **electronic** components. The corresponding rotational, vibrational, and electronic energy levels are always quantized. Light quanta of wavelengths 0.2–20 mm (50–0.5 cm^{-1}; frequencies of 1.5 x 10^{12} to 1.5 x 10^{10} s^{-1}) with energies of 0.6–0.006 kJ/einstein are sufficient to excite molecules from a given rotational energy level to a higher one. Spectra in this "far infrared" or "microwave" region often consist of a closely spaced series of lines. For example, the rotational spectrum of gaseous HCl is a series of lines at 20.7 cm^{-1} intervals beginning at that wave number and reaching a maximum at about 186 cm^{-1} (54 μm). The energies involved in absorption of such light are far lower than energies of activation for common chemical reactions and lower than the average translational energy of molecules in solution at ordinary temperatures (3/2 k_BT or 3.7 kJ/mol at 25°C). However, they are still much higher than energies involved in the nuclear transitions of NMR spectra (Chapter 3). Compare 500 Hz for a proton resonating at 1 ppm in a 500 MHz NMR spectrometer with the 10^{10}–10^{12} s^{-1} frequencies of microwave spectra.

Vibrational energies range from about 6 to as much as 100 kJ mol^{-1} with corresponding wave numbers of ~500–8000 cm^{-1}. The resulting absorption spectra are in the infrared region. Excited electronic energy levels are ~120 – 200 kJ mol^{-1}, and the spectral transitions are at 10,000–100,000 cm^{-1} (1000–100 nm wavelengths) in the visible and ultraviolet region.

3. Infrared (IR) and Raman Spectra

Absorption in the near infrared region is dominated by changes in vibrational energy levels. A typical wave number is that of the "amide A" band at 3300 cm^{-1} (3.0 μm wavelength), approximately 10^{14} s^{-1}. First let us consider the stretching vibrations of a diatomic molecule. The two nuclei of the molecule can be thought of as connected with a spring. The energy of oscillation is approximately that of a harmonic oscillator. Application of quantum theory shows that the discrete energy levels that can be assumed by the oscillator are equally spaced. The difference between each pair of successive energy levels is $h\nu$, where ν is the frequency of light that must be absorbed to raise the energy from one level to the next. In the ground state (unexcited state) the molecule still possesses a **zero-point energy,** $E = 1/2\ h\nu_o$, equal to half the energy needed to induce a transition.

While the harmonic oscillator is a good approximation to the behavior of a molecule in the lower vibrational energy states, marked deviations occur at higher energies. At the lower energy levels the change in the distance between the atomic centers during the course of the vibration amounts to only ±10% or less, but as the energy becomes greater the bond stretches more and the motion becomes **anharmonic**. The energy states of molecules are often in the form of **Morse curves** in which energy is plotted against internuclear distance (Fig. 23-2). As the internuclear distance becomes very short, the energy rises steeply. As the bond is stretched, there comes a point at which addition of more energy ruptures the bond. A diatomic molecule will dissociate into atoms and more complex molecules into fragments. Vibrational energy levels can be portrayed as horizontal lines at appropriate heights on the Morse curve (Fig. 23-2).

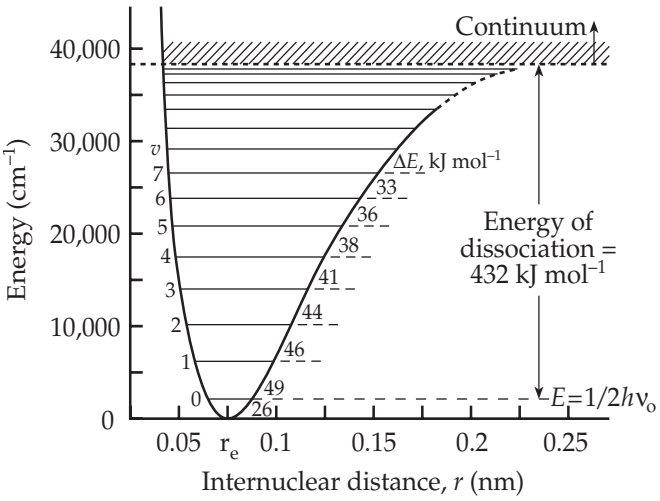

Figure 23-2 The potential energy of the hydrogen molecule as a function of internuclear distance, and the position of its vibrational energy levels. Δ*E* values are energy differences between successive levels; *v* designates vibrational quantum numbers. Adapted from Calvert and Pitts,[2] p. 135.

Because there are many rotational energy levels corresponding to each vibrational level, IR spectra contain absorption bands resulting from simultaneous changes in both the vibrational and rotational energy levels of molecules. Instead of single peaks corresponding to single transitions in vibrational energy, progressions of sharp bands at closely spaced intervals are observed. An example is provided by the band corresponding to the stretching frequency of the H–Cl

bond in gaseous HCl at 2886 cm^{-1} (3.46 μm). There is actually no band at this wave number but a series of almost equally spaced bands on either side of the fundamental frequency from ~2600 to ~3100 cm^{-1} at intervals of ~21 cm^{-1}, i.e., the wave number of the rotational frequency seen in the microwave spectrum (Herzberg,[8] p. 55). The effect is to broaden the band as seen in a low-resolution spectrum. This is only one cause of the broadening of IR bands in solution. Another cause is interaction with solvent to provide a heterogeneity in the environments of the absorbing molecules.

The IR spectra of diatomic molecules are relatively easy to interpret, but for more complex substances the infrared absorption bands often cannot be associated with individual chemical bonds. Instead, they correspond to the **fundamental vibrations** (normal vibrations) of the *molecule*. Fundamental vibrations are those in which the center of gravity does not change. For a molecule containing n atoms, there are $3n - 6$ such vibrations. They are sometimes dominated by a vibration of a single bond, but often involve synchronous motion of many atoms. The fundamental vibrations of a molecule are described by such words as *stretching*, *bending* (in-plane and out-of-plane), *twisting*, and *deformation*. Rarely are all $3n - 6$ bands seen in an infrared spectrum. Some of the vibrations, e.g., the symmetric stretching of the linear CO_2 molecule, are not accompanied by any change in dipole moment, while other bands may simply be too weak to be observed clearly.

Vibrations involving many atoms in a molecule, i.e., **skeletal vibrations**, are often found in the region of 700–1400 cm^{-1} (14–7 μm). Vibrational frequencies that are dominantly those of individual functional groups can often be identified in the range 1000–5000 cm^{-1} (10–2 μm). Examples of the latter are the stretching frequencies of C–H, N–H, and O–H bonds, which have wave numbers of ~2900, 3300, and 3600 cm^{-1}, respectively. The energy (and frequency) of the vibrations increases as the difference in electronegativity between the two atoms increases. When a bond connects two heavier atoms, the frequency is lower, e.g., the wave number for C–O in a primary alcohol is ~1053 cm^{-1}. For a double bond it increases; for C=O it is ~1700 cm^{-1}. This C=O stretching frequency usually gives rise to one of the strongest bands observed in IR spectra. Hydrogen bonding has a strong and characteristic effect. Thus, the O–H frequency at ~3600 cm^{-1} is decreased to ~3500 cm^{-1} by hydrogen bonding.

Theory predicts that for a harmonic oscillator only a change from one vibrational energy level to the next higher is allowed, but for anharmonic oscillators weaker transitions to higher vibrational energy levels can occur. The resulting "overtones" are found at approximate multiples of the frequency of the fundamental. Combination frequencies representing sums and differences of frequencies of individual IR bands may also be seen. The intensities of these bands are low, but their presence at relatively high energies in the near IR region (4000–12,500 cm^{-1}) means that they may be easier to observe than the fundamental frequencies in the more crowded IR region.[12a] Development of the very sensitive **Fourier-transform infrared spectroscopy** (FTIR) has made it possible to record the complex IR spectra of macromolecules in dilute aqueous solutions rapidly. The water spectrum is substracted digitally.[13–16] FTIR has been utilized to study amide groups in peptides, carboxyl groups in proteins,[17] conformations of sugar rings in DNA,[18] and the ionization state of phosphate groups.[19] New computational methods involving use of two-dimensional representations provide simplifications in interpretation of IR spectra.[19a] Another variant is **total reflection FTIR**, a technique that records spectra of thin films and has permitted the recording of transient changes in protein spectra with microsecond time resolution.[20,21]

Vibrational frequencies of amide groups. The IR absorption bands of amide groups, which are present in both proteins and in the purine and pyrimidine bases, have attracted a great deal of attention.[13,22–23a] The **amide I** band at ~1680 cm^{-1} is associated with an in-plane normal mode of vibration that involves primarily C=O stretching. (The band is designated I′ if the N–H has been exchanged to form N–^{2}H.)[16] The **amide II** band at ~1500 $^{-1}$ and the **amide III** band at ~1250 cm^{-1} both arise from in-plane modes that involve N–H bending, while the higher frequency **amide A** band at ~3450 cm^{-1} involves N–H stretching. It is shifted to ~3300 cm^{-1} when the N–H is hydrogen bonded. Examples of IR spectra of proteins, including the amide bands A, I, and II, are shown in Fig. 23-3. The band shapes are complex. Those of the amide bands I and III depend upon the conformation of the peptide chain. For example, (Fig 23-3B) amide groups in α helices have an amide I band about 20 cm^{-1} higher than do those in β structures.

If peptide chains can be oriented in a regular fashion, it may be useful to measure **infrared linear dichroism**.[24,25] Absorption spectra are recorded by passing plane polarized light through the protein in two mutually perpendicular directions, with the electric vector either parallel to the peptide chains or perpendicular to the chains. Such a pair of spectra is shown in Fig. 23-3A for oriented fibrils of insulin. In this instance, the insulin molecules are thought to assume a β conformation and to be stacked in such a way that they extend transverse to the fibril axis (a cross-β structure). When the electric vector is parallel to the fibril axis, it is perpendicular to the peptide chains. Since the amide I band is dominated by a carbonyl stretching motion that is perpendicular to the

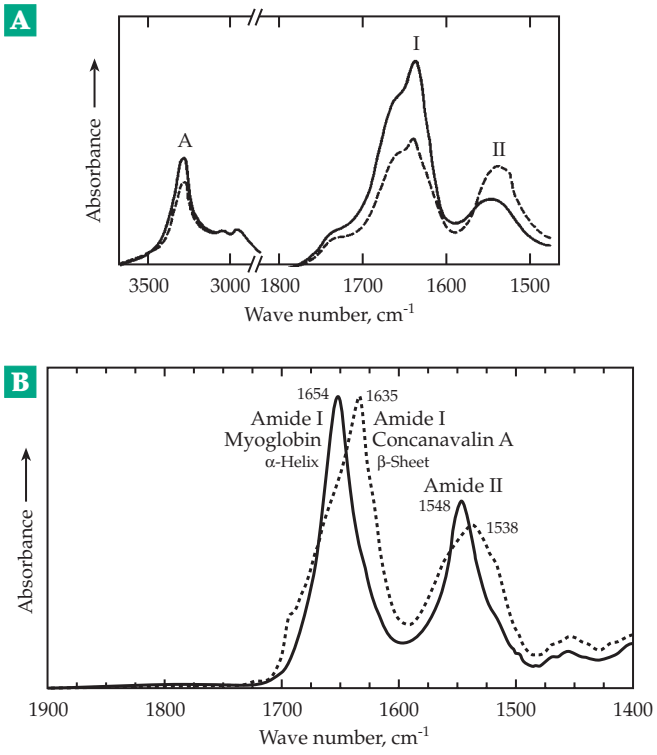

Figure 23-3 Infrared absorbance spectra of the amide regions of proteins. (A) Spectra of insulin fibrils illustrating dichroism. Solid line, electric vector parallel to fibril axis; broken line, electric vector perpendicular to fibril axis. From Burke and Rougvie.[24] Courtesy of Malcolm Rougvie. See also Box 29-E. (B) Fourier transform infrared (FTIR) spectra of two soluble proteins in aqueous solution obtained after subtraction of the background H_2O absorption. The spectrum of myoglobin, a predominantly α-helical protein, is shown as a continuous line. That of concanavalin A, a predominantly β-sheet containing protein, is shown as a broken line. From Haris and Chapman.[14] Courtesy of Dennis Chapman.

peptide chains in the β structure, this band is enhanced when the electric vector is also perpendicular to the peptide chains and is diminished when the electric vector is parallel to the peptide chains (perpendicular to the fibril axis, Fig. 23-3A). The same is true of the amide A band which is dominated by an N–H stretch. On the other hand, the dichroism of the amide II band is the opposite because it tends to be dominated by an N–H bending, which is in the plane of the peptide group but is longitudinal in direction. In **isotope-edited FTIR**, heavy atoms such as ^{13}C are introduced to shift IR bands and assist in their identification. The method can be combined with measurement of linear dichroism of oriented peptides.[25]

The loss of the amide II band in D_2O is one of the major tools for studying protein dynamics.[13,26] (see Chapter 3, Section I,5). In some cases the four main secondary structures, α helix, β sheet, β turn, and random coil, can be distinguished.[27] The amide bands of pyrimidines can also be observed in IR spectra of pyrimidines. Figure 23-4A shows the spectrum of 1-methyluracil in H_2O and also in D_2O. Notice that the amide II band is totally lacking in D_2O. The same figure also shows the IR spectrum of 1-methyluracil containg ^{18}O in the 4 position. The shift of 9 cm^{-1} in the amide II position is part of the evidence that the NH bending vibration is extensively coupled to C=O and C=C stretching modes.

Raman spectra. In a collision between a photon and a molecule, the photon may undergo **elastic collision** in which the photon loses no energy but changes its direction of travel. Such scattering is known as **Rayleigh scattering** and forms the basis for a method of molecular mass determination. Sometimes **inelastic** collisions occur in which both the

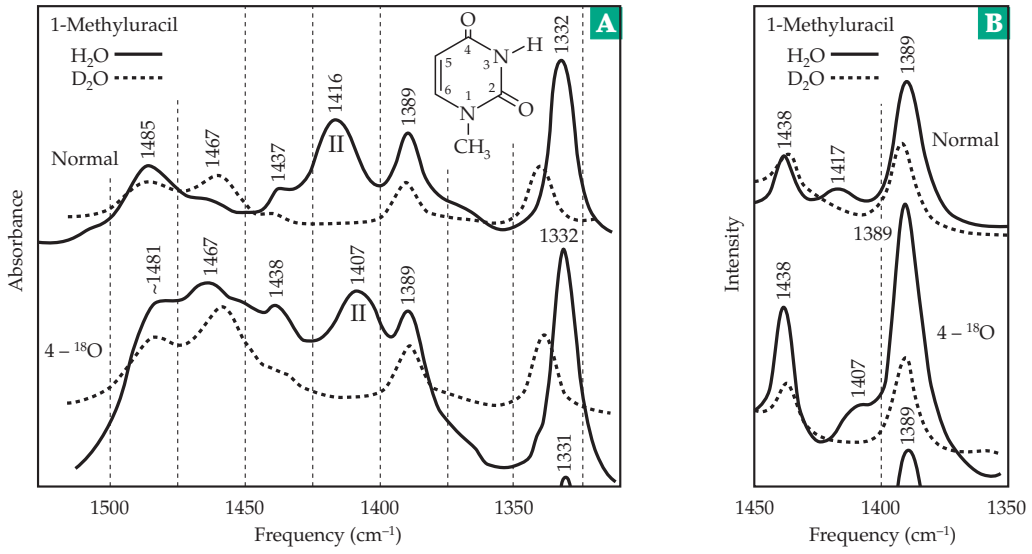

Figure 23-4 (A) Infrared and (B) Raman spectra of 1-methyluracil in H_2O and D_2O. Spectra for normal 1-methyluracil and for the specific isotopic derivatives with ^{18}O in the 4 position are shown. From Miles *et al.*[28]

molecule and the photon undergo changes in energy. Since such changes must be quantized and involve vibrational and rotational levels of the molecule, the spectrum of the scattered light (Raman spectrum) contains much of the same information as an ordinary IR spectrum. However, the selection rules are not the same. Some transitions are "infrared active" and others are "Raman active." IR-active transitions can occur only when the dipole moment varies with time as a molecule vibrates, whereas Raman-active transitions require that the polarizability change with time. For this reason, it, s useful to measure both IR and Raman spectra on the same sample. Until recently, Raman spectroscopy was not used much in biochemistry because of the low intensity of the scattered light. However, with laser excitation the technique is practical[7,13,23,28,29] and can be applied to aqueous or nonaqueous solutions, and to solid or dispersed forms of macromolecules.

Both amide I and amide III bands are seen in Raman spectra of proteins.[30] Lippert *et al.* devised the following method for estimating the fractions of α-helix, β sheet, and random coil conformations in proteins.[31] The amide I Raman bands are recorded at 1632 and 1660 cm^{-1} in D_2O (amide I'). The amide III band, which is weak in D_2O, is measured at 1240 cm^{-1} in H_2O. The intensities of the three bands relative to the intensity of an internal standard (the 1448 cm^{-1} CH_2 deformation) are related to those of standard poly-L-lysine in known conformations. See also Craig and Gaber.[32] The Raman spectrum of 2-methyluracil is shown in Fig. 23-4B. Note the low intensity of the amide II band relative to that of the amide I band, a characteristic of Raman spectra. Linear dichroism observed by polarized Raman microspectrophotometry has provided information about orientation of indole rings of tryptophan in filamentous virus particles.[33,33a]

In **resonance Raman spectroscopy**[34–37] a laser beam of a wavelength that is absorbed in an electronic transition is used. The scattered light is often strongly enhanced at frequencies differing from that of the laser by Raman frequencies of groups within the chromophore or of groups in another molecule adjacent to the chromophore. The resonance effect not only increases the sensitivity of Raman spectroscopy but also allows a person to study specifically the vibrational spectrum of a selected aromatic group or other structure within a macromolecule. Problems associated with the technique are fluorescence, which may be 10^6 times as strong as the Raman emission, and photochemical damage from the intense laser beam. Fluorescence is often quenched with KI (see Section C,1).

If the exciting laser has a frequency ν_0 and the frequency of a vibrationally excitation in a molecule is ν_1 the Raman spectrum will contain a pair of bands,

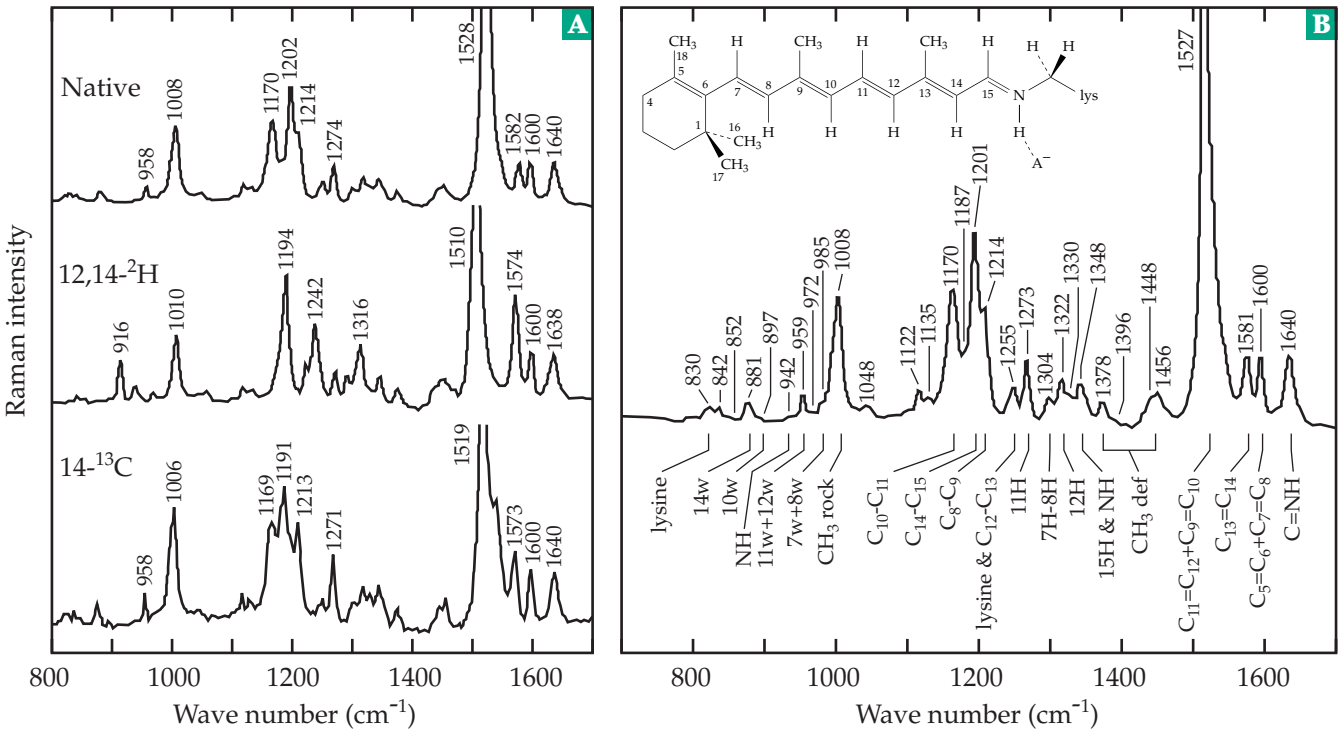

Figure 23-5 Resonance Raman spectra. (A) Of the retinaldehyde-containing bacteriorhodopsin bR_{568} (see Fig. 23-45) and its 12,14-^{2}H and 14-^{13}C isotopic derivatives. the stronger one or "stokes" band of energy $h(\nu_0 - \nu_1)$ and a weaker one or "anti-stokes" band of $h(\nu_0 + \nu_1)$. Special techniques such as **coherent anti-stokes** Raman scattering provide a means of getting around the fluorescence problem.[13,36,38] Raman spectroscopy is also possible with excitation of ultraviolet absorption bands. It can be applied to peptides,[39–41] tryptophan or tyrosine residues of proteins,[42] nucleic acid bases,[43–45] heme proteins,[46–48] other metalloproteins,[49] flavin coenzymes,[50–52] pyridoxal phosphate,[53,54] flavoproteins,[54a] carotenoid-containing proteins,[55] and to substrates undergoing cleavage in the active site of papain.[56] Resonance Raman spectroscopy is very useful in the study of adducts of CO, NO, and O_2 with heme proteins because coupled vibrational modes of both the porphyrin rings and axial ligands can be observed.[56a,b] Resonance Raman spectra are strongly amplified for samples adsorbed to specially prepared colloidal silver particles.[57] Examples of resonance Raman spectra are shown in Fig. 23-5.

4. Electronic Spectra

Biochemists make extensive use of spectroscopy in the ultraviolet (UV) and visible range. Visible light begins at the red end at ~12,000 cm^{-1} (800 nm) and extends to 25,000 cm^{-1} (400 nm). The ultraviolet range begins at this point and extends upward, the upper limit accessible to laboratory spectrophotometers being ~55,000 cm^{-1} (180 nm). The energies covered in the visible–UV range are from ~140 to ~660 kJ/mol. The latter is greater than the bond energy of all but the strongest double and triple bonds (Table 6-7). It is understandable that UV light is effective in inducing photochemical reactions. Even the lower energy red light, which is used by plants in photosynthesis, contains enough energy per einstein to make it feasible to generate ATP, to reduce $NADP^+$, and to carry out other photochemical processes. Although the energies of light absorbed in electronic transitions are large, the geometry of molecules in the excited states is often only slightly altered from that in the ground state. The amount of vibration is increased, and the molecule usually expands moderately in one or more dimensions.

The significance of light absorption in biochemical studies lies in the great sensitivity of electronic energy levels of molecules to their immediate environment and to the fact that spectrophotometers are precise and sensitive. The related measurements of circular dichroism and fluorescence also have widespread utility for study of proteins, nucleic acids, coenzymes, and many other biochemical substances that contain intensely absorbing groups or **chromophores**.[58]

Shapes of absorption bands. Electronic absorption bands are usually quite broad, the width of the band at half-height often being 3000–4000 cm^{-1}. The breadth arises largely from the coupling of electronic excitation to changes in the vibrational and rotational energy levels. Inhomogeneity of environments in the solvent also contributes. Shapes of absorption bands are to a large extent determined by the **Franck–Condon principle**, which states that no significant change in the positions of the atomic nuclei of the molecule occurs during the time of the electronic transition. Since the frequency of light absorbed during these transitions is ~10^{15} to 10^{16} s^{-1}, the absorption of light energy occurs within 10^{-15} to 10^{-16} s, the time equivalent to the passage of one wavelength of light. During this period the vibrational motions of the nuclei are almost insignificant because of the much lower frequencies of vibration. Two types of potential energy curves for excited states of molecules are shown in Fig. 23-6.[2] In the first the geometry of the molecule is little changed between ground state and excited state. At room temperature most molecules are in the lowest energy states of at least the most energetic of the various vibrational modes of the molecule ($3/2\ k_BT$ ~300 cm^{-1}). Therefore, the most probable transitions occur from the lowest vibrational states of the ground electronic states. The most probable internuclear distance for a molecule in the ground state is the equilibrium distance r_e (Fig. 23-2). Since that distance is the same in all of the vibrational levels of the electronically excited state, transitions to any of these states may occur. The transition to the first vibrational level of the excited state is most likely. The result is an absorption spectrum in which the sharp band representing the "0–0 transition" is most intense and in which there are progressively weaker bands corresponding to the 0–1, 0–2, 0–3, etc., transitions (Fig. 23-6A). Many organic dyes with long series of conjugated double bonds have spectra of this type.[59,60]

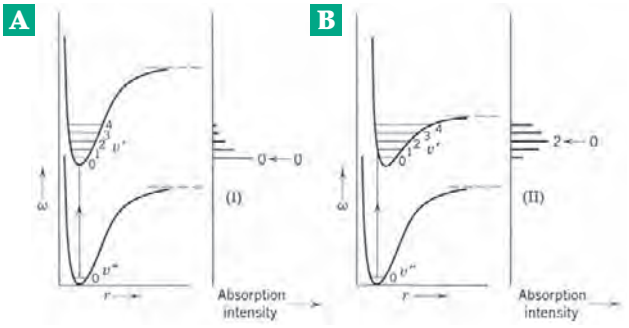

Figure 23-6 Typical potential energy curves for two types of band spectra: (A) For a transition in which the equilibrium internuclear distances r_e are about equal in the ground and excited states. (B) For a transition in which r_e' (excited state) > r_e (ground state). From Calvert and Pitts,[2] p. 179.

A second type of spectrum is illustrated in Fig. 23-6B. In this instance, the molecule has expanded in the excited state, and r_e is greater than in the ground state. The Franck–Condon principle suggests that a transition is likely only to those vibrational levels of the excited state in which the internuclear distance is compressed for a significant fraction of the time, approximately to that of r_e in the ground state. Examination of Fig. 23-6B explains why the resulting absorption spectra tend to have weak 0–0 bands and stronger bands corresponding to transitions to higher levels.

For real spectra of polyatomic molecules the situation is more complex. Some molecules in the ground state do occupy higher vibrational levels of the less energetic modes. Therefore, there will be weaker lines, some of which lie on the low-energy side of the 0–0 transition. Since in polyatomic molecules there are several normal modes of vibration, there will be other progressions of absorption bands paralleling those shown in Fig. 23-6 and filling in the valleys between them. All of the bands are broadened by rotational coupling and by interactions with solvent.

An example of a molecule giving a spectrum of the type shown in Fig. 23-6B is toluene. The vapor phase spectrum contains a large number of sharp lines, some of which can be seen in the low-resolution spectrum of Fig. 23-7. Several progressions can be identified.[61] One begins with the intense 0–0 line at 37.48×10^3 cm^{-1} and in which spacing of ~930 cm^{-1} between lines corresponds to a vibration causing symmetric expansion of the ring (ring breathing frequency), a frequency that can also be observed in the infrared spectrum. Other progressions beginning at the 0–0 line involve additional modes of vibration with frequencies (in the excited electronic state) of 460, 520, and 1190 cm^{-1}. Additional weaker bands are "buried" in the valleys in Fig. 23-6. When the spectrum of toluene is measured in solution, the sharp lines are broadened, but there are still indications of vibrational structure.

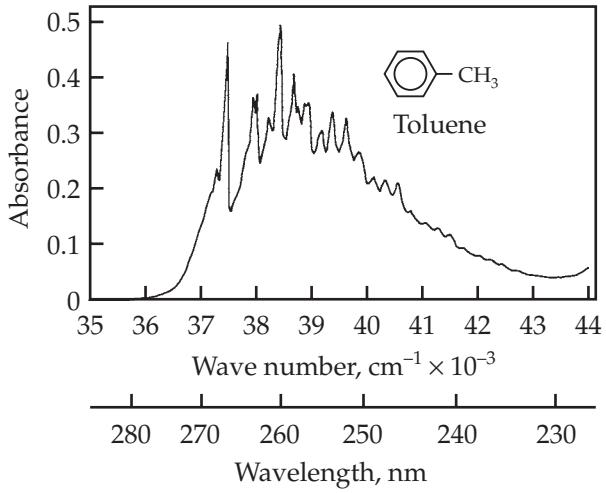

Figure 23-7 The spectrum of the first electronic transition of toluene vapor at low resolution. Cary 1501 spectrophotometer.

Gaussian curves (normal distribution functions) can sometimes be used to describe the shape of the overall envelope of the many vibrationally induced subbands that make up one electronic absorption band, e.g., for the absorption spectrum of the copper-containing blue protein of *Pseudomonas* (Fig. 23-8) Gaussian bands are appropriate. They permit resolution of the spectrum into components representing individual electronic transitions. Each transition is described by a **peak position**, **height** (molar extinction coefficient), and **width** (as measured at the half-height, in cm^{-1}). However, most absorption bands of organic compounds are not symmetric but are skewed

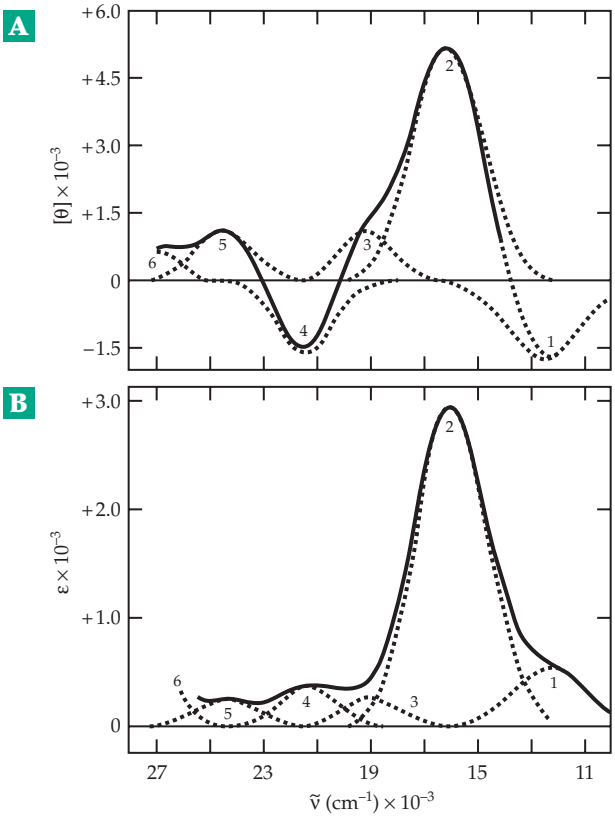

Figure 23-8 Resolution of the visible circular dichroism (ellipticity) spectrum (A) and absorption spectrum (B) of the *Pseudomonas* blue protein into series of overlapping Gaussian bands (—). The numbers 1 to 6 refer to bands of identical position and width in both spectra. Absorption envelopes resulting from the sum of the set of overlapping Gaussian bands (—) correspond within the error of the measurement to the experimental spectra. The *dashed part* of the CD envelope above 700 nm was completed by a curve fitter with the use of a band in the position of *band 1* of the absorption spectrum. From Tang *et al.*[68]

toward the high-energy side. It is best to fit such bands with a skewed function such as the **log normal** distribution curve.[62–64] In addition to position, height, and width, a fourth parameter provides a measure of **skewness**. Computer-assisted fitting with log normal curves gives precise values for the positions, widths, and intensities. In general, the peak position is somewhat to the high-energy side of the 0–0 transition.

Absorption spectra plotted as a linear function of wavelength are sometimes fitted with Gaussian curves. However, Gaussian curves only occasionally give a good fit for such spectra, and it is undesirable to measure bandwidths in nanometers. It is wave number that is proportional to energy. Spectral bands tend to have similar widths across the visible–ultraviolet range when plotted against wave number but not when ploted against wavelength. Another approach to the quantitative description of spectra is to fit the major progressions of vibrational subbands with series of narrow Gaussian curves.[65–67]

Classification of electronic transitions. The intense 600-nm absorption band of the copper blue protein in Fig. 23-8 is attributed to a d–d transition of an electron in the metal ion from one d orbital to another of higher energy.[68] The intensity is thought to arise from transfer of an electron from a cysteine thiolate to the copper (p. 883). The electronic transitions in most organic molecules are of a different type. Transitions lying at energies <55,000 cm^{-1} are classified as either π–π^* or n–π^*. In the π–π^* transitions an electron is moved from a bonding π molecular orbital to an antibonding (π^*) orbital. Such a transition is present in ethylene at 61,540 cm^{-1} (162.5 nm) with a maximum molar extinction coefficient ε_{max} of ~15,000 M^{-1} cm^{-1}. An n–π^* transition results from the raising of an electron in an unshared pair of an oxygen or nitrogen atom into a π^* antibonding orbital. These transitions are invariably weak. For example, acetone in H_2O shows an n–π^* transition at 37,740 cm^{-1} (265 nm). The value of ε_{max} is ~240 and the width is about 6400 cm^{-1}. A characteristic of n–π^* transitions is a strong shift to lower energies as the compound is moved from water into less polar solvents. For example, the peak of the acetone band lies at 36,920 cm^{-1} in methanol and at 35,970 cm^{-1} (278 nm) in hexane. Such a solvent shift is often taken as diagnostic of an n–π^* transition, and it is often stated that the π–π^* bands shift in the opposite direction upon change of solvent character. However, the latter is not true for many of the polar chromophores found in biochemical substances. Thus, the π–π^* bands of tyrosine also shift to lower energies when the molecule is moved from water into hexane. However, the magnitude of the shift is much less than for the n–π^* band of acetone.

A molecule can have several different excited states of increasing energies. In benzene and its derivatives there are three easily detectable π–π^* transitions (see Fig. 3-13). The first is a weak band centered at ~260 nm in toluene (Fig. 23-7) and ~275 nm in tyrosine (Fig. 3-13) with $\varepsilon = 10^2$ to 10^3. The second is a band at a higher frequency (at 1.35 0.10 times the frequency of the first band) with ε_{max} often as high as 10^4. The third band is found at still higher energies with ε_{max} reaching 5×10^4. The excited-state energy levels represented by these transitions were labeled ^1L_b, ^1L_a, and ^1B_a by Platt. Other authors described the levels in terms of the symmetries of the molecular orbitals, the ground state being $^1A_{1g}$, and the three excited states $^1B_{2u}$, $^1B_{1u}$, and $^1E_{1u}$. In these symbols the superscript 1 indicates that the excited states are **singlet** in nature; that is, the electrons remain paired in the excited states. Absorption of visible and ultraviolet light almost always leads to singlet excited states initially. For more complex ring systems the number of possible electronic transitions increases, but attempts are often made to relate these transitions back to those of benzene.

The intensities of electronic transitions vary greatly. The area ($\mathcal{A}$) under the absorption band, when ε is plotted against wave number $\bar{\nu}$, is directly proportional (Eq. 23-6) to a dimensionless quantity called the **oscillator strength** f.

$$f = \frac{2.303\, m_e c^2}{\pi N e^2} F\mathcal{A} = 4.32 \times 10^{-9}\, F\mathcal{A} \qquad (23\text{-}6)$$

In this equation m_e and e are the mass and charge of the electron, c is the velocity of light, N is Avogadro's number, and $\mathcal{A}$ is the area in a plot of ε vs ν in cm^{-1}; F is a dimensionless correction factor that is related to the refractive index of the medium and is near unity for aqueous solutions. If the area is approximated as that of a triangle of height ε_{max} and width (at half-height) W, we find that for a typical absorption band of $\varepsilon_{max} = 10^4$ and $W = 3000$ cm^{-1}, $f = 0.13$.

The oscillator strength is related to the probability of a transition and can become approximately 1 only for the strongest electronic transitions. However, it is rarely this high. For example, the oscillator strength is $\sim 10^{-4}$ for Cu^{2+} and $\sim 2 \times 10^{-3}$ for the toluene absorption band shown in Fig. 23-7. The low intensity of absorption bands of benzene derivatives is related to the fact that these transitions are quantum mechanically forbidden for a completely symmetric molecule. It is only because of coupling with asymmetric vibrations of the ring that the ^1L_b transition of benzene becomes weakly allowed. In the benzene spectrum the 0–0 transition is completely absent, and only those progressions involving uptake of an additional 520 cm^{-1} of a nonsymmetric vibrational energy are observed. In the case of toluene and phenylalanine, the asymmetry of the ring introduced by the substituents permits the 0–0 transition to occur and leads to a higher oscillator

strength than that observed with benzene. The ^1L_a transition of benzenoid derivatives is also partially forbidden by selection rules, and only the third band begins to approach an oscillator strength of one.

Use of plane polarized light. The intensity of a spectral transition is directly related to the **transition dipole moment** (or simply the transition moment), a vector quantity that depends upon the dipole moments of the ground and excited states. For aromatic ring systems, the transition dipole moments of the π–π* transitions lie in the plane of the ring. However, both the directions and intensities for different π–π* transitions within a molecule vary.

The transition moment has a dimension of length (usually given in angstroms) and can be thought of as a measure of the extent of the charge migration during the transition. Light is absorbed best when the directions of polarization (i.e., of the electric vector of the light) and of the transition moment coincide. This fact can easily be verified by light absorption measurements on crystals. As with infrared spectra of oriented peptide chains (Fig. 23-3), the electronic spectra of crystals display a distinct dichroism. Crystals of coenzyme-containing proteins (Fig. 23-9) are very appropriate for spectroscopy with polarized light because the chromophores are spaced far enough apart to avoid electronic interaction and have absorbances low enough to record with crystals of the order of 0.1 mm thickness.[69,70]

In contrast to π–π* transitions, the *n*–π* transitions of heterocyclic compounds and carbonyl-containing rings are often polarized in a direction perpendicular to the plane of the ring. Linear dichroism of cytosine, adenine, and other nucleic acid bases has been measured on single crystals and in partially oriented polymer films.[71] Magnetically induced linear dichroism provides a new tool for study of metalloproteins.[72]

Relationship of absorption positions and intensity to structures. While quantum mechanical calculations permit prediction of the correct number and approximate positions of absorption bands, they are imprecise. For this reason, electronic spectroscopy also relies upon a combination of empirical rules and atlases of spectra that can be used for comparison purposes.[74–76] The following may help to orient the student. The position of an absorption band shifts **bathochromically** (to longer wavelength, lower energy) when the number of conjugated double bonds increases. Thus, **butadiene** absorbs at 46,100 cm^{-1} (217 nm) vs the 61,500 cm^{-1} of ethylene. As the number of double bonds increases further, the bathochromic shifts become progressively smaller (but remain more nearly constant in terms of wavelength than wave number). For **lycopene** (Fig. 23-10) with 11

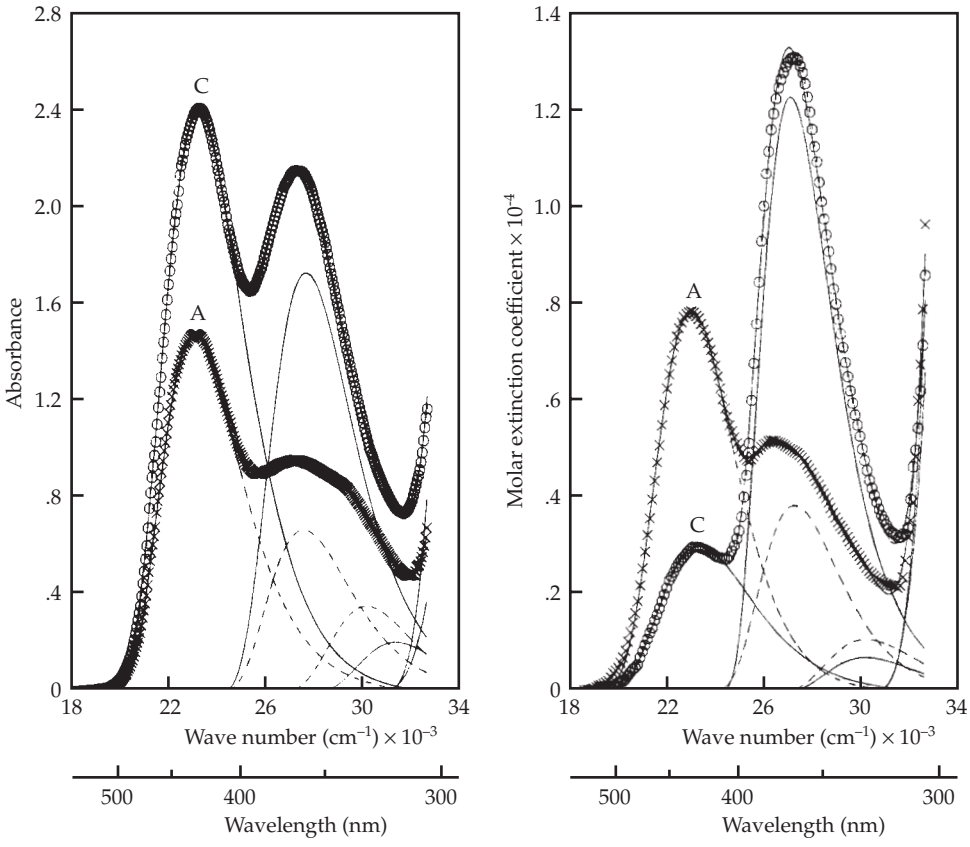

Figure 23-9 Polarized absorption spectra of orthorhombic crystals of cytosolic aspartate aminotransferase. The light beam passed through the crystals along the *b* axis with the plane of polarization parallel to the *a* axis (A) or the *c* axis (C). Left, native enzyme at pH 5.4; right, enzyme soaked with 300 mM 2-methylaspartate at pH 5.9. The band at ~430 nm represents the low pH protonated Schiff base form of the enzyme. Upon soaking with 2-methylaspartate the coenzyme rotates ~30° to form a Schiff base with this quasisubstrate. The result is a large change in the *c*/*a* polarization ratio. The ~364 nm band in the complex represents the free enzyme active site in the second subunit of the dimeric enzyme.[70,73] Courtesy of C. M. Metzler.

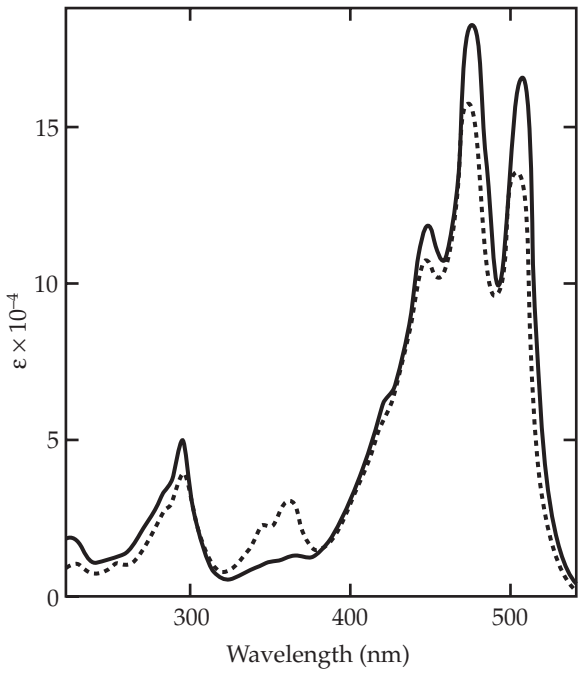

Figure 23-10 The absorption spectrum of lycopene (plotted vs wavelength). Note the vibrational structure, which has a spacing of ~1200–1500 cm^{-1}. The solid line is for all-translycopene while the dashed line is that of the sample after refluxing 45 min in the dark. The new peak at ~360 nm arises from isomers containing some cis double bonds.

conjugated double bonds the absorption band is located at 21,300 cm^{-1} and displays distinct vibrational structure (Fig. 23-10). Certain ring molecules such as the porphyrins and chlorophylls have spectra that can be related back to those of the linear polyenes. Note (Fig. 16-7) that the porphyrin α and β bands represent vibrational structure of a single electronic transition, whereas the intense Soret band results from a different transition.

Substituted benzenes almost invariably absorb at lower energies than the parent hydrocarbon. The stronger the electron withdrawing or donating ability of the substituent, the larger the bathochromic shift. The magnitude of the shift has been correlated with the Hammett σ constants. Thus, the first absorption band of tyrosine in water is shifted 2600 cm^{-1} toward the red from that of benzene, while that of the dissociated tyrosine anion is shifted 4700 cm^{-1}, very roughly in proportion to the σ_p values of Box 6-C. Especially large shifts are observed when functional groups of opposite types (that is, an electron donating group vs an electron accepting group) are both present in the same ring. The effects of ortho and meta substituent pairs are closely similar (in contrast to the differing electronic effects of ortho and meta pairs in chemical reactivity). Substituent pairs in para positions yield somewhat different spectral shifts. When there are more than two substituents, the two strongest groups often dominate in determining the character of the spectrum. Useful empirical rules have been developed.[77,78]

Spectra of proteins and nucleic acids. Most proteins have a strong light absorption band at 280 nm (35,700 cm^{-1}) which arises from the aromatic amino acids tryptophan, tyrosine, and phenylalanine (Fig. 3-14). The spectrum of phenylalanine resembles that of toluene (Fig. 23-7),[61] whose 0–0 band comes at 37.32 x 10^3 cm^{-1}. The vibrational structure of phenylalanine can be seen readily in the spectra of many proteins (e.g., see Fig. 23-11A). The spectrum of tyrosine is also similar (Fig. 3-13), but the 0–0 peak is shifted to a lower energy of ~35,500 cm^{-1} (in water). Progressions with spacings of 1200 and 800 cm^{-1} are prominent.[79] The low-energy band of tryptophan consists of two overlapping transitions ^1L_a and ^1L_b.[65] The ^1L_b transition has well-resolved vibrational subbands, whereas those of the ^1L_a transition are more diffuse. Tryptophan derivatives in hydrocarbon solvents show 0–0 bands for both of these transitions at approximately 289.5 nm (34,540 cm^{-1}). However, within proteins the ^1L_a band may be shifted 3–10 nm (up to 1100 cm^{-1}) toward lower energies, probably as a result of hydrogen bonding to other groups in the protein. The largest shifts can occur when the NH group of the indole ring is hydrogen bonded to COO^-, a ring nitrogen of histidine, or a carbonyl group of amides.[80] In an aqueous medium the ^1L_b band of tryptophan is shifted to higher energies and the ^1L_a band to lower energies than in a hydrocarbon solvent.

In addition to the three aromatic amino acids, disulfide bonds absorb in the near ultraviolet region as indicated in Fig. 3-14. Since the absorption characteristics depend upon the dihedral angles in the disulfide bridges, it is difficult to accurately evaluate the contribution of this chromophore to the 280-nm band.

Tyrosine, tryptophan, and phenylalanine all have additional transitions in the high-energy UV region of the spectrum (Fig. 3-13). Even more intense are the absorption bands of the amide groups, which become significant above 45,000 cm^{-1}.[81] These include a weak $n-\pi^*$ transition at ~45,500 cm^{-1} (210 nm) overlapped by a strong $\pi-\pi^*$ transition at ~52,000 cm^{-1} (192 nm).[82] Histidine also has absorption bands in this region.

As with polypeptides, the light absorption properties of polynucleotides reflect those of the individual components. The spectra of the purine and pyrimidine bases as ribonucleosides are shown in Fig. 5-5. The number of individual electronic transitions and their origins are not immediately obvious, but many measurements in solutions and in crystals, as well as theoretical computations,[7,83,84] have been made. Cytosine has $\pi-\pi^*$ transitions at ~275, 230, 200, and

185 nm,[83] the two highest energy bands being overlapped. Adenine derivatives have seven $\pi-\pi^*$ transitions.[71] Spectra of flavins contain at least four intense transitions (Fig. 15-8).[85]

Whereas proteins have their low energy absorption band at ~280 nm, polynucleotides typically have maxima at ~260 nm (38,500 cm^{-1}). A phenomenon of particular importance in the study of nucleic acids is the **hypochromic effect**. In a denatured polynucleotide the absorption is approximately the sum of that of the individual components. However, when a double helical structure is formed and the bases are stacked together, there is as much as a 34% depression in the absorbance at 260 nm. This provides the basis for optical measurement of DNA melting curves (Fig. 5-45).[45,86] The physical basis for the hypochromic effect is found in dipole–dipole interactions between the closely stacked base pairs.[7,86,87]

Difference spectra and derivative spectra. Changes in light-absorbing properties of proteins and nucleic acids are often measured as a function of some quantity such as pH, temperature, ionic environment, or the presence or absence of another interacting molecule. The induced changes in the spectrum are small but can be seen if the *difference* between the two spectra, one "unperturbed" and the other in the presence of some "perturbant," is recorded. The perturbant might be an additional reagent, an altered solvent (e.g., with added glycerol, D_2O), a change in pH, or temperature. The difference spectrum shown in Fig. 23-11B arises from the binding of an inhibitor succinate together with a substrate carbamoyl phosphate to the catalytic subunit of aspartate carbamoyltransferase (Fig. 7-20).[88] The difference spectrum appears as a pair of peaks and a valley in the aromatic amino acid region. With proper interpretation (caution!) difference spectra can be used to infer something about the change in environment of aromatic amino acids in a protein.[89]

Difference spectra are usually recorded by placing the unperturbed spectrum in the *reference* light beam of a spectrophotometer and the perturbed solution in the *sample* beam in carefully matched cuvettes. However, the spectrum shown in Fig. 23-11B was obtained by recording the two spectra independently and subtracting them with the aid of a computer. The same data have been treated in another way by fitting two log normal curves (p. 1283) to the absorption bands and plotting the differences between the mathematically

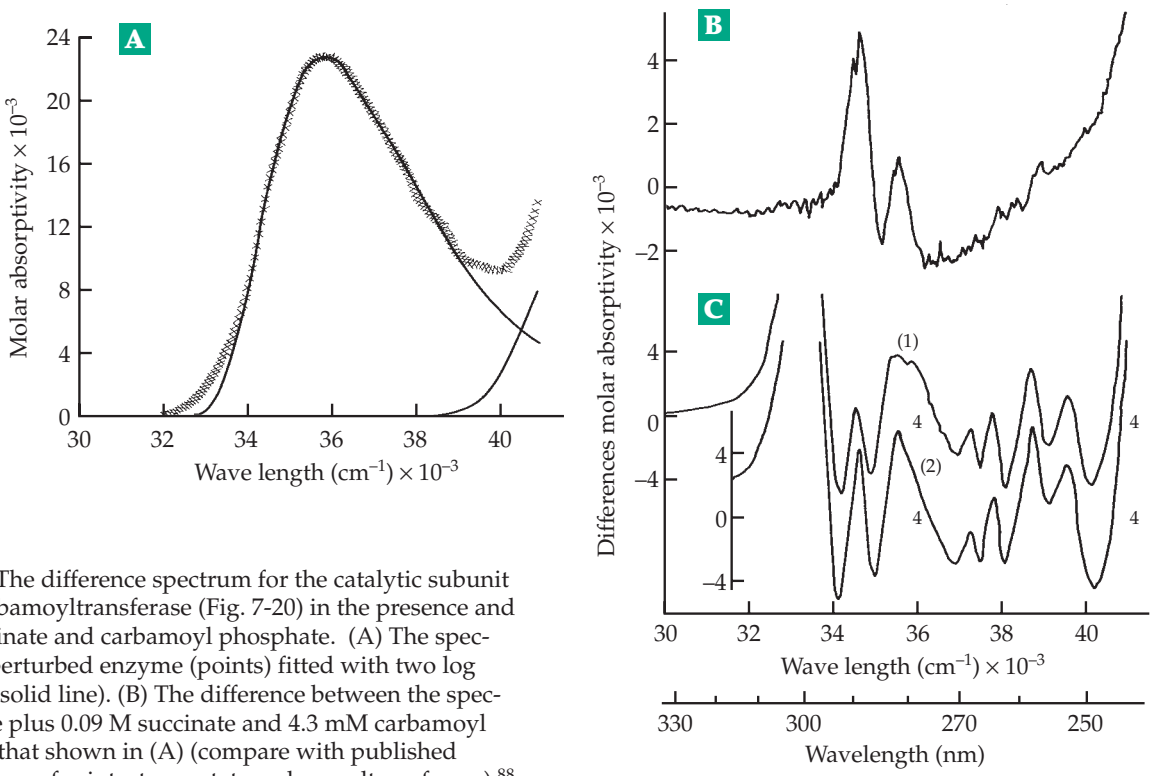

Figure 23-11 The difference spectrum for the catalytic subunit of aspartate carbamoyltransferase (Fig. 7-20) in the presence and absence of succinate and carbamoyl phosphate. (A) The spectrum of the unperturbed enzyme (points) fitted with two log normal curves (solid line). (B) The difference between the spectrum of enzyme plus 0.09 M succinate and 4.3 mM carbamoyl phosphate and that shown in (A) (compare with published difference spectrum for intact aspartate carbamoyltransferase).[88] (C) Curve 1, "fine structure plot" obtained by subtracting the spectrum in A from the smooth curve obtained by summing the two log normal curves. Curve 2, a similar plot for enzyme plus succinate and carbamoyl phosphate. The enzyme was supplied by G. Nagel and H. K. Schachman and the spectra were recorded by I.-Y. Yang.

smooth fitted curve and the experimental points taken at close intervals[90,91] as shown in Fig. 23-11C. The two "fine structure plots" obtained in this way are an alternative way of representing the same data that gave rise to the difference spectrum. The method has the advantage that information about the overall band shape is obtained from the computer-assisted curve fitting process. Thus, the binding of succinate and carbamoyl phosphate caused an almost insignificant shift (of 20 cm^{-1}) in the overall band position and a very slight broadening. The principal effect is an enhancement in the vibrational structure at 34,600 cm^{-1} in the 0–0 band of the two tryptophan residues present in the subunit. The cause of this change is not entirely obvious, a weakness of difference spectroscopy. Another way of examining a spectrum such as that in Fig. 23-11A is to plot a mathematical derivative of the curve. Both second[92] and fourth derivatives[91,93,94] yield curves similar to the difference plots of Fig. 23-11C.

