 - Treat febrile episodes early and aggressively with antibiotics.
- Judicious use of blood transfusions will help:
 - Prevent strokes
 - Correct severe anemia (Hb level <5 g/dL, usually with aplastic crisis or splenic sequestration)
- Management is optimized by early diagnosis with screening of newborns.
- Routine daily prophylactic penicillin and pneumococcal vaccine
 - To prevent high childhood mortality from infections
- Agents that stimulate fetal hemoglobin production (eg, hydroxyurea) may be administered.
- Peripheral or cord blood stem cell transplantation from an HLA-identical sibling
 - High-risk procedure
 - Can be curative
 - Used for certain individuals with markers for adverse outcome (eg, stroke in a young child)
- Future directions
 - Antisickling agents, such as membrane-active drugs
 - Gene therapy

Rare structural hemoglobinopathies

- Unstable hemoglobin
 - Avoid oxidant drugs.
 - Provide transfusions as clinically indicated.
 - Remove the spleen if anemia is severe.
- High oxygen–affinity hemoglobins
 - Maintain hematocrit at 70% by phlebotomy to prevent high viscosity.

- Low oxygen–affinity hemoglobins
 - No specific management is necessary or effective.
 - Cyanosis is relatively well tolerated if strenuous activities are avoided.
- Hb M
 - No management is needed; the amount of Hb M is insufficient to cause physiologic derangements.

WHEN TO ADMIT

- Anemic crisis (Hb level <5 g/dL)
- Sudden splenic enlargement
- Pain not responding to home care and narcotics
- Difficulty in breathing, chest pain
- High fever spikes (>38°C core)
- Any central nervous system symptoms

WHEN TO REFER

- Initial and routine annual or biannual evaluation
- Serious complications, such as stroke, splenic sequestration, recurrent acute chest syndrome
- Care during pregnancy

FOLLOW-UP

- Patients with thalassemia major require regular transfusions for survival.
- Monitoring for chelation regimens
 - Annual audiologic and ophthalmologic examinations
 - Annual echocardiographic examinations

COMPLICATIONS

- Beginning in early childhood, risk of severe bacterial infections is lifelong.
 - Common cause of death
- Transfusion-transmitted infections remain a risk.
- Hb Bart disease
 - Invariably results in death in utero or shortly after birth due to severe anemia
 - Associated with life-threatening complications to the mother
 - Placentomegaly
 - Hypertension and preeclampsia
 - Disseminated intravascular coagulation
 - Hemorrhage

■ Hb H disease

- A serious decrease in hemoglobin can occur with infections or with ingestion of substances that induce oxidant stress.
- Hydrops fetalis syndrome
 - Devastating complication associated with nondeletional forms of Hb H disease
 - Associated with similar fetal and maternal complications as Hb Bart hydrops fetalis, including death in utero

PROGNOSIS

■ Sickling disorders

- Disease is extremely variable in severity.
- Factors that affect disease severity include:
 - Presence of genetic markers, such as the β -gene haplotype
 - Coinheritance of α -thalassemia (beneficial)
 - Amount/distribution of Hb F (higher levels are beneficial)

■ Hb Bart disease

- Invariably results in death in utero or shortly after birth due to severe anemia

PREVENTION

■ Simple awareness of genetic diseases and education and counseling of families at risk

- Low-tech but crucial in avoiding burden of these diseases to individuals and society

■ The primary reason to screen patients for hemoglobinopathy is to identify risk of producing offspring with clinically important disease, such as:

- β -Thalassemia major
- Sickle cell disease
- Severe α -thalassemia (hydrops fetalis)

■ Screening of parents

- Complete blood count while paying attention to RBC indices
 - Thalassemias are usually associated with:
 - Low mean cell volume (microcytosis)
 - Normal or near-normal mean cell hemoglobin concentration

- Hemoglobin concentration may be decreased or normal with a high RBC count.

- Once iron deficiency is ruled out and hemoglobinopathy is suspected

- Perform hemoglobin electrophoresis evaluation for levels of Hb A₂ and F and presence of an abnormal hemoglobin, such as Hb C, Hb S, or Hb E.

• Premarital screening and genetic counseling

- Easy and inexpensive
- Good ways to provide reproductive options for couples at risk for children with hemoglobinopathies
- Nondirective genetic counseling should be provided and targeted to populations with a high prevalence of the hemoglobinopathy traits.

■ Prenatal diagnosis

- Specific tests, such as globin-chain synthesis ratios or DNA analysis by sampling fetal blood or chorionic villus
- Chorionic villus sampling
 - Challenges include technical difficulties of the various methods used, as well as expense.
 - Women with at-risk pregnancies must be assessed for prenatal diagnosis, ideally in the first trimester (8–14 weeks' gestation).
 - Choice of therapeutic abortion for involved pregnancies can be difficult, depending on cultural and religious beliefs.
 - Research studies report a higher acceptance of prenatal diagnosis if another child is affected.
- Preconception diagnosis and implantation of normal embryos after in vitro fertilization
 - Extremely expensive alternative
 - Currently available in the West
- In utero therapy that uses stem cell transplantation
 - Would help at-risk couples that do not opt for termination
 - Currently in early trials

Hemolytic-Uremic Syndrome

DEFINITION

- Hemolytic-uremic syndrome (HUS) is a systemic thrombotic microangiopathy with multiple causes.
- It is characterized by the classic triad of microangiopathic hemolytic anemia, thrombocytopenia, and acute kidney failure.
- The end result is endothelial lesions leading to thrombosis of the microcirculation in many organ systems (see table Hemolytic-Uremic Syndrome Clinical Entities).
- HUS is divided into 2 types, depending on whether the patient has had diarrhea.
 - Presence of diarrhea is designated *D+* HUS.
 - Most common type
 - Caused by toxins from a group of Enterobacteriae, enterohemorrhagic *Escherichia coli* (EHEC)
 - Absence of diarrhea is designated *D-* HUS.
 - Only 10% of cases are classified as *D-* HUS.

EPIDEMIOLOGY

- Geographic distribution
 - Shigatoxin (ST)-associated HUS is prevalent in areas of the world with high incidence of gastrointestinal infections by ST-producing EHEC (STEC).
 - In Argentina, ST-associated HUS is approximately 10 times more frequent than in other locations with high incidence, such as Canada, some Western European countries, and California and Utah.
 - In countries with a high incidence of ST-associated HUS, the prevalence of atypical forms is <10%.

- Incidence
 - The incidence of atypical genetic HUS is low.

ETIOLOGY

- Clinically, HUS caused by genetic mutations tends to be more severe than HUS caused by STEC.
 - Tends to recur and have persistent activity
 - The long-term course is more severe, leading more frequently to chronic renal disease.
- Multiple genetic mutations have been found in patients with atypical HUS.
 - Mutations in the complement system activation can cause atypical HUS.
- Another pathogenetic mechanism for atypical HUS depends on lack of the activity of ADAMTS-13 (a disintegrin and metalloproteinase with thrombospondin-1-like domains).

RISK FACTORS

- Antimotility agents, although useful for symptomatic relief of diarrhea, have been shown to increase the risk of toxic megacolon in patients with HUS and are contraindicated.
- Use of some antibiotics to treat *E coli* bowel infection has been found to increase the risk of HUS by promoting release of ST from the bacteria.
- Patients with factor H and factor I mutations have posttransplantation recurrence rates for HUS of 30–100%.
- ADAMTS-13 deficiency HUS can recur after transplantation.

Hemolytic-Uremic Syndrome Clinical Entities

Classification	Cause	Clinical Manifestation
Infectious	Bacterial cytotoxin (<i>Escherichia coli</i> , <i>Shigella</i> , <i>Salmonella</i>) pneumococcal, viral	Epidemic/classical/ <i>D+</i> enteropathic
Idiopathic	<ul style="list-style-type: none"> • Endothelial dysfunction? • Other regulatory C proteins? 	<ul style="list-style-type: none"> • Hereditary (autosomal dominant, autosomal recessive) • Sporadic, atypical
Genetic	<ul style="list-style-type: none"> • Factor H, factor I deficiency • MCP (CD46) • vWF protease ADAMTS 13 	<ul style="list-style-type: none"> • Recurrent • Recurrent except posttransplant • Recurrent
Immunologic	<ul style="list-style-type: none"> • vWF protease antibodies • Factor H autoantibodies 	TTP
Other	Cancer, pregnancy, malignant hypertension, transplant rejection glomerulonephritis	
Toxic related	Cyclosporine, tacrolimus, sirolimus, mitomycin, radiation	

Abbreviations: ADAMTS, a disintegrin and metalloproteinase with thrombospondin; MCP, membrane cofactor protein; TTP, thrombotic thrombocytopenic purpura; vWF, von Willebrand factor.

SIGNS AND SYMPTOMS

- In the classical form, most patients have:
 - Diarrhea (bloody in two-thirds of cases)
 - Vomiting
 - Fever
- Several days later
 - Sudden onset of pallor
 - Severe malaise
 - Decrease in urine output
 - Edema
- During the acute phase, approximately one-third of patients may have symptoms of central nervous system involvement, including:
 - Change in sensorium (excitement or somnolence)
 - Convulsions
 - Possibly severe coma
- Intestinal (generally colonic) necrosis can be severe enough to require surgical intervention.
- Hypertension in approximately one-half of children with HUS
 - May have either short-term or persistent patterns
 - Short-term hypertension is caused by volume expansion and improves with salt restriction or dialysis.
 - Persistent hypertension is generally associated with renal ischemia in the presence of severe lesions.
- Hyperglycemia caused by pancreatic insufficiency, cardiac involvement, and hepatic failure are rare.

DIFFERENTIAL DIAGNOSIS

- Differential diagnosis of HUS is wide and includes:
 - Thrombotic thrombocytopenic purpura
 - Malignant hypertension
 - Vasculitis
 - Disseminated intravascular coagulation
 - Sepsis
 - Reye syndrome
 - Intussusception
 - Renal vein thrombosis
- The best differential sign of HUS is microangiopathic anemia with schistocytes in the peripheral smear.

DIAGNOSTIC APPROACH

- Both the clinical outcome and short-term and long-term treatment of HUS vary greatly depending on the cause; thus, finding the causes and acting accordingly is important.

LABORATORY FINDINGS

- Laboratory studies reveal:
 - Low hemoglobin
 - Fragmented erythrocytes (schistocytes)
 - Thrombocytopenia, indicating acute microangiopathic anemia
- Urine sample (if one can be obtained) shows signs of:
 - Glomerular involvement (hematuria with erythrocyte casts)
 - Proteinuria
- Decrease in the glomerular filtration rate is indicated by elevated levels of:
 - Serum creatinine
 - Blood urea nitrogen

IMAGING

- Renal ultrasonography shows symmetrical enlargement of both kidneys compared with patients with renal vein thrombosis, in which the kidneys are generally enlarged unilaterally.

TREATMENT APPROACH

- Treatment for HUS remains almost entirely supportive (see table Treatment Strategies for Hemolytic-Uremic Syndrome).
- The advent of dialysis and improvements in management of acid-base, electrolyte, and volume disorders in children has significantly improved outcomes.
- The prudent use of intensive care, nephrology, and genetic counseling can make a difference in the outcome of HUS.

SPECIFIC TREATMENTS

Supportive care

- Antimotility agents, although useful for symptomatic relief of diarrhea, have been shown to increase the risk of toxic megacolon in patients with HUS and are contraindicated.
 - This problem should be explained to both patient and parents, providing clear reasons why the diarrhea is not being treated.
- Use of some antibiotics to treat *E coli* bowel infection has been found to increase the risk of HUS by promoting the release of ST from the bacteria.
- HUS associated with diarrhea seems to respond to plasma exchange.
 - In patients with severe and progressive acute kidney failure and heart failure, plasma exchange might be considered.
 - Plasma exchange is started within 24 hours of presentation, using ≥ 1 volume (40 mL/kg) exchange as needed.
 - In HUS caused by *Streptococcus pneumoniae*, plasma therapy is contraindicated because adult plasma contains antibodies to the Thomsen-Friedenreich antigen and may worsen the disease process.

Treatment Strategies for Hemolytic-Uremic Syndrome^a

	Antibiotics	Antimotility Agents	Plasma Exchange or Plasma Infusion	Kidney Transplant
<i>Escherichia coli</i> associated	Contraindicated	Contraindicated	Not effective	Recommended
<i>Streptococcus pneumoniae</i>	Not known	Not known	Contraindicated	Recommended
Factor H mutation	Not known	Not known	<ul style="list-style-type: none"> • Variably effective • Recommended 	Contraindicated
Factor I mutation	Not known	Not known	<ul style="list-style-type: none"> • Variably effective • Recommended 	Contraindicated
MCP mutation	Not known	Not known	Not effective	Recommended
ADAMTS 13 mutation	Unrelated	Unrelated	Recommended	Risk of recurrence

Abbreviations: ADAMTS, a disintegrin and metalloproteinase with thrombospondin; MCP, membrane cofactor protein.

^aSupportive care is appropriate in all types as needed.

- Angiotensin-converting enzyme inhibitors are recommended in patients with persistent proteinuria.
 - Women should be advised that these agents are teratogenic, and care should be taken to prevent pregnancy.

Kidney transplantation after HUS

- Should be considered for patients (approximately 10–15%) who progress to terminal renal failure after HUS associated with diarrhea
- Depending on the availability of a graft, they may:
 - Require dialysis
 - Get a preemptive transplantation
- These children are excellent candidates because of:
 - The likelihood of recurrence of HUS is low.
 - Patient and graft survival rates are similar or superior to those in children who have received transplants for other renal diseases.
- For patients who are on dialysis as a result of genetic HUS and who then receive a kidney transplant:
 - Overall 1-year graft survival is <30% (vs the expected 95%) because of a 50% recurrence rate of HUS.
 - Results vary depending on the genetic defect.
- Patients with factor H mutations have posttransplantation recurrence rates of 30–100%.
 - In part because factor H is made chiefly in the liver
 - Combined kidney and liver transplants have had mixed success and are not recommended.
- Factor I mutation patients have a similar circumstance and outcome and are not recommended for kidney transplantation.
- ADAMTS-13 deficiency HUS can recur after transplantation.

- Outcomes in the 4 patients with MCP mutations (CD46) who have received transplants were very good.
 - MCP is a protein that is highly expressed in the kidney; thus, kidney transplantation appears to be a good alternative to long-term dialysis.

WHEN TO ADMIT

- All patients with HUS must be admitted.

WHEN TO REFER

- All patients with HUS should be referred to a nephrologist and other subspecialist as indicated.

FOLLOW-UP

- Growth and blood pressure should be closely monitored.
- Regularly test the glomerular filtration rate.
- Proteinuria may remain after all these signs normalize.
 - Persistence for >6 months after the acute stage is a sign of risk for hyperfiltration caused by reduced renal mass, leading to progressive kidney fibrosis.

COMPLICATIONS

- HUS is the most frequent cause of acute kidney injury in children.
- These patients have a hypercatabolic state and may develop several conditions requiring aggressive dialysis.
 - Hypervolemia leading to hypertension, cardiac failure, pulmonary edema, and encephalopathy
 - Hyperkalemia producing cardiac arrhythmias
 - Severe metabolic acidosis
 - Hyponatremia (10% may exhibit hypernatremia), which may be associated with volume contraction caused by the preceding diarrhea or may be dilutional caused by oligoanuria.

PROGNOSIS

- The mortality rate has plummeted over the past 40 years from 40–50% to 3–5%.
- In STEC HUS, >95% of children recover from the acute phase of the illness.
- Mortality is associated with intercurrent infection or severe neurologic, intestinal, or myocardial complications associated with the more severe patterns of the systemic acute disease.
- With current management of fluid and electrolyte disorders and hypertension, no patient should die of complications related to acute kidney injury.
- Long-term renal course depends on intensity of the acute injury and initial destruction of the nephron mass.
- During the acute phase, signs associated with an increased risk of residual kidney lesion and progression to chronic renal insufficiency include:
 - Presence and length of the anuria
 - Need for and duration of dialysis

- Presence of persistent hypertension
- Magnitude of extrarenal involvement (central nervous system, intestine)
- Large groups of patients followed for >3 years after recovery of the acute period have shown that:
 - ~65% may have normal function, normal blood pressure, and no proteinuria .
 - 15% may have persistent proteinuria with or without hypertension but normal creatinine clearance.
 - 20% will have chronic renal failure of different degrees.

PREVENTION

- Properly cooking meats and good hygiene will prevent infections with organisms associated with HUS and thus prevent D+ HUS.

Hemophilia and Other Hereditary Bleeding Disorders

DEFINITION

- Hemophilia A (classic hemophilia)
 - Due to congenital factor VIII deficiency
- Hemophilia B (Christmas disease)
 - Due to congenital factor IX deficiency
- von Willebrand disease (vWD)
 - Most common hereditary coagulation disorder, usually asymptomatic
- Coagulant deficiencies
 - Congenital lack or dysfunction of any of the factors needed for coagulation
 - Factor XI deficiency
 - Afibrinogenemia
 - Dysfibrinogenemia

EPIDEMIOLOGY

- Prevalence
 - Hemophilia is seen in ~1 in 5000 male patients.
 - 80–85% have hemophilia A.
 - 10–15% have hemophilia B.
 - vWD is found in 1% of the population.

RISK FACTORS

- Family history of hemophilia in approximately two-thirds of cases

SIGNS AND SYMPTOMS

- Severe disease is characterized by hemarthroses and hematoma formation with minimal or no apparent trauma.
- Mild disease results in bleeding only with trauma.
- Recurrent bleeding into joints is the most frequent clinical problem for patients with hemophilia.
 - Knees, ankles, and elbows are involved most often.
 - Many have 1 particular target joint.
 - Synovial thickening and vascular friability may develop.
 - Results in vicious cycle with increased susceptibility to bleeding
 - Synovitis accompanied by chronic effusion often develops and may progress to joint destruction (hemophilic arthropathy) and severe disability.
- vWD
 - Bleeding after surgery and trauma
 - Mucosal bleeding; most frequently exhibits as epistaxis
 - Menorrhagia
 - Gastrointestinal bleeding
 - Hemarthrosis and deep hematomas may be seen in severe (type III) vWD.

DIAGNOSTIC APPROACH

- Bleeding disorders are suspected on the basis of family and personal history.
- Laboratory tests will identify the specific deficiency.
 - Hemophilia
 - Severe hemophilia is defined by a factor VIII or IX level <1%.
 - Levels >5% are associated with mild disease.
 - Intermediate levels are associated with moderate disease.
- Most useful screening tests
 - Partial thromboplastin time or activated partial thromboplastin time (aPTT)
 - Prothrombin time (PT)
 - PT alone is not adequate for screening for coagulation disorders because it misses the most common congenital deficiencies.
 - Falsely prolonged clotting tests may result from an insufficient amount of blood in the specimen tube due to difficulty accessing the vein.
 - Tests are sensitive to clotting factor levels <30–40% of normal.

LABORATORY FINDINGS

- Prolonged partial thromboplastin time or aPTT and PT
 - Prolonged aPTT or PT must be followed by individual clotting factor assays.
 - If both test results indicate prolonged times:
 - Abnormal liver function or vitamin K deficiency with multiple reduced factors should be considered.
- Factor XIII deficiency will not be detected with aPTT or PT.
- Individual clotting factor assays
- Thrombin time
 - Measure to look for abnormalities of fibrinogen or possible interference by heparin.
 - If results are abnormal, measure reptilase time (which is not sensitive to heparin).
- Bleeding time
 - Useful screening test for vWD, and acquired and congenital abnormalities of platelet function)
 - Difficult to standardize
 - Assessment in an uncooperative child is difficult.
 - Replaced in many centers by Platelet Function Analyzer-100, which is more sensitive and reproducible.
- vWD
 - Several components of the vWF-factor VIII complex and function can be determined.
 - Factor VIII activity
 - vWF activity (ristocetin cofactor)

- vWF antigen
- Pattern of multimers
- Many variants of vWD
 - Type I
 - All components are similarly reduced.
 - Multimer pattern is normal.
 - Type II
 - Decrease or absence of the larger multimers
 - Type IIB exhibits increased binding to platelets.
 - Type III
 - Very low or absent levels of all components
- Usually, decreased levels of factor VIII
- aPTT may be normal if the factor VIII level is >30–40%.
 - Results may be variable; if normal, the test should be repeated if the index of suspicion is high.
- vWF levels of 35–50% may exist both in patients with vWD and normal individuals with blood type O, making definitive diagnosis difficult.

TREATMENT APPROACH

General management principles

- Ideal management of hemophilia is in a comprehensive center where all needs can be met, including:
 - Medical
 - Orthopedic
 - Physical rehabilitation
 - Dental
 - Psychosocial
- All elective surgical procedures must be performed in a center that has:
 - Experienced personnel
 - Immediate availability of blood clotting factor assays
 - Ready supply of clotting concentrates
 - Factor inhibitor testing prior to procedures
- Factor replacement
 - Should always be given promptly when bleeding is suspected
 - Should be given before radiographic examination or other diagnostic studies
- A patient with severe injury or life-threatening bleeding needs:
 - An immediate dose of the appropriate clotting factor to increase its level to 100%
 - Subsequent transfer to a hemophilia center
- A patient with any significant injury:
 - Must be treated promptly, even without apparent evidence of active bleeding (bleeding is often delayed)

- A small, superficial laceration
 - If not bleeding or in need of cleaning, may be managed with a simple pressure dressing
 - If bleeding occurs or if suturing is required, appropriate clotting factor must be administered immediately.
- Treatment must be given before all surgical procedures, arterial puncture, and lumbar puncture.

Specific scenarios

- Casts
 - Should not be applied without previous administration of factor
 - Factor administration should be continued for several days after casting.
 - The involved area should be monitored closely for evidence of nerve or vascular compression.
- Hemarthrosis
 - Treat as soon as pain, tingling, or limping begins, even if there is no evidence of swelling.
 - If marked swelling is present, joint should be aspirated and immobilized after factor replacement.
- Early synovitis
 - Manage by providing factor VIII or IX prophylactically for several weeks, often with a short course of corticosteroids.
 - Synovectomy may be effective if medical management fails.
 - Accomplished by arthroscopy, even in young children
 - Intensive physical therapy is required with the procedure.
 - Radiosynovectomy
 - A simpler procedure, requiring less factor replacement and physical therapy
 - Has been performed in young children, with good joint outcomes
 - Some concern exists about inducing cancer and interfering with growth.
- Pain
 - Manage with acetaminophen whenever possible.
 - Codeine and other oral narcotics can be provided if necessary.
 - Aspirin must be avoided.
 - Nonacetylated salicylates (eg, choline magnesium trisalicylate [Trilisate]) can be used.
 - Nonsteroidal antiinflammatory drugs (eg, ibuprofen) can be given cautiously if the patient is not receiving zidovudine.
- Treatment for mild hemophilia
 - Desmopressin may be effective if the baseline factor VIII level is >5%, depending on the level desired.
 - Overhydration must be prevented because water retention and hyponatremia may occur, particularly in young children and with repeated doses.

- A concentrated intranasal preparation (Stimate) is available and has been used in children ≥ 6 years of age.
 - A stimulation test with response assessment should be performed in each patient with both intravenous and nasal preparations before they are used for the first time.
 - Desmopressin is ineffective in factor IX deficiency.
 - Treatment for inhibitor antibodies
 - Up to 50% of patients with severe hemophilia A and 3% with hemophilia B develop antibodies that inhibit factor VIII or factor IX.
 - Usually early in treatment
 - Many of these antibodies are present in low titer and may subsequently disappear.
 - Management (by experienced practitioners) may include:
 - Large doses of factor VIII or factors that bypass factor VIII in the coagulation cascade
 - Prothrombin complex
 - Activated prothrombin complex
 - Recombinant factor VIIa
 - Induction of immune tolerance by continuous exposure to high doses of factor over months usually is effective in controlling inhibitor, with or without concomitant immunosuppression.
 - Suspect inhibitor antibodies if response to appropriate therapy is inadequate.
 - Assess for inhibitor antibodies in all patients and before all elective surgery.
 - Bethesda inhibitor assay determines presence and strength of inhibitors.
 - Patients with hemophilia B and inhibitor antibodies
 - May develop anaphylaxis or nephrotic syndrome when given factor IX
 - Recombinant factor VIIa has been effective.
 - vWD
 - Most patients with type I vWD will respond to desmopressin; this approach can be used for most bleeding episodes.
 - Most patients with type IIA and all with type III do not respond to desmopressin.
 - Contraindicated in type IIB disease; may cause platelet aggregation and disseminated intravascular coagulation (DIC)
 - Patients who have severe bleeding or do not respond to desmopressin should be treated with Humate P, a concentrate containing both factor VIII and vWF.
 - Mild epistaxis can often be controlled with ϵ -aminocaproic acid or tranexamic acid.
 - Should be used as adjunctive therapy for mucosal bleeding other than hematuria
 - Deficiencies can be treated with fresh-frozen plasma.
 - Used for patients with factor V or XI deficiency
 - Used in an emergency for patients who are bleeding but whose deficiency has not yet been identified
 - Concentrates are preferable for treating factor VII deficiency because of their short half-life, and because all are virus depleted.
 - Prothrombin complex products contain factor VII, II and X (but content of each factor varies in different lots).
 - May induce thrombosis or DIC
 - Must be used cautiously, particularly in patients with liver disease
- ## SPECIFIC TREATMENTS
- ### Treatment of bleeding episodes in hemophilia, by type of bleeding
- Hematoma, simple
 - Increase factor VIII or IX to 20–40%.
 - Treat only once.
 - Hemarthrosis, mild muscle hematoma
 - Increase factor VIII or IX to 30–40%.
 - Treat once as soon as symptoms begin; if severe, repeat daily until better.
 - Ancillary treatment
 - Aspirate joint after treatment if swelling is marked.
 - Do not use ϵ -aminocaproic acid.
 - Severe muscle hematoma
 - Increase factor VIII or IX to 50–100%.
 - Treat for 3–7 days.
 - Mouth bleeding, epistaxis, dental extractions
 - Increase factor VIII or IX to 80–100%.
 - Treat once.
 - Ancillary treatment: Start ϵ -aminocaproic acid, 75–100 mg/kg every 6 hr, or tranexamic acid, 25 mg/kg every 6–8 hr by mouth for 3–7 days (until clot is gone).
 - Gastrointestinal bleeding
 - Increase factor VIII or IX to 100%.
 - Treat for 3–7 days.
 - Ancillary treatment, ϵ -aminocaproic acid or tranexamic acid
 - Hematuria
 - Factor VIII or IX (in mild cases, may not be needed)
 - Treat for 3–7 days.
 - Ancillary treatment
 - Bed rest
 - Hydration
 - Prednisone, 2 mg/kg daily (in selected patients)
 - Do not use ϵ -aminocaproic acid.

- Life-threatening, central nervous system, airway obstruction, retroperitoneal
 - Increase factor VIII or IX to 100%; do not allow decrease to <50%.
 - Treat for 7–14 days.
 - Monitor levels.
- Surgery
 - Factor VIII or IX should be at 100%; do not allow decrease to <50%.
 - Treat for 7–14 days.
 - Monitor levels.
- Prophylaxis
 - Factor VIII or IX, 20–40 U/kg
 - Treat 3 times per week for factor VIII, 2 times per week for factor IX.

Treating with factor VIII or IX

- Whole vials with the calculated/desired dose or a higher level should be given because products are too expensive to waste.
- Continuous infusion can be used for patients undergoing surgery or those who are bleeding extensively.
- Factor VIII: 1 U/kg increases plasma level by 2%; biological half-life = 10–12 hours
- Factor IX: 1 U/kg increases level by 1%; 1 U/kg of recombinant factor IX increases level by 0.8%; biological half-life = 20–24 hours
- Slightly lower levels of factor IX than of factor VIII are effective.
- Initial dose = 50 U/kg of factor VIII and 80–100 U/kg of factor IX
 - Repeat half the factor VIII dose in 8–12 hours.
 - Repeat half the factor IX dose in 12–24 hours.
 - Alternatively, provide continuous infusion of 3–4 U/kg per hour of either factor after initial bolus dose.

Product: content, dose, and indications

- Fresh-frozen plasma
 - Whole plasma
 - 5–15 mL/kg; 1 U of each of the coagulation factors/mL; 220 or 600 mL/bag
 - Multiple factor deficiency; DIC; reversal of warfarin effect; hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura; unknown coagulation defect; when no specific concentrate exists
- Cryoprecipitate (not virus inactivated)
 - Factor VIII, vWF, factor XIII, fibrinogen, fibronectin
 - 1 U/kg increases factor VIII 2%; 75–100 U factor VIII and vWF/ bag; volume approximately 20 mL; not assayed
 - Factor XIII deficiency, hypofibrinogenemia

- Factor VIII
 - Factor VIII
 - 1 U/kg increases factor VIII 2%; preassayed; up to 100 U/mL
 - Hemophilia A
- Humate P
 - Factor VIII, vWF
 - Preassayed; factor VIII 20–40 U/mL; vWF 50–100 U/mL
 - Severe vWD; mild to moderate vWD if desmopressin is ineffective or inadequate
- Factor IX
 - Factor IX
 - 1 U/kg (1.2–1.4 U/kg of recombinant) increases factor IX by 1%; preassayed; up to 100 U/mL
 - Hemophilia B
- Prothrombin complex
 - Factor II, VII, IX, X
 - Preassayed for factor IX; content of other factors varies among products
 - Hemophilia B when purified factor IX cannot be used; mild bleeding in hemophilia A with inhibitor; congenital deficiency of factor II or X
 - Danger of thrombosis (including myocardial infarction and DIC) in presence of liver disease, prolonged use
- Activated prothrombin complex
 - Factor II, VII, IX, X; factor VIII–bypassing activity
 - Preassayed for ability to shorten aPTT of plasma with high-titer factor VIII inhibitor
 - Hemophilia A or B with inhibitor
 - Cannot evaluate response by measuring factor VIII activity
 - Risk of DIC and thrombosis
- Novoseven
 - Recombinant factor VIIa
 - Preassayed
 - Hemophilia A or B with inhibitor; factor VII deficiency
 - Risk of thrombosis

WHEN TO ADMIT

- Significant trauma is present.
- Bleeding is present in a potentially life-threatening area.
- Severe abdominal pain exists.
- Any surgical procedure must be performed.

WHEN TO REFER

- All children with hemophilia should be seen at least once a year at a comprehensive hemophilia center if possible.
- All elective surgery should be performed at a hemophilia center.

- All patients with significant trauma or potentially life-threatening bleeding should be given an initial loading dose of factor (to 100%) and transferred to a hemophilia center.
- All patients with inhibitors should be managed at a hemophilia center.
- Children with vWD should have an initial evaluation by a specialized coagulation laboratory.

FOLLOW-UP

- If a child has reasonably easy venous access and family dynamics permit it:
 - Parents can be taught to administer treatment to children as young as 3 years.
 - 9- or 10-year-olds can be taught to self-administer factor concentrates.
 - Benefits
 - Much earlier treatment of bleeding episodes
 - Satisfaction of self-sufficiency
 - Prevention of frustration of having to get to a treatment center or emergency department
 - Indwelling venous access devices are simpler, although infections and thrombosis have been problems.
 - Home intravenous therapy is a convenient way to administer prophylaxis or immune tolerance induction.

COMPLICATIONS

- Synovitis accompanied by chronic effusion often develops and may progress to joint destruction (hemophilic arthropathy) and severe crippling.

PREVENTION

- Routine immunizations
 - Must include hepatitis B and hepatitis A vaccines
 - Should be given subcutaneously with a 25-gauge needle; pressure should be maintained for 5–10 minutes
 - Intramuscular injections should be minimized.
- Using appropriate caution while allowing development of independence is a difficult balance.
 - Psychosocial problems can be associated with a serious chronic illness and frequent pain and limitation of normal activities.
 - Family education about the disease is essential.
 - Support groups are beneficial.
- Synovitis leading to joint destruction is minimized by prompt, adequate treatment or prevention of bleeding.
- Prophylaxis for patients with severe hemophilia
 - Prophylactic factor concentrate treatment administered several times a week
 - Prevents hemarthrosis and joint damage
 - Normalizes living
 - More expensive than episodic treatment for bleeding, but saves cost by preventing orthopedic complications
 - Results in psychological benefits

Hemoptysis

DEFINITION

- Hemoptysis is spitting or coughing of blood that originates within the thorax.
- Presentation ranges from flecks of blood in the sputum to massive, potentially life-threatening bleeding that can lead to respiratory distress or death.
- Most commonly associated with previously diagnosed congenital heart disease or cystic fibrosis (CF), but also with infectious respiratory illnesses and, rarely, neoplasms
- May be seen in infants with a variety of congenital defects
 - Arteriovenous malformations
 - Extralobar sequestration
 - Hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber syndrome)
- Diffuse pulmonary hemorrhage is not uncommon in infants of very low birth weight.

EPIDEMIOLOGY

- Rare in children

MECHANISM

- Hemoptysis can result from:
 - Disruption of either arm of the dual pulmonary vascular system
 - Damage to the alveolar endothelial junction
- Localized hemoptysis usually is the result of bleeding from the high-pressure bronchial circulation in inflamed airways.
- The low-pressure pulmonary circulation rarely is to blame for hemoptysis, except in necrotic infarcts and pulmonary arterial aneurysms in tubercular cavities.
 - Both of these conditions are extremely rare in children.
- Increased cardiac output to the bronchial circulation may contribute to hemoptysis and can be caused by:
 - Inflammation in the lungs
 - With chronic inflammation (eg, bronchiectasis), broncho-pulmonary anastomoses are increased, thereby increasing the potential for erosion of vessels in the presence of superimposed infection.
 - Pulmonary vascular obstruction
 - Neoplasia

HISTORY

- 4 important considerations should be kept in mind in evaluating children with hemoptysis.
 - Whether the bleeding requires an emergency resuscitative effort
 - Whether what appears to be hemoptysis is bleeding from the upper airway or gastrointestinal tract
 - The source of the bleeding should be established.

- Children with lower respiratory tract infection but no chronic disease usually:
 - Have mild, self-limited bleeding
 - Require no specific treatment other than management of the underlying acute illness
- Management of hemoptysis that arises from a localized site differs from that which causes a diffuse alveolar hemorrhage, which may be the presenting sign of an underlying immunologic disorder.
- A detailed history of both pulmonary and nonpulmonary symptoms often permits a tentative diagnosis.
- The presumptive diagnosis can then be proven or disproven by findings of specific laboratory tests and procedures.
- Aspects of the history that help focus the evaluation include:
 - Recent trauma
 - Easy bruising
 - Changes in urine color
 - Weight loss
 - Arthralgias
 - Previous heart disease or surgery
 - Medication use
 - Substance abuse
 - Family history of bleeding disorders
 - Surgical procedures
 - Pica
 - Fever
 - Pleuritic chest pain
 - Menstrual irregularities
 - Asthma not responsive to appropriate medical therapy
 - Travel to or from developing countries and areas that raise sheep may necessitate evaluation for mycobacterial, mycotic, or parasitic lung infections.
- Recurrent pneumonitis, sinus infections, and chronic sputum production may be indicative of:
 - Bronchiectasis from CF
 - Foreign body aspiration
 - Ciliary dyskinesias
 - Immunodeficiency disorders
 - Other chronic lung diseases

PHYSICAL EXAM

- Physical examination begins with the vital signs to determine the speed at which the examination should be conducted.
- Thorough inspection of the nasal passages and oropharynx is done to rule out a nonpulmonary cause of the hemoptysis.

- As the examination proceeds caudally, certain findings on inspection and auscultation may suggest a specific diagnosis.
 - Cutaneous telangiectases and a murmur or bruit over the lung fields suggest hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber syndrome).
 - Clubbing with or without adventitial breath sounds suggests bronchiectasis.
 - A saddle nose and stridor suggestive of subglottic stenosis are often seen in patients with Wegener granulomatosis.
 - A pleuritic rub, acute pleuritic chest pain, and history of oral contraceptive use or recent abortion suggest a pulmonary embolic event or other pleural-based lesion.
 - Localized homophonous wheezing over a major airway or decreased breath sounds, with or without a cough, suggests an intraluminal obstruction, such as an aspirated foreign body.
 - Evidence of trauma to the thorax may be subtle.
 - 30% of children who experience major trauma to other organ systems will be found to have thoracic trauma as well.
 - Examination of the heart may provide evidence of pulmonary hypertension or a new murmur.
 - Lymphadenopathy and hepatosplenomegaly raise the possibility of a lymphoproliferative disease with an associated bleeding diathesis.
- ## DIFFERENTIAL DIAGNOSIS
- ### No preexisting medical condition
- For a child or adolescent without a preexisting medical condition who has a first episode of hemoptysis, the most common causes are:
 - Acute infectious pneumonia
 - Foreign body aspiration
 - Classically, a child with pneumococcal pneumonia and hemoptysis who is old enough to expectorate:
 - Is febrile
 - Appears ill
 - Has a cough that is productive of rusty sputum
 - Certain other bacterial and viral lower respiratory tract infections can cause hemoptysis.
 - In these cases, hemoptysis usually:
 - Occurs early in the course of the illness
 - Is self-limited
 - Consists of only blood-tinged sputum
 - Globally, the most common causes of hemoptysis in children probably are:
 - Tuberculosis
 - Echinococcus
 - Paragonimiasis
 - Foreign body aspiration
 - In many cases of aspiration, the initial choking episode is not observed or not remembered.
 - A bout of paroxysmal coughing may occur after the initial event, but as cough receptors in the bronchi or trachea adapt, coughing will stop.
 - Over time, and depending on the location and composition of the foreign object, subsequent inflammation will develop.
 - May result in airway obstruction, with wheezing or recurrent pneumonitis
 - If neovascularization of granulation tissue in the airways occurs, or if bronchiectasis develops, hemoptysis can occur weeks to months after the initial event.
 - Only 40% of children with foreign body aspiration exhibit the classic triad of wheezing, cough, and decreased breath sounds distal to the site of obstruction.
 - Pulmonary tuberculosis, usually with systemic manifestations of anorexia and weight loss
 - Purified protein derivative test may be negative.
 - Autoimmune disorder or other immunologic abnormality, although rare as a presenting symptom
 - More common in girls
 - Rarely produces hemoptysis alone
 - More commonly characterized by systemic manifestations, including (in addition to the hemoptysis):
 - Fever
 - Weight loss
 - Malaise
 - Anorexia
 - Amenorrhea
 - Rashes
 - Hypertension
 - Diffuse pulmonary hemorrhage
 - May be divided into 4 categories, all rare
 - Hemorrhage associated with antglomerular basement membrane antibodies in serum or tissue (eg, Goodpasture syndrome)
 - Hemorrhage associated with an autoimmune-mediated disease (eg, systemic lupus erythematosus)
 - No immunologic abnormalities, but an association with antibodies
 - Idiopathic pulmonary hemosiderosis (IPH)
 - No evidence of immune-mediated mechanism is found.
 - IPH is diagnosed in most children before the age of 7 years or after the age of 16 years.
 - Symptoms include respiratory distress, bilateral alveolar infiltrates, and iron-deficiency anemia.

- Heiner syndrome (pulmonary hemosiderosis associated with cow's milk allergy) manifests as hemoptysis with:
 - Failure to thrive
 - Vomiting
 - Gastrointestinal bleeding
 - Upper respiratory tract congestion
- Congenital malformations
 - Symptoms depend on the nature of the lesion.
 - May be associated with massive hemoptysis or respiratory distress in newborns
- Primary pulmonary neoplasms
 - Extremely rare in children, especially immunocompetent children
 - <5% of tumors reported in the literature have been associated with hemoptysis.
 - The most common presentations of primary pulmonary neoplasms in children are:
 - Fever
 - Cough
 - Pleural pain
- Other rare causes of hemoptysis without preexisting medical problems
 - Pulmonary embolism
 - Pleuritic pain, cough, and dyspnea
 - Probably associated with oral contraceptive use, recent abortion, or trauma to lower extremities
 - Parasitic lung infections (rare in the US)
 - Travel to endemic areas or sheep-raising areas
 - Peripheral eosinophilia
 - Arteriovenous malformations
 - Recurrent epistaxis
 - Positive family history for hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber syndrome)
 - Cutaneous telangiectasia
 - Catamenial hemoptysis
 - Occurs with onset of menses
 - Factitious hemoptysis, a form of Munchausen syndrome
 - A consideration in adolescents with unusual or perplexing symptoms and normal findings
 - Has been reported in children who had undergone numerous invasive procedures and were biting their oral mucosa to simulate hemoptysis

Preexisting medical conditions

- CF
 - The most common chronic disease associated with hemoptysis

- Hemoptysis usually begins in the second or third decade of life and ranges from the production of blood-tinged sputum with excessive coughing to massive bleeding.
- Massive hemoptysis has an annual incidence of 1% among patients with CF and carries a high mortality rate.
- Bronchiectasis
 - The number of children with bronchiectasis has decreased because of the decline of tuberculosis and the use of effective vaccines against measles and pertussis.
 - Children with immunodeficiencies, recurrent aspiration, and ciliary dyskinesias may develop bronchiectasis.
 - Most have a history of a chronic productive cough with purulent sputum and changes on the lung examination preceding the onset of hemoptysis.
- Congenital heart diseases becoming a less common cause of hemoptysis because of advances in corrective cardiac surgery.
 - Seen with Eisenmenger complex and pulmonary venous congestion
- Primary or secondary pulmonary hypertension can lead to hemoptysis as a result of thromboembolic events.
- Right-ventricular outflow obstruction with increased bronchial arterial circulation
 - Hemoptysis is due to hemorrhage from enlarged and tortuous bronchial arteries.
- Pulmonary vascular obstructive disease
 - Hemoptysis occurs because of pulmonary hypertension as well as thrombosis.
 - These vascular changes take years to develop and are usually first observed in adolescents.
- Less common causes in children with a preexisting medical problem
 - Sickle cell anemia
 - Acute chest syndrome or pulmonary infarction
 - Aspergillosis in association with CF or asthma
 - Peripheral eosinophilia and fungi seen on Gram stain of sputum

LABORATORY EVALUATION

- Laboratory tests should be depend on findings at history and physical examination.
- Arterial blood gas measurement if the patient has a compromised airway
 - May aid decisions about need for intensive care
- Urinalysis or specific serologic markers
 - To determine whether the child has an immunologic disease involving the basement membranes of both the kidneys and the lungs
- Complete blood count with eosinophil count
 - To differentiate bacterial from parasitic pneumonia

- Clotting studies
 - Routinely ordered, but invariably normal
 - Bleeding disorders generally do not cause spontaneous hemoptysis.
- Skin tests
 - Should always be performed for suspected mycobacteria
 - Other skin tests, or serologic testing for fungi or other infectious agents, should be guided by clinical acumen.
- Pulmonary fluid culture
 - If sputum is produced or bronchoscopy is performed, it should be cultured and examined for:
 - Bacteria
 - Fungi
 - Ova
 - Parasites
 - Mycobacteria
 - Should be stained for the presence of hemosiderin-laden macrophages
- If warranted, early-morning gastric aspirates can be cultured and stained for microorganisms and macrophages.

IMAGING

- The history and physical examination should produce a tentative diagnosis that guides what imaging studies or procedures are needed to reach a definitive diagnosis.
- Chest radiography should be done if the child is stable.
 - Any abnormality on a chest film should be considered as a potential source for the hemoptysis.
 - A normal radiograph does not exclude the thorax as the source of bleeding.
 - In approximately one-third of children with hemoptysis, initial chest radiographic examination reveals no abnormality.
 - Significant findings on chest film include:
 - Hilar adenopathy
 - Air-fluid level in an abscess
 - Mass
 - Cavitory lesion
 - Mediastinal widening
 - Alveolar infiltrates
 - A common finding in children with autoimmune diseases that involve the lungs
 - Thickening of the bronchial walls with ring shadows and tramlines suggests bronchiectasis.
 - If a foreign body is suspected, views that may help localize the foreign body include:
 - Inspiratory and expiratory films
 - Left and right lateral decubitus films
 - Fluoroscopy

- If a foreign body is causing airway obstruction, then the side of the thorax that does not deflate normally on expiration or when dependent is the side with the foreign body.
- Chest radiography may reveal nothing abnormal if:
 - The foreign body is embedded in the mucosa of the airway.
 - Obstruction is partial.
- The chest radiograph is normal in 25% of children with bronchial foreign bodies and >50% of children with tracheal foreign bodies.
 - Because only 10% of aspirated foreign bodies are radiopaque, a normal chest radiograph does not preclude aspiration.
- Additional imaging studies depend on the presumptive diagnosis.
 - Computed tomography (CT)
 - If the chest radiographic examination is normal or does not add any information to that obtained from the history and physical examination, CT can:
 - Identify airway abnormalities
 - Elucidate abnormalities seen on chest radiographs
 - Define mediastinal structures
 - Detect parenchymal disease
 - Help categorize congenital pulmonary malformations and pulmonary vasculitis syndromes
 - Provide a road map for subsequent bronchoscopy
 - High-resolution CT has replaced bronchography for diagnosing bronchiectasis.
 - Magnetic resonance imaging (MRI) is appropriate for:
 - Evaluating possible congenital vascular malformation
 - Differentiation of structures within the mediastinum and hilum
 - The advantages of MRI do not outweigh its disadvantages, especially if excessive respiratory motion is present or the child's condition is unstable.

DIAGNOSTIC PROCEDURES

- Indications for bronchoscopy include:
 - A diagnosis that is in question
 - Massive hemoptysis
 - Incomplete response to therapy
- Timing and need for bronchoscopy, either rigid or flexible, depend on:
 - Stability of the child's condition
 - Suspected cause of the hemoptysis

- Not every child with hemoptysis needs bronchoscopy.
 - Hemoptysis rarely is the primary indication.
 - If hemoptysis resolves rapidly and completely after medical therapy, bronchoscopy is not needed.
- No studies have compared the use of fiberoptic versus rigid bronchoscopy for evaluating hemoptysis in either adults or children.
 - Fiberoptic bronchoscopy may be used for initial evaluation.
 - If an anatomic lesion or foreign body is discovered, rigid bronchoscopy will be needed.
 - Both instruments can be used to:
 - Administer therapeutic agents to the airways
 - Sample bronchial fluids
 - Take biopsy samples
 - With the rigid bronchoscope, the bronchoscopist has complete airway control and can:
 - Suction through a larger channel
 - Sample suspicious lesions
 - Insert packing material to tamponade the bleeding
 - Remove foreign bodies from the airway (preferred instrument for this purpose)
 - With the fiberoptic bronchoscope:
 - General anesthesia is not required.
 - The scope usually is passed transnasally (so that upper airways can also be examined).
 - The scope can be easily maneuvered into the upper lobes and more distal airways.

TREATMENT APPROACH

- Treatment for hemoptysis is typically directed at the underlying disease process.

SPECIFIC TREATMENT

- CF
 - Mild hemoptysis can be treated with conservative medical therapy, which includes:
 - Bed rest
 - Intravenous or oral antibiotics
 - Withholding of chest physiotherapy
 - Administration of vitamin K
 - Massive or recurrent hemoptysis in CF and other diseases is now treated with bronchial artery embolization.
 - Despite a moderately high rate of recurrent bleeding, embolization can relieve symptoms for a significant period.
- Bronchiectasis
 - Management is similar to that for CF.

- Treatment of acute exacerbations of IPH includes:
 - High-dose oral or intravenous corticosteroids
 - Supportive care for acute bleeding into the lungs
 - Controversy exists regarding the need for long-term immunosuppressive therapy.
 - Most clinicians caring for children with IPH use azathioprine, chloroquine, or cyclophosphamide to help maintain normal lung function and prevent further episodes of hemoptysis.
- Heiner syndrome
 - Although the mechanism whereby milk causes multisystem damage is unclear, elimination of milk from the diet results in dramatic improvement.

WHEN TO REFER

- If evidence for aspiration is definitive, the child should be referred to a pediatric surgeon or otolaryngologist experienced in retrieving foreign bodies for rigid bronchoscopy.
- If the diagnosis is uncertain, the child should be referred to a pediatric pulmonologist or other clinician skilled in the use of the fiberoptic/rigid bronchoscope to determine whether foreign body is present.
- Before bronchial artery embolization, the child should be evaluated by a team consisting of a pulmonologist, thoracic surgeon, and interventional radiologist.

WHEN TO ADMIT

- Evidence of hemodynamic instability
- Mental status changes
- High suspicion of tuberculosis
- Known heart disease
- Chronic lung disease (eg, CF, ciliary dyskinesias, immunodeficiencies)
- High suspicion of pulmonary neoplasm
- Sickle cell anemia, vasoocclusive crisis, or acute chest syndrome
- Inability to protect airway
- Risk of pulmonary embolism
- Lung abscess
- Children <1 year of age
- Foreign body aspiration
- Pulmonary hypertension

FOLLOW-UP

- Children with mild hemoptysis who are not hospitalized need close outpatient follow-up.

PROGNOSIS

- Prognosis depends on the underlying cause of hemoptysis.

Henoch-Schönlein Purpura

DEFINITION

- Henoch-Schönlein purpura (HSP) is the most common form of vasculitis in children.
- A small-vessel vasculitis mediated by immunoglobulin (Ig) A-containing immune complexes and characterized by non-thrombocytopenic purpura, abdominal pain, arthralgias, and renal disease
- Diagnostic criteria published in 1990 by the American College of Rheumatology state that if ≥ 2 of the following are present, sensitivity and specificity for HSP are $>87\%$.
 - Palpable purpura
 - Initial presentation at ≤ 20 years
 - Bowel angina
 - Typical biopsy findings

EPIDEMIOLOGY

- Incidence
 - Annual incidence in the United Kingdom: ~ 20.4 per 100,000 children
- Age
 - HSP mainly affects young children.
 - Peak incidence at 4–6 years of age
- Sex
 - 1.5:1 male-to-female ratio
- Geographic distribution
 - HSP is more common in Europe and Asia than in the US.
- Seasonality
 - More prevalent during the winter and spring

RISK FACTORS

- In $\geq 30\%$ of cases, an upper respiratory infection precedes the onset of symptoms.
- Other conditions that can precipitate HSP
 - Infections
 - Drug allergies
 - Insect bites
 - Vaccines
- Cases have been reported in children with C2 and C4 complement deficiencies.

SIGNS AND SYMPTOMS

- Cutaneous manifestations
 - 50% of patients have a macular-petechial rash.
 - Symmetric
 - Sometimes purpuric
 - Localized predominantly in the extensor surface of the lower extremities, forearms, and buttocks; tends to spare the trunk

- Lesions tend to fade with time, but new lesions appear for up to 3 months after initial presentation.
- Nonpitting edema of the scalp, hands, and feet in 30–70%
- Joint manifestations in 60–80% patients
 - Knees, ankles, wrists, and fingers are most commonly affected.
 - Joints are usually tender and swollen.
 - Symptoms resolve without residual deformity.
- Gastrointestinal manifestations in 50–70%
 - Higher incidence in patients with renal involvement
 - Intermittent colicky abdominal pain, vomiting, or gastrointestinal bleeding are most common.
 - Up to 5% develop intestinal infarction, perforation, or intussusception.
- Renal involvement in 20–50%
 - Responsible for long-term morbidity in affected patients
 - HSP nephritis usually coincides with or follows cutaneous manifestations.
 - Nephritis usually presents within 4 weeks of onset of joint or gastrointestinal manifestations.
 - Spectrum of renal involvement is broad and may include:
 - Microscopic hematuria (transient or persistent)
 - Macroscopic hematuria (initial or recurrent)
 - Proteinuria
 - Nephritic syndrome
 - Nephritic-nephrotic syndrome
- Testicular swelling and tenderness in up to 35% of male patients
 - If present, a thorough evaluation is necessary to rule out testicular torsion.
- Pulmonary hemorrhage and central nervous system involvement have been described.

DIFFERENTIAL DIAGNOSIS

- In a child with acute purpuric and petechial eruptions, clinicians must ensure that the differential diagnosis is kept broad.
- Possible diagnoses include, but are not limited to:
 - Acute bacterial infections (invasive meningococcal disease)
 - Rocky Mountain spotted fever
 - Toxic shock
 - Enteroviral infections
 - Endocarditis
 - Idiopathic thrombocytopenic purpura
 - Parvovirus B19
 - Kawasaki disease
 - Acute hepatitis A

- Differential diagnosis for hematuria is wide and can range from very benign to life threatening.
 - Normal activities, such as bike riding or snowboarding, can cause benign hematuria.
 - Important distinction is whether proteinuria is also present with hematuria.
 - Patients without protein in the urine are more likely to have:
 - Kidney cysts
 - Hypercalciuria
 - Kidney stones
 - Thin basement membrane syndrome
 - When proteinuria is also found, the following should be considered:
 - Poststreptococcal acute glomerulonephritis
 - IgA nephropathy
 - Systemic lupus erythematosus
 - Alport syndrome

DIAGNOSTIC APPROACH

- Diagnosis of HSP is based on clinical findings.
- Hematuria is defined as >5–10 erythrocytes per high-power field from a freshly voided centrifuged midstream urine sample.
 - Hematuria should persist for ≥ 1 month to merit a workup.

LABORATORY FINDINGS

- In general, complete blood count, platelet count, coagulation studies, and complement levels are normal.
- Serum albumin and renal function are usually normal.
 - Vary according to the degree of renal involvement
- IgA levels may be transiently elevated in 50% of patients with HSP.
- Urinalyses obtained at various times in the disease process may reveal:
 - Hematuria
 - Proteinuria

DIAGNOSTIC PROCEDURES

- Renal biopsy is not indicated in all patients with a diagnosis of HSP.
 - It should be considered in patients with:
 - Significant proteinuria for ≥ 1 month
 - Renal insufficiency
 - Hypertension
 - Nephrotic syndrome

TREATMENT APPROACH

- Once the diagnosis of HSP is established, supportive care is the most important first step.
- Partnership between primary care physician and nephrologist ensures a balance of safety and efficacy.
- Careful attention to the following will be the cornerstone of treatment for most patients.
 - Nutrition
 - Volume status
 - Vital signs
 - Laboratory data (complete blood count, kidney function, electrolytes)
- Specific therapy for HSP remains controversial.
- Children who do not show any urinary abnormalities within 6 months of diagnosis do not develop chronic kidney disease (CKD).
 - Therefore, steroids or other immunosuppressants are not advised for this group.
- Children who show only isolated hematuria or proteinuria have a very low risk of CKD (1.6%).
 - This group should receive supportive care only and not more aggressive treatment.
- Patients who have nephritic or nephrotic syndrome have a much higher risk of CKD (10–19.5%).
 - This group merits serious consideration for aggressive therapy.
 - Girls are especially at risk of CKD (2.5 times higher than their male counterparts) and will likely benefit most of all from therapy.

SPECIFIC TREATMENTS

Steroids

- Long-term follow-up of 219 patients (83 children <16 years and 136 adults) with biopsy-proven HSP found that:
 - 60% of children and 72% of adults had been treated with steroids.
 - 14% of children and 22% of adults had received immunosuppressants.
 - Use of steroids or immunosuppressants failed to show any protective influence over supportive care.
 - 7% of these children ended up receiving dialysis after a mean follow-up of 6.7 years.
 - Girls were at higher risk of eventual dialysis.
- Use of steroids in patients with HSP should be decided on individual bases; cases considered for steroid treatment should be referred to nephrologists.

- Steroids for extrarenal manifestations may be of use.
 - Randomized, double-blind, placebo-controlled trial of early steroid therapy that followed patients for 6 months
 - Of the 171 patients who were included, 84 were treated with prednisone and 87 received placebo.
 - Endpoints were renal involvement at 1, 3, and 6 months and healing of extrarenal symptoms.
 - Use of prednisone (1 mg/kg/day for 2 weeks, with weaning over the subsequent 2 weeks) was effective in reducing the intensity of abdominal pain and joint pain (4.6 vs 7.3; $P = 0.030$).
 - Prednisone did not prevent development of renal symptoms, but it was effective in treating them.
 - Renal symptoms resolved in 61% of prednisone recipients and 34% of placebo recipients.
 - Conclusion: general use of prednisone in HSP is not supported, but patients with disturbing symptoms may benefit from early treatment.
 - Prednisone reduces extrarenal symptoms and is effective in altering, but not preventing, the course of renal involvement.

Fish oil, enalapril, and angiotensin-converting enzyme (ACE) inhibitors

- Fish oil and enalapril for hypertension, hematuria, and proteinuria
 - Children in a study were given 1000 mg fish oil twice daily and enalapril 2.5–10 mg/day.
 - Enalapril was subsequently stopped in all patients within 1 year.
 - 6-month follow-up off ACE inhibition but on fish oil
 - Renal function remained the same (mean creatinine level, 0.6 mg/dL) before and after treatment.
 - Hypertension (135/82 vs 100/54; $P < 0.05$) remained better controlled.
 - Proteinuria (1041 mg/day vs 104 mg/day; $P < 0.05$) remained minimal.
 - Conclusion: this case series was very small, but fish oil is a benign treatment that may provide other added benefits, such as reduction of hypertriglyceridemia.
 - Fish oils (omega-3-acid ethyl esters) have been shown to be promising in IgA nephropathy, which many researchers believe is part of the spectrum of disease related to HSP.
 - Antiinflammatory and immune-modulating effects of fish oil have been demonstrated in other studies.
- ACE inhibitors are also indicated for control of hypertension, especially for patients with proteinuria.
 - ACE inhibitors are contraindicated during pregnancy.
- Cyclosporine and prednisone, plasmapheresis, tonsillectomy, dapson, and cyclophosphamide have been tried, with varying degrees of success.
 - These approaches have the possibility of toxicity and lack verification.

WHEN TO ADMIT

- Toxic appearance (febrile, lethargic, hypotensive, or hypertensive, with altered mental status or “not acting themselves”)
- Abdominal pain may indicate acute appendicitis, intussusception, small-bowel obstruction or infarction, or pain caused by HSP.
 - Obtaining a surgical consultation is advisable if abdominal pain is particularly severe or out of proportion to findings on physical examination.
- A significant reduction in urine output for age and weight or inability to keep fluids down
- Any alteration from normal in the patient’s kidney function (blood urea nitrogen or creatinine)
- Given that the presenting rash with HSP may be the manifestation of many other very severe diseases, a short admit in all but the most healthy looking patients may be prudent.
- Any child not able to communicate (infants or mentally handicapped patients) should be admitted for close observation.

WHEN TO REFER

- Significant and persistent signs of kidney inflammation (nephritic or nephrotic syndrome)
- Acute kidney injury (elevation in blood, urea, nitrogen or creatinine levels) should be referred to a nephrologist.

FOLLOW-UP

- Patients must be monitored for changes in renal function and for hypertension.

COMPLICATIONS

- 2–5% of patients with renal involvement progress to end-stage renal disease.

PROGNOSIS

- HSP nephritis
 - When mild, tends to resolve without any particular intervention
 - 2–5% of patients with renal involvement progress to end-stage renal disease.
- Predictors of poor renal prognosis
 - Abnormal creatinine clearance at 3 years after onset
 - Ultrastructural abnormalities in the renal biopsy

Hepatitis

DEFINITION

- *Hepatitis* describes inflammation of the liver and does not imply a cause.
 - Hepatitis in the pediatric age group may be viral, autoimmune, metabolic, or drug related.
- *Fulminant hepatic failure* is hepatic encephalopathy within 8 weeks of onset of illness.
 - Definition is problematic in children because:
 - It is difficult to detect encephalopathy in infants and young children.
 - Encephalopathy may arise late or not at all.
 - In children, fulminant hepatic failure can be defined as lack of preexisting liver disease and severe impairment of hepatic function evidenced by prothrombin time >4 seconds over control values and unresponsive to large doses of vitamin K.

EPIDEMIOLOGY

Viral hepatitis

- Incidence
 - >16,000 cases of viral hepatitis are reported annually to the Centers for Disease Control and Prevention.
 - Additional unrecognized anicteric cases occur, especially in the pediatric population, in which the anicteric/icteric case ratio is thought to approach 10:1.

Hepatitis A virus (HAV)

- HAV is a 27-nm RNA virus that is a member of the picornavirus group.
- Prevalence
 - Antibody to hepatitis A is present in 33% of the US adult population.
- Transmission is predominantly by the fecal-oral route.
 - Saliva and urine are potentially important vehicles, particularly among siblings.
 - Other identified causes for the acquisition of type-A infection include:
 - Contaminated shellfish
 - Polluted water
 - Travel to endemic areas
 - Parenteral transmission is possible but uncommon.
- Children with acute HAV may be completely asymptomatic, but infectious.
- Incubation period is 15–40 days.

Hepatitis B virus (HBV)

- HBV is a common, highly infectious virus of the Hepadnaviridae family.
- Age
 - In highly endemic areas, acquired at a very young age
 - Age at acquisition is the major determinant of chronicity.

- In low-prevalence countries, HBV infection occurs more often in adolescents and occurs sporadically.

Prevalence

- Approximately 90% of children who acquire HBV as neonates will develop chronic hepatitis.
 - Only 20% of children and 10% of adults follow the same course.

Transmission

- More likely (up to 90%) if mother is hepatitis B e antigen (HBeAg) positive
 - Less likely (20%) if mother is HBeAg negative
 - Occurs through contact with:
 - Blood
 - Vaginal and menstrual fluids
 - Semen
 - The virus is stable on environmental surfaces for at least 7 days.
 - Horizontal transmission
 - Most frequent route in hyperendemic areas (Asia, Africa, Southern Europe, Latin America) perinatally or in early childhood
 - Uncommon in early childhood from infectious siblings and among institutionalized patients
 - Improperly sterilized syringes and nosocomial transmission are also means of acquisition in some parts of Africa and Asia.
 - Fulminant hepatitis has been reported if the mother is HBeAg negative.
 - The mechanism is not clear.
 - Thought to be the result of selection of more potent mutant viruses
 - Maternal antibody to HBeAg does not prevent perinatal transmission.
 - Risk of infection to infant seems to be markedly increased (65–100%) if the mother has had clinical hepatitis in the third trimester.
 - Principal route of infection with HBV is at birth by microtransfusions or swallowing blood and genital secretions.
- Incubation period is 50–180 days.

Hepatitis C virus (HCV)

- HCV, recognized in 1989, is a single-stranded RNA virus of the Flaviviridae family.
- Prevalence
 - Seroprevalence of HCV in the US is estimated at 1.8%.
 - In children, the seroprevalence rate for those without known risk factors is:
 - 0.2% for those <12 years of age
 - 0.4% for those 12–19 years of age

- Responsible for the majority of posttransfusion non-A, non-B hepatitis
 - Before screening of donor blood in 1990, most children were infected by parenteral exposure to contaminated blood and blood products.
 - Since screening, risk of HCV infection has been reduced to 0.004–0.0004% per unit transfused.
- The major cause of new pediatric HCV infection is perinatal transmission.
 - Overall risk of transmission is 6% from HCV antibody-positive mothers.
 - Risk is minimal when the mother is HCV RNA negative but higher when mothers are coinfecting with HIV.
 - A recent European multicenter study showed no increase in transmission of HCV from HCV-HIV-coinfecting mothers to their infants.
 - A possible explanation is that effective highly active antiretroviral therapy of coinfecting women led to reduced immunosuppression and reduced maternal viral load.
 - This study also found doubling of the risk of HCV infection in female offspring.
- Horizontal transmission from parent to child, sibling to sibling, and via sexual transmission is extremely low.
- Incubation period is 20 to 90 days.

Hepatitis D virus (HDV)

- HDV, discovered in 1977, is a defective virus that requires replication of HBV for its own replication.
- Its epidemiologic mechanism is parallel to that for HBV infection.
- Prevalence
 - Significantly decreased with better control of HBV infection
- Replication occurs in the liver.
- Pathologic effects are limited to liver.
- Hepatitis D antigen can be found in both liver and serum of individuals with the disease.
- Infection may occur as a coinfection with chronic HBV or as acute superinfection of HBV.
 - In both cases, it causes a more severe illness, with significant morbidity and mortality.
- HDV may be transmitted perinatally with HBV.

Hepatitis E virus (HEV)

- HEV is a 27- to 34-nm single-stranded RNA virus.
- Only imported cases have been identified in the US.
 - Cause of epidemic, enteric transmitted hepatitis in India, Pakistan, Nepal, Russia, China, Algeria, Central Africa, Peru, and Mexico

- Illness usually occurs in areas where the water supply is contaminated by feces.

Hepatitis G virus (HGV)

- HGV, identified in 1995, is an RNA virus of the Flaviviridae family and a distant relative of HCV.
- Prevalence
 - Estimated to be 13.8% among US children, based on a small study of blood bank samples
- Mainly transmitted parenterally through blood, blood products, and intravenous drug use
- Infection may be self-limited, resulting in the production of neutralizing antibody to the E2 envelope protein, or may result in a carrier state.
- Virus does not replicate in the liver and does not appear to alter the course and severity in persons coinfecting with HCV, but it may be protective in HIV infection.

TT virus (TTV)

- TTV is a DNA virus discovered in 1997 in the sera of 3 of 5 patients with biopsy-proven hepatitis and elevated serum alanine aminotransferase levels.
- Prevalence (North America)
 - 10% in volunteer blood donors
 - 13% of commercial blood donors
 - 17% of intravenous drug users
- The role of TTV in the pathogenesis of acute and chronic liver disease is undetermined.

Autoimmune hepatitis (AIH)

- Approximately two-thirds of affected children are girls.
- 2 types
 - Type 1
 - More common
 - Usual onset in adolescence, early adulthood
 - Type 2
 - Less common
 - Usual onset in childhood, before adolescence

Metabolic liver disease

- α_1 -Antitrypsin (α_1 -AT) deficiency is the most common genetic cause of liver disease in children.
 - 1 in 1,600–2,000 live births
- Nonalcoholic steatohepatitis (NASH) generally occurs in prepubertal children (slightly more often in boys than girls), in association with:
 - Obesity (body mass index >30 kg/m²)
 - Insulin resistance
 - Hypertriglyceridemia

ETIOLOGY

■ Causes of hepatitis vary with:

- Age
- Geographic location
- Presence or absence of underlying illness

Types of pediatric hepatitis

■ Viral

- Specific hepatitis viruses (eg, HAV, HBV, HCV)
- Other viruses (eg, Epstein-Barr virus, cytomegalovirus, herpes simplex virus, coxsackievirus)

■ AIH

- A chronic necroinflammatory hepatitis characterized by:
 - Mononuclear cell infiltration of the portal tracts
 - Hypergammaglobulinemia
 - Non-liver-specific autoantibodies
 - Type 1: positive for antinuclear antibody (ANA) and anti-smooth-muscle antibody (SMA)
 - Type 2: positive for anti-liver-kidney microsomal antibodies (LKM)

■ Metabolic

- α_1 -AT deficiency
 - The most common genetic cause of liver disease in children
 - Results from the retention of the mutant α_1 -AT inside the endoplasmic reticulum of liver cells
 - May predispose certain individuals with homozygous phenotype ZZ to significant liver injury
- Wilson disease results from a mutation in the *ATP7B* gene, which encodes a copper-binding membrane protein regulating the transport of copper across cell membranes.
 - >200 mutations that may produce disease in humans have been identified.
 - Accumulation of copper in hepatocytes and other organs results in a constellation of clinical symptoms, including:
 - Hepatitis
 - Neuropsychiatric disease
 - Kayser-Fleischer rings in the Descemet membrane of the cornea
- Tyrosinemia
 - Deficiency in fumarylacetoacetate hydrolase leads to an accumulation of intermediary toxic metabolites, such as maleylacetoacetate and fumarylacetoacetate.
 - Metabolites are thought to cause hepatorenal damage and eventual hepatocellular carcinoma.
- Hereditary fructose intolerance (HFI)
 - Absence of the enzyme aldolase-B
 - Results in the build up of fructose-1-phosphate, which inhibits gluconeogenesis and glycolysis

- Progressive familial intrahepatic cholestasis (PFIC) type 1, or Byler disease
 - Caused by a mutation in the gene *FIC1*, which codes for a P-type adenosine triphosphatase involved in aminophospholipid transport
 - Mechanism by which cholestatic injury occurs in this condition is to be determined.
 - PFIC type 2 is caused by a mutation in the gene encoding for the main adenosine triphosphate-dependent bile acid pump on the canalicular membrane.
 - PFIC type 3 is caused by a mutation in the gene encoding the *MDR* protein, which is a phospholipid flippase also located on the canalicular membrane.
 - PFIC types 1 and 2 cause cholestatic liver disease in infancy.
- Inborn errors of bile acid metabolism lead to severe cholestatic liver disease, necessitating early recognition and treatment.
- Alagille syndrome, or paucity of the intrahepatic bile ducts
 - Caused by a mutation in the human *jagged 1* gene
 - Approximately 50% of patients inherit the disease in an autosomal dominant manner.
 - Others have spontaneous mutations.
 - Multiple mutations have been identified, but genotype-phenotype correlations are more difficult to determine.
- NASH is associated with obesity, but most obese children do not have NASH.
 - Other factors, unidentified as yet, must be involved.

Fulminant hepatic failure

- Acetaminophen toxicity is the most common cause of fulminant hepatic failure in the US.
- In infancy, metabolic disorders may cause fulminant hepatic failure.
 - Galactosemia
 - HFI
 - Tyrosinemia
 - Neonatal hemochromatosis
- See the table Diagnostic Investigations for Liver Disease for appropriate investigations.
- In older children, the following should be considered in the etiology of fulminant hepatic failure.
 - Wilson disease
 - Autoimmune hepatitis, particularly type 2
 - Medications
 - Toxins

Diagnostic Investigations for Liver Diseases

Disease	Investigation	Interpretation
α_1 -AT deficiency	Serologic Pi type	<ul style="list-style-type: none"> • MM (normal) • ZZ (α_1-AT deficiency)
	Serum α_1 -AT	<50 mg/dL
	Liver biopsy	PAS-positive diastase resistant granules in the hepatocytes endoplasmic reticulum
Tyrosinemia	Urinary succinyl acetone	Elevated
	α -fetoprotein	<ul style="list-style-type: none"> • Increased (indicative of immature hepatocytes) • May be increased in many types of neonatal hepatitis but significantly raised in tyrosinemia
PFIC 1, 2, 3	Serum bile acids	Increased
PFIC 1, 2	GGT	Low
PFIC 3	GGT	High
Bile acid metabolic disorder	Fast atom bombardment mass spectroscopy of urine	Typical profiles
	Serum bile acids	Low
	GGT	Low
Hereditary fructose intolerance	Urine reducing substances	Positive when ingesting fructose
	Gene testing	22 Mutations for HFI, 70% of patients have two mutations in exon 5 (<i>A149P, A174D</i>)
Cystic fibrosis	Sweat chloride test	Sweat chloride >60 mEq/L
Autoimmune hepatitis		ANA; anti-SMA or anti-LKM
Neonatal hemochromatosis	Serum transferrin	Low (reflects low functioning liver cell mass)
	Serum ferritin	Markedly increased (nonspecific)
	MRI	Siderosis of pancreas, myocardium
	Buccal biopsy	Siderosis of salivary glands
Niemann-Pick type C	Liver biopsy (electron microscopy)	Whirled inclusions of sphingomyelin in lysosomes
	Skin fibroblast culture	Measurement of sphingomyelinase activity

Abbreviations: α_1 -AT, α_1 -antitrypsin; ANA, antinuclear antibody; anti-LKM, anti-liver-kidney microsomal antibodies; anti-SMA, anti-smooth-muscle antibody; GGT, γ -glutamyl transferase; HFI, hereditary fructose intolerance; MRI, magnetic resonance imaging; PAS, periodic acid-Schiff; PFIC, progressive familial intrahepatic cholestasis.

SIGNS AND SYMPTOMS

- Evaluation of a child with hepatitis depends primarily on:
 - Age of the child
 - Nature of the symptoms
- Common presentations include:
 - Jaundice
 - Incidental finding of elevated liver enzymes during routine workup
 - Fulminant hepatic failure
- Clinical syndromes of viral hepatitis vary from asymptomatic to fulminant hepatic failure, depending on the virus and host factors.
 - Acute viral hepatitis may also progress to chronic liver disease, particularly with HBV and HCV.
 - See table Clinical Features of Acute Viral Hepatitis.

Jaundice in newborns and infants

- Infants with jaundice and elevated liver enzymes may:
 - Be otherwise well
 - Have failure to thrive
 - Display signs of liver decompensation
- The primary care physician must determine:
 - Family history of jaundice, liver, or metabolic disease
 - Maternal exposure to drugs and toxins
 - Maternal serologic status for hepatitis A, B, and C
- Maternal illnesses during pregnancy suggesting the presence of an in utero infection should be noted, particularly if the infant is malnourished.
- A complete dietary history to determine fructose ingestion in the infant (either through food or medication) is required if HFI is suspected.
- Examination may reveal hepatosplenomegaly, icterus, and little else.

Child with jaundice

- HAV infection is heralded by an abrupt onset associated with:
 - Fever
 - Malaise
 - Anorexia
 - Nausea
 - Vomiting
 - Upper abdominal discomfort
 - Darkening of the urine and enlargement and tenderness of the liver
 - Jaundice (infrequent in young children)
 - Disease is rarely fulminant.
 - A small percentage of patients with HAV may have a relapsing or protracted course.