5. Circular Dichroism and Optical Rotatory Dispersion

The circular dichroism of a sample is the difference between the molar extinction coefficients for left-handed and right-handed polarized light (Eq. 23-7) and is observed only for chiral molecules.[7,95–97]

$$\Delta\varepsilon = \varepsilon_L - \varepsilon_R \quad (\text{units are } M^{-1}\ cm^{-1}) \tag{23-7}$$

The **dichrograph** gives a direct measure of $\Delta\varepsilon$. A circular dichroism (CD) spectrum often resembles an absorption spectrum, the peaks coming at the same positions as the peaks in the absorption spectrum of the same sample. However, the CD can be either positive or negative and may be positive for one transition and negative for another (Fig. 23-8). It is most convenient to plot $\Delta\varepsilon$ directly as a function of wavelength or wave number. However, much of the literature makes use of the **molar ellipticity** (Eq. 23-8):

$$\text{Molar ellipticity} = [\theta] = 3299\ \Delta\varepsilon \quad (\text{units are degrees } cm^2\ \text{decimole}^{-1}) \tag{23-8}$$

The **rotational strength** may also be evaluated (Eq. 23-9):

$$\text{Rotational strength} = \int [(\Delta\epsilon)/\lambda] d\lambda \tag{23-9}$$

The integration is carried out over the entire absorption band for a given transition.

Circular dichroism is closely related to **optical rotatory dispersion**, the variation of optical rotation with wavelength. Optical rotation depends upon the difference in refractive index ($\eta_L - \eta_R$) between left-handed and right-handed polarized light. Rotation α is measured as an angle in degrees or radians. Data are customarily reported in terms of **specific rotation**, that of a hypothetical solution containing 1 g / ml in a 1 dm (decimeter) tube. Specific rotation is calculated (Eq. 23-10) from the observed rotation, the concentration c' in g ml^{-1}, and the length of the tube l' in decimeters.

$$\text{Specific rotation} = [\alpha] = \alpha_{obs} / c'l' \tag{23-10}$$

The **molecular rotation** is defined by Eq. 23-11 in which M_r is the molecular mass and c and l are in moles per liter and cm, respectively.

$$\begin{aligned}\text{Molecular rotation} = [\phi] &= 100\ \alpha_{obs} / cl \\ &= [\alpha]\ M_r / 100\end{aligned} \tag{23-11}$$

It is often multiplied by a factor of $3/(\eta^2 + 2)$ to correct for a minor effect of the polarizability of the field acting on the molecules. The rotation in the radians per centimeter of light path can be related (Eq. 23-12) directly to the wavelength of the light and the refractive indices η_L and η_R.

$$\alpha\ (\text{radians / cm}) = [\alpha]\ c' / 1800 = \pi / \lambda [\eta_L - \eta_R] \tag{23-12}$$

In contrast to circular dichroism, optical rotary dispersion (ORD) extends far from absorption bands into spectral regions in which the compound is transparent. As an absorption band is approached, the optical rotation increases in either the positive or negative direction. Then, within the absorption band it drops abruptly through zero and assumes the opposite sign on the other side of the band (the Cotton effect). Although the occurrence of optical rotation in nonabsorbing regions of the spectrum provides an advantage to ORD measurements, the interpretation of ORD spectra is more complex than that of CD spectra. In principle, the two can be related mathematically and both are able to give the same kind of chemical information.[7]

The CD in the d–d bands of the blue copper protein (Fig. 23-8) arises in part from the fact that within the protein the copper ion is in an asymmetric environment. For a similar reason, the aromatic amino acids of proteins often give rise to circular dichroism. In the case of tyrosine, the sign of the CD bands can be either positive or negative but is the same throughout a given transition. The CD bands are similar in shape to the absorption bands.[36,98] The behavior of phenylalanine is more complex. The progression of vibrational subbands at 930 cm^{-1} intervals above the 0–0 band all have the same sign, and the intensities relative to that of the 0–0 band are similar to those in absorption. However, the vibrations of wave numbers equal to

that of the 0–0 transition plus 180 and 520 cm^{-1} sometimes give rise to CD bands of the opposite sign, and the relative intensity relationships are variable.[61,98]

The binding of a symmetric chromophore to a protein or nucleic acid often induces CD in that chromophore. For example, the bands of enzyme-bound pyridoxal and pyridoxamine phosphates shown in Fig. 14-9 are positively dichroic in CD, but the band of the quinonoid intermediate at 20,400 cm^{-1} (490 nm) displays negative CD. When "transimination" occurs to form a substrate Schiff base (Eq. 14-26), the CD is greatly diminished. While the coenzyme ring is known to change its orientation (Eq. 14-39; Fig. 14-10), it is not obvious how the change in environment is related to the change in CD.

A series of octant rules make it possible to predict the sign and magnitude of CD to be expected for $n-\pi^*$ transitions of simple carbonyl compounds.[99] Theoretical approaches to the CD and ultraviolet absorption of proteins in the high-energy ultraviolet region have also been developed. In a regular β structure, in an α helix or in a crystalline array, the transitions of adjacent amide groups may be **coupled**, the excitation energy being delocalized. This **exciton** delocalization leads to a splitting (Davydov splitting) into two transitions of somewhat different energies and polarized in different directions.[7,9] The amide absorption band at 52,600 cm^{-1} is split in an α helix into components at ~48,500 and 52,600 cm^{-1}. Furthermore, low-energy $\pi-\pi^*$ and $n-\pi^*$ states are close together in energy, a fact that allows mixing of the two states and appearance of rotational strength in the $\pi-\pi^*$ band with a sign opposite to that in the $n-\pi^*$ band.[100]

Both the sign and intensity of the CD bands of peptides also depend upon conformation. Well-defined differences are observed among α helices, β structure, and random-coil conformations. Measurements may be extended into the "vacuum ultraviolet" region—up to 60,000 cm^{-1} in aqueous solutions.[101] A useful empirical approach is to deduce spectra of helices, β structures, and unordered peptide chains from measured spectra together with an examination of actual structures obtained by X-ray crystallography[7,95,97,102,103] (Fig. 23-12). Note that the CD curve for the α helix has a deep minimum at 222 nm, whereas the β form has a shallower minimum. The random structure has almost no CD at the same wavelength. The approximate helix content of a protein is often estimated from the depth of the trough at 222 nm in the CD spectrum. Better predictions can be made by using a computer-assisted comparison of an experimental CD spectrum with those of a series of proteins of known 3-D structure.[7]

The circular dichroism of polynucleotides at 275 nm is a linear function of both the helix winding angle and the base pair twist.[103] Measurement of CD spectra on large polynucleotides or large molecular aggregates

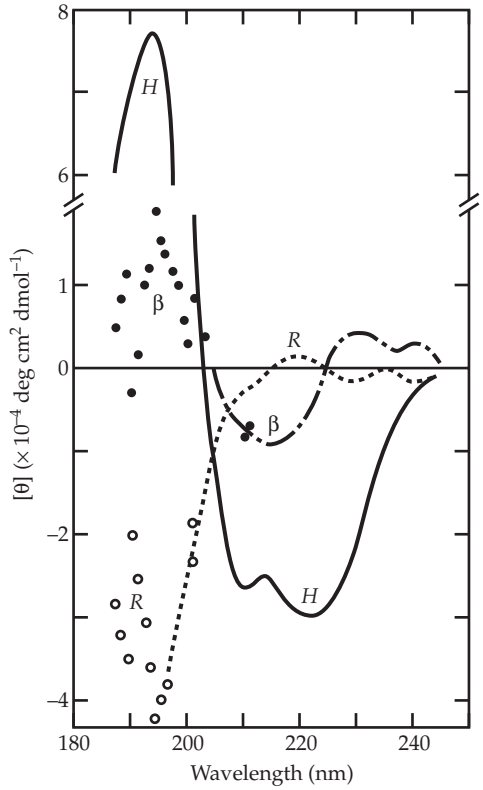

Figure 23-12 Circular dichroism of the helix (H), β, and unordered (R) form computed from the CD of five proteins. Points are plotted when a smooth curve could not be drawn. From Y.-H. Chen *et al.*[102]

is complicated by differential light scattering of right and left circularly polarized light. However, the phenomenon can also provide new structural information.[104] Progress has been made in attempts to predict the optical rotation of molecules from quantitative values for the polarizabilities of individual atoms.[105–109]

Vibrational circular dichroism involves IR absorption bands. The technique has been applied to sugars,[110] oligosaccharides,[111] proteins,[112] and nucleic acids.[113] The related **vibrational Raman optical activity** has also been applied to polyribonucleotides.[114]

6. Photoacoustic Spectroscopy

Photoacoustic spectra are recordings of the energy emitted as heat after absorption of monochromatic light. The sample is placed in a closed photoacoustic cell. The light beam, which is chopped at an audiofrequency, induces a periodic heating and cooling of the gas in contact with the sample in the cell. This is sensed as sound by a sensitive microphone. The

resulting electrical signals are sent to a computer for analysis. The output is an absorption spectrum resembling that measured optically. The samples do not have to be transparent.[5] A related technique is photoacoustic calorimetry.[115,116]

7. X-Ray Absorption and Mössbauer Spectroscopies

The importance of X-ray diffraction (discussed in Chapter 3) to biochemistry is obvious, but techniques related to absorption of X-rays and γ-rays have also come into widespread use.[117] Abbreviations such as **XANES** and **EXAFS** are common in the metalloprotein literature. The names arise from the sharp increase in the absorption coefficient for X-rays as their energy is increased to what is called the **K absorption edge**. At slightly lower energies absorption of an X-ray by an atom leads to expulsion of an electron or the raising of an electron to an excited state. Absorption of X-rays will expel all except the inner 1*s* electrons. As the energy is increased further, the stepwise increase in absorption that constitutes the edge is observed. At higher energies the absorption decreases. However, with a high-resolution instrument distinct oscillations are observed on the high-energy side of the edge, extending for ~20 eV. This is **X-ray absorption near-edge structure** (XANES). When an X-ray absorbing atom in a molecule is surrounded by other atoms, a fine structure that depends upon the nature of these atoms and their distances from the absorbing atom is observed over a range of several hundred electron volts above the edge. This is **extended X-ray absorption fine structure** (EXAFS).[117]

The EXAFS technique has been especially useful for metalloproteins. It has often provided the first clues as to the identity of atoms (O, N, S) surrounding a metal atom and either covalently bonded to it or coordinated with it (Chapter 16). Interpretations are often difficult, and a common approach is to try to simulate the observed spectrum by calculation from a proposed structure.[118] Tautomerism in crystalline Schiff bases (see Eq. 23-24) has been studied by near-edge X-ray absorption fine structure (NEXAFS) employing soft X-rays.[119]

Mössbauer spectroscopy, also called recoil-free nuclear resonance absorption, depends upon resonant absorption of γ-rays emitted by a radioactive source by atomic nuclei.[120] The phenomenon was initially difficult to observe, but the German physicist Mössbauer devised a way in which to record the absorption of a quantum of energy equal to the difference in two energy states of the atomic nucleus. The method depends upon a Doppler effect observed when the sample or source moves. Consequently, Mössbauer spectra, such as that in Fig. 16-18, are plots of absorption versus velocity. Mössbauer spectroscopy has been applied to numerous metalloproteins, especially those containing iron centers. It is a major tool in investigation of Fe–S proteins.[121,122] Since ^{56}Fe is "silent" in Mössbauer spectroscopy, proteins are often enriched with ^{57}Fe for observation.

C. Fluorescence and Phosphorescence

An electronically excited molecule is able to lose its excitation energy and return to the ground state in several ways. One of these is to reemit a quantum of light as fluorescence.[7,123–127] The intensity and spectral properties of fluorescent emission can be measured by illuminating a sample in a cuvette with four clear faces with the measuring photomultiplier set at right angles to the exciting light beam. In absorption spectrophotometry we measure a difference between the light intensity of the beam entering the sample and that emerging from the sample. In fluorescence spectroscopy we measure the absolute intensity of the light emitted. Although this intensity is small, the measurement can be made extremely sensitive, far more so than can light absorption. For this reason, fluorescence is widely used for detection and analysis, e.g., in DNA sequencers. Enzyme kinetics can be studied with fluorescent substrates at very low concentrations.[127a] Fluorescent antibodies, DNA chips, and numerous bioassay and imaging methods are dependent upon measurement of fluorescence. Fluorescence can also yield a wealth of information about the chemical and physical properties of electronically excited states of molecules.

1. Excitation and Emission Spectra

Measurements of the intensity of fluorescence at any wavelength vs the wavelength of monochromatic light used to excite the fluorescence give a fluorescence **excitation spectrum**. The excitation spectrum is an example of an **action spectrum**, which is a measure of any response to absorbed light. At very low concentrations of pure substances, action spectra tend to be identical to absorption spectra. However, since the observed response (fluorescence in this case) is proportional to light absorbed, action spectra should be compared to plots of 1–T (where T = transmittance, Section B,1) vs wavelength rather than to plots of ε vs λ. The two plots are proportional at low concentrations. For a discussion of action spectra see Clayton.[123]

A fluorescence **emission spectrum** is a record of fluorescence intensity vs wavelength for a constant intensity of exciting light. Excitation and emission spectra for a flavin and for the indole ring of tryptophan are both given in Fig. 23-13. The heights of the

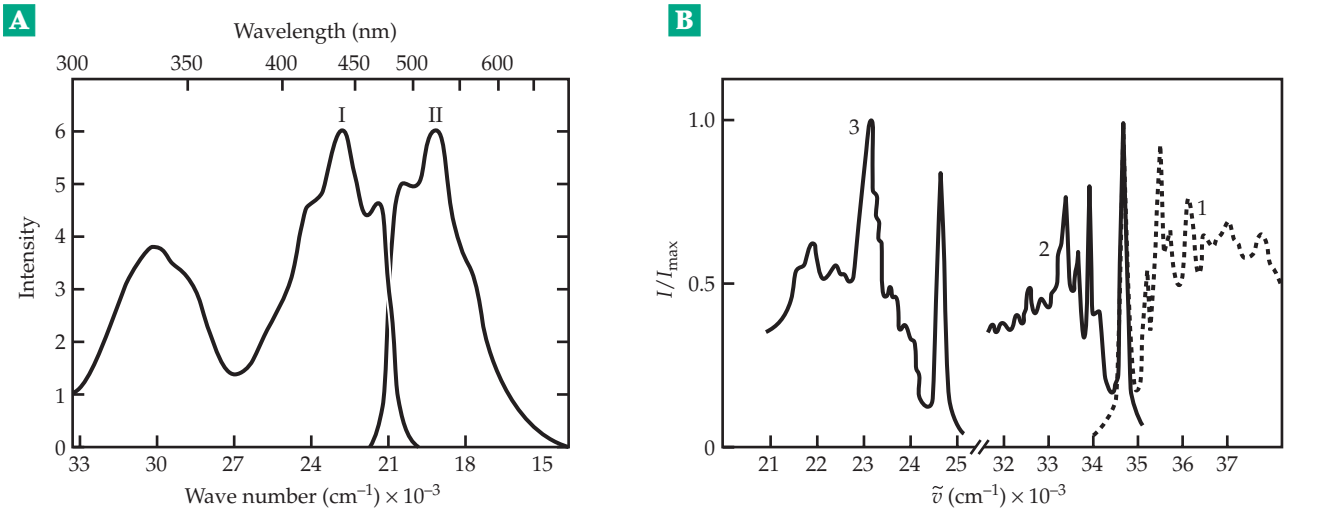

Figure 23-13 (A) Corrected emission and excitation spectra of riboflavin tetrabutyrate in *n*-heptane. Concentration, about 0.4 mg I^{-1}. Curve 1: excitation spectrum; emission at 525 nm. Curve 2: emission spectrum; excitation at 345 nm. From Kotaki and Yagi.[128] (B) Indole in cyclohexane, T = 196 K. 1, Fluorescence excitation spectrum; 2, fluorescence spectrum; and 3, phosphorescence spectrum. From Konev.[125]

emission spectra have been adjusted to the same scale as that of absorption. The fluorescent emission is always at a lower energy than that of the absorbed light. The excitation and emission spectra overlap only slightly, and the emission spectrum is an approximate mirror image of excitation spectrum. To understand this, refer to the diagram in Fig. 23-14. Absorption usually leads to a higher vibrational energy state after light absorption than before. However, most of the excess vibrational energy is dissipated before much fluorescent emission occurs. The excited molecule finds itself in the lowest vibrational state of the upper electronic state, and it is from this state that the bulk of the fluorescent emission takes place. Furthermore, whereas absorption usually occurs from the lowest vibrational state of the ground electronic level, fluorescence can populate many excited vibrational states of the ground electronic state (Fig. 23-14). Consequently, as indicated in the figure, the fluorescent emission spectrum consists of a series of subbands at lower energies than those observed in the absorption spectrum. The two spectra have only the 0–0 transition in common. As can be seen from Fig. 23-14, even the two 0–0 transitions do not coincide exactly. The peak of emission is shifted toward slightly lower energies than that of absorption because during or immediately following absorption of a photon there is some rearrangement of solvent molecules around the absorbing molecule to an energetically more stable arrangement. Just as excess vibrational energy is dissipated in the excited state, so relaxation of these solvent molecules around the excited chromophore leads to a small shift in energy. A similar relaxation

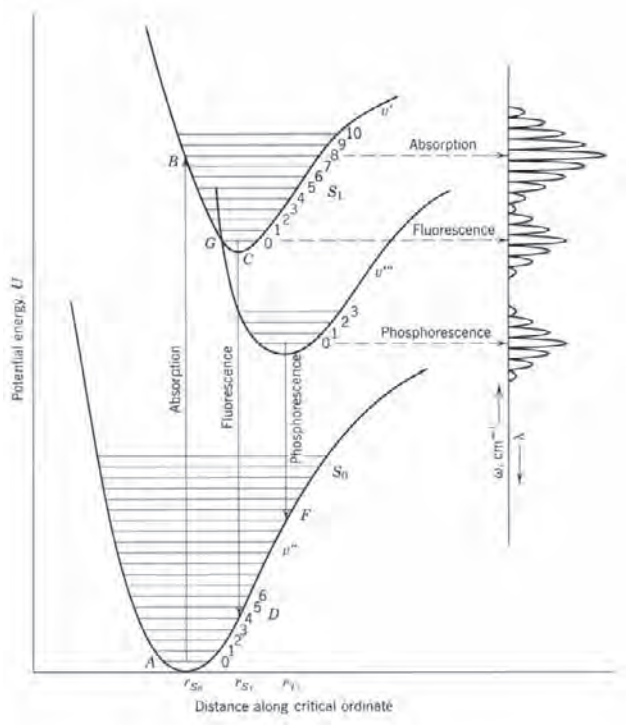

Figure 23-14 Potential energy diagram for the ground state S_0 and the first excited singlet S_1 and triplet T_1 states of a representative organic molecule in solution. G is a point of intersystem crossing $S_1 \rightarrow T_1$. For convenience in representation, the distances *r* were chosen $r_{S_0} < r_{S_1} < r_{T_1}$; thus, the spectra are spread out. Actually, in complex, fairly symmetric molecules, $r_{S_0} \sim r_{S_1} < r_{T_1}$ and the 0–0 absorption and fluorescence bands almost coincide, but phosphorescence bands are significantly displaced to the lower wavelengths. From Calvert and Pitts,[2] p. 274.

occurs in the ground state of a molecule that has just emitted a photon as fluorescence. This also contributes to the shift in position of the 0–0 band in fluorescence (see Parker,[124] p. 13).

Several molecular properties can be measured using emission and excitation spectra. These include fluorescence lifetime, efficiency, anisotropy of the emitted light, mobility of chromophores, rates of quenching, and energy transfer to other chromophores.

Fluorescence lifetimes. Why are some molecules fluorescent, while others are not? The possibility for fluorescent emission is limited by the radiative lifetime τ_r, which is related by Eq. 23-13 to the first-order rate constant k_f for exponential decay of the excited state by fluorescence.

$$\tau_r = 1/k_f \qquad (23\text{-}13)$$

The radiative lifetime is a function of the wavelength of the light and of the oscillator strength of the transition. For molecules absorbing in the near UV, the approximation of Eq. 23-14 is often made.

$$1/\tau_r \sim 10^4 \varepsilon_{max}) \qquad (23\text{-}14)$$

Thus, if ε = 10,000, the radiative lifetime (the time in which the fluorescence decays to $1/e$, its initial value) is $\sim 10^{-8}$ s (10 ns). If the absorption is more intense, the lifetime is shorter, and if it is less intense, it is longer. Other modes of deexcitation compete with fluorescence; therefore, the shorter the radiative lifetime the more likely that fluorescence will be observed.

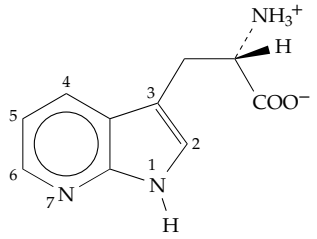
The actual lifetime τ of an excited molecule is usually less than τ_r because of the competing nonradiative processes. The sum of their rate constants can be designated k_{nr}. The **fluorescence efficiency** (or **quantum yield**) ϕ_F is given by Eq. 23-15.

$$\phi_F = k_f/k_f + k_{nr}) = k_r\tau \quad \text{where } \tau^{-1} = k_f + k_{nr} \qquad (23\text{-}15)$$

For a highly fluorescent molecule such as riboflavin, ϕ_f may be 0.25 or more.[129] For tryptophan in water it is about 0.14, and in proteins it varies from near zero to 0.35.[130]

Time-resolved fluorescence spectroscopy. The fluorescence lifetime τ can be measured with either of two different types of fluorometer.[7,127,131–133] **Pulse fluorometers** use pulsed lasers that can deliver pulses of light lasting as little as one picosecond or less. This permits rapid excitation and permits the direct observation of emitted light, using photon countings, over the entire range of time from a few picoseconds to milliseconds required for decay of the fluorescence.[131] The observed value of τ for riboflavin 5'-phosphate (ε_{max} = 12,200 at 450 nm) at 25°C is ~5 ns.[134] That for tryptophan is 3 ns.

Phase fluorometers utilize continuous irradiation by a beam of light that is sinusoidally modulated. If the frequency of the modulation is set correctly, there will be a phase difference in the modulation of the fluorescent emission that will depend upon τ. Phase fluorometry can yield the same information as does pulse fluorometry.[127,132,133] By using two or more modulation frequencies the decay rates and fluorescence lifetimes for various chromophores in a protein can be observed. For example, the protein **colicin A** (Box 8-D) contains three tryptophans W86, W130, and W140. Their fluorescence decays with lifetimes τ_1, τ_2, τ_3 of ~0.6–0.9 ns, 2.0–2.2 ns, and 4.2–4.9 ns at pH 7. While τ_3 originates mainly from W140, both of the other tryptophans contribute to τ_1 and τ_2. Changes in fluorescence intensity with pH reflect a pK_a value of 5.2.[135] Tryptophan, which often occurs at only one or a few places in a protein, is a useful fluorescent probe for study of protein dynamics. The optical properties of 7-azatryptophan, 2-azotryptophan, and 5-hydroxytryptophan are even better because their absorption maxima occur at longer wavelengths. These amino acids can be biosynthetically introduced in place of tryptophan in proteins.[136–138] The maximum fluorescence of tryptophan in one protein is at 350 nm, but for 7-azatryptophan in the same protein it was shifted to 380 nm.[136]



7-Azatryptophan

Triplet states, phosphoresence, and quenching. In addition to emitting fluorescent radiation, molecules can often pass from the excited singlet state to a lower energy **triplet state**, in which two electrons are now unpaired and the molecule assumes something of the character of a diradical (see Fig. 23-14). This process, known as **intersystem crossing**, competes directly with fluorescence and shortens the fluorescence lifetime. The triplet state is long-lived (e.g., for tryptophan in water at 20°C it is 1.2 ms[139]) and is responsible for much of the photochemical behavior of molecules. It also gives rise to the delayed light emission known as **phosphorescence**, as is illustrated in Figure 23-14. Other processes that compete with fluorescence are **photochemical reactions** of the singlet excited state and **internal conversion**. The

latter is the process by which a molecule moves from the lowest vibrational state of the upper electronic level to some high vibrational state of the unexcited electronic level. This is the principal means of depopulating the electronic state and competes directly with fluorescence.

The rate of relaxation by nonradiative pathways can be increased by addition of **quenchers**. Quenching of fluorescence occurs by several mechanisms, many of which involve collision of the excited chromophore with the quenching molecule. Some substances such as iodide ion are especially effective quenchers. The fluorescence efficiency of a substance in the absence of a quencher can be expressed (Eq. 23-16) in terms of the rate constants for fluorescence (k_f), for nonradiative decay (k_{nr}), and for phosphorescence (k_p):

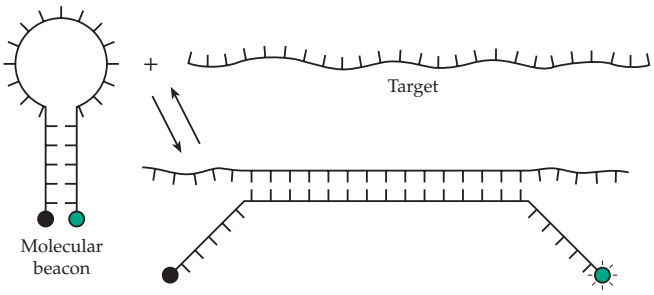
$$\phi_f = k_f / (k_f + k_{nr} + k_p) \qquad (23\text{-}16)$$

In the presence of a quencher, Q, there is an additional rate process for relaxation. The ratio of the fluorescence efficiency in the absence of (ϕ_f^0) and the presence of a quencher is given by the **Stern–Volmer equation**.[7,140]

$$\phi_f^0 / \phi_f = 1 + K[Q] = 1 + k_Q \tau_0 [Q] \qquad (23\text{-}17)$$

The constant K is known as the Stern–Volmer quenching constant; k_Q is the rate constant for the quenching reaction, and τ_0 the lifetime in the absence of quencher. Fluorescence quenching of tryptophan in proteins by acrylamide or O_2 has been used to determine whether tryptophan side chains are accessible to solvent or are "buried" in the protein.[141,142] The long-lived phosphorescence of tryptophan can be studied in a similar way.[143]

A recent application of fluorescence quenching is the development of "**molecular beacons**" for detection of viruses such as the AIDS viruses HIV-1 and HIV-2.[144] A single-stranded oligonucleotide is synthesized with a 25- or 33-nucleotide sequence complementary to a sequence in the target viral RNA. At the ends of this sequence are two 6-nucleotide arms with complementary sequences that will form a stable double-helical stem at the annealing temperature used for PCR amplification of the viral nucleic acid. The end of one arm carries a covalently bonded fluorescent dye, e.g., a fluorescein or rhodamine derivative. The other arm carries a potent covalently linked fluorescence quencher such as 4-(4'-dimethylaminophenylazo)benzoic acid. When the arms form a duplex, the quencher will be next to the fluorophore and no fluorescence will be seen upon irradiation with light of a suitable exciting wavelength. However, if viral DNA is present it will hydridize with the central polynucleotide, keeping the fluorophore and quenchers far apart



(23-18)

and allowing the beacon to signal the presence of a virus (Eq. 23-18). As few as ten retroviral genomes could be detected. By using a series of molecular beacons with different colored fluorescence and specific for different viruses, it is possible to test for more than one virus simultaneously.

Anisotropy. Light emitted from excited molecules immediately after absorption is always partially polarized, whether or not the exciting beam consists of plane polarized light. When light polarized in a vertical plane is used for excitation, part of the emitted light (of intensity I_v) will have its electric vector parallel to that of the exciting light. The remainder of intensity I_h, will be polarized in a horizontal plane. The **polarization *P*** of the emitted radiation is defined by Eq. 23-19 and the **anisotropy *R*** by Eq. 23-20. After excitation by a laser pulse both the fluorescence and its anisotropy decay with time and can be measured. The decay of R (but not of P) can usually be described as the sum

$$P = (I_v - I_h) / (I_v + I_h) \qquad (23\text{-}19)$$

$$R = (I_v - I_h) / (I_v + 2\, I_h) \qquad (23\text{-}20)$$

of simple exponential curves, which are readily obtained by phase fluorometry. These can in turn be related to specific types of motion, such as rotation of the emitting molecule or group.[7,145,146] Rotation of tryptophan rings, both free and restricted, has been studied in a variety of proteins.[145,147] However, interpretation is difficult.[130,148] The rotational rates obtained from anisotropy measurements are strongly affected by the viscosity of the medium (see Eq. 9-35).

2. Fluorescence Resonance Energy Transfer (FRET)

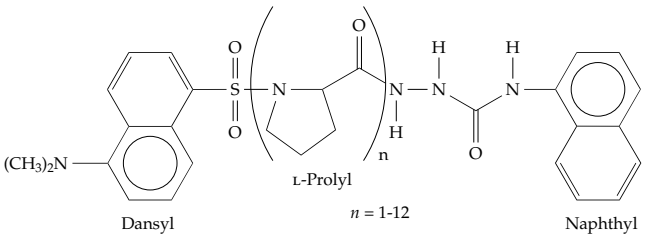
Electronic excitation of one chromophore sometimes elicits fluorescence from a different chromophore that is located nearby. For example, excitation of a monomolecular layer of dye can induce fluorescence in a layer of another dye spaced 5 nm

away. Excitation of tyrosine residues in proteins can lead to fluorescence from tryptophan, and excitation of tryptophan can cause fluorescence in dyes attached to the surface of a protein or in an embedded coenzyme.[134] Such fluorescence resonance energy transfer (**FRET**) is expected for molecules, when the fluorescence spectrum of one overlaps the absorption spectrum of the other. The mechanism is not one of fluorescence emission and absorption but of nonradiative resonant transfer of energy. Resonant transfer of energy is of major biological significance in photosynthesis (Section E). Most of the chlorophyll molecules, which absorb light in a chloroplast, transfer the absorbed energy in a stepwise fashion to a **reaction center**.

Förster[149] calculated that the rate of energy transfer k_t should be proportional to the rate of fluorescence k_f, to an orientation factor K^2, to the spectral overlap interval J, to the inverse fourth power of the refractive index n, and to the inverse sixth power of the distance r separating the two chromophores.

$$k_t \propto k_f K^2 J n^{-4} r^{-6} \qquad (23\text{-}21)$$

Besides predicting the inverse sixth power dependence of energy transfer, Förster provided a formula for calculating R_0, the distance between chromophores at which 50% efficient singlet-singlet energy transfer takes place. R_0 is commonly of the order of 2.0 nm. Making use of these relationships, Stryer proposed a method of measuring distances between chromophores. He calibrated the method by constructing a series of molecules containing various lengths of the rigid threefold polyproline helix to which dansyl groups were attached at one end and naphthyl groups



at the other.[150] By exciting the naphthyl group, which has the higher energy absorption band and is strongly fluorescent, the characteristic lower energy emission of the dansyl group could be observed if energy transfer took place. Since the fluorescent emission band of the naphthyl group overlaps the absorption band of the dansyl group, efficient transfer was expected. The results of a plot of transfer efficiency against distance is shown in Fig. 23-15. The inverse sixth power dependence was followed quite accurately with a value of R_0 ~3.4 nm. Having calibrated his "spectroscopic ruler," Stryer turned his attention to biochemical macromolecules. Attaching the same kinds of fluorescent probe to the visual light receptor rhodopsin, Wu and Stryer were able to estimate distances between specific parts of the molecule and to draw some conclusions about the overall shape.[151]

More recently the FRET technique has been widely applied to a broad range of biochemical problems. Sensitivity has been improved to the extent that fluorescence of single molecules can be detected.[152–154] Use of **terbium** (Tb^{3+}) or **europium** (Eu^{3+}) ions, which can provide luminous labels for metal-binding sites, has provided another advance. These ions absorb light poorly and are therefore only weakly fluorescent. However, they can be excited by resonance energy transfer and become brilliantly luminous. This **luminescence resonance energy transfer** (**LRET**) is a variant of FRET, which allows distances up to ~10 nm to be measured.[155–157] Another advance is the ability to graft into specific proteins fluorescent tags such as the intact **green fluorescent protein** (Section J)[158,159] or an amino acid sequence such as CCXXCC in which the four –SH groups of the cysteines serve to trap an arsenic derivative of fluorescein (see Box 12-B).[159] **Confocal laser scanning microscopy** (Chapter 3) is basic to many applications.[160]

Specific applications of FRET and LRET include observation of myosin movement (Fig. 19-14),[157] measurement of distances between binding sites on tubulin,[161] determining stoichiometry of subunit assembly in a γ-aminobutyrate receptor of brain,[162] association of proteins in peroxisomes,[160] study of hydridization of deoxyribonucleotides,[163] verifying the handedness of various forms of DNA,[164] and other studies of DNA and RNA.[164a,b]

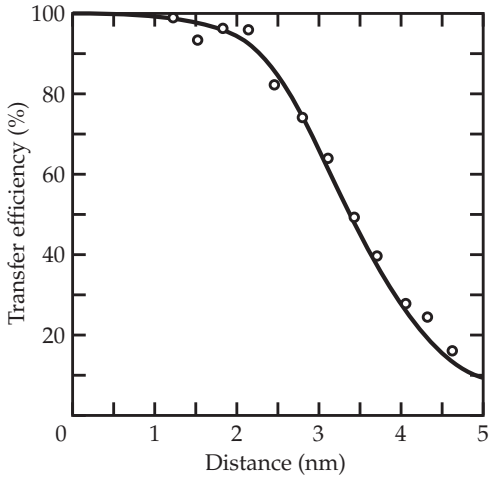


Figure 23-15 Efficiency of energy transfer as a function of distance between α-naphthyl and dansyl groups at the ends of a polyprolyl "rod" (L-prolyl)$_n$. The observed efficiencies of transfer for n = 1 to 12 are shown as points. The solid line corresponds to an r^{-6} distance dependence. From L. Stryer.[150]

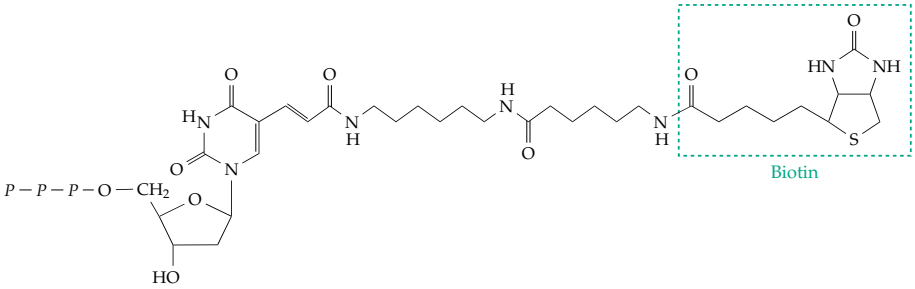
Using the Förster equation the distance between the two calcium-binding sites in parvalbumin (Fig. 6-7) has been estimated by energy transfer from Eu(III) in one site to Tb(III) in the other[165] to within 10–15% of the distance of 1.18 nm based on X-ray crystallography.

3. Energy-Selective Spectroscopic Methods

At low enough temperatures vibrational fine structure of aromatic chromophores may be well resolved, especially if they are embedded in a suitable matrix such as argon or N_2, which is deposited on a transparent surface at 15 K. This **matrix isolation spectroscopy**[77,166] may reveal differences in spectra of conformers or, as in Fig. 23-16, of tautomers. In the latter example the IR spectra of the well-known amino-oxo and amino-hydroxy tautomers of cytosine can both be seen in the matrix isolation IR spectrum. Figure 23-16 is an IR spectrum, but at low temperatures electronic absorption spectra may display sharp vibrational structure. For example, aromatic hydrocarbons dissolved in *n*-heptane or *n*-octane and frozen often have absorption spectra, and therefore fluorescence excitation spectra, which often consist of very narrow lines. A laser can be tuned to excite only one line in the absorption spectrum. For example, in the spectrum of the carcinogen 11-methylbenz(*a*)anthrene in frozen octane three major transitions arise because there are three different environments for the molecule. Excitation of these lines separately yields distinctly different emission spectra.[77] Likewise, in complex mixtures of different hydrocarbons emission can be excited from each one at will and can be used for estimation of amounts. Other related methods of energy-selective laser spectroscopy include **fluorescence line narrowing**[167] and **spectral hole burning**.[167,168]

4. Analytical Applications of Fluorescence

Because of the high sensitivity with which fluorescence can be detected, its measurement is important as an analytical tool. As a result of improved techniques **fluorescence microscopy** has become one of the most important of all tools in biological studies.[168a] New types of microscopes (see also pp. 129–131) have increased resolution beyond what was thought possible.[168b–d] Studies such as those of lipid metabolism in the transparent zebrafish are possible using substrates that carry fluorescent labels.[168e] As mentioned in the preceding paragraph, many aromatic compounds can be detected by their fluorescence. The relatively weak fluorescence of proteins and nucleic acids can be greatly enhanced by the binding of a highly fluorescent dye to the macromolecules. Fluorescent antibodies are widely employed for this purpose. Fluorescent labels are rapidly replacing radioisotopes in analysis of nucleic acids. For example, biotin may be attached to a pyrimidine base of a nucleoside triphosphate by a long spacer arm. The modified base can then be incorporated enzymatically into polynucleotides, e.g., in the synthesis of probes used for hybridization. The attached biotin can be detected by binding to avidin or streptavidin (Box 14-B) and use of fluorescent antibodies to this



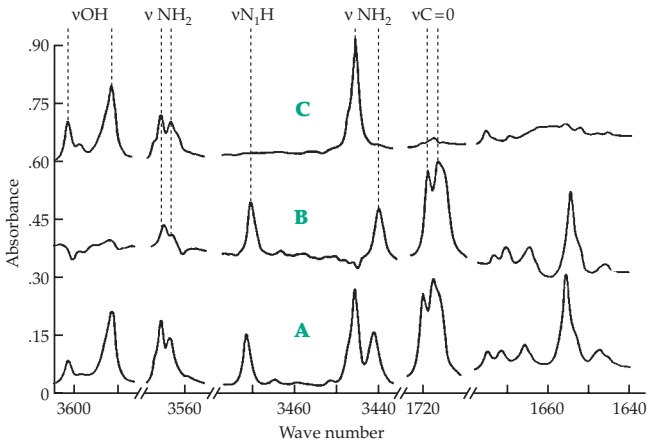


Fig. 23-16 Infrared spectrum of cytosine in the –OH, NH, and C=O stretching region in an argon matrix in 15 K. (A) Initial spectrum of a sample containing both tautomers. (B) Spectrum of the amino-oxo tautomer calculated by substraction of the spectrum of the amino-hydroxy tautomer. (C) Spectrum of the aminohydroxy tautomer obtained by irradiating the initial sample in order to photochemically convert it into the aminohydroxy tautomer. Spectra (B) and (C) were also corrected for residual amounts of the second tautomer. From Szczesniak *et al.*[166] Courtesy of W. B. Person.

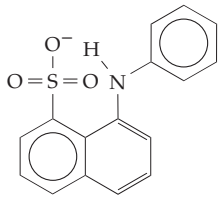
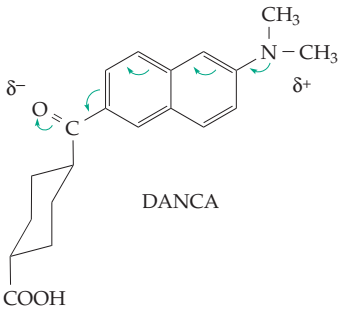
protein.[169,170] Fluorescent dyes can also be covalently attached to nucleotides. Fluorescent dideoxynucleoside triphosphates are used as chain terminators in DNA sequencing (Chapter 5). Using a different dye that fluoresces at a different wavelength for each of the four dideoxynucleosides, polynucleotides can be sequenced automatically using a single column rather than four parallel lanes as in Fig. 5-49.

Fluorescent "probes" such as **1-anilinonaphthalene-8-sulfonate** or 1,6-diphenyl-1,3,5-hexatriene embedded in membranes, contractile fibers, etc., can reveal changes in mobility that accompany alterations in physiological conditions. For example, molecular changes occurring in membranes during nerve conduction and in mitochondria during electron transport



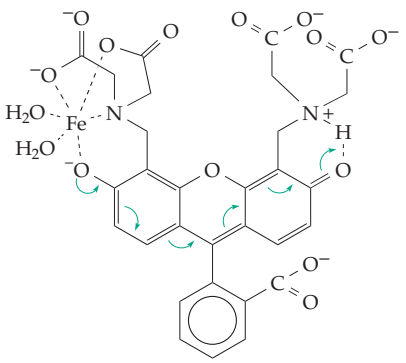
1-Anilinonaphthalene-8-sulfonate



DANCA

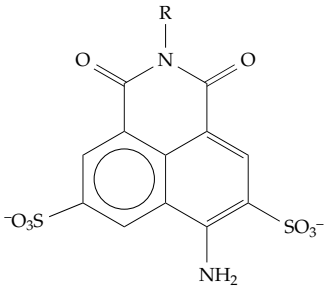
can be observed.[146,171] Another type of probe is exemplified by 2′-(*N*,*N*-dimethylamino)-6-4-*trans*-cyclohexamoic (DANCA). Its emission maximum shifts from 390 nm in cyclohexane to 520 nm in water, presumably as a consequence of increased polarization of the molecule in the excited state, as indicated by the green arrows in the accompanying structural formula.[172] DANCA can be used to obtain some idea of the polarity of sites within macromolecules to which it binds.

Study of calcium ions in living cells has been immensely aided by calcium fluorophores[173] (Box 6-D), which are often derivatives of EDTA (Table 6-9). One of these, **calcein**,[174] is also very specific toward Fe^{3+}. The natural calcium-dependent luminous protein, aequorin (Section J), is also widely used.



Fe^{III} - calcein • H^+

Nontoxic but highly fluorescent dyes are used to study diffusion within and between cells. The so called Lucifer dyes have been employed to trace shapes and branching patterns in neurons.[175]



Structural formula for Lucifer dyes
For Lucifer yellow
R = —NH—CO—NH—NH_2

The recently developed **fluorescence correlation spectroscopy** permits studies of molecular association in one femtoliter of solution using a confocal or two-photon microscope. Two lasers are used to excite two fluorophores of different colors, each one on a different type of molecule. Fluorescence of single molecules can be detected, and molecular associations can be detected by changes in the distribution of the fluctuations in fluorescence intensity caused by Brownian motion.[176–178] A different type of advance is development of computer programs that analyze chromosomes stained with a mixture of dyes with overlapping spectra and display the result as if each chromosome were painted with a specific color.[179–180a] Yet another advance is development of **semiconductor nanocrystals** (or "quantum dots") with narrow absorption bands and intense fluorescence. The wavelength of absorption and fluorescence depends upon the size of the crystals. For example, CdSe crystals of diameter 2–5 nm coated with silica or with a surfactant fluoresce across the visible range. They have a variety of uses in biological staining.[181,182]

D. Photochemistry

Because of their high energy, molecules in either the singlet or triplet photoexcited state undergo a greater variety of chemical reactions than do molecules in the ground state.[5,183,184] Many of these photochemical reactions arise from the triplet state that is formed from the singlet by intersystem crossing. Selection rules forbid transitions between excited triplet state and ground state; therefore, the radiative lifetime of the triplet state is long. The diradical character of the triplet state also makes it unusually reactive. Despite its forbidden character, nonradiative deexcitation of the triplet state is possible, and phosphorescence is observed for most molecules at low temperatures if the solvent is immobilized as a glass. The intense light

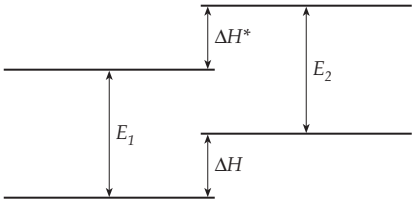
from lasers can also induce a variety of photochemical processes that arise from absorption of two or more photons.

One of the simplest of photochemical processes is the dissociation or uptake of a proton by an excited molecule as a result of a change in the pK_a value of a functional group. Various other bond cleavages may lead to dissociation into ions or radicals. Photoelimination and photoaddition reactions both occur. Molecules may be isomerized, a process of importance in visual receptors. Excited molecules may become strong oxidizing agents able to accept hydrogen atoms or electrons from other molecules. An example is the **photooxidation** of EDTA by riboflavin (which undergoes photoreduction as shown in Fig. 15-8). A biologically more important example is in photosynthesis, during which excited chlorophyll molecules carry out **photoreduction** of another molecule and are themselves transiently oxidized. A frustrating aspect of investigation of photochemical reactions is that the variety of reactions possible often leads to a superabundance of photochemical products, e.g., see the thin layer chromatogram of cleavage products of riboflavin in Fig. 3-5. However, biological photoprocesses are usually much more specific.

1. Chemical Equilibria in the Excited State

When pyridoxamine with a dipolar ionic ring structure (Fig. 14-9) and an absorption peak at 30,700 cm^{-1} (326 nm) is irradiated, fluorescence emission is observed at 25,000 cm^{-1} (400 nm). When basic pyridoxamine with an anionic ring structure and an absorption peak at 32,500 cm^{-1} (308 nm) is irradiated, fluorescence is observed at 27,000 cm^{-1} (370 nm), again shifted ~5500 cm^{-1} from the absorption peak. However, when the same molecule is irradiated in acidic solution, where the absorption peak is at 34,000 cm^{-1} (294 nm), the luminescent emission at 25,000 cm^{-1} is the same as from the neutral dipolar ionic form and abnormally far shifted (9000 cm^{-1}) from the 34,000 cm^{-1} absorption peak.[185,186] The phenomenon, which is observed for most phenols, results from rapid dissociation of a proton from the phenolic group in the photoexcited state. A phenolic group is more acidic in the excited state than in the ground state, and the excited pyridoxamine cation in acid solution is rapidly converted to a dipolar ion.

The variation of fluorescence intensity with pH can provide direct information about the pK_a in the excited state. Förster suggested the following indirect procedure for estimating excited-state pK_a values for phenols. Let E_1 represent the energy of the 0–0 transition (preferably measured as the mean of the observed 0–0 transition energies in absorption and fluorescent emission spectra); let E_2 represent the energy of the 0–0 transition in the dissociated (anionic in the case of a phenol) form, while ΔH and ΔH^* represent the enthalpies of dissociation in the ground and excited states, respectively. It is evident from the diagram that Eq. 23-22 holds.



$$E_1 - E_2 = \Delta H - \Delta H^* \qquad (23\text{-}22)$$

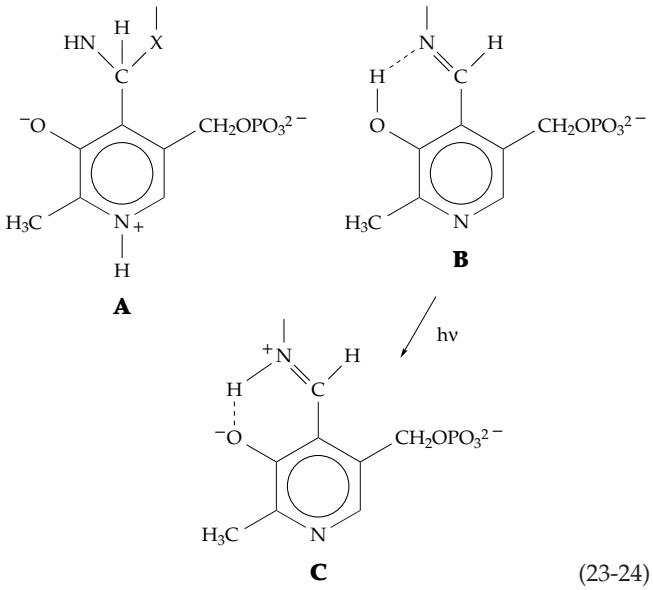
If we assume that the changes in entropy for the reaction are the same in the ground and excited state, Eq. 23-23 follows.

$$\log_{10}(K^*/K) = Nh\,(\Delta\,\bar{\nu})/(2.3RT)$$
$$\text{or}$$
$$pK^* = pK - (2.1 \times 10^3)\Delta\nu\ (cm^{-1}) \text{ at } 25°C \qquad (23\text{-}23)$$

For example, a shift in the spectrum of the basic form by 1000 cm^{-1} to a lower wave number compared with the acid form corresponds to a decrease of 2.1 units in pK_a for dissociation of the acid form. Whereas it is desirable to use both absorption and fluorescent measurements to locate the approximate positions of 0–0 bands, absorption measurements alone are often used, and the positions of the band maxima are taken. Thus, for pyridoxamine the shift in absorption maximum from 34,000 cm^{-1} in the protonated form to 30,700 cm^{-1} in the dissociated form suggests that the pK_a of pyridoxamine of 3.4 in the ground state is shifted by 6.9 units to –3.5 in the excited state. Bridges *et al.*[186] evaluated this same pK_a from the pH dependence of fluorescence as pK^* ~ –4.1.

While phenols and amines are usually more acidic in the singlet excited state than in the ground state, some substances, e.g., aromatic ketones, may become more *basic* in the photoexcited state.

Observation of an abnormally large shift in the position of fluorescent emission of pyridoxal phosphate (PLP) in glycogen phosphorylase answered an interesting chemical question.[187,188] A 330 nm (30,300 cm^{-1}) absorption band could be interpreted either as arising from an adduct of some enzyme functional group with the Schiff base of PLP and a lysine side chain (structure A) or as a nonionic tautomer of a Schiff base in a hydrophobic environment (structure B, Eq. 23-24). For structure A, the fluorescent emission would be expected at a position similar to that of pyridoxamine. On the other hand, Schiff bases of the



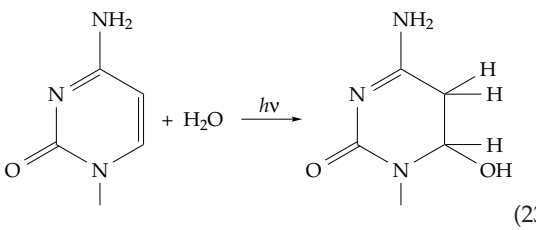
type indicated by structure B would be expected to undergo a photoinduced proton shift (phototautomerization) to form structure C[124,187] with an absorption band at 430 nm (23,300 cm^{-1}) and fluorescent emission at a still lower energy. Since the observed fluorescence was at 530 nm, it was judged that the chromophore does have structure B.