■ HBV

- Onset is usually insidious.
- Extrahepatic manifestations, such as skin rash and arthralgia, are common and may be prodromal.
- Younger children may be asymptomatic.
- Duration of illness is usually 4–6 weeks.
- >80–90% of children recover without sequelae.
- Fulminant hepatitis is seen in infants born to HBeAg-positive mothers with low levels of HBV DNA.
- Liver cirrhosis is encountered in 3–5% of children with chronic HBV.
- Acute HCV infection is asymptomatic in most children.
 - Both acute liver failure and cirrhosis have been reported in infancy.
 - 2 characteristic clinical features of HCV infection are:
 - Fluctuation in the serum aminotransferase concentrations
 - Progression to chronicity in 50–90% of patients
 - Most patients remain asymptomatic without stigmata of chronic liver disease.
 - Liver histologic test shows mild to moderate hepatitis.
- Acute HDV infection in a child who is a chronic HBV carrier may produce a severe episode of hepatitis with fulminant hepatic failure or chronic hepatitis.
- HEV is similar clinically to HAV.
 - Its most unusual clinical feature is a high mortality rate in pregnant women (approximately 10%).
- The mode of presentation of AIH is highly variable.
 - Hepatomegaly, splenomegaly, and jaundice are common.
 - AIH is strongly associated with ulcerative colitis and may precede or follow the colitis.
 - Associated extrahepatic manifestations include:
 - Nephrotic syndrome
 - Autoimmune thyroiditis
 - Behçet disease
 - Crohn disease
 - Insulin-dependent diabetes
 - Urticaria pigmentosa
 - Vitiligo
 - Hypoparathyroidism
 - Addison disease
 - Fibrosis may be seen to a variable degree.
 - True cirrhosis may be present.

Clinical Features of Acute Viral Hepatitis^a

		HAV	HBV	HCV
Characteristics	Age distribution	Children and young adults	All age groups	All age groups
	Route of infection	Predominantly fecal-oral route	Parenteral	Parenteral
	Incubation period (days)	15–40	50–180	20–90
	Onset	Acute	Insidious	Insidious
	Duration of clinical illness	Weeks	Weeks to months	Weeks to months
Virus Present	Feces	Late incubation, acute	May be present	Absent
	Blood	Late incubation, acute	Late incubation, acute, may persist for months	Present chronically
Signs and Symptoms	Fever	High, common early	Moderate, less common	Moderate, less common
	Nausea and vomiting	Common	Less common	Less common
	Anorexia	Severe	Mild to moderate	Mild to moderate
	Arthralgia or arthritis	Rare	Common	?
	Rash or urticaria	Rare	Common	?
Laboratory Findings	Aminotransferase elevation	1–3 weeks	Months	Fluctuates for months
	Bilirubin elevation	Weeks	May be months	Unusual
	HBsAg	Absent	Present	Absent
	Severity	Usually mild	Often severe	Usually mild
	Progression to chronic hepatitis	Rare	More common	High rate
	Immunity	Homologous, lifelong	Homologous, lifelong	Unusual
	Prevention	Immune serum globulin	Hyperimmune globulin; vaccine	Screen donor blood

Abbreviations: HAV, hepatitis A virus; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus.

■ Metabolic diseases

- NASH is seen in children with a significant number of risk factors, including:
 - Obesity (body mass index >30 kg/m²)
 - Many children are obese, but only a minority have NASH.
 - Diabetes
 - Insulin resistance
 - Hypertriglyceridemia

- HFI in the older child with an aversion to fructose-containing products who, after inadvertent ingestion, develops:
 - Vomiting
 - Elevation of serum aminotransferases

- To evaluate for drug or toxin-induced hepatitis, a complete medical history should be obtained for:
 - Prescribed medications
 - Herbal teas

- Poisons
- Wild mushrooms

DIFFERENTIAL DIAGNOSIS

Viral

- Specific hepatitis viruses
 - Such as HAV, HBV, HCV
- Other viruses
 - Such as Epstein-Barr virus, cytomegalovirus, herpes simplex virus, coxsackievirus

Autoimmune

- Type 1
- Type 2

Metabolic

- α_1 -AT deficiency
- Wilson disease
- HFI
- Tyrosinemia
- Galactosemia
- Progressive familial intrahepatic cholestasis
 - 3 types
- Alagille syndrome
- NASH

Drugs

- Anesthetics
- Anticonvulsants
- Antihypertensives
- Chemotherapeutics
- Diuretics
- Laxatives
- Many others

Fulminant hepatic failure

- Acetaminophen toxicity is the most common cause of fulminant hepatic failure in the US.
- In infancy, metabolic disorders may cause fulminant failure
 - Galactosemia
 - HFI
 - Tyrosinemia
 - Neonatal hemochromatosis
- See the table Diagnostic Investigations for Liver Disease for appropriate investigations.
- In children beyond infancy, the following should be considered in the etiology of fulminant hepatic failure.
 - Wilson disease
 - AIH, particularly type 2

- Medications
- Toxins

Newborns and infants

- Other conditions that should be considered in an infant with jaundice include:
 - α_1 -AT deficiency
 - Cystic fibrosis
 - Defects in amino acid synthesis
 - Organic acid synthesis and fatty acid oxidation
 - Glycogen storage disease
 - Niemann-Pick type C disease
 - The association of renal Fanconi syndrome and clotting abnormalities that are unresponsive to vitamin K therapy suggests tyrosinemia.
 - Neonatal hemochromatosis may present with hepatitis but often occurs with acute liver failure.
 - Patients with Alagille syndrome may have jaundice and hepatitis in the first 2 years of life.
 - The diagnosis is a clinical one based on the association of bile duct paucity together with ≥ 3 of the following.
 - Typical facies
 - Posterior embryotoxon (ophthalmologic examination)
 - Butterfly vertebrae (on chest radiograph)
 - Consistent cardiac disease (eg, pulmonary stenosis)
 - Renal disease
 - Other features include:
 - Markedly elevated γ -glutamyl transferase (GGT) level (eg, 800 IU/L)
 - Hypercholesterolemia
 - Growth retardation
 - Intracranial bleeding
 - Tyrosinemia
 - The usual presentation in infants is acute liver failure with pronounced coagulopathy.
 - Galactosemia exhibits in the neonatal period with:
 - Cholestatic jaundice
 - Hypoglycemia
 - Hepatitis
 - HFI manifests as:
 - Metabolic acidosis
 - Hypoglycemia
 - Liver failure
- ### Children
- Viral hepatitis, particularly HAV, HBV, HCV, and Epstein-Barr virus, should be actively sought in this age group.
 - HBV should be considered in the differential diagnosis of serum sickness–like illness.

- Wilson disease should be considered in assessment of pediatric liver disease, because of its variable presentation and availability of effective therapy.
 - Kayser-Fleischer rings and neurologic findings may be absent.
 - Ceruloplasmin may be normal in young children.
- AIH
 - Type 1 is characterized by the presence of ANA and anti-SMA.
 - Type 2 is characterized by the presence of anti-LKM.
- NASH
 - Fat in the liver associated with inflammation
 - Consider in prepubertal children with obesity

DIAGNOSTIC APPROACH

- Complete clinical history and thorough physical examination are important in making a timely diagnosis and preventing unnecessary investigations.

LABORATORY FINDINGS

Jaundice in newborns and infants

- Investigations in the infant in whom a cause of hepatitis is not obvious should include serologic testing for viruses and general investigations, such as:
 - Blood ammonia
 - Serum glucose
 - Blood gases with pH
 - Blood lactate
 - Urine metabolic screen and reducing substances
 - Erythrocyte galactose-1-phosphate uridyl transferase tests
 - Thyroid function tests
 - Serum and urine bile acid tests
 - More sophisticated tests are required for many metabolic and inherited disorders.

Child with jaundice

HAV

- Presence of IgM-class anti-hepatitis A coinciding with clinical symptoms confirms diagnosis of acute HAV.
 - HAV RNA can be detected in serum and stool as early as 2–3 weeks before acute illness.
 - HAV RNA can be detected in serum and stool up to 1 week after the onset of illness.
 - Recovery in the stool decreases as jaundice becomes evident.
 - HAV IgM antibody is short lived.
 - HAV IgG antibody is present at least 10 years after infection.
 - Probably confers lifelong immunity to the virus
 - Bilirubin level increases in both direct and indirect fractions but does not generally exceed 15 mg/dL.
- Generally, aminotransferase level elevation does not last >3 weeks.
 - Clinical and laboratory abnormalities do not generally persist beyond 4 weeks.

HBV

- Its double-stranded overlapping DNA codes for:
 - Surface antigen (HBsAg)
 - Core antigen (HBcAg)
 - HBeAg
 - DNA polymerase
- HBsAg has been found in all body secretions and excretions from infected persons.
- Presence of HBsAg in the serum implies HBV infection.
- First marker to appear; detected 2 weeks to 6 months after exposure
- Children with HBV infection are initially HBsAg and HBeAg positive.
- HBeAg reflects active viral replication and infectivity.
- During this immunotolerant stage, which may persist for years, viral replication and serum HBV DNA levels are very high.
 - Serum aminotransferase levels fluctuate and may be in the upper limit of normal range.
 - HBV aminotransferase elevation usually peaks approximately 1 month after the onset of illness.
- During childhood, conversion from HBeAg to anti-HBeAg may occur spontaneously, at a rate of 3% per year, although rates vary with the mode of acquisition.
- Seroconversion to anti-HBeAg is often preceded by a transient elevation in serum aminotransferases.
- After anti-HBeAg seroconversion, HBV DNA levels remain low or undetectable.
- Most children remain HBsAg positive, and this chronic carrier state is not generally associated with overt disease.
- Annual HBsAg clearance rate in chronic carriers is low (1–2%) and may be associated with persistence of HBV DNA.
- HBV DNA is detectable in serum very early in the infection, but its measurement is limited by the sensitivity of the techniques used.
 - Target amplification techniques, such as polymerase chain reaction (PCR), have a lower limit of detection of 100–400 copies/mL.
 - Signal amplification techniques such DNA hybridization assays and branched chain DNA assays are less sensitive.
 - Interassay variation is significant.
- Viral load from different assays cannot be compared directly.
- To standardize measurements, an international unit has been recently adopted, and most laboratories will report with the new unit in the near future.
- Anti-HBsAg confers immunity and indicates resolving or past infection.

- Anti-HBsAg is also seen after vaccination because the vaccine contains recombinant HBsAg.
- Presence of anti-HBcAg, which appears 3–5 weeks after HBsAg, implies exposure to the native HBV and can indicate ongoing or past infection, but does not appear after vaccination.

HCV

- Presence of antibodies to HCV implies exposure to native HCV virus but does not confer protective immunity.
- Most laboratories currently use third-generation enzyme-linked immunosorbent assay (ELISA) with >99% sensitivity and specificity.
- Recombinant immunoblot assay can be used when HCV infection is suspected but ELISA is negative or inconclusive.
- Both of these tests become positive weeks after exposure to the virus.
- Highly sensitive PCR assay becomes positive within days after exposure to the virus.
- Assays for viral detection may be quantitative or qualitative.
 - Quantitation is an important component of guiding therapy.
 - Quantitative assays are used more often.
- As with HBV infection, an international unit is being adopted to overcome variability between laboratories and commercially available assays.
- Vertically acquired infection is confirmed by:
 - Persistence of anti-HCV antibody beyond 18 months of age
 - Presence of HCV RNA in serum after the first 3 months of life
- PCR testing before this period is unreliable.

HDV

- A test for anti-HDV is commercially available.
- Evaluation for acute HDV is appropriate in a child with fulminant hepatic failure and HBV.

HEV

- Evaluation for acute HEV infection is appropriate in a child from a developing country with acute hepatitis.
- Cholestasis may be more common than with HAV.
- Elevation of serum aminotransferase levels is modest.
- Real-time PCR has recently been developed.

HGV and TTV

- Evaluation for HGV and TTV is not indicated outside of epidemiologic studies.
 - No clear evidence that they are pathogens
- Diagnosed by detection of HGV RNA and TTV DNA by PCR methods

AIH

- AIH should be excluded with serologic testing in all children with signs of acute or chronic liver disease and liver failure.
 - Routine investigations reveal hypergammaglobulinemia and increased ANA, SMA, or LKM antibody titers.
 - In 1999 the International Auto-Immune Hepatitis Group modified a scoring system to diagnose AIH in adults.
 - Useful in children, particularly when a GGT ratio was used instead of alanine aminotransferase/alkaline phosphatase ratio
 - Histologically, portal tracts are infiltrated by lymphocytes and plasma cells.
 - Inflammatory cells often infiltrate the parenchyma, accompanied by necrosis of cells at the periphery of the hepatic lobule (piecemeal necrosis).

Metabolic diseases

- No single test is available to diagnose Wilson disease.
 - The combination of ≥ 2 of the following is highly suggestive.
 - Decreased serum ceruloplasmin level (<20 mg/dL)
 - Elevated urinary copper excretion (>100 mcg/24 hours)
 - Elevated liver copper concentration (>250 mcg/g of dry weight)
 - Kayser-Fleischer rings
 - Genetic testing is available in some centers.

Drug or toxin-induced hepatitis

- Serum acetaminophen should be measured and appropriate therapy instituted immediately.
- Urine toxicologic screen should be performed when the index of suspicion is high.

Abnormal liver enzyme levels

- Systemic disorders may increase aminotransferase levels.
- Elevated levels of aminotransferases have been found in 32% of children with celiac disease.
 - Celiac screen should be performed in all children with unexplained elevation of serum aminotransferase levels after hepatologic causes have been excluded.

PFIC

- Types 1 and 2 and inborn errors of bile acid synthesis should be suspected in any child with:
 - Elevated serum bile acid levels
 - Low GGT level
 - Elevated aminotransferase levels
- Type 3 has a similar clinical picture, except that the GGT level is elevated and presentation may be delayed.

IMAGING

■ Ultrasonography

- In NASH, fatty liver can be identified on sonography by uniform or patchy increased echogenicity.

DIAGNOSTIC PROCEDURES

■ Liver biopsy is required:

- When chronic liver disease is suspected and cannot be diagnosed
- To determine the degree of inflammation and fibrosis, which may influence treatment
- Needle biopsy is usually adequate.
- Risks are low when clotting function is normal, ultrasonographic guidance is used, and the biopsy is performed by an experienced physician.
- The biopsy sample should be sent for histologic testing with additional stains (eg, copper, iron) if necessary.
- A small sample should be preserved in glutaraldehyde for electron microscopy if metabolic liver disease is suspected.
- If Wilson disease is suspected, hepatic copper should be quantified.
 - Obtaining a second biopsy core is usually necessary for this purpose.

SPECIFIC TREATMENTS

HAV

■ Vaccines

- 2 inactivated vaccines against HAV are licensed in the US for children age 1–18 years and adults.

- Twinrix, the HAB-HBV combination vaccine, is licensed for >18 years of age.
- Vaccine is given in a 2- or 3-dose schedule depending on the formulation (see table Recommended Doses and Schedules for Inactivated Hepatitis A Vaccines).
- Children with underlying liver disease should receive the HAV vaccination.
- Either pediatric formulation induces seroconversion rates >90% after the initial dose and 100% after the second dose.
- Indications for HAV vaccination
 - All children at 1 year of age
 - Catch-up immunization of unimmunized children 2–18 years of age
 - Especially with increase in incidence among children and adolescents
 - Travelers to endemic areas
 - Patients with chronic liver disease
 - Men who have sex with men
 - Users of injection and illicit drugs
 - Patients at high risk of exposure secondary to occupation
- No particular diet or restriction of activity appears to affect course or outcome of acute viral hepatitis.
- Return to school 1 week after onset of illness, provided that the child feels well, is recommended.
- Household contacts are already likely to be infected by the time of diagnosis.
 - Infection-control measures should be instituted, including:
 - Scrupulous hand washing
 - Use of disposable eating utensils until jaundice clears

Recommended Doses and Schedules for Inactivated Hepatitis A Vaccines^a

Age (yr)	Vaccine ^b	Hepatitis A Antigen Dose	Volume per Dose (mL)	Number of Doses	Schedule
1-18	Havrix	720 ELU	0.5	2	Initial and 6–12 mo later
1-18	Vaqta	25 U ^c	0.5	2	Initial and 6–18 mo later
≥19	Havrix	1440 ELU	1.0	2	Initial and 6–12 mo later
≥19	Vaqta	50 U ^c	1.0	2	Initial and 6–18 mo later
≥18	Twinrix ^d	720 ELU	1.0	3 or 4	Initial and 1 and 6 mo later OR Initial, 7 and 21–30 days followed by a dose at 12 mo

Abbreviation: ELU, enzyme-linked immunosorbent assay units.

^aFrom: American Academy of Pediatrics. Hepatitis A. In: Pickering LK, Baker CJ, Kimberlin DW, Long SS, eds. *Red Book: 2009 Report of the Committee on Infectious Diseases*. 28th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2009:332.

^bHavrix and Twinrix are manufactured by GlaxoSmithKline Biologicals; Vaqta is manufactured and distributed by Merck & Co, Inc.

^cAntigen units (each unit is equivalent to approximately 1 mcg of viral protein).

^dA combination of hepatitis B (Engerix-B, 20 mcg) and hepatitis A (Havrix, 720 ELU) vaccine (Twinrix) is licensed for use in people 18 years of age and older in a 3-dose schedule. Havrix 360 ELU in single-dose vials is licensed in the US but no longer available.

- Pooled serum Ig given within 2 weeks postexposure is effective in preventing symptomatic infection, as is immunization within an 8-day window period.
- Ig should be given to household contacts; institutional contacts, and persons exposed in common source outbreaks.
- Neonates born of infected mothers do not need special care if the mother is not jaundiced.
- Children traveling to endemic areas should be immunized prophylactically.
 - Vaccination is preferable.
 - If travel is imminent (in <1 month), then IgG may be substituted.

HBV

■ History of vaccination in the US

- In 1991 universal newborn infant HCV immunization
- In 1995 routine vaccination of all adolescents age 11–12 years
- In 1999 inclusion of children <18 years who had not been vaccinated previously
- These efforts resulted in a significant reduction of HBV in children.
- The rate of acute HBV infection in children and adolescents decreased by 89% during 1990–2002.
- Racial disparities in hepatitis B incidence have narrowed.
- A recent study showed that 40% of homeless inner-city children age 13–18 years had no record of HBV vaccination.
 - HBV vaccine must be administered on any chance encounter with such children.
- Persons who should receive HBV immunization:
 - All infants (infants of HBsAg-positive mothers require postexposure immunoprophylaxis with HBIG and vaccine)
 - Infants and children at risk of acquisition of HBV by person-to-person (horizontal) transmission should be immunized by 6–9 months of age.
 - Adolescents (special efforts should be made to vaccinate adolescents at high risk for HBV infection)
 - Users of intravenous drugs
 - Sexually active heterosexual persons with >1 sex partner in the previous 6 months or those with a sexually transmitted infection
 - Men who have sex with men
 - Health care workers at risk of exposure to blood or body fluids
 - Residents and staff of institutions for developmentally disabled persons
 - Staff of nonresidential child care and school programs for developmentally disabled persons, if attended by a known HBV carrier
 - Patients on hemodialysis
 - Patients with bleeding disorders who receive certain blood products

- Household contacts and sexual partners of HBV carriers
- Members of households with adoptees from countries where HBV infection is endemic and who are HBsAg positive
- International travelers who will reside for >6 months in an area of high endemic HBV and who otherwise will be at risk
- Inmates of long-term correctional facilities
- Detailed recommendations regarding doses and postexposure prophylaxis are provided in the tables Recommended Doses of Hepatitis B Vaccines and Guide to Postexposure Immunoprophylaxis of Unimmunized People to Prevent Hepatitis B Virus Infection.
- A neonate born to an HBsAg-positive mother or a mother who has had hepatitis B during pregnancy should be given:
 - 0.5 mL of HBIG intramuscularly within the first 12 hours of life *and*
 - 0.5 mL of HBV vaccine intramuscularly before hospital discharge but definitely within the first week of life *and*
 - 0.5 mL of HBV vaccine intramuscularly at 1 and 6 months
- Data linking breastfeeding to the acquisition of viremia are equivocal.
 - HBsAg-positive mothers whose infants have received immunoprophylaxis may breastfeed without risk of transmitting HBV.
- HBV immunization also protects against HDV infection.
- 2 treatments for HBV in children have been approved.
 - Interferon- α
 - May be given to children ≥ 1 year of age
 - Results in HBeAg seroconversion in 25–50% of children with chronic HBV
 - Effect on HBsAg clearance is poor, but serum aminotransferase levels and liver histologic results improve.
 - Lamivudine (3 mg/kg daily up to 100 mg/day)
 - May be given to children ≥ 3 years of age
 - Has been shown to produce HBeAg seroconversion in 22% of children versus 13% of placebo controls
 - Response is greatest in patients with an elevated alanine aminotransferase level.
 - Resistance rates in the first year of therapy were 19%.
 - Adefovir dipivoxil
 - Latest drug to be approved by the US Food and Drug Administration for HBV infection in adults
 - Currently being evaluated in pediatric trials
- Seroconversion may not be permanent; seroreversion may occur, particularly in the first year after therapy.
 - Newer nucleoside analogues and other families of drugs are available for treating HBV infection; resistance to each has developed after monotherapy.
 - The decision to treat should be made in conjunction with a pediatric hepatologist.

Recommended Doses of Hepatitis B Vaccines^a

Patients	Vaccine ^b		Combination Vaccine
	Recombivax HB ^c dose, µg (mL)	Engerix-B ^d dose, µg (mL)	Twinrix ^e
Infants of HBsAg-negative mothers and children and adolescents <20 yr of age	5 (0.5)	10 (0.5)	Not applicable
Infants of HBsAg-positive mothers (HBIG [0.5 mL] also is recommended)	5 (0.5)	10 (0.5)	Not applicable
Adults ≥20 yr of age	10 (1.0)	20 (1.0)	20 (1.0)
Adults undergoing dialysis and other immunosuppressed adults	40 (1.0) ^f	40 (2.0) ^g	Not applicable

Abbreviations: HBsAg, hepatitis B surface antigen; HBIG, hepatitis B immune globulin.

^a Modified from: American Academy of Pediatrics. Hepatitis B. In: Pickering LK, Baker CJ, Kimberlin DW, Long SS, eds. *Red Book: 2009 Report of the Committee on Infectious Diseases*. 28th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2009:344.

^b Both vaccines are administered in a 3-dose schedule; 4 doses may be administered if a birth dose is given and a combination vaccine is used to complete the series. Only single-antigen hepatitis B vaccine can be used for the birth dose. Single-antigen or combination vaccine containing hepatitis B vaccine may be used to complete the series.

^c Available from Merck & Co Inc.

• A 2-dose schedule, administered at 0 months and then 4 to 6 months later, is licensed for adolescents 11 through 15 years of age using the adult formulation of Recombivax HB (10 µg).

• A combination of hepatitis B (Recombivax, 5 µg) and *Haemophilus influenzae* type b (PRP-OMP) vaccine is recommended for use at 2, 4, and 12 through 15 months of age (Comvax). This vaccine should not be administered at birth, before 6 weeks of age, or after 71 months of age.

^d Available from GlaxoSmithKline Biologicals. The US Food and Drug Administration also has licensed this vaccine for use in an optional 4-dose schedule at 0, 1, 2, and 12 months for all age groups. A 0-, 12-, and 24-month schedule is licensed for children 5 through 16 years of age, and a 0-, 1-, and 6-month schedule is licensed for adolescents 11 through 16 years of age.

• A combination of diphtheria and tetanus toxoids and acellular pertussis (DTaP), inactivated poliovirus (IPV), and hepatitis B (Engerix-B 10 µg) is recommended for use at 2, 4, and 6 months of age (Pediatrix). This vaccine should not be administered at birth, before 6 weeks of age, or at 7 years of age or older.

^e A combination of hepatitis B (Engerix-B, 20 µg) and hepatitis A (Havrix, 720 enzyme-linked immunosorbent assay units [ELU]) vaccine (Twinrix) is licensed for use in people 18 years of age and older in a 3-dose schedule administered at 0 mo, 1 mo, and 6 or more months later. Alternately, a 4-dose schedule at days 0, 7, and 21 to 30 followed by a booster dose at 12 months may be used.

^f Special formulation for adult dialysis patients given at 0, 1, 2, and 6 months.

^g Two 1.0-mL doses given in 1 or 2 injections in a 4-dose schedule at 0, 1, 2, and 6 months of age.

HCV

- No vaccine is available for prevention of HCV.
- Natural infection does not protect from reinfection with the same or different genotypes.
- The most important strategies for controlling hepatitis C include:
 - Screening donor blood for anti-HCV
 - Identifying and educating of persons at risk
 - Establishing risk-minimization programs for intravenous drug users
- Screening should include:
 - Injection drug users
 - Patients receiving hemodialysis
 - Recipients of ≥1 unit of blood or blood products before 1992
 - Children with clinical non-A, non-B hepatitis

- Children >18 months of age born to mothers infected with HCV
- International adoptees born to high-risk mothers
- Patients with HCV infection should:
 - Avoid hepatotoxic medications and alcohol
 - Receive vaccination against HAV and HBV infections to prevent additional liver damage
- The American Association for the Study of Liver Diseases presents arguments for and against treatment of HCV infection in children.
 - On the basis of treatment trials in children, the US Food and Drug Administration has approved treatment of children with HCV age 3–17 years with a combination regimen of:
 - Interferon-α (subcutaneously 3 times per week)
 - Oral ribavirin
 - Side effects are better tolerated in children but require close monitoring.

Guide to Postexposure Immunoprophylaxis of Unimmunized People to Prevent Hepatitis B Virus Infection^a

Type of Exposure	Immunoprophylaxis ^b
Household contact of HBsAg-positive person	Administer hepatitis B vaccine series
Discrete exposure to an HBsAg-positive source ^c : <ul style="list-style-type: none"> • Percutaneous (eg, bite, needlestick) or mucosal exposure to HBsAg-positive blood or body fluids that contain blood • Sexual contact or needle sharing with an HBsAg-positive person • Victim of sexual assault/abuse by a perpetrator who is HBsAg positive 	Administer hepatitis B vaccine + HBIG; complete vaccine series Administer hepatitis B vaccine + HBIG; complete vaccine series Administer hepatitis B vaccine + HBIG; complete vaccine series
Discrete exposure to a source with unknown HBsAg status: <ul style="list-style-type: none"> • Percutaneous (eg, bite, needlestick) or mucosal exposure to blood or body fluids that contain blood with unknown HBsAg status • Victim of sexual assault/abuse by a perpetrator with unknown HBsAg status 	Administer hepatitis B vaccine series Administer hepatitis B vaccine series

Abbreviations: HBsAg, hepatitis B surface antigen; HBIG, hepatitis B immune globulin.

^a Modified from: American Academy of Pediatrics. Hepatitis B. In: Pickering LK, Baker CJ, Long SS, et al, eds. *Red Book: 2009 Report of the Committee on Infectious Diseases*. 28th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2009: 353.

^b Immunoprophylaxis should be administered as soon as possible, preferably within 24 hours after exposure. Studies are limited on the maximum interval after exposure during which postexposure prophylaxis is effective, but the interval is unlikely to exceed 7 days for percutaneous exposures and 14 days for sexual exposures.

^c If person previously was immunized with hepatitis B vaccine series, administer hepatitis B vaccine booster dose.

- Therapy should be supervised by persons who are experienced in treating children.
- Recently, a trial has evaluated pegylated interferon and ribavirin in children.
 - Sustained viral response was documented in 22 (47.8%) of 46 patients with genotype 1.
 - A multicenter, placebo-controlled trial of pegylated interferon with or without ribavirin is currently under way.

HEV

- Treatment of HEV infection is supportive.
- Development of recombinant peptide vaccines is under way.

AIH

- Prednisone can suppress activity in AIH.
 - Has side effects on growth
- Azathioprine, an immunosuppressive, is frequently added.
 - Allows a reduction in dose of or complete weaning from prednisone
- Cyclosporine or tacrolimus may be effective in patients who are refractory to azathioprine and steroids.
- Prednisone is initiated at a steady dose.
 - On improvement, prednisone dose may be tapered at weekly intervals to a dose that maintains remission.
- Azathioprine may be added after symptoms improve.
 - Monitor for azathioprine toxicity (eg, hematopoietic toxicity), particularly in patients with thiopurine S-methyltransferase deficiency.

■ Remission is defined as:

- Absence of clinical symptoms
- Aminotransferase level no more than 2 times normal
- Decreasing serum GGT level
- Resolution of aggressive histologic appearance on a liver biopsy specimen

■ Duration of therapy once remission is achieved is controversial.

- Clinical remission generally occurs within 3–6 months.
- Biochemical remission occurs within 6–12 months.
- Histologic remission occurs within 12–24 months.

■ Once remission is achieved, steroids may be tapered gradually over 2–3 months.

■ Long-term treatment with a low-dose steroid is often required.

■ During steroid taper, monitor at 2- to 4-week intervals for ~3 months for early evidence of recurrence.

- If disease does not recur within this time, the frequency of observation can be decreased.
- ≥80% of children appear to achieve initial remission.
- Although relapses are common, long-term control usually is achieved with continuous immunosuppressive therapy.

■ The child with AIH and fulminant hepatic failure poses a difficult therapeutic problem.

- Prednisone and azathioprine have been used in this situation with success.

- Liver transplantation may be necessary for survival.
- Most children are likely to have prolonged survival on minimal long-term immunosuppression.

Drug-induced hepatitis

- Profound effects of acetaminophen toxicity can be treated with intravenous *N*-acetylcysteine.
- In all other cases of suspected drug-induced hepatitis, supportive care is recommended along with discontinuation of the suspected drug.

Metabolic liver disease

- Aim of therapy in Wilson disease is copper chelation in a controlled manner.
 - First-line therapy is penicillamine in the majority of cases.
 - Requires close monitoring for significant side effects, including allergies and renal disease
 - Triethylene tetramine hydrochloride (trientine) has been effective in the same dose as penicillamine.
 - Also associated with significant side effects
 - Tetrathiomolybdate can be used when significant neurologic disease exists.
 - Toxicity needs to be monitored carefully.
 - Zinc may be used as initial therapy in patients without clinical disease diagnosed incidentally on family screening.
- No specific therapy is available for α_1 -AT deficiency.
 - Liver transplantation should be considered for end-stage liver disease.
- Dietary restriction of galactose is the treatment of choice for galactosemia.
- Tyrosinemia may be treated with a phenylalanine and a tyrosine-restricted diet, together with 2-nitro 4-trifluoromethyl-benzoyl-1,1,3-cyclohexanedione (NTBC).
 - NTBC is an inhibitor of an early enzyme in the tyrosine degradation pathway that is thought to prevent the accumulation of toxic products, resulting in clinical improvement in most patients.
 - Although costly, NTBC has been proposed as an alternative to liver transplantation.
 - Whether it will decrease the risk of hepatocellular carcinoma is not yet determined.
- Bile acid–replacement therapy is the treatment of choice for inborn errors of bile acid synthesis.
- Ursodeoxycholic acid may be used in the treatment of liver disease secondary to cystic fibrosis, although no data exist to support its use.

Fulminant hepatic failure

- Needs to be managed in a setting with liver transplantation expertise
- Requirements of liver support must be balanced with management of fluids, nutrition, and encephalopathy.

- Transferring a child with severe hepatitis early before the need for intensive care management is preferable.

Liver transplantation

- Has improved mortality and morbidity of children who have severe liver disease
- Indications include:
 - Liver failure
 - Growth failure
 - Intractable itch from cholestasis
- Pretransplant management involves aggressive nutritional therapy and prevention of complications, such as bacterial peritonitis and variceal hemorrhage.
- Transplantation for chronic liver failure secondary to HBV infection is complicated by almost 100% recurrence of infection.
 - HBIG followed by lamivudine improves the outcome.
- Recurrence of HCV infection after transplantation is ~90%, but transplantation is recommended because recurrent disease is usually mild.
- Recurrence is related to donor risk factors, recipient risk factors, and viral and clinical factors.
- Liver transplantation for all causes results in 5-year survival rates in children approaching 70–80%.
- Focus is directed toward improving morbidity related to immunosuppressive medications and quality-of-life issues.

WHEN TO ADMIT

- Children with fulminant liver failure of any cause should be promptly hospitalized at a pediatric liver transplantation center.
 - Fulminant hepatic failure is defined as lack of a preexisting liver disease and severe impairment of hepatic function, as evidenced by prolonged prothrombin time (>4 seconds over control value) that is unresponsive to large doses of vitamin K.
- Hospitalization is generally unnecessary for the patient with acute HAV.
 - An infant or young child should be hospitalized if coagulopathy or other evidence of liver decompensation is present.
- Prolonged prothrombin time (>4 seconds over control value) in a child with severe hepatitis of any cause
- Acute encephalopathy in a child with severe hepatitis of any cause
- Dehydration requiring intravenous fluid resuscitation in a child with severe hepatitis
- Gastrointestinal bleeding in a child with acute or chronic hepatitis

WHEN TO REFER

- Children with uncomplicated HAV can usually be managed by a general pediatrician.
 - Chronic hepatitis B, D, or C should be referred to a pediatric gastroenterologist or infectious disease specialist.
- Children with metabolic liver disease, drug-induced hepatitis, or AIH should be referred to a pediatric specialist in metabolic disease or gastroenterology.
- HBsAg-positive serologic test in children ≥ 1 year of age
- Anti-HCV-positive serologic test in children ≥ 3 years of age
- Any diagnosis of drug-induced hepatitis (unexplained elevation of serum aminotransferase levels or bilirubin level in a child who is taking or has recently taken any medication)
- Any diagnosis of metabolic liver disease (unexplained elevation of serum aminotransferase levels or bilirubin level in a child) and a positive screening test, such as low ceruloplasmin level, low galactose-1-phosphate uridyl transferase level, and positive urine-reducing substances

FOLLOW-UP

- HBV
 - Although the best methods and frequency of surveillance have not been determined, careful follow-up includes:
 - Serial serum α -fetoprotein measurement
 - Ultrasonography of the liver

COMPLICATIONS

- HBV
 - Long-term effects of acquiring HBV in infancy include cirrhosis and hepatocellular carcinoma.
 - Many cases of HBV-related liver cancer have been described in children.
 - Most cases of HBV-related hepatocellular carcinoma occur in adults.

- Recent studies suggest that perinatal transmission is important in hepatocarcinogenesis, perhaps related to the high dose of HBV DNA with subsequent tolerance and persistent necroinflammatory activity.

■ HCV

- Fibrosis increases with duration of infection, but in an unpredictable manner.
- Patients with chronic HCV infection who become infected with HAV are at substantial risk of fulminant hepatic failure.
- Chronic HCV infection predisposes patients to cirrhosis and hepatocellular carcinoma over 20 years in those with adult-acquired infection.
- The natural history of perinatally acquired HCV infection is still under evaluation.

PREVENTION

- HAV vaccination routinely after 1 year of age and in all adolescents
- HBV
 - Aggressive immunization programs have substantially lowered risks.
- HCV
 - Maternal-fetal transmission has been linked to in utero monitoring and prolonged rupture of membranes.
 - HCV does not appear to be prevented by cesarean section.
 - Although HCV RNA has been detected in breast milk, current evidence suggests that breastfeeding is not contraindicated.
 - In developed countries, mothers should consider abstaining from breastfeeding if nipples are cracked and bleeding.

Hepatomegaly

DEFINITION

- *Hepatomegaly* denotes an enlarged liver.

MECHANISM

- Hepatomegaly results from an increase in either the number of cells or the size of structures within the liver.
- This may result from broad categories of disorders.
 - Inflammatory/infectious
 - Neoplastic/infiltrative
 - Storage disorders
 - Vascular congestion
 - Biliary obstruction

HISTORY

- Describe the hepatomegaly.
 - Timing of onset
 - Associated signs/symptoms
- Review of systems
 - Pulmonary manifestations (dyspnea, hyperinflation, tracheal deviation)
 - Cardiac manifestations (cough, chest pain)
 - Gastrointestinal symptoms (hematemesis)
 - Neuropsychiatric symptoms
 - Assess for trauma.
 - Assess the likelihood of hypercoagulability.
 - Assess exposure to toxins and medications.
- Medical history
 - Asthma
 - Cardiac disease
 - Infectious exposures
 - Medication history
- Perinatal history
 - Jaundice
- Family history
 - Inflammatory conditions (systemic lupus erythematosus, sarcoidosis)
 - Cancer
 - Metabolic conditions/storage disorders (Wilson disease, glycogen storage disease)

PHYSICAL EXAM

- Vital signs
 - Temperature
 - Heart rate, blood pressure, respiratory rate

■ Physical examination

- Liver
 - Determine size and span.
 - Determine the upper margin by percussion.
 - Determine the lower margin by either percussion or palpation; palpate upwards from iliac.
 - The upper edge of liver dullness is usually at the level of the fifth rib in the right midclavicular line.
 - Normal span ranges from 5.9 cm in the first week of life to 6.5–8 cm by 15 years of age.
 - Estimation of liver span is more strongly correlated with hepatomegaly than is projection below the costal margin.
 - Determine characteristics.
 - Firm and tender suggests an acute inflammatory disorder.
 - A hard liver may be neoplastic.
 - Smooth and exquisitely tender liver may result from vascular distention.
 - Auscultate for bruits.
- Spleen
 - An enlarged spleen with a palpable liver usually suggests significant disease.
- Assess other systems.
 - Ocular: Look for Kayser-Fleischer rings.
 - Respiratory: Examine for evidence of hyperinflation.
 - Cardiovascular
 - Examine for evidence of congestive heart failure.
 - Examine for evidence of cardiac tamponade (eg, pulsus paradoxus).
 - Skin: Assess for jaundice and evidence of trauma.

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis includes inflammatory/infectious causes, neoplastic/infiltrative disorders, storage disorders, vascular congestion, and biliary obstruction.
 - Inflammatory/infectious causes
 - Hepatitis
 - Viral
 - Bacterial (eg, abscess, sepsis)
 - Toxic (eg, drugs, including acetaminophen)
 - Neonatal
 - Autoimmune (eg, systemic lupus erythematosus, sarcoidosis)
 - Trauma

- Neoplastic/infiltrative disorders
 - Primary tumors
 - Hepatoblastoma
 - Hepatocellular carcinoma
 - Hemangioma
 - Focal nodular hyperplasia
 - Metastases
- Storage disorders
 - Fat accumulation
 - Obesity
 - Malnutrition
 - Reye syndrome
 - Cystic fibrosis
 - Diabetes mellitus, type 2
 - Lipid infusion
 - Metabolic liver disease
 - Lipidoses (eg, Niemann-Pick, Gaucher, Wolman diseases)
 - Glycogen excess
 - Glycogen storage diseases
 - Infant of mother who has diabetes
 - Beckwith-Wiedemann syndrome
 - Total parenteral nutrition
 - Copper accumulation
 - Indian childhood cirrhosis
 - Wilson disease
 - α_1 -Antitrypsin deficiency
 - Icterus and acholic stools in first week of life are characteristic.
 - Signs of chronic liver disease in older children
 - Hypervitaminosis A
- Vascular congestion
 - Suprahepatic
 - Congestive heart failure
 - Cardiac tamponade
 - Constrictive pericarditis
 - Intrahepatic
 - Hepatic vein thrombosis (Budd-Chiari syndrome)
 - Hepatic vein web
 - Vascular malformations
 - Cavernous hemangioma
 - Capillary hemangioma
 - Hemangioendothelioma

- Biliary obstruction
 - Congenital biliary atresia
 - Congenital hepatic fibrosis
 - Caroli disease
- Displaced or prominent liver edge, without true hepatomegaly
 - Downward displacement of the right hemidiaphragm
 - Hyperinflated lung (eg, asthma, bronchiolitis, pneumonitis)
 - Tension pneumothorax
 - Congenital diaphragmatic hernia
 - Thoracic tumors
 - Subdiaphragmatic lesions (eg, abscess)
 - Aberrant lobe of liver

LABORATORY EVALUATION

- Evaluation is directed toward the suspected cause; thus, laboratory work is not always indicated.
- Possible tests include:
 - Toxin screens, including acetaminophen, aspirin
 - Complete blood count, peripheral blood smear
 - Hemolytic anemia may indicate Wilson disease
 - Liver enzymes (aspartate aminotransferase, alanine aminotransferase)
 - Liver function studies (prothrombin time, international normalized ration, partial thromboplastin time, albumin, protein; ammonia if mental status changes)
 - Fractionated bilirubin
 - Hepatitis panel
 - Blood cultures
 - Vitamin A level
 - Copper studies
 - Tumor markers

IMAGING

- Imaging studies are determined by clinical suspicion.
- Imaging can help to assess liver size.
 - Radiography
 - May help to identify liver masses, abscesses
 - Ultrasonography
 - Define masses detected on ultrasonography
 - Computed tomography, magnetic resonance imaging, sulfur colloid scintigraphy
 - Define masses detected on ultrasonography
 - Hepatic angiography
 - May be indicated to evaluate suspected vascular tumors

DIAGNOSTIC PROCEDURES

- Percutaneous liver biopsy
 - Can be used to confirm some metabolic and genetic disorders
 - Idiopathic neonatal hepatitis
 - Marked infiltration with inflammatory cells
 - Giant-cell transformation
 - Biliary atresia
 - Bile duct proliferation
 - Giant-cell transformation
 - Congenital hepatic fibrosis
 - Diffuse periportal and perilobular fibrosis on histologic analysis
- Percutaneous liver aspiration
 - Often performed under ultrasonography or computed tomographic guidance
 - Confirms liver abscess and allows sampling of organisms for culture

TREATMENT APPROACH

- Treatment is aimed at the underlying disease entity.

SPECIFIC TREATMENT

Inflammatory disease

- Inflammatory hepatitis
 - Supportive care
- Bacterial infection
 - Appropriate antimicrobial agents

Liver tumors

- Surgical excision
- Chemotherapy may be a helpful adjunct in reducing tumor size either pre- or postoperatively.

Biliary atresia

- Extrahepatic
 - Surgery
- Intrahepatic
 - Hepatoportoenterostomy procedure of Kasai

Other disorders

- Metabolic or genetic disorders
 - Dietary modifications
 - Gaucher disease: imiglucerase, a new synthetic enzyme
 - Wilson disease: D-penicillamine chelation therapy, with zinc acetate for maintenance therapy
 - Glycogen storage disorders
 - Frequent small feedings of a high-protein, complex-carbohydrate diet
 - Continuous nighttime feeding via gastrostomy tubes
- Indian childhood cirrhosis
 - Chelation therapy with D-penicillamine reduces mortality significantly if administered early in the disease course.

WHEN TO REFER

- Refer for hepatomegaly when there is:
 - Concomitant splenomegaly
 - Liver with hard consistency
 - Distended abdominal veins
 - Audible bruit over the liver
 - Suspicion of cancer

WHEN TO ADMIT

- Impending liver failure
- Not clinically stable because of underlying conditions (eg, large pneumothorax, cardiac tamponade, congestive heart failure, hepatitis)
- For intravenous antibiotics

PROGNOSIS

- Biliary atresia
 - Even with treatment, many patients develop cirrhosis and portal hypertension.
- Indian childhood cirrhosis
 - Rapid evolution to cirrhosis and hepatic failure if left untreated

Herpes Infections

DEFINITION

- Herpesvirus hominis, or herpes simplex virus (HSV)
 - DNA virus with a protein coat
 - One of the most common agents infecting humans
 - Although 85–95% of primary infections may be inapparent, in certain circumstances, the disease can be fatal.
 - Can be divided definitively into 2 immunologic types that correlate with clinical manifestations
 - Herpesvirus type 1 (HSV-1): tends to be associated with disease above the waist
 - Herpesvirus type 2 (HSV-2): associated with disease below the waist, with sexually related transmission, or with disease acquired neonatally

EPIDEMIOLOGY

- Prevalence
 - Since the late 1970s, the prevalence of HSV-2 infection has increased dramatically.
 - In lower socioeconomic groups where crowding probably plays an important epidemiologic role
 - 80–100% of adults demonstrate antibodies to HSV-1.
 - 30–40% or more may be positive for HSV-2.
 - Of persons in higher socioeconomic groups:
 - 21% demonstrate antibodies to HSV-2, compared with 34% of those below the poverty level.
- Age
 - Studies have shown
 - Sharp rise in the prevalence of antibodies to HSV-1 between 1 and 4 years of age
 - Slower increase in antibody acquisition between 5 and 14 years of age
 - From adolescence into early adulthood, coincident with the beginning of sexual activity, the presence of antibodies to HSV-2 increases significantly.
 - HSV-2 antibody is now detectable in at least 1 of 5 persons 12 years or older nationwide.
- Neonatal herpes
 - Incidence
 - Varies between 1 in 3200 and 1 in 15,000 deliveries
 - An estimated 1500 to 2200 infants per year in the US are infected with HSV.
 - Prevalence
 - Between 10% and 60% of healthy American women have HSV-2.
 - As many as 50–60% of women from lower socioeconomic groups in the US have antibodies to HSV-2.
 - Postnatal transmission from a caregiver accounts for approximately 10% of cases.

ETIOLOGY

- HSV-1 transmission
 - Presumed to occur via person-to-person respiratory spread
 - Probably involves close contact, such as kissing an infected person
 - Can occur regardless of whether the source is symptomatic with an apparent vesicular lesion at the time
 - After healing and recovering from the initial infection, the host is not rid of the organism.
 - Organism is presumed to remain in a latent phase in the ganglion cells or nerves innervating the region of localized infection.
- Neonatal herpes infections
 - Most are caused by HSV-2.
 - Antibodies to HSV-1 are associated in 25% of cases.
 - Transplacental transmission of HSV can occur and may induce spontaneous abortion or, rarely, congenital defects in newborns.
 - Pediatricians are more often faced with postnatal herpetic disease contracted by the newborn during the second stage of labor while moving through an infected birth canal.

RISK FACTORS

- HSV-1
 - Sports that involve close skin contact
 - Wrestlers may acquire herpes gladiatorum as a result of viral shedding from an infected opponent.
 - Herpes rugbeiorum, or scrum pox, may result from close skin contact between rugby players.
 - 5–10% of cases of genital herpes associated with HSV-1 are believed to result from orogenital sex.
- HSV-2
 - Sexual activity
 - Frequency of infection is high and underestimated by clinical history in the adolescent population.
- Recurrent infection
 - May be induced by various stimuli, including:
 - Sunlight
 - Fever
 - Physical or emotional trauma
 - Menses
- Neonatal
 - Greatest risk occurs when the mother has contracted primary herpes 2–4 weeks before delivery.
 - Disease may be transmitted to the infant in recurrent cases with or without a clinically detectable herpetic lesion.

- Risk for a child born vaginally to a mother with primary genital herpes is 33–50%.
 - <5% if the mother is shedding virus as a result of reactivated infection
 - Distinguishing primary versus recurrent infection may be impossible because both may be asymptomatic.
 - Approximately 75% of infants with HSV infection are born to women without history, physical, or symptomatic evidence of infection.
- Risk factors for neonatal disease include:
 - History of a first HSV infection during the third trimester
 - Invasive monitoring of the fetus
 - Delivery <38 weeks
 - Maternal age <21 years

SIGNS AND SYMPTOMS

■ General

- Incubation period of 2–12 days
- Primary infection, if apparent, is usually heralded by:
 - Classic herpetic enanthem or exanthem
 - Lesions are painful vesicles, usually several millimeters in diameter, on an erythematous base.
- Constitutional symptoms
 - Malaise
 - Fever
 - Anorexia
 - Irritability
- Recurrent episodes
 - Demonstrate a similar vesicular eruption in the same general anatomic area as the primary eruption, but without concomitant constitutional symptoms

■ HSV-1

- Acute gingivostomatitis
 - The most common form of HSV-1 seen in children
 - Peak incidence between 1 and 4 years of age
 - Characterized by abrupt onset of fever, irritability, poor feeding
 - 1–2 days later:
 - Very tender, red, friable mucous membranes surrounding 2- to 3-mm white ulcerations
 - Severe halitosis
 - Vesicular stage is rarely seen.
 - Large, tender anterior cervical and submandibular lymphadenopathy is common.
 - Duration of illness from 5–14 days
 - Severity ranges from mild to so severe that oral intake becomes negligible, and hospitalization for intravenous hydration may be required.

- Herpes labialis (cold sores):
 - Crust and heal without scarring in 7–10 days
 - May be found on either the upper or lower lip
 - Recurrence at the same site is extremely common.
- Traumatic herpes
 - The result of inoculation at the site of local trauma
 - Includes herpetic whitlow, an extremely painful syndrome involving herpetic infection of a digit
 - Although the sore may resemble a bacterial paronychia, it should not be incised.
 - This condition is common in thumb-suckers who have oral herpes.
- Ocular herpes
 - One of the most common causes of corneal blindness in the US
 - Primary infection usually involves acute keratoconjunctivitis with intense swelling of the lids, but without exudate.
 - Frequently, typical herpetic vesicles are found on the skin surrounding the involved eye.
 - Recurrent disease
 - Can be even more severe
 - May involve superficial or deep epithelial ulceration, stromal damage, or uveitis
 - Should always be referred to an ophthalmologist for care
 - The use of topical steroid preparations in a probable case of ocular herpes can have devastating consequences.
- Viral encephalitis
 - Estimated 250–500 cases reported per year
 - Characterized by fever and personality change
 - Often involves seizures
 - Rapidly progressive encephalopathy culminates in death in 1–2 weeks in >70% of untreated cases.
 - Infection most often localizes to a single lobe.
 - Definitive diagnosis in the past was most often made by biopsy, demonstrating the typical morphologic picture of herpes microscopically.

■ HSV-2

- Usually exhibited by typical herpetic vesicles on
 - Penile shaft, prepuce, or glans penis in the male patient
 - The labia minora or majora, mons, or nearby skin or within the vagina in the female patient
- Primary infection is accompanied by:
 - Significant local pain, burning, or paresthesia
 - Constitutional symptoms of fever and malaise, dysuria, and inguinal lymphadenopathy
- Recurrent bouts are less severe than initial occurrences.

■ Neonatal

- Must always be included in the differential diagnosis when the newborn or infant has a skin rash ranging from vesiculopapular to vesiculoulcerative

DIFFERENTIAL DIAGNOSIS

■ HSV-1

- Coxsackievirus A herpangina
 - Most common ulcerative enanthem to be considered
 - Results in lesions very similar in appearance to herpes
 - Is located in the posterior oral cavity, unlike the anterior localization of herpetic lesions
- Other infections include:
 - Varicella
 - Cytomegalovirus
 - Syphilis
- Autoimmune diseases, such as:
 - Behçet syndrome
 - Reiter syndrome
 - Inflammatory bowel disease
- Systemic lupus erythematosus and cyclic neutropenia
 - Might be considered in a broader differential diagnosis
 - Cultures for herpes can confirm the final diagnosis if necessary.

LABORATORY FINDINGS

■ HSV-1

- Clinical diagnosis rarely requires laboratory confirmation.

■ HSV-2

- Viral culture
 - In general, the most sensitive method of diagnosis
 - Requires several days for definitive result, depending on the size of the inoculum
 - Vesicles, stool, urine, and mucosal surfaces may be used as sites to obtain culture sample.
- Direct detection methods, including fluorescent antibody and immunoperoxidase assays
 - Can be used when lesions are available for scraping
 - Test results are rapid but have lower sensitivity; viral culture is still required for confirmation of a negative finding.
- Tzanck test and Papanicolaou stains
 - Neither is sufficiently specific nor sensitive to serve as a screen for HSV.

- Polymerase chain reaction
 - Highly specific and sensitive
 - Can discriminate between HSV-1 and HSV-2 in cerebral spinal fluid
 - The diagnostic method of choice in HSV encephalitis
- Several point-of-care tests are available using glycoprotein-based assays for HSV-2 antibodies, with sensitivities of 80–98% and specificities >95%.

TREATMENT APPROACH

■ No universal cure exists for herpesvirus infections

■ Neonatal herpes involving the central nervous system (CNS)

- By the 1980s, acyclovir had become the treatment of choice.
 - More recent work demonstrates some improved mortality with prolonged high-dose (60 mg/kg/day divided every 8 hours) intravenous acyclovir.
 - Unfortunately, no significant decrease in long-term developmental results among survivors has been demonstrated, allowing morbidity to remain unacceptably high.
 - Due at least in part to the fact that <10% of typical herpetic lesions appear in the first 24 hours of life
 - Early identification of affected infants is difficult; thus, initiation of appropriate therapy is frequently delayed.

SPECIFIC TREATMENTS

Genital herpes

■ First clinical episode

- Oral antiviral therapy shortens the duration of symptoms and viral shedding.
- Definitely indicated for at least a 10-day course
- If begun within 1 day of the onset of the first lesion, then episodic therapy may limit the duration and severity of recurrences as well.
 - Acyclovir 400 mg orally 3 times a day for 7–10 days *or*
 - Acyclovir 200 mg orally 5 times a day for 7–10 days *or*
 - Famciclovir 250 mg orally 3 times a day for 7–10 days *or*
 - Valacyclovir 1 g orally twice a day for 7–10 days
 - Treatment may be extended if healing is incomplete after 10 days of therapy.

■ Episodic therapy for recurrent genital herpes

- Acyclovir 400 mg orally 3 times a day for 5 days *or*
- Acyclovir 800 mg orally 3 times a day for 2 days *or*
- Acyclovir 800 mg orally twice a day for 5 days *or*
- Famciclovir 125 mg orally twice a day for 5 days *or*
- Valacyclovir 500 mg orally twice a day for 3 days *or*
- Valacyclovir 1.0 g orally once a day for 5 days

- **Suppressive therapy for recurrent genital herpes**
 - The same medications have been shown to decrease recurrences by 70–80% when used as long-term suppressive therapy in patients with particularly severe or frequent recurrences.
 - The cost of such therapy may limit its usefulness.
 - Acyclovir 400 mg orally twice a day *or*
 - Famciclovir 250 mg orally twice a day *or*
 - Valacyclovir 500 mg orally once a day *or*
 - Valacyclovir 1.0 g orally once a day
- **Therapy for immunosuppressed individuals**
 - May warrant hospitalization and the use of intravenous acyclovir

Other herpetic syndromes

- **Herpetic gingivostomatitis**
 - Oral acyclovir
 - Can shorten the duration in children by 6 days if begun within the first 72 hours of illness
 - Potential for significant cost savings because of the frequent need of intravenous hydration among children with this syndrome
 - Only modest efficacy has been shown with treatment of episodic oral herpes.
 - Topical antiviral therapy for recurrences has been demonstrated to decrease the duration of symptoms by ≤ 1 day.
- **Keratitis**
 - Topical antivirals treat superficial keratitis effectively.
 - Oral acyclovir may be beneficial in situations of recurrent ocular lesions.
- **Herpes encephalitis**
 - Intravenous acyclovir remains the mainstay of treatment.
 - Acyclovir has significantly decreased mortality from this condition but has only modestly affected morbidity.
 - Therapy must be initiated promptly to ensure the most favorable outcome.
 - Early treatment has improved the prognosis of this disastrous condition among children but is most effective when begun before the onset of loss of consciousness.
 - For neonates < 3 months
 - Treatment should be continued for 21 days.
 - For children ≥ 3 months
 - Treatment should last 14–21 days.

WHEN TO ADMIT

- **Infants with suggested or confirmed neonatal herpes:**
 - Must be carefully monitored and treated with intravenous acyclovir
- **All individuals thought to have herpes encephalitis:**
 - Must be hospitalized and treated expectantly with intravenous acyclovir
- **Immunosuppressed individuals with herpes infections:**
 - May require intravenous antiviral therapy and will require hospitalization

WHEN TO REFER

- **All infants who are thought to have neonatal herpes**
 - Should be considered potentially critically ill
 - Would benefit from subspecialty involvement to include critical care or neonatologic and infectious disease, among others
- **Regardless of age, patients who have known or suggested immunosuppression who contract herpes**
 - May benefit from subspecialty consultation
- **Ocular herpes should always be referred to an ophthalmologist.**
 - Children in whom ocular steroid therapy is considered may benefit from ophthalmologic consultation to rule out possible ocular herpes infection.

COMPLICATIONS

- **HSV-1**
 - Certain human hosts are at more serious risk than others for contracting or developing severe disease.
 - Individuals who may be more likely to show serious disseminated disease are those who:
 - Have deficiencies in cell-mediated immunity
 - Are undergoing immunosuppressive therapy for cancer or transplantation
 - Are extremely malnourished
 - The inoculation of herpes into eczematous skin:
 - Can result in eczema herpeticum, which can vary in severity from mild to fatal
 - Constitutional symptoms are the rule, and temperatures of 39.4°C to 40.6°C may last for ≥ 1 week.
 - Wide areas of skin can become denuded.
 - Enormous fluid, protein, and electrolyte losses are potentially life threatening.
 - Secondary bacterial infection may complicate the condition.
 - Recurrences that are milder than the initial infection occur commonly on areas of the skin affected with chronic eczema.

PROGNOSIS

- Prognosis for the many syndromes of HSV has improved greatly with currently available therapies.
- Neonatal herpes
 - The National Institute of Allergy and Infectious Diseases Collaborative Antiviral Study Group classifies cases of neonatal HSV infection into 3 categories according to clinical manifestations.
 - Infants with disseminated disease involving visceral organs with or without CNS involvement
 - Most likely to die (>80% without treatment and 31% with high dose treatment)
 - Infants with HSV-1 disseminated infection have poorer outcomes than those with HSV-2 infection.
 - Hepatoadrenal necrosis is virtually always found.
 - Microcephaly, hydrocephalus, mental retardation, or seizures occur in many survivors.
 - Infants with CNS abnormalities without involvement of viscera
 - Without antiviral therapy, mortality exceeds 50% and morbidity exceeds 90%.
 - With appropriate antiviral therapy, mortality has decreased to 6%, but morbidity remains high.
 - Infants whose skin, eyes, or mouth (SEM) are involved but not the CNS or viscera.
 - Infants who had SEM involvement before antiviral drugs became available
 - Were not expected to die
 - Only 20–30% were left neurologically impaired.
 - However, many who appeared to have SEM involvement went on to develop disseminated or CNS involvement and to suffer disastrous consequences.
 - Classically, >50% of all neonatal HSV infections exhibited as disseminated disease, with only a minority classified as SEM involved.
 - As a result of earlier diagnosis and treatment:
 - 34% now have SEM involvement.
 - 32% have disseminated disease.
 - 34% have CNS disease.

PREVENTION

- Neonatal herpes
 - Stringent prenatal screening programs
 - Previously recommended to prevent HSV infection in offspring of women with recurrent genital herpes
 - Proved costly, impractical to administer, and medically ineffective
 - Current guidelines for managing labor in women with a history of genital herpes
 - History of genital HSV alone is not an indication for cesarean delivery.
 - Expeditious cesarean delivery is recommended if active genital lesions are present at the time of delivery and duration since rupture of membranes is <4–6 hours
 - Some advocate cesarean delivery if the canal is visibly infected, even when the rupture of membranes has been more prolonged.
 - Several studies demonstrated varied results on the rate of cesarean delivery caused by genital HSV at delivery, but they were underpowered to show an effect on HSV in the infants.
 - Scalp electrodes should be avoided when the mother is suspected of having active genital HSV infection.
 - Daily oral acyclovir has been shown to:
 - Suppress subclinical shedding of HSV-2 in the genital tract
 - Prevent clinical recurrences in pregnant women at delivery
 - Joint guidelines to decrease the likelihood of postpartum herpes infection in the infant (AAP and American College of Obstetricians and Gynecologists):
 - Specify isolation criteria to protect healthy infants from their HSV-infected mothers, other infected infants, or infected staff.

Hirsutism, Hypertrichosis, and Precocious Sexual Hair Development

DEFINITION

- Hirsutism: excessive body hair growth in the sex hormone-dependent areas
 - Represents androgen overproduction or enhanced androgen metabolism in the skin
- Hypertrichosis: generalized increase in fine body hair with no preferential sites
 - Usually not associated with pathologic sex hormone production
- Virilization, or masculinization, results from androgen overproduction manifested by:
 - Phallic or clitoral enlargement
 - Masculine body habitus
 - Temporal hair loss
 - Voice changes
 - Breast atrophy
 - Menstrual disorders
- Gonadarche: the maturation of the hypothalamic-pituitary-gonadal axis
- Adrenarche: the activation of the hypothalamic-pituitary-adrenal axis
- Precocious puberty
 - True (central) precocious puberty: early maturation of the hypothalamic-pituitary-gonadal axis
 - Peripheral precocious puberty: early production of sex steroids independent of an activated hypothalamic-pituitary-gonadal axis
 - In boys: from either the testes or the adrenals
 - In girls: from the ovaries, the adrenals, or both
- Adrenal hyperplasia: the histologic change that occurs in the adrenal glands as a result of a deficiency of 1 of the several enzymes necessary for normal steroid biosynthesis

MECHANISM

Excessive androgen exposure

- Prenatal exposure
 - In female infants, exposure to significant androgens during the first trimester (as in the congenital adrenal hyperplasia syndromes) causes genital ambiguity, including varying degrees of clitoral enlargement and labial fusion.
 - Exposure to excessive androgens after the first trimester results in clitoral enlargement, but not labial fusion.
 - Male infants exposed to excessive androgens in utero are not born with abnormal genitalia.
- Postnatal exposure
 - In the growing child, excessive androgens contribute to:
 - Increased growth velocity
 - Rapid epiphyseal maturation

- Excessive bone age advancement
- Short adult stature

- If the condition causing androgen overproduction is undiagnosed or inadequately treated, the child will:
 - Develop early sexual hair growth
 - Continue to virilize

Gonadarche

- Activation of the pulsatile release of gonadotropin-releasing hormone (GnRH) from the hypothalamus results in:
 - Increased amplitude and frequency of pituitary gonadotropin secretion
 - Gonadal maturation
- Pituitary luteinizing hormone stimulates ovarian androgen synthesis, occurring mainly in theca cells, stroma cells, and the corpus luteum.
- Levels of the major androgens (Δ -4-androstenedione and testosterone) secreted by the ovaries gradually increase during gonadarche.
 - These androgens contribute to the development of:
 - Pubic hair
 - Axillary hair and odor
 - Acne
- The ovary converts androgens to estrogen in the granulosa cell layer via stimulation from pituitary follicle-stimulating hormone.
 - Estrogens contribute to:
 - Breast development
 - Uterine enlargement
 - Vaginal discharge
 - Menarche
 - Puberty is characterized by an increase in growth velocity (pubertal growth spurt) that results from an increase in growth hormone secretion.

Peripheral precocious puberty

- Ovarian tumors producing androgens can cause early sexual hair growth, hirsutism, virilization, or polycystic ovary syndrome (PCOS).

Cortisol

- The most important of the glucocorticoids made by the adrenal gland
- Its synthesis is regulated primarily by a sensitive negative feedback system with pituitary adrenocorticotropic hormone (ACTH).
- Any condition that causes a decrease in cortisol biosynthesis results in a compensatory increase in ACTH.
- In enzymatic defects of cortisol biosynthesis, cortisol levels decrease.

- The compensatory increase in ACTH stimulates adrenal steroidogenesis, with the resultant accumulation of steroids proximal to the enzymatic defect.
 - These precursor steroids are then shunted to the androgen pathways, with resultant hyperandrogenism.
- 3 alleles are associated with the 21-hydroxylase locus.
 - Individuals may be:
 - Unaffected heterozygote carriers *or*
 - Affected, with classical or nonclassical disease
- Deficiency of the 11- β -hydroxylase enzyme is characterized by sexual ambiguity in affected girls.
 - Inadequate therapy can result in early virilization.
 - The accumulation of deoxycorticosterone, a weak mineralocorticoid, eventually leads to low renin hypertension.
 - Milder forms of 11- β -hydroxylase deficiency have been described and exhibit very similarly to the late-onset form of 21-hydroxylase deficiency.

PCOS

- The precise cause of chronic ovarian hyperandrogenism is not known.
- Several factors have been implicated.
 - Altered gonadotropin secretion
 - Hyperinsulinism
 - Insulin-like growth factor-1 and alterations of insulin-like growth factor-1-binding proteins
 - Hyperprolactinemia
 - Thyroid disease
 - Adrenal hyperandrogenism
- Evidence demonstrates a link between PCOS and inappropriate gonadotropin secretion, hyperinsulinemia, and impaired glucose tolerance (IGT) independent of weight.

Adrenal hyperandrogenism

- The adrenal glands produce:
 - Glucocorticoids (cortisol)
 - Mineralocorticoids (aldosterone and desoxycorticosterone)
 - Androgens (dehydroepiandrosterone, Δ -4-androstenedione, and testosterone)
- Glucocorticoid and androgen production are stimulated primarily by pituitary ACTH.
- Exogenous glucocorticoids, by suppressing ACTH, suppress glucocorticoid and androgen production.
- The mineralocorticoids are regulated primarily by the renin-angiotensin enzyme system, which is stimulated and suppressed by low- and high-salt diets, respectively.

HISTORY

- A family history should be obtained.
 - Families of patients with premature adrenarche and PCOS may have a history of cardiovascular disease, atherosclerosis, obesity, or diabetes.
 - A family history of early fetal demise suggests the presence of adrenal hyperplasia.
- Increase in growth velocity with crossing percentile channels suggests:
 - Precocious puberty
 - Sexual hair growth with early breast development is consistent with either central (true) or peripheral precocious puberty.
 - Tumor
 - Adrenal hyperplasia
- Abdominal symptoms (cramps, pain, mass, distention) suggest ovarian androgen-producing tumors.

PHYSICAL EXAM

- The rapid development of sexual hair associated with signs of virilization (eg, severe acne, voice changes, change in body habitus, clitoral or phallic enlargement, rapid growth) suggests marked hyperandrogenism.
 - Severe adrenal enzyme deficiencies
 - Adrenal or ovarian tumor
- Labial fusion indicates exposure to hyperandrogenism during fetal life, which occurs in the congenital adrenal hyperplasia syndromes.
- The presence of sexual hair growth with early breast development is consistent with either central or peripheral precocious puberty.
- Hypertension on physical examination may be caused by:
 - 11-hydroxylase deficiency
 - Adrenal tumor
 - Obesity
- Virilization indicates severe hyperandrogenism.
- Central precocious puberty
 - Clinically, girls have early development of pubic hair, axillary hair and odor, acne, and breast development.
 - Most commonly, breast development occurs initially, but sexual hair growth may precede breast development.
 - In boys, the increase in gonadotropins causes testicular growth and full physical pubertal development.
- Peripheral precocious puberty caused by ovarian androgen-producing tumors
 - The concurrent secretion of estrogen can result in premature breast development, vaginal discharge, or irregular uterine bleeding.
 - Patients may have excessive weight gain, acceleration of linear growth, and advanced bone age.

- PCOS may manifest, in addition to hirsutism, with:
 - Obesity
 - Acne
 - Hyperpigmentation in the intertriginous skin sites, known as *acanthosis nigricans*
 - Male pattern baldness
- Adrenal hyperandrogenism
 - Premature adrenarche
 - Adrenarche in girls before the age of 8 years and in boys before the age of 9 years
 - These children display early sexual hair growth, usually limited to the axillary and pubic areas.
 - The presence of facial, abdominal, or back hair is not consistent with this syndrome.
 - Affected children may develop mildly oily skin and minimal acne, especially on the nose and forehead.
 - Axillary odor is common and generally requires deodorant.
 - Children with premature adrenarche are never virilized; the presence of virilization suggests either a tumor or an enzymatic defect of steroidogenesis.
 - The child's growth velocity may increase slightly.
 - Bone-age maturation may advance but generally stays within 2 years of the chronologic age.
 - Androgen levels are in the range typical of the early Tanner II–III stages of puberty.
 - Enzymatic effects of steroidogenesis
 - Specific symptoms depend on which class of steroids is deficient or overproduced.
 - 21-hydroxylase deficiency
 - Severe salt-wasting form
 - Prenatal exposure of the genetic female external genitalia to the high androgens in the first trimester causes genital ambiguity.
 - Boys with similar exposure do not have genital abnormalities.
 - Children of either sex will develop salt-wasting symptoms, generally within the first 3 months of life.
 - Simple virilizing form
 - The genetic female child is born with genital ambiguity.
 - The genetic male child appears normal.
 - In either form of 21-hydroxylase deficiency, delay in diagnosis or inadequate treatment results in postnatal virilization.
 - Progressive clitoral and phallic enlargement
 - Early development of axillary and pubic hair, axillary odor, and acne
 - Increased growth velocity
 - Advanced bone age
 - Precocious puberty
 - Short adult stature
- Variable signs and symptoms of hyperandrogenism are common to both types of the disorder.
 - Hirsutism
 - Acne
 - Virilization of the external genitalia or the body
 - Short stature
 - Menstrual irregularities
- The nonclassical late-onset form of 21-hydroxylase deficiency has clinical variability.
 - Symptoms of hyperandrogenism can develop at any age.
 - Affected girls do not have genital ambiguity.
 - The spectrum of symptoms includes:
 - Premature pubic and axillary hair growth
 - Premature axillary odor
 - Acne
 - Increased growth velocity and advanced bone age
 - Hirsutism
 - Male-pattern baldness in young women
 - PCOS
- 11- β -hydroxylase enzyme deficiency
 - Characterized by sexual ambiguity in affected girls
 - As with 21-hydroxylase deficiency, inadequate therapy can result in early virilization.
- Idiopathic hirsutism or acne
 - Girls who have these signs have no other signs of androgen excess and normal circulating androgen concentrations.
 - Menses and reproductive function are normal.
 - Hirsutism and acne in these women have been attributed to “increased peripheral metabolism” of androgens.

DIFFERENTIAL DIAGNOSIS

Central (true) precocious puberty

- In most cases, not caused by a specific identifiable lesion
 - A hypothalamic or pituitary lesion may be the cause of early puberty, especially in a child <6 years.
- May be associated with:
 - Astrocytoma
 - Craniopharyngioma
 - Ependymoma
 - Germinoma
 - Glioma

- Hypothalamic hamartoma
- Virtually any central nervous system (CNS) insult
 - Trauma
 - Surgery
 - Inflammation
 - Neurologic or mental deficits
- Prolonged exposure to sex steroids

Peripheral precocious puberty

- Ovarian androgen-producing tumors
 - Symptoms can mimic true precocious puberty in the young child.
 - Rapid pubertal progression suggests the presence of a tumor, but not all ovarian tumors affect pubertal progression.
 - A markedly elevated estradiol, androstenedione, or testosterone level is consistent with an ovarian lesion.
 - In contrast to central precocious puberty, peripheral precocious puberty resulting from an ovarian tumor occurs independently of the hypothalamic-pituitary axis.
- Androgen-producing cells can occur in association with:
 - Embryonal carcinoma
 - Dysgerminoma
 - Choriocarcinoma
 - Gonadoblastoma
 - Granulosa-theca cell tumor
 - Sertoli-Leydig cell tumor
 - Arrhenoblastoma
 - These tumors can occur in phenotypic girls who have an abnormal karyotype containing components of the Y chromosome.

PCOS

- Ovarian hyperandrogenism can occur in certain insulin-resistant syndromes.
 - Leprechaunism (associated with severe congenital growth retardation)
 - Kahn type B insulin resistance syndrome caused by the presence of circulating antibodies for the insulin receptor

Testicular androgen production

- Central (true) precocious puberty
 - CNS disease in boys
 - Rarely, associated with severe chronic hypothyroidism

Testicular tumors

- Leydig cell tumors and seminomas can produce testosterone.
- However, many testicular tumors can cause testicular enlargement without symptoms of hyperandrogenism (eg, embryonal carcinoma, endodermal sinus tumor, and teratoma).
- Boys with cryptorchidism and delayed orchiopexy after the age of 6 years are at increased risk.

- Dysgenetic gonads associated with androgen insensitivity, persistent müllerian syndrome, true hermaphroditism, and Klinefelter syndrome have a higher incidence of germ cell tumors as well.

Chorionic gonadotropin-secreting tumors

- Teratomas, embryonal tumors, hepatoblastomas, and CNS germinomas can produce human chorionic gonadotropin, which has been implicated in peripheral precocious puberty among male patients.

Adrenal hyperandrogenism

- Premature adrenarche may be associated with:
 - Functional ovarian hyperandrogenism
 - ACTH-stimulated androgens >2 standard deviations above the mean for normal Tanner II–III pubertal girls
 - Association among acanthosis nigricans, hyperinsulinism stemming from insulin resistance, and hyperandrogenism in adolescent and adult women with PCOS
 - Marked insulin resistance is associated with more severe hyperandrogenism, with an exaggerated increase $\Delta 5$ steroids in response to ACTH stimulation.
 - Hyperinsulinism, possibly exacerbated by obesity
 - Minority children are known to be at increased risk for the complications of hyperinsulinism.

Drug-related hirsutism and hypertrichosis

- Hirsutism may result from use of:
 - Anabolic steroids
 - Danazol (Danocrine)
 - Metoclopramide (Reglan)
 - Methyldopa (Aldomet)
 - Phenothiazines
 - Progestins
 - Reserpine (Serpasil)
 - Testosterone
- Hypertrichosis may be caused by:
 - Cyclosporine (Sandimmune)
 - Diazoxide (Hyperstat)
 - Hydrocortisone
 - Minoxidil (Rogaine)
 - Penicillamine (Cuprimine)
 - Phenytoin (Dilantin)
 - Psoralens (Oxsoralen)
 - Streptomycin
- Idiopathic hirsutism or acne
 - Girls with these signs have no other signs of androgen excess and normal circulating androgen concentrations.
 - Menses and reproductive function are normal.
 - Hirsutism and acne in these women have been attributed to “increased peripheral metabolism” of androgens.

LABORATORY EVALUATION

- For a summary laboratory findings and recommended additional testing for hirsutism, see the table Causes of Hirsutism, Associated Laboratory Findings, and Recommended Additional Testing.

Precocious puberty

- GnRH stimulation test to distinguish central from peripheral sexual precocity
- ACTH stimulation test
 - If ACTH testing is consistent with an enzymatic defect in the virilized patient, the nonmalignant nature of the condition should be confirmed by suppression of hyperandrogenism with dexamethasone.
- The presence of virilization or high levels of testosterone (>150 ng/dL) or of dehydroepiandrosterone sulfate (>750 mcg/dL) suggests an ovarian or adrenal tumor.

Karyotype

- If an ovarian tumor is suspected

Central (true) precocious puberty

- Pubertal gonadotropin response to a GnRH stimulation test confirms diagnosis.

Ovarian androgen-producing tumors

- A GnRH stimulation test can distinguish these tumors from central precocious puberty.

- The gonadotropin response is suppressed in peripheral precocious puberty.

PCOS

- Compared with age-matched controls, women with PCOS have an 11-fold increase in the prevalence of metabolic syndrome.
- The risk of metabolic syndrome is high even at a young age, highlighting the importance of early and regular screening.
- 33% of adolescent girls with PCOS have abnormal oral glucose tolerance tests indicating IGT or type 2 diabetes mellitus.
- Insulin resistance can be confirmed by fasting hyperinsulinism and a reduced fasting glucose/insulin ratio or an increased homeostatic model assessment.
- Glucose tolerance test is the most reliable screening test for these conditions in girls with PCOS and can detect IGT or type 2 diabetes mellitus.
- Hormonal evidence of PCOS
 - Luteinizing hormone/follicle-stimulating hormone ratio >2
 - Generous levels of Δ -4-androstenedione
 - Increased total and free testosterone with a reduced level of sex hormone-binding globulin
 - Variable levels of estradiol
- Total testosterone level >150 ng/dL suggests the presence of a tumor.

Causes of Hirsutism, Associated Laboratory Findings, and Recommended Additional Testing

Diagnosis	Testosterone	17-OHP	LH/FSH Ratio	Prolactin	DHEAS	Cortisol	Additional Testing
Congenital adrenal hyperplasia	Normal to increased	Increased	Normal	Normal	Normal to increased	Normal to decreased	ACTH stimulation may be necessary to make the diagnosis
Polycystic ovary syndrome	Normal to increased	Normal	Normal to increased LH and decreased to normal FSH	Normal to increased	Normal to increased	Normal	Primarily a clinical diagnosis; consider laboratory testing and ultrasonography of ovaries to rule out other disorders or tumors; consider screening for the metabolic syndrome with lipids, glucose, oral glucose tolerance test
	Increased free testosterone						
	Decreased SHBG						
Ovarian tumor	Increased	Normal	Suppressed/30 suppressed	Normal	Normal	Normal	Ultrasonography or CT to image tumors

Abbreviations: ACTH, adrenocorticotropic hormone; CT, computed tomography; DHEAS, dehydroepiandrosterone; FSH, follicle-stimulating hormone; LH, luteinizing hormone; OHP, hydroxyprogesterone; SHBG, sex hormone-binding globulin.

Testicular androgen production

- In central (true) precocious puberty, levels of testosterone increase and a pubertal pattern of gonadotropin release can be detected with a GnRH stimulation test.
- In familial gonadotropin-independent puberty, boys who clinically have precocious puberty have high testosterone levels and low GnRH-stimulated gonadotropin levels.

Adrenal hyperandrogenism

- Disorders of adrenal hyperandrogenism caused by enzymatic defects of steroidogenesis (congenital adrenal hyperplasia) respond to stimulation and suppression tests.
- Functional adrenal tumors
 - Characterized by their ability to produce steroids independently of pituitary ACTH or the renin-angiotensin enzyme system
 - As a rule, do not respond to the dynamic tests known to affect adrenal steroidogenesis
- Premature adrenarche
 - The increase in adrenal androgen production can be detected at approximately 6 years.
 - As puberty progresses, an ACTH stimulation test detects the gradual increase in androgen levels.
- 3 autosomal-recessive disorders of adrenal steroidogenesis cause cortisol deficiency and hyperandrogenism.
 - 21-Hydroxylase deficiency
 - Molecular genetic studies have identified the responsible gene: *CYP21A2*.
 - Currently, an affected fetus can be identified by chorionic villus sampling between the 8th and 11th week of gestation.
 - 21-Hydroxylase deficiency is confirmed by an elevated 17-hydroxyprogesterone level.
 - A nonclassical late-onset form of 21-hydroxylase deficiency has clinical variability and symptoms of hyperandrogenism can develop at any age.
 - Because the hyperandrogenism in this form of 21-hydroxylase deficiency is not as severe as the classical form, the basal unstimulated 17-hydroxyprogesterone level may not be elevated.
 - The diagnosis is confirmed by an exaggerated 17-hydroxyprogesterone response to ACTH stimulation.
 - 11- β -Hydroxylase deficiency
 - The diagnosis is made by an elevated 11-deoxycortisol that is stimulated by ACTH and suppressed by dexamethasone.
 - 3- β -Hydroxysteroid dehydrogenase deficiency
 - The diagnosis is confirmed by finding elevated precursor steroids either in the basal state or in response to a bolus dose of ACTH.

IMAGING

- Central (true) precocious puberty
 - Evaluation should include magnetic resonance imaging with gadolinium contrast of the hypothalamic-pituitary area.
 - A bone-age radiograph can help identify the child who is at risk for short stature.
 - Early production of sex steroids can cause rapid epiphyseal maturation and result in short stature.
- Peripheral precocious puberty
 - Ovarian androgen-producing tumors
 - Pelvic ultrasonography can be useful in identifying cystic or solid ovarian lesions.
- PCOS
 - The ovaries in PCOS have subcapsular cysts that may be detected by ultrasonography.
 - The absence of cysts on ultrasonography does not exclude PCOS.
 - Hormonal evidence of PCOS can be discerned before morphologic changes can be seen on ultrasonography.
 - Ultrasonography should be performed if an ovarian lesion is suspected.

TREATMENT APPROACH

- For mild hirsutism, local measures, such as shaving, bleaching, depilatories, and electrolysis
- Weight loss
 - Obese patients should be encouraged to lose weight.
- Very few pharmacologic agents are approved by the US Food and Drug Administration for hirsutism.
 - Response to these agents is slow.
 - They often are used with local cosmetic options.

SPECIFIC TREATMENT

PCOS

- Oral contraceptives
 - Decrease circulating androgens in patients with PCOS
 - Synergize with the effects of antiandrogens, such as spironolactone
- Metformin
 - Adolescents with PCOS are severely insulin resistant compared with a control group matched for body composition and abdominal obesity.
 - The use of metformin in girls with PCOS has been reported to:
 - Improve insulin sensitivity
 - Reduce ACTH-stimulated androgens

- Metformin has been reported to prevent development of PCOS symptoms in prepubertal and adolescent girls with premature pubarche and a history of low birth weight.

Central (true) precocious puberty

- Long-acting preparations of GnRH (GnRH analogue)
 - For children whose parents are particularly concerned about the psychosocial issues surrounding early sexual development or the risk for short stature
 - GnRH analogues are effective in halting pubertal progression in girls and boys and preventing menses in girls.
 - Reduction in growth hormone secretion causes the child's growth velocity to decline.
 - The reduction in sex steroids either halts or reduces the rate of bone-age maturation.
 - The net result is an improvement in predicted height and, ultimately, adult stature.

Peripheral precocious puberty

- Ovarian androgen-producing tumors
 - Because dysgenetic gonads, in which differentiation into testis or ovary is either absent or incomplete, are at risk for malignant deterioration, prophylactic gonadectomy is recommended in these girls.

Enzymatic effects of steroidogenesis

- The goal of early diagnosis and treatment is to prevent genital ambiguity in the affected female fetus.
 - Prenatal treatment with dexamethasone should be instituted by 6–7 weeks of gestation (before prenatal diagnosis is possible) to be effective in preventing virilization in female fetuses with congenital adrenal hyperplasia.
 - Preventive therapy is controversial because many unaffected fetuses would be treated prenatally with dexamethasone.

21-Hydroxylase deficiency

- Treatment includes glucocorticoid replacement therapy as hydrocortisone at a dose of 10–25 mg/m² daily to maintain:
 - Normal growth and development
 - Normal rate of bone-age advancement
- Salt-wasting variant
 - Treated with the salt-retaining steroid 9- α fludrocortisone acetate
 - Sometimes useful with elevated plasma renin activity

11- β -Hydroxylase and 3- β -hydroxysteroid dehydrogenase deficiency

- Treatment is similar to that for 21-hydroxylase deficiency, with glucocorticoid replacement.

WHEN TO REFER

- Pubic hair, axillary hair, or axillary odor before 8 years of age in girls and 9 years of age in boys

- Breast development, vaginal discharge, or menses in girls before 8 years of age
- Increased facial or body hair (chest, abdomen, back) in girls with or without menstrual irregularities
- Signs of virilization in girls (clitoromegaly, masculine body habitus, voice changes) or in boys (phallic enlargement, change in body habitus, voice change) before the age of 9 years
- Rapid virilization (<1 year) in a pubertal boy

WHEN TO ADMIT

- Severe hypertension with precocious sexual development
 - 11-hydroxylase deficiency
 - Adrenal tumor
- Severe anemia secondary to vaginal bleeding
 - Ovarian cyst
 - Dysfunctional uterine bleeding
- Any suspicion of sexual abuse
- Severe headaches, visual loss, change in mental status
 - Increased intracranial pressure associated with CNS lesion
- Hypotension or shock
 - Addison disease secondary to ACTH deficiency
 - Pituitary apoplexy secondary to a bleed into a pituitary lesion
- Marked hyperglycemia requiring insulin
 - Type 2 diabetes mellitus
 - PCOS
- Severe abdominal pain (torsion of ovarian cyst)

FOLLOW-UP

- Children with hirsutism, hypertrichosis, and precocious sexual hair development need to be followed carefully to monitor the response to the therapy or progression of pubertal changes, because this may lead to short stature.

COMPLICATIONS

- Girls with precocious pubarche who had low birth weight are at high risk for a variant of PCOS even if they are not obese.
 - Hyperinsulinemic hyperandrogenism
 - Dyslipidemia
 - Dysadipocytinemia
 - Central fat excess
 - Deficit of lean body mass

PROGNOSIS

- Prognosis for children with hirsutism, hypertrichosis, and precocious sexual hair development depends on the underlying conditions leading to these physical findings, early appropriate evaluation, and appropriate treatment.

HIV Infection and AIDS

DEFINITION

- Acquired immunodeficiency syndrome (AIDS) results from progressive immune dysfunction after infection with the human immunodeficiency virus (HIV).
- 2 separate HIV viruses have been identified.
 - HIV-1 is the predominant virus responsible for disease in the US and rest of the world.
 - HIV-2 is primarily detected in patients in West Africa.
- Clinical manifestations of HIV infection range from asymptomatic infection to debilitating disease and death.

EPIDEMIOLOGY

- Prevalence
 - In 2006 approximately 10,000 children <13 years were living with AIDS in the US.
 - Acquisition of HIV through adult behaviors is increasing.
 - AIDS in young adults reflects acquisition of HIV during adolescence.
- Transmission
 - Perinatal transmission is the most common mode of acquisition of HIV infection among children in the US.
 - Before the availability of antiretroviral chemotherapy to prevent perinatal HIV transmission, intrapartum transmission was the most common mode of transmission.
 - Before widespread use of antiretroviral prophylaxis, as many as 1800 HIV-infected children were born in the US annually.
 - Now, <50 infants are diagnosed with HIV in the US each year.
 - Not all infants born to HIV-infected women acquire HIV infection.
 - Estimated perinatal transmission rates from untreated women to infants range from 13–30%.
- Geographic distribution
 - The great burden of pediatric HIV infection is in resource-poor countries of Africa and Asia.

ETIOLOGY

- Prepubertal children most commonly acquire HIV infection through maternal-infant transmission.
 - Rarely, they may be infected through:
 - Receipt of infected blood or blood products
 - Sexual abuse
- Perinatal HIV transmission can occur by 3 mechanisms.
 - Transplacental infection in utero
 - Intrapartum infection during labor and delivery
 - Postpartum infection through mother's milk

- Perinatal HIV infection occurs during the development and maturation of the immune system.
 - This distinguishes pediatric HIV infection from adult infection and has profound effects on the:
 - Clinical course
 - Nature
 - Timing of opportunistic infections and immune responses to immunizations
- A substantial number of adolescents contract HIV through adult behaviors.
 - Unprotected sexual activities
 - Intravenous drug use
- HIV transmission through sexual contact occurs in:
 - Children who are sexually abused
 - Sexually active adolescents

RISK FACTORS

- High maternal plasma HIV levels correlate with increased risk of transmission.
- Women with advanced HIV disease or recently acquired infection are more likely to transmit HIV to newborns.
- Receipt of blood
 - Routine testing of blood donors for HIV antibody began in March 1985.
 - Children who received blood or blood products before this time were at risk.
 - Children with hemophilia were at particularly high risk because they received pooled factors from hundreds to thousands of donors.
 - Risk of HIV infection from blood or blood products is now estimated to be 1 in 2 million from a single unit of blood.
- Behaviors that place adolescents at high risk of HIV infection are:
 - Initiation of sexual activity at a young age
 - Unprotected sexual intercourse
- Risk factors are associated with HIV infection in women of childbearing age include:
 - Illicit drug use
 - Sexual contact with persons at high risk

SIGNS AND SYMPTOMS

Diagnosis of HIV/AIDS

- Clinical manifestations range from asymptomatic infection to debilitating disease and death.
- In children, the time from infection to onset of clinical symptoms may be shorter:
 - For those who have perinatally acquired infection than for those infected through blood or blood products
 - Than for adults

- Frequently asymptomatic
 - Infected infants in the neonatal period
 - Most with untreated perinatal HIV infection develop symptoms by 2 years of age.
 - Other children may have no or few symptoms for many years.
- Early clinical signs and symptoms of HIV infection are nonspecific but generally indicate a systemic illness.
 - Children may exhibit:
 - Failure to thrive
 - Developmental delay
 - Persistent oral candidiasis
 - Lymphadenopathy
 - Hepatosplenomegaly
 - Chronic diarrhea
 - Recurrent bacterial infections
 - Recurrent herpesvirus infections
- Delayed acquisition of developmental milestones and loss of previously acquired milestones are common manifestations.
 - Growth failure is common early in the course of disease.
 - Frequent measurements of weight and height are important in:
 - Detecting growth disturbances early
 - Monitoring response to interventions

Diagnosing illness in HIV-infected children

- Most HIV-infected children with fever and normal clinical examination have self-limited febrile illnesses similar to those of non-HIV-infected children.
 - Fever may indicate a serious infection.
 - Persistent fever can be a diagnostic challenge; identifiable and treatable causes include mycobacterial infection and drug-induced fever.
 - Detailed clinical history and thorough physical examination is essential in the initial assessment.
 - Close attention should be paid to general appearance and potential areas of focal inflammation, such as:
 - Skin
 - Ears
 - Sinuses
 - Lungs
 - Gastrointestinal tract
 - Bacteremia with *Streptococcus pneumoniae* and *Salmonella* can occur in the absence of physical findings.
- Additional diagnostic studies should be obtained on the basis:
 - Child's age
 - Clinical appearance
 - Degree of immunosuppression
 - Signs and symptoms at the time that the patient seeks care
- Primary HIV infection in adolescents and adults is frequently accompanied by a mononucleosis-like illness characterized by:
 - Fever
 - Sore throat
 - Lethargy
 - Lymphadenopathy (seroconversion syndrome)
- See Complications for more information on secondary and opportunistic infections.

DIAGNOSTIC APPROACH

- The most important factor in identifying HIV-infected women and children is consideration of the diagnosis.
 - Absence of identifiable risk factors does not exclude HIV infection.

LABORATORY FINDINGS

- The number of copies of HIV RNA in plasma can be quantified.
 - Given that HIV is an obligate intracellular parasite, virus in the plasma is a replicating virus looking for a new host cell.
 - Plasma HIV RNA levels are useful in:
 - Predicting the rate of disease progression
 - Modifying antiretroviral therapy
 - Understanding viral dynamics
 - In children with perinatally acquired HIV, HIV RNA levels peak in the first few months of life and decline slowly over several years.
 - Steady-state HIV RNA levels in children are not achieved until 2–6 years of age.
 - HIV RNA levels in adults decrease rapidly to steady-state levels within several months after primary infection.
 - Despite this decrease in HIV RNA level, intense viral replication continues.
- Infection with HIV leads to a progressive decrease in CD4⁺ T lymphocytes.
 - Qualitative changes in function of CD4⁺ T lymphocytes occur before the decrease in number.
 - CD4⁺ T lymphocytes are crucial to B-lymphocyte function; thus, humoral immunity (antibody production) can be significantly impaired in HIV-infected children.
 - Results in poor antibody responses to encapsulated bacteria and immunizations, despite increase in total immunoglobulins
- Detection of HIV DNA or RNA by polymerase chain reaction (PCR) is the preferred method for diagnosing HIV infection in infants.
 - PCR amplifies HIV DNA or RNA sequences and is extremely sensitive in detecting small amounts of virus.

- Almost all HIV-infected infants have a positive HIV PCR result by 1 month of age; 40% can be identified in the first 2 days of life.
 - False-positive results occur on rare occasions because of laboratory contamination.
 - Positive results should be confirmed by PCR testing of a second blood specimen.
 - Early detection of HIV infection allows for initiation of combination antiretroviral therapy in infancy.
 - HIV-exposed infants should be tested by 48 hours of age.
 - A positive PCR result at 48 hours of age suggests intra-uterine infection.
 - If negative, PCR testing should be repeated at 14 day.
 - >90% of infected infants will have a positive PCR result by 2 weeks of age.
 - Infants negative for HIV by PCR at 48 hours and at 14 days:
 - Should be tested at 1–2 months of age
 - Again at 3–6 months of age if previously negative
 - HIV infection is diagnosed by 2 positive HIV PCR tests performed on separate blood samples.
 - 2 negative PCR results, one performed at 1–2 months of age and the other at 4–6 months of age, make the diagnosis of HIV infection extremely unlikely.
 - The Centers for Disease Control and Prevention (CDC) is considering a modification of this schedule for diagnosis.
 - The HIV enzyme immunosorbent assay (ELISA) detects antibody to HIV and is appropriate for screening children >18 months of age.
 - HIV ELISA has high sensitivity but lacks specificity.
 - Positive ELISA reactions for HIV are confirmed by Western blot analysis, which detects antibodies to several HIV proteins and is highly specific.
 - False-negative results may occur shortly after primary infection because antibodies to HIV do not achieve detectable levels until 2–3 months after infection.
 - Serologic methods should not be used to confirm HIV infection in children <18 months.
 - Transplacentally derived maternal antibodies result in a positive HIV ELISA with HIV-seropositive mothers, even if the child is not infected.
 - Maternal antibodies can persist for 18 months.
 - Laboratory abnormalities often include:
 - Anemia
 - Thrombocytopenia
 - Increased immunoglobulin levels
 - Laboratory tests to be considered include:
 - Complete blood count with differential, large-volume blood culture
 - Urinalysis and urine culture
 - Lumbar puncture
 - Because HIV antibodies take several months to achieve detectable levels, nucleic acid–based assays (PCR) should be used to diagnose symptomatic primary HIV infection.
- ## IMAGING
- Radiography
 - *Pneumocystis (carinii) jiroveci* pneumonia (PCP) is most commonly characterized by diffuse alveolar infiltrates.
 - Early in the course of PCP in older children, the radiograph may be normal or show minimal changes despite significant cough and even hypoxia.
 - In bilateral lymphoid interstitial pneumonitis (LIP), reticulonodular densities are seen, resembling miliary tuberculosis.
 - Computed tomography
 - Characteristic central nervous system findings include cerebral atrophy and basal ganglia calcifications.
 - Initial diagnostic studies often include brain imaging.
- ## DIAGNOSTIC PROCEDURES
- HIV-infected children with pulmonary disease who fail to respond to empirical antibiotic therapy, those who are severely ill, and those who are suspected of having PCP should undergo an invasive diagnostic procedure, such as:
 - Bronchoscopy with bronchoalveolar lavage
 - Lung biopsy
 - Persistent diarrhea
 - Endoscopy should be considered in refractory cases.
 - Initial diagnostic studies of bacterial and viral pathogens may include analysis of cerebrospinal fluid.
- ## CLASSIFICATION
- CDC immunologic categories based on age-specific CD4⁺ T lymphocyte count and percentage of total lymphocytes
 - No evidence of suppression
 - <1 year: ≥ 1500 mcL, $\geq 25\%$
 - 1–5 years: ≥ 1000 mcL, $\geq 25\%$
 - 6–12 years: ≥ 500 mcL, 25%
 - Evidence of moderate suppression
 - <1 year: 750–1499 mcL, 15–24%
 - 1–5 years: 500–999 mcL, 15–24%
 - 6–12 years: 200–499 mcL, 15–24%
 - Severe suppression
 - <1 year: <750 mcL, <15%
 - 1–5 years: <500 mcL, <15%
 - 6–12 years: <200 mcL, <15%

■ CDC clinical categories of HIV classification in children

- N: No signs or symptoms
 - N1: No evidence of suppression
 - N2: Evidence of moderate suppression
 - N3: Severe suppression
- A: Mild signs or symptoms
 - A1: No evidence of suppression
 - A2: Evidence of moderate suppression
 - A3: Severe suppression
- B: Moderate signs or symptoms
 - B1: No evidence of suppression
 - B2: Evidence of moderate suppression
 - B3: Severe suppression
- C: Severe signs or symptoms
 - C1: No evidence of suppression
 - C2: Evidence of moderate suppression
 - C3: Severe suppression

TREATMENT APPROACH

- Care of HIV-infected children is complex and requires a multidisciplinary team including:
 - Pediatricians
 - Experts in antiretroviral therapy
 - Nutritionists
 - Physical therapists
 - Pharmacists
 - Psychologists
 - Social workers
 - Outreach workers
- A cure remains elusive.
- Effective antiretroviral therapy, with suppression of viral replication and nutritional supplementation, is important to maintaining growth.
 - Supplementation with high-calorie foods or formulas often results in increased body fat rather than lean body weight.
- Effective antiretroviral therapy can minimize or reverse the neurocognitive effects of HIV infection.
- Management of antiretroviral therapy should be directed by a specialist who has knowledge of:
 - Mechanisms of action of antiretroviral agents
 - Potential toxicities
 - Drug interactions
 - Cross-resistance patterns
- Currently available antiretroviral therapy works by interfering with the functions of these enzymes:
 - Nucleoside and nonnucleoside reverse transcriptase inhibitors

- Protease inhibitors
- Entry inhibitors
- Integrase inhibitors

- Most children acquire HIV infection during or near the time of birth, and antiretroviral therapy should be initiated in infancy.
 - Risks of drug toxicity and acquisition of drug-resistant virus are increased.
 - Decisions to initiate early therapy require balancing the benefits and risks.
 - Combination antiretroviral therapy is recommended for all infants in whom HIV infection is diagnosed in the first year of life, regardless of clinical, immunologic, or virologic status.
- For children in whom infection is diagnosed after 12 months of age, the decision to start treatment should be based on:
 - Clinical symptoms
 - Plasma HIV RNA level
 - CD4⁺ T lymphocyte count
- Combination therapy with reverse transcriptase and protease inhibitors block HIV replication and can result in:
 - Dramatic decline in virus production
 - Undetectable plasma HIV RNA levels

SPECIFIC TREATMENTS

Antiretroviral therapy

- The choice of antiretroviral regimen for children is based on several factors, including:
 - Availability of pediatric formulations
 - Potential drug interactions
 - Frequency of drug dosing
 - Potential interactions with other medications
- Before therapy begins, the child's clinical, virologic, immunologic, and nutritional status should be documented.
 - Neuropsychometric testing should be performed in children with deficits.
 - Baseline laboratory studies should include:
 - Complete blood count with differential
 - Liver function tests
 - CD4⁺ T lymphocyte count
 - Plasma HIV RNA level
- Combination antiretroviral therapy consists of a protease inhibitor or nonnucleoside reverse transcriptase inhibitor in combination with ≥ 2 nucleoside reverse transcriptase inhibitors.
 - Protease inhibitors that may be used in children include:
 - Lopinavir/ritonavir (preferred)
 - Nelfinavir
 - Ritonavir (alone)

- Amprenavir
- Indinavir
- Preferred combinations of nucleoside reverse transcriptase inhibitors are:
 - Zidovudine plus either lamivudine or emtricitabine
 - Zidovudine plus didanosine
 - Didanosine plus either lamivudine or emtricitabine
- Alternative combinations that have been less well studied in children are:
 - Abacavir plus zidovudine
 - Abacavir plus either lamivudine or emtricitabine
 - Stavudine plus either lamivudine or emtricitabine
- Stavudine and didanosine should not be used or should be used with substantial caution because of potential synergistic toxicities.
- Several combinations are not recommended because of antagonism (stavudine-zidovudine) or because of overlapping toxicities.
- Nonnucleoside reverse transcriptase inhibitors (nevirapine, delavirdine, and efavirenz) can be used in combination with nucleoside reverse transcriptase inhibitors.
- Protease inhibitors with insufficient data in children to recommend at this time
 - Atazanavir
 - Darunavir
 - Fosamprenavir
 - Tipranavir
 - Saquinavir
- Plasma HIV RNA levels should be measured 4 weeks after the child has started therapy to assess response.

Side effects

- Common side effects of nucleoside reverse transcriptase inhibitors are:
 - Anemia and neutropenia with zidovudine
 - Pancreatitis with didanosine
 - Peripheral neuropathy with didanosine and stavudine
 - Influenza-like hypersensitivity reaction with abacavir
 - Rechallenge with abacavir can be fatal.
- Common side effects of the nonnucleoside reverse transcriptase inhibitors nevirapine, delavirdine, and efavirenz are:
 - Rashes
 - Hepatitis
- Side effects of efavirenz
 - Bad dreams
 - Hallucinations
 - Confusion
 - Impaired concentration

- Side effects of protease inhibitors are gastrointestinal symptoms.
- Long-term complications of combination antiretroviral therapy include:
 - Lipoatrophy
 - Lipodystrophy
 - Hypercholesterolemia
 - Bone demineralization

Compliance

- Compliance to complex drug regimens is hindered by:
 - Large number or volume of medications
 - Poor palatability
 - Varied dosing schedules
 - Different effects of food on drug bioavailability
- Mixing drugs with foods, such as peanut butter or ice cream, may improve compliance in children.
- Behavioral therapy, begun before combination therapy is initiated, can be helpful in:
 - Designing a routine medication schedule
 - Teaching parents and caregivers methods to improve compliance
 - Teaching the child techniques for swallowing unsavory medications
- Gastric tubes may be necessary to ensure medication compliance in children who are not adherent because of medication taste or volume.
- Strict adherence to the treatment regimen is essential for the prevention of drug resistance.
 - Because of cross-resistance, resistance to 1 drug can limit effectiveness of other drugs of the same class.
 - Viral sequences obtained from plasma samples can be tested for:
 - Drug resistance mutations
 - Susceptibility profiles

Drug interactions

- HIV protease inhibitors, as well as the nonnucleoside reverse transcriptase inhibitors, are metabolized in the liver by a cytochrome P450 enzyme.
 - Protease inhibitors can inhibit this enzyme and interfere with the metabolism of many other drugs.
 - Protease inhibitors can act as potent inhibitors of 2 other P450 enzymes active in the metabolism of analgesics: β -blockers and phenytoin.
 - Ritonavir can stimulate glucuronidation, thus decreasing concentration of drugs metabolized by this pathway, including sedatives (such as lorazepam) and the narcotics morphine and codeine.

- Many drugs that have altered metabolism because of protease inhibitors are used in pediatric emergencies, including narcotic analgesics, anticonvulsants, antiarrhythmics, calcium-channel blockers, and corticosteroids.
 - These drugs should be used with caution in children receiving protease inhibitors.
 - Drugs that have narrow therapeutic margins require careful monitoring for adverse effects and measurement of drug concentrations.
- Drugs contraindicated for use with protease inhibitors include:
 - Meperidine
 - Midazolam
 - Astemizole
 - Terfenadine
 - Cisapride
 - Rifampin
- Other medications frequently prescribed for HIV-infected children are inhibitors of cytochrome P450 enzymes, including:
 - Ketoconazole
 - Itraconazole
 - Clarithromycin
 - Erythromycin
- Dose reduction of protease inhibitor may be required because inhibition of cytochrome P450 enzymes by these medications may lead to increase in the plasma concentration of protease inhibitors.
- Inducers of the cytochrome P450 enzyme system are frequently prescribed for HIV-infected children, including:
 - Antimycobacterial drugs (rifampin, rifabutin)
 - Anticonvulsants (phenobarbital, phenytoin, carbamazepine)
 - Glucocorticoids (dexamethasone)
- Increased metabolism of protease inhibitors may result in subtherapeutic levels, with the potential emergence of drug resistance.

PCP

- Before widespread prophylaxis for PCP and early antiretroviral therapy, a subset of HIV-infected children had rapidly progressive disease and died within the first year of life, frequently of PCP.
- Empirical antibiotic therapy depends on the results of clinical assessment and laboratory tests, and likelihood of adequate monitoring.
 - A third-generation cephalosporin, such as ceftriaxone or cefotaxime, can be used against both gram-positive and gram-negative bacteria.
- PCP should be treated early, usually with co-trimoxazole and corticosteroids.

Varicella and herpes zoster

- HIV-infected children who are susceptible to varicella (no prior natural infection or age-appropriate varicella immunization) should receive:
 - Varicella-zoster immunoglobulin preparation within 96 hours of exposure to varicella *or*
 - Intravenous immunoglobulin, if varicella-zoster immunoglobulin is not available
- Disseminated infection can occur with herpes zoster, and oral or parenteral therapy with acyclovir is warranted.

WHEN TO ADMIT

- Ill-appearing children should be hospitalized.

WHEN TO REFER

- HIV-infected children should be managed by physicians who have knowledge and experience in taking care of children with HIV infection.

FOLLOW-UP

- Frequency of medical follow-up visits depends on many factors, including:
 - Child's clinical status
 - Expected compliance with therapy
- Follow-up should include measurements of HIV RNA levels and CD4⁺ T lymphocyte counts every 3 months.
- Child care or school attendance
 - Risk of HIV transmission appears to be negligible, and HIV-infected children should not be restricted from attending child care or school.
 - Special consideration may be warranted for those with unusual risk factors for transmission, such as frequent biting or scratching, severe dermatitis, or bleeding disorders.
- Supportive care
 - Many parents and guardians are not willing to tell the child that he or she is infected with HIV.
 - Most children are made aware of their illness through frequent medical visits and medications.
 - The primary care physician's relationship with the patient provides the best position to promote and assist with disclosure.
 - Appropriate disclosure tailored to the child's cognitive level is helpful in alleviating guilt and allowing discussion among the child, caregivers, and health care professionals.
 - Uninfected siblings of HIV-infected children are emotionally affected by the diagnosis and should be included in support groups and counseling.

- The primary care physician plays a critical role in providing advice and support as the child nears death, helping the family interpret the complexities of critical care and assisting decisions on the appropriateness of heroic interventions.
 - The physician may be able to assist in family care for the dying child at home if critical care is deemed futile.
 - After the child's death, the physician should continue to support the family through the grief process.
 - Because many pediatricians invest much time and emotional energy in caring for an HIV-infected child, many take the opportunity to express sympathy by attending the funeral.

COMPLICATIONS

- HIV infection and secondary opportunistic infections can involve all organ systems.
- Bacterial and viral pathogens causing meningitis and encephalitis are similar to those in nonimmunocompromised children.
 - Common pathogens include:
 - *Cryptococcus neoformans*
 - *Toxoplasma gondii*
 - Cytomegalovirus
- Pulmonary disease
 - PCP
 - Was frequently found before routine prophylaxis of HIV-exposed infants
 - Typically appears at 3–6 months of age
 - Characterized by:
 - Tachypnea
 - Cough
 - Hypoxemia
 - Diffuse alveolar infiltrates on chest radiograph
 - Common respiratory pathogens seen in children with HIV include:
 - Respiratory syncytial virus
 - Parainfluenza virus
 - Influenza virus
 - Adenovirus
 - Pneumococcus is the most common bacterial cause of pneumonia in HIV-infected children.
 - LIP is a chronic lung disease resulting from lymphoid hyperplasia in the lungs.
 - Children may be asymptomatic or may have chronic cough and wheezing.
 - Children are typically older than those with PCP.
 - Children with LIP frequently have generalized lymphadenopathy and parotid enlargement.
- Infectious causes of diarrhea in HIV-infected children include pathogens of healthy children and numerous opportunistic pathogens.
 - Common parasitic pathogens causing persistent diarrhea include:
 - *Giardia lamblia*
 - *Entamoeba histolytica*
 - *Cryptosporidium* species
 - *Isospora belli*
 - Cytomegalovirus may cause colitis in advanced immunosuppression.
 - Persistent diarrhea can significantly compromise quality of life and nutritional status.
- Central nervous system disease
 - Microcephaly
 - Developmental delay
 - Spasticity
 - Abnormal reflexes
 - Gait abnormalities
 - Central nervous system lymphomas (rare)
- Hematologic abnormalities
 - Leukopenia
 - Anemia
 - Thrombocytopenia (may be the presenting illness)
- Dermatologic conditions include:
 - Recurrent herpes simplex
 - Varicella-zoster virus infections
 - Severe molluscum contagiosum
 - Chronic fungal infections
 - Atopic dermatitis
 - Drug-induced eruptions, particularly with co-trimoxazole
- Drug-induced bone marrow suppression can follow therapy with:
 - Zidovudine
 - Co-trimoxazole
 - Ganciclovir
- Hepatomegaly and increases in hepatic aminotransferase levels are commonly seen, often in the absence of clinically apparent liver disease.
- HIV cardiomyopathy may lead to congestive heart failure.
- HIV nephropathy is a common cause of proteinuria and can progress to nephrotic syndrome.
- HIV-infected children in whom virus replication is not controlled by antiretroviral therapy are frequently stunted in growth.
 - Severe wasting may be seen in advanced disease.
- Cancers are not as common in HIV-infected children, but lymphomas and leiomyosarcomas can occur.

PROGNOSIS

- High plasma HIV levels and low CD4⁺ T lymphocyte counts are predictive of poor prognosis.

PREVENTION

Preventing perinatal HIV transmission

- Antiretroviral therapy administered to women during pregnancy and delivery and to infants during the first 6 weeks of life greatly reduces the rate of perinatal HIV transmission.
- Although the total number of perinatal infections has decreased, the proportion caused by intrauterine transmission has increased.
 - This supports a greater role for antiretroviral therapy and mode of delivery on influencing intrapartum transmission.
- Administration of zidovudine to women during pregnancy and labor and to infants for the first 6 weeks of life has been shown to reduce perinatal HIV transmission by two-thirds (from 26% to 8%).
 - This regimen is the standard of care for HIV-infected pregnant women and their newborns.
- Early identification of HIV-infected pregnant women allows for:
 - Appropriate care of the mother
 - Avoidance of ongoing HIV exposure of the infant through human milk
 - Early institution of PCP prophylaxis for the infant at 4–6 weeks of age
- Prevention of maternal-infant HIV transmission
 - Identification of HIV-infected women before or during pregnancy is critical.
 - Prenatal HIV counseling and testing should be provided to all pregnant women.
 - Initial HIV antibody testing should be performed early in pregnancy and repeated in the third trimester for women at risk.

Immunization

- Immunizations are generally safe for HIV-infected children.
- Immune suppression caused by HIV results in less assurance of protection after immunization than in HIV-uninfected children.
- The small risk of serious complications from live viral vaccines has led to special recommendations for HIV-infected children.
- RotaTeq should not be administered to immunocompromised children.
 - HIV-exposed infants with testing that does not support HIV infection may receive an initial dose of RotaTeq before documentation that infant is not infected (negative PCR after 4 months of age).

- Toxoids, subunit vaccines, inactivated vaccines, and recombinant vaccines are not associated with increased risks of complications in HIV-infected children, including:
 - Diphtheria and tetanus toxoids
 - Acellular pertussis vaccines
 - Inactivated poliovirus vaccine
 - *Haemophilus influenzae* type b
 - Pneumococcal conjugate vaccines
 - Inactivated influenza vaccine
 - Hepatitis A and B vaccines
- These vaccines should be administered to HIV-infected children according to routine immunization schedule.
 - Because of an increased risk of invasive infection with *S pneumoniae*, immunization of HIV-infected children with pneumococcal conjugate vaccine is particularly important.
 - HIV-infected children may develop lower antibody titers than healthy children after immunization and are more likely to lose protective antibody earlier.
- Live viral vaccines may result in infection and disease resulting from vaccine virus in severely immunocompromised HIV-infected children, although the risk is quite small. Examples include:
 - Varicella vaccine
 - Measles, mumps, and rubella vaccines
- After a single reported death, advisory groups in the US have recommended withholding measles vaccine from HIV-infected children with severe immunosuppression, defined as CD4⁺ T lymphocyte count <15%.
 - Measles-mumps-rubella vaccine should be administered to HIV-infected children at 12 months unless severely immunocompromised (CD4⁺ <15%).
 - Immune response to measles vaccine in HIV-infected children may be poor, and vaccinated children may remain susceptible.
 - Serious complications after mumps or rubella immunization have not been reported.
- Live varicella virus vaccine is also recommended for HIV-infected children on the basis of their degree of immunosuppression and symptoms.
 - The AAP Committee on Infectious Diseases recommends varicella vaccine for asymptomatic and mildly symptomatic HIV-infected children who have CD4⁺ T lymphocyte percentages ≥15%.
 - Serious adverse events after administration of varicella vaccine to HIV-infected children are rare.

Antimicrobial prophylaxis

- PCP prophylaxis should be administered to HIV-exposed infants beginning at 6 weeks of age, even if HIV infection is not confirmed.
 - Continue until 12 months of age or until HIV has been excluded.

- PCP prophylaxis is administered:
 - For children 1–5 years of age if CD4⁺ T lymphocyte count is <500 cells/mL
 - For children 6–12 years of age if it is <200 cells/mL
- Lifelong PCP prophylaxis is recommended for children who have a history of PCP, despite immune reconstitution.
- Recommended regimen is co-trimoxazole taken orally 3 days a week.
- Alternative regimens include dapsone or pentamidine.
- HIV-infected children who have recurrent oral candidiasis may benefit from antifungal prophylaxis.
 - Oral nystatin
 - Clotrimazole
 - Fluconazole
- *Mycobacterium avium-intracellulare* in children with CD4⁺ T lymphocyte counts <100 cells/mL
 - Weekly oral azithromycin for prophylaxis
 - Daily rifabutin for infection
- Immunoglobulin should be provided to susceptible (no age-appropriate measles immunization) HIV-infected children within 6 days of exposure to measles.
 - Measles immunization should be delayed 6 months after receipt of immunoglobulin.

Postexposure prophylaxis after community needlestick injuries

- Parents, caretakers, and physicians often are most concerned about transmission of HIV after accidental injury from a discarded needle.
- No consensus or recommendation is available to guide management in such circumstances.
- Risk of HIV transmission after occupational exposure to HIV-infected blood is 0.3%.
- Most experts agree that risk after community needlestick injury is lower than risk after occupational exposure.
- Factors to be considered in the use of antiretroviral agents for postexposure prophylaxis include:
 - Potential risk of HIV transmission
 - Drug toxicities
 - Ability and willingness of the family to adhere to therapy
- Regimens for occupational postexposure prophylaxis may be followed.
- Pediatricians caring for adolescents must ensure they have knowledge of risks of acquiring HIV and other sexually transmitted infections through unprotected sex.

Hoarseness

DEFINITION

- Hoarseness is a symptom of vocal dysfunction that describes a breathy, harsh, coarse, strained, or raspy voice.
- In children, “hoarseness” can be used to describe both the quality of voice and the quality of cry.
- Hoarseness results from a pathologic change in the vibratory nature of the vocal folds.
- Although sometimes occurring concurrently, hoarseness should be discerned from stridor, a sign of turbulent airflow caused by obstructive lesions in the airway.
- Causes vary by age group and can be attributed to infectious, anatomic, traumatic, inflammatory, neoplastic, neurologic, and iatrogenic sources.

EPIDEMIOLOGY

- Prevalence
 - Described as 6–38% in childhood

MECHANISM

Congenital causes of hoarseness

- Laryngeal anomalies
 - Laryngomalacia
 - Glottic webs
 - Subglottic stenosis
 - Laryngeal cleft
- Cystic lesions
 - Laryngocele
 - Saccular cyst
 - Thyroglossal duct cyst
- Angiomas
 - Lymphatic malformation
 - Hemangioma
 - Arteriovenous malformation
- Cri du chat syndrome

Neurogenic (congenital and acquired)

- Supranuclear (eg, hydrocephalus)
- Nuclear (eg, Arnold-Chiari malformation, Guillain-Barré syndrome)
- Peripheral (eg, myasthenia gravis, cardiovascular anomalies, recurrent laryngeal nerve trauma)
- Psychogenic hoarseness

Vocal cord abuse

- Vocal cord nodules
- Vocal cord polyps

Neoplasia

- Papilloma
- Squamous cell carcinoma

Physical voice change of puberty

- Inflammatory
 - Infectious
 - Simple laryngitis
 - Diphtheria
 - Laryngotracheitis
 - Supraglottitis (epiglottitis)
 - Noninfectious
 - Laryngopharyngeal reflux (LPR)
 - Chronic laryngitis
 - Allergic laryngitis
 - Angioedema
 - Rheumatoid arthritis
 - Relapsing polychondritis
 - Smoking
- Traumatic
 - General
 - Hematoma
 - Laryngeal cartilage fracture
 - Impacted foreign body
 - Postintubation
 - Arytenoid dislocation
 - Cord avulsion
 - Granuloma
 - Acquired glottic web
 - Subglottic stenosis
 - Recurrent laryngeal nerve injury
 - Thyroidectomy
 - Tracheotomy
 - Cardiac surgery
 - Tracheoesophageal fistula repair
 - Tracheal resection
 - Penetrating neck wound

HISTORY

- A thorough history is an essential.
- Age is a critical factor in the development of an appropriate differential diagnosis.
 - Neurologic and congenital fixed anatomic lesions typically occur at birth.
 - Inflammatory, neoplastic, traumatic, or iatrogenic causes occur later.
- Information on quality of the voice with speech or crying, exacerbating or alleviating factors, and associated symptoms
- The onset and course of dysphonia should be considered.
 - Intermittent dysphonia may be related to infectious or inflammatory causes, such as laryngitis.

- Persistent dysphonia may suggest a fixed anatomic lesion.
- Progressive, unremitting hoarseness may suggest an enlarging neoplasm.
- Underlying reflux may be present in patients with such symptoms as:
 - Regurgitation or vomiting
 - Feeding difficulties
 - Throat clearing
 - Foreign body sensation
 - Cough
- Stridor that accompanies hoarseness should be investigated and treated in an expeditious fashion.
 - Turbulent airflow resulting from airway obstruction may be life threatening.

PHYSICAL EXAM

- Thorough physical examination should include a complete head and neck examination with inspection of cranial nerve function for craniofacial anomalies.
 - Cutaneous head and neck hemangiomas may suggest a potential laryngeal hemangioma.
 - Signs of aspiration during deglutition may be suggestive of sensorimotor causes of dysphonia, such as vocal cord paralysis.

DIFFERENTIAL DIAGNOSIS

- Forming a differential diagnosis for the hoarse child depends on:
 - Quality of hoarseness
 - Progression of symptoms
 - Related infection
 - History of surgery or trauma
 - Associated respiratory distress

Causes, by patient age

- The age of the patient at the onset of hoarseness is a useful way to organize the potential causes.
 - 0–6 months
 - Traumatic intubation
 - Iatrogenic: surgical
 - Neurogenic: central or peripheral
 - Neoplastic: hemangioma
 - Congenital: web, cleft, cyst
 - 6 months to 5 years
 - Traumatic: foreign bodies, intubation
 - Infection: upper respiratory infection (URI)
 - Neoplastic: papillomas
 - Behavioral, traumatic: nodules
 - Inflammatory: allergy, LPR

- 5–13 years
 - Behavioral, traumatic: nodules
 - Infectious: URI
 - Inflammatory: allergy, LPR
 - Neoplastic
- 13–18 years
 - Infectious: URI
 - Inflammatory: allergy, LPR
 - Behavioral, traumatic:
 - Male: mutational or transitional voice
 - Female: nodules
 - Functional: muscle tension dysphonia

Neonate and infant

- Hoarseness at birth or shortly thereafter is most often attributable to causes that are:
 - Congenital
 - Traumatic or iatrogenic
 - Neoplastic
 - Inflammatory
- In this age group, “hoarseness” often refers to a weak or breathy cry.
- Neonatal vocal cord paralysis is a well-known cause of hoarseness and stridor.
 - Bilateral vocal cord paralysis is usually congenital and frequently causes respiratory distress and stridor.
 - Central nervous system disease, such as the Arnold-Chiari malformation, must be ruled out.
 - Unilateral vocal cord paralysis is more likely to exhibit initially as hoarseness or dysphagia.
 - A weak or breathy cry after thoracic or cervical surgery may indicate recurrent laryngeal nerve injury as a source of iatrogenic vocal cord paralysis.
 - Traumatic intubation can cause arytenoid cartilage dislocation, with subsequent vocal cord immobility and hoarseness.
- Congenital laryngeal webs result from failure of larynx to canalize fully during embryologic development.
 - Webs may occur exclusively with hoarseness, but they may be associated with aphonia, stridor, and respiratory distress.
 - Webs vary from thin slips of tissue between the anterior of the vocal cords to complete laryngeal atresia (congenital high airway obstruction syndrome).
- Laryngeal saccular cysts are characterized by symptoms of airway obstruction and dysphagia.
 - Saccular cysts are filled with mucinous fluid and arise as a result of an abnormal dilation of the saccule of the larynx secondary to secretory outflow obstruction.

- Posterior laryngeal clefts are an uncommon anomaly resulting in an abnormal opening in the posterior larynx.
 - Clefts can involve the posterior laryngeal commissure or may extend through the cricoid inferiorly through the tracheoesophageal septum.
 - Symptoms depend on extent of the cleft and at birth, typically include aspiration, stridor, respiratory distress, and weak cry.
- Subglottic hemangiomas classically occur at 1–6 months of age, with varying degrees of respiratory distress, stridor, cough, dysphagia, and hoarseness.
 - Natural history of hemangiomas is that of proliferation followed by involution.
 - Subglottic hemangiomas can be unilateral, bilateral, or circumferential.
 - More common in girls than in boys
 - Cutaneous hemangiomas of the head and neck are found concurrently in ~50%.
 - A relationship may exist between pediatric and adult laryngeal disease and reflux.
 - *Gastroesophageal reflux* (GER) refers to the backflow of stomach contents into the esophagus.
 - *LPR* refers to backflow of stomach contents into the laryngopharynx.
 - GER commonly produces emesis, dysphagia, sleep disturbance, and failure to thrive.
 - The association among GER; LPR; and neonatal laryngeal disorders, such as hoarseness, posterior laryngitis, and silent aspiration, remains complicated and controversial (see Dysphagia and Gastroesophageal reflux disease).
- Vocal nodules arise from phonotrauma or voice abuse more frequently in boys than in girls.
 - Symptoms may fluctuate on the basis of aggravation by vocal abuse and respiratory tract infections.
 - Symptoms may worsen suddenly when polyps swell from internal hemorrhage from vocal trauma.
 - Children with vocal nodules may share symptoms with other family members with similar traits.
- Airway trauma is a potential cause of hoarseness.
 - Sources include blunt or penetrating injuries and intubation trauma.
- Progressive and unrelenting hoarseness suggests a possible neoplastic cause.
 - 98% of pediatric laryngeal neoplasms are benign; recurrent respiratory papillomatosis (RRP) is by far the most common lesion.
 - RRP may be found on other upper aerodigestive tract mucosal surfaces and have a characteristic “cluster of grapes” appearance.
 - RRP may be indistinguishable from the rare laryngeal squamous cell carcinoma of childhood.

Adolescents

- Hoarseness may be of behavioral or psychogenic etiology.
- Mutational voice disorder occurs in male adolescents, resulting in hoarseness and high pitch during the stress of physiologic pubertal voice change.
- Paradoxical vocal fold dysfunction (seen more frequently in girls) is psychogenic in origin and often misdiagnosed as asthma.

IMAGING

- Subject to many of the same sources of hoarseness as adults
- Leading causes include infectious, inflammatory, traumatic, and neoplastic conditions, such as laryngitis, LPR, vocal nodules, and respiratory papillomata.
- Infectious disorders, such as infective laryngitis, supraglottitis, and laryngotracheobronchitis, rarely present a diagnostic challenge.
- Concern over the airway should always take precedence; a hoarse voice may be an early indicator of impending airway compromise by epiglottitis.
- The role of LPR in children is debated; however, infrequent reflux events have been shown to cause hoarseness in adults.
 - LPR has been found in association with pediatric conditions, such as vocal fold nodules, posterior laryngitis, false vocal cord edema, vocal cord granulomas, functional voice disorders, and hoarseness.
 - Animal studies have shown that subglottic stenosis results when gastric acid is applied to the subglottic mucosa of dogs.
- Diagnostic imaging is of prime importance when central nervous system disease, external compression, cancer, or external trauma is suspected.
- Chest and neck plain-film radiography may demonstrate mediastinal masses, cardiovascular anomalies, or abnormalities in the air column suggesting possible infectious or obstructive diseases.
- Computed tomography (CT) and virtual bronchoscopy are excellent methods for:
 - Specifically defining the caliber of the airway
 - Delineating the site and extent of pathologic changes in airway caliber
 - Indications for laryngeal or neck CT include congenital cysts, solid neoplasms, and external trauma.
- Magnetic resonance imaging is helpful:
 - When central nervous system disease is suspected
 - In evaluating possible airway hemangiomas
 - In identifying vascular malformations

- Barium esophagraphy has variable sensitivity and specificity for the diagnosis of LPR.

- Useful mainly for detecting anatomic abnormalities, such as hiatal hernia

DIAGNOSTIC PROCEDURES

Laryngoscopy

- Flexible nasopharyngolaryngoscopy, indirect mirror laryngoscopy, and rigid videostroboscopy are all methods for visualizing the larynx that can provide useful clues.

- Indirect laryngoscopy using a mirror

- Can be performed on cooperative children
- Can visualize gross disease and inflammatory changes in the larynx
- This technique has largely been replaced.

- Flexible fiberoptic nasopharyngolaryngoscopy

- Provides clear views of laryngeal anatomy and function
- Can be performed on virtually all age groups, although toddlers and developmentally delayed patients pose the greatest challenge to the examiner
- Topical anesthesia and topical decongestants can facilitate examination.
- The flexible endoscope is gently passed through the nose or mouth.
- Examination in a nonmonitored setting is not advisable if the patient has a tenuous airway or severe congenital cardiac anomalies.

- Videostroboscopy

- A rigid, angled telescope placed gently into the oropharynx is used for dynamic examination of laryngeal anatomy and function.
- The examination requires a cooperative child.
- Uses rapidly pulsed light to examine vibratory characteristics of the vocal fold mucosa
- Recorded on video to allow repeated assessments viewed at different speeds to enhance visualization of the vibratory quality of the laryngeal mucosa
- Vocal nodules or other lesions on surface of the vocal fold will dampen the mucosal wave.

Reflux testing

- In the absence of identifiable disease in the hoarse child, investigation into LPR may be warranted.

- Several diagnostic modalities exist for the workup of LPR, including:

- pH monitoring
- Impedance testing
- Nuclear medicine scintiscan
- Barium esophagoscopy (see Imaging)
- Direct laryngoscopy with or without biopsy

- Ambulatory 24-hour single-electrode pH monitoring is the gold standard for the diagnosis of GER.

- Double-electrode pH probe, with distal esophageal and pharyngeal electrodes, however, is thought to be the best method for diagnosing LPR and the otolaryngologic manifestations of GER.

- Although pH-monitoring studies remain the gold standard for diagnosis of GER and LPR, they do not detect episodes of nonacidic reflux.

- Multichannel intraluminal impedance monitoring and nuclear medicine scintigraphy

- Measures both acidic and nonacidic episodes of reflux, which may play a role in apnea, apparent life-threatening events, aspiration, and sleep disturbance.
- Nuclear medicine scintiscans have specificity of 83–100% but have been shown to be only 15–59% sensitive and lack a standardized technique, making comparisons between studies of limited use.
- Impedance monitoring evaluates the pH-independent change in intraluminal electrical resistance that occurs with the movement (anterograde or retrograde) of a bolus of food, liquid, or gas within the esophagus.
 - This technique may be a reliable tool for evaluating the association between GER-related symptoms and nonacidic reflux events.
 - It may ultimately replace pH monitoring as the standard tool for detecting LPR in infants and children.

- Laryngoscopy with biopsy

- May be the most specific test for LPR
- At least 1 study has failed to show a correlation between laryngoscopy and upper pH probe findings with significant laryngeal histopathologic inflammatory findings.

TREATMENT APPROACH

- Most pediatric hoarseness results from benign, reversible, and self-limited disease.

- Some causes of hoarseness are progressive, malignant, and potentially life threatening.

- Thorough evaluation, precise diagnosis, and appropriate intervention are therefore essential.

SPECIFIC TREATMENT

Congenital lesions

- Management of hoarse voice resulting from unilateral or bilateral vocal cord paralysis is usually secondary to stabilization of the airway and management of dysphagia and aspiration.
- Tracheotomy is sometimes required in patients with bilateral vocal cord paralysis.

- Conservative management has been advocated in selected patients.
 - Patients with congenital or acquired unilateral vocal cord paralysis frequently experience spontaneous resolution of paralysis or compensatory movement of the unaffected cord over time.
 - Recovery has been noted up to 11 years after paralysis.
- In cases of persistent unilateral cord paralysis with persistent hoarseness, the treatment of choice remains speech therapy.
 - Successful surgical vocal cord medialization techniques have been reported.
- Laryngeal webs are managed surgically, endoscopically, or via more extensive open laryngotracheal reconstruction techniques.
 - The type of operation depends primarily on location and extent of lesion.
 - Thin webs are more amenable to endoscopic management.
- Saccular cysts of the larynx
 - Often managed endoscopically via aspiration and marsupialization using sharp dissection or with a carbon dioxide (CO₂) laser.
 - Cyst recurrence is well documented following endoscopic management.
 - Open resection of the cyst may be necessary.
- Posterior laryngeal clefts vary greatly in extent and symptoms.
 - Extensive or symptomatic clefts must be repaired as early as possible.
 - Endoscopic repair is possible in small clefts limited to larynx and upper trachea.
 - More extensive open techniques are used for larger clefts.
 - Tracheotomy may be placed in cases in which staged reconstruction is necessary.
 - A gastrostomy tube is often necessary to limit aspiration and protect the operative site.

Neoplasia

- Subglottic hemangioma is a complicated airway anomaly without universally accepted treatment.
 - Numerous management options exist, including:
 - Close observation
 - Systemic or intralesional steroids
 - Laser ablation
 - Open surgical excision
 - Tracheotomy
- RRP is an airway tumor with a large number of accepted primary and adjuvant therapeutic modalities.
 - CO₂ laser excision remains a popular method for removing laryngeal papilloma, although it is associated with potentially severe sequelae, such as:
 - Airway fire
 - Scarring

- Chronic laryngeal edema with airway compromise
- Vocal fold scarring
- Poor voice
- Pulsed dye laser therapy was introduced as a less traumatic alternative that can be used safely and effectively under local anesthesia in older patients.
- Powered instrumentation, such as the microdebrider, is successfully used for excision of RRP.
- Adjuvant therapies have been used with varying degrees of efficacy and safety, such as:
 - Intralesional cidofovir
 - Interferon- α
 - Indole-3-carbinol
 - Heat-shock protein E7

Inflammation and infection

- Acceptable for the management of GER and LPR in infants and children
 - Behavioral and lifestyle modifications
 - Pharmacotherapy using:
 - Histamine-2 antagonists
 - Proton-pump inhibitors
 - Prokinetic agents
 - Antacids
 - Surgical therapy with fundoplication
- Viral laryngitis and laryngotracheobronchitis are generally treated conservatively.
 - May require airway protection or intravenous steroids in severe cases
- Bacterial infections, such as epiglottitis and membranous laryngotracheobronchitis, necessitate:
 - Early airway protection
 - Intravenous antibiotics directed against *Staphylococcus aureus* and *Haemophilus influenzae*, unless culture results direct differently

Trauma

- Management of vocal fold nodules resulting from phonotrauma
 - Behavioral modification
 - Speech therapy aimed at maximizing vocal hygiene
 - Surgical excision, rarely, because failure to correct underlying voice misuse is likely to result in recurrence
- Arytenoid dislocation resulting from intubation trauma can be adequately treated if recognized and reduced early under anesthesia with microlaryngoscopy.
- Blunt laryngeal trauma
 - Close observation
 - Possibly systemic corticosteroids

- Tracheotomy in cases of severe laryngeal injury and edema
- In adolescents with laryngeal fracture, open reduction and fixation may be required.

WHEN TO REFER

- Recognized cardiac, esophageal, or neurologic disease
- Progressive hoarseness
- Presence of cutaneous hemangioma

- Hoarseness after external trauma or uneventful intubation
- Poor speech intelligibility or psychosocial sequelae
- Hoarseness that has been present since birth

WHEN TO ADMIT

- Presence of respiratory distress, stridor, tachypnea, or tachycardia
- Hoarseness following external trauma

Human Herpesvirus-6 and Human Herpesvirus-7 Infections

DEFINITION

- Human herpesvirus (HHV)-6, formerly called *human B-lymphotrophic virus*, and HHV-7 are classified as herpesviruses on the basis of their physical and genetic similarities to others of the group.
 - Herpes simplex virus type 1
 - Herpes simplex virus type 2
 - Cytomegalovirus
 - Epstein-Barr virus
 - Varicella-zoster virus
 - Newly discovered virus associated with Kaposi sarcoma, HHV-8
 - HHV-6 and HHV-7 can be distinguished from other herpesviruses by DNA hybridization or by reactions with virus-specific monoclonal antibodies.
 - HHV-6 exists in 2 forms.
 - Variant A
 - The range of illnesses, if any, caused by HHV-6A is unknown.
 - Variant B
 - Typically associated with childhood illnesses, such as roseola, and some adult infections.
 - HHV-6 and HHV-7 are 2 of the known causative agents of roseola.
 - Classic childhood exanthem, also known as:
 - Roseola infantum
 - Exanthem subitum
 - 3-day fever
 - Sixth disease
 - Pseudorubella
 - The spectrum of disease associated with these agents is now understood to be far broader than the benign illness of roseola.
- The prevalence of antibody decreases and reaches a low point by 6 months of age.
 - Nearly 90% of children have detectable antibody to HHV-6 by 1 year of age.
 - Adults from countries around the world show HHV-6 antibody detection rates of 88–90%.
 - Prevalence of antibody to HHV-7 increases with age.
 - 60% of young adolescents have detectable titers.
 - For both viruses, these levels persist unchanged through young adulthood and decrease slightly thereafter.
- Primary HHV-6 infection is clearly a major cause of morbidity in infancy and early childhood.
 - 77% of infants from birth through age 24 months acquired primary HHV-6 infection.
 - >90% of episodes were symptomatic.
 - 39% visited a physician for the illness.
 - Febrile HHV-6 infection is more significant than previously realized.
 - Primary HHV-6 infection exhibiting as an acute febrile illness was documented in:
 - Approximately 10% of children <3 years of age
 - 20% of children 6–12 months of age
 - HHV-6 infection was the cause of one-third of febrile seizures in children <2 years.
 - 13% were hospitalized after seeking care at an emergency department.
 - Most HHV-7 infections seem to be asymptomatic because the rate of seropositivity is high.
 - Detectable viremia with clinical illness occurs in only 1% of children <10 years of age.
 - The contribution of HHV-7 infection to emergency department use, hospitalization, or physician visits is unclear.
 - 1% of children <10 years of age have demonstrated HHV-7 viremia.
 - 86% had fever.
 - 40% had seizures.
 - 20% were hospitalized.

EPIDEMIOLOGY

HHV-6 and HHV-7

- Prevalence
 - The rate of subclinical disease is high.
 - Three-quarters of children are infected with HHV-6 by age 2 years.
 - Most infections are symptomatic.
 - Age
 - Recognition of infection is unusual at other ages.
 - Rare cases in adults and neonates have been reported.
 - Most HHV-6 and HHV-7 infections are sporadic.
 - Family and institutional epidemics are occasionally noted.
 - Serologic surveys show that:
 - Virtually all full-term infants have passively acquired maternal antibody to both HHV-6 and HHV-7 at birth.
- Seizures
 - Not a prominent manifestation of HHV-6 infection, and occur no more frequently than with other febrile illnesses
 - HHV-6 infection is a major factor, accounting for up to one-half of such incidents in children <2 years of age seeking care at an emergency department.
 - HHV-6 DNA can be identified in cerebrospinal fluid (CSF) of up to 70% of children during primary infection and of 28% of previously infected children.

Roseola**■ Prevalence**

- Primary infection with HHV-7 accounts for approximately 10% of first and most second cases of roseola.
- HHV-7 infection occurs somewhat later than HHV-6, at a mean age >12 months.
- Approximately 15% of clinical cases of roseola cannot be attributed to either virus.

■ Age

- 30% of children will experience the clinical roseola between 6 months and 2 years of age.
- The first episode usually occurs when the child is 7–9 months of age.
- 60% will be diagnosed by 3 years of age.
- Nonroseola illness is probably more common.

■ Seasonality

- Cases of roseola are seen year round.

■ Geography

- In Japan, roseola is diagnosed in 60% of children in the first 3 years of life.

ETIOLOGY**■ HHV-6 and HHV-7 are 2 of the known causative agents of roseola.**

- A child's first episode of roseola is usually caused by HHV-6B.

■ The incubation period for HHV-6 and HHV-7 infection is 5–15 days.

- Modes of transmission and period of communicability are unclear.
 - Saliva is thought to be the most likely mode of transmission.
 - HHV-6 and HHV-7 can be isolated from saliva of 70–80% of healthy persons >1 year of age.
- HHV-6 is most frequently isolated from peripheral blood mononuclear cells.
- In an extensive study of 3-generation families, DNA restriction analysis of HHV-7 isolates showed similar patterns within households.
- Most patients have no known exposure.
- Despite direct evidence of intrauterine or perinatal transmission of HHV-6, no consistently recognized sequelae attributed to such infection exist.

■ HHV-6 and HHV-7 exist in many healthy persons, including those who have virus-specific antibody.

- HHV-6 has been isolated from saliva, plasma, and many cell lines.
- HHV-7 is isolated most often from the saliva in healthy persons.

■ As with other herpesviruses, latent or persistent asymptomatic viral infection occurs after the primary infection.

- The site of latency is not clear, but during reactivation these viruses may appear in:
 - Oral or genital secretions
 - Mononuclear leukocytes
 - Human milk
 - CSF
- HHV-6 infection may reactivate during:
 - Primary HHV-7 infection
 - Acute febrile illnesses
 - Periods of immunodeficiency, such as treatment with steroids
- Reactivation characteristics of HHV-7 are unknown.

■ Both viruses interfere with the function of certain classes of T lymphocytes.

- Evidence is emerging that HHV-6, and perhaps HHV-7, act as cofactors in the course of HIV infection.
- Role of these viruses is under investigation in:
 - Lymphoreticular cancer
 - Chronic fatigue syndrome
 - Other conditions, such as multiple sclerosis

RISK FACTORS**■ Poverty and larger family size may be risk factors for early acquisition of HHV-6.****SIGNS AND SYMPTOMS****■ Clinical characteristics of HHV-6 and HHV-7 infections in normal children are shown in the table Clinical Characteristics of Human Herpesvirus (HHV)-6 and HHV-7 Infections in Normal Children.****Roseola**

- The first recognized clinical manifestation of primary HHV-6, and perhaps HHV-7, infection
- Recognition is based almost entirely on the observation of a classic clinical course.
- Fever with temperature as high as 102.2°F to 105.8°F (39°C–41°C) suddenly develops in a previously well infant.
- Except for irritability, the child does not seem as sick as the temperature indicates.
- Physical findings are few.
 - Painless posterior auricular, suboccipital, or cervical lymphadenopathy
 - Slight eyelid edema, giving the child a sleepy-eyed or droopy appearance
 - Nagayama spots, erythematous macules appearing on the soft palate and near the uvula, are observed regularly after 1–2 days.

Clinical Characteristics of Human Herpesvirus (HHV)-6 and HHV-7 Infections in Normal Children

Signs and Symptoms	Roseola (1945)	Febrile HHV-6 (1994)	Primary HHV-6 (2005)	Febrile HHV-7 (1997, 1998)	Viremic HHV-7 (2006)
Fever	100%	98–100%	58%	100%	87%
Rash at presentation	100%	6–4%	31%	13–86%	0%
Pruritus	1.2%	NR	NR	NR	NR
Desquamation	10%	0%	NR	NR	NR
Pigmentation	0%	7%	NR	NR	NR
Lymphadenopathy	97.5%	NR	NR	NR	NR
Cervical	45%	31%	NR	NR	NR
Erythematous tympanic membranes	92.5%	P	NR	NR	NR
Constipation	40%	NR	NR	NR	NR
Upper respiratory tract symptoms	25%	41%	66%	7%	13%
Nonspecific prodromal symptoms	NR	14%	NR	NR	33%
Diarrhea	15%	33–68%	26%	38%	7%
Meningismus	5%	NR	NR	NR	NR
Convulsions	3.7%	8%	0%	7–75%	40%
Bulging fontanelle	NR	26%	NR	NR	NR
Irritability	92%	P	70%	88%	NR
Edematous eyelids	NR	30%	NR	NR	NR
Nagayama spots ^a	87%	65%	NR	NR	NR
Anorexia	80%	NR	NR	NR	NR
Abdominal pain	25%	NR	NR	NR	NR
Cough	11.2%	P, 50%	34%	NR	NR
Headache	5%	NR	NR	NR	NR
Earache or otitis media	2.5%	30%	NR	NR	7%
Aching joints	2.5%	NR	NR	NR	NR
Vomiting	NR	NR	8%	NR	7%
Asymptomatic	NA	NA	6%	NA	0%
Roseola	100%	17–98%	24%	NR	0%

Abbreviations: NA, not applicable to the study design; NR, not reported; P, reported as present with no numerical value.

^a Erythematous streaks or spots on the soft palate and uvula.

- Rarely, mild coryza, otitis media, or a bulging fontanelle
 - After a 2- to 5-day course, fever resolves dramatically while rash simultaneously appears.
 - With defervescence, the child seems to have recovered, despite the rash.
 - Typical exanthem occurs as macular or maculopapular blanching patches surrounded by a lighter halo.
 - Eruption usually begins on the neck and spreads to trunk and extremities, sparing the face.
 - Rash fades within 4 hours to 4 days and may be missed if it is faint or occurs at night.
- Roseola may also occur in a young infant as an afebrile exanthem.

Mononucleosis-like disease

- HHV-6 infection in adults rarely causes a roseola-like illness.
- Both severe and mild infectious mononucleosis-like disease have been reported in adults with HHV-6 infection.
- Disease lasts several weeks and is associated with:
 - Slight fatigue
 - Headache
 - Sore throat
 - Cervical lymphadenopathy
 - Transient increase in liver enzymes
- Infectious mononucleosis-like illness associated with HHV-6 has been noted in infants.
- HHV-7 has been isolated from a child with a clinical picture of chronic Epstein-Barr virus infection, characterized by:
 - Pancytopenia
 - Fever
 - Hepatosplenomegaly

Seizures

- May be single or recurrent, prolonged, and partial or focal
- May be associated with postictal paralysis or acute resolving hemiplegia
- CSF findings are normal or negative.
- Febrile seizures are noted in symptomatic primary or reactivated infection caused by HHV-7.
 - Some indications suggest that febrile seizures may be more common (and possibly more complicated) with primary HHV-7 than with HHV-6 infection.

Other central nervous system involvement

- Severe meningoencephalitis with neurologic sequelae or death in infants and adults and fatal encephalitis has been attributed to HHV-6B in adult recipients of bone marrow transplants.
- Unclear significance of HHV-6 in relation to:
 - Recurrent seizures
 - Chronic fatigue

- Multiple sclerosis
- Other neurologic conditions
- HHV-7 infection has also been described in association with:
 - Encephalopathy
 - Hemiplegia
 - Atypical febrile seizures
- Neurologic conditions associated with HHV-6 and HHV-7 infections are rare.
 - May be severe, requiring intensive care
 - HHV-6 or HHV-7 (or both) infection should be sought to differentiate it from encephalitis associated with vaccines.

Hepatitis

- Mild hepatitis associated with HHV-6 infection is recognized in adults and children.
- A few cases of fulminant or fatal hepatitis have been reported, usually with an associated encephalopathy.
- HHV-6 infection also has been implicated in mild chronic hepatitis in childhood.
- A single case of hepatitis has been reported in relation to HHV-7 infection.

Infection in immunocompromised patients

- Syndrome with fever and rash resembling graft-versus-host disease is recognized in children after they receive bone marrow transplants.
- HHV-6 infection may reactivate during periods of immunosuppression.
- The role of HHV-6 in HIV infection is unclear.
 - Some evidence suggests that HHV-6 may potentiate progression of HIV infection, especially in infants who have acquired HIV vertically.
 - HHV-7 competes with HIV for CD4 receptors on T cells.
 - Virus may interfere with the progression of HIV infection.
- Adult recipients of bone marrow transplants have exhibited the following findings associated with HHV-6 infection.
 - Severe interstitial pneumonitis
 - Disseminated infection
 - Recurrent aseptic meningitis
 - Encephalitis

DIFFERENTIAL DIAGNOSIS

- Roseola is often confused with other exanthematous diseases.
 - Rubella
 - Rash and fever are concurrent.
 - Enlarged lymph nodes are often tender.
 - Rubeola
- Coryza, respiratory symptoms, and Koplik spots distinguish rubeola.

- Enterovirus exanthems
 - Usually occur in epidemics
 - Involve both older and younger children
 - Are more common in the late summer and fall
- Erythema infectiosum, or fifth disease
 - Affects the school-aged child
 - Involves the face most prominently
- Scarlet fever
 - More confluent rash
 - Associated with marked pharyngitis
- Drug eruptions (especially those resulting from sulfa-containing preparations)
 - Not regularly preceded by fever
 - Tend to be diffuse
- HHV-8 (causative agent of Kaposi sarcoma)
 - In Egypt, primary infection in childhood with HHV-8 was associated with a mild febrile exanthem indistinguishable from HHV-6- or HHV-7-related roseola.
 - Epidemiologic and clinical characteristics of HHV-8 infection in children in the US are unknown.
- HHV-6 has been isolated from patients who have many other conditions.
 - Because HHV-6 is reactivated by many acute illnesses, attributing causality to the virus is difficult in most cases.
 - Reported associations include:
 - Chronic bone marrow suppression in an immunocompetent adult
 - Idiopathic thrombocytopenic purpura
 - Thrombocytopenia during primary HHV-6 infection
 - Gianotti-Crosti syndrome
 - Hemophagocytic syndrome
 - Fatal disseminated disease in an immunocompetent infant
 - Lymphoproliferative disorders
 - Certain lymphoreticular cancers
- The role of HHV-7 in other diseases is less clear than its association with roseola.
 - Several studies have suggested reactivation of HHV-7 during relapses of adult pityriasis rosea.
- Signs and symptoms of all other conditions associated with these viruses are too nonspecific to allow definitive diagnosis at the bedside.
- Except in certain situations of infection in immunocompromised hosts and complicated disease in normal hosts, there is no clinical need to confirm infection with HHV-6 or HHV-7 serologically or virologically.
 - Identification of HHV-6 or HHV-7 in febrile infants does not obviate the need to evaluate for serious bacterial infection.
 - Approximately 10% of young infants have concurrent viral and bacterial infections, usually bacteriuria.
- Confirming HHV-6 or HHV-7 infection in children with complex neurologic syndromes may help rule out vaccine administration as the cause.
- Newly developed diagnostic methods to differentiate latent from actively replicating virus may eventually help both diagnosis and pathogenesis of disease associated with HHV-6 and HHV-7.

LABORATORY FINDINGS

- Roseola
 - Leukopenia as low as 2000 leukocytes/mm³ by the third day of fever is the only helpful laboratory finding.
 - Relative lymphocytosis or monocytosis is typical.
 - Results of urinalysis are normal.
- Neither antibody detection methods nor virus isolation techniques are standardized for HHV-6 or HHV-7.
 - These assays are not available commercially.
 - Presence of maternal antibody in the young infant and reactivation of herpesviruses during other infections confound interpretation of the results.
 - Although polymerase chain reaction identification of virus in body fluids is available as a research tool, the clinical use of this test is questionable.
 - HHV-6 can be detected in high titers in saliva specimens of infants for up to 12 months after primary infection.

IMAGING

- Chest radiograph in roseola is normal.

DIAGNOSTIC PROCEDURES

- CSF examination in roseola is normal.

TREATMENT APPROACH

- Management of roseola is based entirely on symptoms.