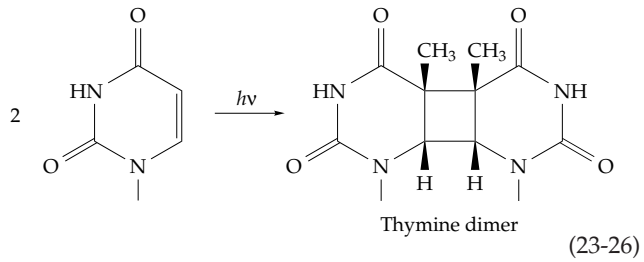
The rate of proton dissociations from the excited states of molecules can be measured directly by nanosecond fluorimetry.[189]

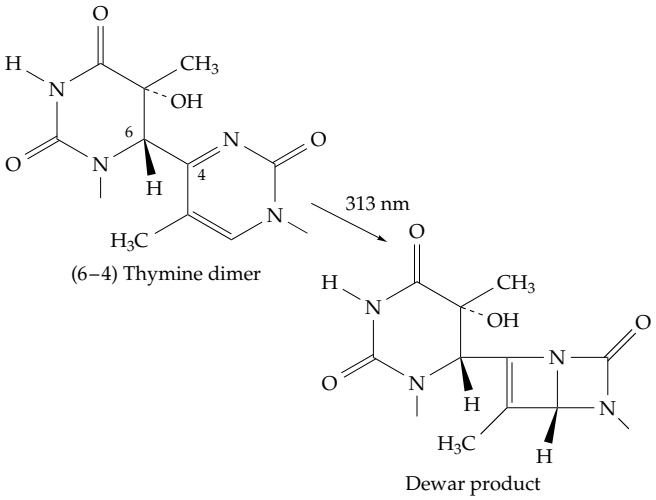
2. Photoreactions of Nucleic Acid Bases

Photochemical reactions of the purines and pyrimidines assume special significance because of the high molar extinction coefficients of the nucleic acids present in cells. Light is likely to be absorbed by nucleic acids and to induce photoreactions that lead to mutations.[190] Both pyrimidines and purines undergo photochemical alterations, but purines are only about one-tenth as sensitive as pyrimidines. **Photohydration** of cytidine (Eq. 23-25) is observed readily. The reaction is the photochemical analog of the hydration of α,β-unsaturated carboxylic acids. Uracil derivatives also undergo photohydration.

A more important reaction is the photodimerization of thymine (Eq. 23-26), a reaction also observed with uracil. A variety of stereoisomers of the resulting

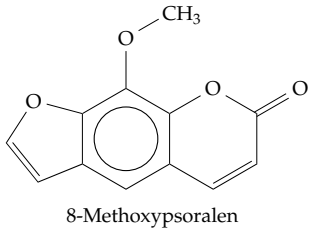






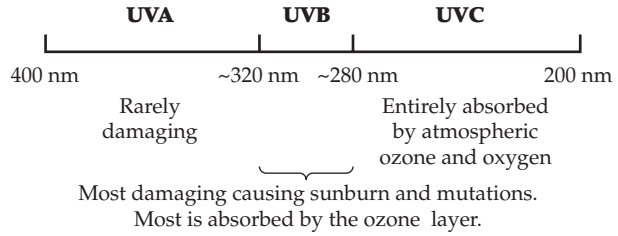
cyclobutane-linked structure are formed. The one shown in the equation predominates after irradiation of frozen thymine. Another important isomer is the 6–4 thymine dimer.[191,191a] Both of these types of **cyclobutane dimers** block DNA replication. This accounts for much of the lethal and mutagenic effect of ultraviolet radiation on organisms. The matter is sufficiently important that a special "excision repair" process is used by cells to cut out the thymine dimers (Chapter 27, Section E). In addition, light-dependent **photolyases**, discussed in Section I, act to reverse the dimerization reactions.

Light can also cause addition and other crosslinking reactions between DNA and proteins or other cell constituents.[192,193] One use of such reactions in the laboratory is DNA "photo footprinting" (Fig. 5-50), a technique which reveals contact regions between DNA and associated proteins.[190] Another type of cellular damage is caused by photosensitization of DNA by a light-absorbing intercalating agent such as **8-methoxypsoralen**.[194,195] DNA as well as adjacent proteins can be damaged.



3. Sunburn, Cancer, and Phototherapy

Ultraviolet light is sometimes classified according to its energy and capacity for damaging cells as follows:[195a]



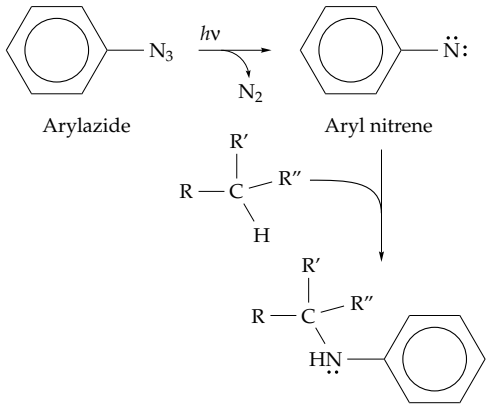
The UVB radiation causes most damage to skin. UVA radiation is at least an order of magnitude less damaging and is usually harmless to human skin. The UVC solar radiation is all absorbed by ozone and dioxygen of the atmosphere. UVC radiation produced by ultraviolet lamps is usually all absorbed in the epidermis.[5]

Ultraviolet light damages proteins as well as DNA. Residues of Trp, Tyr, His, Cys, and Met are especially susceptible to photolysis, or photooxidation by O_2, or by singlet oxygen. Also damaged are unsaturated lipids, porphyrins, flavins, etc. Kynurenic acid (Fig. 25-11) and urocanic acid (Eq. 14-44), an important ultraviolet filter in skin,[196] are also decomposed by light.

Repeated sunburn ages skin and may induce cancer.[4] However, light also has beneficial effects. It allows us to see, provides a source of vitamin D (Box 22-C), induces enzymatic repair of some DNA damage, and provides all of our food energy, directly or indirectly, by photosynthesis.

Light is used in **phototherapy**. This happens most frequently in the irradiation of newborn babies with white light to isomerize bilirubin (Fig. 24-24) from the 4*Z*, 15*Z* form to more readily excreted forms such as the 4*E*, 15*Z* isomer. About half of newborns have some **jaundice** (elevated bilirubin), and if it is severe it must be treated promptly to avoid neurological damage (see Chapter 24). There are sometimes complications, but the treatment is usually effective.[5] **Psoriasis** is frequently treated by irradiation with UVB light, which is thought to inhibit growth of the abnormal skin cells. Ten to 35 treatments are usually required, and the condition may return after some years. An alternative treatment is irradiation with UVA light after ingestion of 8-methoxypsoralen or other psoralen derivative.[5] Another skin condition that may respond to phototherapy is **vitiligo** (Box 25-A). Treatment with UVA and psoralen derivatives may stimulate repigmentation. If depigmentation is extreme, the remaining pigmentation may be reduced by bleaching with the monobenzyl ester of hydroquinone.

Photodynamic therapy is a cancer treatment that involves intravenous injection of a light-absorbing molecule such as a porphyrin, which may be taken up preferentially by cancer cells. Laser irradiation by deeply penetrating red light (650–800 nm wavelength) causes oxygen-dependent photosensitization.[5,197,198] Improvements in lasers, in fiber optics, and in photosensitizers may lead to widespread use of this type of therapy both for cancer and for some other conditions.[5,199]



(23-27)

4. Photoaffinity Labels

Photochemically reactive molecules have often been used as labels for specific sites in proteins and nucleic acids. Psoralen derivatives serve as relatively nonspecific photochemically activated crosslinking agents for DNA and double-stranded RNA.[195] **Aryl azides** are converted by light to aryl nitrenes, which react in a variety of ways including insertion into C–H bonds (Eq. 23-27).[200,201] In some cases UV irradiation can be used to join natural substrates to enzymes or hormones to receptors. For example, progesterone, testosterone, and other steroids have been used for direct photoaffinity labeling of their receptors.[202] Synthetic **benzophenones** have also been used widely as photoactivated probes.[203]

5. Microphotolysis and Ultrafast Light-Induced Reactions

Fluorescence microphotolysis, or photobleaching, has been widely used to study translational mobility of lipids and proteins in membranes. An attenuated laser beam may be focused down to the diameter of a cell or less. Then the intensity can be suddenly increased by several orders of magnitude, bleaching any fluorescent material present. The return of fluorescent material by free diffusion from a neighboring region (**fluorescence recovery after photobleaching**) or by diffusion through a membrane into a cell can then be

observed.[204,205] Diffusion coefficients of labeled biopolymers or of components of cells can be evaluated, and translation and metabolism of lipids and other components can be followed.[206]

Laser-based techniques are being used for ultrafast observation of the results of a photochemical process, e.g., the light-induced dissociation of CO from the hemoglobin • CO complex. A dissociating laser pulse can be as short as 100 fs (0.1 ps) or less. This is shorter than the time of vibrational motion of nuclei in an electronically excited state (~0.3 ps). Using IR spectroscopy, events that follow can be observed at intervals as short as 0.1 ns.[207] X-ray diffraction measurements using 150 ps pulses have allowed direct observation of the CO dissociated from hemoglobin or myoglobin and its recombination with the same protein.[208–210] Femtosecond dynamics of electron transfer along a DNA helix is also being studied.[211,212]

6. Optical Tweezers, Light-Directed Synthesis, and Imaging

The radiation pressure exerted by light is very weak. A bright laser beam of several milliwatts of power can exert only a few piconewtons (pN) of force. However, a force of 10 pN is enough to pull a cell of *E. coli* through water ten times faster than it can swim.[213] In about 1986, it was found that a laser beam focused down to a spot of ~ one λ (~1 μm for an infrared laser) can trap and hold in its focus a refractile bead of ~1 μm diameter. This "optical tweezers" has become an important experimental tool with many uses.[213,214] For example, see Fig. 19-19. Not only are optical tweezers of utility in studying biological motors but also mechanical properties of all sorts of macromolecules can be examined. For example, DNA can be stretched and its extensibility measured.[215] Actin filaments have even been tied into knots![216]

Light-directed solid state synthesis of peptides[217] and oligonucleotides is another new tool.[218] Development of this technology may provide new advances in preparation of DNA chips (Chapter 26) with a higher density of components than are now available.

X-rays and more recently NMR (MRI)-imaging have become well known to us. It might seem impossible to use visible light for a similar type of imaging. However, a laser beam can pass through a person's head. Is it possible, using computer-based techniques, to create an image from the emergent light? Efforts are being made to do exactly this.[219,220] **Optical coherence tomography** using backscattered infrared light and related fast techniques have higher resolution than MRI, computerized tomography (CT), or ultrasound.[220–221a] Ultrabright synchrotron radiation is also being used in **infrared microspectrophotometry**.[222,223]

E. Photosynthesis

The photochemical reduction of CO_2 to organic materials[224–228] is the basic source of energy for the biosphere. Nevertheless, the process is limited to a few genera of photosynthetic bacteria (Table 1-1), eukaryotic algae, and higher green plants. Photosynthetic bacteria include the distinctly different purple, green, and bluegreen (cyanobacteria) groups, each of which has a different array of photosynthetic pigments. However, the basic mechanism of transduction of solar energy into chemical energy is the same in all of the bacteria and in green plants.

As discussed in Chapter 17, photosynthesis involves the incorporation of CO_2 into organic compounds by reduction with NADPH with coupled hydrolysis of ATP. This is most often via the Calvin–Benson cycle of Fig. 17-14. In a few organisms a reductive tricarboxylic acid cycle is employed. The idea that the chloroplasts of plants or the pigmented granules of photosynthetic bacteria generate NADPH or reduced ferredoxin plus ATP (Chapter 17) is now thoroughly accepted. However, it was not always obvious. Consider the overall equation (Eq. 23-28) for formation of glucose by photosynthesis in higher plants:

$$6\,CO_2 + 6\,H_2O \rightarrow 6\,O_2 + C_6H_{12}O_6 \qquad (23\text{-}28)$$

$$6\,CO_2 + 12\,H_2O^* \rightarrow 6\,O_2^* + C_6H_{12}O_6 + 6\,H_2O \qquad (23\text{-}29)$$

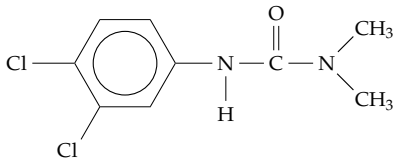
The stoichiometry of the reaction suggests that all 12 of the oxygen atoms of the evolved O_2 might come from CO_2 or that some might come from CO_2 and some from H_2O. In fact, water supplies both of the oxygen atoms needed for formation of O_2, as is indicated by the asterisks in Eq. 23-29. This possibility was suggested by van Niel[229,230] in 1931. He pointed out that in bacterial photosynthesis no O_2 is produced, and that bacteria must have access to a reducing agent to provide hydrogen for the reduction of CO_2 (Eq. 23-30).

$$H_2A \xrightarrow{h\nu} A + 2[H] \qquad (23\text{-}30)$$

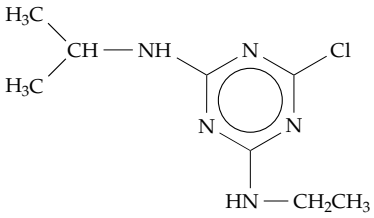
In this equation, H_2A might be H_2S (in the purple sulfur bacteria), elemental H_2, isopropanol, etc. From a consideration of these various reactions, van Niel concluded that in the O_2-producing cyanobacteria and eukaryotic plants water serves as the oxidizable substrate in Eq. 23-30 and is cleaved to form O_2 and to provide hydrogen atoms for reduction. This photochemical cleavage is the only known biological oxidation reaction of H_2O. No oxidizing agents present in living things are powerful enough to dehydrogenate water except for the photochemical **reaction centers** of photosynthetic organisms.

1. Two Photosystems, the Z Scheme, and Reaction Centers

It had long been known that for green plants light of wavelength 650 nm was much more efficient than that of 680 nm. However, Emerson and associates[34] in 1956 showed that a combination of light of 650 nm *plus* that of 680 nm gave a higher rate of photosynthesis than either kind of light alone. This result suggested that there might be two separate photosystems. What is now known as **photosystem I** (PSI) is excited by far red light (~700 nm), while **photosystem II** (PSII) depends upon the higher energy red light of 650 nm. Additional evidence supported the idea. Hill had shown many years before[231] that mild oxidizing agents such as ferricyanide and benzoquinone can serve as substrates for photoproduction of O_2, while Gaffron[232] found that some green algae could be adapted to photooxidize H_2 to protons (Eq. 23-30) and to use the electrons to reduce NADP. Thus, photosystem I could be disconnected from photosystem II. The powerful herbicide **dichlorophenyldimethylurea** (DCMU) was found to block electron transport between the two photosystems. In the presence of DCMU electrons from such artificial donors as ascorbic acid or an indophenol dye could be passed through photosystem I.



3-(3,4-Dichlorophenyl)-1,1-dimethylurea



Atrazine, another PSII inhibitor

The Z scheme. The result of these and other experiments was the development of the series formulation or zigzag scheme of photosynthesis[233] which is shown in Fig. 23-17. Passage of an electron through the system requires two quanta of light. Thus, four quanta are required for each NADPH formed and eight quanta for each CO_2 incorporated into carbohydrate.

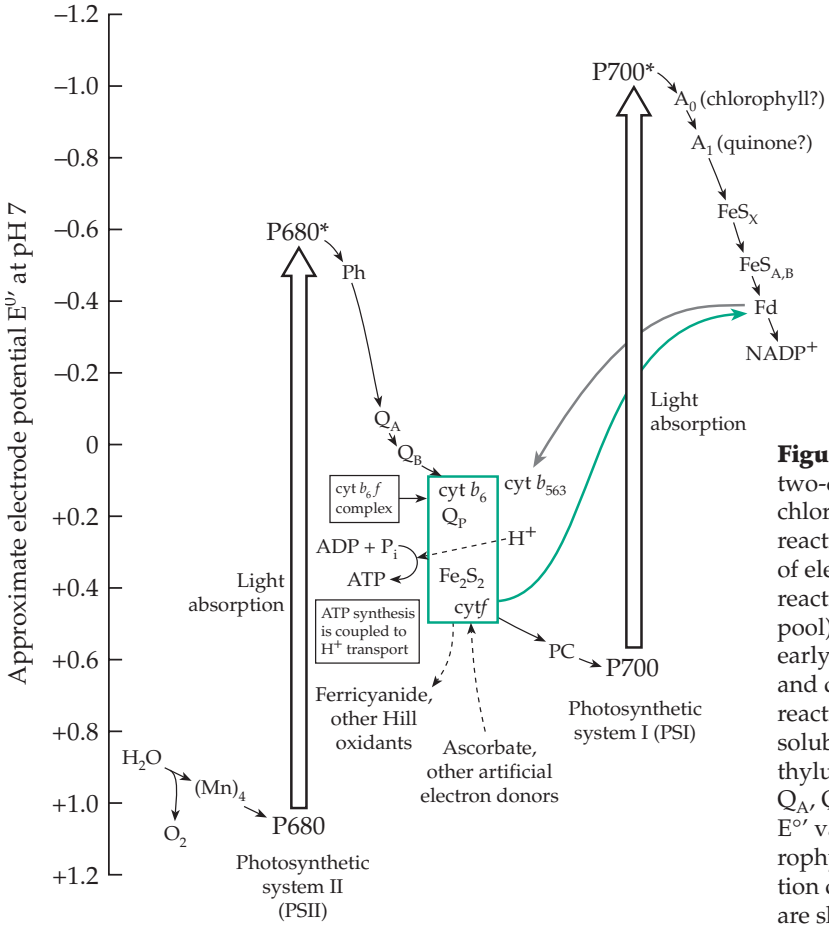


Figure 23-17 The zigzag scheme (Z scheme) for a two-quantum per electron photoreduction system of chloroplasts. Abbreviations are P680 and P700, reaction center chlorophylls; Ph, pheophytin acceptor of electrons from PSII; Q_A, Q_B, quinones bound to reaction center proteins; PQ, plastoquinone (mobile pool); Cyt, cytochromes; PC, plastocyanin; A_0 and A_1, early electron acceptors for PSI, possibly chlorophyll and quinone, respectively; F_x, Fe_2S_2 center bound to reaction center proteins; F_A, F_B, Fe_4S_4 centers; Fd, soluble ferredoxin; and DCMU, dichlorophenyldimethylurea. Note that the positions of P682, P700, Ph, Q_A, Q_B, A_0, and A_1 on the E°′ scale are uncertain. The E°′ values for P682 and P700 should be for the (chlorophyll / chlorophyll cation radical) pair in the reaction center environment. These may be lower than are shown.

An important experiment of Emerson and Arnold[35] employed very short flashes of light and measurement of the quantum efficiency of photosynthesis during those flashes. A striking fact was observed. At most, during a single turnover of the photosynthetic apparatus of the leaf, one molecule of O_2 would be released for each 3000 chlorophyll molecules. However, it could be calculated that for each O_2 released only about eight quanta of light had been absorbed. It followed that about 400 chlorophyll molecules were involved in the uptake of one quantum of light. This finding suggested that a large number of chlorophyll molecules act as a single light receiving unit (usually called a light-harvesting or antenna complex) able to feed energy to one **reaction center**. The concept is now fully accepted.

Electron transport and photophosphorylation. Two molecules of NADPH are required to reduce one molecule of CO_2 via the Calvin–Benson cycle (Fig. 17-14), and three molecules of ATP are also needed. How are these formed? The Z scheme provides part of the answer. There is enough drop in potential between the upper end of PSI and the lower end of PSII to permit synthesis of ATP by electron transport. It is likely that only one molecule of ATP is formed for each pair of electrons passing through this chain. Since, according to Fig. 17-14, one and a half molecules of ATP are needed per NADPH, some other mechanism must exist for the synthesis of additional ATP. Furthermore, many other processes in chloroplasts depend upon ATP so that the actual need for photogenerated ATP may be larger than this.

Arnon[234,235] demonstrated that additional ATP can be formed in chloroplasts by means of **cyclic photophosphorylation**: Electrons from the top of PSI can be recycled according to the dashed lines in Fig. 23-17. An electron transport system, probably that of the Z scheme, is used to synthesize ATP. As isolation of proteins and cloning of their genes progressed, it became clear that a complex of proteins known as **cytochrome b_6f** is closely related to the cytochrome bc_1 of mitochondria (Fig. 18-8).[236–237a] As in that complex, cytochrome b_6 carries two hemes, designated b_h and b_l with E_m of −84 and −158 mv, respectively. E_m values are for *Chlamydomonas* (see Fig. 1-11). Heme b_l is closer to the positively charged membrane surface (lumen side) and heme b_h is closer to the negative surface (stroma side). In maize cytochrome b_6 is a 23-kDa subunit, and the c-type cytochrome *f* is a larger ~ 34-kDa subunit whose heme is close to the lumenal side. Its E_m value is +330 mv. A 20-kDa Rieske Fe–S protein (Chapter 16) and an additional 17-kDa subunit complete the core four-subunit complex, which is found in green plants, green algae,[236] and cyanobacteria.[238,239] Other smaller subunits are also present. It is usually assumed that a Q cycle equivalent to that of mitochondrial complex III (Fig. 18-9) operates in the pumping of protons across the thylakoid membrane (Fig. 23-18).[237b,c] However, at high rates of photosynthesis the electron transfer may bypass cytochrome *f*.[237d] The associated ATP synthase is also subject to complex regulatory mechanisms.[237e] The Rieske protein is encoded by a nuclear gene, but genes for other subunits are chloroplastic. Electrons may be carried from the cytochrome *f* subunit to PSI by plastocyanin[240] or, in many algae and cyanobacteria, by the small **cytochrome c_6**.[241–242b] It is often synthesized when copper is inadequate for synthesis of plastocyanin. Figure 23-18 is a schematic view of PSI, PSII, and the intermediate cyt b_6f complex in a thylakoid membrane.

In spite of the close similarities in structures and function, there are distinct differences between cyto-

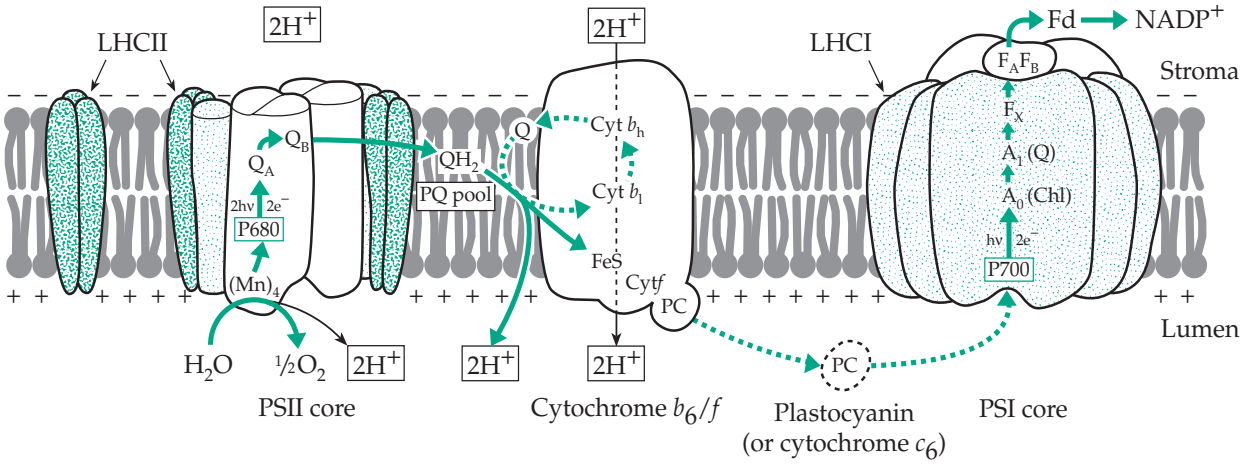

Figure 23-18 Schematic view of photosynthetic reaction centers and the cytochrome b_6f complex embedded in a thylakoid membrane. Plastocyanin (or cytochrome c_6 in some algae and cyanobacteria) carries electrons to the PSI core.

chrome b_6f and the cytochrome bc_1 of mitochondria.[243] Among these are the presence of stoichiometrically bound chlorophyll *a* and β-carotene[238,244] in the photosynthetic complex. The function of the chlorophyll is uncertain, but the carotene is probably there to quench the chlorophyll triplet state,[244] which would probably cause photodamage via formation of singlet O_2.

Bacterial photosynthesis. What is the relationship of the Z scheme of Fig. 23-17 to bacterial photosyntheses? In photoheterotrophs, such as the purple *Rhodospirillum*, organic compounds, e.g., succinate, serve as electron donors in Eq. 23-30. Because they can utilize organic compounds for growth, these bacteria have a relatively low requirement for NADPH or other photochemically generated reductants and a larger need for ATP. Their photosynthetic reaction centers receive electrons via cytochrome *c* from succinate ($E°' = +0.03$ V). The centers resemble PSII of chloroplasts and have a high midpoint electrode potential $E°'$ of 0.46 V. The initial electron acceptor is the Mg^{2+}-free bacteriopheophytin (see Fig. 23-20) whose midpoint potential is −0.7 V. Electrons flow from reduced bacteriopheophytin to menaquinone or ubiquinone or both via a cytochrome bc_1 complex, similar to that of mitochondria, then back to the reaction center P870. This is primarily a cyclic process coupled to ATP synthesis. Needed reducing equivalents can be formed by ATP-driven reverse electron transport involving electrons removed from succinate. Similarly, the purple sulfur bacteria can use electrons from H_2S.

In contrast, the reaction centers of green sulfur bacteria resemble PSI of chloroplasts. Their reaction centers also receive electrons from a reduced quinone via a cytochrome *bc* complex.[245] However, the reduced form of the reaction center bacteriochlorophyll donates electrons to iron–sulfur proteins as in PSI (Fig. 23-17). The latter can reduce a quinone to provide cyclic photophosphorylation. Cyanobacteria have a photosynthetic apparatus very similar to that of green algae and higher plants.

2. Chloroplast Structure

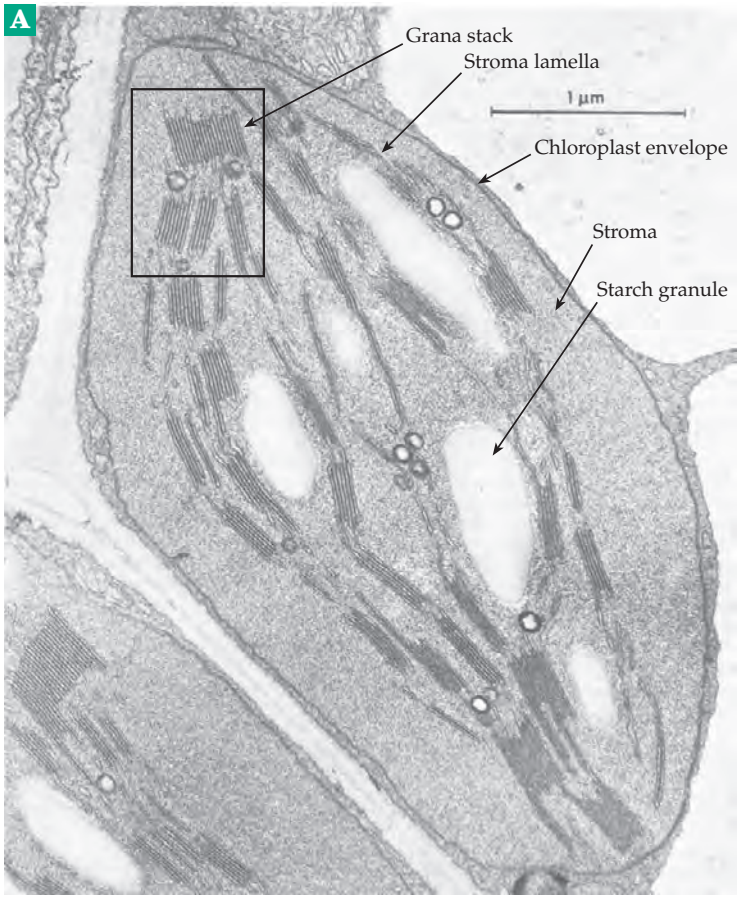
Chloroplasts come in various sizes and shapes, but all contain a small number of DNA molecules ranging in size from 120–160 kb. Complete sequences are known for DNA from chloroplasts of a liverwort (121,025 bp),[246] tobacco (155,844 bp),[247] maize (*Zea mays*),[248] and other plants. The 140,387 bp DNA from maize chloroplasts is a circular molecule containing the genes for 23S, 16S, 5S, and 4.5S RNA, for 30 species of tRNA, and for 70 different proteins. Among them are subunits of RNA polymerase, NADH dehydrogenase, subunits of both PSI and PSII, rubisco (large subunit), cytochromes *b* and *f*, six subunits of ATP synthase, and others. As with mitochondria, some subunits of the enzyme complexes that provide the cell with energy (e.g., ATP synthase) are encoded in the nucleus.

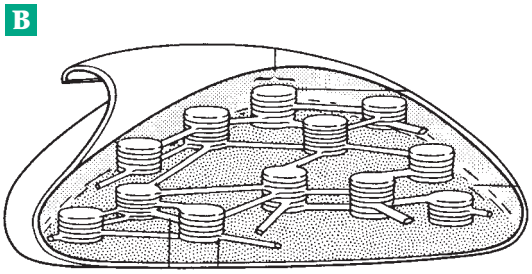
A characteristic of chloroplast genomes is the presence of a pair of large (in maize 22,348 bp) inverted repeat sequences. Since they can form a large hairpin structure with a very large loop, they may stabilize the gene sequence. The mutation rate within the repeat sequence is lower than in the single-stranded regions. The same genes are found in corresponding positions in both maize and rice. Both genomes have a number of sites of departure from the standard genetic code. These "editing sites" give rise to C→U transitions in the RNA transcripts.

Most land plants have similar chloroplast DNA sequences, but considerable divergence is observed among algae.[249] For example, the red alga *Porphyra purpura* has 70 genes not found in chloroplasts of land plants. Each gene of the chloroplasts of the dinoflagellate *Heterocapsa triquetra* is carried on its own DNA minicircle.[250] However, ~2000 chloroplast proteins are encoded by nuclear DNA. The corresponding proteins are synthesized on cytoplasmic ribosomes and are transported into the chloroplasts.[249a] Some of these proteins must pass through both the double membrane of the envelope and the thylakoid membrane. As in mitochondria (Fig. 18-4) an array of different transport proteins are required. They are distinctly different from the mitochondrial transport proteins and involve their own unique targeting mechanisms.[251–253a]

Chloroplast membranes. Like the other energy-producing organelles, the mitochondria chloroplasts are surrounded by an outer double membrane or **envelope** and also contain an internal membrane system.[225–227,254–255a] Within the colorless **stroma** are stacks of flattened discs known as **grana** (Fig. 23-19). The discs themselves (the **thylakoids**) consist of pairs of closely spaced membranes 9 nm thick, each pair being separated by a thin internal space or loculus (Fig. 23-19). At least 75 different proteins are present in the isolated membranes. There is also a high content of **galactosyl diacylglycerol**, **digalactosyl diacylglycerol**, and **sulfolipid** (Chapter 8, Section A,4). Lipids account for half of the mass of thylakoid membranes.

Through the use of freeze-fracture and freeze-etching techniques of electron microscopy, it is possible to see, embeddded in the thylakoid membranes, particles which may represent individual **photosynthetic units** (also called quantosomes).[227,256–258] They are about 20 nm in diameter, and at least many of them presumably contain a reaction center surrounded by light-collecting chlorophyll–protein complexes. Others may represent the cytochrome b_6f complex and





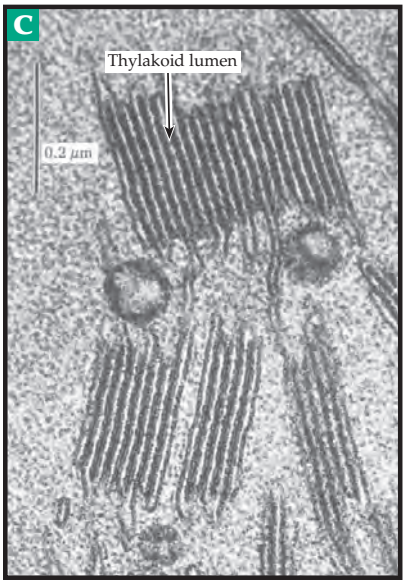


Figure 23-19 (A) Electron micrograph of alfalfa leaf chloroplast. Courtesy of Harry T. Horner, Jr., Iowa State University. (B) Schematic drawing of a chloroplast. From Hall and Rao[227] (C) Enlargement of a portion of (A) to show grana stacks more clearly.

ATP synthase, whose knobs also protrude into the stroma. A photosynthetic unit can also be defined chemically by the number of various types of molecules present in a chloroplast membrane for each four manganese atoms (Table 23-2). Separate units contain PSI and PSII. These reaction centers appear to have a different distribution within the thylakoids, the PSI units being located principally in the unstacked membranes and the PSII units in the grana stacks.[255,259]

Photosynthetic pigments and their environments. The chlorophylls (Fig. 23-20) are related in structure to the hemes (Figs. 16-5, 16-6), but ring IV (D) is not fully dehydrogenated as in the porphyrins. The **chlorin** ring system is further modified in chlorophyll by the addition of a fifth ring (V) containing an oxo group and a methyl ester. Ring V has been formed by crosslinking between the propionic acid side chain of ring III and a methine bridge carbon to give the parent compound **pheoporphyrin**. Chlorophylls contain constituents around the periphery that indicate a common origin with the porphyrins (Fig. 24-23). However, one of the carboxyethyl groups is esterified with the long-chain phytyl group in most of the chlorophylls. Chlorophyll *a* is the major pigment of chloroplasts and is a centrally important chromophore for photosynthesis in green plants. Most of the other chlorophylls, as well as the carotenoids and certain other pigments, are referred to as **accessory pigments**. Many of them have a light-receiving antenna function. Carotenoids are also photoprotectants. The relative numbers of pigment molecules in the photosynthetic units (average of PSI and PSII) of spinach chloroplasts are given in Table 23-2.

While the structure of chlorophyll *a* shown in Fig. 23-20 is the predominant one, other forms exist, e.g., with

$$-CH_2CH_3 \text{ or } -\underset{\displaystyle OH}{\underset{|}{CH}}-CH_3$$

replacing the vinyl group on ring I or with vinyl or hydroxyethyl replacing the ethyl group on ring II. The same kind of variation occurs for chlorophyll *b*.[260] In 80% acetone chlorophyll *a* has a sharp absorption band at 663 nm (15,100 cm^{-1}), but within chloroplasts the absorption maximum is shifted toward the red, the majority of the chlorophyll absorbing at 678 nm. Chlorophyll *b* (Fig. 23-20) is also nearly always present in green leaves.

The absorption peak in acetone is at 635 nm (15,800 cm^{-1}). Chlorophyll *c* found in diatoms, brown algae (Phaeophyta), and dinoflagellates (Fig. 1-9) lacks the phytyl group. Chlorophyll *d* contains a formyl group on ring I.[261]

Photosynthetic bacteria contain **bacteriochlorophylls** in which ring II is reduced (Fig. 23-20). The absorption band is shifted to the red from that of chlorophyll *a* to ~770 nm. The most abundant chlorophylls of green sulfur bacteria, **bacteriochlorophylls *c***, ***d***, and ***e*** (or *Chlorobium* chlorophylls), contain a hydroxyethyl group on ring I; ethyl, *n*-propyl, or isobutyl groups on ring II; often an ethyl group instead of methyl on ring III; and a methyl group on the methine carbon linking rings I and IV. A variety of polyprenyl side chains can replace the phytyl group of the chlorophylls of higher plants.[262,263] The **pheophytins**, which are identical to the chlorophylls but lack the central magnesium ion, play an essential role in photosynthetic reaction centers. They can be formed in the laboratory by splitting the Mg^{2+} out from chlorophyll with a weak acid. Other derivatives are the **chlorophyllides** formed by hydrolysis of the methyl ester group and **chlorophyllins** formed by removal of both the methyl and phytyl groups.

Since chlorophyll can be removed readily from chloroplasts by mild solvent extraction, it might appear that it is simply dissolved in the lipid portion of the membranes. However, from measurements of dichroism (Gregory,[226] p. 111) it was concluded that the chlorophyll molecules within the membranes have a definite orientation with respect to the planes of the thylakoids and are probably bound to fixed structures. The absorption spectrum of chlorophyll in leaves has bands that are shifted to the red by up to 900 cm^{-1} from the position of chlorophyll *a* in acetone. Most green plants contain at least four major chlorophyll bands at ~662, 670, 677, and 683 nm as well as other minor bands[264] (Fig. 23-21). This fact suggested that

TABLE 23-2

the chlorophyll exists in a number of different environments. As a result, the absorption is spread over a broader region leading to more efficient capture of light. Only a small fraction of the total chlorophyll is in the reaction centers; that for PSI absorbs at ~700 nm and that for PSII at ~682 nm.

Bacteriochlorophyll in *Chromatium* has three absorption bands with peak positions at 800, 850, and 890 nm. The last includes the reaction center bacteriochlorophyll and is the only form that fluoresces. Recent studies have established that most if not all chlorophyll is bound to specific proteins, a fact that can account for the various overlapping absorption bands.

The **carotenes** and **carotenoids** are very important accessory pigments (Fig. 23-22). The major component in most green plants is β-carotene. Green sulfur bacteria contain γ-carotene in which one end of the molecule has not undergone cyclization and resembles lycopene (Fig. 22-5). Chloroplasts also contain a large variety of oxygenated carotenoids (xanthophylls). Of these, neoxanthin, violaxanthin (Eq. 22-12), and lutein (p. 1240) predominate in higher plants and green algae. *Euglena* and related microorganisms contain much antheraxanthin (Eq. 22-10). A light-collecting protein from marine dinoflagellates contains both chlorophyll *a* and several molecules of the carotenoid peridinin. See Fig. 23-29.[267,268] Brown algae and diatoms contain mostly fucoxanthin and zeaxanthin (Fig. 22-5), while the bacterium *Rhodospirillum rubrum* synthesizes spirilloxanthin (p. 1240).

It is a striking fact that there are no naturally occurring green plants that lack carotenoid pigments.[269] Carotenoidless mutants are used in photosynthesis research, but they apparently cannot survive under natural conditions. Carotenoids not only participate as members of the light-receiving complex but also confer protection to chlorophyll against light-induced destruction by singlet oxygen. This accounts for the fact that carotenoids are usually intimately associated with chlorophyll in the pigment complexes. For example, see Figs. 23-29 and 23-30 and discussion on pp. 1308–1310.

A third class of accessory pigment of more limited distribution are the **open tetrapyrroles**, sometimes called "plant bile pigments" because of their relationship to the pigments of animal bile (Fig. 24-24). Among these are the **phycocyanins**, which provide the characteristic color to cyanobacteria. They are conjugated proteins (biliproteins) containing covalently bound phycocyanobilin (Fig. 23-24).[270] The red **phycoerythrins** of the Rhodophyta contain bound phycoerythrobilin (Fig. 23-23), an isomer of phycoerythrobilin. There are four common isomeric **bilins**, each having a different number of conjugated double bonds.[272,273] Together, they provide for a broad range

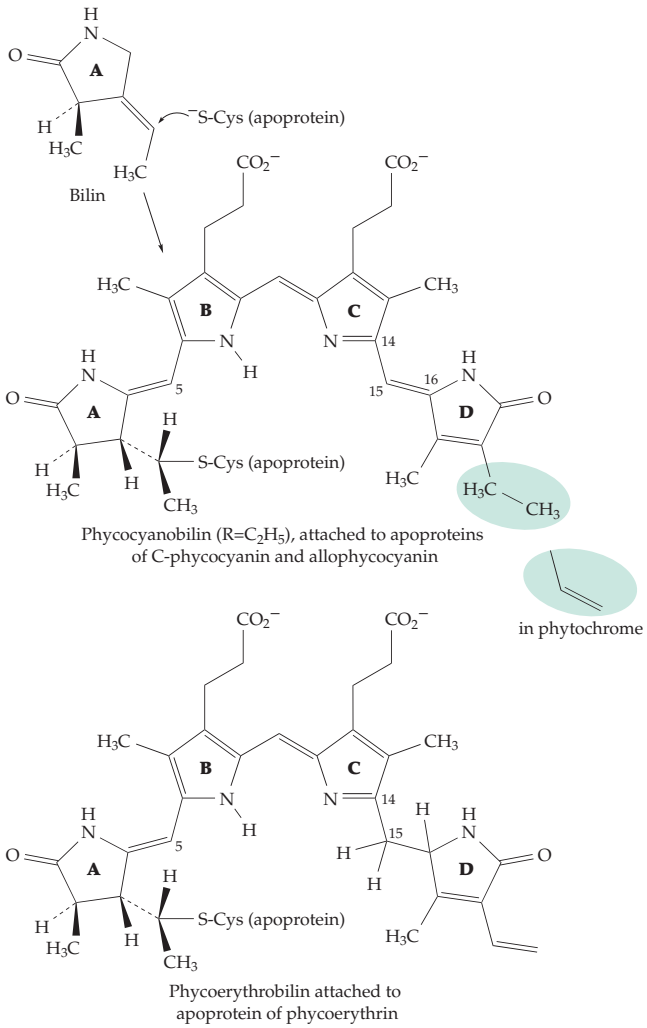

Figure 23-23 Structures of the open tetrapyrroles of plants. See also Fig. 24-24. After Szalontai *et al.*[271]

of colors from blue to red (Table 23-3). The bilins are attached to proteins via addition of a cysteine –SH group to the vinyl group of ring A of the bilin (Fig. 23-23). A double attachment may be formed by addition of –SH groups to both vinyl groups.[273–276] Isolated tetrapyrrole pigments tend to have a helical structure and to absorb light at lower wavelengths than do the protein-bound pigments which assume elongated conformations.

There are three major classes of conjugated phycobiliproteins,[273,277] all of which are αβ heterodimers often associated as $(\alpha\beta)_6$ (Fig. 23-24). The **allophycocyanins** carry one bilin per subunit, the phycocyanins carry one on the α and two on the β subunit, and the phycoerythrins carry two or three on the α subunit and three on the β (Fig. 23-24). Cysteine α-84 is one of the frequent attachment sites.[273] Three-dimensional structures are known for several of these proteins[278–281]

TABLE 23-3
The Common Bilin Pigments Present in Phycobiliniproteins[a]

Isomer	Number of conjugated double bonds	Absorption maximum (nm) when conjugated to proteins
Phycocyanobilin	8	~640
Phycobiliviolin	7	~590
Phycoerythrobilin	6	~550
Phycourobilin	5	~490

[a] Wedemayer, G. J., Kidd, D. G., Wemmer, D. E., and Glazer, A. N. (1992) *J. Biol. Chem.* **267**, 7315–7331.

The bilins are derived biosynthetically rather directly[282] from biliverdin IXα, whose formation is described in Fig. 24-24. The addition of an apoprotein –SH group to a carbon–carbon double bond of the bilin is catalyzed by a specific lyase.[283] **Phytochrome** (Section H) arises in a similar way[284] as does the blue biliprotein **insecticyanin** (Box 21-A).[285]

3. The Light-Receiving Complexes

Irradiation of chloroplasts leads to easily measurable fluorescence from chlorophyll *a*, but no fluorescence is observed from chlorophyll *b* or from other forms of chlorophyll, carotenoids, or other pigments. It appears that the latter all serve as light-collecting or antenna pigments that efficiently transfer their energy to chlorophyll *a* at the reaction centers.[286] As is evident from Fig. 23-22, the light-collecting pigments generally have higher energy absorption bands than do the reaction centers. Thus, a broad range of wavelengths of light are absorbed by an organism, and energy from all of them is funneled into the reaction centers. The light-collecting pigments are bound to specific proteins, which are located close to the reaction centers and are arranged to provide efficient energy-transfer. Distances between adjacent pigment molecules vary from 1 to 7 nm.[287]

Phycobilosomes. Algal and cyanobacterial phycocyanins and phycoerythrins are aggregated in special granules that are on the outsides of the photosynthetic membranes. The granules in the cyanobacteria are known as phycobilosomes (Fig. 23-24).[272,286,286a,288] The $(\alpha\beta)_6$ hexamers form the disks of the phycobilosomes. These are held together by linker proteins,[281,289] which fit asymmetrically into the central cavities. As is indicated in Fig. 23-24C, the disks and linker proteins are assembled into rods which are joined to form the phycobilosomes. The

latter are organized into closely packed parallel arrays on the surface of the photosynthetic membranes.

Purple photosynthetic bacteria. The reaction centers of *Rhodobacter spheroides*, *Rhodospirillum rubrum*, and related purple bacteria are embedded in the plasma membrane. Each center is surrounded by a ring of bacteriochlorophyll *a* molecules bound noncovalently to heterodimeric (αβ) protein subunits made up of ~52- to 54-residue chains. Each αβ dimer binds two molecules of BChl *a*, whose central Mg^{2+} ions are coordinated by conserved histidine imidazole groups, as well as a molecule of spirilloxanthin. About 15–17 αβ subunits form the ring, which is designated LH1 (Fig. 23-25A).[291–293] Most of these bacteria also have smaller rings, designated LH2, floating in the membrane near the LH1 complex. The LH2 rings (Figs. 23-25B, C) consist of about nine αβ subunits with associated BChl *a* and carotenoid.[294–298] Under some conditions a third complex LH3 may be formed.[298a] In *Rhodopseudomonas acidophila* nine of the 27 BChl *a* molecules absorb light maximally at ~800 nm and are designated **B800**. The other 18, designated **B850**, absorb maximally at ~860 nm.[294,299] The B850 BChl *a* molecules have direct contact with the chromophores of neighboring molecules, allowing for easy energy transfer. The B800 chromophores are more isolated.

Low-temperature (1.2 K) single-molecule spectroscopic techniques have been used to obtain the fluorescence-excitation spectra shown in Fig. 23-26C. For an ensemble of LH2 complexes (upper trace) the spectral absorption bands are broad, but for individual LH2 complexes structure can be seen clearly for the B800 chromophores but not for the B850 chromophores. This difference has been interpreted to mean that the excitation energy of an electronically excited B850 molecule is delocalized over the whole ring of 18 BChl *a* molecules as an **exciton**. This permits both fast and efficient energy transfers from B800 to B850 and from B850 of one LH2 ring to another or to an LH1 ring and to the reaction center (Fig. 23-27).[299–300a] Energy transfer may occur by the Förster dipole–dipole mechanism (Section C,2).[298] Many of the antenna are supported by binding through their Mg^{2+} ion to an imidazole group of a protein as can also be seen in reaction center chlorophylls (Fig. 23-31C). Hydrogen-bonding to the C13-oxo groups of the chlorophylls may also be possible.[300b] The orientations of the transition dipole moments of the chlorophyll molecules may be arranged to facilitate rapid energy transfer.[300c]

Green sulfur and nonsulfur bacteria. In these organisms chlorophylls are present in rodlike particles

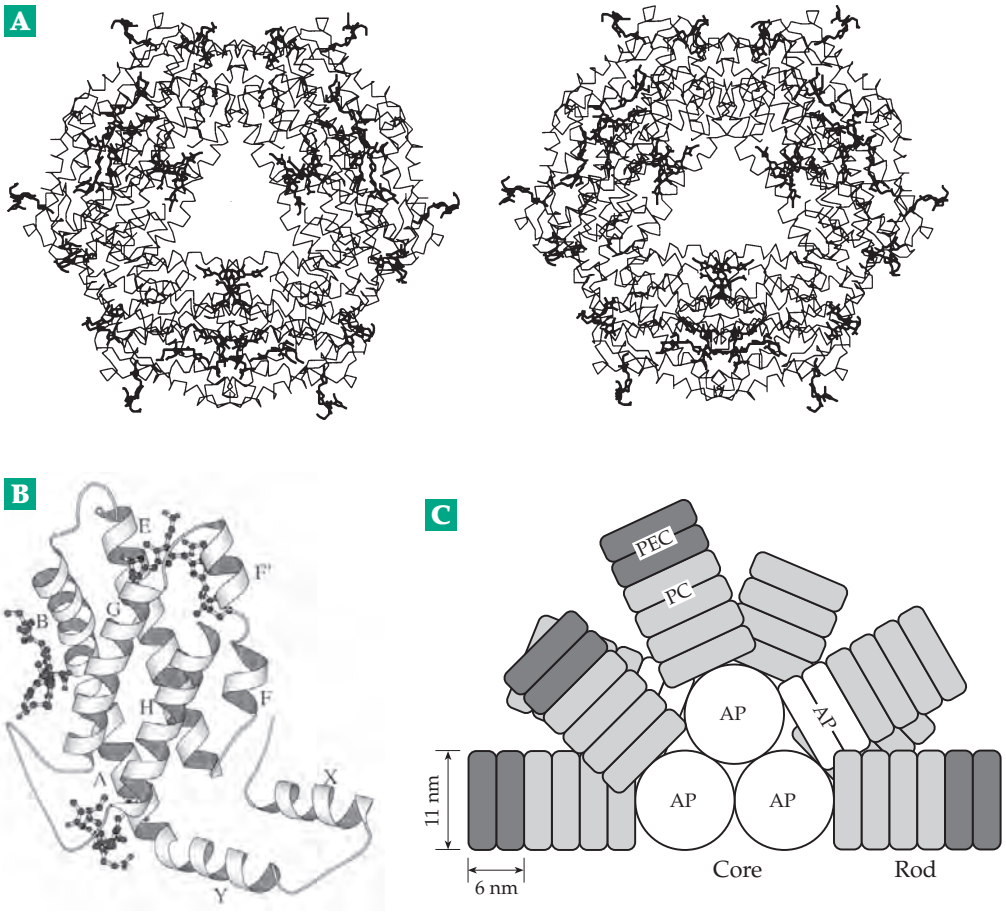

Figure 23-24 (A) Stereoscopic view of a hexameric $(\alpha\beta)_3$ phycobiliprotein. (B) The β subunit of the complex with two molecules of bound phycoerythrobilin and one of phycourobilin. (C) Fluorescence-excitation spectra. Top trace, for an ensemble of LH2 complexes, other traces, for several individual LH2 complexes at 1.2K. Fine structure is evident for the B800 but not for the B850 chromophores. From van Oijen *et al.*[299] with permission.