DIAGNOSTIC APPROACH

- Roseola is the only manifestation of HHV-6 or HHV-7 infection that is clinically easily recognized.
- Presence of virus may be irrelevant to the disease or condition being investigated.
- Because roseola is an inconsequential illness, confirmation of the diagnosis is rarely needed.

SPECIFIC TREATMENTS

- Roseola
 - Acetaminophen is effective in controlling fever.
 - Reassuring parents that the rash is a sign of recovery comforts them and prevents unnecessary office visits.
- Both HHV-6 and HHV-7 have antiviral agent profiles similar to cytomegalovirus, with limited susceptibility to acyclovir.
 - In vitro studies show that either foscarnet or ganciclovir is somewhat effective.
 - No clinical trials have been conducted with these drugs.
 - Because infection with either of these agents is self-limited in the immunocompetent child, antiviral therapy is reserved only for life-threatening infection.
- Infection in immunocompromised patients
 - Some patients have recovered after treatment with foscarnet.

WHEN TO ADMIT

- Hospitalization is usually indicated only when an alternate disease process is suspected, such as:
 - Meningitis
 - Encephalitis
 - Recurrent seizures
- Immunocompromised patients may have severe infection with HHV-6 or HHV-7.
 - Typically hospitalized for their severe clinical presentation, for example:
 - Pneumonitis
 - Encephalitis
 - Suspected graft-versus-host disease

WHEN TO REFER

- Primary HHV-6 or HHV-7 infections almost never are clinically recognized until the disease is over.
- Referral is rarely needed, except to rule out an alternative diagnosis, such as:
 - Seizure disorder
 - Treatable encephalopathy
 - Encephalitis
- Severe clinical symptoms in immunocompromised patients should always be managed by an infectious disease consultant.

COMPLICATIONS

- Long-term sequelae are unusual in the normal child with primary HHV-6 or HHV-7 infection.
- Neurologic damage is occasionally noted in children after complicated seizures associated with either virus.

PROGNOSIS

- Even with recurrent seizures during the same illness, complete recovery is the rule.
- The significance of HHV-6 in relation to recurrent seizures is not clear.
 - One study detected no increase in the risk of recurrent seizures in the first year after febrile seizure associated with primary HHV-6 versus first febrile seizures of other causes.
 - Others have noted an increased incidence of subsequent diagnoses of epilepsy.

PREVENTION

- Breastfeeding may delay acquisition of HHV-7 and HHV6.

Hydrocephalus

DEFINITION

- Hydrocephalus is the accumulation of cerebrospinal fluid (CSF) in the cerebral ventricles.
- All hydrocephalus may be considered an obstruction of CSF flow.
 - *Obstructive hydrocephalus* refers to a blockage between the ventricular system and the spinal subarachnoid space.

EPIDEMIOLOGY

- Hydrocephalus is the most common surgically treatable neurologic disorder in children.
- Congenital hydrocephalus occurs in 3 in 1000 live births.
 - The overall incidence of pediatric hydrocephalus is greater when including forms acquired through:
 - Infection
 - Trauma or hemorrhage
 - Tumors
- X-linked hydrocephalus occurs in 1 in 30,000 male births.
 - Represents <2% of all hydrocephalus
- The incidence of subclinical arrested hydrocephalus, which may result in symptoms later in childhood or in adult life, is unknown.
- Hydrocephalus is a principal diagnosis in approximately 27,870 admissions per year.
- Hydrocephalus results in 36,000 operations per year in the US, with a medical cost >\$1 billion.

ETIOLOGY

- Disturbance in CSF circulation and absorption (and, rarely, production) results in an accumulation of CSF in the ventricles of the brain.
- Ill effects of hydrocephalus are probably caused by:
 - Decreased blood flow as a result of increased intracranial pressure (ICP)
 - Stretching and compressing of neural fiber and blood vessels that is a consequence of ventricular expansion
 - Although an obstruction can occur in the posterior fossa with blocked fourth-ventricle outflow, it most often results from obstruction of the aqueduct of Sylvius between the third and fourth ventricles.
- X-linked hydrocephalus
 - Defect in chromosomal region Xq28

RISK FACTORS

- Congenital defects
 - Spina bifida with myelomeningocele
 - 80–90% of patients with myelomeningocele require shunting for hydrocephalus.
 - Dandy Walker syndrome

- Holoprosencephaly
- Aqueductal stenosis
- Premature birth
 - Intraventricular hemorrhage (IVH)
 - 20% of premature infants in the US have IVH.
 - 20–75% of them will further develop posthemorrhagic hydrocephalus.
 - Hydrocephalus risk increases with IVH severity or grade.
- Infection
 - Cytomegalovirus
 - Toxoplasmosis
 - Meningitis
- Tumors of the midbrain
- Trauma

SIGNS AND SYMPTOMS

- Premature infants
 - Symptoms
 - Attacks of apnea or bradycardia
 - Signs
 - Tense and nonpulsatile anterior fontanelle
 - Distended scalp veins
 - Abnormal head contour with prominent forehead
 - Rapid (>1 cm/wk) skull circumference increase
- Full-term infants
 - Symptoms
 - Irritability
 - Vomiting
 - Drowsiness
 - Signs
 - Full or tense anterior fontanelle
 - Distended scalp veins
 - Frontal bossing
 - Widening of cranial sutures
 - Cracked pot sign on percussion
 - Macrocephaly
 - Poor head control
 - Sixth cranial nerve palsy
 - Setting sun sign (appearance of sclera above iris)
 - Impairment of upward gaze
- Older children
 - Symptoms
 - Steady or progressive headache
 - Vomiting
 - Blurred vision, diplopia

- Lethargy
- Personality and behavior changes
- Developmental delay
- Signs
 - Papilledema
 - Spasticity, more so in lower limbs
 - Sixth cranial nerve palsy
 - Neuroendocrinopathies
 - Clasped thumbs in approximately half of all cases

DIFFERENTIAL DIAGNOSIS

- Enlarging head circumference
 - Benign familial macrocrania
 - Arachnoid cyst
 - Subdural hygroma or hematoma
 - Intracranial-space-occupying lesion
 - Hydranencephaly
- Increased ICP
 - Subdural hematoma
 - Intracranial-space-occupying tumor or lesion
 - Infection
 - Meningitis
 - Brain abscess
- Neurologic deficit
 - Intracranial-space-occupying lesion
 - Cerebrovascular disease
 - Developmental/neural migration disorder

DIAGNOSTIC APPROACH

- The diagnosis is suspected in:
 - Infants with abnormally rapid head growth
 - Children of any age with symptoms of high ICP or focal neurologic deficit
- It is critical to recognize:
 - Congenital hydrocephalus
 - New-onset acquired hydrocephalus
 - Treatment failure in preexisting hydrocephalus
- Symptoms depend on:
 - Rate of progression
 - Child's age
 - In utero
 - At birth
 - Infancy
 - Early childhood
- The diagnosis of hydrocephalus is verified by brain imaging.
 - Images reveal a dilated ventricular system.

IMAGING

- Computed tomography (CT)
 - Most common form of imaging for establishing hydrocephalus
 - Axial anatomy or size of dilated ventricles
 - Diagnosis and follow-up
 - Periventricular edema
 - Acute hydrocephalus
 - Decreased sulcal or subarachnoid space
 - Confirms ventricular shunt catheter placement
 - Better than magnetic resonance imaging (MRI) for this purpose
 - Guidance during lumbar puncture
- Ultrasonography
 - Used in prenatal examination and in infants
 - Dilatation of lateral and third ventricles
 - Intracerebral blood
 - Neonate with open fontanelle
- MRI
 - Provides much more detail than CT on:
 - Etiology
 - Comorbidity
 - Scans can be obtained antenatally.
 - Guidance during lumbar puncture
 - Axial, sagittal, coronal imaging, and high gray matter resolution
 - Bowing or thinning of corpus callosum
 - Aqueductal stenosis, obstructive masses
 - Posterior fossa abnormalities
 - Cine phase-contrast CSF flow studies to assess:
 - Blockage at aqueduct
 - Fourth ventricular outflow
 - Fenestrations
- Radiography
 - Skull
 - Splaying of sutures
 - Increased gyral marking
 - Erosion of dorsum sellae
 - Shunt series
 - Anteroposterior and lateral view of the head, neck, chest, and abdomen
 - Diagnostic for mechanical shunt failure
 - May reveal a complex set of new and old shunt system components

DIAGNOSTIC PROCEDURES

- Spinal tap
 - Can diagnose increased pressure in communicating hydrocephalus
 - Palliation
- Radioactive tracer and dye studies
 - Lumbar injection
 - Assess lumbar shunt patency of CSF clearance rate
 - Shuntography
 - Injection into shunt to assess patency and flow or cerebral communication
 - Diagnostic for shunt obstruction

CLASSIFICATION

- Classification of hydrocephalus
 - Site of obstruction
 - Obstructive: aqueduct of Sylvius, fourth ventricle outlet
 - Communicating: basal cisterns
 - Multiloculated: atrium, foramen of Monroe, aqueduct, and other
 - Progression
 - Acute: may be caused by hemorrhage, infection, progresses to coma in hours
 - Chronic: congenital, partial obstruction, progresses over months to years, gradual cognitive and ambulatory decline
 - Course
 - Recurrent: with shunt failure; may be acute or chronic in onset
 - Arrested: often congenital without symptoms; symptoms of chronic hydrocephalus can develop later
 - Compensated: similar to arrested but with apparent mechanisms of compensation; treated
 - Location
 - Internal: in ventricular system only
 - External: with accumulation over hemispheres (subdural hematoma, benign macrocrania)
 - Etiology
 - Congenital
 - Acquired
 - Pressure
 - High: acute, brain noncompliant, decreased blood flow, shunt reversible if no permanent ischemia
 - Normal: usually chronic hydrocephalus, brain compliance abnormal with labile pressures
 - Low: very compliant brain, ventricles remain large unless drained at very low pressure, coma may persist without aggressive drainage

- Age of onset
 - Fetal: genetic, congenital, development affected; normal ventricular size unlikely
 - Neonatal: congenital or acquired IVH, infection, tumor, other; comorbidity likely
 - Child: acquired via tumor or other
 - Adult: acquired, idiopathic

TREATMENT APPROACH

- Prompt recognition and treatment of hydrocephalus and treatment failure is important for a favorable outcome.
 - Delay in surgical treatment is a risk factor for a poor outcome in hydrocephalic children.
- Surgical treatment with valved silicone shunts
 - CSF diversion from a cerebral ventricle or lumbar canal to a body cavity
 - Usually the peritoneal cavity
 - Treatment with implanted shunts is life saving.
 - Most children live with hydrocephalus as a chronic surgically arrested disease.
 - Patients have the potential to live full lives into adulthood.
- Endoscopic third ventriculostomy (ETV)
 - Allows fluid to escape without a shunt in obstructive hydrocephalus
- Medical management
 - Usually only a means of palliation before more definitive surgical treatment
 - Acetazolamide slows CSF production.
- Invasive nonsurgical techniques
 - Serial lumbar or ventricular puncture via the fontanelle
 - Performed in emergencies or until a premature infant can tolerate surgery

SPECIFIC TREATMENTS

CSF shunting

- Ventricular catheter
 - Soft, flexible, perforated, straight silicon tube inserted through a 1-cm burr hole in the frontal or occipital cranium
 - Usually on the nondominant side
 - Stabilized at the burr hole with an angle flange or a tapping reservoir
 - The preferred site for the catheter tip is in the anterior horn of a lateral ventricle away from potentially obstructing choroid plexus.

- Catheter insertion is most often blind and based on external cranial landmarks.
 - Attempts to visualize catheter tip location with an endoscope during surgery have not resulted in better placement or survival.
- Proximal obstructions are common as a result of tissue growth.
 - Vascular choroid plexus
- Premature infants
 - Implanted ventricular catheter, either externalized or leading to a subgaleal reservoir or space, may be used to obtain more consistent drainage before permanent shunting is considered.
- Valve
 - 2 purposes
 - Allows 1-way flow
 - Regulates the amount of drainage
 - Types of valves
 - Differential-pressure valve
 - Opens when pressure on the cranial side is greater than the distal side
 - High-pressure valve
 - Pressure differential may need to be >140–150 mm Hg.
 - Medium- or low-pressure valve
 - Less of a gradient is needed, and more fluid will be drained.
 - Flow-controlled, antisiphon, or gravity-controlled valve
 - Regulates flow to reduce drainage, especially when standing
 - Overdrainage is common after chronic shunting and can result in slit ventricles or subdural hematomas.
 - Adjustable valve
 - Provides for noninvasive CSF drainage adjustment with growth or if hydrocephalus becomes internally compensated
 - Overdrainage or underdrainage symptoms may be treated with adjustments alone.
- Distal catheter
 - Extends from the valve to the drainage cavity
 - Ventriculoperitoneal
 - Can be placed through an incision ≤ 1 cm
 - Advantages include extra catheter length insertion to allow for growth and less risk of infection problems compared with vascular shunts.
 - Ventriculoatrial
 - Vascular insertion into the right atrium via the subclavian or internal jugular vein
 - Advantages include less siphoning and possible placement when the abdominal cavity must be avoided.
 - Lumboperitoneal
 - Distal end into pleural cavity
 - Pleural catheters are placed only in adults because CSF drainage of the large infant cranium would too easily overwhelm the pleural space.
 - Distal end into gallbladder
 - Complex or loculated hydrocephalus
 - ≥ 2 proximal catheters may be connected to drain multiple ventricles or cysts.
 - Old ventricular catheters may be retained.
 - Pulling catheters out results in some bleeding risk (although they must be removed if a central infection develops).
- The catheter or valve may have a reservoir where fluid can be tapped or pumped.
 - A reservoir that remains depressed (dimpled) after compression is a likely sign of proximal obstruction.
 - This system may be tapped under sterile conditions in the outpatient or emergency department setting to check for patency, pressure, or infection.

ETV

- Used in obstructive hydrocephalus and some cases of communicating hydrocephalus
 - Under endoscopic visualization, fluid trapped in the lateral and third ventricles is released into the basal cisterns through a fenestration made in the floor of the third ventricle, just anterior to the basilar artery.
 - Performed through a right frontal burr hole similar to that used for shunt catheter placement.
 - Advantages
 - Preventing overdrainage
 - Avoiding implanted hardware
- Outcomes
 - Successful in approximately 70% of cases
 - Success does not always decrease ventricular size, as seen with shunting.
 - Failure must often be judged clinically as a return of symptoms.
 - If fenestration is closed (seen in cine phase-contrast CSF-flow MRI or on direct endoscopic inspection), it may be reopened.
 - A shunt may be placed secondarily in other cases.
 - ETV success in communicating hydrocephalus is still not well established.

Serial lumbar or ventricular puncture via the fontanelle**■ Indications**

- Emergencies
- Premature infant not yet able to tolerate surgery (if weight >2 kg)
 - Taps may be performed serially for up to 3–4 weeks in a premature infant with IVH if it is unclear that there will be progressive hydrocephalus requiring a shunt.

■ Methods

- Lumbar puncture
 - Using CT or MRI after confirmation that the hydrocephalus is communicating
 - Lumbar puncture in obstructive hydrocephalus cannot decompress cranial CSF and can cause downward tonsillar herniation.
- Ventricular puncture
 - Performed at the lateral corner of an open fontanel in infants with obstructive hydrocephalus or when lumbar puncture is not successful

Specific clinical situations**■ Myelomeningocele**

- Shunt may be placed at the time of myelomeningocele closure or, if possible, in subsequent days or weeks to reduce infection risk.
- ETV
 - Controversial in myelomeningocele
 - May be considered an option even in later years in the event of shunt failure

■ IVH of prematurity

- Shunting is usually preceded by several weeks of palliative treatment.
 - Delay allows for infant growth (preferably to >2 kg) and for determining progressive hydrocephalus.
 - Ventricular size may stabilize over weeks.
- Palliative procedures
 - Lumbar punctures (taking approximately 10 mL/kg)
 - Fontanelle tap
 - Surgical placement of a ventricular catheter for external or subgaleal drainage

■ Posterior fossa tumors

- Tumor resection
 - Allows CSF flow reestablishment
 - Eliminates the need for shunting in most cases
- ETV or shunt implantation
 - Children with persisting hydrocephalus are excellent candidates for ETV or standard shunt implantation.

■ Dandy Walker syndrome

- Historically treated with cyst resection or fenestration
 - Frequent treatment failure
- Shunting of the cyst or the ventricles
 - In the presence of aqueductal stenosis, both the ventricles and the cyst may be shunted simultaneously.
- ETV
 - May be effective

■ Postinfectious hydrocephalus

- Medical treatment
- External ventricular drain if needed until the infection clears
- A permanent ventriculoperitoneal shunt may be placed later.
- ETV
 - Has been attempted in the hopes of avoiding an implanted shunt
 - Alone or in combination with choroid plexus coagulation
 - Viral infections may especially result in minimal leptomeningeal fibrosis with a simultaneous aqueductal stenosis that an ETV may manage.
 - Extensive cistern scarring may limit potential ETV efficacy in many cases.

■ Multiloculated hydrocephalus

- Loculations present a complex drainage problem, sometimes requiring multiple catheters.
- Open or endoscopic cyst fenestration facilitates fluid communication.
 - Allows simplified drainage through a single shunt catheter

■ Aqueductal stenosis

- ETV
 - Preferred treatment
 - Samples of tectum, posterior third-ventricle, or pineal region tumors can be obtained for biopsy during the same endoscopic procedure.
- Shunt implantation
 - Still commonly performed

WHEN TO ADMIT

- All newly diagnosed cases of hydrocephalus should be admitted.
- All patients who develop shunt complications, such as shunt malfunction or shunt infection, should be admitted.

WHEN TO REFER

- All patients with suspected hydrocephalus should be referred to pediatric neurosurgeons immediately.
- All patients with shunt complications should be referred to pediatric neurosurgeons.

FOLLOW-UP

- Postoperative follow-up schedule
 - 2 weeks after surgery
 - Every 3 months for the first year
 - Every 6 months in the second year
 - Yearly thereafter
- Clinical assessment
 - Developmental milestones
 - Head circumference
 - Symptoms and signs of:
 - Increased intracranial tension
 - Infection
 - Other complications

COMPLICATIONS**Shunt-related complications**

- Intracerebral hemorrhage
 - Any probe insertion into the brain may result in bleeding.
 - Occurs in <2% of cases
 - Risk is greater in removing an old ventricular catheter that is obstructed by an ingrowing choroid plexus than in inserting a new one.
 - Minor bleeding may resolve on its own.
 - The greatest concern is increased risk of shunt obstruction.
 - Surgical evacuation
 - Very rarely necessary for bleeding
- Infection
 - Full treatment usually requires:
 - Removing the shunt
 - Placing a temporary external drain if needed
 - Initiating antibiotic treatment
 - Reinserting the shunt after documenting negative CSF cultures
 - Perioperative prophylactic antibiotics
 - Reduce shunt infection risk by 50%.
 - Antibiotic-impregnated shunts may reduce infection rate by 1–2%.
- Risk increases with presence of an inner lumen.
 - Infection rate is 5–10%.
 - Most infections occur in the first 6 months.
 - Indolent infections have been reported after years.
- Usually involves skin flora
 - *Staphylococcus epidermidis*
 - *Propionibacterium acnes*
 - *Staphylococcus aureus*
- Signs and symptoms
 - Signs of systemic or local infection
 - Symptoms of meningitis
 - Shunt dysfunction may be a sign of an indolent shunt infection.
 - Chronic infection may be difficult to diagnose; little cellular response
- Shunt obstruction
 - Proximal
 - Choroid plexus ingrowth into the proximal ventricular catheter
 - Distal
 - Scar tissue or thrombus developing in vascular shunts
 - Total or partial/intermittent
 - Hydrocephalic symptoms that recur with ventricular expansion
 - Can be sufficient to indicate surgical exploration
- Mechanical failure
 - Breaks
 - Although shunts may last decades, they become more brittle over time.
 - Calcified scar can evolve around the catheter
 - The valve may become incompetent.
 - A break at a tethering point, such as a valve or connector, is common.
 - Kinks
 - Migration
 - Short shunt caused by growth or migration into the preperitoneal space
 - Displacement
- Overdrainage
 - In CSF shunting, too much drainage (acutely or chronically) can be as problematic as too little.
 - Slit ventricles
 - Ventricles become abnormally small.
 - May result in frequent shunt blockages and episodic headaches

- Subdural hygroma
 - Develops in children with severe cortical thinning
- Chronic subdural hematoma
 - Because the brain has limited elasticity and can reexpand after severe hydrocephalus, cortical walls collapse and a subdural hematoma can develop if bridging vessels are injured.
- Management
 - ICP monitoring
 - Shunt revision to reduce CSF drainage, unless an adjustable valve is in place
 - Implantation of antisiphon or gravity devices
- Complications of shunt implantation
 - Infection
 - Nonphysiologic overdrainage
 - Fever
 - Incidence of all complications combined ranges from 6–20%.
 - Most complications are reversible.
- Complications specific to ventriculocardiac shunts
 - Thrombosis around the distal tube
 - Cor pulmonale
 - Shunt nephritis
 - Septicemia and pyemic abscesses
- Complications specific to ventriculopleural shunts
 - Hydrothorax
 - Characterized by respiratory distress
 - Pyothorax
- Complications specific to ventriculoperitoneal shunts
 - Bowel perforation: rare with current catheter materials
 - Pseudocyst: sterile or infected and presenting as obstruction or abdominal swelling
 - Ascites: malabsorption of CSF; sterile or infected
 - Hernia: at shunt insertion incisions

Complications of ETV

- Injury to the hypothalamus and basilar artery
- Undertreatment/treatment failure
 - Ventricles remain large.
 - Failure may be sudden and catastrophic or gradual and insidious.
 - Success is based on clinical resolution alone.
 - Treatment failure or underdrainage may be missed if it occurs gradually.

PROGNOSIS

- A child with isolated hydrocephalus that is well treated and monitored has the potential for a fully functional life.
- Many factors play a role in overall outcome.
 - Concomitant medical conditions
 - Degree of neurologic compromise at the time of surgical treatment
 - Nature and cause of hydrocephalus
 - Complications greatly affect the long-term outcome.
- Survival
 - Overall shunt mortality rate
 - <5% after 10 years
 - Congenital hydrocephalus
 - 5-year survival rate approximately 90%
 - Posthemorrhagic hydrocephalus
 - Grades I and II: mortality rate, 9%
 - Grades III and IV: mortality rate, 49%
- Functional assessment
 - Intellect/IQ in long-term studies
 - Varies widely with each specific cause
 - >90 in 32%
 - 70–90 in 28%
 - 50–70 in 19%
 - <50 in 21%
 - 60% of patients can be integrated into the normal school system.
 - Degree of intellectual impairment
 - Relates more to the degree of severity of underlying CNS anomalies and defects in the neocortex cytoarchitecture
 - Relates less to severity of hydrocephalus
 - Motor deficit: 80%
 - Visual or auditory deficit: 25%
 - Epilepsy: 30%

Hyperhidrosis

DEFINITION

- Hyperhidrosis is excessive localized sweating.

EPIDEMIOLOGY

- Age
 - Axillary hyperhidrosis usually becomes more of a problem in adolescence.

MECHANISM

- Researchers postulate that emotions and temperature of blood perfusing the hypothalamus stimulate the secretion of hormones that regulate the autonomic nervous system's control of perspiration.
- Eccrine sweat glands
 - Control thermoregulation
 - Most numerous on the palms, soles, and axillae
- Axillary hyperhidrosis
 - Probably stimulated by both heat and emotion
 - Apocrine glands are stimulated at puberty by androgenic hormones.
- Palmar and plantar hyperhidrosis
 - Caused by eccrine sweat production
 - May occur at any age
 - Thought to be stimulated by anxiety

HISTORY

- The child or the family reports:
 - Odiferous sweating
 - Sweating so intense that it interferes with:
 - Hand functions
 - Foot functions
 - Axillary hyperhidrosis in adolescence may cause embarrassment.
 - Sweat ring on clothing
 - Odor associated with bacterial degradation of apocrine sweat

DIFFERENTIAL DIAGNOSIS

- Excessive generalized sweating may be caused by a systemic disorder.
 - Infection
 - Hypoglycemia
 - Drug withdrawal
 - Thyrotoxicosis
 - Pheochromocytoma
 - Riley-Day syndrome

TREATMENT APPROACH

- Topical and systemic agents
 - Anticholinergic agents
 - Prescription 20% aluminum chloride
 - Tap water iontophoresis
- For bromhidrosis (malodorous hyperhidrosis) of the soles
 - Frequent cleansing with drying deodorant soaps
 - Topical antibiotics
 - Going barefoot whenever possible
- For combined axillary hyperhidrosis and bromhidrosis
 - Frequent clothing changes
 - Topical antibiotics and deodorant powders
- For sweating caused by emotional stress
 - Propranolol and anxiolytics

SPECIFIC TREATMENT

Pharmacologic treatment

- Systemic anticholinergic agents
 - May block acetylcholine, the sympathetic innervation terminal neurotransmitter to eccrine glands
 - Side effects preclude long-term use.
- Prescription 20% aluminum chloride
 - Application every other day for palmar sweating or plantar hyperhidrosis
 - Prescription 20% solution of aluminum chloride in anhydrous ethanol applied to the axillary vault
 - May cause an irritant contact dermatitis
 - Hydrocortisone 1% cream for relief of inflammation
- Propranolol and anxiolytics are options to reduce emotional stress
- Botulinum A toxin
 - Approved for axillary sweat gland chemodenervation
 - Palmar and plantar hyperhidrosis
 - Subepidermal injections inhibit sweat production
 - Purportedly blocks presynaptic acetylcholine release
 - Effective for up to 12 months
 - Has been used in patients as young as 14 years
 - Temporarily or, rarely, causes permanent muscle and nerve injury from the injections

Other measures

- In extreme cases
 - Excision of local axillary skin
 - Removal of glands by curettage or liposuction
 - Ganglion sympathectomy cannot be recommended for most patients who have axillary hyperhidrosis, because of attendant complications.

WHEN TO REFER

- Hyperhidrosis that interferes with appropriate bodily function (eg, hand so slippery wet that the child cannot hold a pencil)
- Generalized excessive sweating
- Socially isolating hyperhidrosis as a result of odor or excessive drenching of clothing

Hypertension

DEFINITION

- In children and adolescents, hypertension is defined as elevated blood pressure (BP) that persists on repeated measurement at the 95th percentile or greater for age, height, and sex in a healthy population.
 - High-normal or prehypertensive BP is defined as BP \geq 90th percentile but $<$ 95th percentile (normal systolic and diastolic BPs are $<$ 90th percentile).
 - Severe hypertension (with the risk of end-organ injury) is defined as BP $>$ 99th percentile.
 - Body size is the single most important determinant of BP in children and adolescents.
 - Using accurate height percentiles is critical for correctly estimating BP percentiles (see Figure 33 on page F13).
- 2 categories of hypertension
 - Primary or essential
 - Secondary

EPIDEMIOLOGY

- Prevalence
 - Recent studies have shown:
 - Mean BP has increased among children and adolescents in the last decade.
 - Elevated BP in childhood often continues into adulthood, predicting hypertension in young adulthood.
 - Essential hypertension is familial in nature.
 - Chronic hypertension is becoming increasingly common in adolescents.
 - Increase in this population of being overweight and obese
 - Obesity rates have more than doubled for children age 2–5 years and 12–19 over the past 3 decades.
 - The obesity rate has more than tripled among children age 6–11 years.
 - Presently in the US, 9 million children $>$ 6 years of age are considered obese, with a body mass index (BMI) $>$ 95th percentile.
 - Metabolic syndrome
 - Although no standardized definition of metabolic syndrome currently exists, it is increasingly recognized as a significant complication of childhood obesity.
 - National samples indicate that roughly 10% of all 12- to 19-year-olds in the US presently have symptoms of metabolic syndrome.
- Age
 - Essential hypertension
 - The most common type of hypertension in adults
 - Relatively uncommon in (younger) children, but seen more frequently, especially in adolescents

- Secondary hypertension
 - More common in children than in adults
 - Reported in 2–3% of premature infants
- Ethnicity
 - In the US, the distribution of BP in adults differs among racial and ethnic groups.
 - Non-Hispanic black adults have increased prevalence and incidence of hypertension.
 - The age at which differences in BP become apparent across racial and ethnic groups is unclear.
 - Studies repeatedly show that BP levels are higher among black children than among white children.
 - BP levels are significantly higher for black girls than for white girls; the situation for boys is less certain.
 - Mexican-American children have a higher mean-adjusted BP than do non-Hispanic white children.
 - In many instances, a higher BMI explains the difference in BP between different ethnic groups.
 - Increase in BMI in children in the US has accounted for some of the increase in BP.
 - Other factors also probably contribute.

MECHANISM

General

- BP is a product of cardiac output and systemic resistance affected by changes in:
 - Heart rate
 - Stroke volume
 - Blood volume
 - Peripheral resistance
 - Effect of various hormones on vascular bed

Renin-angiotensin system and hypertension

- Angiotensin II
 - Potent vasoconstrictor
 - Major end product of the renin-angiotensin system
 - Exerts the major hormonal control of BP
 - Provides feedback that inhibits renin release
 - Increases intravascular volume
 - Is closely related to renal blood flow
- Renin
 - Enzyme that stimulates production of angiotensin II
 - Release is stimulated by:
 - Volume depletion
 - Hypotension
 - Salt depletion

- Release is inhibited by:
 - Volume expansion
 - Salt loading
 - Elevated electrolyte levels

Other hormonal systems

- Other hormonal systems also affect renin release, such as:
 - Circulating catecholamines
 - Glucagon
 - Adrenocorticotropic hormones
 - Parathyroid hormones

Drugs

- Stimulators of renin release
 - Vasodilators
 - Diuretics
- Inhibitors of renin release
 - Mineralocorticoids
 - β -Blockers
- Sympathomimetics
 - Cocaine
 - Amphetamines
 - Phenylephrine
 - Nonsteroidal antiinflammatory drugs
 - Erythropoietin
 - Cyclosporins

Age

- BP tends to increase with age throughout the first 2 decades of life.
 - Systolic
 - Average on the first day of life is 70 mm Hg.
 - Increases steadily for the first 2 months
 - Tends to remain stable until 1 year of age, when it increases until adulthood
 - Diastolic
 - Increases slowly for the first week, then declines until 3 months of age
 - Then increases gradually until 1 year of age, when it reaches the level found in the first week
 - Remains steady for the first 5–6 years, after which it increases, along with the systolic BP
 - Children tend to maintain the same BP percentile rank relative to their peers as they grow, a pattern that continues through adolescence, supporting the idea that essential hypertension begins in childhood.

Genetics

- Children from families with a history of hypertension tend to have higher BPs.
- Supports the generally accepted conclusion that genetics influence BP
- Other cardiovascular risk factors among parents correlate with those of their children, including:
 - Disorders of lipid and glucose metabolism
 - Hyperuricemia
 - Poor nutrition
 - Passive smoking
 - Physical inactivity

HISTORY

- Medical history should include questions regarding:
 - All cardiovascular risk factors
 - Symptoms suggestive of secondary hypertension
 - Possible target organ damage
- Particular attention needs to be paid to any history suggesting:
 - Recent onset of renal disease
 - Chronic urinary tract infections
 - Exogenous steroids
 - Oral contraceptives
 - Illicit drugs
 - Tobacco
 - Alcohol
- A systems review that includes the following details:
 - Diet
 - Salt intake
 - Exercise
- In adolescents, use of the following should be explored:
 - Exogenous steroids
 - Oral contraceptives
 - Illicit drugs
 - Tobacco
 - Alcohol
- The following may be helpful in directing further evaluations.
 - A history of prematurity
 - Patent ductus arteriosus
 - Bronchopulmonary dysplasia
 - A positive family history, including age of onset, of:
 - Essential hypertension
 - Systemic disease
 - Endocrinopathy

PHYSICAL EXAM**BP measurement**

- Figure 34 on page F14 is an algorithm for diagnosing and managing patients with hypertension.
- Systolic BP: defined as the pressure at the onset of the first Korotkoff (K1) sound
- Diastolic BP: pressure at the fifth Korotkoff (K5) sound or at the disappearance or muffling of the Korotkoff sounds
 - In some children, Korotkoff sounds can continue to be heard until 0 mm Hg, generally excluding a diagnosis of diastolic hypertension.
- Height and weight are related independently to BP at all ages (see tables Blood Pressure Levels for Boys by Age and Height Percentiles and Blood Pressure Levels for Girls by Age and Height Percentiles).
- Measure BP in all children >3 years seen in a medical setting.
- Appropriate techniques are important to avoid false-positive readings.
 - Infants should be supine.
 - Children and adolescents should be seated.
 - Child should be quiet for 5 minutes before measurement.
 - Back should be supported and feet on the floor.
 - Right arm should be supported, with antecubital fossa at heart level.
 - Child should not have recently ingested stimulant drugs or food.
 - Appropriately sized cuff
 - Width of cuff must be $\geq 40\%$ of the mid-arm circumference, as measured midway between the olecranon and the acromion.
 - Cuff should be long enough to cover $\geq 80\%$ of the circumference of the arm.
 - Cuff should be inflated to ≥ 30 mm Hg above the expected systolic BP.
 - Inflating too high in young children or infants may cause agitation.
 - Stethoscope or Doppler crystal should be placed lightly over the brachial artery in the antecubital fossa.
 - Arm should be at the level of the heart.
- Measure in all 4 extremities:
 - Average of at least 2 separate measurements
 - Average 2 systolic and 2 diastolic readings
 - Best to average measurements obtained during several visits
- Assess radial; brachial; and, most important, femoral pulses.
- Automated BP devices
 - In general, auscultation is recommended method of measuring BP in children.

- Advantages
 - Relative simplicity
 - Ability to minimize observer bias and terminal digit preferences
 - Can provide serial noninvasive BP in newborns and infants, in whom auscultation is difficult
 - Good in the intensive care unit, where frequent BP measurements are needed
 - Automated measurements appear to correlate well with intraarterial readings.
- Reliability in the physician's office is less clear.
 - Devices require frequent calibration.
 - Reference standards have not been established.
- Ambulatory monitoring
 - Recently, has been used to help establish the diagnosis of hypertension and track diurnal variations of BP in older children
 - A monitor is worn on the arm for 24 hours.
 - BP is measured periodically and values stored for later analysis.
 - Specifically helpful in evaluating:
 - White-coat hypertension
 - Risk for hypertensive end-organ injury
 - Apparent drug resistance
 - Hypotensive symptoms that may occur with the use of antihypertensive drugs
 - Can be used to evaluate BP patterns in such conditions as:
 - Episodic hypertension
 - Chronic kidney disease
 - Diabetes
 - Autonomic dysfunction
 - Ambulatory BP monitoring of children and adolescents should be used and interpreted only by those experienced in pediatric hypertension.

Complete physical

- Calculation of BMI
 - Weight in kilograms divided by the square of height in meters
- Auscultation for carotid, abdominal, and femoral bruits
- Palpation of the thyroid gland
- Thorough examination of the heart and lungs
- Examination of the abdomen for:
 - Enlarged kidneys
 - Masses
 - Abnormal aortic pulsation
- Palpation of the legs for edema and pulses
- Examination of the optic fundi

	95th	125	126	127	129	130	131	132	82	83	83	84	85	85	86
	99th	133	133	134	136	137	138	139	90	90	91	91	92	93	93

Abbreviation: BP, blood pressure.

^a From: National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents. The fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents. *Pediatrics*. 2004;114(2):555–576.^b The 90th percentile is 1.28 3D, 95th percentile is 1.645 SD, and 99th percentile is 2.326 SD over the mean.

- Neurologic assessment
- Hypertensive neonates often have evidence of:
 - Congestive heart failure
 - Respiratory distress
 - Feeding difficulties
 - Irritability
 - Lethargy
 - Coma

DIFFERENTIAL DIAGNOSIS

General

- Primary hypertension is often seen in patients with:
 - Obesity
 - Positive family history of hypertension or cardiovascular disease

Causes of hypertension in neonates and infants

- Renal parenchymal disease (60–80% of cases)
- Renal artery thrombosis after umbilical artery catheterization
- Coarctation of the aorta
- Congenital structural disease
- Renal artery stenosis
- Bronchopulmonary dysplasia
- Extracorporeal membrane oxygenation

Causes of hypertension in children and adolescents

- In the majority of children, hypertension is secondary to renal or renovascular causes.
 - Renal parenchymal disease
 - The most frequent cause of hypertension in childhood
 - Accounts for 60–80% of cases
 - Hypertension is evident at the initial diagnosis in almost 80% of all cases.
 - Of those who are normotensive at first, nearly one-half will experience hypertension during the course of their illness.
 - Renal artery stenosis, caused by:
 - Fibromuscular dysplasia
 - Takayasu arteritis
 - Williams syndrome
 - Neurofibromatosis
 - Children with renal artery stenosis may have marked symptoms caused by end-organ damage.
 - Congestive heart failure
 - Left ventricular hypertrophy
 - Retinal changes
 - Renal impairment

- Acute poststreptococcal glomerulonephritis
 - Hypertension is evident at the initial diagnosis in almost 80% of all cases.
 - Of those who are normotensive at first, nearly one-half will experience hypertension during the course of their illness.
- Membranoproliferative glomerulonephritis
- Diffuse proliferative glomerulonephritis
- Immunoglobulin A nephropathy
- Hemolytic-uremic syndrome
- Nephrotic syndrome
 - Rarely leads to severe hypertension, unless it is a manifestation of more serious renal disease
- Reflux nephropathy (prevalence of 5–30%)
- Polycystic kidney disease
- Wilms tumor
- Ingestion or abuse of glucocorticoids or other steroids
- Oral contraceptive use
- Coarctation of the aorta
 - The most common nonrenal cause of hypertension in childhood
 - Accounts for 5–15% of cases
 - Hypertension can also occur immediately after repair of coarctation of the aorta and for years thereafter.
 - Risk for postoperative hypertension appears to be lower if the lesion is repaired before 5 years of age.
- Endocrine disorders
 - Mineralocorticoid excess
 - Hyperthyroidism
 - Pheochromocytoma
 - Hypercalcemia
 - Systemic lupus erythematosus
 - Adrenal cortical hyperplasia
- Nervous system disorders
 - Neurogenic tumors
 - Increased intracranial pressure
- Drug-related
 - Ingestion or abuse of glucocorticoids or other steroids
 - Oral contraceptive use
- Immobilization-induced essential hypertension
- Metabolic syndrome is a constellation of risk factors, including:
 - Elevated systolic or diastolic BP
 - Elevated plasma triglyceride level
 - Low high-density lipoprotein cholesterol level
 - Insulin resistance

- A large waist circumference
- Associated with increased risk of type 2 diabetes and with other cardiovascular risk factors
 - A child might have metabolic syndrome if ≥ 3 risk factors are present.

LABORATORY EVALUATION

- General laboratory screening for possible renal dysfunction, including:
 - Urinalysis
 - Complete blood count
 - Serum urea nitrogen
 - Creatinine
 - Serum electrolytes (including glucose)
 - Urine culture (possibly)
- Positive family history of essential hypertension:
 - Lipid profile, including
 - High-density lipoprotein cholesterol
 - Low-density lipoprotein cholesterol
 - Triglycerides (to assess cardiovascular risk)
- If BP remains elevated after initial treatment, more intensive investigations should include:
 - Screening for mineralocorticoid disease
 - Plasma renin level
 - Plasma renin activity
 - If hyperthyroidism or pheochromocytoma is suspected
 - Thyroid function
 - Serum catecholamines

IMAGING

- If a renal cause is suspected
 - Imaging of the genitourinary system
- Renovascular evaluation generally includes:
 - Standard intraarterial angiography
 - Digital-subtraction angiography
 - Scintigraphy (with or without angiotensin-converting enzyme inhibition)
- Echocardiography
 - May identify coarctation of the aorta
 - Will provide information about left ventricular mass
 - Left ventricular hypertrophy is the most prominent evidence of target-organ damage
 - At diagnosis and for regular follow-up of children with established hypertension

DIAGNOSTIC PROCEDURES

- Cardiac evaluation
 - Important part of the examination

- Determine whether elevated BP will respond to salt restriction and whether it is sensitive to stress.
 - Isometric handgrip exercises
 - Serial subtractions from 100
 - If diastolic BP increases by 20 mm Hg or more and the systolic by 30 mm Hg or more, then the patient is a stress reactor.
 - BP may respond to behavioral modification techniques, diet, and exercise.

Formal stress testing

- To assess normal and abnormal BP responses to exercise
- May be especially helpful in young athletes

TREATMENT APPROACH

- Mild to moderate hypertension in childhood is generally not associated with marked symptoms.
 - BP elevation at this level almost certainly warrants:
 - Close attention
 - Lifestyle modifications
 - Possible therapy
- For children with chronic primary hypertension but no hypertensive target-organ damage:
 - The goal should be to reduce BP to below the 95th percentile for sex, age, and height.
- For children with chronic renal disease, diabetes, or hypertensive target-organ damage:
 - The goal should be to reduce BP to below the 90th percentile for sex, age, and height.
- Justification for treating children who have marked hypertension comes from the results of adult trials.
 - Reduction of BP reduces the risk of target-organ damage.
 - Definitive therapy can decrease later morbidity.

SPECIFIC TREATMENT

Therapeutic lifestyle changes

- Low-salt or no-added-salt diet
- Increased intake of:
 - Fresh vegetables
 - Fruits
 - Fiber
 - Low-fat dairy products
- Weight loss
 - Weight loss is often associated with reduction in both systolic and diastolic pressures.
 - BP tracking and weight-reduction studies support the potential for controlling BP in children through weight reduction.
 - Maintaining normal weight in childhood reduces the likelihood of high BP in adulthood.

- Studies of overweight adolescents with high BP have repeatedly shown that weight loss is associated with a decrease in BP.
- Weight loss also is associated with:
 - Decreased sensitivity to salt
 - Decreased dyslipidemia and insulin resistance
- Focus on health reasons for weight loss instead of appearance.
- Exercise
 - Adjunct to weight loss
 - Often reduces BP even more than weight loss alone
 - Increasing regular physical activity and decreasing sedentary activities are important in preventing hypertension.

Pharmacologic therapy

- Indicated in children and adolescents who:
 - Do not respond to lifestyle modifications
 - Have such conditions as:
 - Systemic hypertension
 - Secondary hypertension
- All classes of antihypertensive drugs lower BP in children.
 - Choice of therapy remains with the treating physician (see table Antihypertensive Drugs Commonly Used to Manage Chronic Hypertension in Children).
- Basic strategy
 - Start with a single drug and assess response.
 - Add additional drugs one at a time, always attempting to target a different organ system.
- Drug of first choice
 - Angiotensin-converting enzyme inhibitor or a calcium-channel blocker
- β -Blockers
 - Tend to produce more side effects
 - Can be problematic for patients with:
 - Reactive airway disease
 - Diabetes
- α -Agonists
 - Generally considered to be second-line drugs
- Diuretics
 - Now used less often for initial therapy of chronic hypertension

WHEN TO REFER

- Stage 1 hypertension: average systolic or diastolic BP between the 95th and the 99th percentile plus 5 mm Hg
- Stage 2 hypertension: persistent BP >99th percentile plus 5 mm Hg
- Specific conditions requiring referral:
 - Abnormal BP by 2 to 3 measurements over 1 month
 - Symptomatic essential hypertension
 - Secondary hypertension
 - Hypertension with diabetes
 - Evidence of target-organ damage (left ventricular hypertrophy)

WHEN TO ADMIT

- Hypertensive emergencies associated with manifestations in other organs
- Hypertensive urgencies (severe BP elevation without other organ involvement)
- Specific conditions requiring admission
 - Hypertensive encephalopathy
 - Acute glomerular diseases
 - Poststreptococcal glomerulonephritis
 - Hemolytic-uremic syndrome
 - Renal artery stenosis
 - Fibromuscular dysplasia
 - Previous umbilical artery catheter
 - Neurofibromatosis
 - Pheochromocytoma
 - Coarctation of aorta
 - Noncompliance with current antihypertensive medication
 - Cocaine toxicity
 - Dialysis patients with excessive volume expansion

Antihypertensive Drugs Commonly Used to Manage Chronic Hypertension in Children

Drug		Initial Dose (mg/kg daily)	Maximal Dose (mg/kg daily)	Interval (times/day)
ACE inhibitors	Benazepril	0.2–10	0.6–40	4
	Captopril	0.3–0.5	6	3
	Enalapril	0.08–5	0.6–40	2–4
	Fosinopril	5–10	40	4
	Lisinopril	0.07–5	0.6–40	4
	Quinapril	5–10	80	4
Angiotensin-receptor blockers	Irbesartan			
	6–12 yr	75–150	—	4
	>13 yr	150–300	—	4
	Losartan	0.7–50	1.4–100	4
α- and β-Blockers	Labetalol	1–3	10–1200	2
	Atenolol	0.5–1	2–100	2–4
	Bisoprolol/HCTZ	2.5/6.25	10/6.25	4
	Metoprolol	1–2	6–200	2
	Propranolol	1–2	4–640	2–3
Calcium-channel blockers	Amlodipine (>6 yr)	2.5–5	—	4
	Felodipine	2.5	10	4
	Isradipine	0.15–0.2	0.8–20	3–4
	Extended-release nifedipine	0.25–0.5	3–120	2–4
Central α-agonist	Clonidine (>12 y)	0.2	2.4	2
	Diuretics			
	HCTZ	1	3–50	4
	Chlorthalidone	0.3	2–50	4
	Furosemide	0.5–2	6	2–4
	Spironolactone	1	3.3–100	2–4
	Triamterene	1–2	3–300	2
	Amiloride	0.4–0.625	20	4
Peripheral α-Agonists	Doxazosin	1	4	4
	Prazosin	0.05–0.1	0.5	3
	Terazosin	1	20	4
Vasodilators	Hydralazine	0.75	7.5–200	4
	Minoxidil			
	<12 yr	0.2	50	3–4
	>12 yr	5	100	3–4

Abbreviations: ACE, angiotensin-converting enzyme; HCTZ, hydrochlorothiazide.

Hypertensive Emergencies

DEFINITION

- Hypertension
 - Systolic or diastolic blood pressure (BP) >95th percentile for sex, age, and height
 - Risk increases with body mass index (BMI).
 - Full clinical manifestations represent potential life-threatening events.
- Hypertensive emergency is associated with acute end-organ dysfunction discovered in the history, physical examination, or laboratory studies and not from BP.
- Malignant hypertension
 - Characterized by marked increases in systolic and diastolic BP
 - ≥ 160 mm Hg systolic and ≥ 105 mm Hg diastolic for children <10 years
 - ≥ 170 mm Hg systolic and ≥ 110 mm Hg diastolic for children ≥ 10 years
 - Often associated with spasm and tortuosity of the retinal arteries, papilledema, and hemorrhages and exudates on fundoscopic examination

EPIDEMIOLOGY

- Approximately 30% of children with BMI exceeding the 95th percentile have hypertension.
- Acute hypertensive emergencies are relatively infrequent in the pediatric population.

RISK FACTORS

- BMI that exceeds the 95th percentile

SIGNS AND SYMPTOMS

- Key features in history
 - Duration and onset of hypertension
 - Degree of compliance with any drug therapy
 - Possibility of renal disease
 - Urinary tract infections
 - Failure to thrive
 - Hematuria
 - Edema
 - Umbilical artery catheterization
 - Any joint pain
 - Palpitations
 - Weight loss
 - Flushing
 - Weakness
 - Headaches (including characterization)
 - Nausea
 - Vomiting

- White-coat hypertension
 - Patient with BP levels that exceed 95th percentile in a physician's office or clinic but who is normotensive outside a clinical setting
 - Ambulatory BP monitoring is usually required to make this diagnosis.
- Hypertensive encephalopathy (example of hypertensive emergency)
 - Often seen in malignant hypertension
 - Combination of signs and symptoms that can vary
 - Nausea
 - Vomiting
 - Headaches
 - Altered mental status
 - Visual disturbances
 - Seizures
 - Stroke

DIAGNOSTIC APPROACH

- In severe hypertension, evaluation should progress only after the ABCs (airway, breathing, and circulation) of resuscitation have been accomplished.
 - After BP has been taken several times, immediately perform a focused physical examination, checking for evidence of neurologic dysfunction and congestive heart failure.
 - Funduscopy should be performed to assess for hemorrhage, papilledema, or infarcts.
 - Any discrepancy in upper- and lower-extremity BP measurements should be noted.
 - Presence of abdominal bruit suggests a renovascular cause of hypertension.
- Brief but thorough history and physical examination should be performed to classify the severity.
 - Some key features in the history
 - Duration and onset of hypertension
 - Degree of compliance with any drug therapy
 - Possibility of renal disease
 - Be alert to any history of:
 - Urinary tract infections
 - Failure to thrive
 - Hematuria
 - Edema
 - Umbilical artery catheterization
 - Inquire about any history of:
 - Joint pain
 - Palpitations
 - Weight loss
 - Flushing

- Weakness
- Drug ingestion
- Headaches (including characterization)
- Nausea
- Vomiting
- During initial physical assessment, measure BP in both upper extremities and in ≥ 1 lower extremity.
 - Using the proper-size cuff is important.
 - Cuff should have an inflatable bladder width $\geq 40\%$ of arm circumference at a point midway between the olecranon and the acromion; the cuff bladder length should cover 80–100% of arm circumference.
 - If the cuff is too small, the next largest cuff should be used, even if it appears large.
- When newly diagnosed hypertension is seen in a child, the physician should ask:
 - Is the hypertension primary or secondary?
 - Does evidence exist of target organ injury?
 - Are there risk factors that would worsen the prognosis if hypertension is not treated or unsuccessfully treated?
- Perform laboratory tests and electrocardiography.

LABORATORY FINDINGS

- Initial laboratory studies should include:
 - Complete blood count
 - Electrolytes
 - Blood urea nitrogen
 - Serum creatinine
 - Serum calcium
 - Urinalysis
 - Chest radiography
 - Electrocardiography
- Laboratory and radiologic workup can be divided into 3 categories.
 - Tests for diagnosis of primary or secondary hypertension
 - Urinalysis
 - Urine culture
 - Urinary catecholamines
 - Complete blood count with platelet count and blood smear
 - Serum electrolytes, calcium, phosphorus
 - Serum blood urea nitrogen, creatinine
 - Serum C3 complement, antistreptolysin O titer, anti-nuclear antibody
 - Plasma renin
 - Tests for target organ injury
 - Tests for associated risk factors

IMAGING

- Imaging tests for diagnosis of primary or secondary hypertension
 - Chest radiography
 - Intravenous pyelography
 - Voiding cystourethrography
 - Cardiac catheterization
 - Renal ultrasonography
 - Renal scan
 - Renal arteriography

TREATMENT APPROACH

- Symptomatic hypertensive emergencies should be treated without delay to avoid further damage to vital organs.
 - BP should be decreased by no more than 25% in the first 2 hours.
 - Vascular access should be established immediately.
 - Patient should undergo cardiac and continuous BP monitoring, preferably by intraarterial catheter.
 - Urine output should be monitored from the outset.
 - Any serious complications must be managed before or as hypertension is being treated (eg, anticonvulsants should be administered to a seizing patient along with hypertensive medications).
- Medication choice for hypertensive emergencies depends on several factors.
 - Patient's clinical condition
 - Presumed cause
 - Whether a change occurred in cardiac output or total peripheral resistance
 - Whether end-organ involvement is present
 - The goal is to lower BP promptly but gradually.
 - A sudden decrease can lead to neurologic complications (eg, intracranial bleeding).
 - The aim should be to decrease pressure by $\leq 25\%$ over the first 8 hours, then gradually normalize BP over 26–48 hours.
- Treatment of hypertensive urgency
 - *Hypertensive urgency* is defined as severe hypertension without evidence of end-organ involvement.
 - Oral antihypertensive agents are generally sufficient, although parenteral therapy is sometimes indicated.
 - Theories suggest:
 - One-third of total planned BP reduction during the first 6 hours
 - Another third during next 24–36 hours
 - Final third during next 24–96 hours or longer
 - 4–6 hours of observation should follow administration of antihypertensive in the emergency department to identify untoward effects, such as orthostasis.

- Patients should be discharged with the same medications as used in the emergency department to treat the hypertension.
- Treatment for malignant hypertension
 - Treatment is urgent, because one-third of severely hypertensive children develop neurologic abnormalities that may be sudden in onset and leave permanent neurologic deficits.
 - Cortical blindness
 - Infarction of the optic nerve
 - Hemiplegias
 - Patients are usually admitted to the intensive care unit for continuous cardiac monitoring and frequent assessment of neurologic status and urine output.
 - An intravenous line is placed to permit administration of fluids and medications.
 - The initial goal of therapy is to reduce mean arterial pressure by approximately 25% over the first 24 hours.
 - An intraarterial line is helpful for continuous titration of BP.
 - Sodium and volume depletion may be severe; volume expansion with isotonic sodium chloride must be considered.
 - Drugs are chosen on the basis of:
 - Rapidity of action
 - Ease of use
 - Special situations
 - Convention
- For asymptomatic patients with BP moderately increased (>5 mm Hg above 99th percentile, as defined in the National Heart, Lung, and Blood Institute report), there are 2 options.
 - Arrange for a future outpatient workup, and a low-dose thiazide diuretic or β -blocker may be initiated.
 - Alternatively, the patient may be admitted to begin evaluation and therapy while under hospital observation.

SPECIFIC TREATMENTS

Hypertensive emergency

- Nitroprusside
 - 0.5 mcg/kg per min, IV infusion
 - Onset: instantaneous
 - Second dose: 30–60 min later
 - Duration of action: only during infusion
 - Side effects
 - Headache
 - Chest and abdominal pain
 - Disadvantages
 - Requires close observation; may be inappropriate in the emergency department
 - Requires 10 minutes to prepare and is photosensitive
 - Potential exists for cyanide accumulation.
- Diazoxide
 - 3–5 mg/kg (max 150 mg/dose), rapid IV push
 - Onset: in minutes
 - Second dose: 15–30 min later
 - Duration of action: 4–12 hours
 - Side effects
 - Hyperglycemia
 - Hyperuricemia
 - Tachycardia
 - Causes marked salt and water retention, and in patients with edema, should be followed with a diuretic agent
- Hydralazine
 - 0.1–0.5 mg/kg (max 20 mg), IV infusion over 15–30 min
 - Onset: 30 min
 - Second dose: 10 min later
 - Duration of action: 4–12 hours
 - Side effects
 - Tachycardia
 - Headache
 - Flushing
 - Vomiting
 - May require the introduction of a β -blocker
- Labetalol
 - 0.25 mg/kg (max 3–4 mg/kg), IV infusion while supine
 - Onset: 5 min
 - Second dose: 10 min later
 - Duration of action: up to 24 hours
 - Side effects
 - Gastrointestinal upset
 - Scalp tingling
 - Headache
 - Sedation
 - Effective in management of severe hypertension from pheochromocytoma and coarctation of the aorta
 - Reasonable alternative for hypertensive crises in patients with end-stage renal disease
- Nifedipine
 - 0.25–0.5 mg/kg (max 20 mg), bite and swallow or sublingual
 - Onset: 15–30 min
 - Second dose: 30–60 min later
 - Duration of action: 6 hours
 - Side effects
 - Dizziness
 - Facial flushing
 - Nausea

- Use depends on the patient's state of consciousness.
- Contraindicated in the presence of intracerebral bleeding
- Phentolamine
 - 0.1 mg/kg per dose, IV
 - Onset: instantaneous
 - Second dose: 30 min later
 - Duration of action: 30–60 min
 - Side effects
 - Tachycardia
 - Abdominal pain
 - Used almost exclusively for treatment of catecholamine crisis (pheochromocytoma or ingestion of sympathomimetic agents, such as cocaine)
 - Carries high risk of hypotension after primary lesion (eg, pheochromocytoma) is excised

Hypertensive urgency

- Nifedipine
 - 0.25–0.5 mg/kg, bite and swallow or sublingual
 - Onset: 15–30 min
 - Duration: 6 hours
- Captopril
 - Age <6 mo: 0.05–0.5 mg/kg, by mouth
 - Age ≥6 mo: 0.3–2.0 mg/kg, by mouth
 - Onset: 15–30 min
 - Duration: 8–12 hours
- Minoxidil
 - 2.5–5.0 mg, by mouth
 - Onset: 2 hours
 - Duration: 12 hours
- Other antihypertensive agents
 - Enalapril
 - Maximum serum concentration approximately 1 hour after administration, and 4–6 hours for its metabolite, enalaprilat
 - Amlodipine is a safe and effective drug in children with chronic renal disease.
 - Intravenous nicardipine is safe and effective in lowering the BP in children with severe hypertension.

WHEN TO ADMIT

- All hypertensive emergencies
- Most cases of hypertensive urgency

WHEN TO REFER

- Consultation with a pediatric nephrologist
 - Diagnostic evaluation of cause of hypertension
 - Short- and long-term management suggestions

- Consultation with a pediatric cardiologist or pediatric neurologist
 - If end-organ cardiac or central nervous system injury is suspected
 - If the relationship between end-organ dysfunction and hypertension is unclear

FOLLOW-UP

- All patients with hypertensive urgency or emergency should be followed by primary physicians as well as nephrologists to monitor blood pressure and adjust medications.

COMPLICATIONS

- Seizure disorders
- Cranial nerve palsies
- Stroke, hemiplegia
- Blindness
- Cardiomyopathy
- Progressive renal damage

PROGNOSIS

- Immediate prognosis for a hypertensive emergency depends on:
 - Rapidity of recognition of the problem
 - Achievement of appropriate BP reduction thereafter
- Although initial neurologic and visual disturbances may improve or resolve, risks remain for residual abnormalities.
 - Seizure disorders
 - Cranial nerve palsies
 - Hemiplegia
 - Blindness
- Renal function often deteriorates acutely in patients who have chronic renal diseases after hypertensive emergency or urgency.
 - With sustained BP control, renal function may improve over weeks or longer.
- Long-term prognosis of hypertension depends, to some extent, on underlying cause as well as success in management.
 - Some causes (eg, acute poststreptococcal glomerulonephritis) may resolve on their own.
 - Such causes as isolated vascular abnormalities are amenable to correction.
 - Hypertension associated with chronic glomerulonephritis may be controlled by continued antihypertensive therapy, but failure to comply with medication regimens remains a problem.
 - Development of end-organ damage (eg, hypertensive cardiomyopathy, stroke) is directly related to adequacy of long-term BP control.

Hyperthyroidism

DEFINITION

- Hyperthyroidism is the result of excessive activity of the thyroid gland.
- The clinical manifestation of excessive circulating thyroid hormone is called *thyrotoxicosis*.
 - With a few exceptions, thyrotoxicosis in children is the result of Graves disease.

EPIDEMIOLOGY

- Graves disease
 - Age
 - Occurs most frequently in early adolescence
 - Is rare in infancy
 - Occurs infrequently in childhood
 - Sex
 - Prevalence is 6–8 times greater in girls than boys.

ETIOLOGY

- Graves disease
 - An autoimmune disorder
 - Occurs in patients who have a genetic predisposition, which is linked to certain human leukocyte antigen haplotypes
 - Results from the interaction between environmental influences and genes, some of which are thyroid specific loci and others that are susceptibility or immunoregulatory genes
 - Hyperfunction of the thyroid gland
 - Caused by autoantibodies directed against the receptor for thyrotropin
 - These antibodies, called thyrotropin receptor antibodies (TRAbs), are characterized by an overall predominant stimulatory effect on thyroid cells leading to excessive production and release of thyroxine (T_4).
 - Included among the TRAbs are:
 - Thyroid-stimulating immunoglobulins (TSIs) that mimic thyrotropin in their stimulatory action on the production of T_4
 - Thyrotropin-binding inhibitory immunoglobulins that prevent thyrotropin from binding at its receptor and do not stimulate thyroid cells
 - Thyrotropin-blocking antibodies
 - Other antibodies detected in patients include
 - Thyroid growth-stimulating antibodies, which contribute to goiter formation
 - Antithyroglobulin and antiperoxidase antibodies that also are found in Hashimoto thyroiditis

- Eye findings
 - Due to a combination of hyperactivity of the sympathetic system and of mucopolysaccharide accumulation and infiltration of the orbital fat and ocular muscle cells:
 - TRAbs are thought to be the cause of ophthalmopathy because orbital fibroblasts express thyrotropin receptors.
 - In children, mucopolysaccharide accumulation in skin and subcutaneous tissue, as with pretibial myxedema, is infrequent.
- Other causes of thyrotoxicosis include:
 - Early phase of autoimmune hypothyroidism (Hashimoto thyroiditis) before thyroid function is diminished
 - Hyperfunctioning thyroid nodule
 - Pituitary resistance to T_4 that results in excess secretion of thyrotropin
 - Factitious hyperthyroidism caused by administration of exogenous thyroid hormone

RISK FACTORS

- Graves disease
 - Patients frequently have a family history of thyroid disorder.
 - Can occur in conjunction with:
 - Other endocrine autoimmune diseases, such as type 1 diabetes mellitus, hypoparathyroidism, and Addison disease
 - Other autoimmune diseases, such as myasthenia gravis, periodic paralysis, and vitiligo

SIGNS AND SYMPTOMS

- Graves disease often remains undiagnosed for a long time in children because they can continue normal activities without symptoms that are overtly suggestive of hyperthyroidism.
- Clinical signs and symptoms in children who have Graves disease include:
 - Goiter
 - Prominence of eyes
 - Exophthalmos
 - Tachycardia
 - Nervousness
 - Increased appetite
 - Weight loss
 - Emotional lability
 - Heat intolerance
 - Frequent and loose stools

- Early nonspecific findings include behavioral findings that largely reflect hyperactivity of the sympathetic nervous system.
 - Nervousness
 - Sleeplessness
 - Emotional lability
 - Decreased school performance
 - Deteriorating handwriting
- More prominent cardiovascular signs include
 - Tachycardia
 - A widened pulse pressure
 - An overactive precordium
- Neuromuscular signs and symptoms include:
 - Tremor
 - A shortened deep-tendon reflex relaxation phase
 - Fatigability
 - Proximal muscle weakness
- Despite increased appetite, the child loses weight.
- Symptoms that appear later
 - Increased perspiration
 - Warmth
 - Heat intolerance
 - Smoothness of skin
- With long-standing disease
 - Tall stature may accompany advanced skeletal maturation in childhood.
 - Curtailment of final height as a result of early closure of the epiphyses does not occur.
- Goiter
 - Size when first examined varies, and its presence frequently goes unnoticed.
- Thyroid gland
 - Usually seen as diffusely enlarged
 - May be difficult to discern in overweight or obese youngsters
 - Is soft and has a clearly delineated border
 - Neck exam should include
 - Palpation for the presence of a thrill
 - Auscultation for the presence of a bruit
 - Measurement of the size of the lobes and the isthmus is essential in monitoring disease course.
- Eye findings are variable.
 - Severe ophthalmopathy is far less common among children than adults.
 - If present, it is more likely to resolve completely.

- Findings include:
 - Prominence of the eyes (proptosis or exophthalmos)
 - A conspicuous stare (caused by lid retraction and a widened palpebral fissure [see Figure 35 on page F15])
 - Lag of the upper lid on downward gaze

DIFFERENTIAL DIAGNOSIS

- Hashimoto thyroiditis
 - Rarely, children with this disease are:
 - Thyrotoxic
 - Have a high titer of TSI autoantibodies in addition to antithyroid antibodies
 - The condition has been called *hashitoxicosis*.
 - May be differentiated from routine Graves disease in that the hyperthyroidism is usually a transient phase before progression to permanent hypothyroidism
- Other causes of hyperthyroxinemia are rare, including:
 - Generalized resistance to thyroid hormone that is found in association with attention-deficit/hyperactivity disorder
 - Factitious hyperthyroidism from excessive administration of thyroid hormone
 - Thyrotropin-secreting pituitary adenomas
 - Binding-protein changes characterized by normal free T_4 and thyrotropin levels
 - Autonomous thyroid adenomas
 - Can be seen in association with the McCune-Albright syndrome (precocious puberty, café-au-lait pigmentation, and polyostotic fibrous dysplasia)

DIAGNOSTIC APPROACH

- Diagnosis of Graves disease rests on demonstrating:
 - Elevated levels of T_4
 - Depression of thyrotropin levels to below the lower limit of detectability
- A comparison of the patient's levels and age-appropriate normal values of T_4 must be performed before a diagnosis of hyperthyroidism can be made.

LABORATORY FINDINGS

- Measurement of serum free T_4
 - Should be included in initial assessment
 - In patients with binding protein increases, total T_4 may be high, yet free T_4 and thyrotropin will be normal, thereby ruling out hyperthyroidism.
 - Particularly relevant to women taking oral contraceptives, in whom the estrogen increases the binding protein levels, total T_4 , total triiodothyronine (T_3), and thyrotropin concentrations

- Measurement of T_3
 - May help confirm the diagnosis of T_3 toxicosis, but rarely necessary
- In thyrotoxicosis, the response of thyrotropin to thyroid-releasing hormone is blunted severely or absent.
 - Thyroid-releasing hormone stimulation test
 - Necessary only when Graves disease is thought to exist but the diagnosis is unclear
 - In equivocal situations, measurement of TRAbs, which are present in 95% of patients who have Graves disease, may help to confirm the diagnosis.
- TSI
 - In pregnant patients, high levels are predictive of neonatal Graves disease.

DIAGNOSTIC PROCEDURES

- Measurement of thyroid gland uptake of radioiodine (^{123}I) or technetium ($^{99\text{m}}\text{Tc}$)
 - Useful only to distinguish painless thyroiditis from Graves disease
 - Patients who have thyroiditis (hashitoxicosis) have a low uptake.
 - Patients who have Graves disease have a high uptake.
 - Generally not necessary at the time of diagnosis
 - Required if radioablative therapy is performed

TREATMENT APPROACH

- Graves disease
 - Optimal long-term therapy continues to be the subject of research and some controversy.
 - Some physicians prefer to titrate the dose of antithyroid medication to maintain the patient in a euthyroid state.
 - Others administer antithyroid medication until the patient becomes hypothyroid and supplement thereafter with thyroid hormone.
 - These varying approaches have no effect on rates of relapse.
 - Therapy with antithyroid medication
 - Usually maintained for a minimum of 12–18 months
 - During this time, monitoring the size of the thyroid gland and the TRAb levels can be useful.
 - Shrinkage of the thyroid gland and decreasing TRAb titers predict a greater likelihood of remission after discontinuation of therapy.
 - Thereafter, treatment can be stopped, and 20–40% of patients remain in remission.

- If a relapse occurs on discontinuation
 - Therapeutic choices include either resumption of antithyroid medication or definitive therapy consisting of radioiodine or surgery.
 - The choice depends on factors that affect the chances of success of each form of therapy, such as compliance, patient preference, and surgical expertise.

SPECIFIC TREATMENTS

Antithyroid medications

- Thioamides
 - Aim of treatment is to reduce thyroid hormone production and block its effect on tissue peripherally.
 - Either methimazole or propylthiouracil (PTU) is usually used first.
 - Equally effective in inhibiting thyroid hormone production
 - However, PTU also blocks the peripheral conversion of T_4 to T_3 .
 - The half-life is 3–4 hours for PTU and 6–13 hours for methimazole.
 - Both drugs cross the placenta.
 - PTU does so less than methimazole and therefore is the preferred drug during pregnancy.
 - Both drugs are present in small quantities in breast milk.
 - Breastfeeding may be continued.
 - Methimazole induces euthyroidism somewhat faster than does PTU and does so within weeks to a few months, depending on the size of the thyroid gland.
 - PTU
 - Starting doses range from 5–10 mg/kg body weight, with a maximum of 300 mg/day, given in 3–4 divided doses.
 - Methimazole
 - Dose is approximately 0.5–1 mg/kg, with a maximum of 30 mg/day, given in 2–3 divided doses.
 - Once thyroid hormone secretion is depressed, maintenance doses may be given in 2 or 3 daily doses for PTU and 1 or 2 daily doses for methimazole.
 - Potential side effects
 - Minor reactions that subside spontaneously include a purpuric and papular rash, urticaria, joint pain, stiffness, hair loss, nausea, or headaches.
 - Serious reaction—agranulocytosis
 - An idiosyncratic reaction that occurs in 1:500 to 1:1000 cases
 - Usually occurs within the first few months of therapy after either form of antithyroid medication
 - Leukocyte count monitoring is not useful in anticipating agranulocytosis because its onset is sudden.

- Patients thus need to be told about the significance of a sore throat, mouth sores, and fever as potentially heralding agranulocytosis.
- Supportive treatment, such as antibiotic therapy, and discontinuation of thioamide therapy are necessary.
- Spontaneously reverses
- Resumption of therapy with a different thioamide does not usually cause recurrence.
- Such reactions as drug fever, nephritis, hepatitis, or lupus-like reactions are rare.
- Adjuvant β -adrenergic blockade
 - In addition to antithyroid medication
 - May be accomplished with propranolol to control the sympathetic hyperactivity of severe Graves disease
 - Therapy is necessary but only transiently.
 - May be contraindicated in patients who have cardiac failure or asthma
- Iodide
 - Has a minor short-term role as adjuvant therapy
 - In patients who develop toxicity to either PTU or methimazole
 - As adjunctive therapy immediately before thyroidectomy and for treatment of severe thyrotoxicosis
 - In practice, it is seldom used.
 - Works by transient inhibitory effect on iodine organification, leading to a decrease in T_4 and T_3

Definitive therapy

- Surgery
 - Resolves symptoms faster than radioiodine therapy
 - Permanent hypothyroidism after surgery is frequent.
 - Potential for surgical complications from injury to adjacent structures (recurrent laryngeal nerve damage and hypoparathyroidism) dictates that referral be made to an experienced surgeon.
- Radioiodine therapy
 - Easy to administer
 - Safer than surgery and equally efficacious
 - Is being used more extensively in the pediatric population
 - Fears regarding thyroid carcinoma, leukemia, radiation, and genetic damage after treatment have been alleviated.
 - Radioactive iodine concentrates in the thyroid gland and induces cell death over time.
 - On average, three-quarters of patients are cured after 1 dose of radioiodine.
 - A small proportion may require a second dose months after the first dose.

- Pregnancy is a contraindication to radioiodine therapy.
 - The iodine crosses the placenta and destroys the fetal thyroid.

Ophthalmopathy

- Most affected children can be treated with topical ophthalmic lubrication.
- Severe ophthalmopathy
 - Management can be either medical or surgical (orbital decompression, eye muscle or lid surgery).
 - Medical management includes high-dose glucocorticoids or orbital radiotherapy, either alone or in combination.

WHEN TO ADMIT

- Routine diagnosis and therapy of hyperthyroidism do not require hospitalization.
- Some severe complications of the disorder or its therapy (ocular, cardiovascular, infectious) may be managed by appropriate subspecialists and with hospitalization.

WHEN TO REFER

- New diagnosis of hyperthyroidism
- Surgical management

FOLLOW-UP

- Graves disease
 - Continued patient monitoring with thyroid function tests is indicated to detect any subclinical relapse.

COMPLICATIONS

- Thyrotoxic crisis
 - An exceptional but severe complication
 - Diagnosis rests on finding uncontrolled hyperthyroidism.
 - Characterized by a constellation of findings, including
 - Cardiac failure
 - Tachycardia
 - Hyperthermia
 - Central nervous system abnormalities, such as confusion, apathy, or coma
 - Infection (even relatively minor) and trauma can be precipitating factors.
 - Therapy must be expeditious and aggressive; should include
 - Antithyroid medication
 - Iodide
 - β -Blockade
 - Antipyresis
 - Medications to prevent cardiac failure

■ Neonatal thyrotoxicosis

- Rare
- Due to the transplacental passage of thyroid-directed immunoglobulins from the mother
 - May occur even if the mother no longer has active thyroid disease
 - Stimulatory and blocking maternal thyroid antibodies may disappear at different rates, making the course of neonatal Graves disease difficult to predict.
- Onset may be immediate or delayed for weeks.
- Duration may be brief or prolonged, lasting up to 6 months.
- Notably, transient neonatal hypothyroidism may result from the transfer of maternal thyrotropin-binding inhibitory immunoglobulins.
 - May also be caused by suppression of the hypothalamic-pituitary-thyroid axis by placentally transferred maternal T₄ from mothers with hyperthyroidism
- Clinical signs and symptoms include
 - Microcephaly
 - Frontal bossing
 - Tachycardia
 - Hypertension
 - Irritability
 - Failure to thrive
 - Flushing
 - Exophthalmos
 - Goiter
- Can also occur:
 - Vomiting
 - Diarrhea
 - Hepatosplenomegaly
 - Jaundice
 - Thrombocytopenia
- Cardiac failure and arrhythmias
 - Account for a mortality rate that approaches 25% when the disease is severe and treated inadequately
- Long-term complications
 - Severe
 - Include hypothyroidism, premature craniosynostosis, and intellectual deficits
- Adjunctive therapy
 - May be necessary until the disease resolves spontaneously, usually within 1–3 months as the maternal antibodies are degraded
 - In severely hyperactive neonates, propranolol, 2 mg/kg/day, and digitalis for cardiac failure may be required.
 - Glucocorticoid therapy may also be beneficial.

PROGNOSIS

■ Graves disease

- No reliable factors predict the natural course in a given patient, aside possibly from goiter size and severity of disease at onset.
- The clinical course ranges from progression to overt hypothyroidism on the one hand to progression to thyrotoxic crisis on the other.