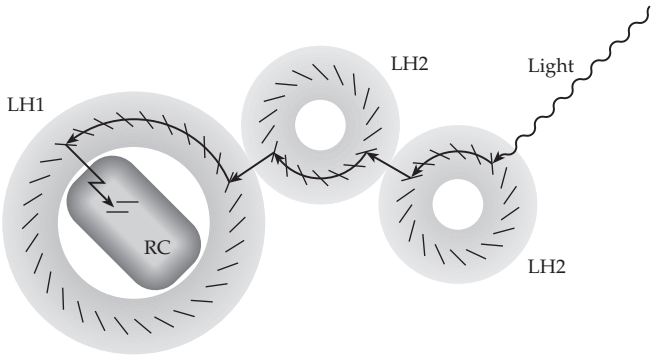

Figure 23-27 Illustration of proposed exciton transfer of the energy of light absorbed by bacteriochlorophyll *a* of purple bacteria. Energy absorbed by the light harvesting complex LH2 is transferred in steps to another LH2, to LH1 and to the reaction center. The short lines within the circles represent the edges of the BChl*a* chromophores. After Kühlbrandt[300] with permission.

of protein present within **chlorosomes**, baglike structures which may be as large as 100 x 260 nm and are attached to the inside of the cytoplasmic membranes,[301–302a] which contain the reaction centers (Fig. 23-28). The over 10,000 light-collecting chlorophylls *c*, *d*, or *e*, which may be present per reaction center, allow these bacteria to live in extremely weak light. The bacteria also contain a smaller "antenna" of ~5000 BChl *a* present as a complex with a water-soluble protein. The three-dimensional structure of this protein is also shown in Fig. 23-28. Each 45-kDa subunit of the trimeric protein contains seven embedded molecules of bacteriochlorophyll *a*.[302,303] Other light-collecting chlorophyll–protein complexes may contain an even higher ratio of chlorophyll to protein.[286]

Eukaryotic plants and cyanobacteria. Photosynthetic dinoflagellates, which make up much of the marine plankton, use both carotenoids and chlorophyll in light-harvesting complexes. The carotenoid **peridinin** (Fig. 23-29), which absorbs blue-green in the 470- to 550-nm range, predominates. The LH complex of *Amphidinium carterae* consists of a 30.2-kDA protein that forms a cavity into which eight molecules of peridinin but only two of chlorophyll a (Chl *a*) and two molecules of a galactolipid are bound (Fig. 23-29).[268]

The allenic carotenoid **fucoxanthin** (Fig. 22-5), which is absent in higher plants, predominates in brown algae, where it occurs in light-harvesting complexes along with Chl *a* and Chl *c*.[306,307]

A family of Chl *a*/*b* binding proteins are found in green plants.[308] These have apparently evolved inde-

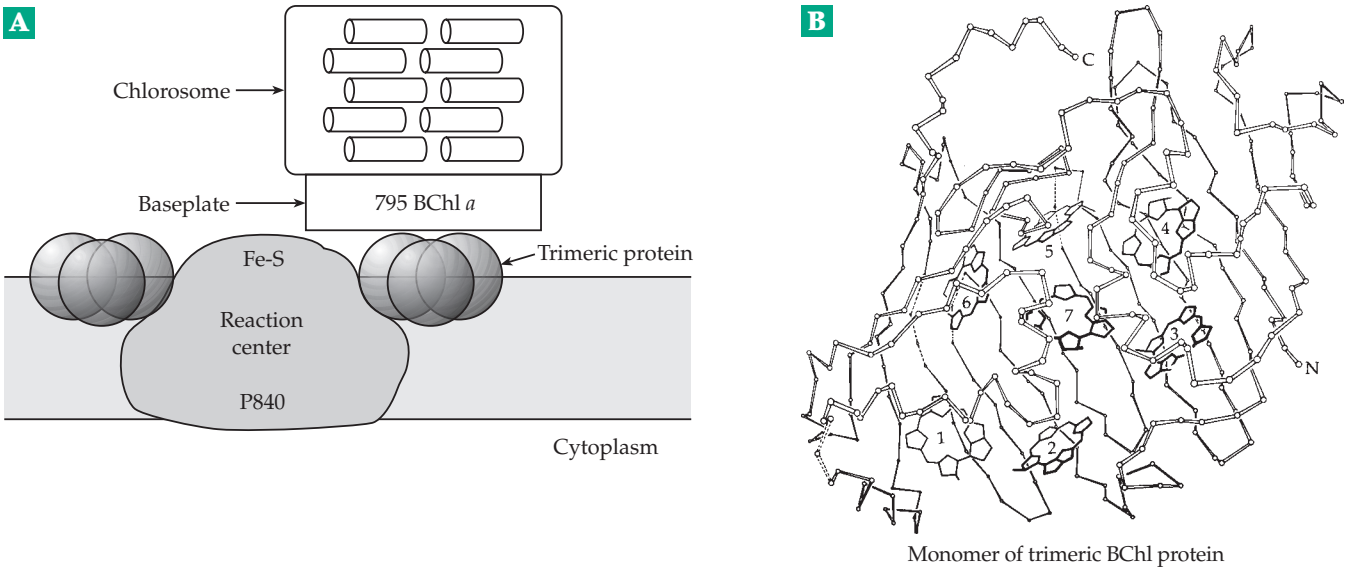

Figure 23-28 (A) Model of a light-harvesting chlorosome from green photosynthetic sulfur bacteria such as *Chlorobium tepidum* and species of *Prosthecochloris*. The chlorosome is attached to the cytoplasmic membrane via a baseplate, which contains the additional antenna bacteriochlorophylls (795 BChl *a*) and is adjacent to the trimeric BChl protein shown in (B) and near the reaction center. After Li *et al.*[302] and Rémigy *et al.*[304] (B) Alpha carbon diagram of the polypeptide backbone and seven bound BChl *a* molecules in one subunit of the trimeric protein from the green photosynthetic bacterium *Prosthecochloris*. For clarity, the magnesium atoms, the chlorophyll ring substituents, and the phytyl chains, except for the first bond, are omitted. The direction of view is from the three-fold axis, which is horizontal, toward the exterior of the molecule. From Fenna and Matthews.[305] See also Li *et al.*[302]

pendently of chlorophyll-binding proteins of green bacteria.[309] Quantitatively most important is the complex known as LHCII, the major Chl *a* / *b* protein associated with PSII and which may also provide energy to PSI. This one protein, whose structure is shown in Fig. 23-30,[310] is thought to bind half of all of the chlorophyll in green plants. The protein is organized as trimers.[311] Each 232-residue monomer binds 5–6 Chl *b*, 7–8 Chl *a*, ~ two molecules of lutein, and one of neoxanthin.[310,311] LHCII also carries all four characteristic thylakoid lipids: mono- and digalactosyl diacylglycerols, phosphatidylglycerol, and sulfoquinovosyl diacylglycerol.[312] The Chl *a* and Chl *b* molecules are in close contact (Fig. 23-30). Subpicosecond transient absorption spectroscopy[311] indicates that half of the Chl *b* to Chl *a* energy transfers occur in < 0.2 ps. Notice the close association of the two luteins in Fig. 23-30 with the chlorophyll rings. The carotenoids are thought to quench chlorophyll triplet states to prevent formation of singlet oxygen.

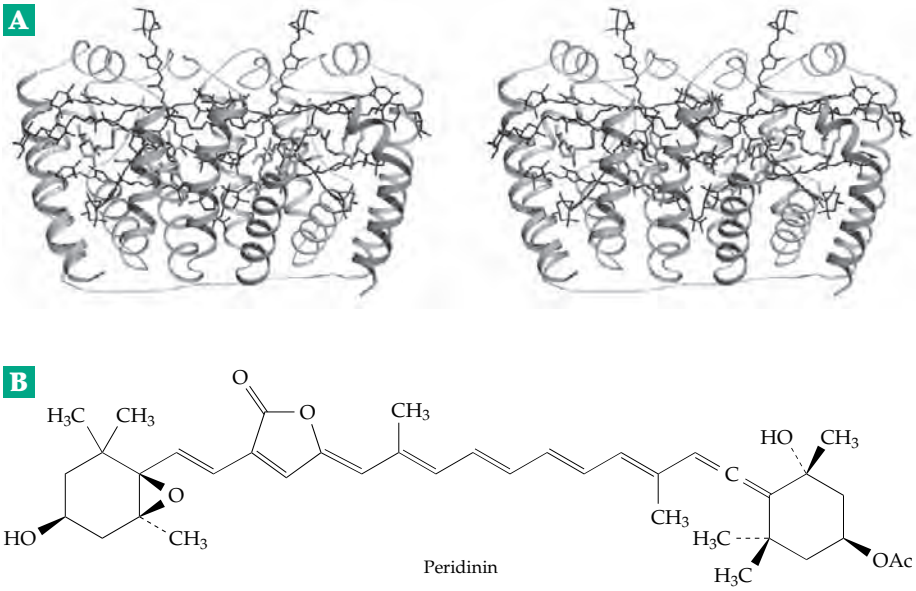

Figure 23-29 (A) Stereoscopic drawing of light-harvesting complex from the dinoflagellate protozoan *Amphidinium carterae*. The central cavity contains eight molecules of peridinin, two of which can be seen protruding from the top. Deeply buried toward the bottom are two molecules of Chl *a*. Also present are two molecules of digalactosyl diacylglycerol. From Hofmann *et al.*[268] Courtesy of Wolfram Welte. (B) Structure of peridinin.

PSII also contains several additional chlorophyll-binding proteins, designated CP24, CP26, CP29, CP43, CP47, etc. These lie on both sides of a pair of reaction-center cores.[313–315a] A large fraction of the LHCII complexes are separate from the reaction centers and are mobile, while a smaller fraction are bound to the outer ends of the core complex.[308,314,315] The light-harvesting chlorophylls of PSI are arranged around the core. Some are bound in the N-terminal part of the major core subunits, the products of genes *PsaA* and *PsaB*.[316] They bind ~90 Chl *a* and 14 β-carotene molecules per reaction center. (See Fig. 23-33.) In addition, the peripheral LHCI, composed of four different proteins arranged around the core, binds ~110 Chl *a* and Chl *b* and ~70 molecules of xanthophyll.[317] Some species of cyanobacteria use antenna rings around their PSI trimers instead of phycobilinosomes.[317a]

In every case the light-harvesting complexes are arranged to allow rapid and very efficient transfer of electronic excitation energy from one chromophore to another and finally to the chromophores of the reaction center.[317b] The speed and efficiency appear to depend upon very rigid structures of the proteins and precise orientations of the bound chromophores to allow direct excitonic transfer of energy at distances of less than 2 nm or transfer by the Förster mechanism at distances not exceeding 10 nm.[302] An example of the precision of protein structures was observed when a posttranslationally modified asparagine N^5-methylasparagine at position 72 of the β subunit of many phycobiliniproteins was substituted by aspartate or glutamine. The fluorescence lifetime of the nearby bilin was reduced 7–10% in the mutants, an effect that could cut the >95% efficiency of energy transfer from the phycobilinisomes to the PSII reaction center.[318]

4. The Reaction Centers and Their Photochemistry

The initial or primary processes of photosynthesis occur in the reaction centers in which chlorophyll or bacteriochlorophyll absorbs a photon.[318a] Then, the chlorophyll, in its singlet excited state (Chl*), donates an electron to some acceptor A to form a radical A^- and to leave an oxidized chlorophyll Chl^+ radical (Eq. 23-31).

$$\mathrm{Chl} \xrightarrow{h\nu} \mathrm{Chl}^* \xrightarrow{\mathrm{A}} \mathrm{Chl}^+ + \mathrm{A}^- \qquad (23\text{-}31)$$

In the scheme of Fig. 23-18, acceptor A is Q_A for PSII and A_0 for PSI. The oxidized chlorophyll (Chl^+) quickly reacts further by receiving an electron from some donor.

The photooxidation of chlorophyll indicated in Eq. 23-31 is accompanied by bleaching in the principal light absorption band. However, since there is so much light-gathering chlorophyll for each reaction center, the effect is small. The study of the process has been aided greatly by preparation of isolated bacterial photochemical reaction centers.

Reaction centers of purple bacteria. The exact composition varies, but the properties of reaction centers from several genera of purple bacteria are similar. In *Rhodopseudomonas viridis* there are three peptide chains designated H, M, and L (for heavy, medium and light) with molecular masses of 33, 28, and 24 kDa, respectively. Together with a 38-kDa tetraheme cytochrome (which is absent from isolated reaction centers of other species) they form a 1:1:1:1 complex. This constitutes reaction center P870. The three-dimensional structure of this entire complex has been determined to 0.23-nm resolution[288,319–323] (Fig. 23-31). In addition to the 1182 amino acid residues there are four molecules of bacteriochlorophyll (BChl), two of bacteriopheophytin (BPh), a molecule of menaquinone-9, an atom of nonheme iron, and four molecules of heme in the *c* type cytochrome. In 1984, when the structure was determined by Deisenhofer and Michel, this was the largest and most complex object whose atomic structure had been described. It was also one of the first known structures for a membrane protein. The accomplishment spurred an enormous rush of new photosynthesis research, only a tiny fraction of which can be mentioned here.

The reaction centers are embedded in the cytoplasmic membranes of the bacteria, with the bottom of the structure, as shown in Fig. 23-31, protruding into the cytoplasm and the heme protein at the top projecting out into the periplasm which lies within infoldings of the plasma membrane. Subunits L and M each contain five ~4.0 nm long roughly parallel helices, which span the cytoplasmic membrane. Another membrane-spanning helix is contributed by subunit H, which is located mainly on the cytoplasmic side. An approximate twofold axis of symmetry relates subunits L and M and the molecules of bound chlorophyll and pheophytin.

Spectral measurements suggesting exciton splitting were among early observations that led to the conclusion that the bacteriochlorophyll involved in the initial photochemical process exists as a dimer or **special pair** (Fig. 23-31),[319,324] a conclusion verified by the structure determination. The special pair of BChl *b* lies in the center of the helical bundle that is embedded in the membrane. Nearly perpendicular to the rings of the special pair are two more molecules of BChl *b*. The central magnesium atoms of all four bacteriochlorophylls are held by imidazole groups of histidine side chains.[319,325] Below the chlorophylls are

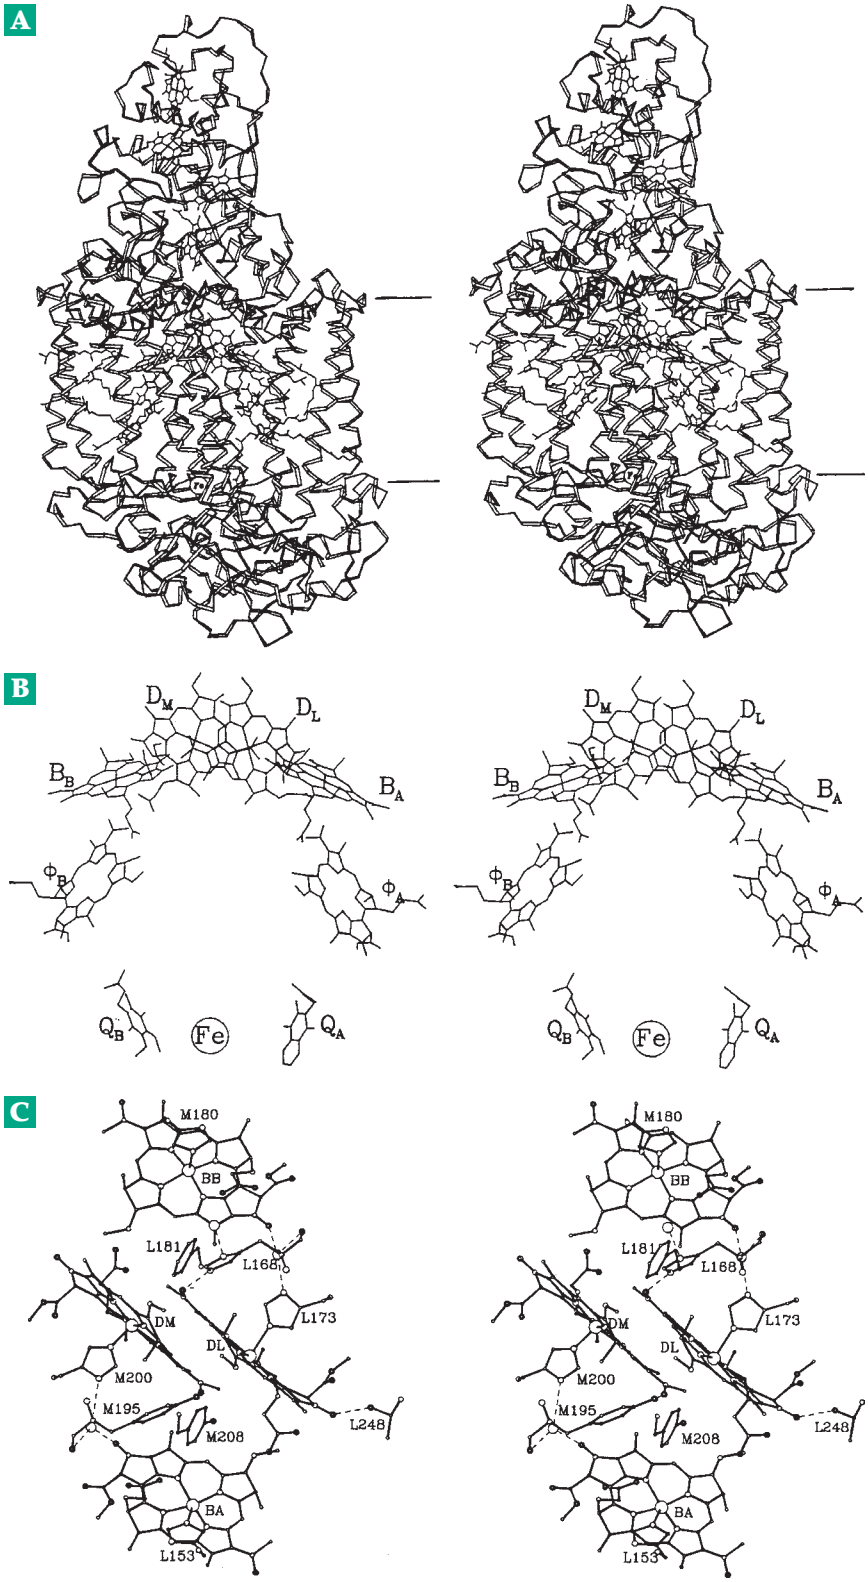

Figure 23-31 (A) Stereoscopic ribbon drawing of the photosynthetic reaction center proteins of *Rhodopseudomonas viridis*. Bound chromophores are drawn as wire models. The H subunit is at the bottom; the L and M subunits are in the center. The upper globule is the cytochrome *c*. The view is toward the flat side of the L, M module with the L subunit toward the observer. (B) Stereo view of only the bound chromophores. The four heme groups He1–He4, the bacteriochlorophylls (Bchl) and bacteriopheophytins (BPh), the quinones Q_A and Q_B, and iron (Fe) are shown. The four hemes of the cytochrome are not shown in (B). From Deisenhofer and Michel.[320] (C) Stereoscopic view of the Bchl *b* molecules along the local twofold axis. The special pair (D_M, D_L) is in the center with its tetrapyrrole rings almost perpendicular to the plane of the paper; the monomeric chlorophylls are labeled B_B and B_A. The four histidine ligands to the magnesium ions of the bacteriochlorophylls as well as two tyrosines (M195 and M208) and three water molecules (large circles) are also shown. From Deisenhofer *et al.*[321] with permission.

the two molecules of bacteriopheophytin and below them the nonheme iron and the menaquinone, the first quinone acceptor Q_A. It corresponds to Q_A of PSII shown in Fig. 23-18.

Isolated reaction centers usually contain or will bind a second quinone, which may be ubiquinone-10 (Q_{10})[325a] and which is usually designated Q_B. Its binding site is to the left of the nonheme iron in Fig. 23-31 in a position symmetrically related to that of Q_A. The reaction centers also contain a carotenoid 1,2-dihydro-

neurosporene.[323] The reaction centers of purple bacterium, *Rhodospirillum rubrum*, each contain one molecule of spirilloxanthin; a variety of carotenoids are present in other species.[326] The reaction centers of a third purple bacterium, *Rhodobacter spheroides*, are closely similar in structure to that in Fig. 23-31 but lack the tetraheme.[327] Reaction centers of these bacteria accept electrons directly from a soluble cytochrome *c*.

Reaction center kinetics. After an 0.8-ps or shorter flash of light the decay of the singlet excited state of the bacteriochlorophyll dimer in isolated reaction centers can be followed by loss of its characteristic fluorescence.[328,329] The lifetime of this excited state in *R. sphaeroides* is only 4 ps indicating a rapid occurrence of the initial electron transfer of Eq. 23-31. A rise in absorbance at 1250 nm is interpreted as formation of the bacteriochlorophyll cation radical $BChl^+$ in the special pair. Other spectral changes support the formation of BPh^- as the first reduction product (A^- in Eq. 23-31). However, this is thought to occur in two steps[323] with the monomeric BChl (B_A in Fig. 23-31B) receiving the electron in ~2.8 ps and passing it to the pheophytin (Phe; ϕ_A in Fig. 23-31B) in ~0.7 ps (Eq. 23-32; corresponding steps for PSII of green plants are also shown).

The quinone Q_A (the secondary acceptor) is next reduced by the BPh^- radical in ~200 ps with development of a characteristic EPR signal[321,330] at $g = 1.82$. Over a much longer period of time (~320 ns) an electron passes from the tetraheme cytochrome subunit to the Chl^+ radical in the special pair.[323,323a] The relatively slow rate of this reaction may be related to the fact that the bacteriochlorophyll of the special pair is 2.1 nm (center-to-center) from the nearest heme in the cytochrome while BPh and Q_A are only 1.4 nm apart (see Fig. 23-31).[288,331] Over a period of ~24 μs after formation of the radical anion Q_A^- an electron from the Q_A^- radical is passed to Q_B, a weakly bound ubiquinone-9, to form the Q_B^- radical. Upon absorption of a second photon by the special BChl pair another electron is passed through the chain to form $Q_A^-Q_B^-$. Uptake of two protons with transfer of the second electron from Q_A^- to Q_B^- yields the ubiquinol QH_2, which dissociates from its binding site (Q_B) into the ubiquinone pool dissolved in the lipids of the membrane bilayer.[331a–g]

Why is this multistep sequence of electron transfers necessary? A variety of techniques such as femtosecond IR[332,333] and electronic[334–335a] spectroscopy, resonance Raman spectroscopy at low temperatures,[336] and study of many mutants[337–338c] have been directed toward an answer to this question. It has been generally accepted that light energy absorbed by any one of the "monomeric" Chl or pheophytins in the reaction centers is funneled "downhill" to the special pair within 0.1–0.2 ps to generate P*.[334,336] The ultrafast ~3 ps electron transfer from P* to the adjacent monomeric BChl or Chl is necessary to prevent loss of energy by fluorescence from P*. The subsequent energetically downhill transfer to a pheophytin and on to Q_A prevents reverse electron transfer, which could also lead to fluorescence. Both the efficiency and the quantum yield are very high.[339]

The rate of the ultrafast proton transfer becomes even higher at cryogenic temperature, suggesting quantum mechanical tunneling.[331,335,340–340b] The transfer is generally treated using Marcus theory (Chapter 16), which indicates a very small reorganization energy for the process. Another aspect of the process is a possible coupling of a vibrational mode of the protein matrix to the electron transfer. Femtosecond near-IR spectra show low-frequency vibrational modes of the excited-state reaction center chromophores which may facilitate electron transfer.[332,336] The transfer of an electron from the tetraheme cytochrome *c* of *R. viridis*[341] or from the small cytochrome c_2 of *Rhodobacter spheroides*[342] to Chl^+ of the special pair has similar characteristics but is slower than the initial electron transfer from P*. On the other hand, electron transfers from Q_A^- to Q_B^- involve two distinct steps and coupled uptake of two protons.[343] An unexplained fact is that photochemical electron transport through the reaction centers always occurs through the L-side to Q_A rather than the M-side.[343a–344] However, rapid electron transfer to the pheophytin on the B-side (M-side) has been observed following excitation with blue light. This may

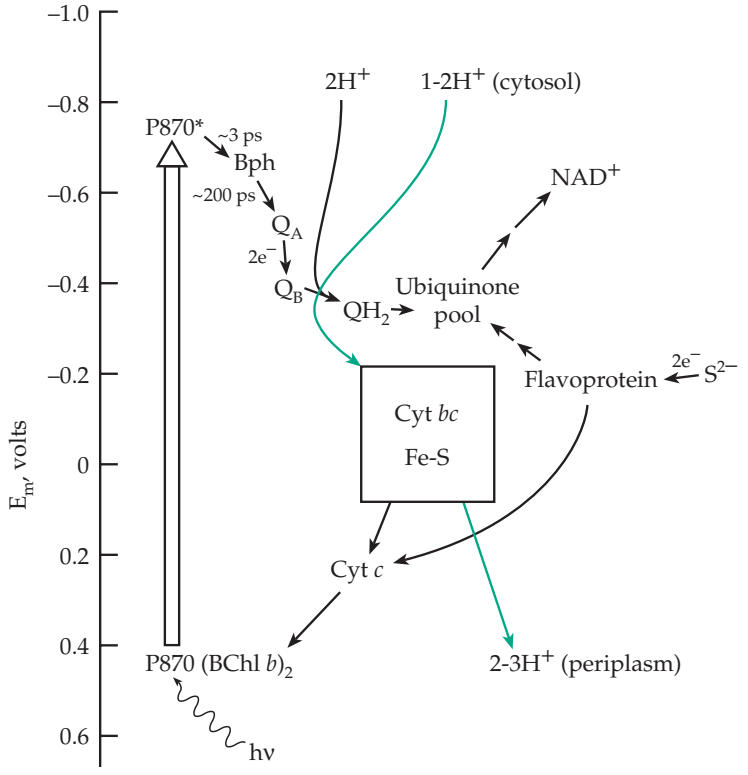

Figure 23-32 Simplified diagram of cyclic electron flow in purple bacteria. Two protons from the cytoplasm bind to Q_B^{2-} in the reaction center to form QH_2 (ubiquinol), which diffuses into the ubiquinone pool. From there it is dehydrogenated by the cytochrome bc_1 complex with expulsion of two protons into the periplasm. A third and possibly a fourth proton may be pumped (green arrows) across the membrane, e.g., via the Q cycle (Fig. 18-9). The protons are returned to the cytoplasm through ATP synthase with formation of ATP. Some electrons may flow to the reaction centers from such reduced substrates as S^{2-} and some electrons may be removed to generate NADPH using reverse electron transport.[345]

represent a photoprotective mechanism.[344a] In the PSI system, in which the two phylloquinones are tightly bound,[344b] both the A-side and the B-side seem to function in electron transfer.[344c]

Cyclic photophosphorylation in purple bacteria. QH_2 is eventually dehydrogenated in the cytochrome bc_1 complex, and the electrons can be returned to the reaction center by the small soluble cytochrome c_2, where it reduces the bound tetraheme cytochrome or reacts directly with the special pair in *Rhodobacter spheroides*. The overall reaction provides for a cyclic photophosphorylation (Fig. 23-32) that pumps 3–4 H^+ across the membrane into the periplasmic space utilizing the energy of the two photoexcited electrons. These protons can pass back into the cytoplasm via ATP synthases located in the same membrane with their catalytic centers in the cytosol (see Figs. 18-5 and 18-14).

Comparison with other reaction centers. Subunit L of the *R. viridis* reaction center was found to have a 25% sequence homology with a quinone-binding protein now known as D1, a component of the reaction center core of PSII of chloroplasts. This protein was identified as the specific target protein for inhibition by herbicides such as DCMU and atrazine (see Section 1 for structures). These compounds act as competitive inhibitors of quinone binding[346] and bind in the Q_B site in the *R. viridis* reaction center. This fact, together with the discovery that the core of PSII of green plants consists of a heterodimer of the related polypeptides D1 and D2, suggested that PSII is very similar to the bacterial center of Fig. 23-31. Both use a quinone as primary acceptor. However, P680 operates at a more positive potential (E_m ~1 V), consistent with the fact that it must provide an oxidizing agent able to oxidize H_2O to O_2 ($E°' = +0.82$ V). Plastoquinone rather than menaquinone is the primary acceptor in PSII. A chlorophyll *a* dimer is apparently the initial electron donor. The methyl ester carbonyl groups on the edges of rings I (Fig. 23-20) of BChl may coordinate to other groups of the proteins.[288,346a] These ester groups are absent in Chl *a*.

The PSI reaction center (P700) of maize chloroplast was also found to contain a pair of homologous polypeptides with appropriately placed histidyl residues for chlorophyll binding.[347] FTIR spectra also indicate the presence of two Chl *a* molecules. Small shifts in IR frequencies upon electronic excitation suggest that one chlorophyll (P_1) is hydrogen-bonded through its 109-ester and 9-oxo groups (Fig. 23-20) while the chlorophyll (P_2) is free. This may account for the low value of E_m (Fig. 23-17). The charge on $P700^+$ appears to be carried in part on both chlorophylls. However, in the triplet state $^3P700^*$, which may be observed at low temperature, excitation is localized on P_1.[348] Although P700 operates at the low E_m of +0.49 V it produces a powerful reducing agent able to reduce ferredoxin. The first identified acceptors are other Fe–S centers present in integral membrane proteins.[345] The reaction centers of green bacteria[349] and PSI of cyanobacteria[245] have similar characteristics. As more genes have been sequenced and X-ray diffraction, electron crystallography, and electron microscopy with single-particle averaging have advanced, the fundamental similarity of all of the photosynthetic centers has been confirmed.[228,300,350–353] Gene sequences are often not highly conserved, but structures are more conserved. An evolutionary relationship of all of the reaction centers can be seen.[316,354]

PSI of cyanobacteria and green plants. The major reaction-center subunits **PsaA** and **PsaB** each have a C-terminal domain, resembling those of the L and M chains of purple bacteria, and a large N-terminal antenna-chlorophyll-binding domain. Cyanobacterial PSI contains ten other subunits, PsaC to PsaF, PsaI to PsaM, and PsaX. Thirty-one transmembrane helices have been assigned to the various subunits, several of which are in positions corresponding closely to those in the reaction centers of the purple bacteria (Fig. 23-33).[355–357] The PSI of higher plants is somewhat larger than that of cyanobacteria and contains somewhat different subunits.[356a,357,357a]

The electron donor to Chl^+ in PSI of chloroplasts is the copper protein plastocyanin (Fig. 2-16). However, in some algae either plastocyanin or a cytochrome *c* can serve, depending upon the availability of copper or iron.[345] Both Q_A and Q_B of PSI are phylloquinone in cyanobacteria but are plastoquinone-9 in chloroplasts. Mutant cyanobacteria, in which the pathway of phylloquinone synthesis is blocked, incorporate plastoquinone-9 into the A-site.[345a] Plastoquinone has the structure shown in Fig. 15-24 with nine isoprenoid units in the side chain. Spinach chloroplasts also contain at least six other plastoquinones. Plastoquinones C, which are hydroxylated in side-chain positions, are widely distributed. In plastoquinones B these hydroxyl groups are acylated. Many other modifications exist including variations in the number of isoprene units in the side chains.[358,359] There are about five molecules of plastoquinone for each reaction center, and plastoquinones may serve as a kind of electron buffer between the two photosynthetic systems.

Look at the Z scheme of Fig. 23-17. The lower end of each vertical arrow is located at an electrode midpoint potential E_m (or $E°'$) for the couple P^+/P, i.e., for a one-electron reduction of the Chl^+ or $BChl^+$ radical.[360] The top of the arrow is at the estimated value of E_m for the excited state P*. It is more negative than the ground-state value of E_m by the energy (in electron volts) of the light absorbed. This is a little misleading

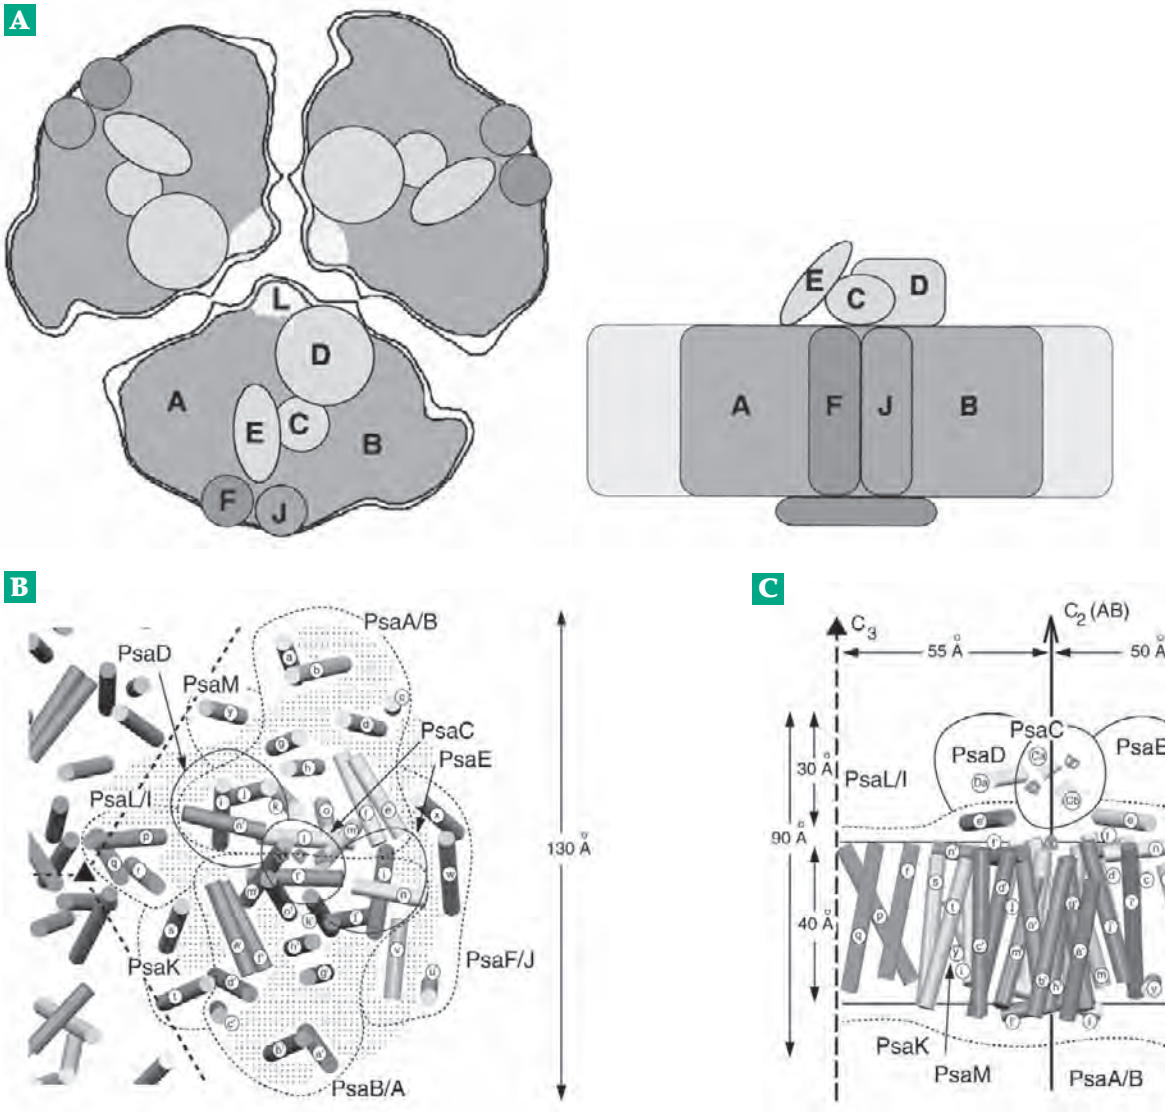

Figure 23-33 Models of the PSI reaction center of the cyanobacterium *Synechocystis* and of higher green plants. (A) Subunit arrangement in trimeric cyanobacterial PSI as gained from EM and crosslinking experiments with wild type and directed mutant forms. From Kruip *et al.*[355] Courtesy of Jochen Kruip: Left, top view; Right, side view. (B) Schematic representation (top view) of the structure of one monomer based on X-ray data at 0.6 nm resolution. The triangle at the left marks the threefold axis of a trimer and the heavy dashed lines the interfaces between monomers. Thirty-one helices, many of which are transmembrane, are shown as shaded cylinders. Fourteen of these are in the central core (light area) while the other 17 are in peripheral regions (light gray) that bind antenna chlorophyll molecules. (C) Side view, stroma at the top showing stromal subunits PsaC, PsaD, and PsaE. for it is not commonly appreciated that light carries entropy as well as energy. An important consequence of this fact is that not all of the energy of sunlight could be harnessed for chemical work. Knox[361] has calculated that at 700 nm at most 78% of the energy could be captured. See Parson[362] for further discussion. Nevertheless, the photoexcited P700* with E_m = – 1.26 V is able to reduce a series of membrane-bound Fe–S centers of $E°' \sim -0.5$ to -0.6 V. There are three of these designated F_X, F_A, and F_B. Center F_X is an Fe_4S_4 cluster located at almost the same position as the single Fe^{3+} of the *R. viridis* reaction center (Fig. 23-31B). F_A and F_B are also Fe_4S_4 clusters both of which are carried on the small 79-residue PsaC.[363,364] This protein binds to the reaction center on the stromal side as shown in Fig. 23-33. Close to it are two other subunits, PsaD and PsaE, which appear to assist the docking of ferredoxin or flavodoxin to PsaC and cluster F_X.[365,366]

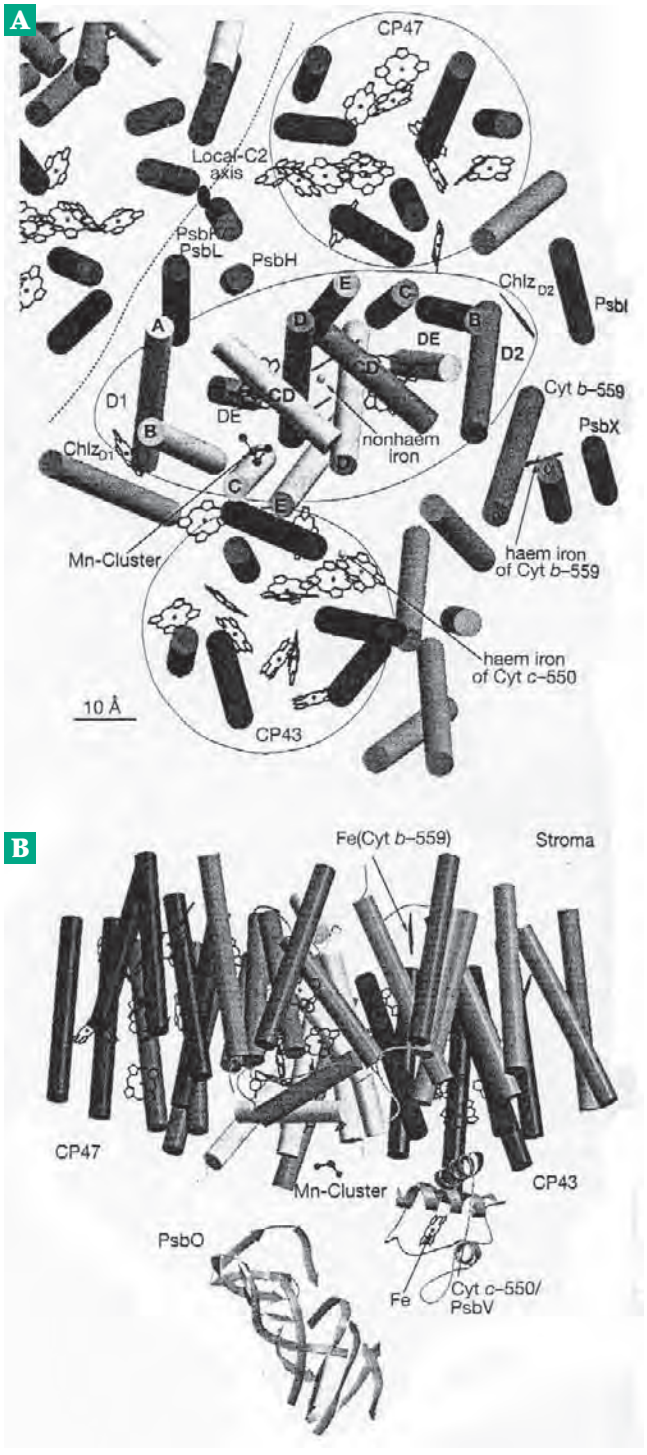

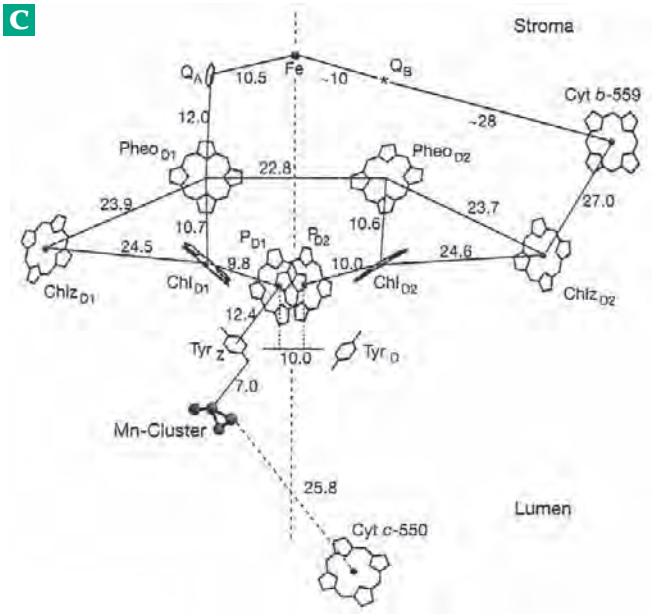

Figure 23-34 Structure of PSII with assignment of protein subunits and cofactors. (A) Arrangement of transmembrane α-helices and cofactors in PSII. One monomer of the dimer is shown completely, with part of the second monomer related by the local-C2 axis (filled ellipse on the dotted interface). Chlorophyll *a* head groups and hemes are indicated by black wire drawings. The view direction is from the luminal side, perpendicular to the membrane plane. The α-helices of D1, D2, and Cyt *b*-559 are labeled. D1/D2 are highlighted by an ellipse and antennae, and CP43 and CP47 by circles. Seven unassigned α-helices are shown in gray. The four prominent landmarks (three irons and the manganese (Mn) cluster) are indicated by arrows. (B) Side view of PSII monomer looking down the long axis of the D1/D2 subunits from the right side in (A), at slightly tilted membrane plane and rotated 180° so that the luminal side is bottom. PsbO (33K protein) is shown as a β-sheet structure, and Cyt *c*-550 as a helical model. (C) Arrangement of cofactors of the electron transfer chain located in subunits D1 and D2. View direction along the membrane plane. Full lines indicate center-to-center distances (nm) between the cofactors (uncertain to about ± 0.1 nm). The pseudo-C2 axis is shown by the vertical dotted line; it runs throught the non-heme iron Fe and is parallel to the local-C2 axis. The asterisk indicates the putative Q_8 binding site. From Zouni *et al.*[371d] Courtesy of Athina Zouni.

The photosynthetic centers of green photosynthetic sulfur bacteria also have centers F_X, F_A, and F_B.

The soluble electron carriers released from the reaction centers into the cytoplasm of bacteria or into the stroma of chloroplasts are reduced single-electron carriers. Bacterial ferredoxin with two Fe_4S_4 clusters is formed by bacteria if enough iron is present. In its absence flavodoxin (Chapter 15), which may carry either one or two electrons, is used. In chloroplasts the carrier is the soluble **chloroplast ferredoxin** (Fig. 16-16,C), which contains one Fe_2S_2 center. Reduced ferredoxin transfers electrons to $NADP^+$ (Eq. 15-28) via **ferredoxin:NADP$^+$ oxidoreductase**, a flavoprotein of known three-dimensional structure.[367–369]

PSII and formation of oxygen. The structure of PSII has been difficult to determine directly, but its core has been modeled in atomic detail using bacterial reaction centers as a guide.[370,371] More recently electron crystallography provided a three-dimensional image at 0.8 nm resolution.[314,371a] The resolution has been extended down to 4 nm by X-ray crystallography.[371b–e] The structure of the cyanobacterial PSII (Fig. 23-34) is very similar to that of green plants.[371e,f] PSII contains at least 17 protein subunits, all of which are encoded by chloroplast genes. The large structurally similar D1 and D2 form the core. They are encoded by genes *PsbA* and *PsbD* and have molecular masses of 38.0 and 39.4 kDa, respectively.[315] Both Q_A and Q_B are plastoquinone. It is of historical interest that these cofactors were first designated simply as Q, not for quinone but for *quencher*. This is because Q_A apparently quenched the fluorescence of P680, the reaction-center chlorophyll *a*. If chloroplasts are irradiated with 650-nm light, PSII is activated but PSI is not. Under these conditions Q_A becomes reduced, and the fluorescence of Chl^+ increases, presumably because the electron acceptor Q_A is absent. If PSI is activated by addition of far-red light, Q_A remains more oxidized, and fluorescence is quenched by a mechanism that appears to depend upon one of the additional bound chlorophylls, as well as the chlorophyll pair Chl_2 and the 9-kDa cytochrome b_{559}. The latter is an essential PSII subunit (*PsbE* gene),[372,373] which forms a tight complex with the D1/D2 pair.

Other subunits in PII include the 56- and 50-kDa antenna proteins CP43 (*PsbC* gene) and CP47 (*PsbB* gene). Three **extrinsic proteins**, which bind to the lumenal side of the thylakoid membrane, are the 33-kDa **manganese stabilizing protein** (*PsbO* gene),[374,375] cytochrome c_{550}, and a 12-kDa subunit (Fig. 23-34). The position of the larger two of these proteins are shown in the model in Fig. 23-34, which is based on 0.8-nm resolution data.[315] These extrinsic proteins seem to function together to facilitate binding not only of Mn ions but also of Ca^{2+} and Cl^-, both of which are essential for O_2 evolution.[376] Other smaller subunits are also present.[376a] Together with its antenna complexes PSII may form large supercomplexes with as many as 25 subunits.[376b] The distribution of complexes varies in the different regions of the thylakoid, e.g., the stroma lamellae and grana stacks (Fig. 23-19).[376c]

The four-electron dehydrogenation of two water

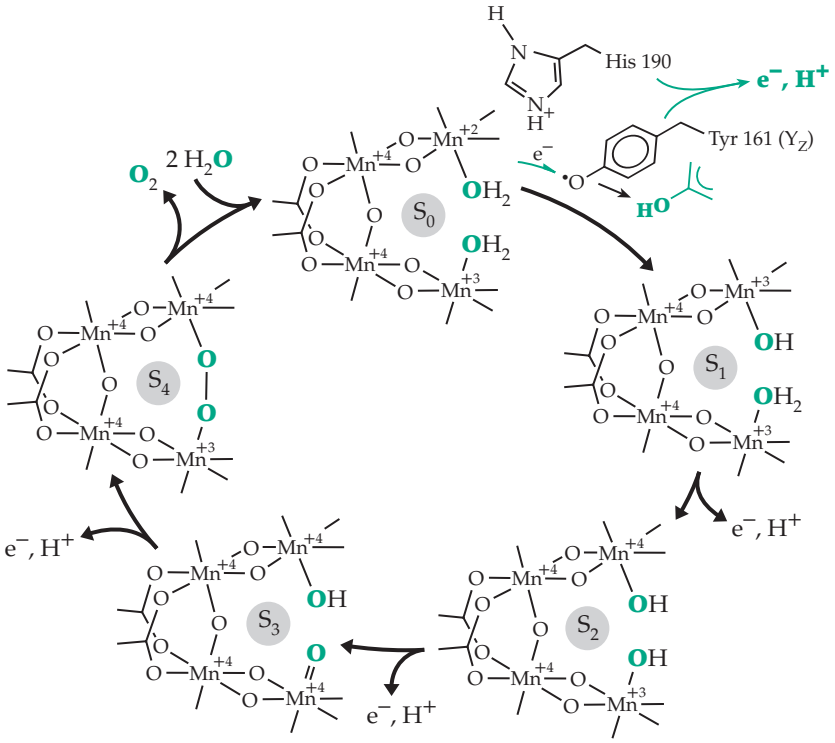

Figure 23-35 Proposed sequence of S-states of the manganese cluster of photosystem II. The successive states as two molecules of H_2O (green oxygen atoms) are converted to O_2 is shown with the successive states S_0–S_4 labeled. To save space and possible confusion tyrosine 161 (Y_Z) and the nearby His 190 are shown only by S_1. The Y_Z radical is thought to remove a hydrogen atom or H^+ from one bound H_2O and an electron from one Mn ion at each of the four S-states S_0–S_3 functioning in each case to eject a proton into the thylakoid lumen and to transfer an electron to P^+ of the reaction center. However, the exact sequence of e^- transfer and H^+ release may not be shown correctly. After Hoganson and Babcock.[392,392a]

molecules to give one molecule of O_2 by PSII is still not well understood. From experiments on oxygen evolution in the presence of repeated short flashes of light it was found that a four-quantum process is required.[376–380] There must be some way of storing oxidizing equivalents until enough are present to snap together an oxygen molecule. There is abundant evidence that manganese is required for this process and that the oxidation of H_2O occurs on a cluster of four atoms of manganese.[379]

The 33-kDa protein PsbO, which is present in all oxygen-forming photosynthetic organisms, is closely associated with the Mn_4 cluster. Removal of this protein leads to a gradual loss of two of the four Mn ions.[375] The structure of the Mn_4 cluster is not yet certain, but on the basis of EXAFS spectroscopy a pair of di-μ-oxo bridged Mn dimers linked by carboxylates and with a fifth μ-oxo bridge as in Fig. 23-35 has been proposed. The distance between Mn ions in the di-μ-oxo-Mn_2 groups is ~0.27 nm, and the planes of these groups are roughly parallel to the surface of the thylakoid membranes.[381,382] The protein groups that bind the Mn atoms include carboxylates, as shown in Fig. 23-35, and probably one or more histidine imidazole groups,[383] perhaps of His 332 and His 337 of the D1 chain.

The immediate donor of an electron to the reaction-center cation P^+ ($ChlZ^+$) of PSII was identified by EPR spectroscopy as a tyrosine radical.[384] On the basis of directed mutations this tyrosine, which is usually designated $\mathbf{Y_Z}$, is Tyr 161 of the D1 chain and is located ~1.2 nm from one of the chlorophylls of the $(Chl)_2$ pair.[371d,376,380,385–387] The two molecules in the pair are not in close contact, their central Mg atoms being ~1.0 nm apart. One of the two probably forms the $P680^{\bullet+}$ intermediate.[371d] Y_Z is also close to the Mn_4 cluster and to the imidazole group of His 190 of subunit D1 as is shown in Fig. 23-34C.[386,388] The $Y_Z^{\bullet}$ radical is able to accept an electron from the Mn_4 cluster within 30–1300 μs depending upon the oxidation state of the cluster (see Fig. 23-35).[388] If a proton is transferred synchronously from a bound H_2O, a neutral –OH group will be created on Y_Z. The proton may then be transferred to His 190, which can eject the proton on its other nitrogen atom into the lumen. Alternatively $Y_Z^{\bullet}$ may accept an electron to become tyrosinate $-O^-$, which then donates an electron to P^+, while His 190 accepts a proton directly from a bound H_2O.

In a mechanism proposed by Hoganson and Babcock (Fig. 23-35) four successive transfers, each of one H^+ + one e^-, leads to a three-electron oxidation of Mn ions, e.g., from the 2^+ and 3^+ oxidation states to all Mn^{4+}, and to joining of the two water oxygens to form a manganese peroxide linkage. Oxidation of the peroxide dianion to O_2 by the adjoining Mn^{4+} and Mn^{3+} ions completes the cycle. This mechanism is hypothetical, and various alternatives have been presented.[387–389b] Most assume a structure similar to that shown in Fig. 23-35. Some are based on nonenzymatic model reactions.[390,391] Chloride ions are essential to O_2 formation[393,394] especially in going from state S_2 to S_3 and S_3 to S_0. This suggests that Cl^- may function in passing electrons between Mn ions.[393,395] Calcium ions are also necessary, but it has been difficult to establish an exact function.[396–397a] A bicarbonate ion may also be an essential ligand in the Mn_4 cluster.[398,398a]

ATP synthesis in chloroplasts. The flow of electrons between PSII and PSI (Fig. 23-18) is of great importance for ATP formation. As previously mentioned, plastocyanin is usually the immediate donor to P700 and serves as a mobile carrier to bring electrons to this reaction center. In this function it is analogous to cytochrome *c* of mitochondrial membranes. The essentiality of plastocyanin was shown by study of copper-deficient *Scenedesmus* (Fig. 1-11). The photoreduction of CO_2 by H_2 is impaired in these cells, but the Hill reaction occurs at a normal rate.

Like mitochondria, chloroplasts (when illuminated) pump protons across their membranes (Fig. 23-18). However, while mitochondria pump protons to the outside, the protons accumulate on the inside of the thylakoids. The ATP synthase heads of coupling factor CF_1 are found on the outside of the thylakoids, facing the stromal matrix, while those of F_1 lie on the insides of mitochondrial membranes. However, the same mechanism of ATP formation is used in both chloroplasts and mitochondria (Chapter 18).