Hypoglycemia

DEFINITION

- Hypoglycemia is serum or plasma glucose concentration <40 mg/dL or whole blood glucose concentration <35 mg/dL.
- The safe plasma glucose is uncertain; some authorities advocate maintaining the plasma glucose level >60 mg/dL in neonates and older children to prevent permanent brain damage.

EPIDEMIOLOGY

- Prevalence
 - Symptomatic hypoglycemia in newborns varies from 1.3 to 3 per 1000 live births.
 - Early feeding decreases the incidence of hypoglycemia.
- Age
 - Hyperinsulinism has 2 peak times of onset.
 - During the first year of life
 - After the 3 years of age
 - Ketotic hypoglycemia is the most likely cause of hypoglycemia with onset after 1 year of age.
 - Hypoglycemia is rare after the age of 5 years.

ETIOLOGY

- Inadequate fasting blood glucose concentration may be due to:
 - Insufficient amounts of endogenous nonglucose precursors
 - Alanine
 - Lactate
 - Glycerol
 - Ineffective hepatic enzyme pathways for gluconeogenesis and glycogenolysis
 - Abnormal hormonal activities for the mobilization of substrates and the regulation of these processes
 - Insulin
 - Growth hormone (GH)
 - Cortisol
 - Glucagon
 - Epinephrine
- Causes
 - Hyperinsulinism
 - Islet cell dysplasia (functional β -cell secretory disorder)
 - Islet cell adenoma
 - Adenomatosis
 - Beckwith-Wiedemann syndrome
 - Hereditary defects in carbohydrate metabolism
 - Glycogen storage diseases (GSD)
 - Glucose-6-phosphatase deficiency types Ia and Ib
 - Amylo-1,6-glucosidase deficiency type III
 - Defects of liver phosphorylase enzyme system

- Enzyme deficiencies of gluconeogenesis
 - Fructose-1,6-diphosphatase (FDPase)
 - Phosphoenolpyruvate carboxykinase
 - Pyruvate carboxylase
- Other enzyme defects
 - Galactose-1-phosphate uridylyltransferase (galactosemia)
 - Fructose-1-phosphate aldolase (hereditary fructose intolerance [HFI])
 - Glycogen synthetase
- Hereditary defects in amino acid and organic acid metabolism
 - Systemic carnitine deficiency
 - Carnitine palmitoyl transferase deficiency
 - Long- and medium-chain acyl-coenzyme A dehydrogenase deficiencies
- Hormone deficiencies
 - Congenital hypopituitarism or hypothalamic abnormality
 - Growth hormone
 - Cortisol
 - Adrenocorticotrophic hormone (ACTH)
 - ACTH unresponsiveness
 - Glucagon
 - Thyroid hormone
 - Catecholamine
- Ketotic hypoglycemia
 - Nonpancreatic tumors
 - Mesenchymal tumors
 - Epithelial tumors
 - Hepatoma
 - Adrenocortical carcinoma
 - Wilms tumor
 - Neuroblastoma
- Poisoning or toxins
 - Salicylate
 - Alcohol
 - Propranolol
 - Oral hypoglycemic agents (eg, sulfonylureas)
 - Insulin
 - Unripe ackees (hypoglycin) (Jamaican vomiting sickness)
 - Pentamidine
- Liver disease
 - Hepatitis, cirrhosis
 - Reye syndrome
- Other
 - Malnutrition
 - Malabsorption

- Chronic diarrhea
- Cyanotic congenital heart disease
- Postsurgery

RISK FACTORS

- Prematurity
- Hypothermia
- Hypoxia
- Maternal diabetes
- Maternal glucose infusion in labor
- Intrauterine growth retardation

SIGNS AND SYMPTOMS

- The physician should inquire about:
 - Frequency of hypoglycemic episodes
 - Possibility of drug ingestion
 - Malicious administration of drugs
 - Temporal relationship of symptoms to food intake
 - In hereditary defects of amino acid and organic acid metabolism, hypoglycemic symptoms may occur shortly after the ingestion of protein.
 - Symptoms that occur after ingestion of lactose suggest galactosemia.
 - Those that occur after sucrose ingestion suggest HFI.
 - Fasting hypoglycemia is characteristic of ketotic hypoglycemia, hormonal deficiencies, hyperinsulinism, GSD, and FDPase deficiency.
- Clinical findings after 1 month of age
 - Incoordination of eye movements
 - Strabismus
 - Excessive irritability
 - Motor incoordination
 - Convulsions
- In the older child
 - Pallor
 - Tachycardia
 - Sweating
 - Limpness
 - Inattention
 - Staring
 - Listlessness
 - Hunger
 - Abdominal pain
 - Ataxia
 - Stupor
 - Coma
 - Convulsions

DIFFERENTIAL DIAGNOSIS

Hyperinsulinism

- The most common cause of persistent or recurrent hypoglycemia in the first year of life.
 - Islet cell dysplasia (functional β -cell secretory disorder)
 - Most children who have hypoglycemia caused by persistent hyperinsulinism (previously called *nesidioblastosis*, *islet cell dysplasia*, or *congenital hyperinsulinism*) have symptoms beginning during the first year of life.
 - Islet cell adenoma
 - Uncommon in children
 - Although hypoglycemia caused by varying histologic types of insulinoma may have its onset in the newborn period, symptoms begin after the age of 4 years in 85% of patients.
 - Adenomatosis
 - Beckwith-Wiedemann syndrome (omphalocele, macroglossia, and gigantism)
 - Hypoglycemia occurs in many affected infants and resolves at several months of age.
 - Some have hemihypertrophy.
 - Increased incidence of adrenal, liver, and kidney (Wilms) tumors
 - More commonly, hyperinsulinism is transient and associated with diabetic mothers.

Inborn errors of metabolism

- Carbohydrate enzyme defects
 - GSD
 - Glucose-6-phosphatase deficiency types Ia and Ib
 - Growth retardation
 - Cherubic facies
 - Protuberant abdomen
 - Large smooth liver
 - Enlarged kidneys
 - Normal intelligence
 - Fasting hypoglycemia of only a few hours' duration
 - Ketosis, lactic acidemia, hyperlipidemia, hyperuricemia
 - Bleeding diathesis
 - In type Ib, also have neutropenia and increased frequency of infections.
 - Death may result if hypoglycemia and lactic acidemia are not treated adequately and promptly with intravenous glucose and sodium bicarbonate.
- Reye syndrome
 - Watch for an underlying metabolic defect in young children or in a child with recurrence of Reye syndrome–like symptoms.

■ Galactosemia

- In a lactose-fed infant, characterized by:
 - Failure to thrive
 - Jaundice
 - Vomiting
 - Susceptibility to infection
 - Hepatomegaly
 - Edema
 - Ascites
 - Tendency to bleed
 - Cataracts
 - Proteinuria
 - Aminoaciduria
 - Galactosuria
- If galactose-containing feedings are not eliminated:
 - Intellectual disability
 - Progressive liver failure
 - Possibly death
- Symptomatic hypoglycemia is not a common finding.

■ HFI (after fructose ingestion)

- Aversion to sweets
- Vomiting
- Profound hypoglycemia
- Convulsions
- If ingestion of fructose continues:
 - Failure to thrive
 - Prolonged vomiting
 - Jaundice
 - Hepatosplenomegaly
 - Hemorrhage
 - Abnormal liver function
 - Fructosuria
 - Hepatic failure and death

■ Fructose-1,6-diphosphatase deficiency

- Episodic hyperventilation
- Fasting hypoglycemia
- Lactic acidosis, ketosis
- Hyperuricemia
- Hepatomegaly
- Refusal to eat and vomiting precipitates the attacks.
- Life threatening in neonates and young children

■ Amino acid and organic acid metabolism defects

- Symptoms usually begin in neonatal period, but they may occur later.
- Amino acid analysis and gas chromatography of blood and urine are often helpful.

- Diagnosis and treatment depend on:
 - Detection of characteristic metabolites in blood and urine
 - Assays of specific enzyme activities in skin fibroblasts or leukocytes

■ Medium-chain acyl CoA dehydrogenase (MCAD deficiency) (defect of fatty acid oxidation)

- Nonketotic hypoglycemia (similar to Reye syndrome)
- Acute life-threatening event
- Sudden death
 - An association has been made between infants with known MCAD deficiency and history of a sibling dying of sudden infant death syndrome.
- Initial screening is best performed with:
 - Analysis of urine organic acids
 - Plasma acylcarnitine profile
 - Measurement of serum carnitine

Hormone deficiencies

■ Hypopituitarism

- Severe hypoglycemia during the first few days of life
- Occasionally, hypoglycemia first appearing later in infancy or childhood
- A few patients' symptoms
 - Midline deformities, including hypotelorism
 - Abnormality of the frontonasal process
 - Cleft lip or palate
- Septo-optic dysplasia (optic nerve hypoplasia and absence of the septum pellucidum) is present in some; it may be accompanied by nystagmus.
- Some male patients have a small penis (microphallus) or genitalia.
- Children with hypopituitarism are often overweight.

■ Cortisol deficiency may be caused by:

- Addison disease
- Congenital adrenal hyperplasia
- ACTH deficiency
- ACTH unresponsiveness

Ketotic hypoglycemia

■ Most common cause of hypoglycemia after 1 year of age

■ Combination of ketonuria, hypoglycemia, and central nervous system symptoms

- Unresponsiveness
- Pallor
- Vomiting
- Coma and convulsions

- Symptoms occurring in the early morning hours associated with an upper respiratory tract infection or prolonged fast, typical of ketotic hypoglycemia for which no cause is known
- Onset is between 9 months and 5.5 years of age, with peak incidence at 2 years.
- Hypoglycemic episode frequency
 - At intervals of a few months to ≥ 1 year
 - Subsequent decrease in frequency and tendency to disappear usually by 7–8 years of age
- GH, glucagon, cortisol, β -hydroxybutyrate, and free fatty acid levels in the blood are elevated.
- Urinary ketones are present.
- Blood glucose levels fail to increase after administration of glucagon.
- Symptoms that mimic those noted in ketotic hypoglycemia may occur in children with:
 - GH deficiency
 - ACTH unresponsiveness
 - FDPase deficiency
 - Glycogen synthetase deficiency
 - Reye syndrome

DIAGNOSTIC APPROACH

- When hypoglycemia is suspected, a diagnostic blood sample is generally taken before correcting blood glucose level.
 - Glucose and insulin (priority to do at least these)
 - GH
 - Cortisol
 - Ketone bodies
 - Lactic acid
 - Amino acids
 - Urinary ketones
 - If present, urine should be tested further for presence of amino acids and organic acids.
 - Specific tests for urinary glucose and non-glucose-reducing substances
- For diagnostic purposes, glucagon administration can be useful.
 - Robust glycemic response to glucagon strongly suggests hyperinsulinism.
- Blood glucose level
 - May be approximated quickly at bedside using a visual test strip or glucose meter
 - Can be confirmed later by appropriate chemical laboratory test
- Things to ask about during history
 - History of other affected family members or occurrence of unexplained infant deaths among close relatives
 - Suggest an inherited metabolic disorder
 - The frequency of hypoglycemic episodes
 - Possibility of drug ingestion
- To establish diagnosis of ketotic hypoglycemia
 - Document hypoglycemic blood glucose levels at the time of symptoms with a diagnostic blood sample.
 - After the child has had several days to recover from acute episode and is eating well, administration of a provocative low-calorie, high-fat ketogenic diet has been useful in establishing diagnosis if a blood sample is unobtainable.
 - The child must be observed carefully for hypoglycemia during the test period.

LABORATORY FINDINGS

- Hyperinsulinism
 - Low fasting plasma levels of β -hydroxybutyrate and free fatty acids
 - Inappropriate insulin secretion
 - Insulin levels are disproportionately high relative to blood glucose values, particularly during hypoglycemia.
 - A high rate of glucose infusion (>12 mg/kg/min) is often necessary to maintain euglycemia.
 - Immunoreactive insulin
 - Leucine tolerance test
- Inborn errors of metabolism
 - Studies should be performed in a pediatric metabolic center when the child's condition is stable and the blood glucose level is normal.
 - Judgment must be exercised in choosing proper diagnostic test to delineate the underlying abnormality.
 - Presence of specific hepatic enzyme deficiencies may be determined by the use of other tolerance tests.
 - Tolerance tests are performed after variable period of fasting and only with a primary care physician in attendance, who is prepared to interrupt by administering intravenous glucose should signs of hypoglycemia occur.
 - Definitive diagnosis of inherited disorders of carbohydrate metabolism, except galactosemia, depends on assay of specific hepatic enzyme activities.
 - Test results for various hepatic enzyme effects (tolerance tests done after variable fasting period)
 - GSD-I
 - Fasting: glucose decreased, lactic acid increased
 - After glucose: glucose increased, lactic acid decreased
 - After glucagon: glucose same, lactic acid increased
 - After galactose: glucose same, lactic acid increased
 - After fructose: glucose same, lactic acid increased
 - GSD-III
 - Fasting: glucose decreased or normal, lactic acid normal
 - After glucose: glucose increased, lactic acid increased

- After glucagon: glucose increased (2 hours after fasting), lactic acid same
- After galactose: glucose increased, lactic acid increased
- After fructose: glucose increased, lactic acid increased
- GSD family
 - Fasting: glucose decreased or normal, lactic acid normal
 - After glucose: glucose increased, lactic acid increased
 - After glucagon: glucose increased or same, lactic acid same
 - After galactose: glucose increased, lactic acid increased
 - After fructose: glucose increased, lactic acid increased
- FDPase
 - Fasting: glucose decreased, lactic acid increased
 - After glucose: glucose increased, lactic acid decreased
 - After glucagon: glucose increased or same (variable; dependent on duration of fast), lactic acid may increase or decrease
 - After galactose: glucose increased, lactic acid same
 - After fructose: glucose decreased, lactic acid increased
- HFI
 - Fasting: glucose normal, lactic acid normal
 - After glucose: glucose increased, lactic acid same
 - After glucagon: glucose increased (no increase at time of fructose-induced hypoglycemia), lactic acid same
 - After galactose: glucose increased, lactic acid same
 - After fructose: glucose decreased, lactic acid increased
- GH or cortisol deficiencies
 - Low blood values of either in the presence of hypoglycemia raise suspicion of deficiencies of these hormones and need for further studies.
- C-peptide, insulin, and insulin antibodies in blood may identify patient with exogenous source of insulin.
 - C-peptide levels are suppressed.
 - Insulin antibodies may be present.

IMAGING

- Magnetic resonance imaging and computed tomography of the brain may be of diagnostic help if hypopituitarism or GH deficiency is suspected.

TREATMENT APPROACH

- Correction of hypoglycemia
 - Administering 2–4 mL/kg of 10–25% glucose intravenously
 - Intravenous fluids containing appropriate electrolytes and glucose are given at a rate sufficient to maintain plasma or serum glucose levels above 50–60 mg/dL.

- It is important to follow up with sufficiently frequent blood glucose monitoring to determine the adequacy of the continuous glucose infusion.
- Blood glucose level should be monitored initially every 30–60 minutes at the bedside until stable then every 2–4 hours; rate of glucose administered should be adjusted accordingly.
- Overcorrection with subsequent hyperglycemia may complicate fluid management by causing an osmotic diuresis.
- Significant hypoglycemia should be evaluated on an inpatient basis to allow close monitoring.
 - During transport to the hospital, personnel experienced in intravenous techniques and rapid bedside blood glucose measurements must ensure continuous infusion of adequate amounts of glucose.
 - Previously obtained diagnostic blood samples should be sent with the patient to the hospital, preferably on ice.

SPECIFIC TREATMENTS

Hyperinsulinism

- Diazoxide
 - Normal glucose level is restored, use of the drug is continued, and the patient is assessed periodically until 5–7 years of age.
 - Clinical improvement may occur with increasing age, while abnormalities of glucose regulation may remain.
 - Parents should be instructed to monitor urinary glucose and ketones due to possible side effects.
 - Hyperglycemia
 - Ketosis
 - Hyperosmolar nonketotic coma
 - Hyperinsulinism caused by SUR mutations may not respond to diazoxide.
 - If hypoglycemia persists or recurs despite diazoxide therapy, then octreotide (a long-acting analogue of somatostatin) may be used.
 - Tachyphylaxis has prevented long-term use in all but a small number of severely affected children.
 - Surgery
 - If medical therapy fails
 - Preoperative catheterization and intraoperative histologic studies may allow partial pancreatectomy in approximately 40% of infants with focal abnormalities, reducing the postoperative incidence of diabetes.
- ### Carbohydrate enzyme defects
- Continuous nocturnal glucose-containing gastric feedings
 - During the day, frequent feedings, at least every 3–4 hours
 - Foods rich in fructose and galactose should be avoided.
 - Daily oral administration of uncooked cornstarch suspension is beneficial in older children but less so in infants.

Galactosemia

- Give galactose-free diet immediately.
- Maintain carefully while awaiting results of erythrocyte enzyme studies.
- Continue if diagnosis is confirmed.
- Long-term management consists of avoidance of lactose- and galactose-containing foods.

HFI

- Reverse acute episodes of hypoglycemia by intravenous administration of glucose.
- Long-term treatment consists of:
 - Strict elimination of dietary fructose
 - Elimination of fructose in cough syrups and other drugs

FDPase deficiency

- Treatment of acute attacks
 - Correction of hypoglycemia and acidosis by intravenous infusion of glucose and sodium bicarbonate
- Long-term management
 - Emphasizes avoidance of fasting and provision of a fructose-free, high-carbohydrate diet

Ketotic hypoglycemia

- Reverse acute hypoglycemic attacks by intravenous administration of glucose
- A liberal carbohydrate diet, including a bedtime snack, should be followed.
- Avoid prolonged overnight fasting, particularly during weekends or holidays and periods of illness.
 - Parents should test the child's urine for ketones during illness or periods of fasting.
 - Carbohydrate-containing foods, given promptly when acetonuria develops, are usually successful in aborting attacks.

WHEN TO ADMIT

- A child with documented hypoglycemia not caused by insulin therapy should be hospitalized for careful monitoring and diagnostic testing.
- Surgery
 - If hypoglycemia is diagnosed in an infant <3 months, surgical intervention may be necessary.
 - Surgical exploration is usually performed in severely affected neonates who are unresponsive to glucose and somatostatin therapy.

WHEN TO REFER

- A child with documented hypoglycemia not caused by insulin therapy should be referred to an endocrinologist.

FOLLOW-UP

- Patients with hypoglycemia should be monitored by parents frequently and followed by primary care physician and endocrinologists frequently.

COMPLICATIONS

- Severe and prolonged hypoglycemia can cause permanent brain damage.

PROGNOSIS

- Prognosis for hypoglycemia depends on the underlying cause, severity of hypoglycemia, and rapidity of therapy.

Hypospadias, Epispadias, and Cryptorchism

DEFINITION

- An external genital deformity in the newborn boy is usually obvious immediately.
 - Hypospadias: the urethral meatus opens on the ventral surface of the penis.
 - Epispadias: the meatus is formed on the dorsum of the penis at various points along the glans and shaft and, on rare occasions, so far back as to be beneath the symphysis pubis.
 - Circumcision should be delayed in infants with hypospadias and epispadias and should not be performed until a pediatric endocrinologist and a pediatric urologist perform a thorough evaluation.
 - Cryptorchism: undescended testes
 - The testes are generally descended in a full-term infant (depending on the birth weight).
 - Frequently, each testis is of somewhat different size.
 - Testes descend from within the abdomen to the scrotum usually by about week 36 of fetal life.
- Retracted penis may seem to disappear (even though it is 4 cm long) in a suprapubic pad of fat; parents should be assured kindly that the condition will correct itself in time.
- Micropenis is a rare dysmorphic abnormality in which the penis has a stretched length <2 standard deviations below the mean, or is <2.5 cm in length.
 - Circumcision should be delayed in these infants and should not be done until a pediatric endocrinologist and a pediatric urologist perform a thorough evaluation.

EPIDEMIOLOGY

- Prevalence
 - Hypospadias is the most common penile abnormality, occurring in 3 per 1000 newborn boys.
 - Some evidence suggests increasing incidence due to various genetic and environmental factors.
 - Epispadias occurs less frequently: 1 per 117,000 live male births.
 - Cryptorchism
 - 2.2–3.8% in male neonates weighing ≥ 2500 g at birth
 - 20–30% in the premature infant

ETIOLOGY

- Cryptorchism
 - The testes are in the inguinal canal or abdomen in 50% of those boys with nonpalpable testes.
 - The testes are absent in the remaining 50% because of intrauterine torsion and infarct.
 - Rate of spontaneous descent is lower for full-term infants (50–70%); occurs earlier (usually by age 1–3 months) than for premature infants.

- In a premature infant, the rate of spontaneous descent is as high as 80–90% and may occur later in the first year of life.
- If spontaneous descent does not happen by the first birthday, concern is warranted.
- Cryptorchism affects child's potential for developing testicular cancer, for reproduction capacity, and for sexual function.
 - Testicular cellular damage is increasingly likely with each passing year.
 - Damage is probably not reversible after the age of 4 or 5 years.

RISK FACTORS

- Hypospadias
 - Endocrine disruptors, such as maternal use of progestins, appear to increase risk.

SIGNS AND SYMPTOMS

- Hypospadias
 - The urethral meatus opens on the ventral surface of the penis, located most often on the distal half of the shaft, including the glans penis (60%).
 - May be located at any proximal point along the shaft or scrotum (25%) or the perineum (15%)
 - The prepuce is incompletely formed, covering only the dorsal surface of the glans penis.
 - Associated unilateral or bilateral cryptorchidism in ~10%
- Epispadias
 - Deformity is more proximal than hypospadias.
 - May be associated with complete urinary incontinence because of involvement of bladder neck area and distortion of the normal architecture of the pubic bones
- Cryptorchism
 - In 10% of boys with undescended testes, testes are nonpalpable.
 - On examination, be sure that the testis truly is undescended.
 - Occasionally, an overactive cremasteric reflex may make palpation difficult.
 - Moving the infant or the older child into the tailor position (sitting cross-legged) or a kneeling position can help overcome this difficulty.
 - The examiner must feel from above downward, milking the testis from the inguinal canal into the scrotum.
 - Older patients can help this process by coughing or straining.
 - Cold hands and abrupt palpation can invoke the cremasteric reflex.

- If 1 or the other testis is not palpable, the examiner should search beyond the scrotum and the inguinal canal to the femoral triangle and the inner thigh.
- Undescended testes are associated with inguinal hernia and possibly hydrocele, which can make palpation of the testes more difficult.
- If the testis is impalpable and a hernia is present, the testis usually lies just inside the internal inguinal ring.
- If undescended, the testes may have stopped descent at some point within the inguinal canal or may still be in the abdomen.
- If a testis has not reached the inguinal canal, the likelihood is greater that it is abnormal.
- The lower the testis lies in the inguinal canal, the more likely that it is normal.
- Some testes that appear descended at birth may ascend later in childhood.
 - Testicular ascent may account for between 2% and 20% of all orchiopexies.

DIAGNOSTIC APPROACH

- Hypospadias
 - Severity of the deformity and position of the meatus on the penile undershaft greatly influence surgical decisions.
 - Any combination of hypospadias and cryptorchidism should be investigated for possible sex development anomaly.

IMAGING

- Hypospadias
 - Many parents request sonography to be assured that the upper tract is normal.
- Cryptorchism
 - Sonography has proved helpful only with inguinal undescended testis.
 - Computed tomography exposes the child to radiation, requires sedation, and has many false-positive and false-negative results.
 - Radiation should be avoided.

DIAGNOSTIC PROCEDURES

- Cryptorchism
 - Patients with nonpalpable testes may need endocrine or genetic evaluation.

TREATMENT APPROACH

- Hypospadias
 - Circumcision should not be performed in the presence of hypospadias, however mild.
 - None of the tissue that might be needed for repair should be sacrificed.

- If hypospadias is mild and situated at or close to the corona with relatively little deformity, repair is quite straightforward.

■ Cryptorchism

- A testis that retracts because of an overactive cremasteric reflex should not be repaired.
- The truly undescended testis needs repair to:
 - Improve chances of fertility
 - Provide accessible examination (particularly in the event of malignant change)
 - Diminish possibility of testicular torsion
 - Prevent the emotional trauma of an empty scrotum
- Risk of cancer in an undescended testis is 4–10 times that of the normal scrotal testis.
 - Risk is 2 times greater in bilateral undescended testes than in unilateral undescended testis.
- If 1 or both testes truly are ectopic or hidden, the management plan raises questions.
 - How long should one wait for descent before surgical intervention?
 - Does a best time exist emotionally?
 - Is worry about infertility warranted?
 - Can repair help in this regard?
- Orchiopexy does not change the incidence of cancer in undescended testis.
- However, the timing of orchiopexy makes a difference in the outcome of fertility.
- If the testis is not descended by 12 months of age, surgery is indicated.

SPECIFIC TREATMENTS

Hypospadias

- Same-day surgery
 - Occasionally, an associated meatal stenosis can be corrected easily at the time of the hypospadias repair.
- Chordee, downward curving of the penis as a result of abnormal ventral fibrous bands, is often present and must be addressed at the time of surgery.
 - Multiple-stage repairs may be required when chordee is very severe and little dorsal foreskin exists.
- Currently, most hypospadias defects can be corrected with a single procedure.
- Frequency of an associated anomaly of the upper urinary tract is low.
- Even if the defect is severe, a single-stage repair can often be performed.

- The pediatric urologist should advise the parents on the right time for surgery and the approach to use.
 - Little research has been conducted on the optimal timing of hypospadias surgery.
 - Many pediatric urologists recommend the surgery as early as age 6 months.
 - In theory, performing the surgery between 6 and 15 months of age avoids any of the sensitive phases of psychosocial development.
- The pediatrician cannot relinquish responsibility for providing concomitant care.
 - Interpretation of events
 - Provision of appropriate counseling to parents and the older child, in a highly charged emotional circumstance
 - Especially important if sexual function is threatened or if sexual identity is of concern
- In the presence of hypospadias alone, little likelihood exists of significant hormonal disturbance, aside from a rare defect in androgen responsiveness.

Epispadias

- Circumcision is to be avoided.

Cryptorchism

- If parents decline surgery or are reluctant, the potential for descent with a therapeutic trial of human chorionic gonadotropin (hCG) can be explored.
 - hCG 1500 U/m² body surface area intramuscularly twice a week for 4 weeks
 - Treating with hCG over a longer period has disadvantages; it can:
 - Hasten onset of puberty
 - Cause testicular damage and sterility
 - Overall success of hCG therapy depends on the initial location of the testis.
 - Greater success reported with lower positioned testes
 - Randomized controlled trials report success rates of 8–43%.
 - Luteinizing hormone–releasing hormone and hCG treatment are equally effective in treating cryptorchism.
- If hormonal treatment fails, surgery is the only other treatment that can be offered:
 - If the testis does not descend
 - If the testis descends but retracts after the hCG trial
- The optimal time for surgical correction of cryptorchism is approximately 12 months of age.
- If surgical correction is delayed until adolescence (eg, because of delayed diagnosis), then possibility of the testis generating viable sperm is significantly decreased.
 - Bringing the testis down at this time does not diminish the potential for cancer, but it increases the likelihood of early detection.

- If the patient with cryptorchism has an associated inguinal hernia (with or without a hydrocele):
 - Herniorrhaphy, along with orchiopexy, should be performed immediately.
 - Elective herniorrhaphy is preferable to a procedure performed in the setting of incarceration and possible strangulation.
- Surgery may be done on an ambulatory basis when the testis is palpated in the inguinal canal.
 - If the testis cannot be felt, a more extensive procedure with an abdominal incision probably is necessary.
 - Unless preliminary laparoscopy reveals the testis to be absent
 - Complete laparoscopic orchiopexy is being performed in specialized centers.
 - In either case, a demonstrably abnormal testis should be removed and replaced with a prosthesis.
- The role of the pediatrician in the care of the patient and his family is important.
 - Emotional support
 - Discussion about child's and parents' fears and concerns in preparation for and after surgery

WHEN TO ADMIT

- Surgical repair of hypospadias
- Surgical repair of epispadias
- Orchiopexy for intraabdominal testis or testes

WHEN TO REFER

- Refer to urology:
 - All cases of hypospadias
 - All cases of epispadias
 - Patients with undescended testis or testes at approximately 1 year of age
- Refer to endocrinology:
 - Hormonal treatment of undescended testes
 - Hypospadias with genital abnormalities

FOLLOW-UP

- Because the incidence of cancer is high in undescended testes/testis, even after orchiopexy, individuals who have undergone orchiopexy should be followed carefully.

PROGNOSIS**■ Cryptorchism**

- For persons who respond to administration of hCG, the outlook for full sexual maturity is excellent.
- If the testes lie within the abdomen and are not palpable in the inguinal canal, then hCG:
 - Will not bring them down into the scrotum
 - May bring them into the inguinal canal, where they are accessible to palpation and long-term observation
 - Avoids immediate surgery
 - If the testes descend into the scrotum, avoids surgery altogether

PREVENTION

- Because the incidence of cancer is high in undescended testes, even after orchiopexy, individuals who have undergone orchiopexy should be taught self-examination of the testes and instructed to seek medical attention if any abnormality is detected.

Hypothyroidism

DEFINITION

- Clinical state in which production (or incipient failure of production) of thyroid hormones is insufficient to the extent that it leads to clinical manifestations
- Primary hypothyroidism: insufficient thyroid hormone from failure of thyroid gland
- Secondary hypothyroidism: insufficient production of thyrotropin from pituitary abnormalities
- Tertiary hypothyroidism: insufficient production of thyrotropin from hypothalamic abnormalities

EPIDEMIOLOGY

- Congenital hypothyroidism
 - Age
 - Present at birth
 - Prevalence
 - Approximately 1 infant of every 4000 live births in iodine-sufficient regions of the world
 - Prevalence is greater in iodine-deficient regions.
- Acquired juvenile hypothyroidism
 - Age
 - Occurs outside the newborn period
 - Prevalence in US population
 - Approximately 2% of children 12–19 years of age

ETIOLOGY

Congenital hypothyroidism

- In most cases of permanent congenital hypothyroidism, the underlying mechanism of condition is unknown.
- Approximately 90% of patients with congenital hypothyroidism have:
 - No thyroid tissue (athyreosis)
 - Ectopic thyroid gland
 - Hypoplastic thyroid gland found in the normal anterior cervical location
- Genetic causes
 - Mutations in genes explain only a small portion of cases.
 - Several inborn errors of thyroid hormone synthesis are inherited as autosomal-recessive traits.
 - Rarely, congenital secondary (pituitary) hypothyroidism is caused by mutations in genes that code for pituitary transcription factors.
- Familial abnormalities of thyroid hormone synthesis and metabolism (familial dysmorphogenesis)
- Maternal disease
 - Evidence of maternal autoimmunity has been found in some cases.
 - The etiologic role of autoimmunity is controversial.

- Therapeutic doses of iodine-131 after the 11th week of gestation
- Transient hypothyroidism
 - Transient hypothyroidism can persist for several weeks or months.
 - Thyrotropin receptor–blocking antibodies produced by a mother who has autoimmune thyroid disease cross the placenta and block fetal thyroid function (2% of cases).
 - Drugs prescribed for mother cross the placenta and block fetal thyroid gland.
 - Propylthiouracil
 - Methimazole
 - Iodides
- Endemic goiter and cretinism
- Hypothalamic-pituitary hypothyroidism
 - Pituitary agenesis or aplasia
 - Thyrotropin deficiency: isolated
 - Hypothalamic hormone deficiency
 - Isolated thyrotropin deficiency
 - Multiple tropic hormone deficiencies
 - Septo-optic dysplasia
 - Anencephaly
 - Hypothalamic-pituitary lesions

Juvenile hypothyroidism

- Autoimmune thyroiditis
 - Most common cause of hypothyroidism in children beyond the neonatal period
 - In rare instances, disease may begin as early as 6 months of age.
 - Progresses rapidly during infancy with few symptoms and signs of hypothyroidism
 - Similar to other autoimmune conditions, believed to be the result of interplay between:
 - Unknown environmental factors
 - Genetic predisposition
 - Associated with certain human leukocyte antigen types
- Atrophic thyroiditis of infancy
- Chronic lymphocytic thyroiditis of childhood
- Atrophic thyroiditis of childhood and adolescence
- Hashimoto thyroiditis (struma lymphomatosa)
- Congenital thyroid dysgenesis
 - Ectopic thyroid
 - Hypoplastic thyroid
- Congenital defects in thyroid hormone synthesis or metabolism

- Iatrogenic thyroid ablation
 - Surgical
 - Radioactive iodine-131
- Ingestion of goitrogens
- Endemic goiter
- Hypothalamic-pituitary disease
 - Occasionally, patients who have hypothalamic or pituitary disease may be seen initially with hypothyroidism.
 - These children usually have other clinical features to suggest abnormality of the hypothalamus or pituitary.

SIGNS AND SYMPTOMS

- Hypothyroidism can affect many different organ systems to varying degrees.
- Many of the symptoms and signs of hypothyroidism are different during infancy compared with childhood.

Congenital hypothyroidism

- During the first month of life, affected infants may have no clinical symptoms or signs of hypothyroidism.
- In infants with no functioning thyroid tissue, clinical signs and symptoms rarely present at birth.
 - Almost always present by 6 weeks of age
- Decreased stooling (<1 stool per day)
- Prolonged hyperbilirubinemia (bilirubin level >10 mg/dL after 3 days of age)
- Respiratory distress in a term infant
- Birth weight >4000 g
- Feeding problems
- Sleepiness
- Hoarse cry
- Facial edema
- Large posterior fontanelle (>0.5 cm)
- Rectal temperature <95°F (35°C)
- Umbilical hernia
- Macroglossia
- Bradycardia (pulse <100 beats/min)
- Lethargy
- Cutaneous mottling, vasomotor instability
- Hirsute forehead
- Milder forms of congenital hypothyroidism may be missed by newborn screening programs.
 - Symptoms do not appear until childhood.
 - Children with these milder symptoms usually have:
 - Familial goitrous hypothyroidism (dyshormonogenesis)
 - Thyroid dysgenesis: ectopic thyroid gland located somewhere between the foramen cecum of tongue and anterior mediastinum

Acquired juvenile hypothyroidism

- Clinical symptoms and signs of older children with hypothyroidism may be nonspecific and insidious in development.
- If disease has been present for >6 months, growth deceleration should be evident.
 - Normal thyroid hormone secretion is essential for normal linear growth.
- Most patients who have juvenile hypothyroidism:
 - Have either thyromegaly or deceleration of growth
 - Are usually short in stature
 - Deceleration of linear growth should be identified by the primary care physician who routinely measures height of the patient.
- Frank obesity is uncommon.
 - Reduction in physical activity, if it occurs, is usually less than reduction in caloric intake.
- Growth retardation (<4 cm/yr)
- Delayed dental development and tooth eruption
- Onset of puberty: usually delayed; rarely precocious
- Menstrual disorders
- Galactorrhea
- Constipation
- Cold intolerance
- Weight gain
- Fatigue
- Delayed bone maturation
- Short stature
- Myopathy and muscular hypertrophy
- Increased skin pigmentation
- Physical and mental torpor
- Pale, gray, cool, mottled, thickened, coarse skin
- Coarse, dry brittle hair
- Bradycardia
- Delayed deep-tendon reflexes

DIFFERENTIAL DIAGNOSIS

- The range of nonspecific symptoms and physical findings associated with hypothyroidism may result in other diagnoses being considered initially.
- In newborns
 - Liver abnormalities, suspected because of prolonged jaundice
- In older children
 - Chronic fatigue in children with depression
 - Delayed growth in children with simple delayed puberty
 - Weight gain in children with exogenous obesity

DIAGNOSTIC APPROACH

- Most newborns with congenital hypothyroidism will not be discovered on the basis of clinical suspicion.
 - Infants are identified via a newborn hypothyroidism detection program using a dried blood spot collected in the first day or two of life.
 - Analyzed at a central laboratory
 - In most programs, thyrotropin levels are determined:
 - For all infants
 - For infants whose total thyroxine (T_4) level falls below a threshold value
 - Infants identified in these programs must have confirmatory laboratory measurements of free T_4 and thyrotropin performed as soon as possible.
- Thyroid function tests: The most useful tests are usually:
 - Serum thyrotropin
 - Free T_4
 - Has widely supplanted the determination of total T_4
 - Total T_4 values are significantly influenced by circulating protein concentrations.
 - Less clinically useful
 - Tests other than serum T_4 and thyrotropin determinations are not usually required in children with suspected hypothyroidism.
- Varying clinical manifestations of disease make diagnosing congenital hypothyroidism on clinical grounds difficult (see Figure 36 on page F15).
 - Some infants may have clinical features suggestive of hypothyroidism but normal thyroid study results.
 - Others may have minimal clinical features, such as:
 - Mild periorbitaledema
 - Enlarged posterior fontanelle
 - Decreased stooling
 - Abdominal distention
 - Children with advanced hypothyroidism and myxedema are usually:
 - Chubby
 - Have periorbital edema
- Physical examination
 - Inspection and palpation of the anterior cervical area enables the examiner to identify an enlarged thyroid gland, even in a neonate.
 - Easiest method for examining thyroid gland of an infant
 - Place the infant in the supine position with the neck hyperextended over the edge of examining table.
 - Feel for the isthmus of the thyroid, just below the hyoid bone.

- After identifying the isthmus, palpate laterally to delineate the lobes.
- Lobes are difficult to define in a healthy infant.
- Thyroid examination of older child is easier.
 - The thyroid rises during swallowing.
 - Having the patient swallow water will facilitate identification and delineation of both thyroid lobes as distinct from adjacent tissue.

LABORATORY FINDINGS

- Identification of primary hypothyroidism
 - The combination of a low serum T_4 value and elevated thyrotropin value is diagnostic.
 - A normal free T_4 level and elevated thyrotropin level indicates mild hypothyroidism.
 - Elevation of the serum thyrotropin value is the most sensitive test.
 - Free T_4 determination by direct dialysis is the most accurate method.
 - Least likely to give false-positive or false-negative results from interfering drugs or other substances in serum
- Hypothalamic or pituitary hypothyroidism
 - Low free T_4 and thyrotropin levels are strongly suggestive and should prompt further evaluation.
- Thyroid binding–protein deficiency
 - A benign condition
 - Male patients with normal free T_4 and thyrotropin levels but low total T_4 levels
- Occasionally, a child or infant with coexisting and severe illness may have nonthyroidal illness syndrome (euthyroid sick syndrome), in which:
 - The free T_4 level may be low.
 - Low serum triiodothyronine
 - Normal thyrotropin
 - Borderline or frankly elevated reverse triiodothyronine levels
- Autoimmune thyroiditis
 - Elevated serum thyroid peroxidase or thyroglobulin antibodies confirms a presumptive diagnosis.

IMAGING

- Congenital hypothyroidism
 - Some experts suggest use of radioisotopic studies for all infants with suspected; others do not.
 - Thyroid scan is listed as optional in the most recent AAP policy.

- If thyroid scan is performed:
 - Iodine-123 or technetium-99m should be used.
 - Do not use iodine-131, which exposes neonatal thyroid to higher radiation doses.
- Thyroid scan will distinguish sporadic disease, such as thyroid dysgenesis, from familial goitrous thyroid dysmorphogenesis.
 - Important distinction for genetic counseling
 - With dysgenesis, the scan will be consistent with agenesis and atopic thyroid tissue.
 - In familial dysmorphogenesis, a normally sized or enlarged thyroid gland will be found in the normal anterior cervical location of neck.
- Acquired juvenile hypothyroidism
 - Radioisotopic studies are rarely needed.
 - Thyroid uptake studies are indicated when the patient has:
 - Diffuse thyromegaly
 - Biochemical evidence of hypothyroidism not caused by autoimmune thyroiditis or goitrogen ingestion
- Assessment of skeletal maturation can provide additional data regarding the duration of hypothyroidism.
 - Not essential
 - Bone age determination consistent with that of a healthy newborn suggests:
 - Recently acquired, mild congenital hypothyroidism
 - Indications that the fetus was affected by hypothyroidism during third trimester are:
 - Absence of ossification centers at the knee
 - Presence of only 2 ossification centers in the foot

TREATMENT APPROACH

- The treatment of choice for hypothyroidism in infancy and childhood is daily administration of oral L-thyroxine.
 - Dosage
 - Full term: 50 mcg/day; 10–15 mcg/kg per day
 - <6 months: 25–50 mcg/day; 8–10 mcg/kg per day
 - 6–12 months: 50–75 mcg/day; 6–8 mcg/kg per day
 - 1–5 years: 75–100 mcg/day; 5–6 mcg/kg per day
 - 6–12 years: 100–125 mcg/day; 4–5 mcg/kg per day
 - >12 years: 100–200 mcg/day; 2–3 mcg/kg per day
- Transient hypothyroidism can persist for several weeks or months.
 - The infant requires thyroxine therapy until the antibodies disappear.
- The following may interfere with absorption of L-thyroxine and should be avoided when possible.
 - Soy formula
 - Iron
 - Calcium
 - High-fiber foods
- Iodine-containing medications should not be applied to the skin or mucous membranes of neonates for more than a few days.
 - Easily absorbed
 - Block the infant's thyroid gland

SPECIFIC TREATMENTS

Congenital hypothyroidism

- The initial dose of L-thyroxine in a term infant is 50 mcg/day for the first 1–2 weeks.
 - Should be started promptly at initial visit when:
 - Screening test results are abnormal.
 - Serum samples have been sent for confirmatory tests.
 - A scan is abnormal.
 - Clinical studies have indicated that rapid normalization of serum free T₄ and thyroid-stimulating hormone levels with initial L-thyroxine dosing of 50 mcg/day is associated with better long-term development outcomes than using 37.5 mcg/day initially.
 - Infants with hypothalamic or pituitary hypothyroidism generally have milder hypothyroidism.
 - Should be given 25 mcg/day
- At the end of the second to fourth week, determine that the amount of L-thyroxine is adequate but not excessive by measuring:
 - Serum T₄
 - Thyrotropin
- After 1 or 2 weeks
 - 50-mcg/day dose may need to be reduced to 37.5 g/day (or, infrequently, to 25 mcg/day) if:
 - Clinical symptoms of hyperthyroidism develop.
 - The serum T₄ value exceeds 16 mcg/dL.
- In athyreotic infants who have low T₄ values, usually 50 mcg/day is adequate.
- Therapy should be adjusted to maintain serum T₄ levels during infancy in the upper half of the age-adjusted normal range.
 - Optimizes developmental outcome
- Occasionally, the thyrotropin value will not return to normal, even if the T₄ dose is excessive and causes clinical thyrotoxicosis.
 - These infants may have an abnormality in the feedback set point of thyrotropin secretion.

- Goal of therapy should be to maintain:
 - Normal serum T_4 values
 - Clinical euthyroidism
- Discontinuing L-thyroxine therapy some time after 3 years of age is a way of testing for transient congenital hypothyroidism.
 - Serum T_4 and thyrotropin levels are determined 2–4 weeks later.
- A trial of no therapy is not necessary for patients documented to have:
 - Thyroid aplasia
 - Ectopic thyroid dysgenesis
 - Elevated thyrotropin values after the initial period of therapy

Acquired juvenile hypothyroidism

- Older children with hypothyroidism do not share the same urgent need to achieve a euthyroid state.
- Patients who have had a recent onset of mild hypothyroidism may be given a full replacement dose of L-thyroxine.
 - Children ≥ 3 years of age with chronic hypothyroidism and clinical symptoms should:
 - Be given a low dose
 - Have the dose gradually increased every 2–4 weeks to the full replacement
- Rapid correction of hypothyroid state can often be associated with undesirable behavioral side effects.
 - These children act thyrotoxic despite biochemical euthyroidism.
 - Often restless
 - Have a short attention span
 - Emotionally labile
 - A gradual increase in dose seems to minimize problems in adjustment.

WHEN TO ADMIT

- Myxedema coma
- Parental noncompliance with treatment of a young infant at increased risk for permanent impairment of central nervous system function if thyroid function test results are not maintained in the normal range

WHEN TO REFER

- Severe congenital hypothyroidism
- Cause of hypothyroidism not established on initial evaluation
- Initial therapy does not normalize thyroid function test results within normal range for age.
 - Often not necessarily the normal range provided by the laboratory

- The physician must know the normal range of thyroid function test results for age for patient management during the first 2 decades of life.
- Acquired hypothyroidism that is atypical or complex
 - Disease occurs in infancy or early childhood.
 - Disease is associated with other endocrine or nonendocrine autoimmune diseases.
- When the diagnosis is hypothalamic or pituitary hypothyroidism based on a low free T_4 level (by a method validated in infants and children) and a normal or low thyrotropin level
 - This form of hypothyroidism is rarely an isolated disease.
 - Expected to be associated with other hypothalamic-pituitary abnormalities
 - If isolated, genetic evaluation is needed to define cause and potential for recurrence in a family.

FOLLOW-UP

- Congenital hypothyroidism
 - AAP policy for monitoring free T_4 and thyrotropin values
 - Age <6 months: every 1–2 months
 - Age 6 months to 3 years: every 3–4 months
 - Age 3 years to completion of growth: every 6–12 months
- Acquired juvenile hypothyroidism
 - Once the patient is receiving a full replacement dose with normal values, adequacy of L-thyroxine therapy is monitored by free T_4 and thyrotropin determinations every 6–12 months.
 - An elevated thyrotropin level with or without low T_4 value indicates either inadequate therapy or poor compliance; the latter is characterized by variable serum T_4 and thyrotropin values.
 - Levels may be normal on one occasion and discordant (normal or elevated T_4 value with elevated thyrotropin value) on subsequent determinations, despite no change in therapy.

COMPLICATIONS

- Congenital hypothyroidism
 - Delays in diagnosis and institution of adequate therapy are usually associated with increased risk of intellectual disability.
 - Infants with prolonged fetal hypothyroidism have increased risk for impaired intellectual function.
 - Due to maternal hypothyroidism during first trimester or other factors that blocked fetal thyroid function throughout pregnancy
 - Infants born with delayed skeletal maturation and low T_4 values are most likely to have neurocognitive problems.

- Mild sensorineural hearing impairment may be fairly common.
 - Should be screened to allow for early intervention
- Acquired juvenile hypothyroidism
 - Adolescents with chronic hypothyroidism and severe growth retardation may never achieve full growth potential.
 - In many cases, linear growth response to therapy is not accelerated.
 - Height percentile achieved as an adult is lower than that predicted by patient's growth before development of hypothyroidism.

PROGNOSIS

- Congenital hypothyroidism
 - Infants treated adequately since the first month of age have an excellent prognosis for normal intellectual function and linear growth.
- Acquired juvenile hypothyroidism
 - No permanent intellectual impairment is found among patients with juvenile hypothyroidism.
 - Early diagnosis will prevent:
 - Development of long-standing hypothyroidism
 - Cessation of linear growth
 - Risk of a decrease in final adult height

Hypotonia

DEFINITION

- Hypotonia indicates diminished resistance to passive movement.

EPIDEMIOLOGY

- Neonatal hypotonia is most commonly central in origin.
- Hypotonia in general is less likely to be associated with an underlying motor unit disorder.
- Infantile spinal muscular atrophy (Werdnig-Hoffmann disease) is the most common anterior horn cell disease in the US.

MECHANISM

- Hypotonia may result from pathology anywhere from the central nervous system (CNS) to the muscle.
- Consider:
 - Brain disorders or dysgenesis
 - Spinal cord injury
 - Anterior horn cell disorders
 - Peripheral nerve disorders
 - Neuromuscular junction disorders
 - Myopathies

HISTORY

- Determine onset of hypotonia.
 - Review birth and perinatal history, including:
 - Maternal history, birth records
 - Breech presentation is common in infants with a subsequently diagnosed motor unit disorder.
 - Perinatal drug administration
 - If premature, factors surrounding prematurity
 - Newborn screening results
 - If the child is the parents' first, they may be less likely to recognize an abnormality.
- Determine the character of hypotonia.
 - Is hypotonia improving or worsening?
 - Is weakness intermittent or constant?
 - What is the predominant distribution of weakness: proximal, distal, or global?
 - Photographs or videos can be used to document findings outside the office setting.
- Medical history
 - Previous infections
 - History of trauma
 - Results of imaging studies
 - Medication history
- Review of systems, including:
 - Feeding difficulties
 - Recent history of constipation

- Family history
 - Construct a pedigree, noting genetic conditions and individuals with weakness or stiffness.
- Developmental history
 - Include a chronology of developmental milestones.
 - Assess the child's current function and behavior.

PHYSICAL EXAM

- It may be difficult to quantify hypotonia.
 - No readily administered, accurate test exists.
 - Tone may vary greatly during the day, or even during the examination.
 - Difficult to determine true strength of infants and young children
- Examining other family members may help to make the diagnosis.
 - For example, myotonia in the mother of an infant with suspected myotonic dystrophy
- Observation
 - Infants and toddlers
 - Apparent mental status (does the infant appear obtunded?)
 - Sound of cry (eg, cri du chat)
 - Facial expressions (including assessing for ptosis)
 - Head control, ability to sit
 - Respirations (normal or paradoxical)
 - Mobility (rolling over, crawling, walking)
 - Ability to stand
 - Strength of kicking and pushing movements
 - Bulkiness of musculature
 - Functional testing
 - Children and adolescents
 - Posture
 - Gower sign
 - Mobility
- Perform a full neurologic examination, including:
 - Cranial nerve testing
 - Facial and extraocular muscles
 - If weak, the child may sleep with eyelids partly open.
 - Facial muscle weakness may be consistent with congenital myopathies and fascioscapulohumeral muscular dystrophy.
 - Tongue (looking for fasciculations or atrophy)
 - Assess with the tongue not protruded.
 - The child should not be crying.

- Strength assessment
 - Manual muscle group testing
 - Generally cannot be accomplished reliably in children <5 years
 - Note whether there is slowed muscle relaxation after contraction (myotonia).
 - Tone assessment
 - In infants, an inability to be held upright and suspended in air without slipping through may indicate poor proximal tone.
 - Decreased tone may be difficult to distinguish from diminished strength.
 - Reflexes
 - Deep-tendon reflexes
 - Present or hyperreflexic with central (upper motor neuron) lesions
 - Reduced or absent in peripheral (lower motor neuron) lesions/motor unit disorders
 - Extensor plantar responses
 - Gait
 - Hearing assessment
 - Examine the skin.
 - Level of jaundice in infants
 - Signs of trauma (including shaken baby syndrome)
 - Examine carefully for clinical findings consistent with genetic conditions.
 - Down syndrome
 - Prader-Willi syndrome
 - High-arched palate and dental malocclusion are observed in some congenital myopathies (eg, nemaline myopathy).
 - An enlarged heart and congestive heart failure may be observed with glycogen storage disease.
 - Skeletal features
 - Joint abnormalities are common.
 - Scoliosis is common.
- ### DIFFERENTIAL DIAGNOSIS
- Focus on diagnosis of the underlying condition.
 - The clinician should conduct a thorough search for systemic disorders
 - In many instances, a specific diagnosis cannot be made.
 - Central hypotonia (brain disorders or dysgenesis)
 - Hypoxic ischemic encephalopathy
 - Intracranial hemorrhage
 - Infection
 - Metabolic disorders
 - Hyperkalemic periodic paralysis (rare autosomal-dominant disorder with onset usually in infancy or early childhood)
 - Trauma (including shaken baby syndrome)
 - Hypoglycemia
 - Hypothyroidism
 - Hyperbilirubinemia
 - Chromosomal abnormalities (Down syndrome, Prader-Willi syndrome, cri du chat syndrome)
 - Spinal cord injury
 - May be a complication of breech deliveries
 - Anterior horn cell disorders
 - Infantile progressive spinal muscular atrophy
 - Locus 5q; autosomal recessive; mutation in telomeric copy of SMN gene
 - Striking paucity of spontaneous movement
 - Weakness and muscle wasting are proximal more than distal; more pronounced in legs than in arms
 - Paradoxical respiration (chest wall moves inward during inspiration instead of expanding)
 - Tongue fasciculations
 - Poliovirus infection
 - Glycogen storage disease type 2 (Pompe disease)
 - Glycogen deposits may form in anterior horn cells.
 - Peripheral nerve disorders
 - Rare in infancy and very early childhood
 - Most frequently caused by hereditary sensorimotor neuropathies
 - Hereditary sensorimotor neuropathies (Charcot-Marie-Tooth disease and variants)
 - Gait abnormalities; with Achilles deep tendon reflexes diminished or absent
 - Demyelinating neuropathy (eg, leukodystrophies)
 - Severe weakness, hypotonia, and areflexia
 - Neuromuscular junction disorders
 - Passively acquired autoimmune myasthenia gravis (transient neonatal myasthenia)
 - Few patients are symptomatic, and symptoms are usually mild.
 - Weakness is unlikely to develop if it is not present by 1 week of age.
 - Perinatal transmission of antibodies from seropositive mother
 - Acquired autoimmune myasthenia gravis (juvenile myasthenia)
 - Nonautoimmune myasthenic syndromes (congenital myasthenia gravis)

- Infantile botulism
 - Rapid onset, usually around age 3 months
 - Constipation; followed by weakness, hypotonia, poor feeding, and diminished activity
- Medications (eg, magnesium, aminoglycosides)
- Myopathies
 - Diverse group of genetic, inflammatory, and metabolic disorders; may exhibit multisystem (muscle, brain, heart) involvement
 - Congenital myopathies (frequently hereditary)
 - Early in life, children will have varying degrees of hypotonia, weakness, and respiratory/feeding difficulties
 - Myotonic dystrophy (locus 19q13; autosomal dominant; trinucleotide repeat disorder)
 - Myotonia will not be present either clinically or electrically until patients are older than 5 years.
 - If suspected in neonatal period, examine mother for characteristic features of the disease
 - Muscular dystrophies
 - Duchenne muscular dystrophy (common)
 - As this condition is progressive, patients do not have hypotonia in infancy
 - Merosin-deficient type
 - Associated with intellectual disability, seizures, white matter abnormalities
 - Fukuyama-type congenital muscular dystrophy (Japan)
 - Associated with severe CNS abnormalities
 - Facioscapulohumeral muscular dystrophy
 - Linked to high-frequency hearing loss
 - Glycogen storage disease
 - May be associated with weakness, marked cardiomegaly/congestive heart failure, hepatosplenomegaly
 - Mitochondrial disease
 - May exhibit CNS and muscle involvement; may have increased serum lactic acid levels
- Benign conditions
 - Benign congenital hypotonia
 - Diagnosis of exclusion
 - Hypotonia with early onset, usually without weakness or developmental delay
 - Frequently associated with joint hyperlaxity, which may lead to dislocations when adult
- Other conditions that may mimic hypotonia
 - Ehlers-Danlos syndrome
 - Hyperlaxity of joints simulates hypotonicity.
 - Inflammatory myopathies (dermatomyositis)
 - Rare in very young children
 - Produce weakness, not hypotonia

LABORATORY EVALUATION

- Laboratory studies may be selected on the basis of the likely cause of hypotonia.
- Central hypotonia
 - If considering infection, consider complete blood count and viral, urine, blood, and cerebrospinal fluid cultures.
 - Consider fractionated bilirubin in a severely jaundiced infant.
 - Consider serum glucose measurement.
 - Consider electrolyte measurement if hyperkalemic periodic paralysis is suspected.
 - Serum thyroid studies
 - Consider if diagnosis is not obvious on physical examination.
 - Neonatal screening generally includes a test for hypothyroidism.
 - Hyperthyroidism or hypothyroidism may be associated with acquired autoimmune myasthenia gravis.
 - Consider genetic studies (see below).
- Anterior horn cell disorders
 - Consider tests for glycogen storage disease type 2 (Pompe disease).
 - Consider stool culture for poliovirus.
 - Consider genetic studies (see below).
- Peripheral nerve disorders
 - Consider genetic studies (see below).
- Neuromuscular junction disorders
 - Acetylcholine receptor antibody test
 - Can be used to confirm diagnosis of acquired autoimmune myasthenia gravis, after edrophonium test
 - May not be positive in milder cases
 - Less useful in children than in older individuals
 - Negative in patients with nonautoimmune myasthenic syndromes (such as congenital myasthenia gravis)
 - Botulism studies
 - Stool analysis: *Clostridium botulinum* or botulinum toxin confirms the diagnosis.
 - Cell culture: Isolation of *C botulinum* confirms the diagnosis.
 - Consider magnesium levels and therapeutic drug monitoring (aminoglycosides).
- Myopathies
 - Serum creatine kinase levels
 - Markedly elevated in:
 - Duchenne muscular dystrophy
 - Becker muscular dystrophy
 - Congenital muscular dystrophies

- Not always increased in congenital myopathies
- Generally normal or only minimally increased in spinal muscular atrophy
- Serum lactic acid
 - May be elevated in mitochondrial disorders
- In setting of hepatomegaly (as can be seen in glycogen storage disease)
 - Consider liver enzymes (aspartate aminotransferase, alanine aminotransferase), liver function tests (prothrombin time, international normalized ratio, partial thromboplastin time, albumin, protein), and ammonia level.
- Genetic studies
 - May confirm genetic disorder suspected on clinical grounds, sparing patient from painful studies when conclusive
 - Consider karyotype and specific studies for:
 - Infantile progressive spinal muscular atrophy
 - Myotonic dystrophy
 - Some hereditary sensorimotor neuropathies (demyelinating and X-linked)
 - Some mitochondrial myopathies
 - Duchenne muscular dystrophy
 - Becker muscular dystrophy
 - Hypomyelinating neuropathy
 - Facioscapulohumeral muscular dystrophy
 - Myasthenic syndromes
 - Cri du chat syndrome
 - Prader-Willi syndrome

IMAGING

- Imaging may be used to examine the CNS or musculature.
- Imaging modalities include:
 - Magnetic resonance imaging or computed tomography
 - Brain scan may reveal a lesion.
 - May be used to assess muscle mass
 - Indicated if muscle biopsy is contemplated in a patient with very small muscles
 - Ultrasonography
 - May be used to assess muscle mass
 - Indicated if muscle biopsy is contemplated in a patient with very small muscles
 - Chest radiograph
 - May be used to assess thymic size in acquired autoimmune myasthenia gravis
- May consider additional focused studies depending on clinical picture (eg, echocardiography in case of cardiomyopathy)

DIAGNOSTIC PROCEDURES

- Procedures may be selected on the basis of the likely cause of hypotonia.
- Sometimes the diagnostic yield of procedures may be higher for other family members.
- Electromyographic studies may be abnormal for neuropathies or myopathies, with differing characteristic findings.
- Peripheral nerve disorders
 - Nerve conduction studies
 - May help to distinguish between axonal and demyelinating neuropathies
 - Nerve conduction is extremely abnormal in hypomyelinating neuropathy.
 - Nerve biopsy is diagnostic for hypomyelinating neuropathy.
- Neuromuscular junction disorders
 - Edrophonium test
 - Diagnostic for myasthenia gravis
 - Specialized test that must be performed by a clinician who can interpret the results
 - Repetitive stimulation studies
 - Helpful in diagnosing disorders of the myoneural junction (eg, infantile botulism)
 - Can be quite painful
- Myopathies
 - Muscle biopsy

TREATMENT APPROACH

- Treatment varies according to the underlying condition.

SPECIFIC TREATMENT

- For most causes of hypotonia, treatment is supportive.
- A multidisciplinary team may coordinate interventions.
- For infantile progressive spinal muscular atrophy, consider:
 - Physical therapy
 - Respiratory therapy
 - Nutritional support as needed
 - Genetic counseling
 - Scoliosis treatments (eg, body jacket, molded back support, surgery)
 - Motorized wheelchair for children with type II at approximately 2–3 years of age
- For children with peripheral nerve disorders, consider:
 - Bracing for children with foot drop
- For children with neuromuscular junction disorders
 - Hospitalization, with respiratory and nutritional support as needed

- Passively acquired autoimmune myasthenia gravis (transient neonatal myasthenia)
 - Give pyridostigmine until asymptomatic, then taper over 1–2 weeks
- Acquired autoimmune myasthenia gravis (juvenile myasthenia)
 - Consider anticholinesterase drugs, immunosuppressive treatment, intravenous γ -globulin, corticosteroids, or thymectomy.
- Nonautoimmune myasthenic syndromes (congenital myasthenia gravis)
 - Consider anticholinesterase inhibitors, corticosteroids, or diaminopyridine (experimental).
- Infantile botulism
 - Antibotulism immune globulin may be therapeutic.
- For children with myopathies
 - Infantile form of myotonic dystrophy–type hypotonia
 - Assisted ventilation as indicated
 - Consider gastrostomy tube feedings.
 - Glycogen storage disease
 - Consider enzyme replacement therapy.
 - Without therapy, prognosis is dismal.

WHEN TO REFER

- New onset of neurologic signs
- Persistent lack of normal motor development
- Regression of motor development
- Sudden or precipitous worsening of tone or strength
- Swallowing dysfunction

WHEN TO ADMIT

- Inability to maintain adequate oxygenation
- Mental status changes
- Not clinically stable

PROGNOSIS

- Benign congenital hypotonia
 - By 5 years, many affected children are indistinguishable from other children their age.
- Infantile progressive spinal muscular atrophy
 - Type I: Progressive, with death at age <2 years
 - Type II: Life expectancy into the 20s or later
 - Type III: Normal life expectancy
 - Tremulousness of outstretched fingers (minipolymyoclonus) is associated with a protracted course.
- Myopathies
 - Infantile form of myotonic dystrophy–type hypotonia
 - A neonate who survives will gain strength and tone and will eventually walk.
 - Myotonic dystrophy
 - Severity correlates with the number of trinucleotide repeats.
 - Glycogen storage disease
 - Prognosis is dismal without enzyme replacement therapy.

PREVENTION

- Genetic counseling
- Prenatal diagnosis

Identification and Early Intervention for Development Delays

BACKGROUND

- Every effort should be made to connect a child found to be developmentally delayed to the early intervention system quickly.
- Amendments to the Education of the Handicapped Act (PL 99-457 Part H), enacted by Congress in 1986 and subsequently incorporated into the Individuals with Disabilities Education Act (IDEA) of 1989
 - Requires participating states to develop a system of early intervention services for young children (birth to 3 years) and their families
 - Key components of the legislation
 - Definition of developmental delay
 - Comprehensive system of identifying and referring children (“Child Find”)
 - Procedural safeguards to ensure protection of confidentiality and rights of families to due process
 - Requirement of comprehensive, multidisciplinary evaluation to determine the needs of children and families
 - A lead agency in each state is designated to administer, supervise, and monitor early intervention programs and activities.
 - Most states have assigned these roles to the department of education or the department of health.
- Although children may outgrow various problems, a physician should always investigate the parents’ concerns thoroughly before reassuring them.
 - Without careful screening and monitoring, only children who have more severe delays are likely to be identified.
 - Evidence suggests that early intervention may make a critical difference in:
 - Development
 - Behavior
 - School success
 - The primary care physician (PCP) is ideally situated to provide ongoing support to families who must navigate the early intervention system.

GOALS

- After evaluation, family members and professionals work together for a child with delays to:
 - Develop an individualized family service plan that describes
 - Services
 - Supports
 - Coordination of services to be provided for the child and family

GENERAL APPROACH

- Screen and refer.
- Monitor progress and guide parents.
- Help overcome barriers to care.

SPECIFIC INTERVENTIONS

Providing early intervention

- Identify and serve children who have developmental delays.
 - May be interpreted narrowly or broadly, depending on the physician’s training, interest, level of comfort
 - Screen:
 - For developmental delays by routinely asking the parents during health maintenance visits about their concerns
 - Using appropriate, validated screening instruments
 - Developmental surveillance questions and developmental milestones outlined in the Bright Futures guidelines are effective tools.
 - Routine vision screening and auditory screening are components of health maintenance.
 - Refer:
 - Children whose development is questionable or delayed for evaluation and services
 - Interpret medical information for early intervention providers.
 - Monitor the outcomes of intervention.
- Provide a family orientation.
 - Help parents understand the child’s strengths and weaknesses.
 - Support the child’s future independent functioning.
 - Any factor affecting a child’s functioning affects parents and family, regardless of the cause.
 - Parents need and value the support of their PCP in dealing with the possibility or reality of developmental delay in their child.

Monitoring early intervention

- Areas the PCP should monitor in children with developmental delay
 - Developmental diagnosis
 - Current parental concerns
 - Current intervention
 - Progress reported by parent, with or without a preschool or school report
 - Observed functioning
 - Changes in the child’s functioning may require a change in type of intervention.
 - Newly identified needs of child or family
 - Plan for evaluation, coordination, and service provision
 - Ongoing follow-up
 - Ongoing contact with the child enables the PCP to determine that some delays have resolved and to identify others that have emerged.
 - Sharing this information with parents helps them obtain and understand modifications in the child’s intervention program.

■ Parental expectations

- Parents often expect that the intervention will correct the developmental delay, although this is not universally true.
- After dealing with the stress of identifying the delay, parents often need the period of optimism that starting intervention provides.
 - However, some developmental problems will persist and will require different kinds of intervention at different ages.
 - The PCP must be aware of and help parents understand this issue.

■ Autism spectrum disorder

- Increased publicity about early diagnosis has resulted in parents turning to their PCPs for advice.
- Many biomedical and psychosocial interventions are promoted by various advocacy or professional groups.
 - Only a few have been scientifically studied.
 - For parents seeking guidance, the AAP Committee on Children With Disabilities statement on complementary and alternative medicine is a useful resource.

Barriers to care

■ Reluctance to identify developmental delays

- Parents must be confronted with the possibility.
- Some parents wait for the PCP to voice the concerns they have begun to feel.
 - They interpret the physician's silence as an indication that no problem exists.
- The PCP creates a comfortable atmosphere for discussing concerns by:
 - Routinely questioning parents about development and behavior at all contacts
 - Observing the child's development along with the parent

■ Questions about the efficacy of early intervention

- A PCP who is convinced that early intervention will help a child and family is more likely to identify children who need this service.
- The efficacy of early intervention in improving children's developmental outcomes is documented in well-designed studies.
 - Higher IQ
 - Intervention-related advantages in cognitive and receptive language
 - Stronger school achievement
 - Fewer failing grades at age 12 years
 - Less grade retention and special education placement at age 15 years
- The best developmental outcomes have been associated with early intervention programs that are:
 - Comprehensive

- Involve both the family and the child
- Focus on strengthening the parent-child relationship
- The 2 groups that appear to benefit most:
 - Children who have biological risk factors and are growing up in adverse circumstances
 - All children who have mild degrees of developmental delay

■ Concerns about overidentifying delays, upsetting the family, and subjecting the child to unnecessary evaluations

- Sensitive exploration of possible delays harms neither the parents nor the child.
 - Avoiding the issue may be detrimental.
- Evaluation is a way of:
 - Gaining a better understanding of the child
 - Educating the parent
 - Supporting the parent in observing and interpreting the child's behavior
 - Helping the parent explore new ways of interacting with the child
- Diagnosis of developmental delay is often required to enter the developmental services system.

■ Time pressures

- No other professional whose opinions carry the same authority is involved in the lives of children as their PCP.
- Several strategies may enable a busy PCP to address developmental issues.
 - Use of short questionnaires for parents who are literate, such as the Child Development Review.
 - Train an office nurse or another staff member to perform developmental screening.
 - Schedule a separate appointment for developmental screening by the PCP when developmental concerns are identified on regular visits.
- Some early intervention systems and most payors will reimburse participating PCPs for performing developmental screenings.

■ Lack of familiarity with resources

- PCPs must learn how to connect patients and families to the early intervention system so that children may obtain services to which they are entitled.
- Literature for patients can be obtained from state or county health departments that describe early intervention programs.
 - Such literature should be available in the PCP's office.
- Most medical school-affiliated pediatric departments have specialists in developmental disabilities.
 - These specialists are a useful resource for evaluation and referral to publicly funded services.

Immune Thrombocytopenia Purpura

DEFINITION

- Immune thrombocytopenia purpura (ITP) of childhood is an acquired immune-mediated, and usually self-limiting, condition of low platelet counts.

EPIDEMIOLOGY

- Incidence
 - Estimated to be between 4 and 8 cases per 100,000 children annually
 - The rate is probably higher because of subclinical cases.
- Age
 - Most common in children 2–10 years of age
 - Peak incidence at 2–4 years of age
- Sex
 - In children, both sexes are equally affected.
 - Female predominance over male (2.3:1) is seen during adolescence and adulthood.

ETIOLOGY

- ITP is caused by antibodies (mostly IgG) directed against antigens normally present on platelet membranes.
- The antibody-coated platelets are then recognized and destroyed by reticuloendothelial cells found mostly in the spleen.

RISK FACTORS

- History of a preceding infection, subsequently resolved
 - Elicited in the majority of patients
 - >70% of cases occur after viral infections.
- In some cases, ITP is seen after measles-mumps-rubella immunization.
 - The best estimate of absolute risk is 1 in 24,000 doses.
 - Usually occurs within 6 weeks of vaccination
 - This risk is considerably less than that of ITP that occurs after natural infections with measles, mumps, or rubella.

SIGNS AND SYMPTOMS

- Typically, there is sudden onset of petechiae, purpura, and ecchymoses in the absence of other signs of illness.
- Mucosal (nose, mouth, and gingival surfaces) bleeding may be present.
- Usually, there are no significant abnormalities on history and physical examination.
 - No other systemic symptoms, such as fever, weight loss, bone pain, or joint pain
 - No significant enlargement of lymph nodes, liver, or spleen
 - If any of these symptoms or physical findings is present, the case is not typical of ITP.
 - Other diagnoses should be considered.

DIFFERENTIAL DIAGNOSIS

- Such infections as Epstein-Barr virus, hepatitis C, and HIV can be ruled out by:
 - History
 - Physical examination
 - Liver enzymes/function tests and viral studies if needed
- Such drugs such as heparin and sulfonamides can be ruled out by history.
- Other autoimmune diseases, such as systemic lupus erythematosus:
 - May be difficult to diagnose
 - Are more likely to affect teenagers and adults than younger children
- Acute leukemia or bone marrow failure
 - Children with leukemia usually have other symptoms and abnormal physical findings not seen in ITP.
 - Hepatosplenomegaly
 - Lymphadenopathy
 - Leukocytosis (leukocyte count >10,000 cells/ μ L)
 - Significant anemia (hemoglobin level <10 g/dL)
- Acquired aplastic anemia
 - Low platelet count is usually associated with other significant changes in peripheral blood, such as:
 - Macrocytic anemia
 - Leukopenia
 - Neutropenia
- Inherited thrombocytopenia
 - Although thrombocytopenia in most children is either autoimmune or drug related, keeping this category in mind is important.
 - Eliciting a family history of thrombocytopenia, especially parent-child or maternal uncle-nephew, may be important.
 - Diagnostic features on peripheral smear that may point to inherited thrombocytopenia
 - Abnormal size of platelets (either small or giant)
 - Absence of platelet α -granules (gray platelets)
 - Döhle-like bodies
 - Microcytosis
 - Clinical features that suggest inherited thrombocytopenia
 - Bleeding out of proportion to the platelet count
 - Onset of thrombocytopenia early in life
 - Associated features, such as:
 - Absent radii
 - Intellectual disability
 - Renal failure
 - High-frequency hearing loss
 - Cataracts
 - History of a stable level of thrombocytopenia for years

DIAGNOSTIC APPROACH

- ITP is a diagnosis of exclusion after considering the likelihood of other causes of isolated thrombocytopenia.
- For patient with mucocutaneous signs of bleeding who is otherwise healthy, a reasonable workup includes:
 - Complete blood count
 - Peripheral blood smear
 - Reticulocyte count
 - Blood typing

LABORATORY FINDINGS

- Complete blood count
 - Thrombocytopenia is usually the only laboratory abnormality.
 - Platelet count is usually $<20,000$ cells/ μL .
- Peripheral blood smear
 - Will reveal morphologically normal leukocytes and erythrocytes
 - Large, freshly produced platelets are usually seen.
 - These young reticulated platelets contain messenger RNA and are metabolically active.
 - May explain why patients with ITP do not bleed as severely as patients with bone marrow failure, who have similarly low platelet counts
 - If other abnormalities are seen, obtaining additional tests may be indicated, such as:
 - Viral antibodies (HIV, cytomegalovirus, Epstein-Barr virus, varicella, rubeola, mumps, or parvovirus, depending on the clinical picture)
 - Tests for rheumatologic and other hematologic conditions (eg, leukemia, bone marrow failure)
- Reticulocyte count
 - Helpful when diagnosis of ITP is not straightforward (ie, in cases in which associated mild anemia exists, which is not rare)
- Blood typing
 - For determination of Rh status, which determines whether a patient is treatable with anti-D antibodies.
- Both reticulocyte count and blood typing are not strictly needed for evaluation.
 - However, drawing blood to keep aside for reticulocyte count and blood typing is preferable to performing multiple traumatic blood draws on a thrombocytopenic child.
- Platelet antibodies tests
 - Although ITP is caused by platelet antibodies, these tests are sensitive but not specific.
 - Not indicated for the diagnosis of acute ITP in children
- Assessment of bleeding time
 - Bleeding time is prolonged in ITP, but this test is unnecessary, traumatic, and inaccurate in children.

- Tests for prothrombin time and activated partial thromboplastin time are unnecessary.
 - Results are typically normal in these patients.