The cleavage of water at PSII also occurs on the inside of the thylakoids. The splitting of one water molecule leaves two protons (one per electron) inside the thylakoids, while the electrons are "photoejected" through the lipid bilayer to acceptor Q_A on the outside. The chlorophyll in PSI is likewise in contact with the inside of the bilayer with acceptor A_0 (Fig. 23-18) on the outside. Since the conversion of NAD^+ to NADH on the outside generates a proton, the overall reaction would be the pumping of one and a half protons per electron passing through the Z scheme.

The pathways involved in cyclic photophosphorylation in chloroplasts are not yet established. Electrons probably flow from the Fe–S centers Fd_x, Fd_a, or Fd_b back to cytochrome b_{563} or to the PQ pool as is indicated by the dashed line in Fig. 23-18. Cyclic flow around PSII is also possible. The photophosphorylation of inorganic phosphate to pyrophosphate (PP_i) occurs in the **chromatophores** (vesicles derived from fragments of infolded photosynthetic membranes) from *Rhodospirillum rubrum*. The PP_i formed in this way may be used in a variety of energy-requiring reactions in these bacteria.[399] An example is formation of NADH by reverse electron transport.

Protection of chloroplasts against radiation and oxygen. Carotenoids often act as accessory light-receiving pigments, but an additional function is protecting photosynthetic organisms against toxic effects of light.[400–403] Carotenoid photoprotection has been demonstrated in photosynthetic bacteria and in the reaction centers and light-harvesting complexes (LHC) of green plants. Excited chlorophyll molecules can pass from the singlet (^{1}Chl*) to the triplet (^{3}Chl*) state by intersystem crossing (Fig. 23-14). The triplet chlorophyll can then react with ordinary oxygen ($^3O_2$) to form singlet oxygen ($^1O_2$). The formation of ^{3}Chl* is favored when the intensity of sunlight is high and energy is absorbed in the LHCs faster than it can be utilized in the reaction centers. Carotenoids are able to quench excitation of both ^{3}Chl* and $^1O_2$. Strains of *Rhodobacter sphaeroides* that lack carotenoids rapidly form both ^{3}BChl* and BChl$^+$ cation radicals in their LH1 and LH2 complexes (Fig. 23-26). However, the presence of carotenoids quenches the triplet bacteriochlorophyll effectively and no formation of BChl$^+$ radicals is seen.[403] Another effect of excessive light energy is the reaction of O_2 with the highly reducing P700* of photoexcited PSI. This interaction can form triplet oxygen, which can react to generate superoxide anion radicals, H_2O_2, and hydroxyl radicals.[224,227,402]

In higher plants the quenching of both ^{3}Chl* and $^1O_2$ depends upon carotenoids[404] and also upon the large transthylakoid membrane potential that is generated by high light intensities.[405,406] High light intensity also induces a rapid reductive deoxygenation of epoxycarotenoids via the **xanthophyll** or **violaxanthin cycle** (Eq. 22-10).[401,407,407a,b] Epoxycarotenoids are found only in photosynthetic O_2 evolving organisms. Although occurring in response to light, the cyclic photodeoxygenation and reoxygenation is not a non-photochemical process. Violaxanthin contains the epoxy structure at both ends of the molecule. Reduction of one end produces **antheroxanthin** and of both ends **zeaxanthin**. These three carotenoids are found in almost all higher green plants and algae. The de-epoxidation is mediated by ascorbic acid, occurs in the lumen of the thylakoids, and is favored by the low pH developed during illumination. Epoxidation (Eq. 22-10) is catalyzed by a monooxygenase located on the stromal side. The significance of the xanthophyll cycle is puzzling. There may be specific binding sites, perhaps in the inner antenna complex on CP29 (Fig. 23-34), that bind zeaxanthin or antheroxanthin. This could alter the antenna structure to form an "exciton trap" in which the fluorescence lifetime would be decreased and excitation energy would be dissipated rapidly as heat.[408] Zeaxanthin is also found in the macular area of the primate retina.[401]

Recent studies, using an *Arabidopsis* mutant defective in the xanthophyll cycle, point to a chlorophyll-binding protein PsbS, which participates in nonphotochemical quenching at high light intensity.[401a,b] Another *Arabidopsis* protein, which is probably a blue light receptor, participates in an avoidance response by which chloroplasts move to the side wall to avoid strong light.[401c]

Yet another carotenoid function in PSII has been proposed. Under some conditions, when electron flow from Tyr_z is blocked, the bound monomeric chlorophyll Z (Chlz) acts as a secondary electron donor to P680$^+$. The cytochrome b_{559} subunits may have a similar function. Both cyt b_{559} and the carotenoid are essential for assembly of PSII, and both may participate in a protective cycle.[409,410] Chloroplasts generate both O_2 and powerful reducing materials such as the membrane-bound FeS centers of PSI, which may form superoxide ions by single-electron donation to O_2. Probably for this reason, chloroplasts are rich in superoxide dismutase which converts superoxide to O_2 and H_2O_2. The latter can diffuse into peroxisomes and react with catalase and peroxidases. It can also be reduced to H_2O within the chloroplasts by ascorbic acid and ascorbate peroxidase.[224,227] The resulting dehydroascorbate (Box 18-D) can be reduced back to ascorbate by glutathione (Box 11-B) and dehydroascorbate reductase, in the following electron transfer sequence:

$$\text{NADPH} \rightarrow \text{G–S–S–G} \rightarrow \text{dehydroascorbate} \rightarrow H_2O_2 \qquad (23\text{-}33)$$

Under extreme conditions of excess light energy **photoinhibition** is observed as a result of damage to the PSII structure.[411–415] The D1 polypeptide is cleaved, probably as a result of oxidation by $^1O_2$ and proteolysis. Damaged proteins are replaced and the PSII structure rebuilt, but the effect is a long-lasting decrease in photosynthetic efficiency. The cyanobacterium *Synechococcus* has three *PsbA* genes and resists UV-B radiation by exchanging a delicate D1 polypeptide with more resistant ones as necessary.[415] Other adaptations to varying light-intensity involve movement of light-harvesting complexes from the thylakoid stacks, which contain much PSII, to the stroma lamellae (Fig. 23-19), which contain more PSI. Some herbicides act by binding into the Q_B site in PSII. They may cause light-induced oxidative stress that kills the plant.[415a]

5. Control of Photosynthesis

The key reaction of the Calvin–Benson cycle of CO_2 reduction is the carboxylation of ribulose bisphosphate to form two molecules of 3-phosphoglycerate (Eq. 13-48). The properties of ribulose bisphosphate carboxylase (**rubisco**, Figs. 13-10 to 13-12), which catalyzes this reaction, are discussed in Chapter 13. It

is controlled in part by CO_2 and by natural inhibitors,[416] but regulation of rubisco starts at the transcriptional level.

Light-induced transcription. Plants depend upon light both as a source of energy and also for control of development. Many genes are activated by light in response to at least three groups of photoreceptors. These are **phytochromes** (Section H) and the blue light responsive **cryptochromes** (Section I) and the ultraviolet light **UV-B photoreceptors**.[417] The synthesis of chlorophyll, of reaction center proteins, and of many enzymes are controlled by light-induced transcription.[418–420] Among these processes are synthesis of both the large and small subunits of rubisco (Fig. 13-10). The small subunits are synthesized in the cytoplasm in a precursor form. After illumination the concentration of the rubisco mRNA may be increased 100-fold.[421,422] On the other hand, the large subunit of the carboxylase is encoded in chloroplast DNA, and stimulation of its synthesis by light appears to be at the translational level.[423]

Light-induced control via the ferredoxin/thioredoxin system. Rubisco is activated by CO_2 (Chapter 13) and by fructose 6-*P* and is inhibited by fructose 1,6-P_2 (Fig. 23-36),[424] whose accumulation is a signal to turn off the carboxylase. Conversely, fructose 6-*P* in high concentrations turns on the Calvin–Benson cycle. Like the reactions of gluconeogenesis (Chapter 17), photosynthetic CO_2 incorporation is dependent on the highly regulated fructose-1,6-bisphosphatase. In chloroplasts it is activated by light through the mediation of reduced ferredoxin and thioredoxin.[424–427] The small mobile thioredoxin (Box 15-C) is reduced to its dithiol form by reduced ferredoxin[428–429a] and then reduces one or more disulfide linkages in the fructose 1,6-bisphosphatase to activate that enzyme (Fig. 23-36). Other light-activated enzymes of the Calvin–Benson cycle include sedoheptulose-1,7-bisphosphatase, the phosphoribulokinase that forms ribulose 1,5-bisphosphate and the $NADP^+$-dependent glyceraldehyde-3-phosphate dehydrogenase. $NADP^+$-dependent malate dehydrogenase, which has a major function in C_4 plants (see Fig. 23-38), is totally inactive in the dark but is activated by the ferredoxin–thioredoxin system in the light.[427] The activity of the LHCII complex is also affected.[429b]

Another aspect of chloroplast metabolism is synthesis of starch. Formation of ADP-glucose from glucose 1-phosphate is induced by 3-phosphoglycerate, a "feed-ahead" type of regulation (Fig. 23-36). Although fructose 2,6-bisphosphate is absent from chloroplasts, it has an important regulatory function in the cytoplasm of plants as it does in animals.[425,430] In the plant cytosol triose phosphates from the chloroplasts are converted to fructose 6-*P*, glucose 6-*P*, UDP-glucose, and sucrose. Inorganic phosphate P_i, which accumulates in plant vacuoles, also has a regulatory function.[431] It activates the kinase that converts fructose 6-*P* to fructose 2,6-P_2 and inhibits the phosphatase that converts the bisphosphate back to fructose 6-*P*. The accumulated fructose 2,6-P_2 inhibits fructose-1,6-bisphosphatase and slows the conversion of triose phosphates to sucrose (Eq. 23-34). Accumulation of fructose 6-*P* due to decreased utilization for sucrose formation will have a similar effect. However, both 3-phosphoglycerate and dihydroxyacetone phosphate have opposite effects and will act to remove the inhibition by lowering the fructose 2,6-P_2 level and to promote rapid sucrose formation (Eq. 23-34).[430]

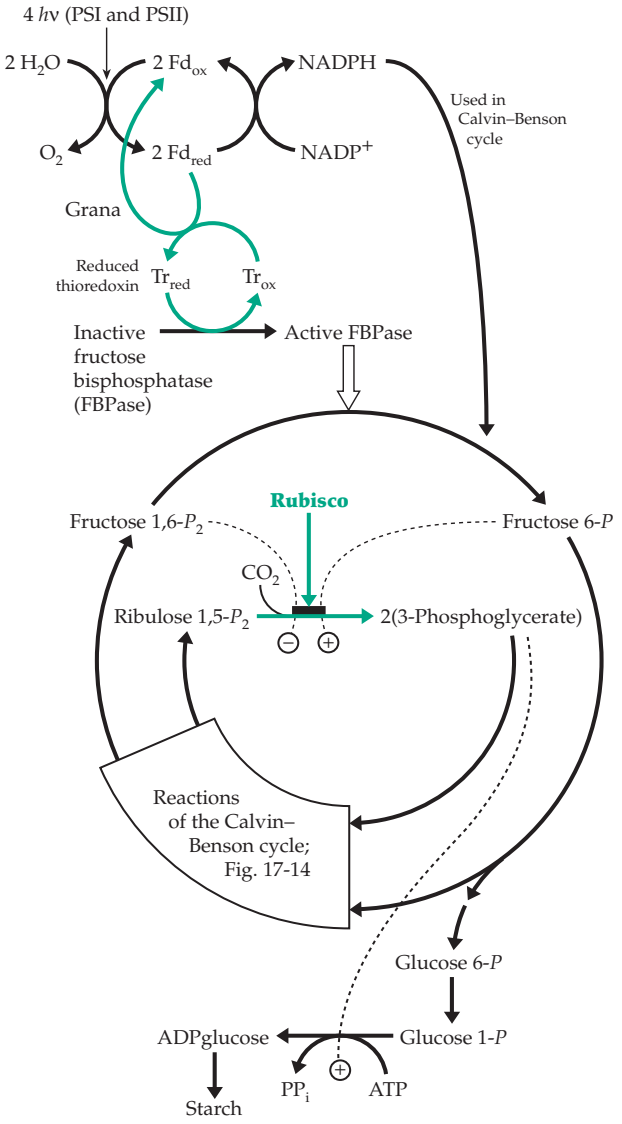

Figure 23-36 Some control mechanisms for photosynthetic assimilation of carbon dioxide. After Buchanan and Schurmann[424] with modifications.

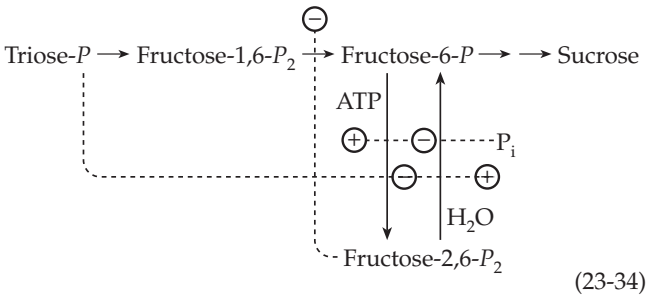

(23-34)

6. Photorespiration; C_3 and C_4 Plants

The first product of incorporation of CO_2 via the Calvin–Benson cycle is 3-phosphoglyceric acid (Box 17-E). It was the rapid appearance of radioactivity from $^{14}CO_2$ in phosphoglycerate and other three-carbon (C_3) compounds that permitted Calvin and associates, using green algae, to work out the complex cycle as it is shown in Fig. 17-14. Green algae, spinach, and many common crop plants are often known as **C_3 plants**. Another group of plants, mostly of tropical origin and capable of extremely fast growth, behave differently.[224,227,432] In these plants, which include sugar cane, maize, and crabgrass, radioactivity from ^{14}C-containing CO_2 is found first in the C_4 compounds oxaloacetate, malate, and aspartate. These **C_4 plants** are characterized by high efficiencies in photosynthesis, a fact that explains the rapid growth of crabgrass and the high yield of corn. Maximum rates of CO_2 incorporation may attain 40–60 mg of CO_2 per square decimeter of leaf surface per hour (~0.3 mmol CO_2 $m^{-1}s^{-1}$ or ~0.10 mol CO_2 per mol of total chlorophyll per second), more than twice that for common crop plants.

Like all other organisms plants respire in the dark, but illumination of C_3 plants markedly increases the rate of oxygen utilization. This light-enhanced respiration (**photorespiration**) may attain 50% of the net rate of photosynthesis. Photorespiration prevents plants from achieving a maximum yield in photosynthesis. For this reason, its understanding and control assume great importance in agriculture. It is difficult to measure the rate of photorespiration, and the literature on the subject often refers instead to the **CO_2 compensation point**. This is the CO_2 concentration (at a given constant light intensity) at which photosynthetic assimilation and respiration balance. (Similarly, the **light compensation point** is the light intensity at which the rate of photosynthetic CO_2 incorporation and that of respiration exactly balance.) Normal air has a CO_2 content of ~0.03% or 300 ppm. For common C_3 crop plants the CO_2 compensation point is ~40–60 ppm at 25°C. The C_4 plants are characterized by a much lower CO_2 compensation point, often less than 10 ppm. In strong sunlight the CO_2 level of air in a field of growing plants drops. Furthermore, as the temperature rises on a hot day, the CO_2 compensation point rises. The result is a serious decrease in efficiency of photosynthesis for the C_3 plants but not for the C_4 plants.

Metabolism of glycolic acid. The 2-carbon glycolic acid is formed in large quantities in the chloroplasts of C_3 plants and moves out into the cytosol.[433,434] The major source of this acid is phosphoglycolate whose formation is catalyzed by rubisco in the chloroplasts through competition of O_2 for the CO_2 binding site of the enzyme (Eq. 13-50). It is easy to understand why an increase in the O_2 pressure in air increases the CO_2 compensation point for a plant. Another less important source of glycolate is transketolase, which may yield glycolaldehyde as a side product (Eq. 17-15). Glycolaldehyde can be oxidized readily to glycolate. Glycolate is metabolized rapidly, some in the chloroplasts,[435] but most in the peroxisomes. There the flavoprotein glycolate oxidase converts it to glyoxylate with formation of H_2O_2 (Fig. 23-37).[436] Some of the hydrogen peroxide formed may react nonenzymatically, decarboxylating glyoxylate to formate and CO_2, but most is probably destroyed by peroxidases or catalase. The latter enzyme is lacking in chloroplasts, one reason why oxidation of glycolate must occur in the peroxisomes.

Glyoxylate undergoes transamination to glycine, which can be oxidatively decarboxylated (Fig. 15-20) in the mitochondria. It can also be converted to serine,[437] some of which returns to the peroxisomes to be oxidized to hydroxypyruvic acid and glyceric acid (Fig. 23-37). The latter can be synthesized into glucose. The net result is the stimulation of a large amount of metabolism that ultimately produces CO_2 and apparently accounts for the light-induced respirations of plants. Because much of the glycine formed in the peroxisomes is oxidatively decarboxylated in the mitochondria, photorespiration also generates large amounts of NH_3. This is recycled into amino acids within the photosynthetic cells (green lines in Fig. 23-37), an energy-requiring process.[438]

Although much metabolism occurs as a result of photorespiration, it appears to waste energy rather than to provide energy to the plant. Why then don't plants avoid this process? Wouldn't a small change in the structure of ribulose bisphosphate carboxylase allow plants to avoid photorespiration and to grow more efficiently? The answer is not clear. It has been difficult to create such modified plants, and there is a possibility that they would not grow well. One theory is that photorespiration protects plants when the CO_2 pressure is low and the absorbed light would damage the chloroplasts if there were not a way to utilize the accumulating reduced Fe–S proteins generated by PSI. Photorespiration provides a mechanism.[434] Most

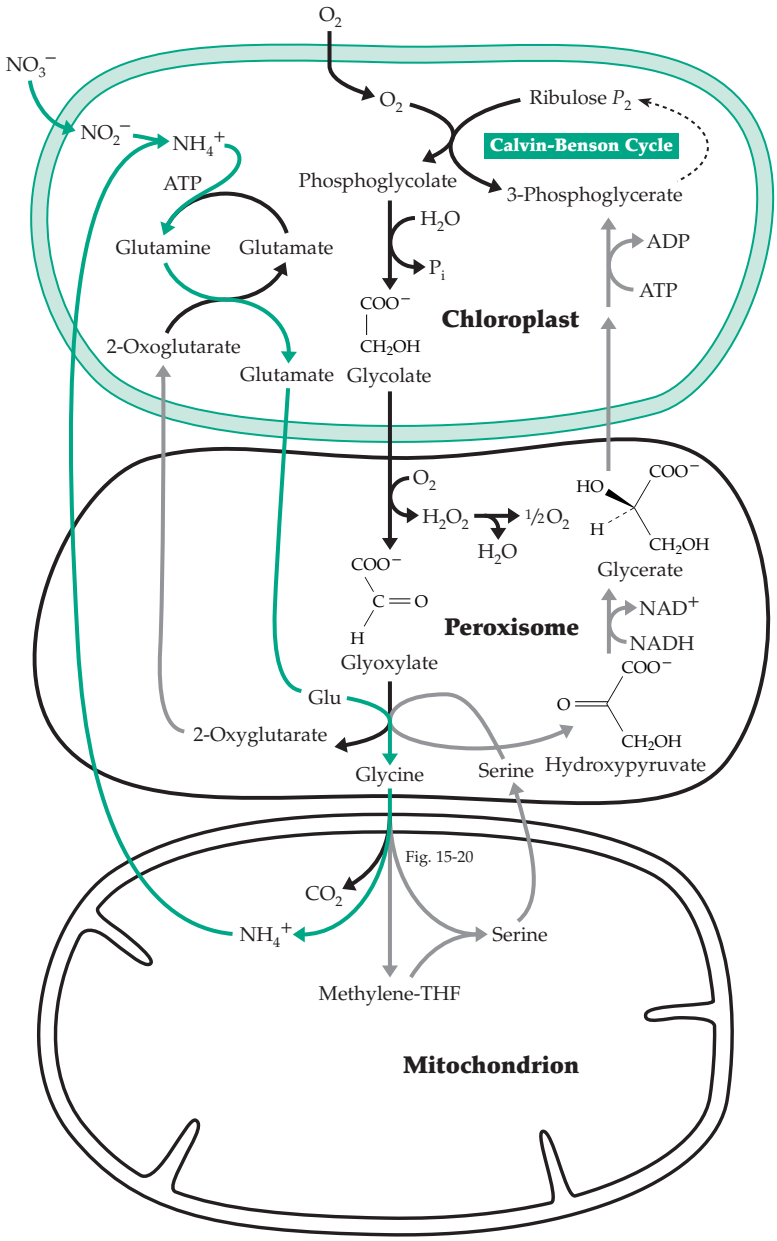

Figure 23-37 Production of glycolate by chloroplasts and some pathways of its metabolism in peroxisomes and in mitochondria. After Tolbert[436] and Givan *et al.*[438]

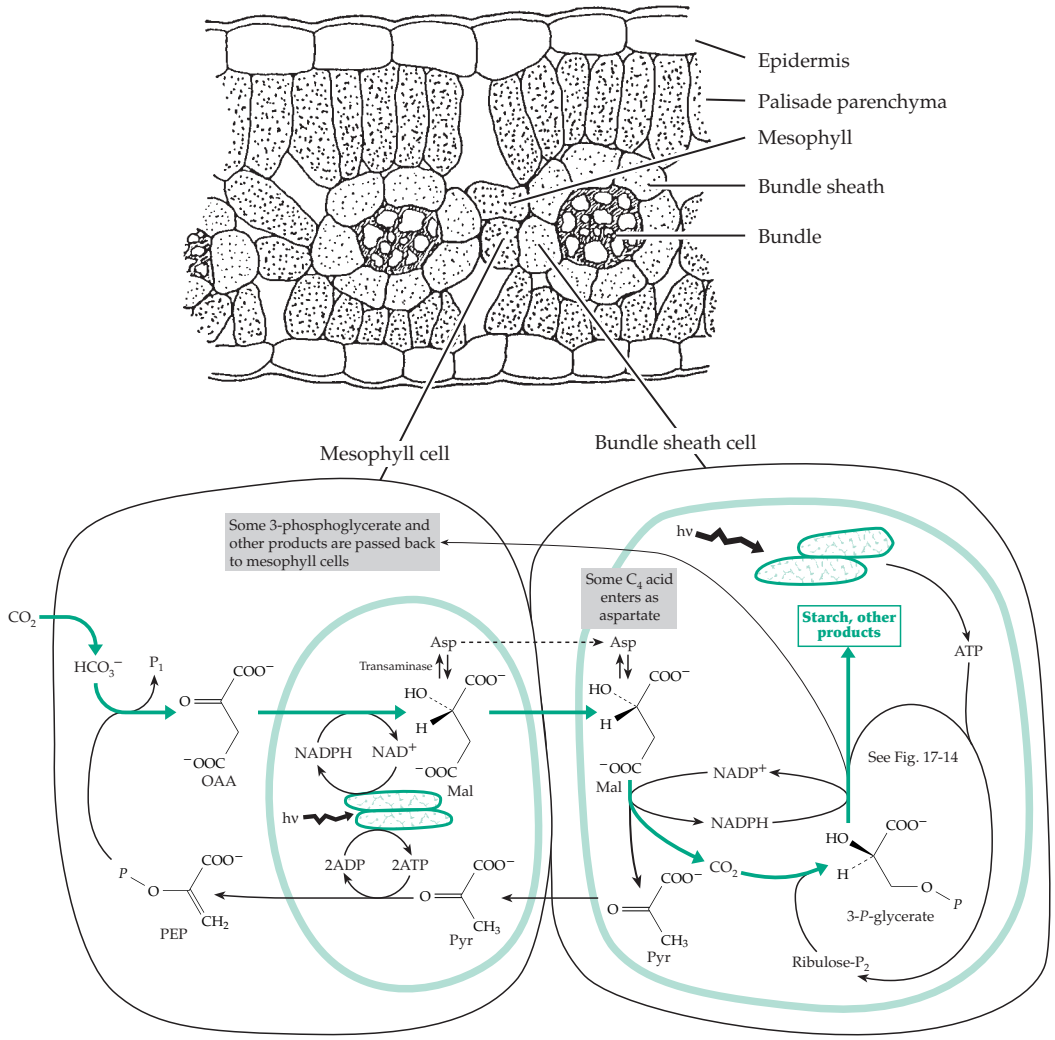
efforts to breed plants with lower photorespiration rates or to inhibit it chemically have failed.[433,439]

The C_4 cycle for concentration of carbon dioxide. The C_4 plants reduce their rate of photorespiration by using a CO_2 concentrating mechanism that enables them to avoid the competition from O_2. All species of C_4 plants have a characteristic internal leaf anatomy in which a single dense layer of dark green cells surrounds the vascular bundles in the leaves. This **bundle sheath** is surrounded by a loosely packed layer of cells, the **mesophyll**, an arrangement that is sometimes called the "Kranz anatomy." In C_4 plants there is a separation of the chemical reactions between the mesophyll and the bundle sheath cells. The incorporation of CO_2, as bicarbonate ion into oxaloacetate, occurs in the mesophyll cells, principally through the action of PEP carboxylase (Fig. 23-38). Oxaloacetate is reduced to malate by light-generated NADPH. Alternatively, it undergoes transamination to aspartate. Both malate and aspartate then diffuse out of the mesophyll cells and into bundle sheath cells where the malate undergoes oxidative decarboxylation via the malic enzyme (Eq. 14-42) to pyruvate (Fig. 23-38). Aspartate also can be converted to oxaloacetate, malate, and pyruvate in the same cells. The overall effect is to transport CO_2 from the mesophyll cells into the bundle sheath cells along with two reducing equivalents, which appear as NADPH following the action of the malic enzyme. The CO_2, the NADPH, and additional NADPH generated in the chloroplasts of the bundle sheath cells are then used in the Calvin–Benson cycle reactions to synthesize 3-phosphoglycerate and other materials. Of the CO_2 used in the bundle sheath cells, it is estimated that 85% comes via the C_4 cycle and only 15% enters by direct diffusion. The advantage to the cell is a higher CO_2 tension, less competition with O_2, and a marked reduction in photorespiration.

The pyruvate produced in the bundle sheath cell is largely returned to the mesophyll cells where it is acted upon by **pyruvate-phosphate dikinase**.[441] This unusual enzyme (Eq. 17-55) phosphorylates pyruvate to PEP while splitting ATP to AMP and PP_i. The latter is in turn degraded to P_i. In effect, two high-energy linkages are cleaved for each molecule of pyruvate phosphorylated. Because of this extra energy need, it is thought that cyclic photophosphorylation is probably more important in the chloroplasts of the mesophyll cells than in the bundle sheath cells. It also accounts for the fact that C_4 plants are less efficient than C_3 plants under cool or shaded conditions.[442] Other CO_2-concentrating mechanisms exist in plants.[442a] For example, cyanobacteria accumulate HCO_3^- ions in carboxysomes, polyhedral bodies to which rubisco adheres. An ABC type ATP-dependent transporter powers the bicarbonate accumulation.[442b]



(23-35)

Figure 23-38 The C_4 cycle for concentrating CO_2 in the C_4 plants. From Haag and Renger with alterations.[440]

Metabolism in the family Crassulaceae. The crassulacean plants are a large group that includes many ornamental succulents such as *Sedum*. They have a remarkable metabolism by which large amounts of malic and isocitric acids are synthesized at night. During the day when photosynthesis occurs these acids disappear. The stomata in the leaves (Chapter 1) stay closed during the day and open only at night, an adaptation that permits the plants to live with little water. However, this requires that the plant accumulates carbon dioxide by night and incorporates it photosynthetically into organic compounds by day.[443] A possible mechanism is shown in Fig. 23-39. On the left side of the figure are reactions by which starch can be broken down at night to PEP. While it would also be possible to produce that compound by the glycolysis reactions, labeling studies have indicated that the pentose phosphate pathway is more important.[330] The PEP acts as the CO_2 acceptor to create oxaloacetate, which is then reduced to malic acid. A balanced fermentation reaction (Fig. 23-39; Eq. 23-35) can be written by using the NADPH formed in the conversion of glucose 6-*P* to ribulose 5-*P*. During the day when ATP and NADPH are available in abundance from photoreactions, the conversions on the right side of the figure can take place. The initial step, the release of CO_2 from malic acid by the malic enzyme, is the same as that employed by C_4 plants. In this case, it is used to release the CO_2 stored by night, making it available for incorporation via the Calvin–Benson cycle. The remaining pyruvate is reconverted to starch.

$$C_6H_{10}O_5\ (\text{starch}) + 2\ CO_2\ (g) \rightarrow 2\ C_4H_4O_5^{2-}\ (\text{malate}) + 4\ H^+$$
$$\Delta G'\ (\text{pH}\ 7) = -159\ \text{kJ mol}^{-1} \qquad (23\text{-}35)$$

Many plants store substantial amounts of malate in their cytoplasm and in vacuoles. It apparently

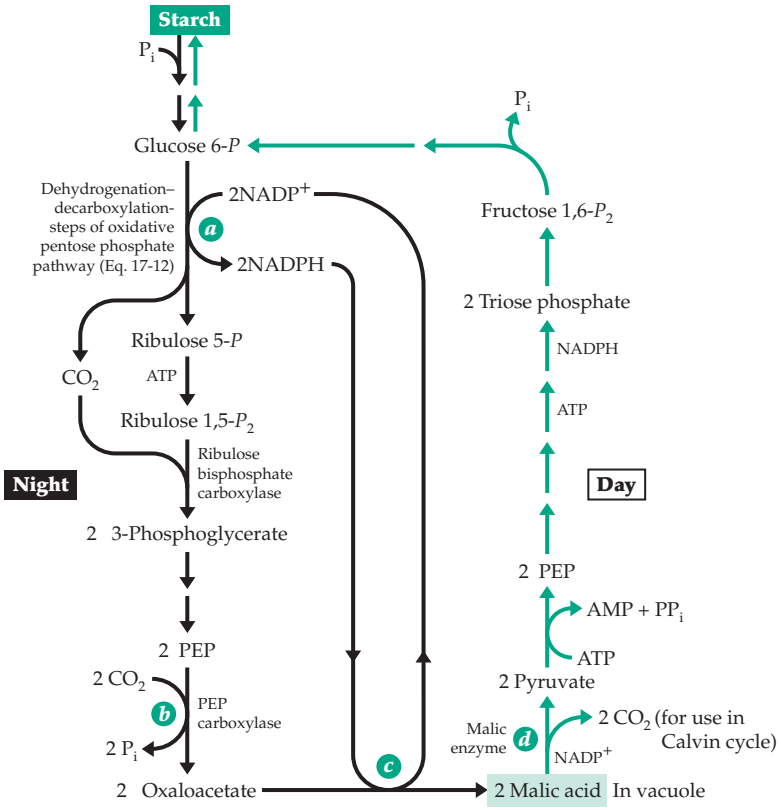


Figure 23-39 A proposed night–day cycle of crassulacean acid metabolism.

serves as a ready reserve for carbohydrate synthesis.

7. Photosynthetic Formation of Hydrogen

A system consisting of chloroplasts, ferredoxin, and hydrogenase has been used to generate H_2 photosynthetically.[444] This may be a prototype of a method of solar energy generation for human use. Another photochemical hydrogen-generating system makes use of both the nitrogen-fixing heterocysts and photosynthetic vegative cells of the cyanobacterium *Anabaena cylindrica*.[445] In this instance hydrogen production is accomplished by nitrogenase (Eq. 24-6). Photogeneration of H_2 by bacteria is just one of many kinds of photometabolism observed among photosynthetic microorganisms.

F. Vision

The light receptors of the eye perform a very different function from those of chloroplasts. Visual receptors initiate nerve impulses, and their primary requirement is a high sensitivity. By the use of stacked membranes containing a high concentration of an intensely absorbing molecule[446,447] the most sensitive visual receptors are able to trap nearly every photon that strikes them. The retina of the human eye contains more than 10^8 tightly packed receptor cells of two types. The **rod cells** are extremely sensitive. Used for night-time vision, they give a "black and white picture" and are concentrated around the periphery of the retina. The retina works as a coincidence detector. An ensemble of ~500 rods must register 5–7 isomerizations within a few tenths of a second in order to trigger a nerve impulse.[448] The less sensitive **cone cells**, which are most abundant in the center of the retina, are of three types with different spectral sensitivities. They provide color vision.

The retinal receptors have a very active metabolism. Human rod cells (Fig. 23-40) may live and function for a hundred years.[190] A self-renewal process leads to a casting off of the older membranous discs from the end of the rod[194] and replacement by new discs at the end nearest to the nucleus. The rod outer segment is surrounded by a plasma membrane. Within the membrane but apparently not attached to it are ~500 stacked discs of ~2 μm diameter and with a repeat distance between centers of ~32 nm. Each disc is enclosed by a pair of membranes each ~7 nm thick with a very narrow space between them. From electron micrographs it appears that this space within the discs is sealed off at the edges. Somewhat larger spaces separate adjacent discs.

The membranes of the rod discs are ~60% protein and 40% lipid (Table 8-3). About 80% of the protein is **rhodopsin** (visual purple), a lipoprotein that is insoluble in water but soluble in detergent solutions. Digitonin is widely used to disperse rhodopsin molecules because it causes no change in optical properties. In addition to rhodopsin, in the outer segment discs of frog retinal rods, there are ~65 molecules of phospholipid and smaller amounts of other materials for each molecule of rhodopsin (Table 8-3). The cone cells have a similar architecture but have a different shape and contain different light receptors. The receptors in the cones are present in deep indentations of the plasma membrane rather than in discs within the cytoplasm.

1. Visual Pigments

The rod pigment rhodopsin is readily available from cattle retinas and has been studied for many

years. It has a molecular mass of ~41 kDa of which ~2 kDa is contributed by two asparagine linked oligosaccharides.[195] Both bovine and human rhodopsins consist of a 348-residue protein known as **opsin** to which is bound a molecule of vitamin A aldehyde, **retinal**. Human and bovine opsins are 93% homologous. A totally synthetic 1057 base pair gene for bovine rhodopsin was made by Khorana and associates.[449,450] The gene was constructed with 28 unique sites for cleavage by specific restriction endonucleases. These have allowed easy specific mutation of the gene and production of a wide variety of mutant forms of opsin. Similar synthetic genes have been constructed for the three human cone pigments[452] and for the related bacterial protein **bacteriorhodopsin**.[453]

Transmembrane structure.

From its circular dichroism rhodopsin was estimated to be 60% helical, and its amino acid sequence suggested that it contains seven parallel membrane-spanning helices (Fig. 23-41)[451] just as does bacteriorhodopsin (Section G; Fig. 23-45). Rhodopsin and other visual pigments are also members of the large family of **G-protein coupled receptors**, which includes the β_2 adrenergic receptor pictured in Fig. 11-6. It has been hard to determine the three-dimensional structure of rhodopsin or other receptors of this family. However, their relationship to bacteriorhodopsin, whose structure was obtained in 1975 by electron crystallography[454] and more recently by X-ray crystallography at 0.15 nm resolution,[455] permitted modeling based on similarities among the proteins.[456–458] New results of electron crystallography[459,460] and mass spectrometry[461] have been combined with studies of mutant forms of rhodopsin and other visual pigments to provide the picture given in Fig. 23-41A,B. Recently a higher resolution structure (Fig. 23-41D) has been obtained by X-ray diffraction.[461a–c] Mutations have been introduced in every part of the rhodopsin molecule, and the effects on photoreception, protein stability, and other properties have been observed.[448,450,462–465] Some of the essential residues identified are indicated in Fig. 23-41A, a schematic diagram showing the seven helices and connecting loops. Figure 23-41B shows an end view of the helix bundle with its retinal prosthetic group buried in the interior of the protein. Rhodopsin is roughly cylindrical with a length of 6–6.5 nm and a diameter of ~2.8 nm and is embedded in the phospholipid bilayer with its long axis perpendicular to the membrane surface (Fig. 23-40). The two oligosaccharide chains, which are attached near the N terminus, project into the intradiscal space on the side away from the cytoplasm. Palmitoyl groups on two cysteine side chains help to anchor the protein. Rhodopsin apparently exists in the mem-

Figure 23-41 (A) Model of the topological organization of bovine rhodopsin according to the consensus analysis of Baldwin.[456] Oligosaccharide chains are portrayed on the glycosylation sites Asn 2 and Asn 15. Glutamate 113 provides the counter ion for the *N*-protonated retinal Schiff base. Cysteines 110 and 187 form an essential disulfide linkage. Histidine 211 modulates the interconversion of the metarhodopsin forms I and II. Lysine 296 forms a Schiff base with 11-*cis*-retinal. Cysteines 322 and 323 are sites of palmitoylation, and as many as six serine and threonine hydroxyls (indicated by green arrows) may become phosphorylated during desensitization of rhodopsin. Aspartate 83, glutamate 134, and histidine 211 may be essential for proton movements. The point mutation C203R in the green-sensitive pigment causes red-green color blindness. The mutation

branes as monomers. From the composition it can be calculated[451] that the average center-to-center distance of the cylindrical molecules must be ~5.6 nm.

The visual chromophores. Rhodopsin has been an object of scientific interest for over 100 years.[462] Wald and associates[469,470] established that rhodopsin contains 11-*cis*-retinal bound to the opsin in Schiff base linkage (Eq. 23-36). When native rhodopsin is treated with sodium borohydride, little reduction is observed. However, after the protein is bleached by light, reduction of the Schiff base linkage becomes rapid, and the retinal is incorporated into a secondary amine, which was identified as arising from Lys 296.

In a crystal structure[471] 11-*cis*-retinal has the 12-*s*-*cis* conformation shown at the top in Eq. 23-36 rather than the 12-*s*-*trans* conformation at the center and in which there is severe steric hindrance between the 10–H and 13–CH_3. Nevertheless, ^{1}H– and ^{13}C–NMR spectroscopy suggest that the retinal in rhodopsin is in a twisted 12-*s*-*trans* conformation.[472,472a] The Schiff base of 11-*cis*-retinal with *N*-butylamine has an absorption maximum at ~360 nm but *N*-protonation, as in the structure in Eq. 23-36, shifts the maximum to 440 nm with ε_{max} = 40,600 M^{-1} cm^{-1} (Fig. 23-42). This large shift in the wavelength of the absorption maximum (the *opsin shift*) indicates that binding to opsin stabilizes the light-excited state by almost 33 kJ/mol compared to that in the free *N*-protonated Schiff base. This is evidently the result of a fixed negative charge, that of Glu 113, which is near the polyene chain of the retinal (Fig. 23-41B) and probably separated from it by a hydrogen-bonded water molecule.[473–477]

(23-36)

Three types of cone cells in the human retina are needed for color vision. Four genes specify the proteins for rhodopsin and for related cone photoreceptors absorbing blue (~425 nm), green (~530 nm), and red (~560 nm) light.[477–479b] All of the cone opsins also bind 11-*cis*-retinal. The rhodopsin gene is located on human chromosome 3, while that of the blue pigment is found on chromosome 7. However, the green and red sensitive pigment genes, whose sequences are 96% identical,[478] are close together on the q arm of the X-chromosome and near the gene for glucose-6-phosphate dehydrogenase. Examination of cloned DNA from persons with inherited red-green color-blindness shows that loss of a functional form of one of these genes is usually responsible for the problem.[480–482] Among Caucasians 8% of males and 1% of females differ from the normal in their color vision. About 30% of affected males are **dichromats** and lack either the red-sensitive pigment (they are protanopes) or the green-sensitive pigment (deuteranopes). They usually have a partial gene deletion. The other 70% often have hybrid genes created by errors in recombination during cell division.[483] A few deuteranopes have the point mutation C203R in the green pigment. John Dalton, of atomic theory fame, reasoned that his red-green confusion resulted from a blue tint in the vitreous humor of his eyes and ordered that they be dissected after his death (in 1884). There was no blue tint but DNA analysis performed more recently showed that Dalton was a deuteranope.[484] Defects in the blue-sensitive receptor are relatively rare affecting about 1 in 500 persons, while only one person in 100,000 has a total lack of color discrimination.[481,485]

All retinal-dependent visual pigments form Schiff bases with lysine side chains of the photoreceptor proteins. How can the same chromophore be "tuned" to absorb across the wavelength range of 360 to 635 nm? Modern techniques such as resonance Raman[477,479] and FTIR spectroscopies and study of mutant forms[488] have shown that interaction of the conjugated double bond system of the chromophores with immediately adjacent dipoles of side chain groups and peptide linkages is sufficient to account for the great variability in absorption maxima.

Visual pigments of many species have been investigated. Most vertebrate animals have a rhodopsinlike pigment plus a variable number of cone pigments. Mammals typically have only two, a short-wavelength pigment absorbing maximally in the ultraviolet, violet, or blue region[488a-c] and a long-wavelength pigment with maximum absorption in the green or red region.[489] The bottlenose dolphin has only a rod pigment of λ_{max} 524 nm.[489] In contrast, the chicken has four cone pigments with maximum absorption for violet, blue, green, and red.[490,490a] The red light receptor, called **iodopsin**, absorbs maximally at 571 nm. However, it binds chloride ions which induce an additional 40-nm red shift. The Cl^--binding site involves His 197 and Lys 200 which are present in an extracellular loop (Fig. 23-41A) and quite far from the bound retinal.[490] Human red and green color vision pigments, and also a green-sensitive pigment of the reptile *Gecko gecko*, undergo spectral shifts upon binding of Cl^- in the same site.[491] However, rhodopsin and most other visual pigments do not share this behavior.

Fishes live in a variety of environments and have a diversity of visual pigments. Goldfish have genes for five opsins, one of which gives rise to an ultraviolet light receptor. They are also sensitive to polarized light.[492] Related visual pigments occur throughout the animal kingdom. Even the eyespot of the alga *Chlamydomonas* (Fig. 1-11) contains rhodopsin with some sequence homology to invertebrate opsins.[493,494] The pineal glands of chickens and probably of reptiles[495–496a] as well as those of fish[497] also contain rhodopsinlike pigments. In a few freshwater marine species the visual pigments (**porphyropsins**) contain **3-dehydroretinal**. The peak positions of light absorption depend both upon the nature of the bound alde-

hyde and on the protein, the latter having the larger effect. Thus, retinal-based pigments absorb in the entire range 467–528 nm (18,900–21,400 cm^{-1}). The fruit fly, *Drosophila*, contains 3-hydroxy-11-*cis*-retinal in its rhodopsin and also contains other related photoreceptors.[498]

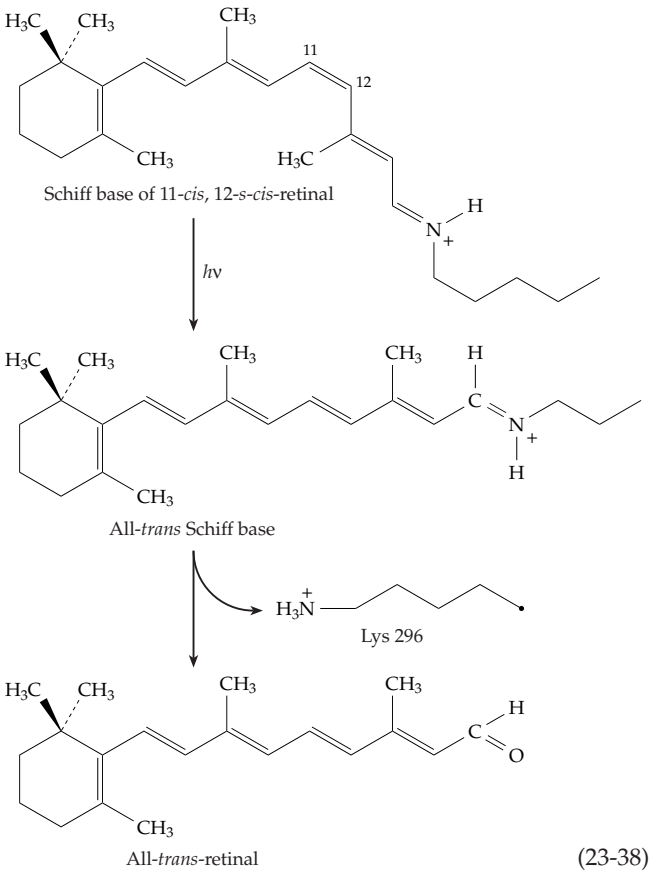
2. The Light-Induced Transformation

The retinal Schiff base chromophore is embedded in rhodopsin with its transition dipole moment parallel to the plane of the discs, i.e., perpendicular to the direction of travel of the incoming photons. Absorption of a photon leads to a sequence of readily detectable spectral changes.[37,461b,499,500] The relaxation times indicated in Eq. 23-37 are for 20°C.

Rhodopsin (498 nm, 20.1 x 10^3 cm^{-1})
$h\nu \downarrow \tau < 6 \times 10^{-12}$s
Bathorhodopsin (prelumirhodopsin; 543 nm, 18.4 x 10^3 cm^{-1})
$\downarrow \tau$ ~50 ns
Lumirhodopsin (497 nm), 20.2 x 10^3 cm^{-1})
$\downarrow \tau$ ~ 50 μs
Metarhodopsin I (478 nm, 20.9 x 10^3 cm^{-1})
$\downarrow\uparrow$ milliseconds
Metarhodopsin II (380 nm, 26.2 x 10^3 cm^{-1})
$\downarrow$ seconds
All-*trans*-retinal (387 nm, 25.8 x 10^3 cm^{-1}) + opsin (23-37)

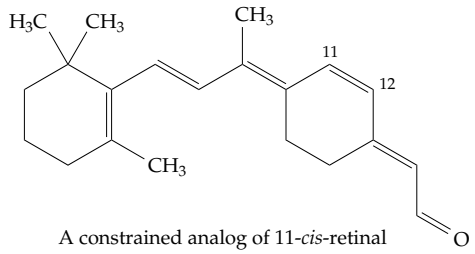
The intermediate chemical species have been named bathorhodopsin, lumirhodopsin, and metarhodopsin I and II. At very low temperatures a transient form **photorhodopsin** with a wavelength maximum at ~580 nm may precede bathorhodopsin.[461b,501–502a] Furthermore, nanosecond photolysis of rhodopsin has revealed a **blue-shifted intermediate** that follows bathorhodopsin within ~40 ns and decays into lumirhodopsin.[500,503,504] The overall result is the light-induced isomerization of the bound 11-*cis*-retinal to all-*trans*-retinal (Eq. 23-38) and free opsin. The free opsin can then combine with a new molecule of 11-*cis*-retinal to complete the photochemical cycle.

What are the chemical structures of the intermediates in Eq. 23-37, and why are there so many of them? The answer to the last question is that the initial photochemical process is very fast. Subsequent conformational rearrangments and movement of protons are slower, occur in distinct steps, and give rise to the observed series of intermediates. To shed light on these processes many experiments have been done with analogs of retinal,[502,505–508] often using very rapid spectroscopic techniques.[37,508] These studies have shown that the isomerization of the Schiff base from 11-*cis* to all-*trans* occurs in the first very rapid step of



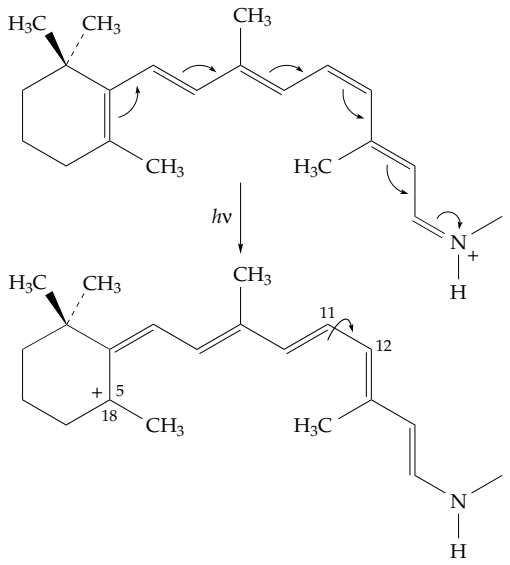
(23-38)

Eq. 23-37.[499,509–510a] Constrained analogs of 11-*cis* retinal also combine with opsin to form rhodopsinlike molecules with absorption maxima near 500 nm.



However, most of these analogs cannot isomerize and illumination does not produce bathorhodopsinlike molecules.[504,509,511]

In the photoexcited state the positive charge on the Schiff base is delocalized. For example, with some of the positive charge located on C5, rotation could occur around the more nearly single C11–C12 bond to give the all-*trans* isomer (Eq. 23-39). However, it seems more likely that simultaneous rotation occurs around two connected single and double bonds.[511a] The mechanism of this photoisomerization, which is among the fastest known chemical reactions, is still being investigated.[511b] In native rhodopsin the conversion to bathorhodopsin occurs with a high quantum



(23-39)

yield of 0.67 within 0.2 ps, a time comparable to the period of torsional vibrations of the retinal. This extreme speed suggests that the isomerization is a concerted process that is **vibrationally coherent**.[511c] Vibrational motion in the electronically excited state is utilized in the isomerization process.[506,512]

The reaction sequence of Eq. 23-37 can be slowed by lowering the temperature. Thus, at 70K illumination of rhodopsin leads to a **photostationary state** in which only rhodopsin, bathorhodopsin, and a third form, **isorhodopsin**, are present in a constant ratio.[510] Isorhodopsin (maximum absorption at 483 nm)[513] contains 9-*cis*-retinal and is not on the pathway of Eq. 23-37. Resonance Raman spectroscopy at low temperature supports a distorted all-*trans* structure for the retinal Schiff base in bathorhodopsin.[510] The same technique suggests the *trans* geometry of the C=N bond shown in Eqs. 23-38 and 23-39. Simple Schiff bases of 11-*cis*-retinal undergo isomerization just as rapidly as does rhodopsin.[514]

Some step in the sequence of Eq. 23-37 must initiate a chemical cascade that sends a nerve impulse out of the rod cell. This is accomplished through a GTP-dependent G protein cascade as outlined in Fig. 23-43. Light-activated rhodopsin initiates the cascade by interacting with the G protein **transducin**. Energy for the activation comes from the quantum of absorbed light. While the primary chemical reaction has long been recognized as the isomerization of the retinal Schiff base,[515] it is not obvious how this generates the signal for transducin to bind and become activated.

The seven helices of rhodopsin form a "box" around the bound retinal. The environment of the retinal is largely hydrophobic. However, there are also buried polar groups, some of which lie in conserved positions in more than 200 G-protein-coupled receptors[458] and internal water molecules whose vibrational spectra can be detected.[516] As in bacteriorhodopsin (Fig. 23-41, C) the buried polar groups and water molecules are doubtless hydrogen-bonded in an internal network. We can anticipate two effects of the isomerization reaction: (1) It will distort the shape of the box in which it occurs. (2) It will break some hydrogen bonds and allow new ones to form and may affect the balance of electrical charges within the protein. This in turn can lead to proton movements and alterations in the internal hydrogen-bonded network. Both of these anticipated effects have been observed.

Conformational changes induced in the rhodopsin protein by the isomerization of the retinal Schiff base include significant movement of the end of helix VI(F) at the cytosolic surface as well as smaller movements of other helices.[517,518] Spectroscopic measurements indicate that the Schiff base nitrogen remains protonated in both the bathorhodopsin and metarhodopsin I forms and in metarhodopsin II, the first long-lived form in the sequence.[518a,b] It seems likely that the proton has jumped via a bridging water molecule and the E113 carboxylate to the external (intradiscal) surface of the molecule. At the same time one or more protons are apparently taken up on the cytoplasmic side.[519] Study of mutant forms suggests that glutamate 134, near the cytosolic surface, and histidine 211 may be involved in proton transport.[520] By analogy with bacteriorhodopsin, aspartate 83 is probably also involved. The combination of conformational change plus altered charge distribution may be needed to create a binding surface with a suitable shape and charge constellation to bind tightly to transducin for the next step.