DIAGNOSTIC PROCEDURES

- Bone marrow biopsy
 - Performed in the past by many pediatric hematologists to rule out acute lymphocytic leukemia for fear of partially treating and thus masking a leukemic process.
 - Now, typically performed when patients have clinical or laboratory features atypical of ITP at presentation that suggest an alternate diagnosis, such as acute leukemia or a bone marrow failure syndrome
 - Also indicated for patients in whom ITP is initially diagnosed but who do not respond to treatment
 - Timing of bone marrow evaluation is an individualized decision.
 - Most likely time is between 7–14 days after treatment is begun, but response is poor
 - May be considered:
 - In patients who have an atypical clinical course
 - In patients in whom splenectomy is contemplated for additional confirmation of diagnosis
 - To rule out a malignant process
 - Bone marrow in ITP
 - Is cellular, with normal erythroid and myeloid precursors
 - Usually shows increased numbers of megakaryocytes

TREATMENT APPROACH

- Most cases in children can be managed on an outpatient basis.
- Consensus is that treatment is indicated for the patient with overt bleeding.
 - Treatment and management recommendations for patients who have different clinical manifestations remain a subject of debate.
 - Current therapy recommendations are not evidence based, but rather are based on expert consensus opinions.
- American Society of Hematology guidelines
 - Children with ITP and platelet counts $>30,000$ cells/ μL
 - These patients require no treatment if they have few or no symptoms, as is usually the case.
 - Patients with platelet counts between 10,000 and 30,000 cells/ μL
 - Treatment recommendations are based on the presence and severity of associated bleeding symptoms or the risk of bleeding
 - Severity of symptoms depends on the degree of thrombocytopenia.
 - The lower the platelet count, the more likely the patient is to receive treatment, even in the presence of relatively mild symptoms.

- Children who should be treated
 - Those with platelet counts $<10,000$ cells/ μL and only minor purpura
 - Those with any concomitant or preexisting bleeding disorder
 - Those with extensive purpura of the mucosal membranes may have a higher bleeding risk and should be treated more often than not.
- Other important factors in treatment decision include:
 - Child's age
 - Child's degree of activity
 - Social variables, such as reliability of caregivers and ease of access to emergency medical care, always play a role in the decision to treat or not to treat.
- When therapy is indicated, the primary treatment options for the newly diagnosed patient are:
 - Corticosteroids
 - Intravenous immunoglobulin (IVIG)
 - Intravenous anti-D Ig
- Platelet transfusions
 - Ineffective because the transfused platelets are rapidly destroyed
- General useful advice to families with an affected child includes
 - Avoid activities that are associated with increased likelihood of trauma, such as contact sports.
 - Make sure the child uses a helmet when riding a bicycle.
 - Avoid medications that interfere with platelet function, such as aspirin and nonsteroidal antiinflammatory drugs.

SPECIFIC TREATMENTS

Corticosteroids

- Used for many years in all age groups
- Reduce the risk of symptoms by different mechanisms, most likely by reducing reticuloendothelial system phagocytosis of antibody-coated platelets
- Most pediatric hematologists use prednisone for 2–3 weeks.
 - Shorter courses at higher doses are also effective.
 - Intravenous or oral methylprednisolone up to 3–7 days and dexamethasone for 4 days every 4 weeks have been given.
- Most patients respond to steroids.
 - Response is faster with higher doses (seen after 72 hours of starting treatment).
 - Platelets usually decrease after steroids are discontinued if the titer of platelet antibodies remains elevated.
- A second course of treatment may be necessary:
 - If bleeding develops
 - If the platelet count decreases to $<10,000$ cells/ μL

- Side effects of brief courses of corticosteroids include:

- Behavioral changes
- Sleep disturbance
- Increased appetite
- Hyperglycemia
- Weight gain
- Side effects are more pronounced at higher doses.

IVIG

- Compared with patients receiving steroids
 - Rapid improvement in platelet count is seen, usually within 24 hours.
- Probably interferes with Fc receptor activity, resulting in prolonged survival of antibody-coated platelets
 - Other mechanisms of action include:
 - Regulatory properties of anti-idiotypic antibodies in IVIG
 - IVIG effects on cytokine synthesis and on receptors for cytokines and complement
 - 1 intriguing proposal for mechanism of action
 - Concentration-dependent elimination of IgG can be found from the plasma, and IVIG administration causes acceleration of the rate of IgG catabolism.
 - Such a process would eliminate individual IgG molecules in direct proportion to their relative concentration in plasma.
 - Thus elimination of antiplatelet antibodies is accelerated.
- Far more expensive than steroid therapy
- Side effects
 - Chills
 - Fever
 - Headache
 - Nausea and vomiting
 - Tend to be more pronounced in older patients
 - Neutropenia (absolute neutrophil count <1500 cells/ μL) develops in approximately 30% of patients.

Anti-Rho (D) Ig

- Binds to the D-antigen in Rh-positive individuals; the antibody-coated red cells block the Fc receptor of reticuloendothelial cells
 - Results in rapid increase in platelet count, usually in 1–2 days
- A single dose of 50 $\mu\text{g}/\text{kg}$ is most commonly used.
 - Many physicians start with a 75- $\mu\text{g}/\text{kg}$ dose.
 - Achieves a more rapid increase in platelet count that is similar to that seen with IVIG therapy

- An average decrease in the hemoglobin level of approximately 1.3 g is seen as a result of the mild hemolysis of the patient's Rho (D)-positive red cells.
 - Should be used with caution in children with preexisting anemia
 - Should probably be given only to children with a hemoglobin level >10 g/dL

WHEN TO ADMIT

- Significant bleeding
- Severe anemia
- Significant concern for possible traumatic injury
- Any neurologic change in the setting of thrombocytopenia

WHEN TO REFER

- History of fever or bone pain
- Hepatomegaly, splenomegaly, significant lymphadenopathy
- Family history of thrombocytopenia
- Platelet count <20,000/ μ L
- Abnormal leukocyte count on peripheral smear or associated anemia
- Lack of response to initial therapy

FOLLOW-UP

- Patients should have blood counts done once or twice weekly.
- Blood counts should be done less frequently when the platelet count is:
 - Stable
 - >30,000 cells/ μ L
 - Increasing with time

COMPLICATIONS

Intracranial hemorrhage

- Approximately 15–20% of pediatric patients will develop moderate or major hemorrhagic problems.
- Intracranial hemorrhage (ICH) is rare; it occurs in 0.1–1% of acute ITP.
- The most serious complication and most likely cause of death in ITP
- Recognizing which patients are more likely to develop ICH is difficult.
 - A literature review of 62 reported pediatric and adolescent cases of ICH in the setting of ITP showed:
 - Median time from the diagnosis of ITP to ICH was 32 days (range, 0 days to 8 years).
 - 72% of cases occurred within 6 months of diagnosis.
 - Platelet count was <10,000 cells/ μ L in 71.4% of the cases.
 - Treatment before the ICH was primarily steroids but also included IVIG, splenectomy, and others.

- A significant number of patients developed ICH despite having already initiated steroid treatment.
- Many patients have other risk factors, including:
 - Preceding head injury
 - Other preceding mucocutaneous bleeding
 - Prior aspirin treatment
 - Arteriovenous malformations

- Management is an emergency that requires:

- Immediate imaging (computed tomography) to determine the location and extent of the bleeding
- Immediate consultation with:
 - Pediatric intensivist
 - Hematologist
 - Neurosurgeon
 - General surgeon

- Treatment includes:

- Administration of IVIG, steroids, continuous platelet transfusions to rapidly increase the platelet count
- Surgical intervention, if needed, including:
 - Craniotomy (especially with posterior fossa hemorrhages that are more likely to cause herniation or brainstem compression)
 - Splenectomy

Immune thrombocytopenia in the neonate

- Most neonatal thrombocytopenia is not immune in nature but is caused by:
 - Sepsis
 - Congenital infections
 - Drugs
 - Asphyxia
 - Necrotizing enterocolitis
- 2 conditions occur when immune thrombocytopenia is seen in neonates.
 - Neonatal alloimmune thrombocytopenia (NAIT)
 - A condition in which the mother develops antiplatelet antibodies directed against specific antigens found on fetal platelets but lacking on hers
 - Associated 20% risk of ICH
 - Treatment usually involves administration of maternal washed platelets and IVIG.
 - Importance of detection and accurate diagnosis of NAIT is in the ability to prevent complications in future pregnancies by:
 - Treating the mother with IVIG and steroids
 - Performing in utero blood sampling and intervening in case of thrombocytopenia
 - Hematologist and high-risk fetal-maternal specialist should be involved in management.

- Another less serious condition is that resulting from passive transfer of maternal platelet autoantibodies in a mother with ITP.
 - Only 4% of babies born to mothers with ITP have platelet counts $<20,000$ cells/ μL .
 - The risk of ICH is low ($<1\%$), and no proof exists that cesarean delivery alters that risk.
- Usually resolves within a few weeks as the antibodies are used up
 - Physicians may choose to treat the babies with IVIG in case the platelet count decreases to $<30,000$ cells/ μL .
 - Maternal ITP is not a contraindication to breastfeeding.

Chronic ITP

- Defined as persistence of thrombocytopenia lasting for >6 months from the time of diagnosis
 - $\sim 10\%$ of patients with typical ITP develop chronic thrombocytopenia.
 - In a prospective Dutch study, variables that predicted the development of chronic disease included:
 - Platelet count $>10,000$ cells/ μL at the onset
 - Absence of infection shortly before the onset of the disease
 - The 232I/T Fc gamma receptor IIB genotype
- Given sufficient time (even years), a significant proportion of such patients will improve or remit.
 - Management should focus on:
 - Minimizing the individual's risk for bleeding
 - Maintaining a safe platelet count, knowing that many patients will require no treatment
- If treatment is needed
 - Periodic short courses of steroids may be given.
 - In case of long-term need for steroids
 - Alternate-day dosing may be effective in preventing bleeding while reducing side effects.
 - IVIG or anti-Rho (D) Ig has also been used, but these measures are only temporary.
 - Splenectomy
 - Effective in improving the platelet count and reducing the associated risk of bleeding in 60–90% of children
 - However, anticipated improvement in hemostasis and platelet count must be balanced with consideration of the small but real risk of overwhelming postsplenectomy sepsis, which may be life threatening.
 - Usually delayed until the child is >5 years because the risk of overwhelming sepsis decreases with age.
 - No universally accepted standards for timing of splenectomy exist.
 - American Society of Hematology guidelines recommend waiting until ≥ 12 months after diagnosis, if possible.

- Platelet counts in splenectomized patients
 - Generally monitored for an indefinite period
 - Any drop in platelet counts or increase in symptoms should prompt assessment for the presence of an accessory spleen.
- If not previously done, recommendations are to perform a bone marrow biopsy on patients who are being considered for splenectomy.
- Presplenectomy immunizations and subsequent penicillin prophylaxis are necessary.
- Rituximab for refractory chronic ITP
 - A chimeric murine-human anti-CD20 monoclonal antibody
 - Acts by destroying B-lymphocytes by activating complement-dependent and an antibody-dependent cellular toxicity
 - Therefore, mechanism of action is a slow but effective decrease in production of antibodies.
 - In a study of 24 patients 2–19 years of age who received 375 mg/ m^2 of rituximab in 4 weekly doses
 - 63% achieved complete remission for 4–30 months (platelet count of $>150,000$ cells/ μL):
 - Although long-term remissions have been documented, use of rituximab in ITP is relatively recent.
 - Long-term follow-up may be needed for accurate prognostication.
 - Use may be associated with:
 - Infusion-related reactions
 - Development of transient hypogammaglobulinemia

PROGNOSIS

- Treatment does not alter the course (ie, the incidence of patients who go on to develop chronic ITP).
 - However, it does shorten the duration of thrombocytopenia in some patients.
- For typical cases of childhood ITP
 - 80% of patients will have platelet counts return to normal within 2 months of presentation, with or without therapy.
 - Another 10% will recover normal platelet levels in the next few months.
 - $\sim 10\%$ will go on to have chronic thrombocytopenia (>6 months' duration).
- Approximately 25% of children will have a relapse after initial treatment.
 - 10% have chronic ITP.
 - 10% have recurrence but resolution within 6 months.
 - 5% have episodes of ITP recurrences and remissions throughout their lives.

Immunization

BACKGROUND

- Vaccination was one of the most important achievements in public health in the 20th century.
- Current US disease levels are 92–100% lower than prevaccination-era disease levels.
- However, many children in the US, as well as other countries, still die from vaccine-preventable diseases.

GOALS

- Routine childhood vaccination is one of the few health care interventions that saves both lives and dollars.
- Routine vaccination saves from \$29 (for measles-mumps-rubella [MMR] vaccination) to \$2 (for hepatitis B vaccination) for every dollar spent.
- The primary reason for the record low disease incidence is record high immunization coverage levels.
- The process of vaccinating children is becoming increasingly complicated as the number of vaccines and vaccine combination choices increases.
- The current US recommended childhood and adolescent immunization schedule is updated annually or biannually.

GENERAL APPROACH

Live vaccines

- Live vaccines include:
 - MMR
 - Varicella
 - Rotavirus
 - Live attenuated influenza intranasal vaccine (LAIV)
 - Yellow fever
 - Vaccinia
 - Oral poliovirus vaccine (OPV)
 - Bacille Calmette-Guérin (BCG)
 - Oral typhoid vaccine
- Live vaccines replicate in the body.
- Live injected vaccines usually induce immunity through a single dose.
 - Unlike inactivated vaccines, live vaccines are susceptible to vaccine failure caused by circulating antibodies, including residual maternal antibodies in infants.

Inactivated vaccines

- Inactivated vaccines include:
 - Inactivated polio vaccine (IPV)
 - Hepatitis A
 - Rabies
 - Acellular pertussis
 - Hepatitis B
 - Human papillomavirus (HPV)
 - Split virus influenza

- Typhoid Vi
- Toxoid agents
 - Diphtheria
 - Tetanus
- Polysaccharides, unconjugated
 - Pneumococcal
 - Meningococcal
- Polysaccharides, conjugated
 - *Haemophilus influenzae* type B (Hib)
 - Pneumococcal
 - Meningococcal

Inactivated vaccines

- Do not contain infectious particles that can replicate in the body
- Generally require several doses to immunize patients completely

Timing of administration

Routine schedule

- The routine vaccination schedule is harmonized among:
 - The American Academy of Pediatrics (AAP)
 - The American Academy of Family Physicians (AAFP)
 - The Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices (ACIP)
- The harmonized schedule allows for office preferences by indicating acceptable ranges for routine on-time vaccination scheduling.
- The ranges were created so that offices might accommodate routine vaccination into their well-child care schedule.
- To ensure timely vaccinations, vaccinating early within the acceptable age range is important.
- Intervals between different vaccines not administered simultaneously
 - Using all routine vaccines simultaneously is safe and effective, provided that vaccines are not combined within a single syringe.
 - No contraindications exist to giving any 2 different routine childhood vaccines at the same visit.
 - Vaccines that are not administered simultaneously may be given without regard to intervals, with 1 or 2 exceptions:
 - Live vaccines not given orally (ie, MMR, varicella, LAIV) that are not administered simultaneously should be separated by at least 4 weeks.
 - The 4-week separation rule is intended to reduce theoretical risk of interference from the first vaccine on the subsequent vaccine.
 - If, for example, varicella vaccine is given only 1 week after an MMR, then the varicella vaccine should be repeated or serologic testing should be used to confirm seroconversion.

- AAP guidelines specify that if the adolescent formulation (tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis [Tdap], adsorbed) is not given at the same visit as meningococcal conjugate vaccine, then the 2 should be separated by at least 4 weeks.
 - ACIP guidelines do not make this stipulation.
- Combination vaccines:
 - Reduce the number of injections
 - Are preferred by ACIP, AAFP, and AAP when available
 - Are preferred by providers, parents and, no doubt, children
 - As a consequence of the increasing number of diseases that can be prevented through vaccination, the number of required injections increased dramatically.
 - The number of combination vaccines available also increased.
- All vaccines for which the child is eligible should be offered whenever possible.
 - Keeps the child on schedule
 - Eliminates an additional, unnecessary office visit

Minimal age and intervals between different doses of a multidose vaccine

- Vaccine doses that are given too early in life or too soon after a previous dose may be less effective.
 - The table Recommended and Minimum Ages and Intervals Between Vaccine Doses shows the earliest acceptable ages of administration of the routinely recommended childhood vaccines and minimal spacing between their doses.
- Does a vaccine dose given at an interval shorter than the minimal interval count?
 - State requirements for school entry vary, but ACIP considers a vaccination valid if the vaccine dose was given within 4 days of the minimal interval.
- Vaccine doses are considered invalid if an incorrect amount was used.
 - Steps should be taken to prevent these errors from occurring.
 - The clinician should remember that vaccination is a safe procedure, even if the child is given more than the recommended number of doses.
- Overvaccination
 - With live vaccines, overvaccination is without consequence, because the extra vaccine virus will not infect an already immune person.
 - With inactivated vaccines, an increase in local reactions may occur if antibody levels are high.
- Prolonged intervals between doses of a multidose vaccination series do not diminish vaccine effectiveness once the series has been completed.
- Series never need to be restarted because of prolonged intervals (with the exception of oral typhoid vaccine).
 - Late-start or interrupted schedule
 - Some children start routine vaccination late.
 - The recommended schedule for such children is derived from the minimal intervals for the routine vaccinations.
 - A catch-up schedule is published annually with the routine schedule.
 - For a new patient whose vaccination status is unknown:
 - If available, obtain a copy of the record or a report from the previous provider.
 - If records are unavailable, the child should be presumed to be unvaccinated, and the vaccination series should be given using the accelerated schedule.
 - Serologic testing can be considered for some antigens (eg, MMR, hepatitis B).

Intervals between live injected vaccines and antibody-containing blood products

- Live injected vaccines (eg, MMR and varicella vaccines)
 - Must replicate in the body to induce immunity
 - May be compromised by circulating antibodies against the vaccine virus
- Live vaccines not administered by injection are thought to be unaffected by circulating antibodies.
 - LAIV
 - Oral typhoid
 - OPV
- Inactivated vaccines
 - Are not affected significantly by circulating antibodies
 - Relative timing of the administration of immune globulin-containing products need not be considered.
- MMR and varicella vaccine doses given >14 days before administration of immune globulin-containing products have time to replicate and are effective.
- When live injected vaccines are given after antibody-containing blood products, the situation is more complex.
 - The specific immune globulin-containing product and its dose dictate the waiting period necessary before a live injected vaccine is given.
 - MMR and varicella vaccination should be delayed from 3–11 months, depending on the specific immune globulin preparation administered.
 - Waiting period details can be found in the AAP *Red Book* and on the CDC Web site.

Vaccinations administered outside the US

- Determining the immunization status of children who have been partially or completely vaccinated in another country can be difficult.
 - Immunization status must be determined for all children.
 - Attention must be paid to the rest of the family in the case of recent immigration.

Recommended and Minimum Ages and Intervals Between Vaccine Doses^a

Vaccine and Dose Number	Recommended Age for This Dose	Minimum Age for This Dose	Recommended Interval to the Next Dose	Minimum Interval to the Next Dose
Hepatitis B (Hep B)-1 ^b	Birth	Birth	1–4 months	4 weeks
Hep B-2	1–2 months	4 weeks	2–17 months	8 weeks
Hep B-3 ^c	6–18 months	24 weeks	—	—
Diphtheria-tetanus-acellular pertussis (DTaP)-1 ^b	2 months	6 weeks	2 months	4 weeks
DTaP-2	4 months	10 weeks	2 months	4 weeks
DTaP-3	6 months	14 weeks	6–12 months ^d	6 months ^{d,e}
DTaP-4	15–18 months	12 months	3 years	6 months ^d
DTaP-5	4–6 years	4 years	—	—
<i>Haemophilus influenzae</i> type b (Hib)-1 ^{b,f}	2 months	6 weeks	2 months	4 weeks
Hib-2	4 months	10 weeks	2 months	4 weeks
Hib-3 ^g	6 months	14 weeks	6–9 months ^d	8 weeks
Hib-4	12–15 months	12 months	—	—
Inactivated poliovirus (IPV)-1 ^b	2 months	6 weeks	2 months	4 weeks
IPV-2	4 months	10 weeks	2–14 months	4 weeks
IPV-3	6–18 months	14 weeks	3–5 years	6 months
IPV-4	4–6 years	4 years	—	—
Pneumococcal conjugate (PCV)-1 ^f	2 months	6 weeks	2 months	4 weeks
PCV-2	4 months	10 weeks	2 months	4 weeks
PCV-3	6 months	14 weeks	6 months	8 weeks
PCV-4	12–15 months	12 months	—	—
Measles-mumps-rubella (MMR)-1 ^h	12–15 months ⁱ	12 months	3–5 years	4 weeks
MMR-2 ^h	4–6 years	13 months	—	—
Varicella (Var)-1 ^h	12–15 months	12 months	3–5 years	12 weeks ⁱ
Var-2 ^h	4–6 years	15 months	—	—
Hepatitis A (HepA)-1 ^b	12–23 months	12 months	6–18 months ^d	6 months ^d
HepA-2	18–41 months	18 months	—	—
Influenza, Inactivated (TIV) ^j	6–59 months	6 months ^k	1 month	4 weeks
Influenza, Live attenuated (LAIV) ^j	—	2 years	1 month	4 weeks

Recommended and Minimum Ages and Intervals Between Vaccine Doses^a, continued

Vaccine and Dose Number	Recommended Age for this Dose	Minimum Age for this Dose	Recommended Interval to the Next Dose	Minimum Interval to the Next Dose
Human papillomavirus (HPV)-1 ^p	11–12 years	9 years	2 months	4 weeks
HPV-2	11–12 years (+2 months)	109 months	4 months	12 months
HPV-3 ^q	11–12 years (+6 months)	114 months	—	—
Rotavirus (RV)-1 ^r	2 months	6 weeks	2 months	4 weeks
RV-2	4 months	10 weeks	2 months	4 weeks
RV-3 ^s	6 months	14 weeks	—	—
Zoster ^t	60 years	60 years	—	—

Abbreviations: DTaP, diphtheria and tetanus toxoids and acellular pertussis vaccine; MMR, measles, mumps, and rubella; TIV, trivalent (inactivated) influenza vaccine; LAIV, live, attenuated (intranasal) influenza vaccine; Td, tetanus and reduced diphtheria toxoids; Tdap, tetanus toxoid, reduced diphtheria toxoid, and reduced acellular pertussis vaccine.

^a Use of licensed combination vaccines is preferred over separate injections of their equivalent component vaccines. (CDC. Combination vaccines for childhood immunization: recommendations of the Advisory Committee on Immunization Practices [ACIP], the American Academy of Pediatrics [AAP], and the American Academy of Family Physicians [AAFP]. *MMWR*. 1999;48[No. RR-5]). When administering combination vaccines, the minimum age for administration is the oldest age for any of the individual components; the minimum interval between doses is equal to the greatest interval of any of the individual components.

^b Combination vaccines containing the Hepatitis B component are available (HepB-Hib, DTaP-HepB-IPV, HepA-HepB). These vaccines should not be administered to infants younger than 6 weeks of age because of the other components (i.e., Hib, DTaP, IPV, and HepA).

^c HepB-3 should be administered at least 8 weeks after HepB-2 and at least 16 weeks after HepB-1, and it should not be administered before age 24 weeks.

^d Calendar months.

^e The minimum recommended interval between DTaP-3 and DTaP-4 is 6 months. However, DTaP-4 need not be repeated if administered at least 4 months after DTaP-3.

^f For Hib and PCV, children receiving the first dose of vaccine at age 7 months of age or older require fewer doses to complete the series (CDC. Recommended childhood and adolescent immunization schedule – United States, 2006. *MMWR*. 2005;54 [Nos. 51 & 52]:Q1-Q4).

^g If PRP-OMP (Pedvax-Hib[®], Merck Vaccine Division), was administered at 2 and 4 months of age a dose at 6 months of age is not required.

^h Combination measles-mumps-rubella-varicella (MMRV) vaccine can be used for children 12 months through 12 years of age. Also see footnote i.

ⁱ The minimum interval from Var-1 to Var-2 for persons beginning the series at 13 years or older is 4 weeks.

^j One dose of influenza vaccine per season is recommended for most people. Children younger than 9 years of age who are receiving influenza vaccine for the first time, or received only 1 dose the previous season (if it was their first vaccination season) should receive 2 doses this season.

^k The minimum age for inactivated influenza vaccine varies by vaccine manufacturer. Only Fluzone (manufactured by sanofi pasteur) is approved for children 6–35 months of age. The minimum age for Fluvirin (manufactured by Novartis) is 4 years. For Fluarix and FluLaval (manufactured by GlaxoSmithKline) and Afluria (manufactured by CSL Ltd), the minimum age is 18 years.

^l Some experts recommend a second dose of MPSV-3 years after the first dose for people at increased risk for meningococcal disease.

^m A second dose of meningococcal vaccine is recommended for people previously vaccinated with MPSV who remain at high risk for meningococcal disease. MCV is preferred when revaccinating persons aged 2-55 years, but a second dose of MPSV is acceptable. (CDC. Prevention and Control of Meningococcal Disease Recommendations of the Advisory Committee on Immunization Practices [ACIP]. *MMWR*. 2005;54: No. RR-7.)

ⁿ Only one dose of Tdap is recommended. Subsequent doses should be administered as Td. If vaccination to prevent tetanus and/or diphtheria disease is required for children 7 through 9 years of age, Td should be administered (minimum age for Td is 7 years). For one brand of Tdap the minimum age is 11 years. The preferred interval between Tdap and a previous dose of Td is 5 years. In persons who have received a primary series of tetanus-toxoid containing vaccine, for management of a tetanus-prone wound, the minimum interval after a previous dose of any tetanus-containing vaccine is 5 years.

^o A second dose of PPSV is recommended for persons at highest risk for serious pneumococcal infection and those who are likely to have a rapid decline in pneumococcal antibody concentration. Revaccination 3 years after the previous dose can be considered for children at highest risk for severe pneumococcal infection who would be younger than 10 years of age at the time of revaccination. (CDC. Prevention of pneumococcal disease: recommendations of the Advisory Committee on Immunization Practices [ACIP]. *MMWR*. 1997;46[No. RR-8]).

^p HPV is approved only for females 9–26 years of age.

^q HPV-3 should be administered at least 12 weeks after HPV-2 and at least 24 weeks after HPV-1, and it should not be administered before 114 months of age.

^r The first dose of RV must be administered at 6–14 weeks of age. The vaccine series should not be started after a child has reached 15 weeks of age. RV may be administered on the day a child reaches his or her 8 month birthday but not later, regardless of the number of doses administered previously.

^s If Rotarix (RV1) is administered as age appropriate, a third dose is not necessary.

^t Herpes zoster vaccine is approved as a single dose for persons 60 years and older with a history of varicella.

Adapted from: Advisory Committee on Immunization Practices (ACIP) General Recommendations on Immunization. *MMWR*. 2006;55(No. RR-15):1–48. Source: Centers for Disease Control and Prevention. Recommended and Minimum Ages and Intervals Between Vaccine Doses. Available at: www.cdc.gov/vaccines/pubs/pinkbook/downloads/appendices/A/age-interval-table.pdf.

- Vaccines, their abbreviations, and vaccination age criteria often differ among countries.
 - The first assumption to make is that the vaccines administered in other countries were as potent as those available in the US.
 - Then, it is necessary to determine which vaccines were administered and in what doses.
 - Determining which vaccines were administered can be difficult, because the standard abbreviations recorded in handheld vaccination records may be different from those used in the US.
 - Translation of foreign-language terms can be facilitated with materials from the CDC.
 - Assistance with specific questions can be obtained from:
 - Your state immunization program
 - The CDC National Center for Immunization and Respiratory Diseases
 - Telephone: 800/232-4636
 - E-mail: nipinfo@cdc.gov
 - Once the vaccine types are determined, the table Recommended Immunization Schedule for Children and Adolescents Who Start Late or Who Are More Than 1 Month Behind can be used to determine:
 - Which doses are valid
 - Which, if any, need to be repeated
 - Doses given earlier than the minimal age or interval generally should be repeated.

Contraindications and precautions

- The CDC's detailed *Guide to Contraindications to Vaccinations*
- *Summary of Recommendations for Childhood and Adolescent Immunization*
- Anaphylactic-type allergy to a vaccine or a vaccine component
 - Includes even mild urticarial reactions
 - Contraindication to further vaccination with the vaccine in question
- Encephalopathy after a previous dose of a pertussis-containing vaccine
 - Contraindication to further vaccination with a pertussis-containing vaccine (eg, diphtheria-tetanus-acellular pertussis [DTaP], Tdap).
- Minor, acute illness
 - Some children are ill at the time of a well-child visit or are in need of a vaccination at an illness visit.
 - In these situations, the clinician must decide whether to recommend vaccination on the basis of 2 questions.
 - Will vaccination be safe for this ill child?

- If the child is not vaccinated at this visit, will he or she be brought back for vaccination?
 - Past appointment-keeping behavior may help in the judgment.
 - Vaccinating the ill child is best, especially if he or she has missed previous preventive care visits.
- Minor illnesses are not valid contraindications to vaccination.
 - Upper respiratory tract infections
 - Otitis media
 - Diarrheal illnesses, whether the individual is febrile or not
- A second, more difficult, consideration is whether minor vaccine side effects, such as fever, will cause diagnostic confusion during the follow-up period for the illness.
 - Particularly likely to be a problem when the patient is a very young infant

Immunocompromised children

- Immunocompromised children and their close contacts require individual attention.
 - Live vaccines
 - In general, live vaccines cannot be used in immunocompromised individuals.
 - Potential for severe or fatal reactions from uncontrolled replication of the vaccine virus
 - Live vaccines should not be given in cases of:
 - Congenital immunodeficiency
 - Leukemia
 - Lymphoma
 - Generalized cancer
 - Treatments that cause immunosuppression (eg, alkylating agents, antimetabolites, and radiation therapy)
 - Persons receiving daily, large doses of corticosteroids (the equivalent of 2 mg/kg of prednisone per day) for ≥ 14 days
 - Live vaccines should be deferred for at least 30 days after cessation of therapy or reduction in dose.
 - Live vaccine use is not contraindicated:
 - If the corticosteroid is aerosolized (as in asthma inhalers) or a topical agent
 - If it is given on an alternate-day, short course (<14 days)
 - If the child is on a physiologic replacement schedule
 - Inactivated vaccines
 - Cannot replicate and are safe for use in immunocompromised children
 - Immunocompromised children may have a diminished immune response to inactivated vaccines.

Recommended Immunization Schedule for Children and Adolescents Who Start Late or Who Are More Than 1 Month Behind^a

Catch-up schedule for children aged 4 months through 6 years

Vaccine	Minimum Age for Dose 1	Minimum Interval Between Doses			
		Dose 1 to Dose 2	Dose 2 to Dose 3	Dose 3 to Dose 4	Dose 4 to Dose 5
Hepatitis B ^b	Birth	4 weeks	8 weeks (and at least 16 wks after 1st dose)	—	—
Rotavirus ^c	6 weeks	4 weeks	4 weeks ^c	—	—
Diphtheria, tetanus, pertussis ^d	6 weeks	4 weeks	4 weeks	6 months	6 months ^d
<i>Haemophilus influenzae</i> type b ^e	6 weeks	<ul style="list-style-type: none"> • 4 weeks (if 1st dose is given at age <12 mo) • 8 weeks as the final dose (if 1st dose is given at age 12-14 mo) • No further doses needed (if 1st dose is given at age ≥15 mo) 	<ul style="list-style-type: none"> • 4 weeks^e (if current age is <12 mo) • 8 weeks as the final dose^e (if current age is ≥12 mo and 1st dose is given at age <12 and 2nd dose is given at age <15 mo) • No further doses needed (if previous dose is given at age ≥15 mo) 	8 weeks as final dose (this dose is only necessary for children aged 12 mo through 59 mo who received 3 doses before age 12 mo)	—
Pneumococcal ^f	6 weeks	<ul style="list-style-type: none"> • 4 weeks (if 1st dose is given at age <12 mo) • 8 weeks as final dose for healthy children (if 1st dose is given at age ≥12 mo or current age is 24–59 mo) • No further doses needed for healthy children (if 1st dose is given at age ≥24 mo) 	<ul style="list-style-type: none"> • 4 weeks (if current age is <12 mo) • 8 weeks as final dose for healthy children (if current age is ≥12 mo) • No further doses needed for healthy children (if previous dose is given at age ≥24 mo) 	8 weeks as final dose (this dose is only necessary for children aged 12 mo through 59 mo who received 3 doses before age 12 mo or high-risk children who received 3 doses at any age)	—
Inactivated poliovirus ^g	6 weeks	4 weeks	4 weeks	6 months	—
Measles, mumps, rubella ^h	12 months	4 weeks	—	—	—
Varicella ⁱ	12 months	3 months	—	—	—
Hepatitis A ^j	12 months	6 months	—	—	—

Recommended Immunization Schedule for Children and Adolescents Who Start Late or Who Are More Than 1 Month Behind^a, *continued*

Catch-Up Schedule for Children Aged 7 through 18 Years

Vaccine	Minimum Age for Dose 1	Minimum Interval Between Doses			
		Dose 1 to Dose 2	Dose 2 to Dose 3	Dose 3 to Dose 4	Dose 4 to Dose 5
Tetanus, diphtheria/ Tetanus, diphtheria, pertussis ^k	7 years ^k	4 weeks	<ul style="list-style-type: none"> • 4 weeks (if 1st dose is given <12 months) • 6 months (if 1st dose is given at ≥12 months) 	6 months (if 1st dose is given at age <12 months)	—
Human papillomavirus ^l	9 years	Routine dosing intervals are recommended ^l			
Hepatitis A ^j	12 months	6 months	—	—	—
Hepatitis B ^b	Birth	4 weeks	8 weeks (and at least 16 weeks after 1st dose)	—	—
Inactivated poliovirus ^g	6 weeks	4 weeks	4 weeks	6 months	—
Measles, mumps, rubella ^h	12 months	4 weeks	—	—	—
Varicella ⁱ	12 months	<ul style="list-style-type: none"> • 3 mo (if 1st dose is given at ≤13 years) • 4 weeks (if 1st dose is given at ≥13 years) 	—	—	—

^a This table provides catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child's age.

^b Hepatitis B vaccine (HepB).

- Administer the 3-dose series to those not previously vaccinated.
- A 2-dose series (separated by at least 4 months) of adult formulation Recombivax HB is licensed for children aged 11 through 15 years.

^c Rotavirus vaccine (RV).

- The maximum age for the first dose is 14 weeks 6 days. Vaccination should not be initiated for infants aged 15 weeks 0 days or older.
- The maximum age for the final dose in the series is 8 months 0 days.
- If Rotarix was administered for the first and second doses, a third dose is not indicated.

^d Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP).

- The fifth dose is not necessary if the fourth dose was administered at age 4 years or older.

^e *Haemophilus influenzae* type b conjugate vaccine (Hib).

- Hib vaccine is not generally recommended for persons aged 5 years or older. No efficacy data are available on which to base a recommendation concerning use of Hib vaccine for older children and adults. However, studies suggest good immunogenicity in persons who have sickle cell disease, leukemia, or HIV infection, or who have had a splenectomy; administering 1 dose of Hib vaccine to these persons who have not previously received Hib vaccine is not contraindicated.
- If the first 2 doses were PRP-OMP (PedvaxHIB or Comvax), and administered at age 11 months or younger, the third (and final) dose should be administered at age 12 through 15 months and at least 8 weeks after the second dose.
- If the first dose was administered at age 7 through 11 months, administer the second dose at least 4 weeks later and a final dose at age 12 through 15 months.

^f Pneumococcal vaccine.

- Administer 1 dose of pneumococcal conjugate vaccine (PCV) to all healthy children aged 24 through 59 months who have not received at least 1 dose of PCV on or after age 12 months.
- For children aged 24 through 59 months with underlying medical conditions, administer 1 dose of PCV if 3 doses were received previously or administer 2 doses of PCV at least 8 weeks apart if fewer than 3 doses were received previously.
- Administer pneumococcal polysaccharide vaccine (PPSV) to children aged 2 years or older with certain underlying medical conditions, including a cochlear implant, at least 8 weeks after the last dose of PCV.

^g Inactivated poliovirus vaccine (IPV).

- The final dose in the series should be administered on or after the fourth birthday and at least 6 months following the previous dose.
- A fourth dose is not necessary if the third dose was administered at age 4 years or older and at least 6 months following the previous dose.
- In the first 6 months of life, minimum age and minimum intervals are only recommended if the person is at risk for imminent exposure to circulating poliovirus (ie, travel to a polio-endemic region or during an outbreak).

Recommended Immunization Schedule for Children and Adolescents Who Start Late or Who Are More Than 1 Month Behind^a, *continued*

^h Measles, mumps, and rubella vaccine (MMR).

- Administer the second dose routinely at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 28 days have elapsed since the first dose.
- If not previously vaccinated, administer 2 doses with at least 28 days between doses.

ⁱ Varicella vaccine.

- Administer the second dose routinely at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 3 months have elapsed since the first dose.
- For persons aged 12 months through 12 years, the minimum interval between doses is 3 months. However, if the second dose was administered at least 28 days after the first dose, it can be accepted as valid.
- For persons aged 13 years and older, the minimum interval between doses is 28 days.

^j Hepatitis A vaccine (HepA).

- HepA is recommended for children older than 23 months who live in areas where vaccination programs target older children, who are at increased risk for infection, or for whom immunity against hepatitis A is desired.

^k Tetanus and diphtheria toxoids vaccine (Td) and tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap).

- Doses of DTaP are counted as part of the Td/Tdap series
- Tdap should be substituted for a single dose of Td in the catch-up series or as a booster for children aged 10 through 18 years; use Td for other doses.

^l Human papillomavirus vaccine (HPV).

- Administer the series to females at age 13 through 18 years if not previously vaccinated.
- Use recommended routine dosing intervals for series catch-up (ie, the second and third doses should be administered at 1 to 2 and 6 months after the first dose). The minimum interval between the first and second doses is 4 weeks. The minimum interval between the second and third doses is 12 weeks, and the third dose should be administered at least 24 weeks after the first dose.

Information about reporting reactions after immunization is available online at <http://www.vaers.hhs.gov> or by telephone, 800-822-7967. Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, including precautions and contraindications for immunization, is available from the National Center for Immunization and Respiratory Diseases at <http://www.cdc.gov/vaccines> or telephone, 800-CDC-INFO (800-232-4636).

Department of Health and Human Services • Centers for Disease Control and Prevention

- For vaccination of bone marrow transplant recipients, the clinician should consult the *Red Book* or the CDC guidelines.
- Persons without evidence of severe immunosuppression—even if infected with HIV—should receive MMR and varicella vaccines.
 - Children with symptomatic HIV infection should not receive either of these vaccines.
- Immunocompromised people with limited humoral immunodeficiency (eg, hypogammaglobulinemia, immunoglobulin A deficiency) may be routinely vaccinated with varicella vaccine.
- Persons living with an immunocompromised household contact should be vaccinated as indicated.
- MMR and varicella vaccines, which are live vaccines contraindicated for use in immunocompromised people themselves, should be given to susceptible contacts of immunocompromised people.
- OPV, which is used in countries other than the US, should not be given to people who are immunocompromised or who are close contacts of immunocompromised persons.
- Detailed guidelines for vaccinating pregnant women can be found at the CDC Web site.
- Prematurity
 - Preterm infants should be vaccinated using the routine schedule on the basis of their chronologic age (ie, time since birth, regardless of gestational age) and the standard doses of vaccine.
 - To maximize hepatitis B vaccine efficacy, infants weighing <2000 g and whose mothers are documented to be hepatitis B surface antigen (HBsAg) negative should not receive hepatitis B vaccine until they reach a body weight of 2000 g or chronologic age of 1 month.
 - Premature infants whose mothers' HBsAg status is positive should receive the vaccine and hepatitis B immune globulin (HBIG).
 - If the mother's HBsAg is unknown, the hepatitis B vaccine and HBIG should be given within 12 hours of birth, regardless of birth weight.
 - The birth dose should not be counted as part of the vaccine series.

Pregnancy

- Pregnant women generally should not receive live vaccines because of the theoretical risk of fetal damage.
- Women should avoid pregnancy for 4 weeks after receiving the MMR, MMR with varicella (MMRV), or varicella vaccine.
- Pregnant women generally may receive inactivated vaccines and toxoids.

Vaccine safety

- Vaccine safety concerns have been based on:
 - Data (eg, RotaShield and intussusception)
 - A biologically plausible but unsubstantiated association (eg, thimerosal in the birth dose of hepatitis B vaccine and autism)
 - Speculation (MMR vaccine and autism)

■ New concerns are likely to arise.

- Reliable sources of vaccine safety information that are regularly updated include:
 - Immunization Action Coalition
 - National Network for Immunization Information
 - Vaccine Education Center
 - Institute for Vaccine Safety

SPECIFIC INTERVENTIONS

Universal childhood vaccines

DTaP vaccine

■ Recommended form of the oldest combination vaccine, DTP

- Combination of diphtheria toxoid, tetanus toxoid, and acellular pertussis vaccine

■ Vaccination against tetanus and diphtheria has been highly successful.

■ DTaP is licensed for all preschool doses.

■ Two-thirds of reported cases of pertussis occur in older children and adults, who represent a reservoir for the bacteria and a continuing source of infection for young children.

■ Storage

- DTaP, DTP, or DTP-Hib vaccines should arrive at the office unfrozen.
- The vaccine should be refrigerated on arrival at a temperature of 2°C to 8°C.
- The vaccine should not be frozen.
- Shelf life is up to 1 year.
- The vials must be shaken vigorously before withdrawing the individual doses.

■ Administration

- The vaccine is administered intramuscularly using a dose of 0.5 mL.
- The ACIP has stated that, although completing the pertussis vaccination series using vaccine from a single manufacturer is preferred, when this is not feasible, any available licensed pertussis vaccine may be used.
 - Revaccinating individuals with the same manufacturer's product is not necessary to complete the vaccination series; the series can be finished with any of the pediatric acellular vaccines.

■ Adverse reactions to diphtheria and tetanus toxoids include:

- Local reactions, such as redness and induration
- Nodule at the injection site
- Arthus-type hypersensitivity reactions
- Mild adverse reactions to DTaP include:
 - Local reactions of redness, swelling, induration, and tenderness
 - Systemic reactions of drowsiness, vomiting, crying, and low-grade fever

• Moderate-to-severe reactions include:

- High fevers, with temperature $\geq 40.5^{\circ}\text{C}$ (105°F)
- Persistent and inconsolable crying of >3 hours' duration
- Hypotonic-hyporesponsive episodes
- Febrile seizures
- All of these reactions occur much less frequently with DTaP than with DTP, and all are believed to occur without permanent sequelae.

■ Contraindications and precautions

- Contraindication to DTaP vaccination include:
 - A history of severe (anaphylactic) allergic reaction after a prior dose of DTaP vaccine or a vaccine component
 - Encephalopathy within 7 days of a previous dose
- Precautions to DTaP include:
 - A convulsion within 3 days of a previous dose
 - Persistent, severe, inconsolable screaming or crying for ≥ 3 hours within 48 hours of a previous dose
 - Collapse or shock like state within 48 hours of a previous dose
 - A temperature of 40.5°C (105°F) that is unexplained by another cause within 48 hours of a previous dose
- Vaccination should be deferred in the event of a moderate to severe acute illness until the illness subsides.

Hepatitis A virus vaccine

■ Recommended for all children between 12 and 23 months of age, with optional catch-up vaccination through the preschool years

■ Recommended for persons at increased risk of hepatitis A virus infection, ie, those who:

- Travel or work in countries of high to intermediate endemicity
- Have homosexual sex with men
- Use illegal drugs
- Work with hepatitis A-infected primates or laboratory specimens
- Take clotting factor concentrates

■ Recommended for people with chronic liver disease

■ 2 manufacturers make inactivated hepatitis A vaccines; both brands are given by intramuscular injection.

■ A 2-dose schedule is used for the hepatitis A vaccine.

- Efficacy is $>90\%$ after the first dose.
- Efficacy is $\sim 100\%$ after the second dose.

■ Storage

- Vaccine should arrive unfrozen.
- Should be stored at temperatures between 2°C and 8°C
- Shelf life is up to 3 years.

■ Contraindications and precautions

- Hepatitis A vaccine should not be given to individuals who have a history of severe (anaphylactic) allergy to the vaccine or its components, such as alum and phenoxyethanol.
- Serious adverse events have not been associated with hepatitis A vaccination.
- The most frequent side effects are local reactions, including soreness at the injection site.

Hepatitis B virus (HBV) vaccine

■ Prevents HBV infection and its complications, which include hepatocellular cancer

■ Risk factors for HBV infection are lifestyles, occupations, or environments in which contact with blood or other body fluids from infected persons occurs frequently.

■ A large proportion of infected individuals were not known to have any risk factor.

■ The ACIP recommends hepatitis B vaccination for all unvaccinated children ages 0 to 18 years and makes hepatitis B vaccine available to this group through the Vaccines for Children program.

■ Storage

- Vaccine should arrive with a refrigerant but unfrozen.
- Vaccine should be refrigerated on arrival and stored at 2°C–8°C.
- Vaccine should not be frozen.
- Shelf life is up to 3 years.

■ Administration

- A vaccination series started with one manufacturer's product can be completed with the other manufacturer's product.
- The vaccine is 80–100% effective at preventing infection.
- A 3-dose schedule is recommended for active immunization.
 - For routine infant immunization, the initial dose should be given to the newborn before hospital discharge.
 - The minimal intervals between doses are:
 - Between the 1st and 2nd doses—4 weeks
 - Between the 2nd and 3rd doses—8 weeks
 - Between the 1st and 3rd doses—16 weeks
 - The 3rd dose should be administered no earlier than 24 weeks of age.
- For infants, children, and adolescents through 19 years of age, the dose is 0.5 mL of either the pediatric formulation of Recombivax HB or Engerix B.
- The seroconversion rate is >95% for infants, children, and adolescents receiving all 3 doses.

■ Contraindications and precautions

- Administration of hepatitis B vaccine is contraindicated for individuals who had a serious (anaphylacti) allergic reaction to a prior dose of hepatitis B vaccine or a vaccine component.

– Serious systemic adverse events and allergic reactions are rare.

- The most common adverse event after receiving the hepatitis B vaccine is pain at the injection site.
- Mild systemic symptoms, including fatigue, headache, and irritability, occur in <20% of children.
- Low-grade fever occurs in up to 6% of children.

■ High-risk groups for hepatitis B

- Native Alaskans, Asian Americans, and Pacific Islanders
- Children of immigrants or refugee families from countries having high rates of HBV infection
 - Special efforts should be made to vaccinate non-US born and immigrant children.
 - These children also should be screened for HBsAg.
- Babies born to HBsAg-positive mothers
 - All women should be screened for HBsAg during pregnancy.
 - Women at high risk of HBV infection (eg, intravenous drug users) should be screened again at delivery.
 - The results of hepatitis B testing should be available at the time of delivery so that perinatal transmission can be prevented by administration of both hepatitis B vaccine and HBIG.
 - The regimen is approximately 95% effective in preventing infection.
 - All infants born to women who are HBsAg positive should receive hepatitis B vaccine and HBIG (at a different injection site) within 12 hours of birth, regardless of gestational age or birth weight.
 - For infants weighing <2000 g, this birth dose should not be counted as part of the series; that is, 3 additional doses of hepatitis B vaccine should be given, the first of which should be at 1 month of age.
 - Combination vaccines containing a hepatitis B component, COMVAX and Pediarix, cannot be given to infants before 6 weeks of age.
- Although these combination vaccines are not licensed for use in infants born to HBsAg-positive mother, ACIP has recommended off-label use of COMVAX or Pediarix after 6 weeks of age to complete the hepatitis B vaccination series for these infants after a birth dose of a single-antigen hepatitis B vaccine.
- After the hepatitis B immunization series is complete (preferably at 6 months of age), all infants of HBsAg-positive mothers should be tested for the presence of anti-HBs and HBsAg at 9–15 months of age.
- Infants born to women who were not tested for HBsAg should receive an initial dose of hepatitis B vaccine within 12 hours of birth.
 - The mother should be tested immediately, and if she is positive, then the infant should receive HBIG within 7 days.

■ Low-birth-weight infants

- Hepatitis B vaccination should be postponed if:
 - The mother is HBsAg negative, and
 - The infant weighs <2000 g
- If the mother's surface antigen status is positive or unknown, these infants should receive immediate vaccination and HBIG, as previously described.

Hib vaccine

■ The Hib vaccines in use today are conjugated vaccines.

- The polysaccharide component of the capsule (polyribosyl-ribitol phosphate [PRP]) is bonded chemically to a protein carrier to enhance immunogenicity (especially in infants) and response to booster doses.

■ Available vaccines vary by the carrier protein to which PRP is bonded.

- Carriers include:
 - A mutant diphtheria toxin (HbOC)
 - Tetanus toxoid (PRP-T)
 - A *Neisseria meningitidis* outer membrane protein complex (PRP-OMP)

■ Efficacy is ~97% after 3 doses.

■ Storage

- Hib vaccines should arrive in insulated containers to prevent freezing.
- They should arrive unfrozen and should be refrigerated immediately and stored between 2°C and 8°C.
- Freezing reduces or destroys potency.
- Shelf life is up to 2 years.

■ Administration

- Differences among the vaccines result in slightly different administration schedules.

– PRP-T (Act-Hib) and HbOC (Hib titer)

- 4-dose series
- Given at 2, 4, 6, and 12–15 months of age

– PRP-OMP (COMVAX, PedvaxHIB)

- 3-dose series
- Given at 2, 4, and 12–15 months of age

– If a child receives different brands of Hib vaccine at 2 and 4 months of age, the Hib vaccine dose should be given at 6 months—even if 1 of the earlier doses was PRP-OMP—and this primary series should be followed by a booster at 12–15 months of age.

- Hib vaccine is marketed in several combination vaccines, including separate combinations with DTaP and hepatitis B vaccines.
- The package insert should be consulted for product-specific dosing schedules.
 - The DTaP-Hib combination (TriHibit) is licensed only for the 4th dose of the DTaP-Hib series.
- Completing the series with a different Hib product from the product used to start the Hib vaccination series is acceptable.
 - Necessitates a 3-dose primary series, after which a booster is given at 12–15 months of age
- The number of doses needed to complete the Hib series is different for children who have a late start on Hib vaccination or who have a lapsed series.
- The table Detailed Vaccination Schedule for *Haemophilus Influenzae* Type b Conjugate Vaccines gives a detailed Hib vaccination schedule.
- Adverse events after Hib vaccination are mild and infrequent.
 - 5–30% of children have a local reaction consisting of swelling, redness, or pain.

Detailed Vaccination Schedule for *Haemophilus Influenzae* Type b Conjugate Vaccines^a

Vaccine	Age at 1st Dose (months)	Primary Series	Booster
PRP-T (ActHIB)	2–6	3 doses, 2 months apart	12–15 months ^b
	7–11	2 doses, 2 months apart	12–15 months ^b
	12–14	1 dose	2 months later
	15–59	1 dose	None
PRP-OMP (PedvaxHIB)	2–6	2 doses, 2 months apart	12–15 months ^b
	7–11	2 doses, 2 months apart	12–15 months ^b
	12–14	1 dose	2 months later
	15–59	1 dose	None

^a From: Centers for Disease Control and Prevention. Detailed Vaccination Schedule for *Haemophilus influenzae* type b Conjugate Vaccines. Available at www.cdc.gov/vaccines/pubs/pinkbook/downloads/hib.pdf.

^b At least 2 months after previous dose.

- Systemic adverse events, such as fever, are uncommon.
- **Contraindications and precautions**
 - History of severe (anaphylactic) allergic reaction after a prior dose of Hib vaccine or a vaccine component
 - Vaccination should be deferred in the event of a moderate to severe acute illness until the patient's health improves.

Influenza virus vaccine

- In 2008 the AAP approved the recommendations to expand the ages for annual influenza vaccination of children to include all youths from 6 months through 18 years of age.
- Annual influenza vaccination is recommended for:
 - Older children with any of the following conditions:
 - Asthma and other chronic pulmonary or cardiovascular system diseases (does not include hypertension)
 - Any condition that can compromise respiratory function or the handling of respiratory secretions or that can increase the risk for aspiration
 - Immunosuppressive conditions, HIV infection, sickle cell disease, and other hemoglobinopathies
 - Chronic metabolic diseases, including diabetes mellitus, renal dysfunction, and long-term aspirin use
 - Persons who live with or care for an individual for whom the vaccine is recommended or an infant who is too young to be vaccinated (ie, <6 months of age)
 - Women who will be pregnant during influenza season
 - Residents of nursing homes and other chronic care facilities
- Currently, influenza immunization can be achieved using an injectable trivalent inactivated vaccine (TIV) or an LAIV.
 - Both vaccines consist of 3 highly purified, egg-grown influenza virus subtypes.
 - The composition is based on the viral strains expected during the winter influenza virus season.
 - TIV consists of either purified surface antigens or viral particles prepared by disrupting the membrane.
 - TIV is licensed for use in persons ≥ 6 months of age.
 - LAIV is licensed only for use in healthy persons (ie, those without a chronic illness) who are 2–49 years of age and are not pregnant.
- **Administration**
 - TIV is administered intramuscularly and LAIV is administered intranasally are given in an age-dependent schedule as follows.
 - 6–35 months of age: require 2 doses the first time they receive influenza vaccine, with single annual doses thereafter (TIV dose is 0.25 mL at this stage)
 - 3–8 years of age: require 2 doses the first time they receive influenza vaccine, with single annual doses thereafter (TIV dose is 0.50 mL at this stage)
 - ≥ 9 years of age: 1 dose annually (TIV dose is 0.50 mL at this stage)
 - For the 2-dose regimen, the minimum interval recommendation between doses of either TIV or LAIV is 4 weeks.
 - In 2008 in addition to the LAIV made by a sole manufacturer, injectable vaccines from 5 manufacturers have been licensed in the US as shown below along with the age category for which the product is licensed.
 - sanofi pasteur (Fluzone): ≥ 6 months of age
 - Novartis vaccine (Fluvirin): ≥ 4 years of age
 - GlaxoSmithKline (Fluarix): ≥ 18 years of age
 - CSL Biotherapies (Afluria): ≥ 18 years of age
 - ID Biomedical Corporation of Quebec (FluLaval): ≥ 18 years of age
- **Storage**
 - All influenza vaccine (TIV and LAIV)
 - Should be stored between 35°F–46°F (2°C and 8°C)
 - FluMist
 - Now refrigerator stable
 - Should be shipped frozen
 - Upon receipt, should be stored in refrigerator between 35°F–46°F (2°C–8°C)
 - Should not be refrozen
 - Additional details on influenza vaccine storage, shipping, and handling can be found on the Web site of the Minnesota Department of Health.
- **Adverse events**
 - TIV
 - Rarely causes febrile or other systemic reactions
 - Local reactions, including soreness, redness, and induration at the site of the injection, occur in <30% of vaccinees.
 - Immediate hypersensitivity reactions, such as hives, angioedema, allergic asthma, or anaphylaxis, occur rarely after influenza vaccination.
 - LAIV
 - May be associated with coryza or nasal congestion, headache, fever, vomiting, abdominal pain, and myalgias
 - These symptoms are associated more often with the first dose and are self-limited.
- **Contraindications and precautions**
 - Administration of influenza vaccine is contraindicated for individuals who have had a serious (anaphylactic) allergic reaction to a prior dose of influenza vaccine or a vaccine component (eg, eggs).
 - For details about specific influenza vaccines, consult their package inserts at the US Food and Drug Administration's (FDA) Center for Biologics Evaluation and Research Web site.

MMR vaccine

- A combination of 3 live attenuated vaccines that together protect against measles, mumps, and rubella

- The purpose of the measles and mumps vaccines is to protect against these specific diseases.
- The purpose of the rubella vaccine is to prevent congenital rubella syndrome by preventing the occurrence of rubella, (which itself is a mild disease) in the general population, thereby preventing its spread to susceptible pregnant women.
- MMR is also licensed in combination with varicella vaccine as MMRV (ProQuad, Merck Vaccine Division).
- In the US, only 1 strain of each vaccine virus in MMR is available.
 - Each one is highly immunogenic, leading to seroconversion in $\geq 90\text{--}95\%$ of recipients vaccinated at ≥ 15 months of age.
- Storage
 - MMR vaccine
 - Should arrive at the office in an insulated container at a temperature $< 10^\circ\text{C}$
 - Should be refrigerated on arrival and stored between 2°C and 8°C (never frozen)
 - The shelf life is up to 2 years; the expiration date is marked on the vials.
 - On reconstitution, the vaccine should be stored in a dark place between 2°C and 8°C and must be used within 8 hours.
 - MMRV
 - Must be shipped and stored at $\leq 4^\circ\text{F}$ (-20°C) at all times
 - Must not be stored at refrigerator temperature at any time
 - Must be administered within 30 minutes of reconstitution
- Administration
 - The AAP and ACIP recommend administration of 2 doses of MMR vaccine for children; these doses are 0.5 mL delivered subcutaneously.
 - The 1st dose should be given at 12–15 months of age.
 - The 2nd dose should be given before elementary school entry (4–6 years of age).
 - The purpose of the 2nd dose is to produce immunity in the small proportion of children who fail to respond to the first.
 - MMRV is approved only for children 12 months through 12 years of age and may be administered whenever MMR or varicella vaccines, or both, are indicated.
- Adverse reactions
 - Because MMR is composed of live attenuated vaccines, if side effects other than those related to allergy occur, they do so 5–12 days after administration.
 - Adverse reactions include:
 - Rash: 5–10% (measles, rubella)
 - Fever: 5–15% (measles)
 - Thrombocytopenia: 1 per 30,000 (measles)
 - Parotitis: rare (mumps)

- Transient arthritis: $< 1\%$ (rubella)
- Arthralgia: adults, but not children
- An association between autism and MMR has been postulated but is not supported by scientific evidence.
- Contraindications and precautions
 - Contraindications to MMR vaccination include:
 - History of a severe (anaphylactic) allergic reaction to a prior dose or a vaccine component (eg, neomycin, gelatin)
 - Significant immunosuppression from any cause, including cancer or its treatment, immunodeficiency diseases, or immunosuppressive therapy
 - Asymptomatic HIV infection is not a contraindication to receipt of MMR.
 - Pregnancy
 - Precautions regarding MMR vaccination include:
 - Moderate or severe acute illness (defer vaccination until illness improves)
 - Recent receipt of a blood transfusion, blood products, or immune (γ) globulin
 - A history of thrombocytopenia or thrombocytopenia purpura
 - MMRV
 - Contraindications and precautions include all of those for both MMR and varicella vaccines.

Pneumococcal vaccine—conjugated

- The pneumococcal conjugate vaccine (PCV) is analogous to the Hib conjugate vaccine, in which a protein is joined to the polysaccharide.
- The currently licensed formulation contains 7 serotypes (thus the acronym PCV7) that accounted for most of the invasive pneumococcal diseases in children in the prevaccine era.
- Prelicensure studies of the conjugate vaccine indicated:
 - High efficacy against invasive disease
 - 10% reductions in acute otitis media
 - Reductions in nasopharyngeal carriage of the bacteria
- Postlicensure studies have confirmed marked reductions in invasive pneumococcal disease, as well as possible indirect protection of other populations, such as older adults through herd immunity.
 - For these reasons, the AAP and ACIP recommend that all children should be routinely vaccinated with PCV7 beginning at 2 months of age.
- Special efforts should be made to ensure on-time vaccination of children with medical conditions that put them at increased risk of invasive pneumococcal disease, such as:
 - Sickle cell disease
 - Asplenia
 - HIV infection or other immunocompromising conditions

- Chronic disease (eg, cardiopulmonary disease except asthma, chronic liver disease, or diabetes mellitus)
 - Black, American Indian, and Native Alaskan children also are considered to be at high risk.
 - Administration
 - PCV7 is administered intramuscularly as a 0.5-mL dose.
 - Administration should begin at 2 months but not earlier than 6 weeks of age.
 - The recommended interval between the subsequent 2 doses is 2 months; the minimal interval is 4 weeks.
 - The booster dose should be given at 12–15 months of age, at least 2 months after the 3rd dose.
 - Recommended schedules vary for children who had a delayed 1st dose or a lapse in vaccination. See tables Recommended Schedule for Use of 7-Valent Pneumococcal Conjugate Vaccine (PCV7) and Recommendations for Use of 7-Valent Pneumococcal Conjugate Vaccine (PCV7).
 - Adverse reactions
 - Local reactions (1 in 4) and low-grade fever (1 in 3 with temperature >100.4°F) are common following PCV7.
 - Fever >102.2°F is not common (1 in 50).
 - To date, no serious reactions have been associated with the vaccine.
 - Contraindications and precautions
 - A severe (anaphylactic) allergic reaction following a prior dose of PCV7 or its components
 - Vaccination should be deferred for children with a moderate to severe acute illness until the illness improves.
- Pneumococcal vaccine—polysaccharide (PPV23)
- The pure polysaccharide pneumococcal vaccine (PPV23) consists of purified capsular polysaccharide antigen from 23 types of pneumococcal bacteria.
 - It is given by intramuscular or subcutaneous injection.
 - Unlike PCV:
 - Does not reduce nasopharyngeal pneumococcal carriage
 - Does not protect children <2 years of age
 - Use of PPV23 is recommended for all persons ≥65 years of age, as well as children ≥2 years of age who have conditions that place them at increased risk of systemic pneumococcal infection.

Recommended Schedule for Use of 7-Valent Pneumococcal Conjugate Vaccine (PCV7)^a

Age at 1st Dose (months)	Number of Doses in Primary Series	Additional Dose
2–6	3 doses, 2 months apart ^b	1 dose at 12–15 months, at least 8 weeks after the primary series has been completed
7–11	2 doses, 2 months apart ^b	1 dose at 12–15 months, at least 8 weeks after the primary series has been completed
12–23	2 doses, 2 months apart ^c	None
24–59 without high-risk condition	1 dose	None
24–59 with high-risk condition ^d	2 doses, 2 months apart	None
>59	0	None

^a Among previously unvaccinated infants and children by age at time of first vaccination.

^b For children vaccinated at age <1 year, the minimum interval between doses is 4 weeks.

^c The minimum interval between doses is 8 weeks.

^d High-risk conditions include sickle cell disease, asplenia, HIV infection, chronic illness, cochlear implant, and immunocompromising conditions.

Recommendations for Use of 7-Valent Pneumococcal Conjugate Vaccine (PCV7)^a

Age at Visit (months)	Previous PCV7 Vaccination History	Recommended Regimen
7–11	1 dose	1 dose at 7–11 mo; another ≥2 mo later at 12–15 mo
	2 doses	Same as above
12–23	1 dose before age 12 mo	2 doses ≥2 mo apart
	2 doses before age 12 mo	1 dose ≥2 mo after the most recent dose
24–59	Any incomplete schedule	1 dose ^b

^a Among children with a lapse in vaccine administration.

^b Children with high-risk conditions (eg, sickle cell disease, asplenia, HIV infection, chronic illness, cochlear implant, immunocompromising conditions) should receive 2 doses ≥2 mo apart.

- At least 2 months should separate the last dose of PCV7 and 1st dose of PPV23.
- For children undergoing splenectomy or chemotherapy initiation, vaccination should occur >2 weeks before splenectomy or the start of chemotherapy, if possible.
- Details on the use of PPV23 after vaccination with PCV7 are found on the Centers for Disease Control and Prevention (CDC) Web site.
- Storage
 - Should arrive at the office unfrozen
 - Should be refrigerated immediately on arrival
 - Should be stored between 2°C and 8°C
 - Shelf life is up to 2 years.
- Adverse reactions
 - Mild local reactions in ~50% of recipients
 - Fever or severe local reactions in <1%
- Contraindications and precautions
 - Severe (anaphylactic) allergic reaction following a prior dose of the vaccine or its components
 - Vaccination should be deferred for children with a moderate to severe acute illness until the illness improves.

Polio vaccine

- 2 polio vaccines have been developed: enhanced-potency IPV and OPV.
- Routine polio vaccination in the US is currently accomplished with IPV, which is administered subcutaneously (or intramuscularly) with a dose of 0.5 mL and consists of formaldehyde-killed polio virus.
- OPV is a live attenuated vaccine that is administered orally.
 - Although still used routinely in many countries (eg, Mexico), use of OPV was discontinued in the US in 2000.
- Storage
 - IPV should arrive at the office unfrozen and should be refrigerated between 2°C and 8°C.
 - The shelf life is up to 18 months.
- Administration
 - In many states, 4 polio vaccinations are required before school entry—3 doses in the primary series and 1 supplementary dose.
 - If an all-IPV schedule is used and the 3rd dose is administered after the child's 4th birthday, then no supplemental dose is indicated.
- Adverse reactions
 - No serious adverse effects have been reported following IPV.

Rotavirus vaccine

- Rotavirus is the most common cause of severe gastroenteritis in infants and young children in the US.
- The CDC estimates that rotavirus infection leads to 55,000 hospitalizations each year for acute gastroenteritis.

- In February 2006 an attenuated pentavalent bovine-human rotavirus vaccine (PRV) was licensed for use in the US.
- PRV is expected to cover >80% of the strains that currently are responsible for rotavirus acute gastroenteritis worldwide.
- In large prelicensure studies, PRV was efficacious and well tolerated.
 - The efficacy of the vaccine against rotavirus gastroenteritis caused by G1 through G4 serotypes was 74% against any severity and 98% against severe disease.
 - Use of this vaccine was associated with a 94.5% reduction in G1 through G4 rotavirus-related hospitalizations and emergency department visits in the 1st full rotavirus season after the 3rd PRV dose.
- Schedule
 - The 1st dose should be given between 6 and 12 weeks of age.
 - An interval of 4–10 weeks should pass between doses in the series.
 - All 3 doses should be given by 32 weeks of age.
 - Age should be calculated based on chronological age.
 - Premature infants can be immunized if they are clinically stable and are being or have been discharged from the hospital nursery.
 - If a child spits out or vomits after vaccination, then the dose should not be repeated; the series should simply continue according to the recommended intervals.
- Storage
 - The recommended dose of PRV is 2 mL orally.
 - This dose comes as a liquid in latex-free single-dose tubes.
 - PRV should be transported and stored at 2°C–8°C (36°F–46°F) and protected from light.
- Contraindications and precautions
 - A severe (anaphylactic) allergic reaction after a prior dose of the vaccine or its components
 - Moderate-to-severe acute illness: vaccination should be deferred until the illness improves.
 - Other precautions include:
 - Altered immunocompetence
 - Preexisting chronic gastrointestinal disease
 - History of intussusception
- Adverse reactions
 - Within a week of receiving PRV, children are slightly (1–3%) more likely to have mild, temporary diarrhea or vomiting than unvaccinated children.
 - Unlike a previously licensed rotavirus vaccine, no evidence has been found that PRV causes intussusception or other serious adverse events.
- Other live oral rotavirus vaccines are in development.

Varicella vaccine

- The AAP and ACIP first recommended routine varicella vaccination in 1996.
- Most states now have varicella vaccination requirements for child care and school entry.
- The Oka/Merck strain, a live attenuated vaccine virus developed in the early 1970s in Japan, is the sole vaccine virus strain licensed in the US today.
 - The efficacy of the vaccine is:
 - ~70% for preventing any varicella disease
 - >95% for preventing severe varicella disease
- In 2007 ACIP expanded their recommendations to include
 - A routine 2-dose varicella vaccination program for children (at age 12–15 months and again at age 4–6 years)
 - A second dose for all persons who previously had received only 1 dose
 - Routine vaccination of all healthy persons age >13 years without evidence of immunity
 - Prenatal assessment and postpartum vaccination
 - Expansion of the use of the varicella vaccine for specific groups of HIV-infected children
- Varicella vaccine is also licensed in combination with MMR vaccine as MMRV for use in children 12 months to 12 years of age (see MMR Vaccine section).
- Administration
 - The recommended dose is 0.5 mL injected subcutaneously.
 - For children 12 months to 12 years of age, the recommended minimum interval between the two doses is 3 months.
 - Any dose given >28 days after the first dose is considered valid.
 - For persons ≥13 years of age, the recommended minimum interval is 4 weeks.
 - Varicella vaccine may be given simultaneously with MMR, but, if not given on the same day, at least 28 days should elapse between the administration of the 2 doses.
 - Whether immunity is lifelong is unknown, and the answer to this question is complicated by persistent exposure to circulating wild type varicella virus, which boosts immunity in vaccinated children.
- Storage
 - Varicella vaccine has stringent cold chain and storage requirements.
 - The vaccine should arrive at the office frozen, having been shipped in dry ice, which should still be present in the shipping container.
 - It must be stored in a freezer with a separate door at 5°F or colder.
 - The shelf life of vaccine that is properly handled is 18 months.
- If stored at refrigerator temperatures, then varicella vaccine must be used within 72 hours, and it cannot be refrozen.
 - MMRV must be stored frozen at all times and cannot tolerate refrigerator temperatures.
- After reconstitution, varicella vaccine must be administered within 30 minutes.
- Contraindications and precautions
 - Contraindications include:
 - History of a severe (anaphylactic) allergic reaction to a prior dose or a vaccine component (eg, neomycin, gelatin)
 - Substantial suppression of cellular immunity from any cause, including cancer or its treatment, immunodeficiency diseases, or immunosuppressive therapy (although persons with impaired humoral immunity may be vaccinated).
 - Pregnancy
 - Asymptomatic HIV infection and pure humoral immunodeficiencies (eg, immunoglobulin A deficiency, hypogammaglobulinemia) are not contraindications to receipt of varicella vaccine.
 - Precautions include:
 - Moderate or severe acute illness (vaccination is deferred until illness improves)
 - Receipt of a blood transfusion, blood products, or immune (γ) globulin
 - The manufacturer recommends discontinuing salicylates for 6 weeks after receiving varicella vaccine because of the association between aspirin use and Reye syndrome after acquiring chickenpox.
 - Contraindications and precautions to MMRV include all of those for both MMR and varicella vaccines.
- Adverse reactions
 - Local symptoms, such as pain, soreness, redness, and swelling, which occur in 19% of young children and 24–33% of adolescents
 - A varicella-like rash at the injection site, which occurs within 2 weeks in 3% of first-dose recipients
 - A varicella-like rash at noninjection sites, which occurs within 3 weeks in 4–6% of children
 - The incidence of zoster is less after varicella vaccination than after natural infection, but zoster may be caused by varicella vaccine virus.

Routine adolescent immunization

- A major effort is under way to protect adolescents from vaccine-preventable diseases.
- Routine well-child visits should be established for adolescents to provide vaccines and other preventive care measures.
- 3 main categories of vaccines for adolescents should be considered.
 - Routinely recommended vaccines (discussed below)

- Vaccines needed because of special high-risk conditions (eg, influenza, pneumococcal polysaccharide)
- Vaccines that were missed previously
 - Persons who have had no previous varicella vaccination (or history of disease), <2 doses of MMR, or <3 doses of hepatitis B vaccine

Meningococcal conjugate vaccine

- *N meningitidis* is a much-dreaded cause of meningitis and overwhelming sepsis.
- Freshmen college students living in dormitories are at greater risk than their similarly aged peers.
- In January 2005 a quadrivalent meningococcal conjugate vaccine (MCV4) was licensed in the US for persons aged 11–55 years.
- In 2007 ACIP expanded the recommendations to include routine vaccination of all persons aged 11–18 years with 1 dose of MCV4 at the earliest opportunity.
 - College freshmen living in dormitories
- ACIP also reiterated the recommendation to ensure vaccination of groups with an elevated risk of meningococcal disease.
 - College freshmen living in a dormitory
 - Military recruits
 - Persons with anatomic or functional asplenia
 - Persons with terminal complement component deficiencies
 - Persons who travel to or reside in countries in which *N meningitidis* is hyperendemic or epidemic
 - Microbiologists who are routinely exposed to isolates of *N meningitidis*
- Persons 2–55 years of age who are at increased risk, MCV4 (rather than MPSV4) is the preferred formulation.
- Unlike MPSV4, MCV4 is conjugated (ie, the polysaccharide is linked to a protein); thus, it offers improved duration of immunity.
- Whereas the older polysaccharide vaccine guarded against disease for 3–5 years, the new vaccine may offer protection for a decade.
 - Conjugated vaccines are known to limit disease spread among unvaccinated persons by reducing asymptomatic bacterial carriage among those who are vaccinated.
- MCV4 is serogroup specific against groups A, C, Y, and W-135, similar to the polysaccharide vaccine.
- No vaccine is available against serogroup B disease, which causes >50% of meningococcal disease in young children and 30% of meningococcal disease in adolescents and young adults.
- MCV4 has been shown to have high immunogenicity, with significant titers in 98% of recipients after 1 dose.
- Administration
 - The meningococcal conjugate vaccine is licensed for ages 2–55 years.

- It is administered intramuscularly at a dose of 0.5 mL.
- The vaccine can be given concomitantly with other vaccines, including Td or Tdap.

■ Storage

- Vaccine should be stored at temperatures of 2°C–8°C (35°F–46°F) and should not be frozen.
- It is packaged in single-dose vials.
- Product that has been frozen should not be used.

■ Adverse reactions

- Common adverse effects from the vaccine include local pain (59%), headache (35%), and fatigue (30%).
- Guillain-Barré syndrome (GBS)
 - Has been associated with receipt of MCV4
 - Specifically, at a rate of 0.20 per 100,000 person-months, the ratio of the Vaccine Adverse Event Reporting System (VAERS) reporting rate of GBS after MCV4 vaccination to the expected incidence rate was 1.77 (CI=0.96–3.07).
 - Because persons with a history of GBS might be at increased risk for postvaccination GBS, ACIP recommends that persons who have a personal or parental history of GBS should discuss the decision to receive MCV4 with their health care provider.