3. The Nerve Impulse

Which of the intermediates in Eq. 23-37 is responsible for initiation of a nerve impulse? Some evidence favored metarhodopsin I,[326] but its lifetime may be too short. On the other hand, the transformation of metarhodopsin I to metarhodopsin II is the slowest step that could trigger a nerve impulse, which must travel the length of the rod to the synapse in about one ms,[521] and metarhodopsin II is generally believed to be the activated signaling form of rhodopsin.[521a–c]

Transducin, cyclic GMP, and phosphodiesterase. The essential consequence of light absorption is an alteration in the membrane potential in the vicinity of the absorbed photon with the resulting propagation of a nerve impulse down the plasma membrane to the synapse by cable conduction (Chapter 30). The type of potential change that is transmitted differs among vertebrates and invertebrates.[522] In the case of mammalian photoreceptors the rod outer segment is permeable to sodium ions so that a large

dark current of sodium ions flows in through the plasma membrane and is pumped out by sodium pumps in the inner portion of the cell. Visual stimulation causes this permeability to Na^+ to be decreased with an increase in polarization of the membrane. Absorption of a single photon by rhodopsin blocks the outflow of ~10^6 sodium ions.

At one time calcium ions seemed to be the logical internal messenger between rhodopsin and the plasma membrane. If light absorption opened channels from the internal space of the rod discs, calcium ions could be released and diffuse quickly to the plasma membrane and block the entrance of sodium ions.[523] However, light *does not* increase the free [Ca^{2+}] in the cytoplasm but may decrease it from 500 nM to as low as 50 nM.[524,525] Stryer suggested that the essential messenger is **cyclic GMP** (Chapter 11)[526–528] and that a *decrease* in cGMP concentration initiates the nerve response. Cyclic GMP is apparently responsible for keeping the sodium ion channels open. Absorption of a photon in the rod disc (Fig. 23-43) produces activated rhodopsin R* (metarhodopsin II), which acts as an allosteric effector for the heterotrimeric G protein transducin whose structure and properties have been discussed in Chapter 11. Like proteins G_s and G_i of the adenylate cyclase system, transducin contains three subunits: α, 40 kDa, 350 residues; β, 36 kDa; and γ, ~8 kDa.[529] In the resting state they are associated as $T_{\alpha\beta\gamma}$ with a molecule of GDP bound to the α subunit. When activated rhodopsin R* binds to transducin (step *a*, Fig. 23-43) it catalyzes a rapid exchange of GTP for GDP (step *b*). This is followed by dissociation of $T_{\beta\gamma}$ from T_α GTP. The latter serves as an allosteric effector for a **cGMP phosphodiesterase** bound to the disc surface converting it to an active form (step *c*).[529a,b] The activated phosphodiesterase, an $\alpha\beta\gamma_2$ oligomer,[530] hydrolyzes the cGMP (step *d*, Fig. 23-43), reducing its concentration and thereby inhibiting the Na^+ outflow.

Because one molecule of activated cGMP phosphodiesterase can hydrolyze more than 10^5 molecules of cGMP per second the light response is highly amplified. There is also an earlier stage of amplification. Each molecule of light-activated rhodopsin (R*) is able to catalyze the exchange of GTP for GDP on hundreds of molecules of $T_{\alpha\beta\gamma}$ before R* passes on to other intermediates and releases all-*trans*-retinal from opsin (light green lines, Fig. 23-43).

Rhodopsin kinase, recoverin, and arrestin.

Metarhodopsin II (R*) can become phosphorylated by rhodopsin kinase on as many as seven serine and threonine side chains on its cytoplasmic surface (Fig. 23-41).[531,532] The 45-kDa protein arrestin binds to such phosphorylated R*,[533–535a] which is rapidly deactivated and desensitized so that it is less likely to be immediately reactivated. This is important in the adaptation of the eye to bright light. At the same time T_α2GTP is hydrolyzed back to T_α2GDP and reforms $T_{\alpha\beta\gamma}$2GDP, and guanylate cyclase regenerates the cGMP.[536] At least four different arrestins are known. Some function in nonvisual tissues. In all cases they seem to serve as "uncouplers" of G protein-coupled receptors.[536a]

Recovery of the inhibited rhodopsin, which occurs most rapidly in dim light, depends upon calcium ions. In dim light both Ca^{2+} and Na^+ enter the visual cells through the cGMP-controlled channels. At the same time Ca^{2+} flows out through a Na^+/Ca^{2+} exchanger. When the channels are blocked by cGMP formed in

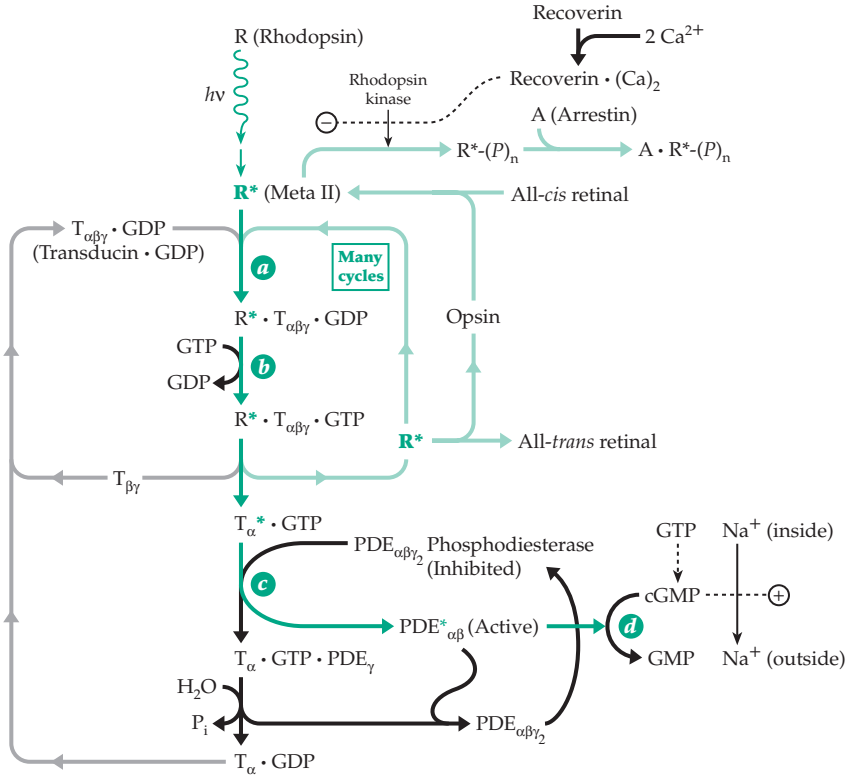


Figure 23-43 The light-activated transducin cycle. In step *a* photoexcited rhodopsin (R*) binds the GDP complex of the heterotrimeric transducin ($T_{\alpha\beta\gamma}$). After GDP–GTP exchange (step *b*) the activated transducin T*•GTP reacts with the inhibited phosphodiesterase ($PDE_{\alpha\beta\gamma 2}$) to release the activated phosphodiesterase ($PDE_{\alpha\beta}$). Based on scheme by Stryer[528] and other information.

response to light, [Ca^{2+}] falls as a result of continuing export by exchange with Na^+.[524,537] In the dark the [Ca^{2+}] concentration rises again and binds to a 23-kDa calcium sensor molecule called recoverin. Recoverin, like calmodulin (Fig. 6-8), has four EF-hand Ca^{2+}-binding motifs and also an unexpected feature. A **myristoyl group** attached at the N terminus is bound into a deep hydrophobic pocket in the protein. However, when two Ca^{2+} ions bind, recoverin undergoes a conformational change that allows the myristoyl group to be extruded and to bind to a membrane surface. This allows recoverin to move out of the cytosol to the surface of the disc membrane where it binds to and inhibits the activity of rhodopsin kinase,[538–541] increasing the sensitivity of photodetection.

Some details about cone cells and invertebrate vision. The biochemistry of retinal cones is less well known but is similar to that of rod cells. Cone pigments are present in the plasma membrane rather than in isolated discs (Fig. 23-40C). Different α, β, and γ subunits of transducin are formed in rods and cones.[522] Many differences are seen among various invertebrate visual systems. Inositol triphosphate (IP_3) and Ca^{2+} often serve as signals of photoexcitation. G proteins also play prominent roles.[522]

4. Regeneration of Visual Pigments; the Retinal Cycle

How is all-*trans*-retinal released from photobleached pigments and isomerized to 11-*cis*-retinal for the regeneration of the photopigments? Since new 11-*cis*-retinol is continuously brought in from the bloodstream and oxidized to retinal, isomerization can occur in other parts of the body. However, much of it takes place in the **pigment epithelium** of the retina, the layer of cells immediately behind the rod and cone cells. As indicated in Fig. 23-44, all-*trans*-retinal can leave the photoreceptor cells and, after reduction to retinal, be carried to the pigment epithelial cells by an **interphotoreceptor retinoid-binding** protein.[542,543] There it becomes esterified by the action of **lecithin:retinol acyltransferase**, an enzyme that transfers a fatty acyl group from lecithin to the retinol. The resulting retinyl esters are isomerized, and 11-*cis*-retinol is released.[543a] Some is stored as 11-*cis*-retinyl esters but enough is dehydrogenated to 11-*cis*-retinal to meet the needs of the photoreceptor cells and is transported back to them (Fig. 23-44). In the cephalopods the inner segment of the receptor cells contain a second pigment **retinochrome** that carries out a photochemical conversion of all-*trans*-retinal to 11-*cis*-retinal.[544,544a]

5. Diseases of the Retina

An important cause of blindness is **retinitis pigmentosa**, an inherited disease affecting about one in 3000 persons. Symptoms include progressive night blindness, degeneration of the rod cells, and gradual loss of cone cells and of nerve function in the retina. An autosomal dominant form of the disease arises from deletions or point mutations in the rhodopsin gene. In the United States 15% of cases arise from the mutation P23H.[545] By 1996 ~70 point mutations that cause retinitis pigmentosa had been discovered.[448,546–548] These mutations are found in all three of the rhodopsin domains: intradiscal, transmembrane, and cytosolic. Other rhodopsin point mutations such as G90D and A292E cause congenital night blindness.[549] Retinitis pigmentosa also arises from defects in **peripherin-RDS**, a structural component of rod cells identified originally from the gene *rds* (retinal degeneration slow) of the mouse.[545,550] Another form of congenital night blindness results from mutations in rhodopsin kinase.[551] A dominant **rod–cone dystrophy** is caused by a defect in the photoreceptor guanylate cyclase.[552] The most frequent cause of combined deafness and blindness in adults (**Usher syndrome**) is a defect in a cell adhesion molecule.[553] In **choroideremia**, another X-linked form of retinitis pigmentosa,

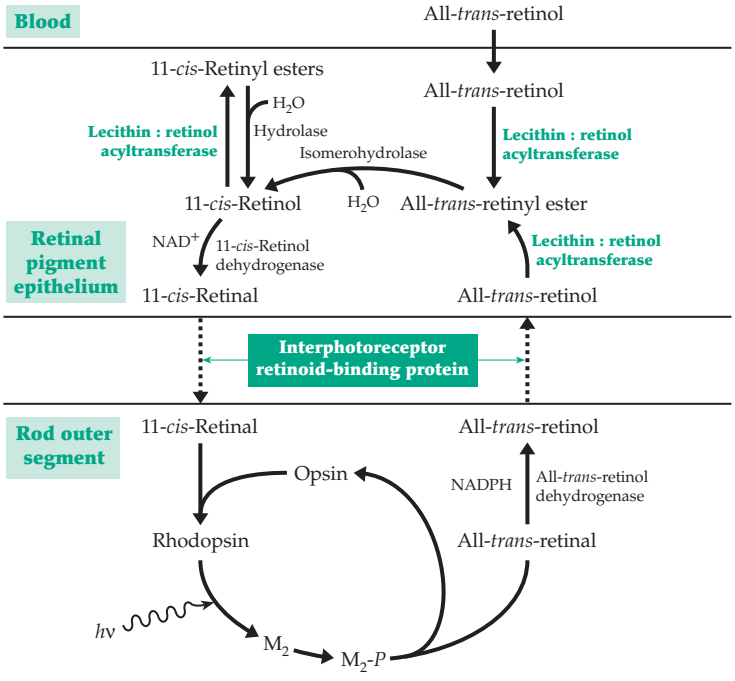

Figure 23-44 Reactions of retinol and the retinal cycle of mammalian rod cells. After Palczewski *et al.*[543]

the choroid layer behind the pigment epithelium also deteriorates. A geranylgeranyl transferase specific for the Rab family of G proteins is defective.[554]

The most frequent cause of vision loss in the elderly is **macular degeneration**. Mild forms of the disease occur in nearly 30% of those over 75 years of age and more serious forms in 7% of that age group. There are many causes, some hereditary.[555–556a] Excessive accumulation of fluorescent lipofuchsin, perhaps arising in part from Schiff base formation between retinal and phosphatidylethanolamine, is sometimes observed.[557]

6. Proteins of the Lens

The lens of the eye encloses cells that cannot be replaced and contains proteins that don't turn over and must last a lifetime.[558] The fiber cells, which make up the bulk of the lens, have no nuclei. They elongate and stretch to cover the central nucleus, the original fetal lens, like the layers of an onion, the edges of the cells interdigitated with the next cell like a piece in a child's construction set.[559] These cells are tightly packed with proteins in aggregates whose size is on the order of the wavelengths of light. The high concentration of proteins is needed to provide transparency and also a high refractive index.[560–562] The membranes of the lens cells acquire increasing amounts of a 28-kDa **major intrinsic protein** as they age.[563] Three classes of soluble lens proteins, called **crystallins**, are found in virtually all lenses. Alpha crystallins, which account for ~40% of the total soluble protein, are heterodimers of ~20-kDa subunits that associate into ~800-kDa complexes.[564] They have a chaperoninlike activity.[565] Beta crystallin, which may account for ~35% of the protein, as well as the γ crystallins are β-sheet proteins with "Greek key" folding motifs.[558]

In addition to the α, β, and γ crystallins many animals have recruited additional "taxon-specific" crystallins δ, ε, λ, etc., that have evolved from prexisting enzymes, chaperonins, or other proteins.[561,566–568] For example, avian and reptilian lenses contain a δ crystallin homologous to argininosuccinate lyase.[569] Many crystallins are derived from dehydrogenases, e.g., for lactate dehydrogenase (duck),[570] hydroxyacyl-CoA dehydrogenase (rabbit),[571] and aldehyde dehydrogenase (squid and octopus).[572] A high concentration of NADH may be present.[568] A crystallin of a diurnal gecko is a retinol-binding protein with bound 3-dehydroretinal (vitamin A_2), which probably acts as an ultraviolet filter that improves visual acuity and protects against ultraviolet damage.[567,572a] Human lenses contain small molecules that act as UV filters, e.g., glucosides of **3-hydroxykynurenine** (Fig. 25-11) and 4-(2-amino-3-hydroxyphenyl)-4-oxobutanoic acid. Lenses tend to discolor and become fluorescent with age, in part by irreversible reactions of crystallins with these compounds.[573–574a]

A common problem with lenses is **cataract**, a term that describes any loss of opacity or excessive coloration. There are many kinds of cataract, most of which develop in older persons.[560,562] Since lens proteins are so long-lived deamidation of some asparagine occurs. However, the reactions are slow. One of the asparagines in α crystalline has a half-life of 15–20 years, and some glutamines are undamaged after 60 years.[575]

G. Bacteriorhodopsin and Related Ion Pumps and Sensors

Under certain conditions, the salt-loving *Halobacterium salinarum* forms a rhodopsinlike protein, which it inserts into patches of **purple membrane** in the surface of the cell. These membranes, which may constitute up to 50% of the cell surface, contain light-operated proton pumps that translocate protons from the inside to the outside of the cells.[454,576–578] In this manner they may provide energy for a variety of cell functions including ion transport and ATP synthesis. The 248-residue retinal-containing **bacteriorhodopsin** makes up 75% of the mass of the membrane. Its molecules aggregate into a two-dimensional crystalline array in the purple patches of the membrane. This allowed determination of the three-dimensional structure to 0.7 nm resolution in 1975 by electron microscopy and neutron diffraction.[454] More recently the structure has been established at progressively higher resolution by electron crystallography[579–581] and X-ray diffraction.[455,582] The most recent studies have been focused on determination of the structural alterations in the protein that accompany the proton pumping.[582a–e] A step-by-step picture is emerging.[582f] Internal changes in the retinal chromophore, movements of protons, and alterations in the shapes of some of the protein helices are involved. The surface loops have been studied both by electron crystallography and by atomic force microscopy.[583] Each bacteriorhodopsin molecule is folded into seven closely packed α-helical segments which extend roughly perpendicular to the membrane. Although 100 residues shorter than rhodopsin, the folding pattern is very similar (Figs. 23-41C; 23-45). The protein molecules form an extremely regular array with phospholipid molecules (mostly of phosphatidylglycerol) filling the spaces between them. The retinal is buried in the interior of the protein and is bound as an *N*-protonated Schiff base with the side chain of lysine 216.

The retinal in bacteriorhodopsin (bR) exists in both all-*trans* and 13-*cis* configurations. The all-*trans* form has an absorption maximum at 568 nm and the 13-*cis*

at 548 nm. The two exist in a slow nonphotochemically mediated equilibrium in the dark.[584,584a] However, in the light the all-*trans* bR_{568} undergoes a rapid photochemical cycle of reactions, which is presented in simplified form in Fig. 23-46. The subscript numbers designate the wavelength of maximum absorption. Many efforts have been made to determine the structures of the intermediates K, L, M, and O and to relate them to a mechanism of proton pumping.[585–585c] Both K and L contain 13-*cis* retinal. Therefore, as with rhodopsin (Eq. 23-39) the very first step is a photochemical isomerization. Intermediate M appears to contain a deprotonated Schiff base, but O is both *N*-protonated and again all-*trans*. It follows logically that the proton bound initially to the Schiff base is pumped out of the cell and is then replaced by a new proton in the O form. However, several questions must be answered if we are to understand this proton pump. Where in the sequence do proton transfers occur? How is the sequence driven by the absorbed light energy? Protons must enter the pump from the cytosol and exit on the exterior (periplasmic) side, flowing out against a concentration gradient. There must be a "gating" or "switch" mechanism that ensures that protons enter and leave the pump in the correct direction.[586]

Some aspects of a possible mechanism for pumping the single proton bound to the retinal Schiff base are included in Fig. 23-46. In bR_{568} the Schiff base bound proton is H-bonded, via a water bridge, to the carboxylate group of Asp 85 (Fig. 23-45B). The charge constellation in the interior of the protein, part of which is shown in this figure, is such that protonation of the Schiff base is stable and the pK_a of the protonated Schiff base is high, with estimates of 16 or above.[587] One cause of the high pK_a is the presence of the nearby negative charges on D85 and D212. Absorption of light and isomerization of the retinal causes a downward movement of the $=NH^+-$ group of the Schiff base[588] and facilitates movement of the Schiff base proton via the water molecule to the D85 carboxylate as indicated by the green arrows in Fig. 23-45B. Loss of the positive charge will instantly substantially raise the pK_a of D85 from a low value, while the loss of the negative charge will lower the pK_a of the Schiff base to closer to 7. The electrostatic interactions of the D212 and E194 carboxylates with the positive charge of R82 may also be altered. At some point in the sequence the interaction of R82 with the E194 carboxylate could cause E204, which is known by spectroscopic measurements to be protonated in the intermediate, to lose its proton to the outside. At some other point, perhaps between M_{412} and another intermediate, M_{408} (Fig. 23-46), a conformational switch must occur to limit flow of a proton back to E204 and to allow a new proton to enter from the cytosol. The D96 carboxylate is thought to accept this proton and to transfer it via a chain of

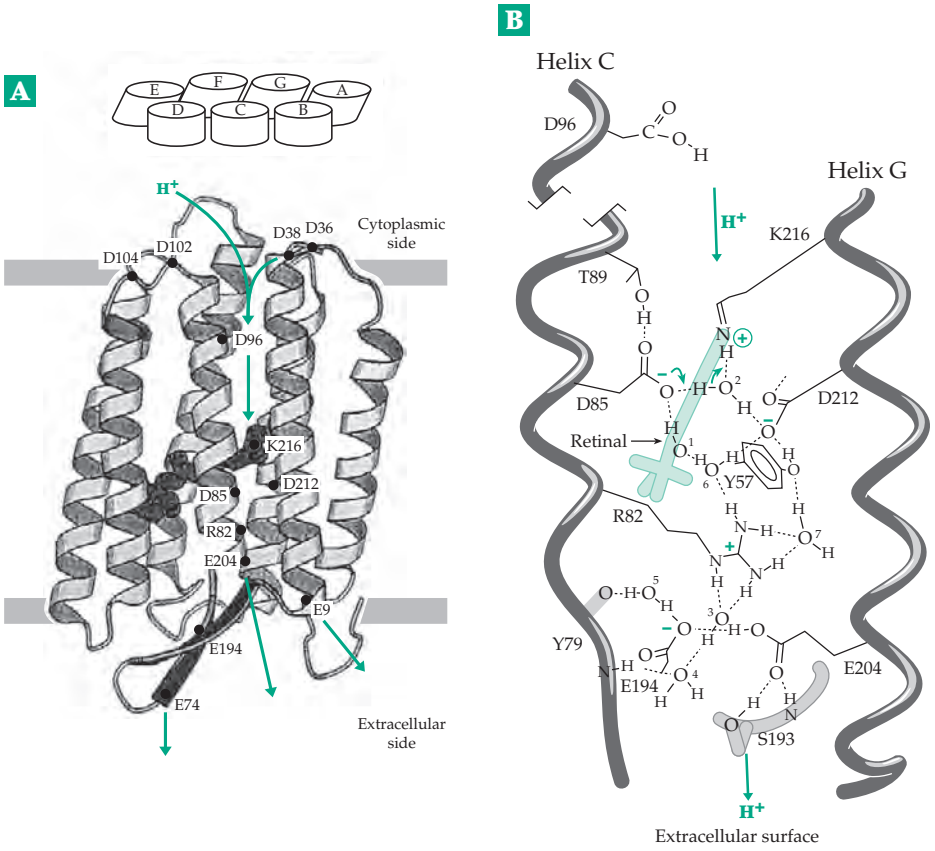

Figure 23-45 (A) Some aspects of the structure of bacteriorhodopsin. Ribbon diagram with the retinal Schiff base in ball-and-stick representation. At the top the helices are labeled as in Fig. 23-41. The locations of aspartate, glutamate, and arginine residues that might carry protons during the proton pumping action are indicated. Retinal is shown attached to lysine 216. From Kimura *et al.*[580] Courtesy of Yoshiaki Kimura. (B) Schematic drawing illustrating hydrogen-binding observed in the three-dimensional structure at 0.14 nm resolution. From Luecke *et al.*[455] The side chains shown are those thought to be involved in proton transport and in a hydrogen-bonded network with bound water molecules, principally between helices C and G. The positions of many of the hydrogen atoms in this network have not been established. They have been placed in reasonable positions in this figure but may be quite mobile. For another view of the hydrogen-bonded network see Fig. 23-41C.

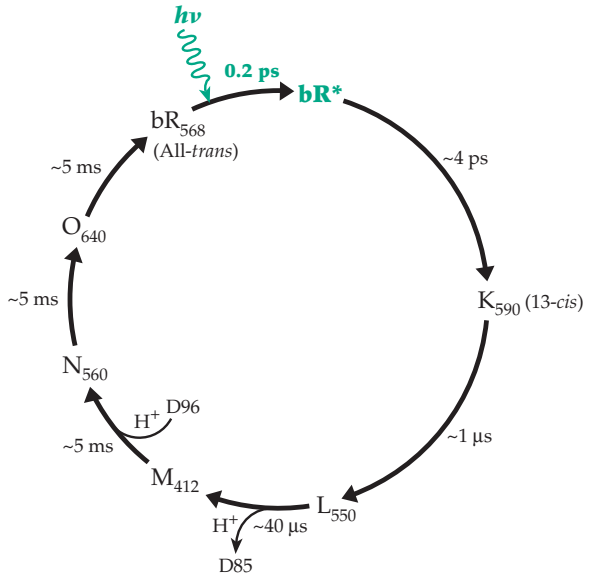

Figure 23-46 The photoreaction cycle of bacteriorhodopsin. After Bullough and Henderson.[585] The subscript numbers indicate the wavelengths of maximum absorption of each intermediate and the approximate lifetimes are given by the arrows. Resting bacteriorhodopsin as well as intermediates J and O have all-*trans* retinal but K through N are thought to all be 13-*cis*. A proton is transferred from L to aspartate 85 and then to the exterior surface of the membrane. A proton is taken up from the exterior surface via aspartate 96 to form N.

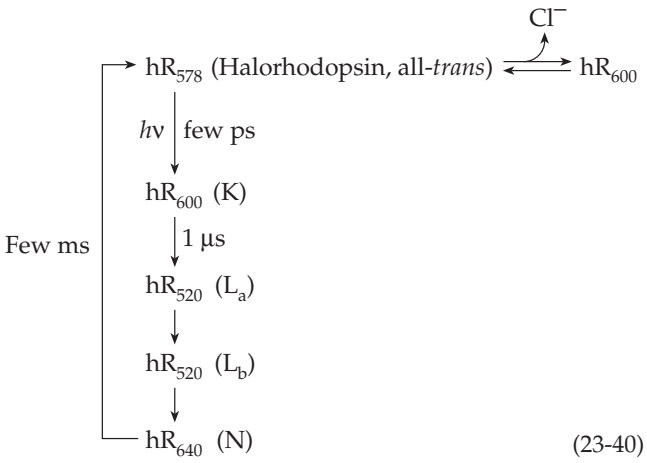
water molecules or water molecules plus protein groups to the Schiff base, which may isomerize back to all *trans* in going from intermediate N to O. Isomerization to all-*trans* O is a slow step. Both O_{640} and bR_{568} are all-*trans* and have a 15-*trans* Schiff base linkage. There may be a difference in protein conformation with the chromophore being more distorted in O than in bR_{568}. Many recent studies have provided additional information.[588a–j]

Halorhodopsin. In addition to bacteriorhodopsin there are three other retinal-containing proteins in membranes of halobacteria. From mutant strains lacking bacteriorhodopsin the second protein, **halorhodopsin**, has been isolated. It acts as a light-driven *chloride ion pump*, transporting Cl^- from outside to inside. Potassium ions follow, and the pump provides a means for these bacteria to accumulate KCl to balance the high external osmotic pressure of the environment in which they live.[578] The amino acid sequences of halorhodopsins from several species are very similar to those of bacteriorhodopsin as is the three-dimensional structure.[589] However, the important proton-carrying residues D85 and D96 of bacteriorhodopsin are replaced by threonine and alanine, respectively, in halorhodopsin.[590] Halorhodopsin (hR)



(23-40)

undergoes a light-dependent cycle (Eq. 23-40) that involves an all-*trans* to 13-*cis* photoisomerization with some intermediates resembling those of the bacteriorhodopsin cycle.[590a]

Sensory rhodopsins. The third and fourth light-sensitive proteins of halobacteria are **sensory rhodopsins** (SR)[578,591,591a,b] that are used by the bacteria to control **phototaxis**. These bacteria swim toward long-wavelength light, the maximum in the action spectrum being at ~580 nm. They are repelled by blue or ultraviolet light, the maximum in the action spectrum being at ~370 nm. Evidently the bacteria can detect either a decrease with time in red light intensity or an increase with time in blue light intensity. Either is interpreted as unfavorable and causes the bacteria to tumble and move in a new direction (see Chapter 19). Sensory rhodopsin I (SRI) appears to be able to provide both light responses. Absorption of orange light by SRI_{587}, which contains all-*trans*-retinal, yields SRI_{373}, in which the retinal Schiff bases have been isomerized to 13-*cis* as in bacteriorhodopsin. The red light response is proportional to the fraction of SRI_{373} present. However, this is converted spontaneously back to SR_{587} within seconds. Nevertheless, photoexcitation of SRI_{373} with blue light causes a faster reconversion and induces swimming reversals, the repellent response.[592,593] SRI exists in the bacterial membranes in a complex with a 57-kDa protein designated **halobacterial transducer I** (HtrI), which resembles bacterial chemotaxis receptors (Figs. 11-8 and 19-5) and is modulated by action of a methyltransferase.[591b,c] Interaction of SRI with HtrI depends upon a histidine residue, H166 of SRI. It may be part of a proton transfer pathway.[593]

Sensory rhodopsin II (SRII, also called phoborhodopsin) is specialized for repellant phototaxis.[591a] Blue light converts $SRII_{487}$ in < 1 ms to UV-absorbing $SRII_{360}$. It decays in ~100 ms to $SRII_{540}$ which reverts to the initial $SRII_{487}$ in ~0.5 s. The cycle is accompanied by swimming reversals that result in a repellent

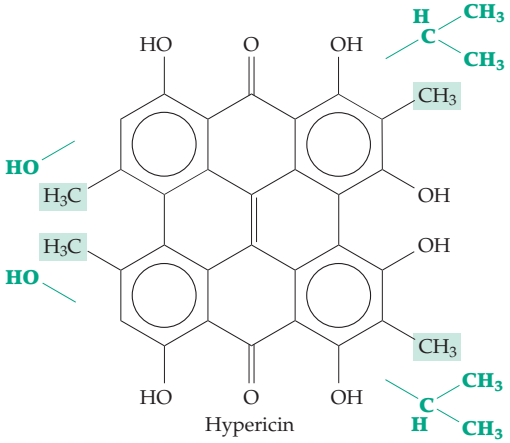
effect of light.[594–596] The three-dimensional structure is known.[593a,b]

Whereas retinal-based proton pumps all have the conserved residues D85 and D96 of bacteriorhodopsin, only the aspartate correspnding to D85 is conserved (as D73) in the sensory rhodopsins. D96 is replaced by tyrosine or phenylalanine.[586] In SRI D73 appears to be protonated and, therefore, does not form a counterion for the Schiff base iminium ion.[597] However, in SRII D73 is apparently unprotonated and available to -serve as a counterion and as a proton acceptor as in bacteriorhodopsin.[597a,b] There is also a corresponding aspartate (Asp 83) in rhodopsin (Fig. 23-41). This suggests a common signaling mechanism for rhodopsin and the sensory rhodopsins. Finally, there are retinal-containing proteins in fungi and in algae. They may serve as blue light receptors.[598,598a]

The photoactive yellow proteins (xanthopsins). A 124-residue, 14-kDa yellow protein isolated from a halophilic phototrophic purple bacterium, *Ectothiorhodospira halophila*, was at first thought to be a rhodopsin-type pigment. However, this photoactive yellow protein (PYP) carries a covalently bonded **coumaroyl (4-hydroxycinnamoyl) group** in thioester linkage,[599–601c] which is completely surrounded by the small protein.[601] The coumaroyl group, which was probably derived from coumaroyl-CoA (Fig. 25-8), is bound as a phenolate anion by hydrogen bonds to tyrosine and glutamate side chains (Eq. 23-41). After a laser flash at room temperature a readily observed intermediate I_1 (also called pR) absorbing maximally at 460–465 nm appears within ~3 ns and decays within a few milliseconds to a bleached intermediate I_2 (also called pB or pM)[602,603] with maximum absorption at ~355 nm. This returns to the original 446-nm form within a few seconds. Earlier intermediates I_0 and $I_0^{\ddagger}$ have been identified by picosecond spectroscopy,[601c,604,605] and others have been identified at low temperatures.[602,606]

The structure of PYP is known to 0.1 nm resolution (Fig. 23-47).[601,607] Structures have also been determined for a very early intermediate by trapping at –100°C[607] and for I_1 (pR). The cofactor structures are shown in Eq. 23-41. The light-induced step is apparently the *cis–trans* isomerization,[608] and changes in hydrogen-bonding follow. The hydrogen bond between the phenolate ion of the coumaroyl group and glutamate 46 appears to break, and E46 may donate a proton to the phenolate group to form the 337-nm chromophore of I_2.[602,609,609a] The signaling mechanism may be similar to that in sensory rhodopsins.

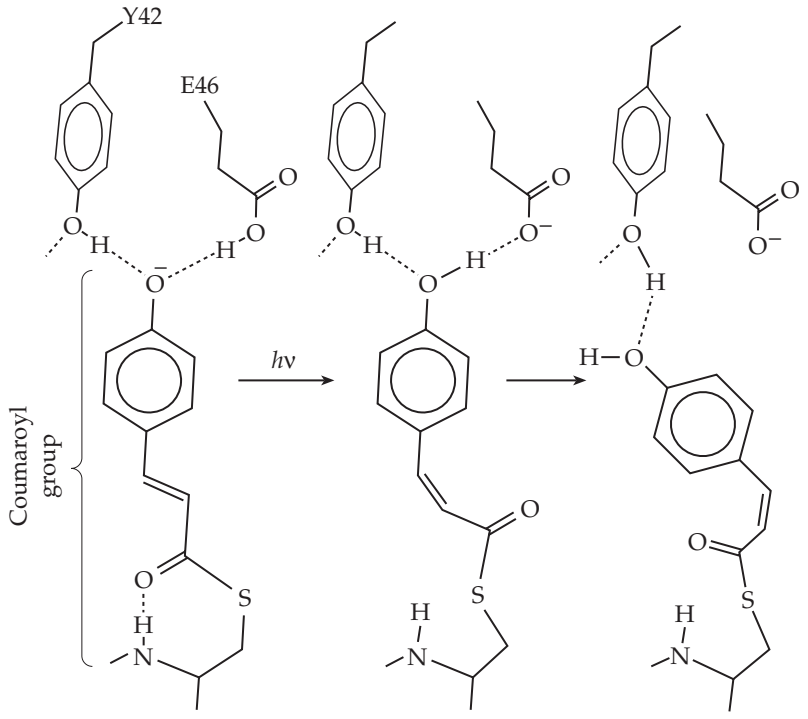
Stentorin. A protein with a bound chromophore called stentorin mediates the light-avoidance response of the protozoan *Stentor*. Stentorin,[610] which is found in pigment granules in the cell surface, is a derivative of **hypericin**, a plant compound with antidepressant activity and the active ingredient in the herb St. John's wort.



Hypericin

Replaced in stentorin by the green groups

Stentorin is covalently bonded to a 16-kDa protein in an acid-labile linkage. Its photocycle is not well investigated, but it is thought to initiate a response via



(23-41)

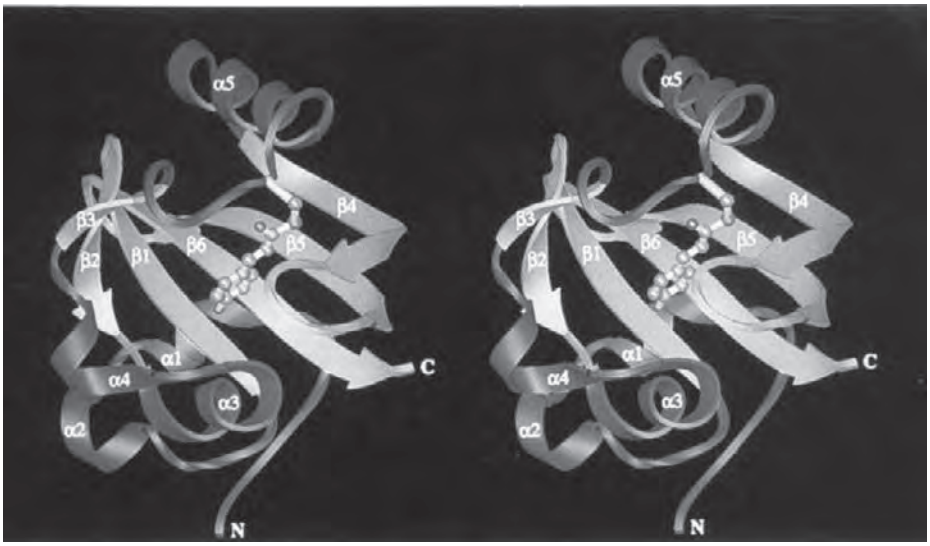


Figure 23-47 Ribbon drawing of the structure of the 125-residue yellow photoactive protein. The 4-hydroxycinnamoyl chromophore, which is attached to cysteine 69, is represented with balls and sticks. From Borgstahl *et al.*[601] Courtesy of Gloria Borgstahl.

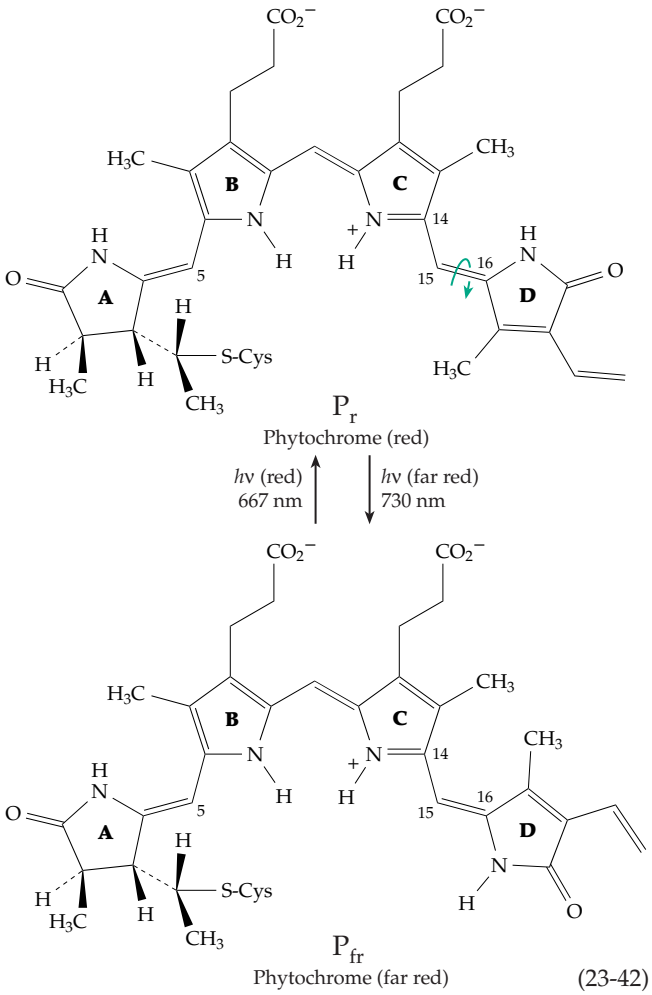
proton transfer.[611] However, stentorin proteins apparently do not belong to the bacteriorhodopsin family.

Hypericin and related compounds have also aroused interest because of their antiviral and antitumor activities.[612,613] Hypericin is a strong photoactivator which produces singlet oxygen with a quantum efficiency of 0.73. However, antiviral activity may involve a radical mechanism.[613] Hypericin is attractive as a possible agent for photodynamic therapy (Section D,3). It can also receive energy from photoexcited firefly luciferin (Section J). A proposed application is to incorporate the gene for the enzyme luciferase of the firefly luminescence system into DNA from the virus HIV. This DNA could be used to promote synthesis of luciferase only in virus-infected cells. Addition of the nontoxic hypericin would lead to photoactivation of hypericin only in virus-infected cells, where the luciferin–luciferase complex would act as a "molecular flashlight" to activate the hypericin and destroy the cell.[613]

H. Phytochrome

In 1951, it was discovered that a flash of red light (maximum activity at 660 nm) during an otherwise dark period promoted a variety of responses in plants.[614] These included flowering, germination of seeds (e.g., those of lettuce), and the expansion of leaves in dark-grown pea seedlings. Interestingly, the effect of the short flash of red light could be *completely reversed* if followed by a flash of *far-red light* (730 nm). This discovery led to the isolation, in 1959, of the chromoprotein phytochrome, a kind of molecular switch that initiates a whole series of far-reaching effects in plants. The phototransformation[615] is completely reversible (Eq. 23-42; Fig. 23-48), and the switch can be thrown in one direction or the other many times in rapid succession by light flashes.

Green plants have a family of phytochromes. There are five genes for the ~125-kDa chains of about 1100 residues each in *Arabidopsis*,[618–619c] and the corres-



(23-42)

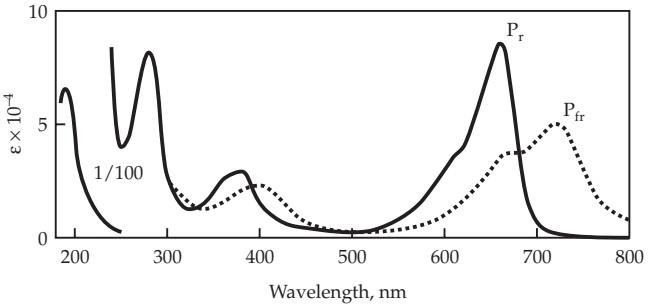


Figure 23-48 Absorption spectra of red (P_r) and far-red (P_{fr}) forms of purified oat phytochrome following saturating irradiations with red and far-red light. See Quail[616] and Anderson *et al*.[617]

sponding phytochromes A – E each appear to have distinct functions. The chromophore is an open tetrapyrrole closely related to phycocyanobilin and covalently attached to the peptide backbone near the N terminus through a cysteine side chain (top structure in Eq. 23-42). The initial photochemical reaction is thought to be the $Z \rightarrow E$ isomerizion around the C15 – C16 double bond, but there may also be rotation about the C14 – C15 single bond. The initial step occurs within a few microseconds and up to four intermediate species have been seen in the $P_r \rightarrow P_{fr}$ conversion and at least two other different ones in the $P_{fr} \rightarrow P_r$ conversion.[620–623c]

Phytochromes exist as two distinct domains, the N-terminal domain bearing the chromophore. However, the first 65 residues at the N terminus as well as the C-terminal domain probably interact with other proteins to transmit a signal. The slow responses to phytochrome are thought to involve regulation of transcription.[619b,623d] Thus, the synthesis of mRNA molecules specific for the small subunit of ribulose bisphosphate carboxylase and for the chlorophyll *a*/*b* binding protein increases in response to formation of P_{fr}. These responses are quite rapid occurring within 15–30 min.[614] Another response to P_{fr} is a decrease in the amount of the specific mRNA for phytochrome itself. That is, light induces a decrease in the concentration of this light-sensing molecule thereby decreasing the sensitivity of the system.[614]

Phytochrome is found not only in higher plants but also in algae, where it controls the movement of chloroplasts,[611] and also in cyanobacteria.[623e,f] Cyanobacterial phytochromes contain histidine kinase domains, which may function in a two-component system with a response regulator similar to protein CheY of the chemotaxis system in *E. coli* (Fig. 19-5).[624,625] Some nonphotosynthetic bacteria also use bacteriophytochromes for light sensing. In some cases biliverdin (Fig. 24-24) is the chromophore.[625a]

Phytochromes of higher plants also have histidine kinase-like N-terminal domains. Searches for associated signaling proteins have revealed a phytochrome-interacting factor in *Arabidopsis*. A possible partner for phytochrome B, it is a nuclear helix–loop–helix protein that may be a transcription factor.[626–627a] Phytochrome A may signal via a WD-repeat protein to control morphogenesis.[628]

One response under phytochrome control is the closing of leaflets of *Mimosa* at the onset of darkness. The response occurs within 5 min, too short a time to be the result of transcriptional control. This and the finding that some phytochrome is tightly bound to membranes have led to the proposal that one primary effect of phytochrome is to alter membrane properties. It is not certain whether it is P_r or P_{fr} that is active in causing a response, but P_{fr} seems to be the most likely candidate for the "active" form. According to one suggestion, phytochrome in plastid membranes may mediate the release of gibberelins stored within the plastids.[629]

I. Some Blue Light Responses

Numerous biological responses to light of wavelength 400–500 nm are known. These include phototropism in higher plants, the phototaxis of *Euglena*, and photorepair of DNA. On the basis of action spectra both carotenoids and flavins were long ago proposed as photoreceptors.[630–632] The action spectrum for opening of the stomates in coleoptiles matches the absorption spectrum of zeaxanthin.[631] On the other hand, genetic evidence[633,634] has strengthened the view that a flavin acts as the photoreceptor in the fungus *Phycomyces*. Recently compelling evidence for a flavoprotein receptor for phototropism in *Arabidopsis thaliana* has been obtained. Deficiency of a gene called *nph*1 (nonphototropic hypocotyl 1) is associated with loss of blue light-dependent phosphorylation of a 120-kDa protein. This protein was identified as the product of *nph*1 gene. The **nph1** protein is a soluble autophosphorylating Ser / Thr protein kinase with an N-terminal flavin-binding region. It apparently binds FMN and is a photoreceptor for phototropism in higher plants.[635–636b]

The complexity of the action spectra suggested the existence of more than one receptor.[634] In higher plants there are not only blue light receptors but also violet receptors and phytochrome. In addition to nph1 and a related protein **npl1**, *Arabidopsis* employs two cryptochromes (next section) and **phototropins**.[636c–e] These are also riboflavin 5'-phosphate (FMN)-dependent proteins. The action of light apparently causes addition of a highly conserved cysteinyl –SH group to the C4a position of the flavin.[636c] Phytochrome absorbs blue and ultraviolet light to some extent (Fig. 23-48) as well as red or far-red. This adds

considerable complexity to the interpretation of light responses in plants.[637] The fern *Adiantum* contains a protein with a phytochrome photosensory domain fused to an NPH1 structure. It may mediate both real far-red and blue-light responses.[636] The protist *Euglena* (Fig. 1-9) makes use of a **photoactivated adenylate cyclase**, also a photoactivated enzyme, in a light avoidance response.[637a]

Fungi such as *Neurospora crassa* provide a simpler system for study of blue-light signaling than do green plants.[637] *Neurospora* contains no phytochromes. However, numerous genes including some involved in carotenoid biosynthesis and some that control the circadian cycle are regulated by blue light. Two mutants defective in riboflavin synthesis show a reduced sensitivity to blue light. A deficiency of either of two other genes *wc*-1 and *wc*-2 results in "blind" *Neurospora* unable to respond to light but able to grow. Proteins WC1 and WC2 are probably transcription factors, which act as a heterodimer. WC1, which contains bound FAD, is the photorecetor.[637,637b,c] Recently a rhodopsinlike protein NOP-1 of *Neurospora* has been identified.[637d]

1. Cryptochromes

The elusive nature of the principal blue-light receptor in plants gave rise to the name cryptochrome.[632] The gene for a cryptochrome in *Arabidopsis thaliana* was isolated by gene tagging and was cloned. It is surprisingly similar in sequence to the gene for the well-known **DNA photolyase** (Section 2).[638] It was soon recognized that cryptochromes, like photolyases, carry a bound flavin and also an antenna chromophore. The latter is probably a 5,10-methylenetetrahydrofolate, as in plant photolyases. It is a better light absorber than the flavin and passes electronic excitation to the flavin.

Two cryptochrome genes, *cry*1 and *cry*2, are present in *Arabidopsis*. The encoded proteins affect many aspects of plant growth. The cry-1 protein, together with NPH1, has a role in controlling phototropisin[639] while cryptochrome cry-2 affects flowering time, apparently via antagonistic signals from cry-2 and phytochrome B.[640–640b] cry-1 is also involved in controlling the daily rhythm of the plant, the **circadian cycle**. The circadian clock, which is discussed in Chapter 30, provides the organisms an oscillator with a period of about 24 hours. However, the oscillator must be **entrained** by the daylight cycle so that it remains in proper synchrony. The nature of the light signal and the mechanism of the entrainment are being investigated in many different organisms from fungi to human beings. In *Arabidopsis* the cycle is controlled by phytochromes A and B and by the cryptochrome cry-1.[641]

Cryptochrome genes have been found in many organisms. In the fly *Drosophila* cryptochrome appears to interact directly with the clock proteins that control the circadian cycle. Most important are products of two genes *per* (period) and *tim* (timeless). They are helix–loop–helix DNA binding proteins that form heterodimers, are translocated to the nucleus, and repress their own transcription. Morning light leads to a rapid disappearance of the TIM protein. The cryptochrome CRY appears to react directly with TIM to inactivate it. However, details remain to be learned.[642] The circadian clock mechanism appears to be universal and the cryptochrome-2 (*mcry*2 gene) appears to function in the mouse.[643,643a] A human cDNA clone was found to have a 48% identity with a relative of cryptochromes, the **(6–4) photolyase** of *Drosophila*. A second related human gene has also been found. The protein products of these two genes (*hcry*1, *hcry*2) lack photolyase activity. They too may encode cryptochromes.[644]

Where in the body is the light sensed for entraining the circadian cycle? Genes for CRY1 and CRY2 are specifically expressed in ganglion cells of the retina in mice. Severing of the optic nerve destroys both vision and light entrainment of mammals. However, in mice with the retinal degeneration (*rd*) syndrome all rod cells and virtually all cone cells are destroyed but the circadian rhythm is normal.[645] Furthermore, many blind persons with no conscious perception of light have normal light entrainment of their circadian cycle. For these reasons the ganglion cells of the retina, which are close to the location of the master circadian clock in the **suprachiasmatic nucleus** of the brain, are the most probable light sensory cells for the cycle[646,647] (see also Chapter 30). Recent evidence points to a retinal-based photoreceptor, **melanopsin**.[647a,b,c] However, vitamin A-deficient mice still display a normal circadian response.[647d]

2. Photolyases

A curious discovery was made many years ago. Bacteria given a lethal dose of ultraviolet radiation can often be saved by irradiating with visible or near ultraviolet light. This **photoreactivation**, which permits many bacteria to survive, results from the action of a **DNA photolyase**,[648,649] which often absorbs light maximally around 380 nm and carries out a photochemical reversal of Eq. 23-26, cutting the pyrimidine–pyrimidine covalent bonds of thymine dimers in DNA. The enzyme is present in cells in such small amounts, only 10–20 molecules per cell, that it was difficult to investigate until the gene had been cloned.[650,651] The significance cannot be doubted, for photoreactivation enzymes appear to be found in most organisms including some mammals. However, there

is some doubt about the presence of a photolyase in the human body.

The *E. coli* DNA photolyase contains a blue flavin radical that arises from **FAD** and absorbs maximally at 580 nm (see also Chapter 15, Section B,6). The enzyme also contains a second chromophore in the form of bound 5,10-methenyltetrahydrofolylpolyglutamate with 3–6 γ-glutamyl residues.[652–653b] as shown in Fig. 23-49. The pterin coenzyme binds near the N terminus in a domain with an α/β folding pattern, while the FAD binds into a larger mostly helical domain. The pterin cofactor is not essential for repair activity, and it is generally agreed that because of its high molar extinction coefficient it acts as an effective **antenna**. It transfers energy in a nonradiative fashion to the $FADH^-$ anion located ~3 nm away.

The enzyme as isolated is in a stable blue radical form (Fig. 23-50; also Fig. 15-13) which must undergo a one-electron light-induced reduction to the anion $FADH^-$ before becoming active. A nearby indole ring of Trp may donate the electron and be reoxidized by a tyrosyl ring.[654] The $FADH^-$ donates an electron to the pyrimidine dimer, initiating the sequence of radical reactions[654a–c] which cleaves both pyrimidine–pyrimidine bonds in the photodimers (Fig. 23-50).

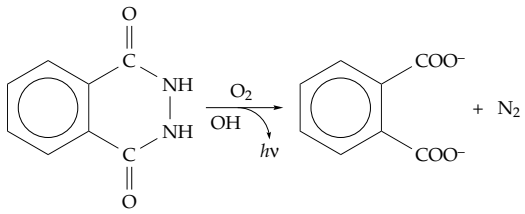
The structures of all of the photolyases are thought to resemble that in Fig. 23-49. However, in one large group, which includes methanogenic bacteria, **8-hydroxy-5-deazariboflavin** acts as the antenna chromophore.[649] Another light-induced defect in DNA is the so-called 6–4 photoproduct, a different pyrimidine dimer. The 6–4 dimers are normally removed in most organisms by efficient **excision repair** (Chapter 27). However, a 6–4 photolyase was discovered in both *Arabidopsis* and *Drosophila* and has also been found in *Xenopus* and the rattlesnake.[655,655a] It has a structure similar to that of the *E. coli* photolyase and presumably acts by a related mechanism[191,656–657a] that uses the light-excited reduced flavin in an electron donation and return cycle as in Fig. 23-50. A homolog of the *Drosophila* 6–4 photolyase gene has been found in human cells, but there is uncertainty about its function.[658] Is it really a photolyase or is it a cryptochrome involved in the circadian cycle?

Figure 23-49 Overall view of the DNA photolyase structure from *E. coli*. The ribbon traces the 471-residue chain. The bound cofactors FAD (left) and 5,10-methenyltetrahydrofolate (right) are shown in ball-and-stick representation. From Park *et al*.[652] Courtesy of Johan Deisenhofer.