Tdap vaccine

- Vaccinating adolescents for pertussis is intended to reduce both pertussis morbidity among adolescents and the reservoir of disease.
 - The latter effect presumably will decrease infant mortality, especially among children who are too young to have received the childhood DTaP series.
- 2 Tdap vaccines for adolescents are FDA approved.
 - Adacel (for ages 11–64)
 - Boostrix (for ages 10–18)
 - Both vaccines are indicated only as boosters.
 - Both contain lower amounts of diphtheria toxoid and pertussis antigen than the childhood vaccine (DTaP).
 - Neither is interchangeable with the infant formulation.
 - Both vaccines were shown to produce significant pertussis antibody booster responses in 95–99% of patients and induced similar tetanus-diphtheria antibody responses to Td vaccine.
- Administration
 - The ACIP and AAP recommend that adolescents ages 11–12 years old be given Tdap in place of the Td booster previously given.
 - The committee also recommended that Tdap be given to adolescents ages 13–18 who missed the early adolescent dose of Td.

- Adolescents ages 11–18 who have already been vaccinated with Td are encouraged to receive a dose of Tdap to further protect against pertussis.
 - A dose of Tdap is also recommended for adults <65 years of age.
 - Although the manufacturers' prescribing information recommends a 5-year interval after a Td vaccination before administering Tdap, ACIP does not recommend any absolute minimum interval between Td and Tdap.
 - ACIP suggests administering Tdap regardless of interval since last Td if pertussis immunity is imparative (eg, for health care professionals or for those who have an infant in the household).
 - Tdap may be given concomitantly with any other vaccine and is recommended for wound management in place of Td.
 - If the individual has no history of receipt of the primary DTaP series, then he or she should receive 3 doses of vaccine; the 1st should be with Tdap, and the next 2 should be Td at 4 weeks and 6 months after Tdap.
- **Storage**
- The dose for both brands of Tdap is 0.5 mL injected intramuscularly.
 - Boostrix is available in 0.5-mL single-dose vials and syringes.
 - Adacel is available in 0.5-mL single-dose vials.
 - Both products should be refrigerated (2°C–8°C [35°F–46°F]) but not frozen.
- **Adverse reactions**
- Side effects of Tdap include:
 - Mild pain at the injection site (75–88%)
 - Redness and swelling (11–22%)
 - Low-grade fever
 - Headache
 - Fatigue
 - All side effects are similar to those from Td vaccination.
- **Contraindications and precautions**
- Contraindications include:
 - A severe (anaphylactic) allergic reaction after a prior dose of the vaccine or its components
 - A history of encephalopathy within 7 days of administration of a pertussis-containing vaccine
 - Vaccination should be deferred for persons with a moderate to severe acute illness until the illness improves.
- **HPV vaccine**
- HPV is the most common sexually transmitted infection in the US, with an estimated 6 million infections each year, 74% of which occur in adolescents age 15–24 years.
 - Although 32–46% of adolescents and young women are infected with HPV, a small percentage go on to develop cervical dysplasia and eventually cervical cancer.
 - Specific subtypes of HPV are high-risk (types 16, 18, 31, and 45 are associated with genital cancers and their precursors) or are low-risk (types 6 and 11 are associated with low grade cervical abnormalities, genital warts and, in infants, laryngeal papillomas).
 - HPV subtypes 16 and 18 are known to be present in ≥70% of cervical cancers, and types 6 and 11 are related to 90% of anogenital warts.
 - The vaccine has been shown to be cost effective when combined with continued Papanicolaou testing.
 - Papanicolaou testing would continue to be recommended because not all HPV types could be included in 1 vaccine.
- Other sexually transmitted infections
- May become available within the next decade
 - Herpes simplex virus (HSV)
 - A vaccine against HSV was found to have an efficacy of 74% in HSV-seronegative women, but was not effective for men or HSV-1-seropositive women.
 - The potential effect of such a vaccine depends, in large part, on its ability to blunt viral shedding.
 - Chlamydia
 - Several vaccines against *Chlamydia trachomatis* are in development, ranging from DNA vaccines to live attenuated vaccines.
 - Animal studies are promising, but vaccines for adolescents are still several years away.

Increased Intracranial Pressure

DEFINITION

- Increased intracranial pressure (ICP) is a potentially life-threatening neurologic or neurosurgical emergency.
- Rapidly identifying and managing the cause can prevent serious morbidity and possible death.
- Increased ICP has many causes, and symptoms can be acute, subacute, or chronic.

ETIOLOGY

Causes of increased ICP in children

- Head trauma
 - Cerebral edema
 - Intracerebral hemorrhage
 - Extracerebral hemorrhage (subdural, epidural)
- Vascular causes
 - Arterial or venous infarctions
 - Intracerebral hemorrhage
 - Dural sinus thrombosis
 - Subarachnoid hemorrhage
 - Vascular anomalies (vein of Galen malformation, arteriovenous malformations)
- Neoplastic causes
 - Primary brain tumors
 - Metastatic (intracerebral, meningeal infiltration)
- Hydrocephalus (congenital or acquired, communicating or noncommunicating)
- Pseudotumor cerebri (benign intracranial hypertension)
- Central nervous system infections
 - Meningitis (bacterial, fungal, mycobacterial)
 - Encephalitis (focal or diffuse)
 - Abscess
- Metabolic causes
 - Inborn errors of metabolism (hyperammonemia)
 - Hepatic encephalopathy
 - Diabetic ketoacidosis
 - Renal failure
 - Reye syndrome
 - Hypoxic-ischemic encephalopathy
 - Fluid-electrolyte abnormalities (hyponatremia, hypernatremia)
- Structural causes
 - Craniosynostosis
 - Status epilepticus

Mechanism

- Depending on the cause, intracranial hypertension can be:
 - Chronic (as with pseudotumor cerebri)

- Acute (as with head trauma resulting in cerebral edema or intracerebral hemorrhage)
- Based on experimental data, 2 primary mechanisms are thought to be involved.
 - Vasogenic extracellular brain edema
 - Delayed reabsorption through the arachnoid villa
- Idiopathic intracranial hypertension may be compounded by secondary exacerbation of intracranial venous sinus compression that results in further reduction of flow across the arachnoid villi.
 - Predominantly affects young obese women of childbearing age

RISK FACTORS

- In the young, risk factors include:
 - Medications
 - Vitamin A in infants
 - Isotretinoin (Accutane)
 - Corticosteroids
 - All-trans-retinoic acid for treatment of promyelocytic leukemia
 - Levothyroxine
 - Tetracycline
 - Trimethoprim-sulfamethoxazole
 - Cimetidine
 - Nalidixic acid
 - Nitrofurantoin
 - Recombinant growth hormone
 - Endocrinopathies
 - Recent weight gain
 - Menstrual irregularity
 - Adrenal insufficiency
 - Cushing disease
 - Hypoparathyroidism
 - Hypothyroidism
 - Excessive thyroxine replacement
 - Chronic renal failure
 - Systemic lupus erythematosus

SIGNS AND SYMPTOMS

Infants

- Acute increased ICP
 - Irritability
 - Poor feeding or emesis
 - Split sutures (especially lambdoid)
 - Bulging fontanelle
 - Altered mental status

- Seizures
- Parinaud sign (upgaze paresis)
- Chronic increased ICP
 - Irritability
 - Poor feeding or emesis
 - Increased head circumference
 - Bulging fontanelle
 - Split sutures (especially lambdoid)
 - Apparent developmental arrest or regression
 - Parinaud sign (upgaze paresis)

Children

- Acute increased ICP
 - Severe, acute headache
 - Seizures
 - Emesis
 - Rapidly deteriorating mental status
 - Decerebrate or decorticate posture
 - Focal neurologic deficits
 - Papilledema
 - Pupillary abnormalities
 - Autonomic dysfunction (Cushing triad)
- Chronic increased ICP
 - Chronic, progressive headache
 - Seizures
 - Early morning emesis
 - Change in school performance
 - Altered mental status
 - Cranial neuropathy (eg, sixth cranial nerve palsy)
 - Focal neurologic deficits
 - Papilledema
 - Visual changes

Differentiating between acute and chronic ICP

- Many of the signs and symptoms of acute and chronic ICP are the same, demonstrating their somewhat nonspecific nature.
- The temporal pace of development differs between the 2 forms.
- Acute signs of rapidly increasing ICP result from displaced neuronal tissue through several dural openings, with subsequent compression and ischemic changes to cerebral structures.
 - With uncal herniation, in association with supratentorial masses, the uncus is displaced through the tentorial opening, leading to compression of the ipsilateral third nerve and displacement of the peduncles and brainstem laterally.
 - Clinically, the patient is comatose.
 - Ipsilateral pupillary dilation (third nerve palsy)

- Ipsilateral hemiparesis, suggesting a falsely localizing lesion in the contralateral hemisphere
- The pupil reliably localizes the side of the lesion.
- Downward herniation of the cerebellar tonsils through the foramen magnum leads to compression and vascular compromise of the lower brainstem structures (medulla).
 - Patients are comatose.
 - Decorticate or decerebrate rigidity
 - Autonomic (respiratory and circulatory) changes
- Cushing triad (rarely seen clinically)
 - Widened pulse pressure
 - Bradycardia
 - Deep, slow respiration

DIAGNOSTIC APPROACH

- The key to managing increased ICP is rapidly recognizing intracranial hypertension.
- History and physical and neurologic examinations are the most important aspects of the initial evaluation.
- It is critical to obtain information on the pace of illness, to discern the need for urgent versus emergent management.
- If process is rapidly evolving (eg, impending herniation), stabilizing the patient is essential before proceeding to definitive diagnosis and therapy.

IMAGING

- Computed tomography (CT) is performed more often than magnetic resonance imaging (MRI).
 - MRI provides better anatomic differentiation than CT, but it is frequently unavailable in the emergency setting.
- If a mass lesion is suspected, neuroimaging (regardless of modality) should include contrast enhancement.
- Both modalities are effective in evaluating the cause of intracranial hypertension.
- If the patient is suspected of having a subarachnoid hemorrhage, CT followed by lumbar puncture (LP) remains the mainstay of initial diagnosis.
- Ultrasonography is a reasonable alternative to CT or MRI in infants suspected of having aqueductal stenosis.
- Other neuroimaging studies, such as angiography, rarely play a role in the initial diagnostic management of intracranial hypertension.
- Imaging studies are recommended to screen for mass lesions or hydrocephalus, although most patients have normal scans.
 - CT of the head may show small, slit ventricles.
 - MRI of the brain with gadolinium enhancement is preferred for its sensitivity in screening other conditions.
 - Magnetic resonance venography:
 - Is recommended for suspected dural venous sinus thrombosis

- May show extraluminal narrowing of the transverse sinus that may be a typical feature of pseudotumor cerebri

DIAGNOSTIC PROCEDURES

- LP provides an opportunity to evaluate ICP.
 - LP is performed by inserting a spinal needle into the thecal sac and attaching a manometer.
 - Cerebrospinal fluid (CSF) column height is measured while the patient is in the lateral decubitus position with legs extended.
 - Between 12 and 18 cm is normal.
- If a mass lesion is suspected, withdrawing lumbar CSF may create a pressure gradient intracranially and precipitate herniation syndrome; thus, neuroimaging is generally recommended before LP.
- In children suspected of having meningitis, neuroimaging before LP may unnecessarily delay antibiotic treatment.
 - If meningitis is a serious consideration and a CT scan is still desired, antibiotic therapy should not be delayed.
- Spinal fluid analysis should always include glucose and protein measurement and a total and differential cell count.
- Depending on the clinical situation, other studies can be obtained, including microbial cultures, special stains, and cytology.

TREATMENT APPROACH

- Rapid recognition and stabilization of the patient suspected of having acutely increased ICP is essential in preventing greater morbidity and mortality.
- Goals of early management
 - Decrease ICP without compromising cerebral perfusion
 - Identify the cause so that definitive therapy can be provided
- Neurologically stable patients with evidence of chronically increased ICP
 - Management is directed toward definitive therapy.
 - Evacuation of the chronic subdural hematoma
 - Appropriate tumor management (corticosteroids, surgery or radiation plus chemotherapy or both)
 - Treatment with acetazolamide, loop diuretics, steroids, or lumbar drain in patients with more benign causes of intracranial hypertension

SPECIFIC TREATMENTS

Emergency management

- Assess the airway, breathing, and circulation (the ABCs).
- Obtain a urine dextrostick and, in the case of trauma, expose the patient completely to identify injuries.

- When acute increased ICP is suspected:
 - Stabilize the airway.
 - In most instances, this requires rapid, controlled intubation, taking care to minimize Valsalva maneuvers, which increase ICP further (albeit transiently).
 - Obtain intravenous (IV) access.
 - Use only isotonic solutions, minimizing fluids initially unless circulatory compromise is evident.
 - Measure the vital signs, and assess the neurologic state rapidly and frequently.
 - Position the head at 30 degrees, and maintain midline position if an injury to the cervical spine exists or is suspected.
 - Maintain adequate intravascular volume and blood pressure.
 - Maintain adequate oxygenation.
- Further interventions should be attempted on the basis of the clinical situation.
- The pediatric section of the Society of Critical Care Medicine and the World Federation of Pediatric Intensive and Critical Care issued evidence-based guidelines for acute medical management of severe traumatic brain injury in infants, children and adolescents.
 - These guidelines were adapted from previously published guidelines for adult traumatic brain injury treatment.
 - Interventions to treat intracranial hypertension described here are based on these guidelines.

Monitoring ICP and removing cerebrospinal fluid

- Monitor ICP, especially in traumatic brain injury.
 - Maintaining normal ICP allows maintenance of cerebral perfusion pressure (CPP), oxygenation, and metabolic substrate delivery and prevents cerebral herniation.
 - ICP-targeted protocols and therapies have clearly improved outcomes.
 - Guidelines recommend treatment goals to keep ICP <20 mm Hg and maintain CPP > 40 mm Hg.
- Numerous invasive devices are available to assess ICP.
 - Intraventricular catheters allow CSF drainage, reducing ICP.
 - The disadvantage is higher risk of infection, seizures, and hemorrhage compared with other available devices.
 - Fiberoptic catheter tip pressure transducers or strain gauge devices (Camino catheter or Codman catheter) placed within the brain parenchyma provides effective, continuous monitoring of ICP with minimal morbidity.
 - Intraparenchymal catheters that measure brain tissue oxygenation (PbO₂) and oxygen delivery (DO₂) (Licox catheter) and microdialysis catheters that allow measurement of substrates, such as pyruvate and lactate, enable monitoring for brain ischemia and can be used in conjunction with ICP monitoring.
 - Jugular bulb indwelling catheters enable measurement

of cerebral venous oxygenation.

- Transcutaneous and transcranial near infrared spectroscopy are used to assess ICP and cerebral perfusion indirectly and noninvasively.
- In severe traumatic brain injury, standard ICP and CPP monitoring often do not reflect true DO_2 .
 - Combination of ICP and PbO_2 monitoring (Licox) using PbO_2 -directed critical care are associated with improved outcomes.
 - High ICP correlates with decreased cerebral DO_2 .
 - Monitoring ICP and PbO_2 allows early recognition of low oxygen delivery states, enabling appropriate therapeutic interventions.

Hyperventilation

- Cerebral blood flow is exquisitely sensitive to carbon dioxide levels.
- Low carbon dioxide levels lead to cerebral vasoconstriction; elevated levels lead to dilation.
- Early hyperventilation (HV) of the patient with increased ICP decreases cerebral blood volume and ICP.
 - The most rapid, effective way to decrease ICP acutely
 - This effect is transient; therefore, other methods must be used to maintain normal or near-normal ICP.
- In general, carbon dioxide should be decreased to the low thirties (mm Hg).
 - Further decreases can lead to a significant decrease in cerebral blood flow, producing ischemia and increasing ICP.
- Failure to respond to HV is often a poor prognostic sign.
- Evidence suggests that the alkalizing effect of HV—and therefore decreased ICP—can be minimized with IV buffers, such as tris hydroxymethyl aminomethane.
- HV was recently called into question as possibly causing more harm than good.
 - HV induces a more pronounced change in cerebral blood flow than in cerebral blood volume.
 - This can lead to a reduction in oxygen pressure despite the beneficial effect on CPP and ICP.
 - One study found that aggressive HV had worse outcomes for patients with early, severe head trauma than for those who were normocapnic.
 - Although HV is the most rapid method to decrease ICP acutely, aggressive HV is not beneficial for long-term treatment.
- For intracranial hypertension refractory to other maneuvers, recent guidelines suggest considering:
 - Aggressive HV (carbon dioxide pressure <30 mm Hg) for short periods
 - Mild HV (carbon dioxide pressure 30–35 mm Hg)
- For longer periods, HV should be used judiciously with cerebral oxygenation monitoring if possible.

Osmotic agents and diuretics

- Intravenous osmotic agents (mannitol and glycerol) do not permeate the blood-brain barrier.
- Mannitol and glycerol are probably equally effective and may be complementary because of their different properties.
- They draw fluid from the intracellular brain compartment to the vascular space, reducing ICP and allowing increased cerebral perfusion.
- Traditionally, mannitol is favored over glycerol.
 - One study found that although mannitol decreased ICP, it did not improve cerebral oxygen pressure.
 - Mannitol is given rapidly in an initial IV bolus of 0.5–1 g/kg.
 - After administration, additional boluses 0.25–0.5 g/kg should be given every 2–5 hours, depending on the patient's status.
 - Response to IV mannitol is rapid and usually occurs within 10–20 minutes.
 - Serum osmolarity should be maintained in the 295- to 320-mOsm/L range.
 - Mannitol is excreted renally; thus, it cannot be given in renal failure because it can provoke potentially life-threatening pulmonary edema.
- Glycerol acts in a similar fashion but is used less often.
 - Glycerol has the advantage of being a physiologic agent with caloric value, which is beneficial for nutritional support.
 - Because glycerol has less diuretic effect and is not dependent solely on renal function, it can be given to patients with renal insufficiency.
 - The main side effect is intravascular hemolysis, which can be prevented by giving a low concentration (<20%) at a slow infusion rate (>1 hour).
 - Glycerol is most effective via enteroduodenal administration.
 - Direct oral intake or gastric tube administration is less effective.
 - Glycerol is usually given as a continuous drip.
- Loop diuretics, such as furosemide
 - Reduce ICP by provoking a diuresis of water and electrolytes, establishing a gradient between the intravascular compartment and the brain
 - Diuretics must be used cautiously in patients with traumatic brain injury and subarachnoid hemorrhage.
 - Volume depletion can worsen outcome.
 - Diuretics are frequently used in combination with osmotic diuretics but are infrequently used alone.
 - Care must be taken when using any of the aforementioned agents to maintain intravascular volume and adequate blood pressure.
 - Electrolytes must be monitored carefully.

Hypertonic saline

- A more recent treatment for increased ICP is IV administration of 3–23.4% hypertonic saline.
- IV boluses can reduce ICP and augment CPP for several hours.
 - Creates an osmotic gradient and draws water from the intracellular and extracellular spaces into the intravascular compartment
- Hypertonic saline can be given quickly and requires lower fluid volumes than osmotic agents.
- No immediate concern exists for volume depletion, as can occur with mannitol.
- Potential side effects
 - Hyperosmolar central pontine myelosis
 - Congestive heart failure
 - Subdural hematomas
 - Coagulopathy (rarely)
- The trauma guidelines recommend:
 - Continuous infusion of 3% saline between 0.1 and 1.0 mL/kg/hour
 - Administration on a sliding scale, with the minimal dose needed to maintain ICP under 20 mm Hg
- Serum osmolarity should be maintained below 360 mOsm/L when using hypertonic saline as the only hyperosmolar therapy, to control brain edema.

Neuromuscular blockade

- Pancuronium and vecuronium can effectively decrease ICP by preventing maneuvers that increase intrathoracic pressure, such as coughing, straining, or bucking the ventilator.
- These agents do not provide analgesia or sedation; they should be used in conjunction with analgesic agents and short-acting sedatives.

Temperature control

- Hyperthermia leads to greater cerebral metabolism; measures should be taken to prevent body temperature elevation.
- Includes judicious use of:
 - Antipyretics
 - Cooling blankets
 - Antibiotics if infection is suspected
- Hypothermia decreases cerebral metabolism and may be advantageous in managing increased ICP.
 - Shivering should be prevented and efforts made to maintain full cardiorespiratory function.
- Body temperature should be maintained between 96.8°F and 98.6°F (36°C and 37°C).

Seizure control

- Seizure activity (clinical or subclinical) places excessive metabolic demand on already compromised brain tissue.

- Treatment with antiepileptic drugs is necessary for any patient having or suspected of having seizures, especially if neuromuscular blocking agents are to be used.
 - To treat acute seizures
 - Diazepam (0.1 mg/kg/dose IV)
 - Lorazepam (0.05–0.1 mg/kg/dose IV)
 - For more prolonged therapy
- If possible, the cause of seizure activity (eg, fever, drug toxicity, hypoglycemia, electrolyte abnormalities) should be identified and treated.

Corticosteroids

- Corticosteroids remain controversial in managing acutely elevated ICP associated with:
 - Head trauma
 - Intracerebral hemorrhage
 - Ischemic stroke
- Several controlled studies involving glucocorticoids in head injury did not find any change in outcome or benefit for controlling increased ICP.
 - Thus steroids are rarely used to treat increased ICP in patients with head injury.
- Steroids do have clear utility in managing edema associated with:
 - Brain tumors
 - Refractory pseudotumor cerebri
- Mechanism of action is unknown, but hypotheses include stabilizing the blood-brain barrier, enhancing brain energy supplies, decreasing tumor growth, reducing CSF production, and stabilizing cellular membranes.
- Dexamethasone is generally used.

Glycemic control

- Hyperglycemia after head injury is associated with a poorer outcome than that for patients who are normoglycemic.
- Many centers now remove glucose from IV fluids and aggressively treat hyperglycemia.

High-dose barbiturates

- Treating refractory increased ICP with high doses of barbiturates can sometimes be effective.
- These agents decrease cerebral blood flow and metabolism.
- Pentobarbital is given for prolonged therapy.
 - IV loading dose of 3–10 mg/kg is given, followed by a maintenance infusion of 1–2 mg/kg/hour.
 - Dose should be titrated according to the electroencephalogram, with a goal of obtaining a burst-suppression pattern.
 - Therapy should be maintained for ≥24 hours and then tapered.
 - Side effects are frequent and include myocardial suppression and hypotension, often requiring pressors.

FIGURE 90. Irritant diaper dermatitis.

FIGURE 91. Candidal diaper dermatitis.

FIGURE 92. This figure demonstrates the interaction of adequate volume status (preload or central venous pressure) and contractility (cardiac output). **Point a** represents the situation in hypovolemic shock. Fluid administration increases preload and cardiac output increases. **Point b** is a patient with a high preload who would most likely have congestive signs on examination: rales, hepatomegaly, and a low cardiac output state. This condition might be caused by primary cardiogenic shock or with myocardial dysfunction in late stages of septic shock. Evidence of poor perfusion would be obvious on examination: cold clammy skin, prolonged capillary refill rate, and thready, rapid pulses. The restoration of acid-base, glucose, calcium, and magnesium homeostasis and the addition of inotropic agents can improve cardiac patients and return function toward normal. Notably, infants' resting cardiac output is near the maximum, and infants rely on increasing heart rate, whereas adults increase cardiac output by mechanisms intended to increase stroke volume. **Point c** is a patient who is vasodilated, with hyperdynamic cardiac output and relatively low cardiac preload. This scenario would occur in distributive forms of shock: anaphylaxis and septic shock. This state would be reflected in the physical examination by presence of flash capillary refill, bounding cardiac pulses, and a hyperdynamic precordium with tachycardia.

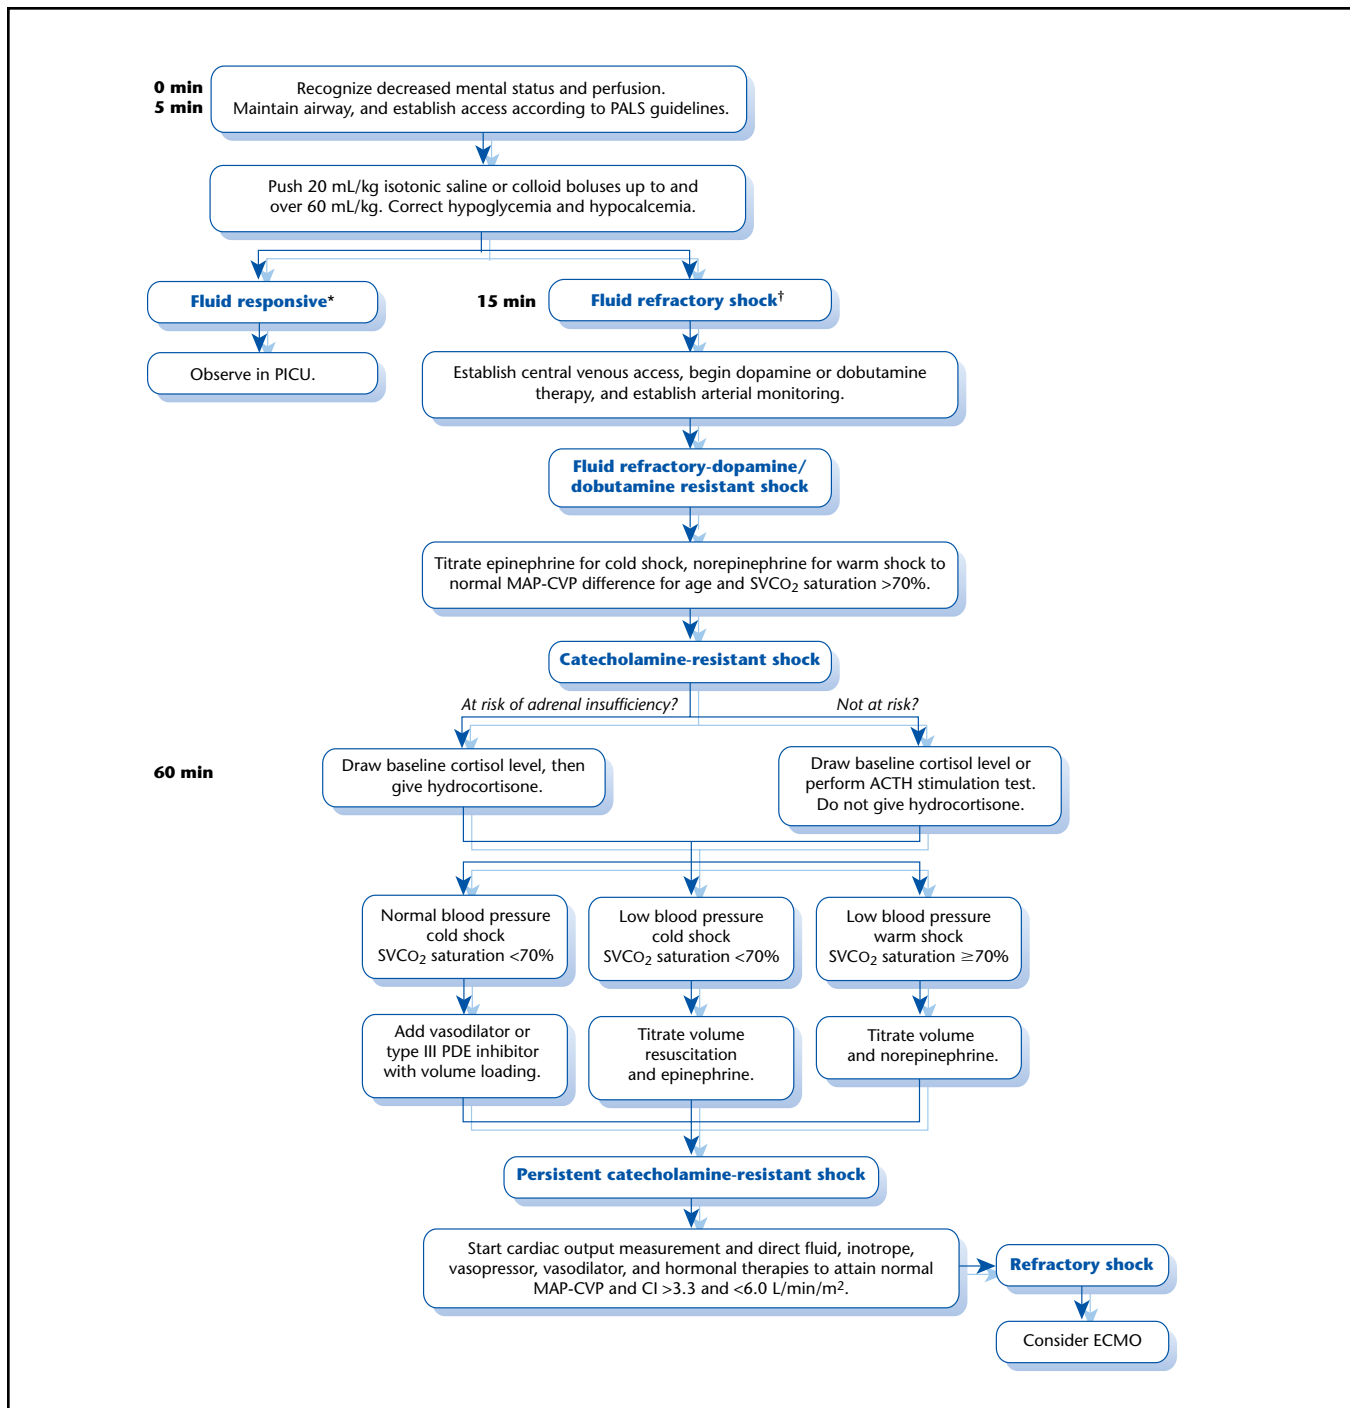

FIGURE 93. American College of Critical Care Medicine Pediatric Advanced Life Support (ACCM-PALS) guidelines for children in septic shock. The 1st hour of care can be crucial to outcome and is easily accomplished in the primary care setting. Recommendations are presented for stepwise management of hemodynamic support in infants and children with goals of normal perfusion and perfusion pressure (MAP-CVP). Proceed to next step if shock persists.

*Normalization of blood pressure and tissue perfusion.

FIGURE 96. Condylomata acuminata appear as skin-colored papules and plaques.

- It is not yet known which patients with refractory increased ICP benefit from this therapy.
- Pentobarbital should be used only when all other medical and surgical therapies failed.

Surgical decompression

- Removing large intracranial masses causing acutely increased ICP can be life saving.
- Surgery may play a role:
 - In decreasing ICP in select patients with large intracerebral hemorrhages by removal of clot
 - In trauma patients with massive edema and contusion
 - In patients who have a large cerebral infarction through craniectomy or decompression of the edematous mass
 - In the latter 2 instances, surgery is performed after all other measures have failed and increased ICP becomes refractory.
 - Surgery should be considered before the ICP critically impairs the CPP.
- Trauma guidelines recommend considering decompressive craniectomy to treat:
 - Severe traumatic brain injury
 - Medically refractory intracranial hypertension, particularly when a potentially recoverable brain injury occurs
- Craniotomy has shown to be effective in reducing ICP and can be associated with favorable outcomes in surviving patients.
 - Mortality in children with severe traumatic brain injury remains high.

Pseudotumor cerebri

- Management is based on symptoms (intractable headache) or when signs of papilledema or visual loss are detected.
- Patients in whom medical therapy fails or those experiencing progressive visual loss may be considered for surgical treatment that includes:
 - CSF shunting procedures (ventriculoperitoneal, ventriculoatrial shunts, or lumboperitoneal shunt) *or*
 - Optic nerve sheath fenestration
- LP is recommended to document opening CSF pressure and may be used therapeutically to decrease ICP by draining CSF.
- Medical management includes carbonic anhydrase inhibitors (acetazolamide) to decrease CSF production.
- Digoxin has been suggested as a similar alternative with the same effect but lesser side effects.
- Patients with severe symptoms or visual loss and those in whom standard medical therapy is failing may benefit from a short course of high-dose corticosteroids (prednisone).

Future trends

- In the future, cerebral protectants may be part of the cocktail in the initial emergent management of acutely increased ICP.
 - Free radical scavengers
 - Excitotoxic amino acid antagonists
 - Lazeroids
 - N-methyl-D-aspartate-receptor antagonists

WHEN TO ADMIT

- Bulging fontanelle
- Altered mental status
- Prolonged seizures
- New focal neurologic deficits
- Moderate to severe papilledema
- Cushing triad (widened pulse pressure; bradycardia; and deep, slow respirations)

WHEN TO REFER

- Macrocephaly or accelerating head growth (crossing percentiles)
- Chronic unremitting headache or new onset of severe headache
- Mild papilledema
- Visual abnormalities (field cuts, diplopia)
- Developmental arrest or regression

COMPLICATIONS

- Herniation of uncus or cerebellar tonsils

PROGNOSIS

- Increased ICP is a major complication that affects morbidity and ultimate outcome in:
 - $\geq 50\%$ of children with severe head injuries
 - Children who are comatose from other cerebral insults (hypoxia, infections, metabolic disorders)
- Which variables—ICP, CPP, or initial Glasgow Coma Scale score (see table)—are helpful in predicting prognosis remains uncertain.
- Regardless, significant morbidity remains for children with increased ICP.
- Early identification and treatment before a catastrophic increase in ICP will improve outcome in select children with mass lesions or treatable metabolic disorders.

Glasgow Coma Scale^{a,b}

Eye-Opening Response			
Score	>1 Year	<1 Year	
4	Spontaneous	Spontaneous	
3	To verbal command	To shout	
2	To pain	To pain	
1	None	None	
Motor Response			
Score	>1 Year	<1 Year	
6	Obeys commands	Displays spontaneous response	
5	Localizes pain	Localizes pain	
4	Withdraws from pain	Withdraws from pain	
3	Displays abnormal flexion to pain (decorticate rigidity)	Displays abnormal flexion to pain (decorticate rigidity)	
2	Displays abnormal extension to pain (decerebrate rigidity)	Displays abnormal extension to pain (decerebrate rigidity)	
1	None	None	
Verbal Response			
Score	>5 Years	2–5 Years	0–23 Months
5	Is oriented and converses	Uses appropriate words and phrases	Babbles, coos appropriately
4	Conversation is confused	Uses inappropriate words	Cries, but is consolable
3	Words are inappropriate	Cries or screams persistently to pain	Cries or screams persistently to pain
2	Sounds are incomprehensible	Grunts or moans to pain	Grunts or moans to pain
1	None	None	None

^a Modified from: Teasdale G, Jennett B. Assessment of coma and impaired consciousness: a practical scale. *Lancet*. 1974;304(7872):81–84. Copyright © Elsevier 1974.

^b Glasgow Coma Scale score equals sum of best eye opening, motor, and verbal responses. Range is 3–15. Usual definitions of severity of head injury: severe, ≤9; moderate, 9–12; mild, 13–15.

Injury Prevention

BACKGROUND

- Injury is the most significant health problem of childhood and adolescence.
- Injuries cause a majority of deaths of children and adolescents aged 1 to 19 years.
- The major causes of nonfatal injury encompass those that produce fatal injury; these include
 - Motor vehicles
 - Firearms
 - Drowning
 - Suffocation
 - Fires
- Injury results in:
 - Acute morbidity
 - Short- and long-term disability
 - High medical care costs
- Although leading causes of injury death vary by age group, events involving the following are important in every age group:
 - Falls
 - Burns
 - Poisonings
 - Fights
 - Sports
- Injuries are often classified as unintentional or intentional.
 - Strategies that prevent unintentional injury may also prevent some intentional injuries:
 - Locking up firearms
 - Turning down the water heater temperature
 - Some forms of intentional injury are so important as causes of pediatric morbidity and mortality that they demand focused attention:
 - Child abuse
 - Child and adolescent suicide
 - Homicide
 - Causes of intentional injury are extremely complex.
- The number of unintentional childhood injury deaths has been decreasing, partially as a result of the hard work of pediatricians and public health professionals.
- For almost all types of injury, boys are at greater risk than girls.
 - Not yet fully explained but may stem from several factors, including:
 - Innate behavioral differences
 - Societal expectations
 - Exposure
- Children living in poverty are more likely to suffer serious and fatal injury of many types than advantaged children.

GOALS

- Injury control includes:
 - Preventing events that might cause injury
 - Diminishing the likelihood or severity of injury, even though events with injury-causing potential occur
 - Minimizing the after effects of the injury through:
 - State-of-the-art emergency response
 - Medical care
 - Rehabilitation
- Role of the pediatrician:
 - To persuade individuals to decrease risk of injury through education and behavior change strategies
 - To become involved with injury-control advocates through the following activities:
 - Media campaigns
 - Legislation
 - Regulation
 - Litigation
 - Environmental design
 - Cultural change
 - To become involved in research to:
 - Identify risk and protective factors for injury
 - Evaluate preventive interventions
 - For most causes of injury, multiple strategies will need to be applied.

GENERAL APPROACH

- Prevention strategies
 - Active strategies
 - Require involvement of the child or the child's parent every time protection is needed.
 - Example: Seat belts in automobiles
 - Require compliance, but may not be fully used
 - Often least likely to be adopted by the persons at greatest risk
 - Passive (or automatic) strategies
 - Protect the individual whether the person needing protection is mindful of the need and takes appropriate action or not.
 - Example: Automobile airbags
 - Usually favored over active strategies
- Events leading to injury are usually predictable and preventable.
 - Should not be considered as *accidents*, implying a sense of randomness and lack of preventability
 - In some instances, prevention is achieved through:
 - Eliminating injury-producing events
 - Example: building divided highways to reduce motor vehicle crashes

- Eliminating injury even though the event takes place
 - Example: protecting passengers by restraining them in car safety seats
- When energy affects the body acutely at a damaging level, injury results.
 - For most pediatric injuries, the energy is mechanical.
 - Other agents of injury include:
 - Thermal energy
 - Chemical energy
 - Radiation
 - Electrical energy
- Injury prevention
 - Keep energy away from the child.
 - Example: building a bicycle path as an alternative to riding on streets
 - Diffuse energy transfer to tissue over time and/or space so that it does not reach damaging levels.
 - Example: use of bicycle helmet
 - Helmet absorbs and dissipates the forces of the impact.
 - Brain is exposed to a lower level of energy over a longer period.
- Injury-control strategies
 - May be categorized in several ways.
 - Haddon's matrix (see table Haddon's Matrix and Examples of Variables and Injury Prevention Interventions) places strategies in a framework according to:
 - Phase
 - Pre-event
 - Event
 - Post-event

- Factor
 - Human
 - Vector or vehicle
 - Physical environment
 - Socioeconomic environment
- Comprehensive injury-prevention efforts incorporate interventions from multiple matrix cells.

SPECIFIC INTERVENTIONS

Education, engineering, and enforcement

- Education: the most familiar approach to prevention
 - Examples include:
 - Counseling during health supervision visits
 - Public education campaigns
- Engineering: modifying a hazard or the environment to
 - Prevent injuries
 - Reduce the severity of injuries
 - Enactment and enforcement of legislation and regulation can
 - Motivate people to adopt safety-promoting behaviors
 - Require environmental modifications to reduce hazards
 - Facilitate changes in social norms
- Injury prevention is usually most effective when all 3 approaches are incorporated.
 - Example: bicycle helmet use can be promoted through
 - Education in schools
 - Design of more comfortable or attractive helmets
 - Local laws or ordinances requiring helmet use

Haddon's Matrix and Examples of Variables and Injury Prevention Interventions^a

Phase	Epidemiologic Dimension			
	Human	Vector or Vehicle	Physical Environment	Socioeconomic Environment
Pre-event	Judgment Coordination	Safe storage of firearms Infant walker ban	Bicycle paths Swimming pool barriers	Speed limits Graduated driver licensing
Event	Car safety seat use Use of protective equipment	Airbags Energy-absorbing surfacing on playgrounds	Smoke alarms Highway guard rails	Helmet laws Enforcement of seat belt laws
Post-event	Age Physical condition	Activated charcoal Fuel system integrity	Time to emergency treatment Availability of rehabilitation programs	Training of emergency medical system personnel Cardiopulmonary resuscitation training

^aAdapted from: American Academy of Pediatrics, Committee on Injury and Poison Prevention. *Injury Prevention and Control for Children and Youth*. 3rd ed. Elk Grove Village, IL: American Academy of Pediatrics; 1997; and Pedialink continuing medical education course, Moving Kids Safely: Introduction to Car Safety Seats.

Injury prevention counseling

- Scientific evidence of positive outcomes in clinical practice.
- Evidence for effectiveness of injury-prevention counseling is stronger in some areas than others, prompting continual calls for:
 - Additional research
 - Improvements in counseling
 - Investment in more passive injury-control strategies
- Counseling is a cornerstone of pediatric practice, but can be daunting.
 - Requires time and expertise
 - Sources of possible injury are very diverse.
 - A pediatrician cannot counsel on all possible risks.
- Injury-prevention can be prioritized based on:
 - Severity of the injury
 - Frequency with which the injury occurs
 - Availability of effective preventive strategies
- Pediatricians will want to:
 - Be sensitive to individual circumstances of patients and families.
 - Customize anticipatory guidance.
 - Recognizing different needs of farm versus city families, various ethnicities
 - Discussing drowning risk if a family has a boat or backyard swimming pool
 - Counseling a family that has 2 automobiles about car safety seats
- The AAP recommends that parents be given advice by the pediatrician about various injury issues, depending on the age of the child
 - Infants
 - Traffic safety: Appropriate use of car safety seats rear-facing in the back seat
 - Burn prevention: Smoke alarms, hot water temperature no higher than 120°F
 - Fall prevention: Window and stairway guards and gates, avoiding walker use
 - Choking and strangulation prevention: Keeping small objects and balloons or plastic bags away from infants, blind and drapery cord safety
 - Drowning prevention: Supervising baths, emptying buckets
 - Safe sleep environment: Back to sleep in a crib that meets current safety standards
 - CPR training: Parent knowledge of infant or child CPR and local emergency medical services (911)
 - Preschoolers
 - Traffic safety: Appropriate use of car safety seats, not leaving children unsupervised in or around cars
 - Burn prevention: Smoke alarm batteries; keeping children away from hot objects
 - Fall prevention: Window and stairway guards and gates; preventing furniture tip-overs
 - Poison prevention: Storage of poisons; poison control phone number (1-800-222-1222)
 - Drowning prevention: Pool fencing; *touch supervision*
 - Firearm safety: Preferably keeping firearms out of the home or at least keeping firearms unloaded and locked separately from locked ammunition
 - School-aged children
 - Traffic safety: Booster seat and seat belt use, avoiding riding on ATVs and in the beds of pickup trucks; safe pedestrian practices; helmets for biking
 - Water safety: Swimming lessons, but no swimming alone; personal flotation devices for boating
 - Sports safety: Safety equipment, physical conditioning, and protective equipment for rollerblading and skateboarding
 - Firearm safety: Preferably keeping firearms out of the home or at least keeping firearms unloaded and locked separately from locked ammunition; asking about firearms in other homes the child visits
 - Adolescents
 - Traffic safety: Seat belt use, role of alcohol in motor vehicle crashes, and minimizing distracted driving; graduated driver licensing; rules for teenage drivers; helmets for biking, motorcycling, and riding an ATV
 - Water safety: Role of alcohol and other drugs in water-related injuries; personal flotation devices for boating
 - Sports safety: Safety equipment; physical conditioning
 - Firearm safety: Preferably keeping any firearms out of the home or at least unloaded and locked separately from locked ammunition
- Counseling about any injury-prevention topic requires both knowledge and counseling skill.
- Counseling technique is not specific to injury prevention.
- Approach can be adapted from existing methods for prompting and supporting healthy behavior change (eg, motivational interviewing).
- Traffic safety is a lifetime issue
 - Car safety seats (see table Appropriate Car Safety Seat Selection Based on Child's Age, Height, and Weight)
 - Motor vehicle crashes are the leading cause of death of children and adolescents.
 - Topic warrants frequent discussion during well-child care.
 - Pediatricians should know how to counsel parents on appropriate car safety seat selection based on developmental milestones.
 - Know where to refer parents for more information.
 - Be familiar with state laws.

Appropriate Car Safety Seat Selection Based on Child's Age, Height, and Weight

If the child is...	Use the following type of car safety seat...	And remember the following...
Younger than 1 year OR under 20 lb	Rear-facing car safety seat (infant-only or convertible)	NEVER place a rear-facing car safety seat in the front seat with an airbag.
Older than 1 year AND over 20 lb	Recommended: rear-facing convertible seat to seat's height or weight (usually 30 or 35 lb) limit Then: forward-facing car safety seat (convertible, combination, or forward-facing only) to seat's height or weight limit	When switching a convertible seat from rear-facing to forward-facing, adjustments are usually needed to the harness, the angle of the seat, and the seat belt.
Too tall or heavy for a forward-facing seat with a harness (often around 4 years of age or 40 lb)	Booster seat	Booster seats must be used with lap and shoulder belts.
Big enough to fit in the adult seat belt (usually around 4' 9" and between 8 and 12 years of age)	None. Use the vehicle's seat belt if it fits properly (shoulder belt across chest and shoulder, lap belt low and snug on thighs, child's back against vehicle seat back and knees bent at edge of vehicle seat).	Children should sit in the back seat until they turn 13 years of age.

^a Adapted from: American Academy of Pediatrics, Committee on Injury and Poison Prevention. Selecting and using the most appropriate car safety seats for growing children: guidelines for counseling parents. *Pediatrics*. 2002;109(3):550-553.

- Recognize when state laws often do not reflect best practice in car safety seat use.
- Encourage parents to:
 - Read instruction manuals for their car safety seats and vehicles.
 - Learn how to install and use car safety seats.
- Refer parents to local *child passenger safety technicians*.
- A staff member can complete the 3- to 4- day training course to become a certified technician.
- Teen drivers
 - Motor vehicle–related death rates increase dramatically in adolescence.
 - Novice teen drivers and their passengers are at particularly high risk.
 - Pediatricians can play a key role in helping parents and teens:
 - Negotiate their changing relationship
 - Balance the need to ensure the teen's safety with the teen's growing independence and increasing mobility.
 - Pediatricians should be familiar with their states' laws.
 - A state's graduated driver licensing (GDL) system may provide a good starting point for counseling.
 - Under GDL, teen drivers graduate from a learner's permit to an intermediate/provisional license to a regular driver's license after a required amount of time and demonstration of proficiency.
 - Each stage has its own restrictions.
 - Both parents and teens should be counseled on:
 - Seat belt use
 - Dangers of impaired driving
- Teens and parents should also be encouraged to have a safe ride agreement
 - Teen promises to call the parent rather than driving while impaired or with another impaired driver.
 - Parent agrees to provide a ride home in a nonjudgmental way.
- Pediatricians can consider having a family develop a parent-teen driving contract that:
 - Specifies restrictions on teen drivers
 - Determines when restrictions will be relaxed
 - Outlines the consequences for violating the restrictions
- Firearms
 - Second leading cause of death of children and adolescents
 - Pediatricians are often reluctant to counsel on this topic because of concerns about parent reactions.
 - Parents may view such counseling as intrusive or outside the purview of pediatrics.
 - Strategies are available that can make counseling on firearms more palatable to both parents and pediatricians.
 - Families with infants and toddlers
 - Discuss firearms in the context of childproofing and children's natural curiosity.
 - Parents of depressed adolescents
 - Discuss association between presence of firearms in the home and higher risk of teen suicide.
 - Introduce the concept of asking about the presence of guns in other homes where their children spend time.

Insect Bites and Infestations

DEFINITION

■ Insect bites and stings

- Insects and arachnids (mites, ticks, and spiders) are often vectors of serious or fatal disease.
 - Viral encephalitis
 - Malaria

■ Infestation

- Pediculosis (lice)
 - Capitis (scalp)
 - Palpebrum (eyelashes)
 - Corporis (limbs and trunk)
 - Pubis (pubic area)
- Scabies
 - Highly pruritic dermatosis caused by mites

EPIDEMIOLOGY

■ Insect bites

- Worldwide, malaria is still one of the most common causes of serious childhood morbidity and death.
- Ticks
 - Most common insect vectors of disease in the US (Lyme disease and other infections)

■ Infestation

- Bedbug infestations
 - Incidence has increased.
 - Epidemic in urban US
- Pediculosis capitis
 - Outbreaks occur mainly among school-age children.

ETIOLOGY

■ Pediculosis

- Lice are obligate human ectoparasites that create pruritic dermatoses after their bites puncture the skin and inject saliva.
 - The saliva incites inflammation and sometimes hypersensitivity.
 - Lice can transmit diseases, including typhus.
 - Head lice are spread primarily by close personal contact and occasionally by fomites.
 - Body lice are primarily spread by clothing.

■ Scabies

- Infestation with the mite *Sarcoptes scabiei hominis*, causes scabies.
 - The burrowing of the female mite into the stratum corneum initiates infestation.
 - Eggs are laid within the stratum corneum.
 - Over the next 2–6 weeks, itching and papules develop gradually as the eggs hatch and the host develops delayed hypersensitivity.

- Generally spread by close personal contact
 - Usually through persistent or repeated skin-to-skin contact, such as individuals sleeping in the same bed or holding a child closely

RISK FACTORS

■ Infestation

- Sleeping in the same bed or otherwise maintaining close contact
- Pediculosis pubis is often sexually transmitted.

SIGNS AND SYMPTOMS

Insect bites

- Discrete, erythematous or flesh-colored papules, nodules, or wheals
 - Some bites have central puncta or vesicles; others are capped by pustules or by hemorrhagic or serous crusts.
 - Usually pruritic
 - Excoriations created by scratching are common.
- Often clustered
 - Linear or arcuate pattern, especially when caused by a crawling insect
 - Most commonly found on surfaces not covered by clothing
- Sensitized child (prior exposure)
 - Larger nodules or blisters are a robust reaction to insect- or arachnid-associated toxins.
- Unsensitized child
 - Discomfort varies from mild itch to pain caused by toxin injection.

Pediculosis

■ Pediculosis capitis

- Grayish, crawling, 6-legged louse may be seen in areas of thick terminal hair growth close to the scalp.
 - Louse eggs (nits) may be seen as minute, white-gray fixed attachments to hair shafts.
 - Nits or the insects themselves may be visible on the eyelashes or pubic hair.
- Pruritus
 - Sometimes accompanied by erythematous papules (bites), 1–2 mm in diameter
 - Noted around the nape of the neck and the hairline, especially posteriorly
- Other possible signs
 - Cervical adenopathy
 - Urticaria-like changes
 - Involvement of other body areas
- Family members
 - Should be examined for head lice, especially if combs, towels, and other personal items are shared

- Pediculosis pubis
 - Often sexually transmitted
 - Affected individuals may have othersexually transmitted infections.
- Pediculosis corporis
 - Should be suspected when widespread pruritus is present
 - In most instances, the body louse and nits are not found on the body but in the seams of clothing or bedding.
 - Bites consist of erythematous macules and papules, which are often obscured by the results of scratching.
 - Excoriation
 - Impetiginization
 - Eczematization
 - Overt infection
 - Pigmentation

Scabies

- Highly pruritic dermatosis
 - In the setting of worsening or persistent widespread pruritus, a diagnosis of scabies must be considered, especially if close contacts are also itching.
 - The distribution of skin changes is often the best clue to the diagnosis along with itching that is more widespread than the objective skin findings.
- Varied and protean manifestations
 - Ranges from rare scattered erythematous papules to widespread eczematous dermatitis and excoriations
 - Multiple areas of mite-laden, crusting, possibly infectious complications of any presentation (Norwegian scabies)
 - As eggs hatch, repeated infestation of host leads to more rapid development of itching and other manifestations, often within 24–96 hours.
- Common sites of infestation
 - Digital web spaces
 - Extensor surface of the elbows and knees
 - Flexor aspect of the wrists
 - Axilla
 - Upper trunk
 - Groin
- Infants
 - Involvement of palms and soles, especially with vesicles
 - Skin changes on the face and head
- Burrows created by female mites
 - Help establish diagnosis in some patients
 - Often disguised by excoriations, eczematous reactions, or superimposed infection

- Family members, sexual partners, and other close contacts of index cases should be examined when possible.
 - The patient's history may reveal that several people in a household are itching.
 - Fomites rarely transmit scabies, especially in temperate climates.
 - Although humans may acquire subspecies of scabies mites that infest other mammals, such infestation is self-limiting, as other mite subspecies do not reproduce in human skin.

DIAGNOSTIC APPROACH

- Insect bites
 - Discrete, erythematous, or flesh-colored papules, nodules, or wheals, usually pruritic, suggest the diagnosis of insect or arachnid bites.
- Infestation
 - In pediculosis, the louse and/or nits will be found.
 - Worsening or persistent widespread pruritus suggests scabies.
 - Especially if close contacts are also itching
 - Distribution of skin changes (eg, digital web spaces) is also a clue.

LABORATORY FINDINGS

- Light microscopy
 - Diagnosis of scabies in infants
 - A drop of mineral oil is placed on the skin.
 - Scrapings of burrows or papules from palms or soles are removed by scalpel.
 - Confirmatory ova, mites, or feces are revealed under low magnification.

TREATMENT APPROACH

- Insect bites
 - Topical corticosteroid creams
 - Oral antihistamines
- Pediculosis
 - Head lice
 - Physical removal is as effective as drug treatment.
 - Chemical treatments should be avoided in infants.
 - Body lice
 - 5% permethrin cream
 - All methods depend on following instructions carefully.
 - All methods will need to be repeated.
 - Clothing, bedding, towels, etc must be washed in hot water.
- Scabies
 - Should be treated regardless of symptoms
 - 5% permethrin to the entire body, except the face

SPECIFIC TREATMENTS

Insect bites

- Topical corticosteroid creams plus oral antihistamines
 - Primary treatment
 - Reduces inflammation and pruritus
- Topical antipruritics (calamine) and cold soaks/ice
 - Soothing
- Topical antihistamines should be avoided.
 - Ineffective
 - May cause allergic contact dermatitis
- Oral systemic corticosteroids (rare cases)
 - Sometimes indicated for:
 - Extensive bites
 - Hypersensitivity manifesting as papular urticaria or in other ways that involve >20% of the body
 - ≤1-week course of approximately 0.5 mg/kg of prednisone or equivalent
 - Longer-term or chronic treatment is not indicated for this circumstance alone.
 - Topical therapy should be started at the same time.
 - Prevents rebound phenomenon
 - All contraindications must be excluded.
 - The risk of adverse events, although small with brief treatment courses, must be considered.

Pediculosis

- Head lice, pubic lice
 - Physical removal of lice and eggs
 - Careful, repeated removal of head lice has shown superior results to drugs, even malathion.
 - Kits are available.
 - Chemical treatment
 - Resistance to chemical agents is increasing.
 - Chemical treatments are used only with great caution by pregnant or nursing women and should be avoided by persons with allergies to any component of the treatment.
 - Infants should not be treated unless essential and only with very close supervision.
 - Pyrethrins
 - Several nonprescription preparations are available.
 - Nix cream rinse contains 1% permethrin.
 - A fine-toothed comb can be used to remove nits from hair shafts after chemical treatment.
 - Retreatment is usually necessary about 1 week after the first application to kill lice that have hatched from viable nits that were not killed initially.
- Malathion 0.5% solution
 - Must be left on for 8–12 hours
 - Flammable
- Dimethicone 4%
 - Recently found to be effective
- Other insecticides
 - Lindane (gamma-benzene hexachloride [GBH]) is more toxic and probably less effective with much resistance and should only be used when all other treatment options have failed.
 - California has banned lindane for human use because of its neurotoxicity.
 - Oral ivermectin
 - 2 doses given 7 days apart are effective for treatment of several kinds of lice infestation.
 - This application is an off-label use.
- Body lice
 - Total-body application of 5% permethrin cream (Elimite) for 8–14 hours
 - May be necessary to apply to the hair
 - A limited number of treatments spaced approximately 7 days apart may be required for eradication, using various pediculicides, such as:
 - Permethrin
 - GBH
 - Pyrethrins
 - Vinegar rinse to remove stubborn nits
 - Pruritus
 - May continue for ≥2 weeks after treatment
 - Patients should be advised that itching might continue, so that they do not overtreat themselves through repeated applications.
 - Oral antipruritics, soothing bland lotions, and topical corticosteroids can help.
- Pediculosis palpebrarum
 - Apply plain petrolatum to the eyelashes 3–5 times daily.
 - Treatment is required for approximately 8–10 days.
 - A moustache comb can be used daily to remove lice and nits from the eyelashes.
 - Other infested body areas should be treated simultaneously.
 - If this method fails, physostigmine 0.25% may be similarly applied to eyelashes.
 - Usually curative in 3 or 4 days, but may interfere with vision.

- All potentially infested items should be treated with wet or dry heat (or both)
 - Minimum of 65°C (149°F) for minimum of 15 min (preferably at least 30 min)
 - Clothing
 - Bedding
 - Combs
 - Towels
 - Clothing, stuffed animals, comforters, and other items that cannot be washed or dry cleaned:
 - Store in a sealed plastic bag for 2 weeks.

Scabies

- Should always be treated, regardless of symptoms
 - Patients may be asymptomatic carriers.
 - Chemical treatments are used only with great caution in:
 - Pregnant or nursing women
 - Infants
 - Persons with allergies to any component of the treatment (should be avoided)
- Permethrin 5%
 - Thorough application to the entire body, except the face
 - Treatment of choice because of high efficacy and relatively low toxicity
- Alternate treatments
 - Lindane or a similar GBH preparation
 - Probably less effective than permethrin
 - Lindane is associated with irritant dermatitis.
 - GBH is associated with adverse reactions and toxicity.
 - Should be dispensed in limited quantities and used only when other treatment options have failed.
 - Parents should be informed about possible neurotoxicity and other complications from organophosphate exposure.
 - Repeated treatments, especially when based only on symptoms, should be actively discouraged.
 - Crotamiton 10% (Eurax)
 - Probably less efficacious
 - Must be applied at least twice
 - Benzyl benzoate
 - Widely used as an inexpensive emulsion, sometimes recommended by the World Health Organization
 - Not available in the US.
- If topical treatment fails or is not feasible
 - Oral ivermectin
 - Highly effective used at appropriate dosing for weight
 - Off-label indication, but widely used for scabies

- Published clinical data in young children are limited
- 2 doses, separated by approximately 1–2 weeks, may be necessary.
- All potentially infested items should be washed immediately after treatment of all individuals in the same household.
 - Minimum of 65°C (149°F) for minimum of 15 min (preferably at least 30 min)
 - Clothing
 - Bedding
 - Combs
 - Towels
- Pruritus and rash
 - Often persist for ≥ 2 –4 weeks after successful eradication of an infestation
 - Treatment should be repeated only when continued infestation with live mites is clearly demonstrated.
 - Pruritus can be treated with oral antihistamines or mild topical agents, such as emollients, pramoxine, or very minimal concentrations of menthol.
 - Nodular scabies, postscabetic nodules
 - Hypersensitivity reaction
 - Red to purple discrete nodules up to 2 cm in diameter on surfaces usually covered by clothing
 - Usually on the genitals or around the axillae
 - Usually respond to topical or intralesional injections of corticosteroids

WHEN TO ADMIT

- The patient has severe systemic allergic reactions to insect bites.
- The patient needs intravenous antibiotics to treat secondary bacterial infection or cellulitis.
- The patient develops noninfectious complications, such as:
 - Acute postinfectious glomerulonephritis
 - Hypertension
- Patient is suspected of having contracted:
 - Viral meningitis
 - Other severe or systemic illness through insect bites

WHEN TO REFER

- Refer to an allergist if:
 - The patient develops a severe allergic reaction to insect bites, especially repeatedly.
 - Hymenoptera allergy is suspected.

COMPLICATIONS

Insect bites

- Infection
 - Impetigo
 - Cellulitis
- Eczematous changes
 - Inflamed plaques
 - From scratching
 - From topical remedies that cause irritant or allergic contact dermatitis, eg, neomycin
- Localized hypersensitivity reactions
 - Papular urticaria
 - Recurrent crops of urticarial (hive-like) papules, nodules, or wheals on exposed surfaces; may be either new or reactivated old bites
 - Occurs in some sensitized individuals
 - Can last weeks or months
 - The patient experiences profound itch, especially if repeatedly scratched or otherwise traumatized.
 - Scratching can leave scarring or postinflammatory pigment change, most often hyperpigmentation.
- Systemic reactions
 - Viral encephalitis or tick-borne disease
 - More thorough follow-up
 - Consideration of hospital observation
 - Bacterial infection
 - Can lead to cellulitis or a multitude of toxin-induced or immune-mediated complications, such as nephritis

Infestation

- Bacterial infection
 - Toxin-producing strains
- Cellulitis
- Systemic treatment may be necessary.
 - Especially in immunosuppressed children

PREVENTION

- Insect bites
 - Cover as much of the body as possible with clothing.
 - Judicious use of repellents
 - *N,N*-diethyl-metoluamide (DEET) at exposed areas (avoiding children's hands, eyes, and mouth areas)
 - DEET can cause central nervous system and systemic symptoms in children.
 - Usually safe to use intermittently and in moderation at concentrations $\leq 30\%$ in children >2 months.
 - Alternate repellents may be less effective or toxic.
 - Mosquitoes
 - Avoid potential attractants, such as bright clothing.
 - Use of bed nets impregnated with repellents can be extremely effective in preventing bites.
- Infestation
 - Pediculosis
 - No-nit policies aimed at excluding children from school are ineffective.
 - Such policies penalize children excessively by causing missed school days.

Intellectual Disability

DEFINITION

■ *Intellectual disability* is the preferred synonym for mental retardation.

- The recent change from the term *mental retardation* to *intellectual disability* does not match the current legal definition for entitlement to services for individuals with intellectual disability.
- However, for individuals who meet diagnostic criteria, the label of mental retardation remains essential to obtaining educational and social services.
 - Therefore, primary care physicians should continue to use this term to assist clients in obtaining appropriate supports.

■ American Association on Intellectual and Developmental Disabilities (AAIDD) guidelines for the accurate use of the term *intellectual disability*

- The level of functioning of an individual should be considered within their particular social and cultural context.
- Any assessment of cognitive and adaptive ability should take into account communication, as well as sensory, motor, and behavioral functioning.
- An individual's strengths must be emphasized in assessments and included in support plans.
- The purpose of assessing limitations is to guide the development of appropriate supports for the individual in question.
- The provision of individualized supports is expected to improve functioning significantly.

■ The AAIDD defines intellectual disability as impairments in cognitive functioning and adaptive behavior that develop before age 18 years.

- *Cognitive impairment* is defined as performance in the abnormally low range on standard assessments of intelligence.
 - Cognitive impairment implies significantly low scores in all domains of intelligence testing.
 - Widely discrepant scores in various domains would be best defined as learning disability, not intellectual disability.
- Adaptive impairment is defined by functioning in the abnormally low range on formal measures of adaptive functioning, eg, Vineland Adaptive Behavior Scales.
 - Includes such domains as communication, self-care, home living, social or interpersonal skills, ability to use community resources, self-direction, functional academic skills, work, leisure, health, and safety

■ Implicit is the understanding that, although cognitive and adaptive impairments are not reversible, intellectual disability can be ameliorated by environmental modifications and supports.

■ *Developmental delay* reflects functioning at <75% of expectations for chronologic age in a particular developmental domain.

- Some children experience this development in a single domain, whereas others have delays in multiple or all domains.
- Conceptually, this term suggests the child will at some time make up the delay.
 - Catch-up frequently occurs in the case of delays in isolated domains.
 - The child who is delayed in all domains, frequently described as having *global developmental delay*, is less likely to catch up.
- In general, psychologists are hesitant to describe children as having intellectual disability until they are approximately at the age of school entry.
 - This hesitation allows parents to focus on interventions that maximize the child's potential while de-emphasizing what the child cannot accomplish.

ETIOLOGY

- In most cases of mild intellectual disability, the cause is multifactorial.
 - No single cause is identified or identifiable.
- In moderate to severe intellectual disability, a single cause may be identified by systematic investigation.

SIGNS AND SYMPTOMS

Intellectual disability, by level of function

■ Mild

- IQ: 55–70
- 5th-grade academics by 18 years of age
- Support level: intermittent
- Adults generally function well independently, are able to work in competitive employment, and manage domestic affairs adequately.
- Individuals may have difficulty with stress.
- Individuals with mild intellectual disability usually benefit from the intermittent support of a care coordinator.

■ Moderate

- IQ: 40–55
- 2nd-grade academics by 18 years of age
- Support level: limited
- Most adults are able to work in the community but often require ongoing job coaching, particularly to cope with changes in routine.
- Adults are typically able to manage many aspects of their domestic life, such as hygiene and taking public transportation, but require some assistance with daily living.

■ Severe

- IQ: 25–40
 - Preschool academics by 18 years of age
 - Support level: extensive
-

- Individuals with severe intellectual disability typically cannot work in the community.
- Individuals often require significant daily assistance with many aspects of their domestic life.
- Profound
 - IQ: <25
 - Support level: pervasive
 - Individuals with profound intellectual disability cannot work in the community.
 - Individuals require significant daily assistance with many aspects of their domestic life.

Physical examination

- Can provide important clues to the cause of intellectual disability
- In the workup of global developmental delay or intellectual disability, referral for assessment of hearing and vision may be important.
- In addition to determining potential causes of intellectual disability, physical examination:
 - Establishes a connection with the child
 - Aids in assessment of interpersonal interactions

Behavioral symptoms

- Avoidance of diagnostic “overshadowing” or attributing all symptoms to intellectual disability is important.
 - Autism is a common comorbid feature of intellectual disability.
 - Several behavioral symptoms, such as irritability, aggression, and self-injury, are seen in both intellectual disability and autism.
 - Autism occurs at a higher rate in individuals with intellectual disability; a diagnosis of autism prompts differences in management.
 - For this reason, authorities strongly recommend that autism be considered, particularly in the face of characteristic symptoms.
 - Irritability and aggression have long been seen as intrinsic features of intellectual disability, often precluding more meticulous investigation.
 - Frequently, they are symptoms of psychiatric illness, such as depression or anxiety.
 - Self-injury may be a sign of physical illness.
 - For example, hitting the chest may be an indication of undiagnosed gastroesophageal reflux.
 - Apparent hypersexuality may be a manifestation of an uncomfortable erection in the context of inadequate sexuality education.

Nonspecific dysmorphic features associated with anomalous brain development

- Microcephaly
 - Reduced brain growth
- Cranial asymmetry
 - Premature suture fusion vs deforming external forces vs abnormal underlying brain growth
- Hair: absent or multiple (>2) parietal whorls
 - Abnormal brain development between 10 and 16 weeks’ gestation
- Cowlick, or anterior upsweep of scalp hair
 - Posterior displacement of junction of parietal and frontal hair streams, resulting from reduced frontal brain development
- Short palpebral fissures
 - Deficient frontal brain growth
- Up-slanted palpebral fissures
 - Relatively deficient frontal brain growth compared with midface
- Low-set ears (top of helix below outer canthi)
 - Reflects delayed morphogenesis, as ears are low set in the early fetus
- Posterior rotation of ears (axis tilted backward >15 degrees)
 - Reflects delayed morphogenesis, as ears are posteriorly rotated in the early fetus
- High-arched mouth
 - Persistent lateral palatal ridges, indicative of oral hypotonia or other oral-motor dysfunction

DIFFERENTIAL DIAGNOSIS

Syndromes associated with intellectual disability

- Down syndrome
 - Brachycephaly
 - Microcephaly
 - Epicanthal folds
 - Brushfield spots
 - Upslanting palpebral fissures
 - Small ears
 - Small nose with low nasal bridge
 - Brachydactyly and clinodactyly
 - Single transverse palmar crease
 - Wide gap and plantar crease between first and second toes
 - Hypotonia
 - Short stature
- Fragile X syndrome
 - High forehead
 - Long jaw or face

- Large protuberant ears
- Velvety palmar skin with dorsal redundancy
- Hyperextensible joints
- Peripubertal macroorchidism
- Early onset overgrowth
- Initial shyness
- Repetitive behaviors and stereotypies
- Fetal alcohol syndrome
 - Microcephaly
 - Short palpebral fissures
 - Maxillary hypoplasia
 - Flat philtrum
 - Thin upper lip
 - Small distal phalanges and small fifth fingernail
 - Joint anomalies of position and function
 - Short stature
- Williams syndrome
 - Stellate iris
 - Short palpebral fissures
 - Medial eyebrow flare
 - Periorbital fullness
 - Flat nasal bridge
 - Anteverted nares
 - Long philtrum
 - Prominent lips
 - Hoarse voice
 - Heart murmur
 - Hyperactive deep-tendon reflexes
 - Friendly personality
 - Hyperactivity
 - Short stature
- Velocardiofacial syndrome
 - Narrow palpebral fissures
 - Cleft palate
 - Velopharyngeal insufficiency
 - Prominent nose with narrow base
 - Abundant scalp hair
 - Long face
 - Retruded mandible
 - Heart murmur
 - Slender, hypotonic limbs with hyperextensible hands and fingers
- Rett syndrome
 - Acquired delay in head growth
 - Acquired diminished eye contact and loss of speech

- Repetitive purposeless midline hand movements, such as wringing or washing
- Apraxia
- Hypotonia, principally in girls

Neurocutaneous findings associated with intellectual disability

- Tuberous sclerosis complex
 - Hypomelanotic macules
 - Oval or ash-leaf shaped, few mm to cm, mostly on trunk or extremities; may occur in infancy
 - Shagreen patches
 - Firm yellow to red clusters of nodules, few mm to cm, on dorsum of body; particularly lumbosacral area; typically occurring at puberty (less commonly before)
 - Facial angiofibroma
 - Pink or red shiny nodules, on face, especially on nasolabial folds, usually appearing between 2 and 5 years of age
 - Forehead fibrous plaque
 - Yellowish-brown or flesh-colored, raised soft or hard plaque, few mm to cm, on forehead or scalp; can occur at any age
 - Periungual fibroma
 - Reddish or flesh colored, arising from nail bed or cuticle, found on toes more often than fingers, usually occurring at puberty or later
- Neurofibromatosis
 - Café-au-lait macules
 - Usually hyperpigmented, but also includes hypopigmented macules ≥ 5 mm
 - Axillary freckling
 - Small brown macules in axillae and perineum
 - Cutaneous neurofibroma
 - Small, raised, soft, pigmented nodules
- Sturge-Weber syndrome
 - Cranial port-wine stain
 - Light pink to deep purple birthmark, typically involving ≥ 1 upper eyelid and the forehead

DIAGNOSTIC APPROACH

General

- Diagnosis of intellectual disability requires documentation of impairment of cognition and of adaptive functioning.
- Communicating with families and patients about diagnosis is challenging.
 - Thoughtful communication is essential in helping families acknowledge a diagnosis that is difficult to accept.
 - Acceptance is essential in accessing important services.

- Careful and specific use of diagnostic labels and the consistent use of person-first language shows respect and compassion.
 - To state impairment first, as in *the intellectually disabled child*, implies that disability is the most salient characteristic of the child.
 - Saying the *child with a disability* is preferable.
- The American Academy of Neurology (AAN) has established criteria (below) for diagnosis of intellectual disability; these may be used for the diagnostic workup of intellectual disability and global developmental delay.
- A useful framework (below) for organizing the collection of these data, and for organizing the care plan, is provided by the International Classification of Functioning (ICF).
 - Emphasis on function over diagnostic labels and consideration of environmental factors
 - Congruent with guidelines put forth by the AAIDD
 - For the primary care physician, the ICF can serve as a review of functional status.
- International classification of functioning to organize evaluation and care plan

Guidelines from the AAN

- Cognitive impairment (IQ ≤ 90)
 - IQ is defined by a mean of 100, with standard deviation of 15.
 - Cognitive impairment is defined as an IQ ≥ 2 standard deviations below the mean.
- Adaptive impairment
 - Adaptive skills include such domains as communication, self-care, home living, social or interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, health, and safety.
 - Adaptive impairment is identified by functioning in the range of impairment in these areas.
 - ≥ 2 standard deviations below the mean, as measured by formal testing on measures of adaptive functioning, such as the Vineland Adaptive Behavior Scales
- Onset of cognitive and adaptive impairment during the developmental period (<18 years of age)
 - Onset of cognitive and adaptive impairment after the developmental period would be referred to by etiology, for example, as traumatic brain injury.