J. Bioluminescence

The emission of visible light by living beings is one of the most fascinating of natural phenomena. Luminescent bacteria, glowing toadstools, protozoa that can light up ocean waves, luminous clams, fantastically illuminated railroad worms,[659] and fireflies[660–661a] have all been the objects of the biochemists' curiosity.[662–664] The chemical problem is an interesting one. The firefly's light with a wavelength of 560 nm (17,900 cm^{-1}) has an energy of 214 kJ/einstein. What kind of chemical reaction can lead to an energy yield that high? It is far too great to be provided by the splitting of ATP. Even the oxidation of NADH by oxygen would barely provide the necessary energy.

A clue comes from the fact that chemiluminescence is very common when O_2 is used as an oxidant in nonenzymatic processes. The slow oxidation of alcohols, aldehydes, and many nitrogen compounds (Eqs. 23-43, 23-44) is accompanied by emission of light



Luminol, a synthetic luminescent compound

(23-43)

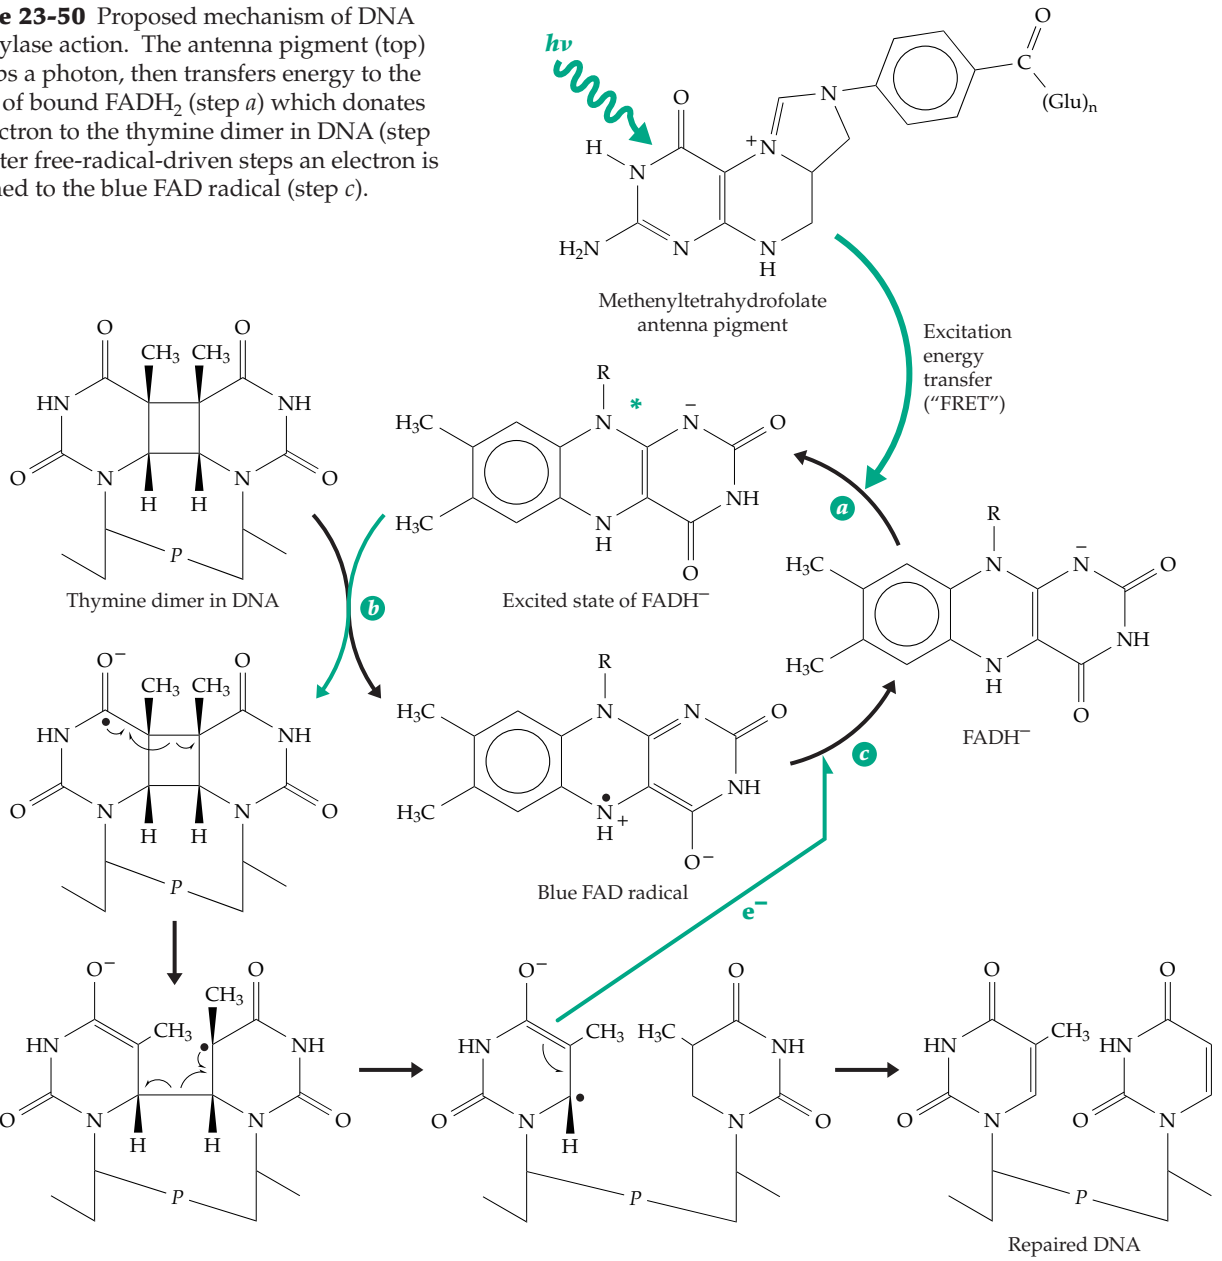


Figure 23-50 Proposed mechanism of DNA photoylase action. The antenna pigment (top) absorbs a photon, then transfers energy to the anion of bound $FADH_2$ (step *a*) which donates an electron to the thymine dimer in DNA (step *b*). After free-radical-driven steps an electron is returned to the blue FAD radical (step *c*).

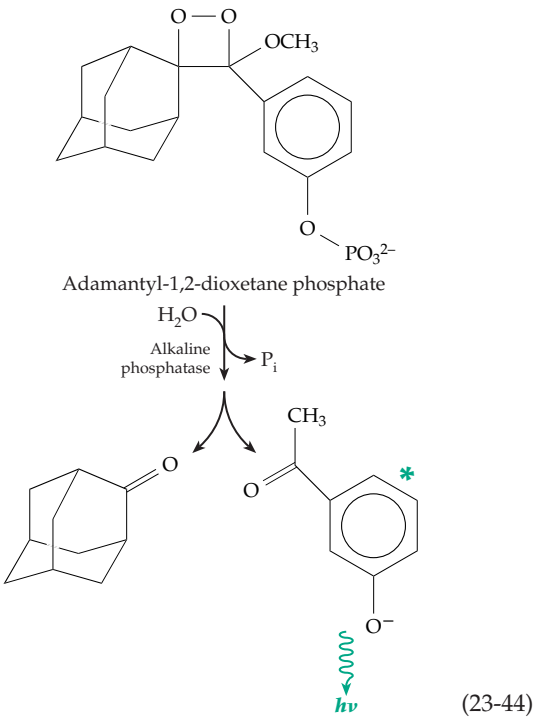
visible to the eye. Chemiluminescence is especially pronounced in those reactions that are thought to occur by radical mechanisms. The recombination of free radicals provides enough energy to permit the release of visible light. Cleavage of a peroxide linkage, e.g., in a dioxetane (Eq. 23-44),[665] is often involved.[666] For example, the reaction of Eq. 23-44 is used in a sensitive light-detected assay for alkaline phosphatase.

In view of these facts it is perhaps not so surprising that many organisms have mastered the ability to channel the energy released in an oxygenation reaction into light emission. Attempts to extract luminous materials from organisms date from the last century when the French physiologist, DuBois, in 1887 prepared both a cold-water extract and a hot-water extract of luminous clams.[662] He showed that the material in the cold-water extract, which he named **luciferase**, caused emission of light when a heat-stable material (which he called **luciferin**) present in hot-water extract was added. These names have been retained and are now used in a general way. Thus, the luciferins are a family of compounds whose structures have been determined for a number of species (Fig. 23-51). Firefly luciferin is a carboxylic acid, but it must be activated in an ATP-requiring reaction to give **luciferyl adenylate**, whose structure is shown in the figure. The latter emits light in the presence of O_2 and luciferase. It can be seen that the original carboxyl group becomes CO_2, while the ring becomes oxidized. In addition, the acyl adenylate linkage is broken. In



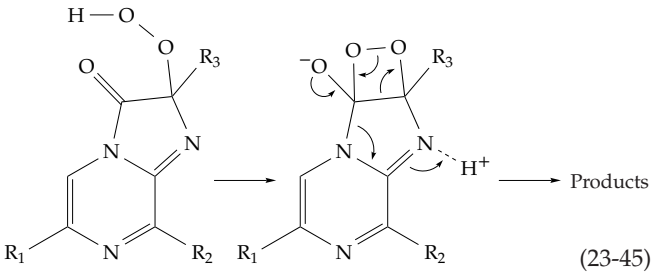
Adamantyl-1,2-dioxetane phosphate

(23-44)

the "sea pansy" *Renilla reniformis* (a coelenterate) the luciferin has quite a different structure.[667,668] However, the reaction with O_2 to produce CO_2 and an oxidized product causes the light emission, just as in the firefly. The luciferin of *Renilla*, which is called **coelenterazine** (Fig. 23-51), is also found in the jellyfish *Aequorea*, the shrimp *Oplaphorus*,[669] the "firefly squid" *Watasenia scintillans*,[670] and other luminous organisms.

In *Renilla* the coelenterazine is stored as a coelenterazine sulfate, possibly having the structure shown. To convert this storage form to the active luciferin the sulfo group is transferred onto adenosine 3',5'-bisphosphate to form 3'-phosphoadenosine 5'-phosphosulfate, the reverse of step *d* of Eq. 17-38. The luciferin of the ostracod crustacean *Vargula hilgendorfii* has a structure (Fig. 23-51) close to that from *Renilla*. In *Vargula* (formerly *Cypridina*) the luciferin and luciferase are produced in separate glands and are secreted into the surrounding water where they mix and produce a bright cloud of light.[671]

In most mechanisms suggested for luciferase action O_2 reacts at the carbon atom that becomes the carbonyl group in the product to form an intermediate peroxide. In the case of *Renilla* luciferin this can easily be visualized as a result of flow of electrons (perhaps one at a time) from the pyrazine nitrogen (at the bottom of the structure in Fig. 23-51) into the O_2. According to one proposal, the peroxide group that is formed adds to the carbonyl to form a four-membered dioxetane ring as shown in Eq. 23-45 for coelenterazine peroxide. The latter opens, as indicated by the arrows, to give the products. This theory was tested using



(23-45)

$^{18}O_2$. In the case of *Vargula* luciferin the expected incorporation of one atom of ^{18}O into CO_2 was observed, but with firefly and *Renilla* luciferins no ^{18}O entered the CO_2. In these two cases, a somewhat different mechanism may hold.

The jellyfish *Aequorea* contains a **photoprotein**, which emits light only when calcium ions are present.[672,673] Since light emission can be measured with great sensitivity (modern photomultipliers can be used to count light quanta) the protein **aequorin** and related photoproteins[674a] are used as a sensitive indicator of calcium ion concentration.[674] (In a similar way the firefly luciferin–luciferase system, which requires ATP for activation, is widely used in an assay for ATP.)

To identify the chromophore in aequorin over 4000 kg of jellyfish were used to obtain 125 mg of electrophoretically pure photoprotein.[674] From this one mg of a chromophoric substance AF-350 (Fig. 23-51) was isolated and characterized as a product. The close relationship to the *Renilla* and *Vargula* luciferins is obvious, and it is thought that coelenterazine is present in aequorin and other photoproteins as a peroxide (as in Eq. 23-45). For this reason no additional oxygen is needed to complete the reaction when Ca^{2+} acts to alter the conformation of the protein.[675–676a] The structure of a photoactive intermediate from the coelenterazine-containing protein obelin (from *Obelia longissima*), however, shows only one oxygen atom attached to C2 (Fig. 23-51)[676a] Although coelenterazine is utilized by many cnidarians they apparently cannot synthesize the compound but must obtain it through their diet. The source of biosynthesis is unknown.[676b] Some dinoflagellates emit light from a 137-kDa luciferin that contains three homologous domains each of which binds a molecule of a tetrapyrrole.[676c] From its structure the latter appears to have arisen from chlorophyll (Fig. 23-20), whose ring has been opened to give a structure somewhat similar to that of phytochrome (Fig. 23-23).[676d]

The first step in the formation of light in the firefly is a reaction with ATP to form luciferyl adenylate (Eq. 23-46, step *a*).[676e] The proton on the carbon may then be removed making use of the electron accepting properties of the adjacent ring system and carbonyl group before addition of the O_2. The reactions should be compared to those catalyzed by oxygenases, e.g., Eq. 18-42. The large 62-kDa firefly luciferase has a

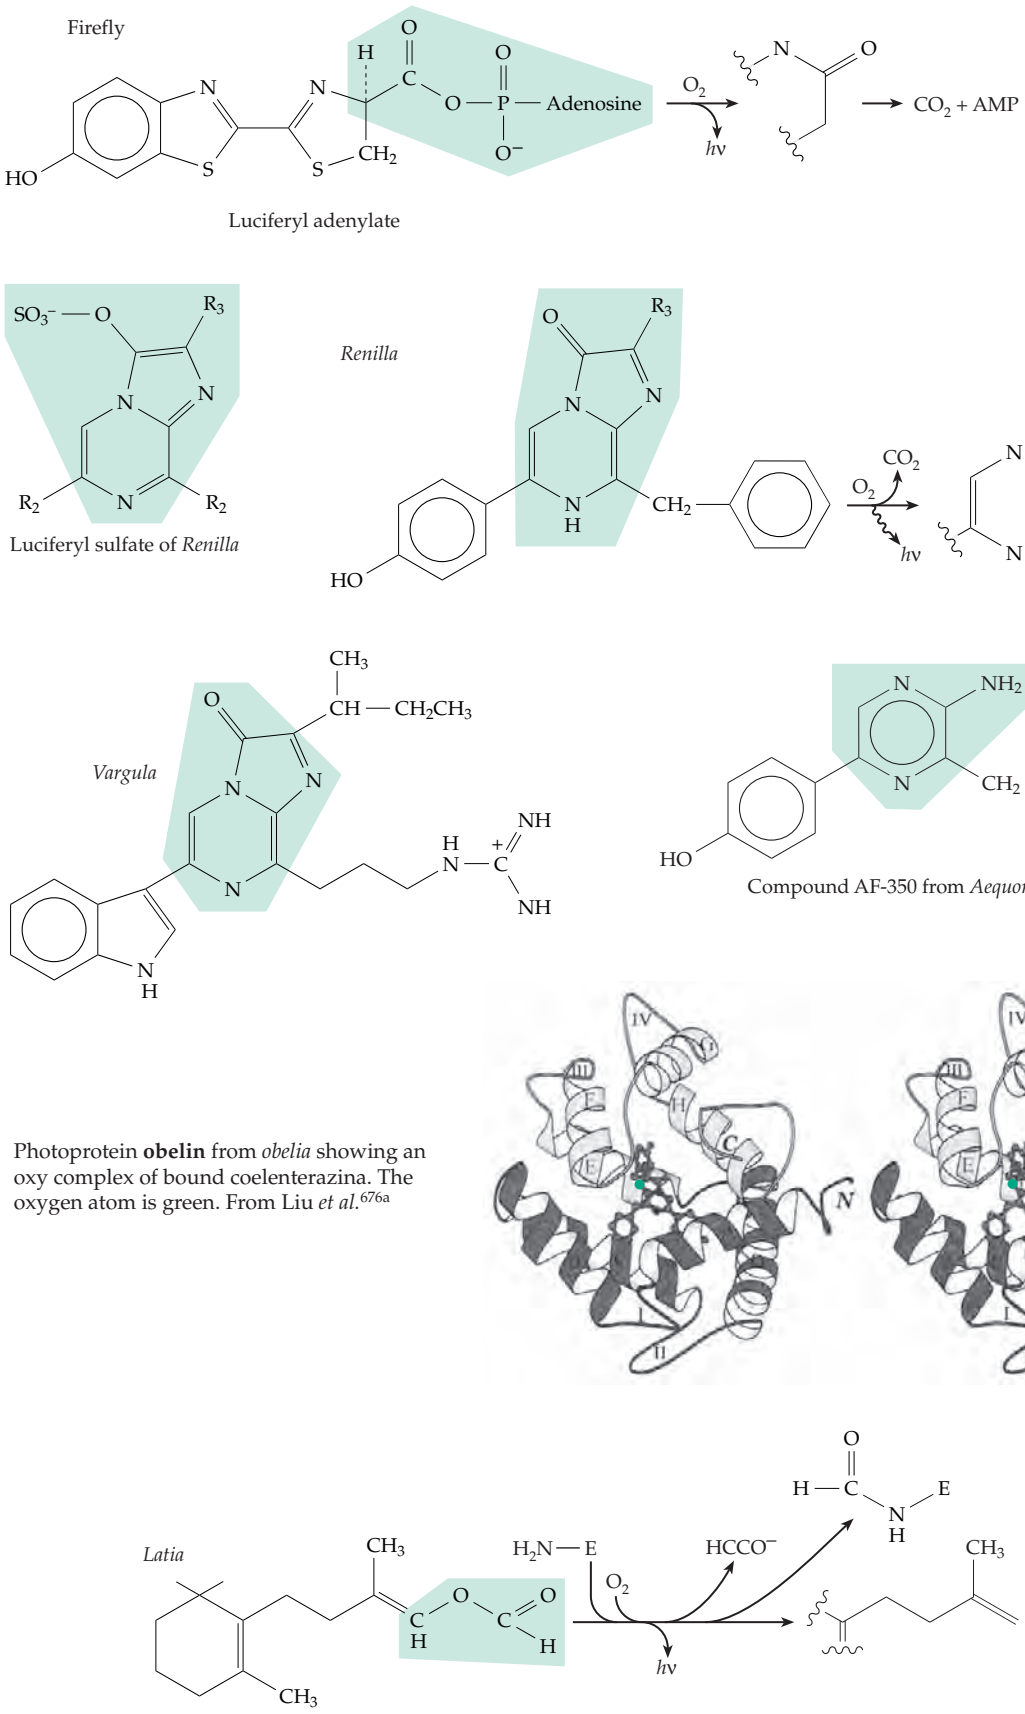


Figure 23-51 Structures of luciferins from several luminous organisms. The forms shown are the "activated" molecules ready to react with O_2. However, compound AF-350 is a breakdown product of the Ca^{2+}-activated luminous protein aequorin.

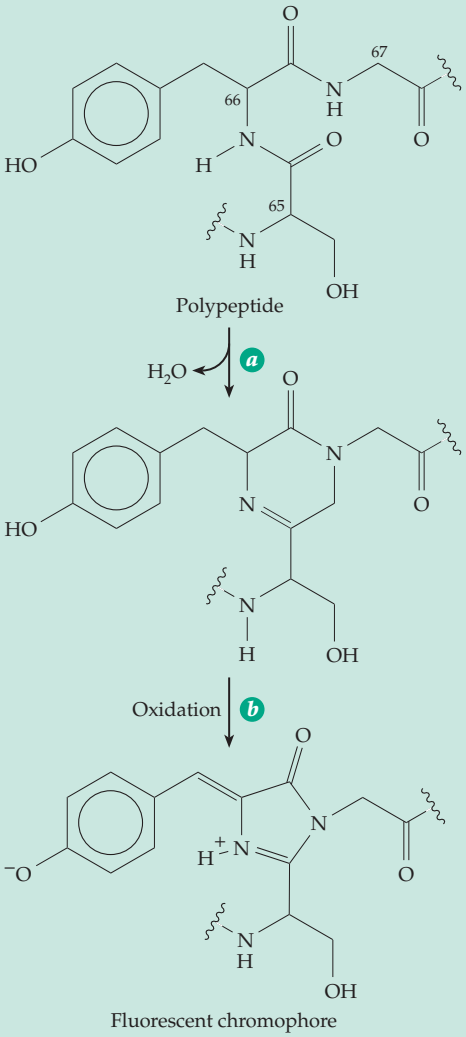
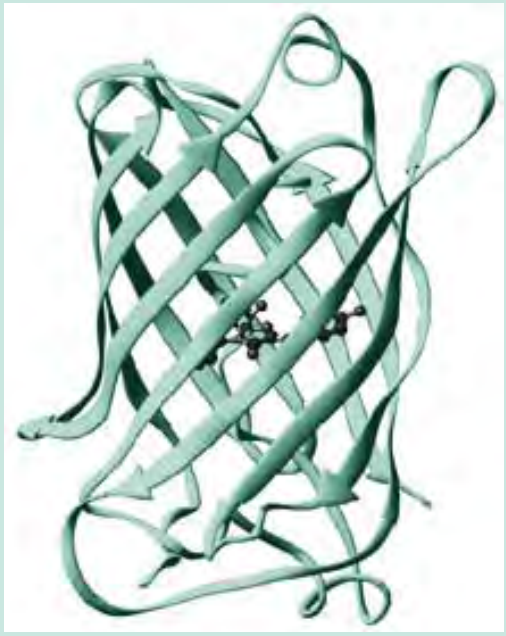
BOX 23-A THE GREEN FLUORESCENT PROTEIN AND OTHER LIGHT-EMITTING ANTENNAS

The Ca^{2+} -dependent luminescence of the jellyfish *Aquorea*, discussed in the main text, consists of blue light with a maximum intensity at 470 nm. However, the living organism has a more brilliant green luminescence. The excitation energy is transferred in a nonradiationless process to a green fluorescent protein with absorption maxima at 395 and 475 nm and an emission maximum for fluorescence at 508 nm.[a–c] A similar protein is used by *Renilla*.[d] The 238-residue green fluorescent protein (**GFP**) has a compact three-dimensional structure, an 11-stranded antiparallel β barrel with helices at one end and longer loops at the other, a "**β can**." The chromophore lies in the center of the cylinder. Numerous mutant forms have been made but only 15 residues in the terminal regions could be deleted without loss of fluorescence.[e]

The chromophore of GFP is formed spontaneously from -Ser-Tyr-Gly, residues 65–67 of the protein.[a,f,g] The entire protein has been synthesized chemically and forms the fluorescent chromophore just as in the protein produced biologically.[h] The reaction is autocatalytic, requiring only O_2 as the oxidant. Although in the living organism it accepts energy from the aqueorin chromophore a near ultraviolet lamp will elicit the fluorescence in the laboratory.





Ribbon drawing of the 238-residue green fluorescent protein showing the embedded chromophore as a ball-and-stick structure.[i] Courtesy of S. James Remington.

The green fluorescent protein is used widely in molecular biology as a fluorescent tag. Its rugged chemical nature, resistance to degradation by proteases and ability to form the chromophore autocatalytically from its own amino acids have permitted many applications. The entire GFP can be attached covalently to numerous cell components. Its gene can be spliced into the genome of an organism to form green-glowing worms, flies, and plants. Put behind a suitable promoter the fluorescent protein may be synthesized or not depending upon the control mechanism of a particular promoter (Chapter 28).[c,j–m]

The phenolic group of the GFP chromophore is apparently dissociated in the form absorbing at 395 nm and is in a tautomeric equilibrium with the other species. However, some histidine-containing replacement mutants have pH-dependent spectral changes in which the dipolar ionic form shown above, and absorbing at a longer wavelength, loses

BOX 23-A (continued)

a proton to form the anion. Observation of the excitation spectra for fluorescence of such mutant proteins within cells provides a new method for measuring the internal pH of cells and their organelles.[n–q] Some mutants emit blue or yellow light.[r,s] Two different color mutants have been fused with a molecule of calmodulin in such a way that the Ca^{2+}-induced conformational change in calmodulin allows fluorescence resonance energy transfer (FRET) between the two fluorophores. This provides a new type of calcium ion indicator.[s–u] A structurally similar red fluorescent protein, produced by a coral, extends the range of colors available as biological markers and may be useful in applications based on resonance energy transfer.[v,w,x]

Bioluminescent bacteria of the genus *Photobacterium* produce large amounts of a highly fluorescent 189-residue **lumazine protein** which contains bound 6,7-dimethyl-8-ribityllumazine (see Fig. 25-20).[y,z] Like the green fluorescent protein, it serves as a secondary light emitter receiving its energy by transfer from the flavin primary emitter. Its presence shifts the light-emission from the 495 nm of the luciferase to as low as 470 nm. *Vibrio fischeri* synthesizes a **yellow fluorescent protein** with either bound FMN or riboflavin. Its emission is at 542 nm, a longer wavelength than that of the luciferase emission. The value to the bacteria may be the higher quantum yield of fluorescence from the antenna emitter than from the luciferase. The luciferase fluorescence has a lifetime of 10 ns but on addition of the yellow fluorescent protein it is decreased to 0.25 ns with a greatly intensified emission.[u]

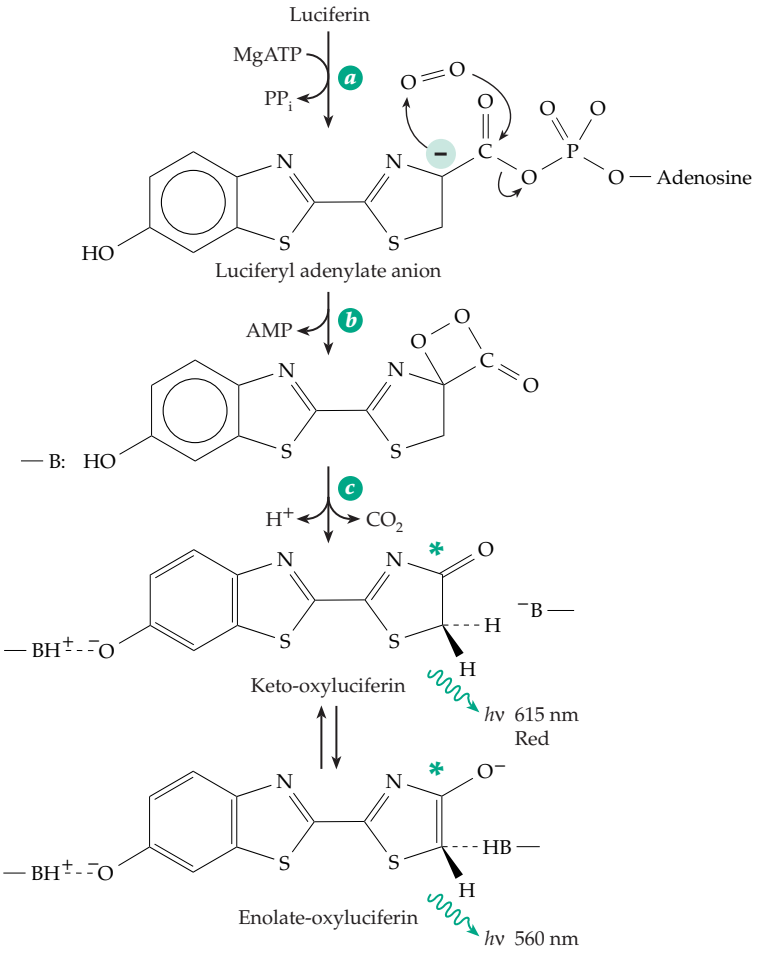
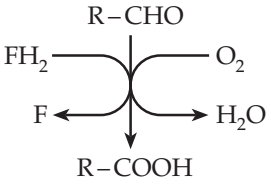
two-domain structure that suggests that domain movement may be essential to bring reactants together.[660] The structure is homologous to those of acyl-CoA ligases and peptide synthetases which share a similarity in step *a*. Formation of the dioxetane intermediate is assisted by the loss of AMP (Eq. 23-46, step *b*). The electronically excited decarboxylation product interacts with groups in the protein. It apparently exists as an anion bound to acidic and basic groups of the protein. An equilibrium between oxo- and enolate forms is thought to regulate the color of the emitted light which can vary from red to yellow and green in various fireflies, other beetles, and larvae.[661,661a,677,677a] Oxyluciferin can be reconverted to luciferin for the next flash.[677b]

A very different light-producing reaction is used by the limpet *Latia*. The luciferin is an unusual terpene derivative (Fig. 23-51) that lacks any chromophore suitable for light emission.[678] Evidently oxidation of this luciferin causes electronic excitation of some other molecule, presumably a "purple protein" which is also needed for luminescence. A complex of luciferin plus the purple protein is believed to react with the luciferase (abbreviated E-NH_2 in Fig. 23-51). It is



(23-46)



(23-47)

thought that the formyl group is released from its enolic ester linkage in the luciferin. A Schiff base of the resulting aldehyde may form with the enzyme and react with oxygen. Yet another type of luciferin is found in dinoflagellates (Fig. 23-51).[679]

Luminescent bacteria all appear to obtain light from a riboflavin-5'-phosphate dependent oxygenase, which converts a long-chain aldehyde (usually *n*-tetradecanal) to a carboxylic acid (Eq. 23-47). Here FH_2 is the riboflavin 5'-*P*, which is thought to be supplied by a flavin reductase.[679a]

Bacterial luciferases are αβ heterodimers with subunit masses of ~40(α) and 35 (β) kDa.[664,680,681] In *Vibrio harveyi* these are encoded by the *lux A* and *lux B* genes. At least five other genes are essential for light production including two regulatory genes.[682,683] The tetradecanal and other long-chain aldehydes are supplied by reduction of the corresponding acyl-CoA (Eq. 23-48). A special thioesterase releases a myristoyl group from an acyl carrier protein, diverting it for luminescence in *V. harveyi*.[684] There is good evidence from ^{13}C NMR and electronic spectra for an enzyme-bound reduced flavin hydroperoxide as in Eq. 15-31. While this hydroperoxide can decompose slowly to flavin and H_2O_2 in the dark, it can also carry out the oxidation of the aldehyde with emission of light.[685,685a] The luminescent emission spectrum resembles the fluorescence spectrum of the 4a –OH adduct (Eq. 23-49), which is probably the light-emitting species.[686–688]

Cells of *Vibrio fischeri*, from the light organ of the fish *Monocentrus japonicus*, emit light only in dense cultures where a chemical inducer identified as N-(2-oxocaproyl)homoserine lactone[689,690] accumulates.

Study Questions

1. Why is the Emerson enhancement effect (i.e., light at 650 nm plus 680 nm gives a higher rate of photosynthesis than either one alone) not observed with photosynthetic bacteria?

2. Agents that uncouple oxidative phosphorylation in mitochondria uncouple photoelectron transport and ATP formation in photosynthesis. Explain.

3. The action spectrum of photosynthesis, which describes the efficiency of photosynthesis as a function of the wavelength of incident light, has a valley around 550 nm. Why?

4. Plants exposed to $C^{18}O_2$ will have the ^{18}O first appear in a) carbohydrate; b) water; c) oxygen gas. (More than one answer may be true.)

5. Plants exposed to $H_2{}^{18}O$ will have the label first appear in a) oxygen gas; b) carbohydrate; c) CO_2. (More than one may be correct.)

6. The general equation describing the photosynthesis of glucose in higher plants is:

$$6\,CO_2 + 6\,H_2O \rightarrow C_6H_{12}O_6$$

   We know that the oxygen gas comes from water, yet the equation shows only six atoms of oxygen in water on the left-hand side vs 12 in oxygen gas on the right. Explain.

7. The fructose bisphosphatase of green plants has an amino acid sequence which is very similar to those of the corresponding enzymes isolated from other sources such as yeast or mammals, except that the plant enzyme has an additional sequence of 20 or so amino acids that has no counterpart in the enzymes found in the other species. What function might this additional sequence have in the plant enzyme?

8. The following substances are either inhibitors or activators of rubisco, the enzyme that catalyzes the condensation of CO_2 with ribulose bisphosphate to yield 3-phosphoglycerate. State whether the substance should be an activator or an inhibitor of the enzyme and succinctly provide the logic supporting your conclusion.
   a) Fructose 1,6-bisphosphate
   b) Visible light
   c) NADPH

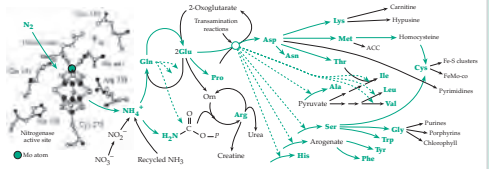
9. The reagent DCMU specifically inhibits electron transfer to plastoquinone in photosystem II. Discuss how the administration of this compound to a suspension of illuminated chloroplasts will affect the production of oxygen, ATP, and NADPH.

10. A chemical reagent is added to a solution of plant chloroplasts which immediately and specifically poisons photosystem II. What is the *short-term* effect of each of the following? Give a one-sentence defense for your conclusion.
    a) Cyclic photophosphorylation
    b) Noncyclic photophosphorylation
    c) Photorespiration
    d) NADPH production

11. If a C_3 and a C_4 plant are placed together in a sealed illuminated box, the C_3 plant withers and dies long before the C_4 plant. Explain.

12. What tricarboxylic acid cycle enzyme is analogous to the malate enzyme of bundle-sheath cells? What is the mechanism of the reaction?

13. There are two different forms of glyceraldehyde-3-phosphate dehydrogenase in higher plant cells.
    a) In which cell compartment is each one found?
    b) What are the reactions catalyzed by these two isozymes?
    c) Why are there two forms?



The air provides an abundant source of nitrogen for living organisms. Nitrogenase present in specialized bacteria utilizes the molybdenum- and iron-containing FeMo-co to reduce N_2 to two molecules of NH_3 (or NH_4^+). NH_3 is incorporated into the side chain of glutamine and much is transferred to the 5-carbon skeleton of 2-oxoglutarate to form glutamate. Nitrogen from glutamate and glutamine moves into the other amino acids via action of transaminases and glutamine amidotransferases. Thousands of compounds, a few of which are indicated here, are formed. (The 20 amino acid constituents of proteins are shown in green.) NH_3 from decaying materials is recycled, often after oxidation to nitrite or nitrate. Nitrates may also be formed by lightening and NH_3 industrially by catalytic reductions of N_2 by H_2 at high temperature and pressure (the Haber process).

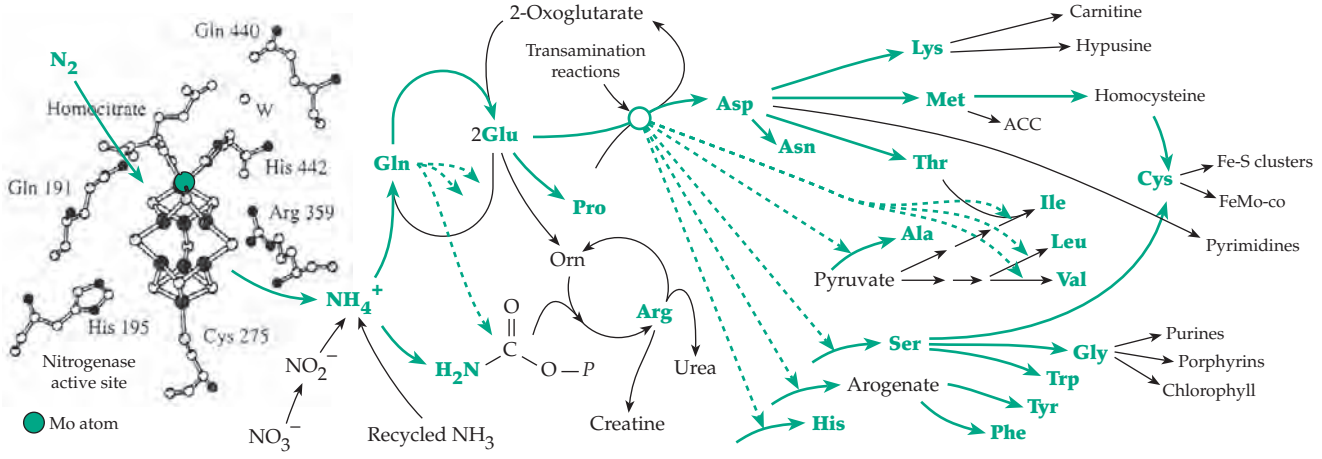
The Metabolism of Nitrogen and Amino Acids

24



Because it is found in so many compounds and can exist in several oxidation states, nitrogen has a complex metabolism. The inorganic forms of nitrogen found in our surroundings range from the highly oxidized nitrate ion, in which N has an oxidation state of +5, to ammonia, in which the oxidation state is −3. Living cells both reduce and oxidize these inorganic forms. The organic forms of nitrogen are most often derived by incorporation of **ammonium ions** into amino groups or amide groups. Once it has been incorporated into an organic compound, nitrogen can be transferred into many other carbon compounds. Certain compounds including glutamic acid, aspartic acid, glutamine, asparagine, and carbamoyl phosphate are especially active in these transfer reactions. They constitute a **nitrogen pool** from which nitrogen can be withdrawn and to which it can be returned.

In addition to the pathways for synthesis and degradation of nitrogenous substances, many organisms have specialized metabolism for incorporation of excess nitrogen into relatively nontoxic excretion products. All of these aspects of nitrogen metabolism will be dealt with in this and the following chapter. We will look first at the reactions by which organic nitrogen compounds are formed from inorganic compounds, then at the reactions of the nitrogen pool. After that we will examine the specific reactions of synthesis and catabolism of individual nitrogenous compounds.

A. Fixation of N_2 and the Nitrogen Cycle

Most of the nitrogen of the biosphere exists as the unreactive N_2, which makes up 80% of the molecules of air. The "fixation" of N_2 occurs principally by the action of a group of bacteria known as **diazotrophs** and to a lesser extent by lightning, which forms oxides of nitrogen and eventually nitrate and nitrite. Human beings also contribute a smaller but significant share through production of chemical fertilizer by the Haber process. These reactions are an important part of the **nitrogen cycle**.[1,2] Quantitatively even more important are the biochemical processes of **nitrification**, by which ammonium ions from decaying organic materials are oxidized to NO_2^- and NO_3^- by soil bacteria (Fig. 24-1), and reactions of reduction and **assimilation** of nitrate and nitrite by bacteria, fungi, and green plants. Another reductive process catalyzed by **denitrifying bacteria** returns N_2 to the atmosphere (Fig. 24-1).

1. Reduction of Elemental Nitrogen

One of the most remarkable reactions of nitrogen metabolism is the conversion of dinitrogen (N_2) to ammonia. It was estimated that in 1974 this biological nitrogen fixation added 17×10^{10} kg of nitrogen to the earth (compared with 4×10^{10} kg fixed by chemical reactions).[3] The quantitative significance can be more easily appreciated by the realization that one square meter of land planted to nodulated legumes such as soybeans can fix 10–30 g of nitrogen per year.

Fixation of N_2 by *Clostridium pasteurianum* and a few other species was recognized by Winogradsky[4] in 1893. Subsequent nutritional studies indicated that both iron and molybdenum were required for the process. Inhibition by CO and N_2O was observed. While ammonia was the suggested product, the possibility remained that more oxidized compounds such

as hydroxylamine were the ones first incorporated into organic substances. When cell-free preparations capable of fixing nitrogen were obtained in 1960 rapid progress became possible.[5] It was discovered that nitrogen-fixing bacteria are invariably able to reduce acetylene to ethylene, a catalytic ability that goes hand in hand with the ability to reduce N_2. A simple, sensitive **acetylene reduction test** permits easy measurement of the nitrogen-fixing potential of cells.

Application of this test revealed that nitrogen fixation is not restricted to a few species, but is a widespread ability of many prokaryotes. Most studied are *Azotobacter vinelandii*, Winogradsky's *C. pasteurianum*, *Klebsiella pneumoniae* (a close relative of *E. coli*), and several species of *Rhizobium*, the symbiotic bacterium of root nodules of legumes. The latter deserves special attention. Although some free-living rhizobia reduce N_2, the reaction usually takes place only in nodules developed by infected roots. Within these nodules the bacteria degenerate into **bacteroids**; and the special hemoglobin **leghemoglobin**,[6,7] whose sequence is specified by a plant gene,[8] is synthesized.

Legumes are not the only plants with nitrogen-fixing symbionts.[9] Some other angiosperms are hosts to nitrogen-fixing actinomycetes and some gymnosperms contain nitrogen-fixing blue-green algae. Leaf nodules of certain plants infected with *Klebsiella* fix nitrogen. While the nutritional significance is uncertain, nitrogen-fixing strains of *Klebsiella* have also been found in the intestinal tracts of humans in New Guinea. Of the free-living nitrogen-fixing organisms, cyanobacteria appear to be of most importance quantitatively. For example, in rice paddy fields cyanobacteria may fix from 2.4 to 10 g of nitrogen per square meter per year. Cyanobacteria in the oceans fix enormous amounts of nitrogen.[9a]

2. Nitrogenases

Cell-free nitrogenases have been isolated from a number of organisms. These enzymes all share the property of being inactivated by oxygen, a fact that impeded early work. Apparently nitrogen fixation occurs in anaerobic regions of cells. Leghemoglobin may protect the nitrogen-fixing enzymes in root nodules from oxygen. It probably also functions to deliver O_2 by facilitated diffusion to the aerobic mitochondria of the bacteroids at a stable, low partial pressure.[6,10] Some bacteria utilize protective proteins to shield the nitrogenase molecules when the O_2 pressure is too high.[10a]

Nitrogenases catalyze the six-electron reduction of N_2 to ammonia (Eq. 24-1) and are also able to reduce

$$N_2 + 6\,H^+ + 6\,e^- \rightarrow 2\,NH_3 \qquad (24\text{-}1)$$

many other compounds. For example, the reduction of acetylene to ethylene (Eq. 24-2) is a two-electron process. Azide is reduced to N_2 and NH_4^+ in another two-electron reduction (Eq. 24-3). Cyanide ions yield methane and ammonia (Eq. 24-4).[11] Alkyl nitriles as well as N_2O and carbonyl sulfide (COS) are also reduced. Carbon dioxide is reduced slowly to CO[12], and nitrogenases invariably catalyze reduction of protons to H_2 (Eq. 24-5).

$$HC{\equiv}CH + 2\,H^+ + 2\,e^- \rightarrow H_2C{=}CH_2 \qquad (24\text{-}2)$$

$$N{=}N{=}N^- + 4\,H^+ + 2\,e^- \rightarrow N_2 + NH_4^+ \qquad (24\text{-}3)$$

$$^-C{\equiv}N + 8\,H^+ + 6\,e^- \rightarrow CH_4 + NH_4^+ \qquad (24\text{-}4)$$

$$2\,H^+ + 2\,e^- \rightarrow H_2 \qquad (24\text{-}5)$$

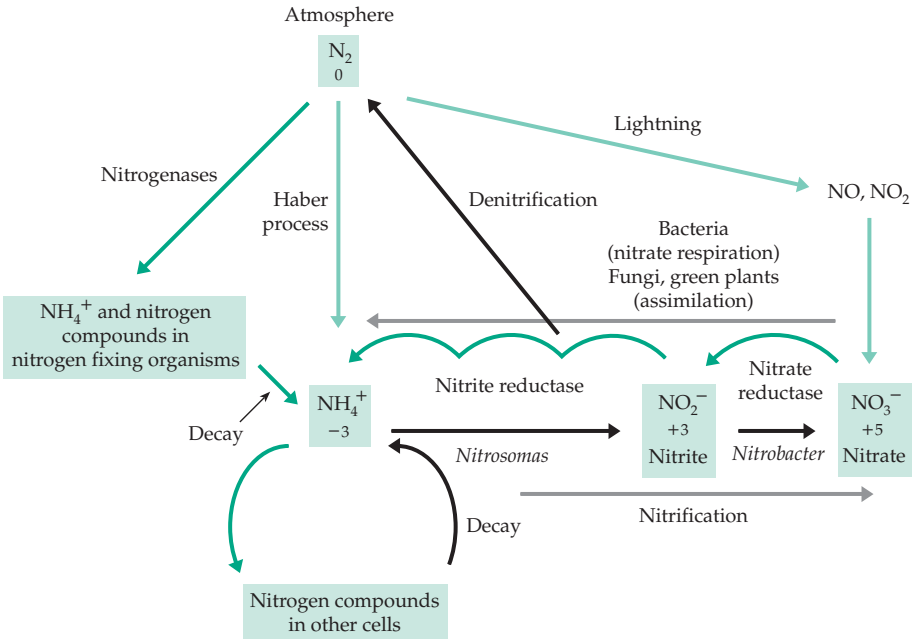


Figure 24-1 The nitrogen cycle. Conversion of N_2 (oxidation state 0) to NH_4^+ by nitrogen-fixing bacteria, assimilation of NH_4^+ by other organisms, decay of organic matter, oxidation of NH_4^+ by the nitrifying bacteria *Nitrosomas* and *Nitrobacter*, reduction of NO_3^- and NO_2^- back to NH_4^+, and release of nitrogen as N_2 by denitrifying bacteria are all part of this complex cycle.[1]

In early experiments it was found that sodium pyruvate was required for fixation of N_2 in cell-free extracts, and that large amounts of CO_2 and H_2 accumulated. Investigation showed that cleavage of pyruvate supplies cells with two important products: ATP and reduced ferredoxin. Pyruvate can be replaced by a mixture of ATP plus Mg^{2+} and reduced ferredoxin (Fd_{red}). Furthermore, the nonbiological reductant dithionite ($S_2O_4^{2-}$) can replace the reduced ferredoxin. Since ADP is inhibitory to the nitrogenase system, it is best in laboratory studies to supply ATP from an ATP-generating system such as a mixture of creatine phosphate, creatine kinase, and a small amount of ADP (Eqs. 6-65, 6-67).

The commonest type of nitrogenase can be separated easily into two components (Fig. 24-2). One of these, the **iron protein** (dinitrogenase reductase, azoferredoxin, or component II), is an extremely oxygen-sensitive iron-sulfur protein. It consists of two identical ~32-kDa peptide chains; those of *A. vinlandii* each contain 189 amino acid residues. The three-dimensional structure of the dimeric protein[13–16] shows that each subunit forms a nucleotide-binding domain with an ATP-binding site. About 2 nm away from this site is *a single Fe_4S_4 cluster which is shared symmetrically by the two subunits of the protein*. Each subunit contributes two thiolate groups from Cys 97 and Cys 132 as well as three N–H--S hydrogen bonds from NH groups at helix ends.[13]

The other component, the **molybdenum–iron protein** (dinitrogenase, molybdoferredoxin, or component I), contains both iron and molybdenum as well as labile sulfide. It is a mixed ($\alpha_2\beta_2$) tetramer of ~240-kDa mass and an analytical metal ion composition ~$Mo_2Fe_{30}S_{26}$. However, the X-ray structure[16–19a] suggests the composition $Mo_2Fe_{34}S_{36}$. The MoFe protein is a symmetric molecule in which each αβ subunit contains two types of complex metal clusters. The active sites for N_2 reduction, which are embedded in the α subunits, contain the **FeMo-coenzyme** molecules, each with the metal composition $MoFe_7S_9$ and also containing a molecule of **homocitrate**.[20–22a] The other clusters, known as **P-clusters**, are shared between the α and β subunits, which for *A. vinlandii* contain 491 and 522

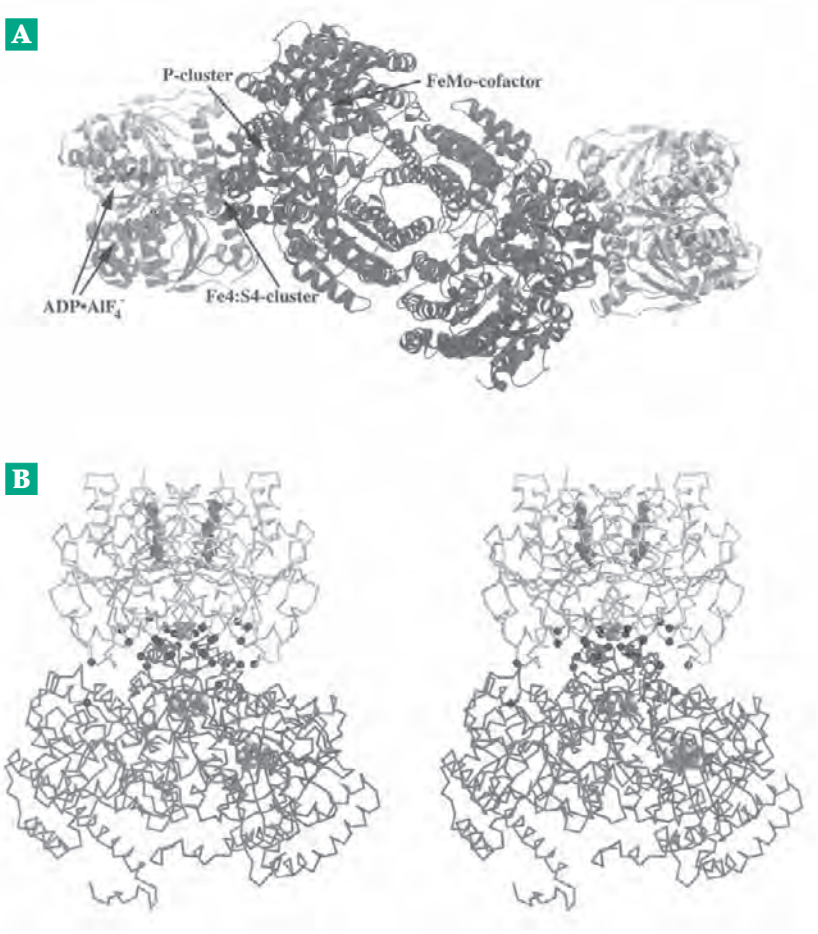

Figure 24-2 (A) Ribbon drawing of the three-dimensional structure of the nitrogenase from *Azotobacter vinlandii* viewed down the twofold axis of the molecule. The αβ subunits of the MoFe-protein are in the center while the Fe-protein subunits are at the outer ends. The Fe_4S_4 cluster of the Fe-protein and the FeMo-co and P-cluster of the MoFe-protein are marked for the left-hand complex. The site of binding of ATP is identified by the bound ADP•AlF_4^- complex. (B) Stereoscopic view of one complete half of the nitrogenase complex at a 90° angle to the view in (A). The Fe-protein is at the top, and the MoFe-protein is below. The ADP•AlF_4^- complex is visible in the two symmetrically located binding sites of the Fe-protein. The shared Fe_4S_4 cluster is in the center above the P-cluster. The small black spheres mark α-carbons of residues that interact in forming the complex of Fe-protein and MoFe-proteins. When the Fe_4S_4 cluster accepts one electron from a molecule of ferredoxin or flavodoxin, the Fe-protein binds to the MoFe-protein and donates an electron to one of the two nearby P-clusters (one of which is in each of the αβ subunits). At the same time both of the molecules of ATP bound to the Fe-protein are hydrolyzed. The oxidized Fe-protein then dissociates from the complex and is replaced by another reduced Fe-protein–ATP complex. The net result is that each electron is "pumped" from the Fe_4S_4 cluster of the Fe-protein into a P-cluster of one of the αβ units of the MoFe-protein. Electrons then move from the P-clusters into the FeMo-coenzyme. From Schindelin *et al.*[19] Courtesy of Douglas C. Rees.

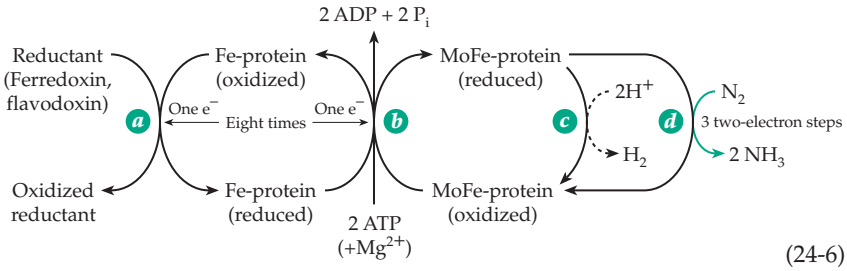
amino acid residues, respectively. Each P-cluster is actually a *joined pair* of cubane-type clusters, one Fe_4S_4 and one Fe_4S_3 with two bridging cysteine –SH groups and one iron atom bonded to three sulfide sulfur atoms (Fig. 24-3).[17,23] The FeMo-coenzyme can be released from the MoFe-protein by acid denaturation followed by extraction with dimethylformamide.[24] While homocitrate was identified as a component of the isolated coenzyme, the three-dimensional structure of FeMo-co was deduced from X-ray crystallography of the intact molybdenum–iron protein.[14,17,18]



(24-6)

When the Fe-protein is reduced an EPR signal at $g = 1.94$, typical of iron–sulfur proteins (Fig. 16-17), is observed. This signal is altered by interaction with Mg and ATP, whereas ATP has no effect on the complex EPR signals produced upon reduction of MoFd. These are among the observations that led to the concept that the Fe-protein is an electron carrier responsible for reduction of the molybdenum in the MoFe-protein. The Mo(IV) or two atoms of Mo(III) formed in this way could then reduce N_2 in three two-electron steps with formation of Mo(VI) (Eq. 24-6). Three successive two-electron steps are required to completely reduce N_2 to two molecules of ammonia. An unexpected feature of nitrogenase action is that there is inevitably what was once regarded as a side reaction, the reduction of protons to H_2.[25,26] The amount of H_2 formed is variable and may be much greater than that of N_2 reduced. However, at high pressures of N_2 the ratio of H_2 formed to N_2 reduced is 1:1. This led to the suggestion[28] that H_2 formation is not a side reaction but an essential step in preparing the active site for the binding of N_2. Two protons that are bound somewhere on the reduced MoFe-protein could be reduced to H_2 in an obligatory step (Eq. 24-6, step *c*) that would, for example, cause a conformational change required for binding of N_2. If no reducible substrate (N_2, C_2H_2, etc.) is present, H_2 would still be formed slowly. Reducible substrates inhibit H_2 formation. However, addition of N_2 or any other reducible substrate causes an initial "burst" of H_2 to be released. This can be measured readily when a slow substrate such as CN^- is used as the inhibitor. The amount of H_2 released in the burst is stoichiometric with one H_2 per Mo being formed.[26] The overall stoichiometry for reduction of one N_2 becomes:

$$N_2 + 8\ e^- + 8\ H^+ + 16\ MgATP \rightarrow 2\ NH_3 + H_2 + 16\ MgADP + 16\ P_i \quad (24\text{-}7)$$

A second remarkable feature of nitrogenase is a requirement for hydrolysis of MgATP that is coupled to reduction of the MoFe-protein (Eq. 24-6). Two molecules of ATP are hydrolyzed to ADP and inorganic phosphate for each electron transferred. This large ATP requirement seems surprising in view of the fact that reduction of N_2 by reduced ferredoxin (Eq. 24-8) is thermodynamically spontaneous:

$$N_2 + 6\ Fd_{red} + 8\ H^+ \rightarrow 2\ NH_4^+ + 6\ Fd_{ox}^+$$
$$\Delta G'\ (pH\ 7) = -89.3\ kJ\ mol^{-1} \quad (24\text{-}8)$$

However, N_2 is exceedingly unreactive. In the commercial Haber process high pressure and temperature are needed to cause H_2 and N_2 to combine. Evidently cleavage of 16 molecules of ATP must be coupled to the nitrogenase reduction system to overcome the very high activation energy.

Not only are two molecules of ATP hydrolyzed to pump each electron, but the Fe-protein must receive electrons from a powerful (low $E^{\circ\prime}$) reductant such as reduced ferredoxin, reduced flavodoxin, or dithionite. *Klebsiella pneumoniae* contains a **pyruvate:flavodoxin oxidoreductase** (Eq. 15-35) that reduces either flavodoxin or ferredoxin to provide the low potential electron donor.[29,30] In some bacteria, e.g., the strictly aerobic *Azotobacter*, NADPH is the electron donor for reduction of N_2. The Fe-protein is thought to accept electrons from a chain that includes at least the ordinary bacterial ferredoxin (Fd) and a special one-electron-accepting **azotoflavin,** a flavoprotein that is somewhat larger than the flavodoxins (Chapter 15) and appears to play a specific role in N_2 fixation.[31] In *Clostridium* and *Rhizobium* reduced ferredoxins generated by cleavage of pyruvate reduce nitrogenase directly.[32]

The mechanism of nitrogenase action. The one-electron reduction of the Fe_4S_4 cluster of the Fe-protein (step *a* of Eq. 24-6) initiates the action. This reaction occurs before the Fe-protein forms a complex with the MoFe-protein. Following this initial reduction step the two molecules of ATP required for step *b* of Eq. 24-6 bind to the Fe-protein. One is bound to each subunit of this protein but neither is immediately adjacent to the shared Fe_4S_4 cluster, as can be seen from Fig. 14-3B. The binding to MgATP appears to induce a conformational change that permits the "docking" of the Fe-protein with the MoFe-protein to

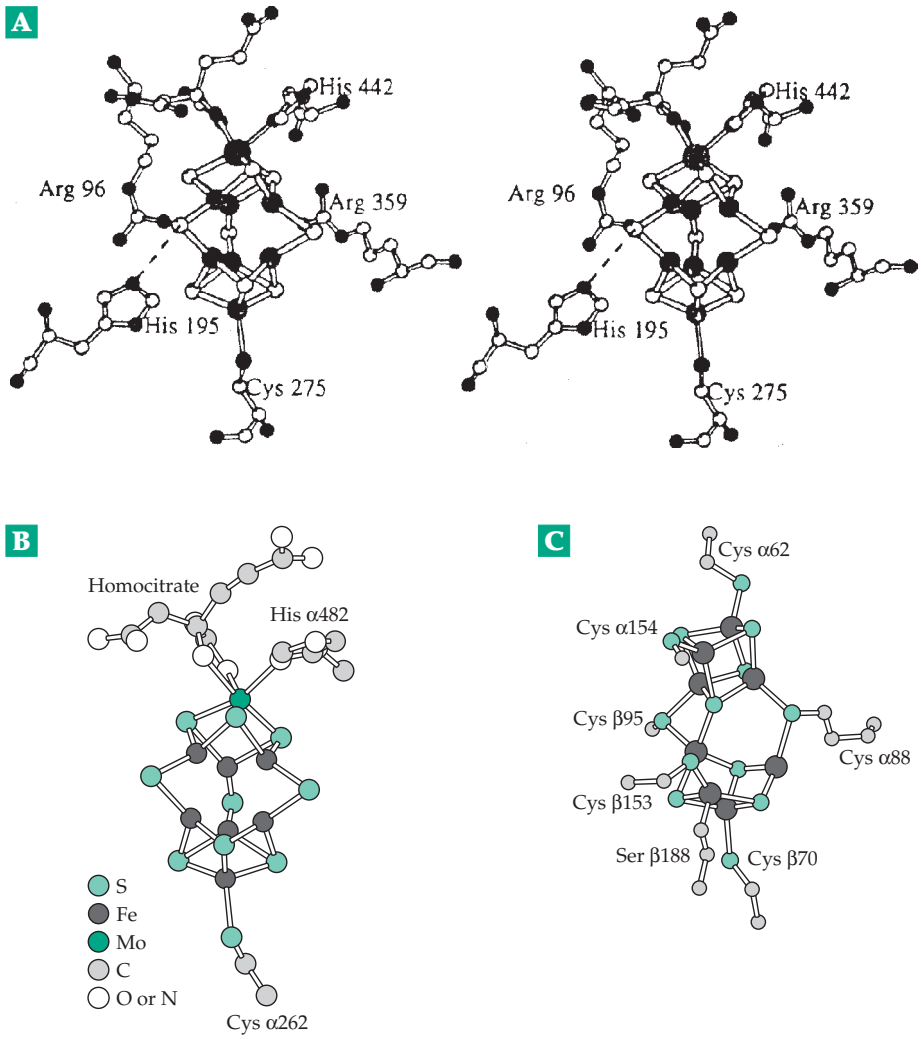


Figure 24-3 Structures of the metal-sulfide clusters of the MoFe-protein. (A) Stereoscopic view of the FeMo-co coenzyme with interacting side chains from the MoFe-protein of *A. vinlandii*. After Kim *et al.*[27] (B) FeMo-co with atom labels. From Kim *et al.*[18] (C) The structure of the oxidized form of the P-cluster. From Peters *et al.*[23] Recent studies by Einsle *et al.*[22a] indicate that the cluster probably also contains a nitrogen atom that is held within the cluster by coordination to six of the iron atoms.

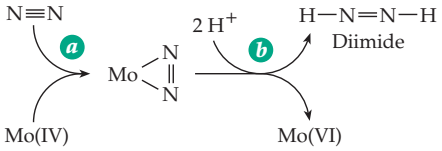
form the complex in which the electron transfer of step *b* (Eq. 24-6) occurs. Abundant evidence indicates that electron transfer does not occur without the binding of MgATP.[33–35d] The electron transfer is coupled to the hydrolysis of the ATP, but the two reactions appear to be consecutive events. In a deletion mutant of the Fe-protein (lacking Leu 127) the hydrolysis of ATP does not occur, but the complex between Fe-protein and MoFe-protein is formed and electron transfer to the MoFe-protein takes place.[36–37a] The binding of the MgATP causes the midpoint redox potential to drop from −0.42 V to −0.62 V, assisting the transfer.[38] X-ray crystallographic studies reveal a distinct conformational change similar to those observed with G-proteins (Chapter 11) and involving movement of the Fe_4S_4 center into a better position for electron transfer.[19,38a]

After electron transfer the complex of the two proteins is thought to be tightly bonded when unhydrolyzed ATP is present.[35] This has allowed the direct observation and imaging of the complex at low resolution (~1.5 nm) using rapid synchrotron X-ray scattering measurements.[39] The ATP is hydrolyzed, and the Fe-proton is released from the complex.

Only one electron is transferred to the MoFe-protein in each catalytic cycle of the Fe-protein. Thus, the cycle must be repeated eight times to accomplish the reduction of $N_2 + 2\ H^+$. Where in the MoFe-protein does a transferred electron go? EPR spectroscopic and other experiments with incomplete and catalytically inactive molybdenum coenzyme[40] have provided a clear answer. The electron is transferred first to one of the two P-clusters, both of which are close to the Fe_4S_4 cluster of the Fe-protein. The transfer causes an observable change both in the spectroscopic properties and in the three-dimensional structure of the P-cluster.[23,40a] Since protons are needed at the active site for the reduction reactions (the FeMo-coenzyme), it is probable that hydrolysis of ATP in the Fe-protein is accompanied by transport of protons across the interface with the MoFe-protein. The electron transfer from the P-cluster on to the FeMo-co center would be assisted by a protic force resulting from ATP cleavage.

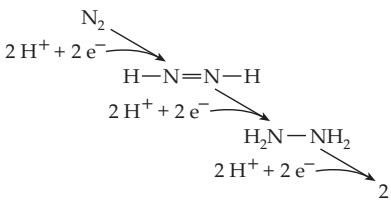
With defective FeMo-co (apparently lacking homocitrate) no reduction of N_2, acetylene, or protons is observed.[40] If intact FeMo-co is present, reduction of the cofactor can be observed. An $s = 3/2$ EPR signal arising from the Mo is seen,[40] and EXAFS measurements reveal decreased Mo–Fe distances as the coenzyme is reduced.[41] The molybdenum is probably present as Mo(VI) in the oxidized state of nitrogenase,[42] but after reduction it isn't clear whether it is Mo(III) or Mo(IV). Isolated FeMo-co exists in three identified oxidation states related by $E^{\circ\prime}$ values of −0.17 and −0.465 V.[43] Only the middle state is EPR-active, but it is the most reduced state that is involved in N_2 reduction.[42,43] With its P-cluster and FeMo-co center each αβ unit of the MoFe-protein could store several electrons. Two or more might be stored in a P-cluster, and Mo(VI) could, in principle, accept three electrons to form Mo(III). However, it is a little hard to imagine storage of the eight electrons needed to reduce both N_2 and H_2 (Eq. 24-8). The reduction of N_2 may begin before all eight electrons have been transferred into the MoFe-protein.

Another uncertainty lies in the mode of binding of N_2 and other substrates. Does N_2 bind end-on to Mo, does it slide between Fe atoms within the coenzyme, or does it bind in some other way? While N_2 is unreactive, it forms nitrides with metals and complexes with some metal chelates. These complexes are generally of an end-on nature, e.g., N≡N–Fe. Stiefel suggested that N_2 first forms a complex of this type with an iron atom of the MoFe-protein.[44] Then an atom of Mo(IV) could donate two electrons to the N_2 (Eq. 24-9, step *a*) to form a complex of N_2 and Mo(VI). Addition of two protons (Eq. 24-9, step *b*) would yield a molecule of **diimide**, which would stay bound at the



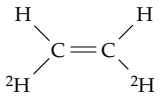
(24-9)

iron site while the molybdenum underwent another round of reduction. The diimide could be reduced to hydrazine and finally to ammonia (Eq. 24-10):



(24-10)

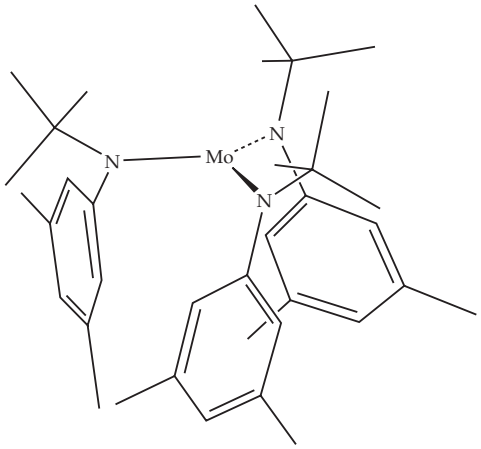
Mo(VI) attracts electrons sufficiently strongly that protons bound to surrounding ligands, such as H_2O, tend to dissociate completely. Thus, the molybdate ion MoO_4^{2-} is not protonated. The same would be true of nitrogenous ligands of a protein that might be coordinated with the bound molybdenum. On the other hand, reduction to Mo(IV) would tend to favor protonation of ligands such as the His 442 imidazole seen in Fig. 24-3A. Concurrently with the electron transfer from molybdenum to N_2 these protons could be transferred to the N_2 molecule (Eq. 24-10). The fact that strictly *cis*-dideuteroethylene is formed from acetylene in the presence of ^2H_2O is in accord with this idea.



However, looking at the FeMo-co molecule and the crowded surroundings of the Mo atom it may be more likely that reduction of N_2 occurs while it is bound to iron. Theoretical calculations as well as experimental data support this possibility.[44a] Recent crystallographic studies at a resolution of 0.12 nm revealed the presence of an atom, probably N, coordinated to six Fe atoms of FeMo-Co. This suggets, as previously proposed by Thorneley and Lowe,[44b,c] that a nitride ion (N_3^-) may be an intermediate in the formation of N_2.

Many mutant forms of nitrogenase have been investigated. Substitutions of His 195, Lys 191, and Gly 69 of the α chain affect reactions with various substrates.[45–45d] For example, the mutant obtained by substitution of His 195, whose imidazole forms an N–H--S hydrogen bond to a central bridging sulfide atom of FeMo-co (Fig. 24-3A), with glutamine (H195Q mutant) reduces N_2 only very slowly.[45] However, it still reduces both acetylene and protons.[27,44a,45b] Thus, it may be that different modes of substrate binding are needed for the individual steps of Eq. 24-10.

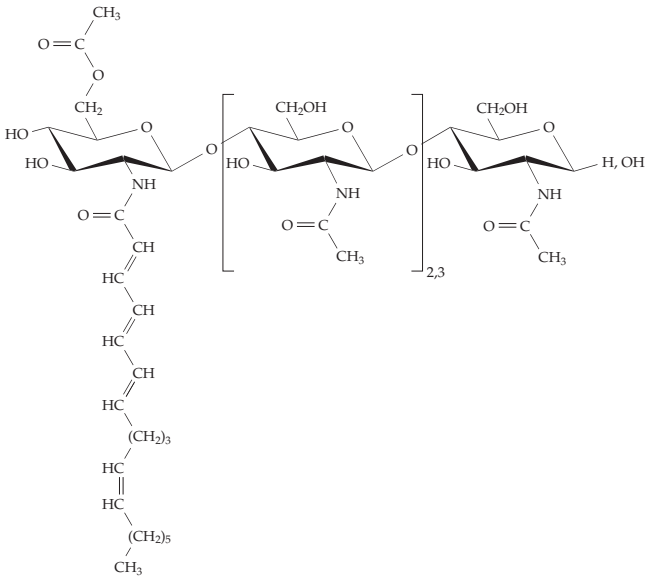
Because of the practical significance to agriculture there is interest in devising better nonenzymatic processes for fixing nitrogen using nitrogenase models that mimic the natural biological reaction.[42,46–49a] One interesting catalyst is the following molybdenum complex Mo(III)$(NRAr)_3$ where R = $C(C_2H_3)_2CH_3$ and Ar = 3,5-dimethylphenyl.[47,50,51]



Many other synthetic complexes have been studied including cubic $MoFe_3S_4$ clusters.[46] However, no exact chemical model for the FeMo-co coenzyme has been developed, and the rates of reaction for all of the model reactions are much slower than those of nitrogenases.

Nitrogen fixation genes. At least 17 genes needed for nitrogen fixation are present in the 23-kb *nif* region of the *Klebsiella* chromosome[52,53] (Fig. 24-4). A similar gene cluster in *A. vinlandii*[54] contains five polygenic transcriptional units and one monogenic unit. The nitrogenase structural genes are *nifK, D*, and *H* as is indicated in Fig. 24-4. The *nifF* and *J* genes encode associated electron-transport proteins. *NifM* is needed to activate the Fe-protein in an unknown fashion. *NifS* encodes a cysteine desulfhydrase needed for assembly of Fe–S clusters in the nitrogenase and the nifU and nifY proteins assist the assembly.[54a,b] The chaperone GroEL is also required.[54c] *Nif Q, B, V, X, N, E_1*, and *H* are needed for synthesis of FeMo-co and for its incorporation into the MoFe-protein.[55,55a] *NifA* is an activator gene for the whole cluster including the *nifL* gene product, which is altered by the presence of O_2 or of glutamine. Accumulation of the latter in cells (see Section B,2) strongly represses transcription of the nitrogenase genes.

Legume nodules and cyanobacterial heterocysts. Nitrogen fixation requires an anaerobic environment. Free-living bacteria fix nitrogen only when anaerobic. However, Rhizobia produce their own anaerobic environment by symbiotic association with the roots of legumes.[10,57–59] Formation of root nodules is a genetically determined process, several nodulation (*nod*) genes of the bacterium being required along with an unknown number of plant genes.[57,58] Initiation of nodulation results from a two-way molecular conversation between root hairs of the plant and bacterial cells.[60,61] The roots secrete **flavonoid compounds** (Chapter 21) which are recognized by bacterial sensors and induce transcription of the *nod* genes. Several of these genes encode enzymes required for synthesis of **Nod factors**,[62,63] small β-linked *N*-acetyl-D-glucosamine oligosaccharides containing 3–5 sugar residues and an *N*-linked long-chain fatty-acyl substituent at the nonreducing terminus (**lipochitooligosaccharides**). See also Box 20-E. Genes *nodA, B, C* specify enzymes needed for synthesis of the oligosaccharide core present in all Nod factors.



Structure of a Nod factor secreted by *Rhizobium leguminosarum*.[64]

Other Nod genes provide for modifications that restrict infection to specific species of legumes. For example, *nodS* encodes a methyltransferase and *nodU* a carbomoyltransferase.[65] NodH is a sulfotransferase.[66] NodD is a transcriptional activator that binds to DNA and induces the synthesis of the other Nod factors needed to initiate nodulation.[67] When an appropriate Nod factor is recognized, the root hairs on the legume

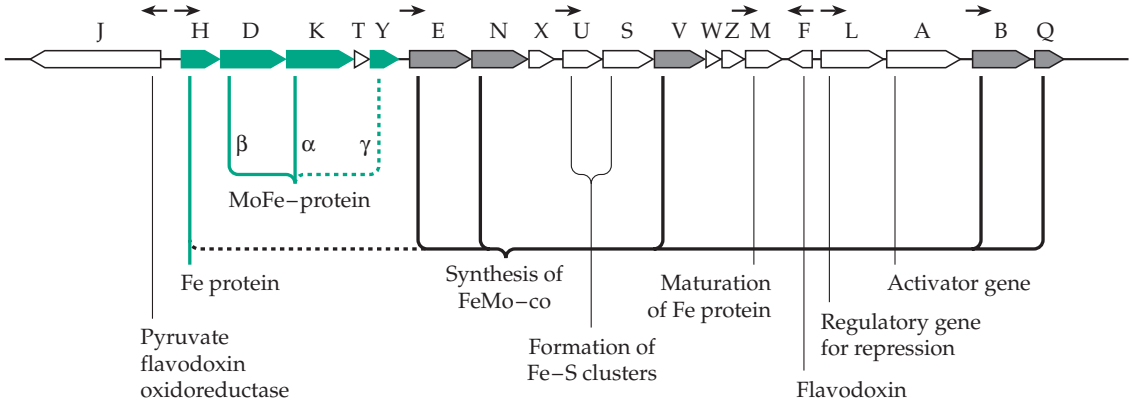


Figure 24-4 Sequence of *nif* genes of *Klebsiella pneumoniae*.[56] These precede the *his* operon directly at the right side. The nitrogenase structural genes are marked with green.

curl around the bacteria to initiate nodulation.[60,61] However, there are other factors. Infecting bacteria must reach a region of low oxygen in the plant. A hemoprotein **FixL** is a sensor kinase that regulates phosphorylation of transcription factor **FixJ**. This two-component system induces transcription of *nifA* (Fig. 24-4) and others.[68–69a] Nitrogen-fixing nodules, which are filled with the bacteroids derived from the infecting bacteria, synthesize leghemoglobin. The polypeptide chain of this protein is encoded by the plant, but its heme may be synthesized by bacteroid enzymes.[10,57] In at least one strain of *Rhizobium* the *nod* genes as well as the *fix* and *nif* genes are all carried on a 536-kb plasmid, which is almost as large as the whole 580-kb genome of *Mycoplasma genitalium* (Table 1-3).[70,71] This arrangement seems to have allowed these bacteria to form an unusually large number of Nod factors and to colonize a wider variety of hosts including a non-leguminous tree.

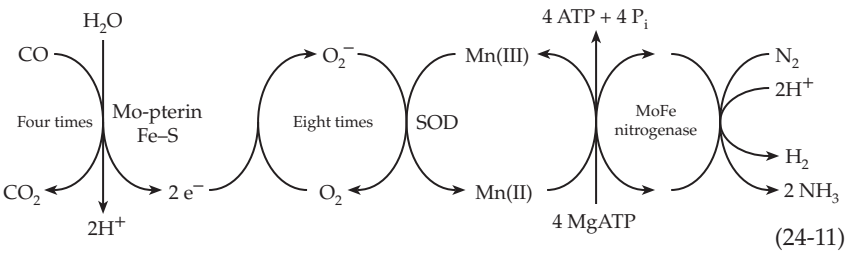
The H_2 that is produced in Eq. 24-6 (step *c*) may be used by bacteroids or by the plant cells. Some nodules evolve H_2, but in others it is utilized by hydrogenases as a source of energy.[57] From Eq. 24-6 it can be seen that up to 1/4 of the ATP utilized can, ideally, be recovered by use of the H_2 in this manner.

In cyanobacteria nitrogen fixation occurs in the **heterocysts**, specialized cells with thickened cell envelopes. They supply NH_4^+ to other cells in the filament of which they are a part. The cell envelopes prevent rapid diffusion of O_2 into the cells but do permit rapid enough entry of N_2 to maintain the observed rate of fixation of N_2.[72] In actinomycetes of the genus *Frankia*, which forms root nodules with woody plants, nitrogen fixation occurs in vesicles that are sheathed by multiple layers of **hopanoid lipids** (see Chapter 22).[73]

Genetic engineering. Because of the high cost of nitrogen fertilizers there is intense interest in improving biological nitrogen fixation. Ideas range from increasing the efficiency of nitrogenase by using fewer molecules of ATP, by limiting excessive evolution of H_2, or transferring the whole *nif* region of a bacterial genome into nonleguminous plants. The last proposal has generated much publicity, but it will probably be difficult because of the need to create an anaerobic environment suitable for nitrogen fixation. A crop plant engineered in this way might not resemble the hoped-for product. It would have an enormous energy requirement for nitrogen fixation, which would have to be met by photosynthesis. At present genetic engineering on *nif* genes to increase efficiency seems most likely to succeed.

Other nitrogenases. Although the well-characterized Mo-containing nitrogenase is responsible for most of their nitrogen fixation, bacteria often have alternative nitrogen fixation systems.[74] *Azotobacter vinlandii* produces three different nitrogenases in response to varying metal compositions in its surroundings.[75–76a] When the molybdenum level is adequate nitrogenase 1 is formed with its FeMo-coenzyme. In a low-molybdenum environment containing vanadium nitrogenase 2 is formed with an FeV-coenzyme.[75–77] If both molybdenum and vanadium are lacking, the bacteria form nitrogenase-3, which has an iron-only FeFe-coenzyme.

An unusual nitrogenase is formed by the chemolithotrophic *Streptomyces thermoautotrophicus*, which obtains energy from reduction of CO_2 or CO by H_2 (Eq. 17-50). These organisms form a MoFe nitrogenase that utilizes a manganese-containing superoxide dismutase to generate superoxide anion radicals. The latter transfer electrons to the MoFe protein in an ATP-dependent process. Electrons for generation of superoxide are formed using another molybdenum enzyme, a CO dehydrogenase containing molybdpterin cytosine dinucleotide (Fig. 16-31) and Fe–S centers.[78] The two systems function together as indicated by Eq. 24-11.



(24-11)

3. Interconversion of Nitrate, Nitrite, and Ammonium Ions

As is indicated in Fig. 24-1, the interconversions of nitrate and nitrite with ammonia and with organic nitrogen compounds are active biological processes. Two genera of nitrifying soil bacteria, which are discussed in Chapter 18, oxidize ammonium ions to nitrate. *Nitrosomas* carries out the six-electron oxidation to nitrite (Eq. 18-17) and *Nitrobacter* the two-electron oxidation of nitrite to nitrate (Eq. 18-18).[79]

The opposite sequence, reduction of nitrate and nitrite ions, provides a major route of acquisition of ammonia for incorporation into cells by bacteria, fungi, and green plants (Fig. 24-1). **Assimilatory** (biosynthetic) **nitrate reductases** catalyze the two-electron reduction of nitrate to nitrite (Eq. 16-61). This is thought to occur at the molybdenum atom of the large ~900-residue highly regulated[79a] molybdopterin-dependent enzyme. In green plants the reductant is

usually NADH while in fungi it is more often NADPH.[80–82] In all cases the cofactors FAD, heme, and molybdopterin are bound to a single polypeptide chain with the molybdopterin domain near the N terminus, and the heme in the middle. The electron-accepting FAD domain is near the C terminus[83–85a] and is thought to transfer the two electrons through the following chain.

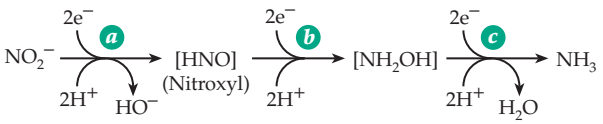
$$\text{NAD(P)H} \rightarrow \text{FAD} \rightarrow \text{Cyt } b \rightarrow \text{Mo-pterin} \rightarrow NO_3^- \qquad (24\text{-}12)$$

Bacterial assimilatory nitrate reductases have similar properties.[86,86a] In addition, many bacteria, including *E. coli*, are able to use nitrate ions as an oxidant for **nitrate respiration** under anaerobic conditions (Chapter 18). The **dissimilatory nitrate reductases** involved also contain molybdenum as well as Fe–S centers.[85] The *E. coli* enzyme receives electrons from reduced quinones in the plasma membrane, passing them through cytochrome *b*, Fe–S centers, and molybdopterin to nitrate. The three-subunit αβγ enzyme contains cytochrome *b* in one subunit, an Fe_3S_4 center as well as three Fe_4S_4 clusters in another, and the molybdenum cofactor in the third.[87] Nitrate reduction to nitrite is also on the pathway of denitrification, which can lead to release of nitrogen as NO, N_2O, and N_2 by the action of **dissimilatory nitrite reductases**. These enzymes[87a] have been discussed in Chapters 16 and 18.

Assimilatory nitrite reductases of plants, fungi, and bacteria carry out the six-electron reduction of nitrite to ammonium ions (Eq. 24-13) using electron donors such as reduced ferredoxins or NADPH.

$$NO_2^- + 6\,e^- + 8\,H^+ \rightarrow NH_4^+ + 2\,H_2O \qquad (24\text{-}13)$$

The enzymes from green plants and fungi are large multifunctional proteins,[80] which may resemble assimilatory sulfite reductases (Fig. 16-19). These contain **siroheme** (Fig. 16-6), which accepts electrons from either reduced ferredoxin (in photosynthetic organisms) or from NADH or NADPH. FAD acts as an intermediate carrier. It seems likely that the nitrite N binds to Fe of the siroheme and remains there during the entire six-electron reduction to NH_3. Nitroxyl (NOH) and hydroxylamine (NH_2OH) may be bound intermediates as is suggested in steps *a*–*c* of Eq. 24-14.



(24-14)

B. Incorporation of NH_3 into Amino Acids and Proteins

Prior to 1935, amino acids were generally regarded as relatively stable nutrient building blocks. That concept was abandoned as a result of studies of the metabolism of $^{15}NH_3$ and of ^{15}N-containing amino acids by Schoenheimer and Rittenberg[88] and more recent studies using ^{13}N by Cooper *et al.*[89,90] These investigations showed that nitrogen could often be shifted rapidly between one carbon skeleton and another. This confirmed proposals put forth earlier by Braunstein, Meister, and others who had pointed out that the C_4 and C_5 amino acids, aspartate and glutamate, which are closely related to the tricarboxylic acid cycle, are able to exchange their amino groups rapidly with those of other amino acids via transamination (Fig. 24-5, step *d*). Since ammonia can be incorporated readily into glutamate (Fig. 24-5, step *a*; see next section), a general means is available for the biosynthesis of amino acids. The citric acid cycle is able to provide any needed amount of 2-oxoglutarate for the synthesis of both glutamate and glutamine.[91–94]

Glutamine, and to a lesser extent asparagine, act as soluble, nontoxic carriers of additional ammonia in the form of their amide groups. An active synthase converts glutamate and ammonia to glutamine (Fig. 24-5, step *d*), and another enzyme transfers the amide nitrogen into aspartate, in an ATP-dependent reaction, to form asparagine (Fig. 24-5, step *e*). The amide nitrogen of glutamine is incorporated in a similar way into a great variety of other biochemical compounds, including carbamoyl phosphate (Fig. 24-5, step *f*; Section C,2), glucosamine (Eq. 20-5), NAD^+, *p*-aminobenzoate,

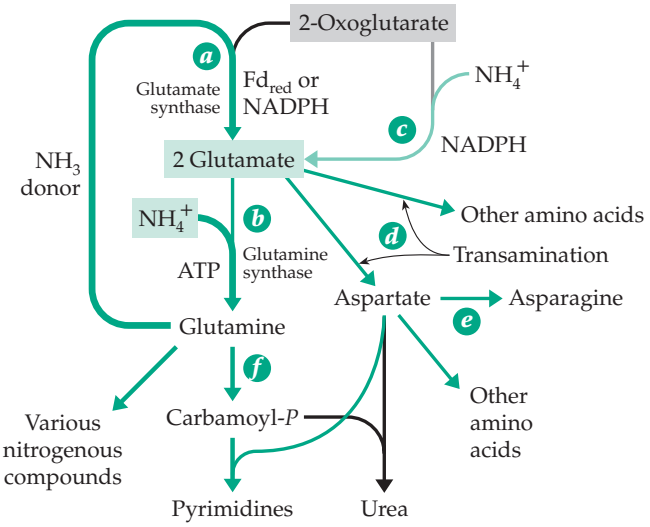


Figure 24-5 Major pathways of incorporation of nitrogen from ammonium ions into organic compounds, traced by green arrows.

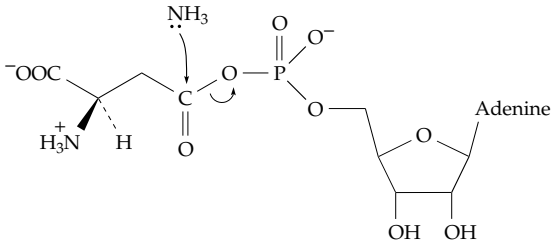
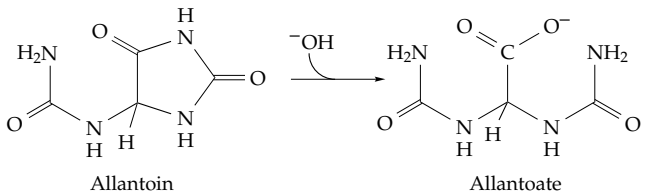
histidine, CTP, and purines (Chapter 25). These reactions are catalyzed by a family of **amidotransferases**,[95–97d] which hydrolyze the glutamine to glutamate and NH_3. The last is entrapped until it reacts with the second substrate. **Asparagine synthetase** apparently first binds ATP and aspartate, which probably react to form β-aspartyl adenylate (β-aspartyl-AMP). Glutamine then binds and is hydrolyzed.[98,98a]



β-Aspartyl adenylate

The liberated NH_3 can attack the β-aspartyl-AMP as indicated in the accompanying diagram to form asparagine. However, it is also possible that NH_3 is transferred via covalently bonded complexes[99] and is never free NH_3. An asparagine synthetase that utilizes free NH_3 as a nitrogen donor is also present in many organisms.

A third mechanism of synthesis, which was only recently recognized, appears to provide the sole source of asparagine for many bacteria.[98b] The asparagine-specific transfer RNA $tRNA^{Asn}$ is "mischarged" with aspartic acid to form Asp-$tRNA^{Asn}$. This compound is then converted to the properly aminoacylated Asn-$tRNA^{Asn}$ by a glutamine-dependent amidotransferase. (The entire ATP-dependent sequence is shown in Eq. 29-6.) The activated asparaginyl group is then transferred from Asn-$tRNA^{Asn}$ into proteins as they are synthesized.



Allantoin Allantoate

(24-15)

Most green plants transport nitrogen from roots to growing shoots as asparagine. However, in peanuts **β-methyleneaspartate** is the major nitrogen carrier,[100] and in some legumes, including soybeans, **allantoin** and **allantoate** (Eq. 24-15) play this role. Allantoin arises from hydrolysis of purines (see Fig. 25-18), which are synthesized in root nodules of nitrogen-fixing plants.[101]

Glutamate, glutamine, and aspartate also play central roles in *removal* of nitrogen from organic compounds.[102] Transamination is reversible and is often the first step in catabolism of excess amino acids. 2-Oxoglutarate is the recipient of the nitrogen, and the glutamate that is formed can be deaminated to form ammonia which can then be incorporated into glutamine. Glutamate can also donate its nitrogen to form aspartate. In the brain glutamate is a major neurotransmitter but is toxic in excess. The astrocyte glial cells take up glutamate from the synaptic clefts between neurons, converting it to glutamine, which is then released into the extracellular space for reuptake by neurons.[103,104] In the animal body both aspartate and glutamine (via carbamoyl phosphate) are precursors of **urea**, the principal nitrogenous excretion product. These relationships are also summarized in Fig. 24-5, and details are provided in later sections.

While reductive amination of glutamate via glutamate synthase appears to be the major pathway for incorporation of nitrogen into amino groups, some direct amination of pyruvate and other 2-oxoacids in reactions analogous to that of glutamate dehydrogenase occurs in bacteria.[105,106] Another bacterial enzyme catalyzes reversible addition of ammonia to fumarate to form aspartate (p. 685).

An initially surprising conclusion drawn from the studies of Schoenheimer and Rittenberg was that proteins within cells are in a continuous steady state of synthesis and degradation. The initial biosynthesis, the processing, oxidative and hydrolytic degradative reactions of peptides, and further catabolism of amino acids all combine to form a series of metabolic loops as discussed in Chapter 17 and dealt with further in Chapters 12 and 29. Within cells some proteins are degraded much more rapidly than others, an important aspect of metabolic control. This is accomplished with the aid of the ubiquitin system (Box 10-C) and proteasomes (Box 7-A).[107] Proteins secreted into extracellular fluids often undergo more rapid turnover than do those that remain within cells.

1. Uptake of Amino Acids by Cells

While cells of autotrophic organisms can make all of their own amino acids, other organisms utilize many preformed amino acids. Human beings and other higher animals require several **essential amino acids** in their diets. Additional amounts of "nonessential" amino acids are also needed. It is true that amino groups can be transferred from one carbon skeleton to another among most of the amino acids. However, the body must take in enough amino groups to supply its need for all of the 20 amino acid components of proteins.[107a,b] Because of an unfavorable equilibrium constant, and the normally low concentration of NH_4^+, glutamate dehydrogenase (step *c* in Fig. 24-5) does not normally synthesize glutamate in the animal body. Its function is to deaminate excess glutamate. Furthermore, cells of some tissues take up amino acids that are made in other tissues. The active transport systems of bacteria have been described in Chapter 8. In mammals the absorption of amino acids takes place through epithelial cells of the intestinal tract, kidney tubules, and the brain (blood–brain barrier). Both Na^+-dependent transport (as for sugars; see Chapter 8) and Na^+-independent processes occur.[107c] Among the latter is the proposed **γ-glutamyl cycle,** which is described in Box 11-B. The cycle makes use of the γ-carboxyl group of glutamate, the same carboxyl that carries ammonia in the form of glutamine. Glutathione supplies the activated γ-glutamyl group. The amino acid to be transported reacts on the membrane surface by **transpeptidation**[108–109a] to form a **γ-glutamylamino acid** which enters the cytoplasm. It releases the free amino acid through an internal displacement by the free amino group of the glutamyl group. The natural tendency of the 5-carbon glutamate to undergo cyclization is used to provide the driving force for release of the bound amino acid. The cyclic product 5-oxoproline is then opened hydrolytically in an ATP-requiring reaction.[110] Cysteinylglycine formed in the initial transpeptidation is hydrolyzed by a peptidase, and glutathione is regenerated in two ATP-dependent steps as indicated in the scheme in Box 11-B.

The significance of the γ-glutamyl cycle is not fully understood. However, the finding of a mentally retarded individual who excretes 25–50 g / day of 5-oxoproline in the urine (possibly because of a defective 5-oxoprolinase) suggests that the pathway is a very active one.[111] A few persons deficient in γ-glutamyl transpeptidase have been found. They excrete glutathione and have a variety of medical problems.[109]

2. Glutamate Dehydrogenase and Glutamate Synthase

In animal tissues and in some bacteria the **glutamate dehydrogenase** reaction (Fig. 24-5, step *c*; see also Chapter 15)[112–115] provides a means of incorporating ammonia reversibly into glutamic acid. In eukaryotic cells the allosteric enzyme is found largely in the mitochondria.[115a] Glutamate dehydrogenase is also found in chloroplasts where it may function in glutamate synthesis when ammonia is present in excess.[116] The action of aminotransferases, both within and without mitochondria, distributes nitrogen from glutamate into most of the other amino acids. Especially active is aspartate aminotransferase (Eq. 14-24; Fig. 24-5, step *d*) which equilibrates aspartate and oxaloacetate with the 2-oxoglutarate–glutamate couple. However, the body obtains glutamate, as well as other amino acids, from foods, the initial source being largely green plants.

In plants as well as in *E. coli* and many other bacteria most glutamate is formed by **glutamate synthase**, which carries out reductive amination of 2-oxoglutarate (Fig. 24-5, reaction *a*). Glutamate synthase (also called **GOGAT**) utilizes the amide side chain of glutamine as the nitrogen donor. It is one of the previously mentioned amidotransferases in which glutamine is hydrolyzed to glutamate and NH_3 within the active site of the enzyme. Formation of a Schiff base and reduction probably occurs as in the reverse of reaction B of Table 15-1. However, one of the two glutamate molecules formed in reaction *a* of Fig. 24-5 must be reconverted by glutamine synthase to glutamine with the utilization of a molecule of ATP (Fig. 24-5, step *b*). Because of this coupling of ATP cleavage to the reaction the equilibrium in reaction *a* lies far toward the synthesis of glutamate. The low value of K_m for NH_4^+ that is characteristic of glutamine synthase favors glutamate synthesis even when little nitrogen is available.

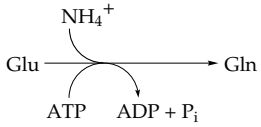
Bacterial glutamate synthases are large oligomeric proteins containing flavin and Fe–S centers. That of *Azospirillum brasilense* consists of αβ units in which the 53-kDa β chains contain FAD and an NADPH binding site.[117–118a] The NADPH evidently transfers electrons to the FAD, which transfers them to an Fe_3S_4 center in the large 162-kDA α subunit. A molecule of bound FMN receives the electrons and reduces the iminoglutarate to glutamate. The site of binding and hydrolysis of glutamine is also present in subunit α. Chloroplasts of higher plants contain two glutamate synthases. One resembles the bacterial enzyme and utilizes NADPH as the reductant. The other requires reduced ferredoxin.[118–120]

Bacteria utilize both D-alanine and D-glutamate in the synthesis of their peptidoglycan layers (Fig. 8-29). Both D-amino acids are formed by racemases. That of

alanine uses PLP (Chapter 15) but **glutamate racemase**[121–122a] does not. It may be able to remove the α-H of glutamate by utilizing the –COOH of the substrate, rather than the PLP ring, as an electron sink. Small amounts of D-amino acids occur also in animals.[123] Animal livers and kidneys contain **D-amino acid oxidase** and **D-aspartate oxidase,** which apparently function to metabolize D-amino acids from foods or those formed by brain activity (Chapter 30) or by aging.

3. Glutamine Synthetase

The formation of glutamine from glutamate (Eq. 24-16) also depends upon a coupled cleavage of ATP:



(24-16)

Glutamine synthase, as isolated from *E. coli*, contains 12 identical 51.6-kDa subunits arranged in the form of two rings of six subunits each with a center-to-center spacing of 4.5 nm. The units in one layer lie almost directly above those in the next,[104,124,125] the center-to-center spacing between the two layers is also 4.5 nm, and the array has 622 dihedral symmetry. The enzyme displays complex regulatory properties,[112,126–129] which are summarized in Fig. 24-7. The enzyme exists in two forms. **Active glutamine synthase** requires Mg^{2+} in addition to the three substrates glutamate, NH_4^+, and ATP. If the glutamate precursor, 2-oxoglutarate, is present in excess, the enzyme tends to remain in the active form because conversion to a modified form is inhibited; when the oxoglutarate concentration falls to a low value and glutamine accumulates, alteration is favored. The modifying enzyme **adenylyltransferase** (AT) in its active form AT_A transfers an adenylyl group from ATP to a tyrosine hydroxyl on glutamine synthase to give an adenylyl enzyme (GS-AMP). This **modified enzyme** requires Mn^{2+} instead of Mg^{2+} and is far more sensitive than the original enzyme to feedback inhibition by a series of end products of glutamine metabolism. All nine of the feedback inhibitors (serine, alanine, glycine, histidine, tryptophan, CTP, AMP, carbamoyl-*P*, and glucosamine 6-*P*) seem to bind to specific sites on the enzyme surface and to exert a cumulative inhibition. Serine, alanine, and glycine appear to be competitive inhibitors at the glutamate binding site.[130]

Relaxation of adenylylated glutamine synthase to the unmodified form is not catalyzed by a separate hydrolase but is promoted by a modified form of the adenylyltransferase AT_D. The active enzyme AT_A is

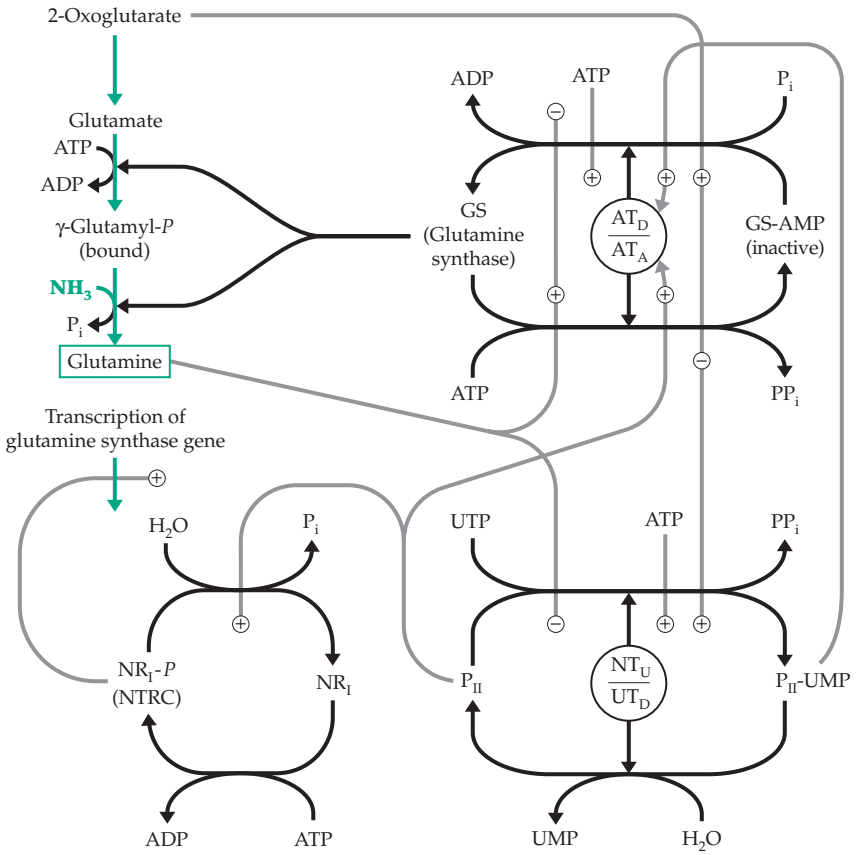


Figure 24-7 Regulation of glutamine synthase of *E. coli* using activation (+) and inhibition (–). Glutamine synthase (GS upper center) is converted by adenylylation of Tyr 397 into an inactive form GS-AMP by the action of an adenylyltransferase AT_A in complex with regulatory protein PII. PII is uridylylated at up to four sites by action of uridylyltransferase UT_U, which resides in the same polypeptide chain as a uridylyl removing enzyme UT_D (or UR). When PII carries a uridylyl group (PII-UMP), AT_A is transformed to AT_D, which reconverts the inactive GS-AMP to active GS by phosphorolytic removal of the adenylyl group. The ratios of AT_A / AT_D and UT_U / UT_D are controlled by the concentrations of the metabolites 2-oxoglutarate, a precursor, and glutamine, the immediate product. The amount of GS formed is controlled at the transcriptional level by an enhancer-binding transcription factor called NRI or NtrC (lower left). It is active when phosphorylated. Dephosphorylation of NRI-*P* is catalyzed by yet another protein and is stimulated by PII. Thus, PII both decreases synthesis of GS and promotes conversion of GS to its inactive form.

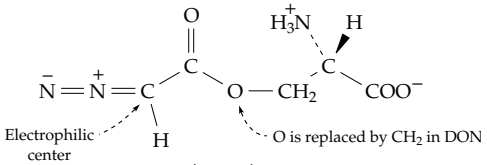
actually a complex AT • PII containing the regulatory protein PII. Subunit PII can be uridylylated on a tyrosine side chain by action of a 95-kDa **uridylyltransferase** (UT)[127,131] to form the modified glutamine synthetase AT • PII-UMP orAT_D. This form catalyzes phosphorolytic deadenylylation of glutamine synthetase, P_i displacing the adenylyl group to form ADP. Removal of the uridylyl group from PII-UMP is catalyzed by a fourth enzyme, UT_D (or UR), which is part of the same polypeptide chain as UT_U.[127] The cycle of interconversions of PII catalyzed by the UT_U and UT_D activities is shown at the lower right side of Fig. 24-7. From the allosteric modification reactions indicated by the gray lines, it is seen that glutamine not only promotes the adenylylation of glutamine synthetase but also inhibits the uridylylation of PII, thereby preventing AT_D from removing the adenylyl group from the synthetase. Furthermore, it allosterically inhibits the deadenylylation reaction itself. On the other hand, 2-oxoglutarate acts in the opposite way.

The glutamine synthase regulatory system has another important function. Protein PII stimulates the dephosphorylation of the enhancer-binding transcriptional regulator NRI-*P* (NtrC-*P*).[131,132] This slows transcription of the glutamine synthase gene (see Fig. 24-7) as well as a variety of other genes including those for the nitrogenase proteins in organisms that have them.[133] As a consequence, a deficiency of glutamine turns on a number of genes involved in nitrogen metabolism. Accumulation of glutamine promotes PII accumulation, modification of the synthase, and loss of gene activation.

Nitrogen can be transferred from glutamine into many other substrates.[102] Several antibiotic analogs of glutamine have been useful in studying these processes. Examples are the streptomyces antibiotics **L-azaserine** and 6-diazo-5-oxo-L-norleucine (DON).



L-Azaserine

These compounds act as alkylating agents; N_2 is released and a nucleophilic group from the enzyme becomes attached at the carbon atom indicated.[134] Other inhibitors bind noncovalently to form dead-end complexes.[134a]

4. Catabolism of Glutamine, Glutamate, and Other Amino Acids

Glutamine is hydrolyzed back to glutamate by glutaminases that are found both in eukaryotic tissues and in bacteria.[135,136] Liver contains an isozyme whose function appears to be to release NH_3 from glutamine for urea synthesis.[135,137] Glutamate dehydrogenase deaminates excess glutamate back to 2-oxoglutarate, which is degraded to succinyl-CoA and via β oxidation to malate, pyruvate, and acetyl-CoA. The last can reenter the citric acid cycle and be oxidized to CO_2 (Eq. 24-17). In fact, in mammalian tissues glutamate is essentially in equilibrium with 2-oxoglutarate and other citric acid cycle intermediates (see Box 17-C).

$$\text{Glu} \rightarrow \text{2-oxoglutarate} \rightarrow \text{succinyl-CoA} \rightarrow \rightarrow \rightarrow \text{malate} \rightarrow \text{pyruvate} \rightarrow \text{acetyl-CoA} \rightarrow CO_2 \qquad (24\text{-}17)$$

Many other amino acids are degraded in similar ways. In most cases the sequence is initiated by transamination to the corresponding 2-oxoacid. Beta oxidation and breakdown to such compounds as pyruvate and acetyl-CoA follows.

Catabolism initiated by decarboxylation. An alternative pathway for glutamate degradation is through the γ-aminobutyrate shunt (Fig. 17-5). This pathway is initiated by a PLP-dependent decarboxylation rather than by a deamination or transamination. Since decarboxylases are known for most amino acids, there are usually alternative breakdown pathways initiated by decarboxylation. In many cases these pathways lead to important products. For example, γ-aminobutyrate functions in the brain as an important neurotransmitter. Dihydroxyphenylalanine is converted to noradrenaline and adrenaline, tryptophan to serotonin, and histidine to histamine. All of these are neurotransmitters (Chapter 30) and/or have other hormonal functions. A calmodulin-dependent glutamate decarboxylase occurs in higher plants, which accumulate γ-aminobutyrate in response to a variety of stresses.[138] However, the significance of this accumulation is unclear.

Fermentation of glutamate. Special problems face anaerobic bacteria subsisting on amino acids. Their energy needs must be met by balanced fermentations.[138a] For example, glutamate may be converted to CO_2, ammonia, acetate$^-$, and butyrate$^-$ according to the reactions of Fig. 24-8. The end result is described by Eq. 24-18.

$$2\ \text{Glutamate}^- + 2\ H_2O + H^+ \rightarrow 2\ CO_2 + 2\ NH_4^+ + 2\ \text{acetate}^- + \text{butyrate}^- \qquad \Delta G'\ (\text{pH } 7) = -131\ \text{kJ} \qquad (24\text{-}18)$$