ICF guidelines to evaluation

- Learning and applying knowledge
 - Elements to include in evaluation: Learning, thinking, problem solving, and decision making
- General tasks and demands
 - Elements to include in evaluation: Carrying out tasks, organizing routines, handling stress

- Communication
 - Elements to include in evaluation: Use of language, signs, and symbols; receiving and producing messages; carrying on conversation; use of communication devices and techniques
- Mobility
 - Elements to include in evaluation: Moving body position or location; transferring from one place to another; carrying, moving, and manipulating objects; walking, running, climbing; using transportation
- Self-care
 - Elements to include in evaluation: Washing, dressing, grooming, eating, drinking, hygiene, health practices
- Domestic life
 - Elements to include in evaluation: Acquiring food, clothing, place to live; household chores; assisting others
- Interpersonal interactions and relationships
 - Elements to include in evaluation: Basic and complex interactions with people, including strangers, friends, relatives, immediate family members, and intimate relations in a socially appropriate manner
- Major life areas
 - Elements to include in evaluation: Carrying out tasks related to education, work, and economic transactions
- Community, social, and civic life
 - Elements to include in evaluation: Recreation and leisure, religion or spirituality, political life or citizenship

LABORATORY FINDINGS

- Karyotype
 - Recommended in all children with moderate to severe global developmental delay or intellectual disability
- Metabolic workup
 - Not generally recommended if newborn screen is documented
 - Recommended with specific family history, consanguinity, regression, or episodic decompensation
- Fragile X syndrome (DNA methylation testing)
 - Recommended in boys with moderate to severe global developmental delay or intellectual disability
 - Particularly recommended when characteristic features are present
- Rett syndrome (*MECP2* gene testing)
 - Recommended in girls with moderate to severe global developmental delay or intellectual disability
 - Particularly recommended when characteristic features are present

- Subtelomeric fluorescence in situ hybridization
 - Before the development of complete genomic hybridization technology, this was the best test for the detection of small subtelomeric rearrangements.
 - This test has been replaced by microarray comparative genomic hybridization.
- Microarray comparative genomic hybridization
 - Consider in moderate to severe global developmental delay or intellectual disability.
 - This test has higher yield when ≥ 1 of the following features are present.
 - Family history of unexplained moderate to severe intellectual disability
 - Prenatal onset growth retardation
 - Postnatal growth abnormalities, including micro- or macrocephaly or short or tall stature
 - ≥ 2 dysmorphic facial features or nonfacial congenital anomalies
- Thyroid function testing
 - Recommended if no newborn screen documented or with characteristic symptoms, such as:
 - Late tooth eruption or fontanelle closure
 - Weight for age above height for age
 - Constipation
 - Delayed relaxation phase of deep-tendon reflexes
- Lead testing
 - Levels are found to be elevated at higher rate in children with intellectual disability than in children without.
 - Pica is a behavioral characteristic associated with intellectual disability.

IMAGING

- Brain magnetic resonance imaging
 - Recommended for global developmental delay, although clinical picture should be taken into account
 - Lower yield in mild global developmental delay, which tends to be familial
 - Higher yield with focal or abnormal neurological examination, in the presence of cranial anomalies or neurocutaneous features

DIAGNOSTIC PROCEDURES

- Ophthalmologic assessment
 - Recommended in all children with moderate to severe global developmental delay or intellectual disability

- Audiologic assessment
 - Recommended in all children with moderate to severe global developmental delay or intellectual disability
- Electroencephalography
 - Recommended only if a clinical indication of seizures is present

WHEN TO REFER

- Infants and toddlers failing to meet developmental milestones using standard reference instruments, such as:
 - Ages and Stages Questionnaire
 - Child Development Inventory
 - Parents' Evaluation of Development Status
 - Bright Futures guidelines
- A pediatrician need not conduct formal developmental screening to refer for evaluation through early intervention programs.
- Referrals can be based on objective criteria or clinical judgment.
- Parents who express concerns about their child's development should have their concerns validated by a referral to early intervention services.
- If the primary care physician even suspects developmental delay, erring on the side of caution would be advisable.
- Children with a new diagnosis of global developmental delay or of intellectual disability:
 - Should have a medical evaluation to determine the causes of the delays
 - The primary care physician may wish to refer to subspecialists in genetics, developmental and behavioral pediatrics, or neurodevelopmental disabilities.
- Children of sufficient age who are suspected of having intellectual disability and who have not had a formal psychological assessment should be referred for evaluation of cognitive abilities, academic achievement, and adaptive skills.
 - Families may obtain such testing free of charge through their local school district by making a formal request for a multidisciplinary evaluation.
 - Primary care physicians can support families in this endeavor by providing references to the process of requesting an evaluation through the school district.
 - Families may obtain an independent psychological evaluation from a private psychologist.

Iron-Deficiency Anemia

DEFINITION

- Iron-deficiency anemia (IDA) is the most common nutritional deficiency worldwide.
- Children with iron deficiency in infancy continue to have poor cognition and school achievement and increased behavior problems into middle childhood.
- Iron deficiency is associated with deficits in work productivity.
- Severe anemia is associated with maternal and child mortality.
- Prevention of iron deficiency is therefore an important public health issue.
- Iron deficiency occurs when total body iron content is diminished.
- When absorption exceeds losses, iron surplus is stored in the reticuloendothelial system.
 - Liver
 - Spleen
 - Bone marrow
- Iron is removed from the reticuloendothelial storage pool to compensate for negative iron balance.
- Development of iron deficiency proceeds through a series of overlapping stages:
 - Stage 1
 - The first stage of iron deficiency is storage iron depletion.
 - Anisocytosis and an increased percentage of microcytic cells are the first hematologic abnormalities.
 - During this stage, no deficit of iron supplied to the erythroid marrow for red blood cell (RBC) production occurs.
 - Stage 2
 - If the negative iron balance continues, iron-deficient erythropoiesis (IDE) will occur.
 - Mean corpuscular volume (MCV) and mean corpuscular hemoglobin (MCH) decrease.
 - During this stage, erythroid iron supply is diminished, but hemoglobin concentration remains in the normal range.
 - Stage 3
 - If the negative iron balance persists, IDA finally develops.
 - The third stage is characterized by a decrease in the hemoglobin concentration and reduction in RBC size and hemoglobin content.
 - Hematologic abnormalities in iron deficiency progress as impairment of hematopoiesis progresses.
 - Characterized by:
 - Low MCH
 - Hemoglobin concentration <9 g/dL
 - Transferrin saturation <16%

EPIDEMIOLOGY

- In the US
 - Common, despite the generally good standard of nutrition and the widespread use of iron-fortified foods
 - Most common among women and young children
- Age
 - IDA is most prevalent among:
 - Toddlers age 1–2 years (7%)
 - Adolescent girls
 - Adult women age 12–49 years (9–16%)
- Race/ethnicity
 - Prevalence is 2 times higher among African-American and Latino-American women (19–22%) than among white women (10%).
 - Prevalence remains higher than the goal of national health objectives for 2010 to reduce iron deficiency in vulnerable populations by 3–4 percentage points.

ETIOLOGY

- The 4 most important factors in the development of iron deficiency in children are:
 - Iron endowment at birth
 - Iron needs during rapid body growth
 - Exogenous iron absorption
 - Blood loss

Causes of iron deficiency

- Inadequate iron absorption
 - Diet low in bioavailable iron
 - Formula not fortified with iron
 - Cow's milk before the age of 6 months
 - Strict vegetarian diet
 - Poor dietary habits in adolescents
 - Impaired absorption
 - Intestinal malabsorption
 - Gastric surgery
 - Hypochlorhydria
- Increased iron requirements
- Blood loss
 - Menstruation
 - Gastrointestinal tract
 - Milk enteropathy
 - Food sensitivity
 - Inflammatory bowel disease
 - Meckel diverticulum
 - Peptic ulcer disease

- Reflux esophagitis
- Hookworms
- Cancer
- Genitourinary tract
- Respiratory tract
 - Idiopathic pulmonary
 - Hemosiderosis
 - Cystic fibrosis
 - Pulmonary tuberculosis
- Cardiac
 - Hemosiderinuria due to cardiac hemolysis
- Blood donation
- Pregnancy
- Growth
 - Prematurity
 - Infancy
 - Adolescence

During gestation

- Fetal iron stores in newborns are related to maternal iron status, and the maternal-fetal unit is dependent on exogenous iron.
- The ratio of iron content to weight in the human fetus remains constant throughout gestation.
- The healthy full-term newborn has sufficient iron stores to last for 6 months, if sufficient small amounts of iron are ingested from the diet.
- The infant's iron endowment can be compromised by blood loss during pregnancy or the perinatal period.
- Common causes of blood loss include:
 - Third-trimester bleeding
 - Abruptio placentae
 - Placenta previa
 - Fetomaternal hemorrhage
 - Twin-to-twin transfusions

During growth

- Iron is needed not only for many metabolic functions and tissue replacement, but also for growth.
- Growth rates vary with age and are maximal during infancy and adolescence, the same periods associated with the highest frequency of iron deficiency.
- Blood loss causes iron deficiency in children less frequently than in adults.
- In infancy and childhood, iron deficiency caused by blood loss is most commonly associated with the ingestion of unprocessed cow's milk and with parasitic infections.
 - Hypersensitivity to whole cow's milk causes an exudative enteropathy and frequently leads to gastrointestinal blood loss.

- Less common causes of blood loss in children include:
 - Meckel diverticulum
 - Intestinal duplication
 - Peptic ulcer disease
 - Hereditary hemorrhagic telangiectasia
 - Long-term use of medications that prolong the bleeding time (eg, aspirin)

RISK FACTORS

- Gestational conditions that result in lower newborn iron stores include:
 - Severe maternal iron deficiency
 - Maternal hypertension with intrauterine growth retardation
 - Maternal diabetes mellitus
- Stable, very low-birth-weight premature infants are also at risk for early postnatal iron deficiency because they:
 - Accrete less iron during gestation
 - Grow more rapidly after birth
 - Typically are undertreated with enteral iron

SIGNS AND SYMPTOMS

History

- The onset and progression of iron deficiency are usually gradual.
- Most children will not have major symptoms.
- Iron deficiency in infants and children is associated with:
 - Generalized weakness
 - Irritability
 - Easy fatigability
 - Headaches
 - Poor feeding
 - Anorexia
 - Pica
 - Poor weight gain

Physical examination

- The physical examination is usually unremarkable except for marked pallor of the mucous membranes and skin.
- Other physical findings associated with IDA but rarely observed include:
 - Mild hepatosplenomegaly
 - Lymphadenopathy
 - Glossitis
 - Stomatitis
 - Blue sclerae
 - Koilonychia (spoon-shaped nails)

DIFFERENTIAL DIAGNOSIS

- Iron deficiency must be distinguished from other hypochromic microcytic anemias.
- Serum transferrin receptor levels help discriminate iron deficiency from the anemias of chronic disease.

Thalassemia trait

- IDA and thalassemia trait are the most common causes of mild microcytic anemia with hemoglobin level ≥ 9 g/dL.
- The RBC count is often increased above normal despite the presence of a mild anemia and microcytosis in thalassemia trait, whereas it is reduced in IDA.
- The RBC distribution width (RDW) is increased in iron deficiency.
- The Mentzer index, defined as the MCV divided by the RBC count in millions, can help distinguish the anemia of iron deficiency from that of β -thalassemia trait.
 - In IDA, the Mentzer index is often >13.5 .
 - In β -thalassemia trait, it is <11.5 , with 82% specificity.
 - The RDW index (RDWI) is calculated using the formula $RDWI = (MCV \div RBC \times RDW)$
 - An RDWI ≥ 220 is indicative of IDA.
 - An RDWI <220 is indicative of thalassemia trait, with a specificity of 92%.
- The RBC count and RDWI are the most reliable discrimination indices in differentiation between β -thalassemia trait and IDA.
- If α - and β -thalassemia trait or hemoglobin E disease is suspected, the diagnosis can be established by:
 - Review of the newborn screen
 - Performing hemoglobin electrophoresis (only in case of β -thalassemia and not α -thalassemia)
 - Because thalassemia trait is frequently not associated with a hemoglobin level <9 g/dL, it is not included in the differential diagnosis in severe anemia.
 - The diagnosis of α -thalassemia trait can be assumed when a patient with a familial hypochromic microcytic anemia has normal results of iron studies (including ferritin), normal levels of hemoglobin (Hb) A₂ and Hb F, and normal hemoglobin electrophoresis.
 - It is a diagnosis of exclusion, except in the newborn period, when infants with α -thalassemia trait have 3–10% Hb Barts (γ_4), which may be detected in the newborn screen.

Hb H disease

- Hb H disease, another form of α -thalassemia, results from deletion of 3 of the 4 α -globin genes.
- It is characterized by hypochromia and microcytosis.

- A mild hemolytic component is present from instability of the β -chain tetramers (Hb H) resulting from a deficiency of α -globin chains.
- Beyond infancy, Hb H is readily identified by hemoglobin electrophoresis.
- During the newborn period, the moderately severe α -globin deficiency allows accumulation of more γ chains, and the concentration of Hb Barts is $>20\%$.

Anemia of chronic disease or inflammation

- Inflammation impairs the supply of iron to the plasma and ultimately results in a form of anemia called *anemia of chronic disease* or *anemia of inflammation*.
 - It is usually normocytic, although it may occasionally be slightly microcytic.
 - Because inflammation alters screening tests for iron status in the same manner as true iron deficiency, the distinction between anemia of chronic disease and IDA requires tissue-related iron measurements.
 - Usefulness of the serum ferritin in the diagnosis of IDA is compromised by the effect of inflammation on the value.
 - Consequently, a serum ferritin concentration >30 mg/L in an anemic patient does not exclude IDA in the presence of chronic inflammation.
- C-reactive protein level is generally considered to be the best laboratory marker of inflammation.
 - If it is <30 mg/L, the inflammation is generally considered unlikely to be sufficient to increase the serum ferritin level.
 - Suggested ferritin levels of <40 mg/L and <70 mg/L are used to diagnose IDA in anemic patients without and with inflammation, respectively.
 - The serum transferrin receptor (sTfR) measurement for identifying IDA is one in which the concentration is not affected by inflammation.
 - Use of the sTfR/ferritin ratio further improves the specificity of the diagnosis of IDA and may eliminate the need for bone marrow examination for assessment of iron stores.

Lead poisoning and anemia

- Lead poisoning and IDA are both associated with high levels of RBC zinc protoporphyrins (ZnPP).
- Iron deficiency and lead poisoning frequently coexist.
- Although the nature of their relationship is not completely elucidated, characterization of a common iron-lead transporter and epidemiologic studies among children strongly suggest that iron deficiency may increase susceptibility to lead poisoning.
- In cases of lead poisoning associated with iron deficiency, the RBCs are morphologically similar, but coarse basophilic stippling of the RBCs is frequently prominent.
- Increases in blood lead, ZnPP/heme (ZnPP/H) ratio, and urinary coproporphyrin levels are seen.

Laboratory Abnormalities in the Three Stages of Iron Deficiency^a

Normal Iron States		Stage 1 Storage Iron Depletion	Stage 2 Transport Iron Depletion	Stage 3 Functional Iron Depletion (Iron Deficiency Anemia)
Hemoglobin	N	N	↑	↓
Serum iron	N	N	↓	↓
TIBC	N	N	↑	↑
Ferritin	N	↓	↓	↓

Abbreviation: N, normal.

^b ↑, increased; ↓, decreased.

DIAGNOSTIC APPROACH

- Diagnosis of iron deficiency is made by the combination of:
 - RBC indices
 - Serum transferrin saturation
 - Ferritin
- Transferrin saturation and ferritin may be altered by:
 - Infection
 - Inflammation
 - Cancer
 - Starvation
- Although absence of iron stores in the bone marrow remains the gold standard for a diagnosis of iron deficiency, this test is rarely used because of patient discomfort and the difficulty of standardizing bone marrow iron stain.
- Once IDA is diagnosed, efforts should be undertaken to establish its cause.
- A therapeutic iron trial has been proposed as a convenient method to diagnose iron deficiency in patients with anemia.
 - This approach is reasonable in otherwise healthy individuals.
 - Making a definitive laboratory diagnosis at the outset is preferable for those at high risk of deficiency, such as:
 - Infants
 - Teenage girls
 - Pregnant women

LABORATORY FINDINGS

- Specific laboratory findings are associated with each of the 3 stages of iron deficiency.
- Laboratory test findings characteristic of each stage are summarized in table Laboratory Abnormalities in the Three Stages of Iron Deficiency.
- Tests demonstrate either a reduced supply of plasma iron or poor hemoglobinization of circulating RBCs.

- Definitive tests identify IDA by measuring iron-related proteins derived from either iron storage compartment in macrophages or iron utilization compartment in RBC precursors.

Screening measurements

Hemoglobin concentration

- The most commonly used screening test for iron deficiency
- Someone with normal body iron stores must lose a large portion of body iron before hemoglobin falls below laboratory definitions of anemia.
- Low hemoglobin does not distinguish among the causes of anemia other than iron deficiency, so additional testing is required.

Serum iron and transferrin saturation

- Serum iron levels normally fluctuate daily, with maximal levels occurring in the morning and minimal levels in the evening.
- Total iron-binding capacity (TIBC) varies less than serum iron but is harder to measure accurately.
- Normal TIBC is 250–400 mg/dL, but as serum iron levels decrease, TIBC increases to ≥450 mg/dL.
- Iron and TIBC measurements are useful in distinguishing IDA from anemia of chronic disease.
- Serum iron levels decrease with both, but TIBC levels also decrease in chronic disease states (table Laboratory Findings Associated With the Differential Diagnosis of Microcytic Anemias).
- Degree of iron saturation of plasma transferrin is calculated as follows: transferrin saturation = (serum iron concentration ÷ TIBC) × 100.
- Serum iron and TIBC levels help confirm the diagnosis of iron deficiency, with a low serum iron and a high transferrin level, resulting in a transferrin saturation <10–15%.
- Transferrin levels are increased in iron-deficiency states because of increased hepatic synthesis of the protein and greater liberation of apotransferrin (the transport protein without iron) from hemoglobin-synthesizing sites.

Laboratory Findings Associated With the Differential Diagnosis of Microcytic Anemias^a

Finding	Iron Deficiency	Lead Poisoning	β-Thalassemia Trait	Chronic Disease
Ferritin	↓	Normal	Normal	↑
Serum iron	↓	Normal	Normal	↓
Total iron-binding capacity	↑	Normal	Normal	↓
Erythrocyte zinc protoporphyrin	↑	↑↑	Normal	↑
Red blood cell distribution width	↑	Normal	Normal	Normal
Serum transferrin receptor	↑	Normal	↑	Normal

^a↑, increased; ↑↑, very increased; ↓, decreased. Iron deficiency and lead poisoning frequently co-exist.

Red Blood Cell Indices During Infancy and Childhood^a

Age		Hemoglobin (g/dL)		Hematocrit (%)		Reticulocytes (%)	MCV (fL)
		Mean	Range	Mean	Range	Mean	Lowest
Child	Cord blood	16.8	13.7–20.1	55	45–65	5.0	110
	2 wk	16.5	13.0–20.0	50	42–66	1.0	107
	3 mo	12.0	9.5–14.5	36	31–41	1.0	80
	6 mo–6 yr	12.0	10.5–14.0	37	33–42	1.0	70–74
	7–12 yr	13.0	11.0–16.0	38	34–40	1.0	76–80
Adult	Female	14	12.0–16.0	42	37–47	1.6	80
	Male	16	14.0–18.0	47	42–52	1.6	80

Abbreviations: MCV, mean corpuscular volume; WBC, white blood cells.

^a Modified from: Behrman RE. *Nelson Textbook of Pediatrics*. 17th ed. Philadelphia, PA: WB Saunders; 2004. Copyright © Elsevier 2004.

- This relatively inexpensive measurement is widely available.
- Marked diurnal variation in plasma iron values and numerous clinical disorders that affect transferrin saturation limit its use in the clinical setting.
- Transferrin saturation
 - Normal or high transferrin saturation is useful for excluding IDA.
 - Low transferrin saturation is useful for identifying IDA.

RBC indices

- Development of electronic counters has made use of RBC indices widely available for initial screening of infants and children.
- These tests are highly reproducible and less subject to sampling error compared with hemoglobin determinations because tissue fluid dilution does not affect RBC size.
- RBCs become smaller than normal (decreased MCV), and their hemoglobin content decreases (decreased MCH).
- RDW approximates the standard deviation of the RBC size variation.

- Normal RDWs occur in the range of 12–17%.
- In IDA, a marked dispersion exists in cell volumes (sizes), such that the RDW increases.
- RBC indices in infancy and childhood are described in table Red Blood Cell Indices During Infancy and Childhood.

ZnPP

- A simple and reliable measurement of IDE is the RBC ZnPP, a product of abnormal heme synthesis.
- Normally, a trace of zinc rather than iron is incorporated into protoporphyrin during the final step of heme biosynthesis.
- In states of IDE, ZnPP formation is enhanced.
- An increase in the ZnPP/H ratio >80 mcmol/mol is a sensitive, specific, and cost-effective test for identifying preanemic iron deficiency.
- A major advantage is the ability to measure the ZnPP/H ratio directly on a drop of blood using a portable instrument called a *hematofluorimeter*.
- Initially, ZnPP was erroneously characterized as metal-free protoporphyrin or free RBC protoporphyrin or RBC protoporphyrin.

- Now, most presumed metal-free protoporphyrin in RBCs is known to be largely an artifact of older analytical procedures (still used in some laboratories).
- Because approximately 95% of the nonheme protoporphyrin in RBCs is ZnPP, this procedure should not create a diagnostic problem.
- The ZnPP/H ratio is an indicator of iron available to developing RBCs in bone marrow regardless of the cause, such as iron deficiency, inflammation, or functional iron deficiency such as in chronic renal failure.
- Another significant limitation of ZnPP are with lead toxicity and the normal range with environmental lead exposure, infections, inflammatory diseases, and protoporphyria.
- However, the ZnPP/H ratio is not increased in thalassemia trait, which makes ZnPP/H ratio determinations helpful in distinguishing iron deficiency from α - or β -thalassemia trait, in addition to its use screening for IDA (table Laboratory Findings Associated With the Differential Diagnosis of Microcytic Anemias).

Reticulocyte hemoglobin

- The mean reticulocyte hemoglobin content is analogous to the RBC mean corpuscular hemoglobin, but with the advantage of monitoring hemoglobinization of the most recently produced RBCs.
- A reticulocyte hemoglobin concentration <26 pg is an early indicator of iron-restricted hematopoiesis and IDA in children.
- The diagnostic power of reticulocyte hemoglobin is limited in patients with high MCV or with RBC disorders, such as thalassemia.

Peripheral blood smear

- Examination of the blood smear in IDA reveals:
 - Hypochromic microcytes
 - Poikilocytes
 - Elliptocytes
 - Target cells
- Presence of basophilic stippling suggests associated lead poisoning.
- RBC changes seen on the blood smear are not specific for iron deficiency.
- Leukocyte count and morphology in IDA are usually normal.
- Both thrombocytosis and thrombocytopenia occur with iron deficiency.
 - Thrombocytopenia is more common in severe iron deficiency and resolves once iron therapy is begun.

Definitive tests

- Absence of stainable iron in bone marrow is a definitive test for IDA but is not routinely applicable for obvious reasons.

- The 2 key definitive measurements for diagnosing iron deficiency are serum ferritin, which measures the size of iron stores, and serum transferrin receptor, which measures the extent of tissue iron deficiency.

- Serum ferritin
 - Definitive serum ferritin levels vary with age during infancy and childhood.
 - In healthy individuals, serum ferritin levels reflect body iron stores.
 - Levels <30 ng/L indicate iron deficiency.
 - Ferritin is an acute-phase reactant.
 - Serum ferritin levels are increased during infections, inflammatory processes, liver disease.
 - Although low serum ferritin is diagnostic of iron deficiency, high ferritin associated with inflammation or liver disease does not rule out concomitant iron deficiency.
- sTfR
 - Proteolytic cleavage of transferrin receptors can be measured in serum as sTfR.
 - sTfR directly correlates with total mass of erythroid precursor.
 - sTfR is high in iron deficiency and in conditions resulting in increased production of RBCs, including thalassemia and sickle cell disease.
 - Because sTfR is not affected by inflammation, it is useful in distinguishing iron deficiency from chronic inflammatory states that do not have high sTfR (table Laboratory Findings Associated With the Differential Diagnosis of Microcytic Anemias).
 - Infants have higher baseline sTfR levels than children and adults, indicating the need to establish age-specific reference values.
 - The ratio of sTfR to serum ferritin has been shown to have excellent performance in estimating body iron stores but is limited by lack of standardization.

Bone marrow iron

- The staining of a normal bone marrow aspirate sample with Prussian blue dye reveals the presence of iron in RBC precursors (normoblasts) and serves as a reliable index of body iron stores.
- In iron deficiency, the number of iron granules in normoblasts is decreased, and stainable iron in the marrow aspirate is almost completely absent.

TREATMENT APPROACH

- The treatment of choice for iron deficiency is oral administration of iron.

SPECIFIC TREATMENTS

Oral administration of iron

- Although various iron salts are available, ferrous sulfate is inexpensive and well tolerated, although adverse effects may occur, such as:
 - Nausea
 - Dyspepsia
 - Constipation
 - Diarrhea
- Adverse effects can be managed by administering the iron with or immediately after meals.
- If symptoms persist, reductions in the amount of iron in each dose or reduction in frequency to a single daily dose may help control side effects.
- If intolerance is persistent, then switching to ferrous gluconate may be helpful.
- Iron polysaccharide complex has the advantage of availability as tablets or elixir and is well tolerated.
- Approximately twice as much iron is absorbed on an empty stomach as at mealtime.
- Consumption of milk should be limited, allowing increased intake of iron-rich foods and reduction of blood loss from intolerance to cow's milk proteins.
- Soy-based formulas can lead to blood loss, so children with milk enteropathy should be switched to a primary diet of iron-containing solids.
- In the absence of ongoing blood losses, response to iron therapy is rapid and predictable.
- Response of decreased irritability and increased appetite has been noted within 12–24 hours (table Responses to Iron Therapy in Iron-Deficiency Anemia).
- Reticulocyte response peaks 5–7 days after the institution of iron therapy.
- In an otherwise healthy individual, recovery from anemia is approximately two-thirds complete within 1 month.
- Hemoglobin should be measured again at 1 month to check therapeutic progress and to emphasize compliance.
- If after 4 weeks anemia does not respond to iron treatment despite compliance and absence of acute illness, then anemia can be further evaluated by using other laboratory tests, including MCV, RDW, and serum ferritin concentration.
- Serum ferritin concentration ≤ 15 mcg/L confirms iron deficiency, and a concentration >15 mcg/L suggests that iron deficiency is not the cause of the anemia.
- Once diagnosis is confirmed, either by a response to a therapeutic trial or by further tests, oral therapy with elemental iron at 3–6 mg/kg per day should be continued for 2–3 months after normal hemoglobin levels have been restored.

Responses to Iron Therapy in Iron-Deficiency Anemia^a

Time After Iron Administration	Response
12–24 hr	Replacement of intracellular iron enzymes; subjective improvement; decreased irritability; increased appetite
36–48 hr	Initial bone marrow response; erythroid hyperplasia
48–72 hr	Reticulocytosis, peaking at 5–7 days
4–30 day	Increase in hemoglobin level
1–3 mo	Repletion of stores

^aFrom: Behrman RE. *Nelson Textbook of Pediatrics*. 17th ed. Philadelphia, PA: WB Saunders; 2004. Copyright © Elsevier 2004.

- This regimen allows the repletion of body iron stores.
- Anemia, microcytosis, and increased free RBC protoporphyrin levels are corrected completely with 3–5 months of treatment.

Intramuscular or intravenous iron

- Use of intramuscular or intravenous iron is rarely warranted.
- Parenteral iron administration may be indicated.
 - If ongoing blood loss exceeds the body's ability to replenish iron stores through oral absorption
 - In the presence of iron malabsorption
 - When the patient cannot tolerate or will not take oral iron preparations
- Intramuscular injections are painful, and skin discoloration is common.
- Anaphylactic reactions have occurred with both intramuscular and intravenous injection, and deaths have been reported.
- Parenteral treatment should therefore be used only when oral therapy is not possible, eg, in patients with inflammatory bowel disease.
- 3 drugs are licensed in the US.
 - Iron dextran has been used for several years but is associated with significant risks.
 - Iron sucrose and iron gluconate may have a better safety profile than iron dextran.

Blood transfusion

- Blood transfusion is indicated only when severe anemia leads to congestive heart failure and cardiovascular compromise.
- If a blood transfusion is clinically warranted, then packed RBCs should be given slowly or a partial exchange transfusion performed.
- Vital signs should be monitored carefully.

Failure to respond to therapy

- When a patient fails to respond to oral iron treatment, the following factors should be considered:
 - Noncompliance with oral therapy
 - Inadequate iron dose
 - Persistent or unrecognized blood loss
 - Malabsorption of iron (eg, primary gastrointestinal disease)
 - Other diagnoses (eg, α - or β -thalassemia trait and Hb E disease)
 - Poor iron utilization (eg, chronic inflammatory disease, sideroblastic anemia, lead poisoning, congenital atransferrinemia)

WHEN TO ADMIT

- The patient exhibits signs of cardiac failure.
- The patient requires intravenous iron.
- The patient has moderate to severe blood loss.

WHEN TO REFER

- The cause of anemia is unknown.
- Gastrointestinal blood loss is suspected.
- Anemia is not explained by nutritional imbalance.
- Anemia is refractory to treatment.
- The patient requires intravenous iron.
- The diagnosis of iron deficiency is questionable.

FOLLOW-UP

- After an iron therapy is initiated, the patient should be re-evaluated at 1 month to see whether there is response.
 - If, despite compliance, there is no response to treatment, an alternate diagnosis should be considered.

COMPLICATIONS

- Iron is an important ingredient of hemoglobin and is involved in numerous cellular processes.
- Children with iron deficiency in infancy have:
 - Poor cognition
 - Poor school achievement
 - Increased behavior problems into middle childhood
- Iron deficiency is also associated with deficits in work productivity.
- Severe anemia is associated with maternal and child mortality.

PROGNOSIS

- Prognosis for nutritional iron deficiency is good.

PREVENTION

- Prevention of iron deficiency is an important public health issue.
 - Iron balance is maintained by regulation of iron absorption.
 - The amount absorbed depends both on amount and bioavailability of dietary iron and on regulation of iron absorption by the intestinal mucosa.
 - Most dietary iron occurs in the nonheme form and is much less bioavailable than that in heme proteins.
 - The iron in hemoglobin and myoglobin is particularly bioavailable; up to 30% is directly absorbed by the gastrointestinal tract.
 - Human milk and cow's milk contain small amounts of iron (0.5–1 mg/1000 mL).
 - However, 50% of the iron in human milk is absorbed, compared with only 10% in cow's milk.
 - Full-term infants who are exclusively breastfed for the first 6–9 months do not become iron deficient.
 - Nonheme iron absorption is inhibited by:
 - Bran in cereals
 - Polyphenols in many vegetables
 - Tannins in tea
 - Addition of solids to an infant's diet can greatly impair iron absorption and puts the infant at risk for developing iron deficiency.
 - The introduced solids should contain abundant amounts of iron (eg, iron-fortified cereals).
 - Increased iron intake among infants has resulted in a decline in childhood IDA in the US.
 - Consequently, use of screening tests has become a less efficient means of detecting iron deficiency in some populations, whereas for women of childbearing age, iron deficiency has remained prevalent.
 - The Centers for Disease Control and Prevention (CDC) has developed recommendations for primary prevention of iron deficiency through appropriate dietary intake and secondary prevention through detecting and treating IDA.
- CDC recommendations**
- Primary prevention of iron deficiency in infants, children, and adolescents**
- Breastfeeding and iron-fortified formula
 - Encourage exclusive breastfeeding of infants (without supplementary liquid, formula, or food) for 4–6 months after birth.
 - When exclusive breastfeeding is stopped, encourage use of an additional source of iron (approximately 1 mg/kg daily), preferably from supplementary foods.
 - For infants <12 months who are not breastfed or who are partially breastfed, recommend only iron-fortified infant formula as a substitute for human milk.

- For breastfed infants who receive insufficient iron from supplementary foods by age 6 months (ie, <1 mg/kg daily), suggest 1 mg/kg daily of iron drops.
 - For breastfed infants who were preterm or who had low birth weight, recommend 2–4 mg/kg daily of iron drops (to a maximum of 15 mg/day) starting at 1 month after birth and continuing until 12 months after birth.
 - Encourage use of only human milk or iron-fortified infant formula for any milk-based part of the diet (eg, in infant cereal) and discourage use of low-iron milks (eg, cow's milk, goat's milk, soy milk) until age 12 months.
 - Suggest that children age 1–5 years consume no more than 24 oz of cow's milk, goat's milk, or soy milk each day.
 - Solid foods
 - At age 4–6 months or when the extrusion reflex disappears, recommend that infants be introduced to plain, iron-fortified infant cereal.
 - ≥2 servings per day of iron-fortified infant cereal can meet an infant's requirement for iron at this age.
 - By approximately age 6 months, encourage 1 feeding per day of foods rich in vitamin C (eg, fruits, vegetables, juice) to improve iron absorption, preferably with meals.
 - Suggest introducing plain, pureed meats after age 6 months or when the infant is developmentally ready to consume such food.
 - Adolescent girls and nonpregnant women
 - Encourage adolescent girls and women to eat iron-rich foods and foods that enhance iron absorption and to optimize their dietary iron intake.
- Screening for iron deficiency in infants, children, and adolescents**
- Anemia screening before age 6 months for preterm infants and low-birth-weight infants who are not fed iron-fortified infant formula
 - Annual assessment of children age 2–5 years for risk factors for IDA (eg, a low-iron diet, limited access to food because of poverty or neglect, special health care needs)
 - Assessment at age 9–12 months and 6 months later (at age 15–18 months) for infants and young children for risk factors for anemia
 - Preterm or low birth weight infants
 - Infants fed a diet of non-iron-fortified infant formula for ≥2 months
 - Infants introduced to cow's milk before age 12 months
 - Breastfed infants who do not consume a diet adequate in iron after age 6 months (ie, who receive insufficient iron from supplementary foods)
 - Children who consume ≥24 oz daily of cow's milk
 - Children with special health care needs (eg, children who use medications that interfere with iron absorption and children who have chronic infection, inflammatory disorders, restricted diets, or extensive blood loss from a wound, an accident, or surgery)
 - In populations of infants and preschool children at high risk for IDA (eg, children from low-income families, children eligible for the Special Supplemental Nutrition Program for Women, Infants, and Children, migrant children, or recently arrived refugee children), screen all children for anemia between ages 9 and 12 months, 6 months later, and annually from age 2–5 years.
 - Starting in adolescence, screen all nonpregnant women for anemia every 5–10 years throughout their childbearing years during routine health examinations.
 - Annually screen for anemia women with risk factors for iron deficiency (eg, extensive menstrual or other blood loss, low iron intake, a previous diagnosis of IDA).

Irritability

DEFINITION

- Irritability is excessive response to a stimulus.
- Not a quantifiable symptom
 - Includes episodes of crying or fussiness despite attempts to comfort

MECHANISM

- May result from:
 - Lack of vital nutrients (eg, oxygen, glucose)
 - Presence of noxious stimuli (eg, pain, toxins)
 - An emotional state (eg, anger, frustration)
- Causes and manifestations may be different in infants, children, and adolescents.

HISTORY

- Acute irritability may be associated with life-threatening illnesses requiring urgent intervention and stabilization before a search for the cause can begin.
- A parent who seeks care for an infant who is fussier than usual may arrive with a child who is in shock, in respiratory distress, or having a seizure.
- If the child's condition is not immediately life-threatening, then a complete history and thorough physical examination are the first steps in the evaluation of irritability, and, in many cases, will reveal the cause of the symptom.

PHYSICAL EXAM

- A thorough head-to-toe examination, including special attention to the eyes, ears, digits, and genitalia, is essential to establish a diagnosis.
- Irritability and nonspecific crying episodes may be related to:
 - Foreign body in the ear or nose
 - Corneal abrasion
 - Hair wrapped around a digit or penis
 - Diaper rash
 - Nonspecific vaginitis
 - Balanitis
 - Insect and spider bites or stings
 - Vaccination pain
- A systematic search for injuries should be performed on any child with a history of trauma.
 - Inflicted injuries are more difficult to diagnose.
 - Signs may be subtle, and the history often is misleading.
 - Causes may be easily apparent, such as fractures or dislocations.

DIFFERENTIAL DIAGNOSIS

Acute irritability in the ill-appearing child

Central nervous system

- Children <2 years are at high risk for significant brain injury after accidental head trauma.
 - Overall rates of brain injury are:
 - Approximately 12% in the 0- to 2-month age group
 - 6% in the 3- to 11-month age group
 - 2% in infants >12 months of age
 - A history of a fall is often found.
 - A high index of suspicion should be maintained in infants <3 months.
- Concussion may be sustained from sports-related injuries.
 - The term *postconcussive syndrome* refers to a constellation of acute symptoms, which can be:
 - Somatic (headache, dizziness, blurriness)
 - Emotional (irritability, anxiety)
 - Cognitive (concentration and memory difficulties)
 - The term *second impact syndrome* has been proposed for an athlete who:
 - Has sustained a concussion and then sustains a second head injury before symptoms associated with the first have fully cleared
 - These athletes are at risk for a catastrophic outcome, such as permanent disability or death.
- Brain tumor
 - Increased intracranial pressure (ICP) from a brain tumor may produce acute irritability and altered behavior without the usual preceding symptoms, such as headache or loss of coordination.
 - Diagnosis may be delayed in young children because their symptoms are subtle (eg, headache, irritability, or drowsiness) or similar to those of more common illnesses, such as gastrointestinal disorders (eg, vomiting).
- Hydrocephalus
 - Causes increased ICP
 - Often occurs in infancy with irritability, vomiting, a tense or bulging fontanel, and an increasing head circumference that crosses percentile lines
 - Older children usually complain of headaches.
 - Obstruction, infection, or malfunction of the ventriculo-peritoneal shunt may lead to over- or underdrainage, initially causing irritability, headache, vomiting, or lethargy.
- Undiagnosed migraine headache may be the reason for irritability in the preverbal child.
 - Migraine headaches occur in 8–12% of children <3 years.
- Seizures
 - Children with seizures, especially unwitnessed, may appear irritable during an aura or the postictal phase.

- Neonatal seizures
 - More common in preterm infants than term infants
 - May have only subtle symptoms
 - Ocular or pedaling movements
 - Lip smacking
 - Apnea
- Nonconvulsive status epilepticus, which includes absence and partial complex seizures, is a relatively rare cause of abnormal behavior.
 - Produces continuous or intermittent seizure activity in the absence of any motor component and without a return to baseline for >30 minutes
 - Irritability and a change in behavior or mental status may be associated findings.
- Infant botulism
 - Initial findings may include:
 - Difficulty in feeding
 - Irritability
 - Lethargy
 - Weak cry
 - Constipation
 - Findings in advanced disease may include:
 - Drooling
 - Dysphagia
 - Loss of head control
 - Respiratory distress and flaccid paralysis from progressive bulbar involvement

Infections

- Bacterial infection should be suspected in a child with fever and irritability.
 - In infants and children, the most common bacteria are *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae* type B.
- Meningitis
 - Infants with meningitis may have irritability, lethargy, and poor feeding.
 - If the fontanelle is still open, it may be bulging.
 - Group B streptococci and gram-negative bacilli are the most common causes in neonates.
- Irritability and decreased movement of a limb should raise concern for osteomyelitis.
 - Swelling and erythema of the soft tissue overlying the bone may exist, often with a history of preceding trauma.
- Joint pain, fever, irritability, and a limp should raise concern for septic arthritis.
 - Examination reveals erythema, swelling, or warmth over the affected joint, with restricted movement.

- With septic arthritis of the hip, swelling and redness may not be visible, and the pain may be referred to the knee.
- An orthopedist should be consulted for possible surgical drainage.

- Children with Kawasaki disease, a vasculitis triggered by an unknown infectious agent, are often more irritable than patients with other febrile illnesses.
- Occult sepsis, urinary tract infections, and pneumonia also can produce irritability, along with fever and other signs that cause a patient to appear toxic.

Trauma

- Shaken baby syndrome
 - Occurs most commonly in children <2 years
 - The rotational forces sustained during shaking cause movement of the brain within the subdural space and tearing of the bridging veins.
 - Clinical signs may be poor feeding, vomiting, lethargy, or irritability.
- Blunt trauma
 - In infants and young children, pressure from the lap belt of a restraint system in a motor vehicle crash or other blunt abdominal trauma can lead to intraabdominal bleeding, initially displayed as irritability from tissue hypoperfusion and pain.
- Occult fracture

Acute abdomen

- Intussusception is most common between the ages of 3 months and 5 years, with a peak incidence at 6–11 months.
 - The child appears colicky, cries, and may draw the knees upward toward the chest; this may last a few minutes and then subside.
 - The child often looks better between episodes, and irritability gradually increases and vomiting becomes more frequent and sometimes bilious.
 - The classic triad is intermittent colicky abdominal pain, vomiting, and bloody mucous stools.
 - This triad is present in only 20–40% of cases.
 - ≥ 2 of these findings are present in approximately 60% of patients (see Acute Surgical Abdomen).
- Malrotation with midgut volvulus peaks during the first month of life but can occur anytime in childhood.
 - The neonate will be irritable initially.
 - As bowel becomes obstructed and necrotic, bilious vomiting and shock may result from perforation.
- Appendicitis is the cause of abdominal pain in 2–3% of children seen in ambulatory clinics or emergency departments.
 - Abdominal pain in a young child may first manifest as irritability, before the appearance of nausea, vomiting, fever, and right lower quadrant tenderness.

- Perforation rates for appendicitis are higher in children (30–60%) than in adults.
- Because the omentum is less developed in children, perforations are less likely to be walled off or localized.
- Hypertrophic pyloric stenosis may become symptomatic as early as the first week of life and as late as the fifth month.
 - Symptoms begin with nonbilious vomiting after feeding.
 - As the disease progresses, vomiting becomes projectile.
 - The baby may appear normal initially, but hunger makes the infant irritable, and signs of dehydration eventually become apparent.
- Necrotizing enterocolitis typically is seen in premature infants in their first few weeks of life.
 - It may be seen rarely in full-term infants, within the first 2 weeks after birth, particularly with a stressor, such as infection or anoxic event.
 - Infants are ill-appearing, irritable, and lethargic, with distended abdomen and bloody stools.
- Inguinal hernia
 - 60% of incarcerated inguinal hernias occur during the first year of life, with symptoms of irritability, vomiting, and pain in the groin and abdomen.
 - Testicular examination is imperative in all boys with irritability or abdominal pain.
 - On examination, a nonfluctuant tender mass is present in the inguinal region and may extend down into the scrotum.
 - With the onset of ischemia of the involved bowel, pain becomes more intense and localized to the scrotum, and the infant may have bilious vomiting with the presence of bloody stools.
- Irritability with scrotal pain also may result from epididymitis, torsion of the testis, or torsion of the appendix testis.

Cardiac system

- Acute myocarditis
 - 3 phases have been identified in the pathogenesis.
 - Viral replication
 - Autoimmune injury to myocytes
 - Dilated cardiomyopathy
- Anomalous left coronary artery originating from the pulmonary artery
 - Occurs in early infancy with irritability during or soon after feedings
 - Associated signs may include poor weight gain, diaphoresis, a murmur, and respiratory distress.
- Supraventricular tachycardia
 - May cause irritability and poor feeding

Hypoxic or ischemic events

- Carbon monoxide (CO) poisoning and methemoglobinemia cause irritability in response to hypoxia.

- A history of smoke inhalation and exposure to an indoor gas stove or to automobile exhaust fumes is indicative.
- Early findings with CO poisoning are influenza-like: headache, irritability, and dizziness.
- Prolonged exposure may result in altered mental status.
- Methemoglobinemia
 - Characteristic blue-gray cyanosis that is not improved with oxygen, despite normal arterial oxygen tension, and chocolate brown appearance of arterial blood are the hallmarks of methemoglobinemia.
 - In infancy it may be hereditary; the hereditary form usually is mild.
 - May be acquired, related to:
 - Hypoxic events
 - Medication use (sulfonamides, topical anesthetics, metoclopropamide)
 - Ingestion of products containing nitrites and nitrates (contaminated well water or foods with naturally occurring nitrates, such as spinach, green beans, carrots, and squash)
 - Diarrhea, probably caused by the nitrite-forming bacteria in the gut
- Sickle cell anemia
 - Ischemia may cause a painful vasoocclusive crisis.
 - Initial presentation in infants and younger children usually is irritability and dactylitis, and painful swelling of the hands and feet as a result of vascular stasis and ischemia.

Metabolic system

- Hypoglycemia, hypo- or hypernatremia, hypo- or hypercalcemia, hypomagnesemia, and inborn errors of metabolism can all cause irritability.
- Hypoglycemia is defined as a glucose level ≤ 40 mg/dL.
 - Can be a primary process
 - Can be caused by sepsis, ingestion, or cardiac or respiratory failure
- Hyponatremia can result from gastrointestinal losses or water intoxication.
- Hypernatremia is seen with diarrhea in which the water losses exceed salt loss, when replacement fluid has too high a sodium content, or with improper preparation of infant formula.
- Hypocalcemia
 - In the newborn period, may cause irritability, poor feeding, and lethargy
 - Later in infancy and during childhood, it is seen with rickets.
- Hypercalcemia is a rare electrolyte disturbance resulting from hyperparathyroidism, vitamin D intoxication, or idiopathic causes.
- Hypomagnesemia is found with hypocalcemia.

- Inborn errors of metabolism that cause irritability are those in which a toxic intermediate accumulates.
 - Organic and aminoacidemias and urea cycle disorders result in metabolic acidosis or hyperammonemia.
 - Symptomatic in the first few weeks of life, with vomiting, poor feeding, irritability, and lethargy
 - When a milder degree of enzyme dysfunction is present, clinical disease may be triggered by a bacterial or viral illness.

Toxins and drugs

- Life-threatening intoxications may result from:
 - Heavy metals, such as lead and mercury
 - Drugs of abuse, such as cocaine and alcohol
 - Envenomations by scorpions and snakes
 - Overdoses of or idiosyncratic reactions to medications
 - Contact with agricultural, industrial, or household chemicals
 - Thorough questioning about recent use of lawn chemicals, pesticides, and cleaning products may be the only clues to these factors as a cause of irritability, because many are not detected by standard toxicologic screening.
 - Prescribed or over-the-counter medications may cause irritability, even when used as directed and certainly when overused.
 - β -Agonists
 - Antiepileptics
 - Decongestants
 - Antihistamines
 - Antitussives
 - Various cold medicines
 - Certain drugs of abuse are known to cause irritability.
 - Cocaine
 - Alcohol
 - Phencyclidine hydrochloride
 - Inhalants
 - Exposure in infants and children may occur:
 - By passive means
 - Transplacentally
 - By ingestion of human milk
 - By inhalation
 - By accidental ingestion
 - A positive history may be difficult to elicit, and toxicologic screen may not always be helpful; thus, a strong index of suspicion is needed.
 - Substance use or withdrawal should be considered in the differential diagnosis when any adolescent has chronic persistent irritability.
 - In rare instances, intentional poisoning may be the cause of a child's distress.
- Irritability and intermittent fever sometimes indicate leukemia with bone pain.
 - Cancer of all sorts may have a component of irritability among their symptoms and must be considered carefully when no other diagnosis is forthcoming.

Acute irritability in the well-appearing child

- Irritability in infants has been attributed to a variety of causes of pain or discomfort that may become obvious during the evaluation.
- Dental caries and teething may cause an infant to be fussy or irritable (see Prevention of Dental Caries).
 - Teething may be accompanied by loose stools but not fever.
- Acute otitis media is a common cause of irritability, with or without fever, in children <2 years and in those attending child care.
- Gastroesophageal reflux
 - Particularly common in the first year of life
 - May be asymptomatic
 - May be indicated by postprandial irritability, recurrent vomiting, and inadequate weight gain
- Other sources of irritability and nonspecific crying episodes may be related to:
 - A foreign body in the ear or nose
 - If present for a prolonged period, results in foul-smelling discharge
 - Disk batteries need to be removed emergently because they may leak and can cause tissue destruction.
 - An insect in the ear canal can make a child very irritable and may be removed after first killing the insect with mineral oil or lidocaine.
 - Corneal abrasion
 - Foreign bodies under the eyelid, inward-turned eyelashes, or eye scratching may cause corneal abrasion.
 - Irritability, increased tearing, conjunctival injection, and photophobia
 - The foreign body may be removed by a moistened cotton-tipped applicator or by irrigation.
 - A hair tourniquet around the digit or genitals can cause pain and irritability.
 - Thorough examination of creases is essential; prolonged constricting bands may compromise distal circulation.
 - In some instances, the source of a child's irritability will be found only on thorough examination of the genitalia, which may reveal evidence of vaginitis, balanitis, or anal fissure.
 - Diaper dermatitis, common after a diarrheal illness, with *Candida* infection or as an allergic reaction to the diaper material
 - Insect and spider bites or stings

- Infants may be irritable after vaccination, with local erythema, swelling, and tenderness at the injection site.
 - Persistent, inconsolable crying lasting ≥ 3 hours within 48 hours of receiving whole-cell pertussis DTP vaccine has been reported but not with the newer acellular pertussis DTaP vaccine.

Chronic irritability

- Chronic irritability may be recurrent or persistent.
 - Psychosocial causes are most common.
 - Toxic, neurologic, metabolic, and miscellaneous causes
 - Abuse and neglect
- Irritability as a chronic feature of a child's behavior may indicate significant problems with familial relationships and the ability to master the environment.
 - Infants may be irritable because of maternal-infant temperament mismatches, maternal depression, or stress within the family.
- An older child or adolescent who has a psychiatric problem, such as depression, psychosis, autism, posttraumatic stress disorder, or substance abuse, may be described as "irritable."

Chronic recurrent irritability

- Colic
 - Usually occurs in infants < 3 months
 - Characterized by paroxysms of screaming, which may persist for several hours
 - Criteria for the diagnosis
 - Crying for ≥ 3 hours per day
 - For ≥ 3 days per week
 - Over > 3 weeks
 - Typically peaks at 6 weeks and abates by 3–4 months
- Constipation
 - Associated with inadequate fluid intake, low-fiber diet, dietary changes, and toilet training
 - Large, hard stools can result in anal fissures, which make the situation worse as the child becomes even more reluctant to use the bathroom because of the pain.
- Food allergy
 - Affects approximately 6–8% of infants and young children and approximately 3.5–4% of adults
 - The most common food allergens include cow's milk, eggs, peanuts, wheat, and shellfish.
 - Milk protein allergy usually is seen in the first few months of life.
 - Children are irritable and have blood-streaked stools, although they are otherwise healthy.
 - Treatment involves switching to hypoallergenic formulas derived from cow's milk, then gradually advancing to an unrestricted diet by 9–12 months of age.

Sleep disturbance

- Night terrors
 - Typically occur between 2 and 4 years of age during non-rapid eye movement sleep
 - Usually begin with sudden and prolonged periods of inconsolable crying and end spontaneously, with the child rapidly returning to sleep
- Nightmares
 - A nightmare occurs during rapid eye movement sleep, characterized by a frightening dream, which fully awakens the child; return to sleep is delayed.
 - Vivid recollection of dream appropriate to the child's developmental and maturational stage
- Neurologic disorders
 - Brain tumors
 - Migraine headaches
 - Seizures
 - Postconcussion syndrome
 - Particularly distressing to families because head injury may have occurred months or years before and may have seemed minor, yet irritability and behavior changes may be persistent

Chronic persistent irritability

Psychosocial disorders

- Attention-deficit/hyperactivity disorder is the most commonly diagnosed biological-behavioral disorder of childhood, occurring in approximately 6–9% of school-age children.
 - Children may have coexisting externalizing disorders (conduct disorder and oppositional defiant disorder) and internalizing disorders (depression and anxiety disorders).
 - A common presentation in infants and young children may be irritability from frustration as a result of family and peer relationships, propensity to accidental injury, and difficulty with academic work.
- Autistic disorder usually occurs in children < 3 years.
 - Early symptoms include irritability, deficits in verbal and social interaction, repetitive behaviors, failure to participate within groups, and hours spent in solitary play.
- Children with cognitive impairments
 - Children with severe cognitive impairments cannot verbalize what they are experiencing.
 - Although caregivers are usually adept at reading a child's body language and behaviors to know when the child is in pain, they often cannot identify the specific cause.
 - These children are likely to experience pain from the same sources as unimpaired children (eg, teething, sore throat, headache, minor trauma) but are at risk for additional sources of pain and discomfort.
 - Constipation, muscle spasms, and irritation from feeding tubes are frequent causes of irritability.

- In children with spastic quadriplegia, pathologic fractures are a common finding, related to limb rigidity, joint contractures, bone demineralization, and anticonvulsants.
- Children with cognitive impairments often receive multiple drugs for seizures, respiratory conditions, and constipation, with a high incidence of behavioral side effects (irritability, aggression, and hyperactivity).
- A wide variety of chronic disorders have irritability as a prominent or sole component.
- Hormonal effects associated with adolescence in both boys and girls can cause moodiness and irritability.

LABORATORY EVALUATION

- Infection
 - Cultures
 - Complete blood count
 - Erythrocyte sedimentation rate
 - C-reactive protein
- Metabolic system
 - Glucose
 - Electrolytes
 - Anion gap calculation
 - Ammonia
- Toxins and drugs
 - Blood and urine screening
- Acute myocarditis
 - Serum troponin level
- Carbon monoxide poisoning
 - Arterial measurement of carboxyhemoglobin

IMAGING

- Unexplained irritability or lethargy, or a scalp hematoma in an irritable child, protracted vomiting, or neurologic deficits, all warrant computed tomography of the head.
- Plain films, ultrasonography, magnetic resonance imaging, and bone scanning can be helpful in the evaluation of:
 - Suspected bone abnormalities
 - Fractures
 - Osteomyelitis
 - Infarction in sickle cell disease
 - Joint processes
 - Septic arthritis, particularly of the hip
 - Trauma

- Plain films of the abdomen can be helpful in diagnosing:
 - Necrotizing enterocolitis (pneumatosis intestinalis)
 - Malrotation with midgut volvulus
- Ultrasonography and computed tomography can be helpful with intraabdominal processes:
 - Appendicitis
 - Intussusception
 - Pyloric stenosis
 - Blunt abdominal trauma
- Acute myocarditis
 - Echocardiogram will show reduced ventricular function.
- Anomalous left coronary artery originating from pulmonary artery
 - Cardiomegaly on radiograph is almost universal.

DIAGNOSTIC PROCEDURES

- Corneal abrasion
 - Diagnosis is made by Wood lamp examination after instillation of fluorescein into the eye.
- Acute myocarditis should be considered in an irritable child with tachycardia, especially if accompanied by poor perfusion.
 - Electrocardiography may reveal sinus tachycardia with low-voltage QRS complexes, arrhythmias, and ST changes.
- Anomalous left coronary artery originating from pulmonary artery
 - Myocardial ischemia on electrocardiographic examination is almost universal.
- Nonconvulsive status epilepticus
 - Electroencephalography can be diagnostic.

TREATMENT APPROACH

- Treatment is based on the cause of irritability.

WHEN TO ADMIT

- Infants <1 month of who are irritable, for evaluation and observation
- Children in whom child abuse and neglect are suspected
- Children with a life-threatening condition, such as meningitis or brain tumor, that causes irritability

Jaundice

DEFINITION

- *Jaundice* is a yellowish discoloration of skin, sclerae, and mucous membranes that results from an increase in the serum concentration of bilirubin.
- Jaundice becomes evident at serum bilirubin concentrations:
 - >3 mg/dL in older children
 - >5 mg/dL in newborns
- *Hyperbilirubinemia* is defined as total serum bilirubin concentration >1.5 mg/dL.
 - Typically characterized by the fraction of bilirubin that is increased, unconjugated (indirect), or conjugated (direct)
 - Normal conjugated fraction accounts for <5% of total serum bilirubin.
 - *Conjugated hyperbilirubinemia* refers to direct bilirubin concentration >2 mg/dL or >20% of the total bilirubin concentration.
 - Conjugated hyperbilirubinemia should always be considered important because it suggests liver or biliary tract dysfunction.
- *Neonatal hepatitis* refers to infants <3 months who have cholestatic jaundice with nonspecific histologic features of hepatic inflammation and no defined cause.
 - The number of patients categorized as having neonatal hepatitis has been decreasing with:
 - Better understanding of the causes of neonatal cholestasis
 - Availability of many new advanced diagnostic techniques

EPIDEMIOLOGY

- Prevalence
 - All newborn infants have a total bilirubin level greater than an adult's normal limit of 1.5 mg/dL.
 - >50% of newborn babies will develop clinical jaundice in the first week of life.
 - Most have unconjugated hyperbilirubinemia.
 - Hemolysis
 - ABO incompatibility occurs in approximately 15% of all pregnancies.
 - Results in hemolytic disease in ~3% of newborns, with <0.1% of infants needing exchange transfusion
 - In the US, Rh negative genotype seen in:
 - 15% of white persons
 - 5% of black persons
 - <1% of Asian persons
 - Rh incompatibility occurs in ~1.06 per 1000 live births.
 - Prophylactic use of RhoGAM (anti-D γ -globulin) in Rh-negative mothers has decreased incidence of hemolytic disease to <0.11% of Rh-negative pregnancies.

- Polycythemia
 - 1–5% of newborns
 - Unconjugated hyperbilirubinemia develops in 2–22% of affected babies.
- Parenteral nutrition
 - 30–50% of infants and 80% of preterm babies who receive total parenteral nutrition (TPN) for >2 weeks develop cholestatic jaundice.
- α 1-Antitrypsin deficiency
 - Found in 1 in 1600–2000 live births
- Galactosemia
 - Occurs in 1 per 60,000
- Gilbert syndrome
 - Affects 7% of the general population

MECHANISM

- Bilirubin is the end product of heme degradation.
- Heme is produced from the breakdown of hemoglobin (70–80%) and other hemoproteins (20–30%).
- The conversion from heme to bilirubin follows a 2-step process that occurs mainly in the reticuloendothelial cells of the spleen, liver, and bone marrow.
 - Heme is converted to biliverdin by the microsomal enzyme heme oxygenase
 - Biliverdin is converted to bilirubin by the cytosolic enzyme biliverdin reductase.
 - This unconjugated bilirubin is a hydrophobic compound that is:
 - Tightly bound to serum albumin
 - Transported to the liver for conjugation and clearance
- Metabolism of bilirubin in the liver follows 4 distinct steps.
 - Bilirubin is taken up across the sinusoidal (basolateral) membrane of the hepatocyte by a membrane receptor carrier.
 - Bilirubin then binds to ligandin, an intracellular binding protein and is conjugated with glucuronic acid in the endoplasmic reticulum by the enzyme bilirubin uridine diphosphate-glucuronosyl transferase (BUGT) to form bilirubin mono- and diglucuronides.
 - The isoform *UGT1A1* is responsible for bilirubin conjugation.
 - Different mutations in the gene for this enzyme have been found in such diseases as Gilbert syndrome and Crigler-Najjar syndrome.
 - Water-soluble bilirubin glucuronides are excreted into bile through the apical canalicular membrane.
 - This process is mediated by an adenosine triphosphate-dependent export pump.

- Genetic mutations in the gene for this pump are found in cystic fibrosis and in Dubin-Johnson and Rotor syndromes.
- Almost all bilirubin in adult human bile is of the conjugated form.
 - 15% as bilirubin monoglucuronides
 - 85% as diglucuronides
- Neonates have a higher concentration of bilirubin monoglucuronides in their bile because of lower BUGT enzyme activity.
 - Monoglucuronides are easily deconjugated and reabsorbed in the intestine.
- Excreted bilirubin is further metabolized by intestinal bacteria to form urobilinoids, which are then eliminated in the feces.
 - This prevents intestinal reabsorption of bilirubin.
 - Bilirubin glucuronides can also be deconjugated by bacterial or tissue β -glucuronidase in the intestine and then reabsorbed in the terminal ileum, a process known as *enterohepatic circulation*.
 - Newborns are more likely to absorb bilirubin from the intestine because they lack bacterial flora to form nonabsorbable urobilinoids.
 - Conditions that delay passage of meconium, which contains large amounts of bilirubin and β -glucuronidase, can result in neonatal hyperbilirubinemia.
 - Breast milk contains high levels of β -glucuronidase, which may be a contributing factor in the development of breast milk jaundice.
- Direct bilirubin consists of 2 components.
 - Conjugated bilirubin
 - δ -bilirubin
 - Conjugated bilirubin-albumin compound formed when bilirubin glucuronides reflux into systemic circulation and covalently bind to albumin
 - The terms *direct* and *conjugated* bilirubin are used interchangeably.
- α -, β -, and γ -bilirubin correspond to unconjugated, monoconjugated, and diconjugated forms.
 - δ -Bilirubin is clinically important because it is not excreted in bile or urine until albumin is degraded.
 - This accounts for prolonged direct hyperbilirubinemia occasionally observed after restoration of normal bile flow.
- Abdominal pain or distention
- Acholic stools
- Dark urine
- Pruritus
- In patients with neonatal jaundice, focus on:
 - Prenatal history
 - Quality of prenatal care
 - Maternal blood test results
 - Birth history
- In older children, focus on:
 - Patient's age at onset of jaundice
 - Associated signs and symptoms before and during the period of jaundice
 - Exposure to hepatotoxic agents
- Detailed family history should include:
 - Information about the presence of persistent jaundice
 - Chronic liver diseases
 - Hemolysis
 - Metabolic diseases
- Goals of initial evaluation are to distinguish:
 - Acute from chronic liver diseases
 - Intrahepatic processes from extrahepatic biliary tract obstruction
 - Primary liver diseases from systemic diseases

PHYSICAL EXAM

- Patients with jaundice from unconjugated hyperbilirubinemia have bright yellow-colored skin.
- Patients with jaundice from conjugated hyperbilirubinemia have dark yellow-greenish-colored skin.
- Patients should undergo a complete physical examination, with special focus on:
 - General appearance
 - Growth and development
 - Signs of cardiovascular dysfunction
 - Neurologic signs
 - Organomegaly
- The size and character of the liver should be determined.
 - The newborn or infant liver is a large organ relative to body size.
 - In newborns, mean liver span is 5.9 cm along the mid-clavicular line, calculated by measuring the distance between the percussed upper and palpated lower liver edge.
 - Normal infant liver may be palpable and is typically <2 cm below the right costal margin.

HISTORY

- A detailed history is essential when evaluating a patient with jaundice.
- Special attention should be paid to the presence of:
 - Fever
 - Viral prodrome

- Consistency and character of the liver edge may help determine nature of underlying liver disease.
 - Enlarged liver resulting from an acute intrahepatic process is usually tender but soft.
 - Cirrhotic liver may have a hard and irregular edge, but its edge is not always palpable.
- Thorough abdominal examination to identify:
 - Enlarged spleen
 - In newborns and infants, the tip of the spleen can normally be palpated below the left costal margin.
 - Splenomegaly in a patient with underlying liver disease implies portal hypertension, especially in the presence of ascites and a prominent abdominal cutaneous venous pattern.
 - Other abdominal masses
 - Areas of tenderness
 - Ascites
 - Abdominal cutaneous venous pattern
 - Other physical findings may indicate a particular cause, such as:
 - Xanthomas in primary biliary cirrhosis
 - Kayser-Fleischer rings in Wilson disease
 - Characteristic facial features and posterior embryotoxon in Alagille syndrome

DIFFERENTIAL DIAGNOSIS

General

- Differential diagnosis of jaundice is categorized as either unconjugated or conjugated hyperbilirubinemia in 2 age groups:
 - Newborn and young infants
 - Older infants and children
- Unconjugated hyperbilirubinemia is common in neonates but relatively rare thereafter.
 - Typically transient and benign, but marked increases of bilirubin can be toxic to the central nervous system.
- Conjugated hyperbilirubinemia is always pathological.
 - When present in young infants, it is often related to:
 - Primary hepatobiliary disorders
 - Systemic or metabolic diseases
 - Genetic defects in bilirubin or bile acid metabolism or transport.
 - More prevalent in older children
 - Viral hepatitis
 - Drug- or toxin-induced liver damage

Jaundice in newborns and young infants

Unconjugated hyperbilirubinemia

- Nonphysiological jaundice should always be considered in neonatal jaundice.

- A pathological cause suggested by:
 - Early onset
 - Rapid progression
 - Persistence beyond 2 weeks of life
 - Association with other signs or symptoms
- In most instances, pathological unconjugated hyperbilirubinemia results from either excessive production of bilirubin or abnormal hepatic clearance of bilirubin.

Increased production of bilirubin

- Hemolysis (ABO or Rh incompatibility, erythrocyte defects, erythrocyte enzyme defects, disseminated intravascular coagulopathy)
- Weakly positive direct Coombs test, high reticulocyte count, spherocytes on blood smear, and high levels of unconjugated bilirubin.
 - The most common cause of excessive bilirubin production in neonates
 - Usually observed within the first 24 hours of life
 - Often seen in association with maternal-fetal blood type incompatibility (ABO or Rh incompatibility)
 - Positive direct Coombs test, high reticulocyte count, spherocytes on blood smear, and high levels of unconjugated bilirubin
 - ABO incompatibility is usually seen in newborn infants with blood type A or B born to blood type O mothers.
 - Hemolytic disease in Rh incompatibility usually develops when an Rh-negative mother has become sensitized after exposure to Rh-positive fetal blood during a previous pregnancy.
 - Rh incompatibility is less common and usually more severe than ABO incompatibility.
 - Affected infants usually experience onset of jaundice in the first hours of life, and have anemia and hepatosplenomegaly.
 - In severe cases, the infant may be born with fetal hydrops from intrauterine hemolysis.
- Hemoglobinopathies
 - Polycythemia
 - Can cause an increase in bilirubin production as a result of absolute increase in erythrocyte mass
 - α -thalassemia
 - Suspect in newborns with jaundice and moderate hypochromic, microcytic, hemolytic anemia
 - Erythrocyte enzyme defects
 - Erythrocyte enzyme defects, such as glucose-6-phosphate dehydrogenase (G6PD) or pyruvate kinase deficiency, may cause hemolysis at any age.

- G6PD deficiency is often benign in the newborn period; however, clinically important hemolysis and jaundice may develop in the presence of oxidant stressors, such as infections.

- Cephalohematoma resorption

- Increased bilirubin production caused by rapid breakdown of erythrocytes in the extravascular space

- **Decreased hepatocellular uptake or conjugation**

- Prematurity

- Congenital hypothyroidism

- Presumably caused by delayed maturation of BUGT

- Physiological jaundice of the newborn

- Breast milk jaundice

- Usually occurs in a thriving breastfed newborn during the second and third weeks of life
- Thought to be related in part to inhibition of BUGT activity by compounds found in breast milk

- Drugs

- Aspirin, cephalosporins, and sulfonamides can impair bilirubin transport by altering bilirubin-albumin binding
- Rifampin can inhibit hepatocellular uptake of bilirubin.

- Gilbert and Crigler-Najjar syndromes

- Gilbert syndrome is a common inherited condition characterized by mild unconjugated hyperbilirubinemia.
 - An insertional mutation of the *UGT1A1* gene results in a reduced level of expression of the gene.
 - Gilbert syndrome is usually diagnosed during or after adolescence.
- Crigler-Najjar syndrome is a rare familial form of unconjugated hyperbilirubinemia caused by mutations in the gene encoding BUGT1.
 - Leads to either absent (type 1) or decreased (type 2) BUGT activity.
 - Type 1 is an autosomal-recessive disease and exhibits in the first hours of life with severe nonhemolytic jaundice.
 - Type 2 is an autosomal-dominant disease with less severe jaundice and may improve with phenobarbital to promote bile flow.

- **Conjugated hyperbilirubinemia**

- Also known as *cholestatic jaundice*, regardless of cause

- Usually associated with liver dysfunction, and always pathological

- It can result from:

- Impaired bile formation by the hepatocyte
- Obstruction to the flow of bile through the intrahepatic or extrahepatic biliary tree from
 - Primary hepatobiliary disorders
 - Genetic or metabolic diseases

- Systemic infections

- Drug toxicity

- **Liver diseases**

- Acute liver damage (ischemia, hypoxia, acidosis)

- Conditions that alter systemic circulation, such as cardiopulmonary arrest, shock, and severe metabolic acidosis, may lead to an acute ischemic insult to the liver and necrosis of hepatocytes.
- Affected patients have a marked and rapid increase in serum aminotransferase levels and direct hyperbilirubinemia within 24–48 hours after the insult.
- In most, liver function will normalize once the initial insult is corrected.
- A small number of patients may develop acute liver failure.

- Infection

- Sepsis
 - The most frequently associated bacterial organisms are *Escherichia coli*, *Streptococcus* group B, and *Listeria monocytogenes*
- TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex)
 - Low birth weight, hepatosplenomegaly, cutaneous manifestations, and ophthalmologic and central nervous system involvement
 - Diagnosis is often made by virus culture, serologic titers, imaging studies, and ophthalmologic examination.
 - Anemia, thrombocytopenia, increased aminotransferase levels, and cholestasis
 - Other infections, such as HIV and hepatitis B and C, have decreased with improved prenatal screening.
- Urinary tract infections

- Viral or other hepatitis

- TPN-related liver disease

- Factors thought to contribute include lack of enteral feeds, immaturity of the hepatobiliary system, infused nutrient composition, and sepsis.
- In most infants, liver function abnormalities usually resolve within 4–6 months after discontinuation of TPN.
- In severe cases, progression to end-stage liver disease may occur.

- Metabolic liver disease (galactosemia, neonatal hemochromatosis, α_1 -antitrypsin deficiency, tyrosinemia, mitochondrial defects)

- Neonatal hemochromatosis

- Typical laboratory findings include increased ferritin and transferrin saturation and relatively low transferrin levels.
- Liver aminotransferase levels can be slightly increased or even normal.

- Tyrosinemia type 1
 - Markedly increased α -fetoprotein level
 - Presence of succinylacetone in urine or blood is pathognomonic.

■ Hormones and drugs

Obstruction of biliary system

■ Congenital anomalies (biliary atresia, choledochal cyst)

- *Extrahepatic biliary atresia* (EHBA) is an idiopathic, destructive, inflammatory process of both the intra- and extrahepatic bile ducts.
 - One of the few causes of neonatal cholestasis that can be treated with surgery
 - Infants typically exhibit symptoms of cholestatic jaundice and acholic stools when they are approximately 2–4 weeks of age.
 - In early stages, the stool may still have some bile pigment.
 - When EHBA is suspected, exploratory laparotomy with intraoperative cholangiography should be performed to confirm the diagnosis.
 - Patients then undergo hepatopertoenterostomy, or the Kasai procedure.
 - The highest success rate of reestablishing bile flow after surgery is seen when the procedure is performed before the child is 8 weeks of age.
- Choledochal cysts are rare congenital anomalies characterized by varying degrees of cystic dilation of the intra- or extrahepatic biliary tree.
 - May be detected at any age; 18% of cases are diagnosed during the first year of life.
 - Classic presentation of jaundice, abdominal pain, and right epigastric mass is often not observed in infants and young children.
- *Alagille syndrome*, also known as *arteriohepatic dysplasia*, is inherited as an autosomal-dominant condition with variable penetrance.
 - Characterized by paucity of intrahepatic bile ducts, peripheral pulmonary stenosis, butterfly vertebrae, posterior embryotoxon, and peculiar faces.
 - Jaundice and pruritus are often the main clinical features during infancy.

Defects of bilirubin metabolism or transport

■ Progressive familial intrahepatic cholestasis

- Identified as a distinct group of conditions involving intrahepatic cholestasis from bile acid transport defects leading to impairment of bile excretion.
 - Affected patients often develop jaundice in the 1st few months of life.
 - They may also have severe pruritus, growth failure, fat-soluble vitamin deficiency, abnormal coagulation profile, and increased serum bile acids.

- Disease usually progresses to cirrhosis and liver failure early in life.

■ Dubin-Johnson syndrome, Rotor syndrome

■ *Galactosemia* is an inborn error of galactose metabolism inherited as an autosomal-recessive trait.

- Can affect many organs, including the liver, kidneys, brain, eyes, intestines, and gonads
- Hepatocellular damage is caused by accumulation of toxic metabolites of galactose-1-phosphate and galactitol in the liver.
- Clinical presentation varies from mild liver disease to fulminant liver failure in the neonatal period.
- Jaundice and hepatomegaly can develop in association with vomiting, diarrhea, poor feeding, or *E coli* sepsis.

■ Other inborn errors of carbohydrate metabolism, such as hereditary fructose intolerance and certain types of glycogen storage diseases, can also have jaundice as part of their clinical picture.

- Onset of symptoms rarely occurs during early infancy.

■ *Neonatal hemochromatosis* is a rare idiopathic syndrome characterized by liver disease of prenatal onset and excess iron deposition in extrahepatic sites.

- Infants are usually born early and have experienced intra-uterine growth retardation.
- In most, signs and symptoms of acute liver failure are present at birth or develop soon thereafter.
- Clinical presentation includes hypoglycemia, hypoalbuminemia, profound coagulopathy, and cholestatic jaundice.
- The diagnosis should be considered in every case of neonatal liver failure.

■ α_1 -Antitrypsin deficiency is a genetic disorder, with the homozygous PiZZ genotype.

- Only 10% of patients with α_1 -antitrypsin deficiency develop signs and symptoms of liver disease.
- The most common genetic cause of neonatal liver disease
- Typically shows in the first few months of life with jaundice, although onset of liver disease can occur later in life
- Injury to the liver is thought to be the result of the hepatotoxic effect of retained mutant α_1 ATZZ molecule in the endoplasmic reticulum of the hepatocyte.

■ *Tyrosinemia type 1*, also known as *hepatorenal tyrosinemia*, is a rare disorder that can affect the liver, kidneys, and peripheral nerves.

- Deficiency of fumarylacetoacetate hydrolase, an enzyme involved in tyrosine degradation, results in tissue accumulation of tyrosine and other intermediate metabolites.
- Clinical findings range from severe liver disease or acute liver failure in early infancy to chronic liver disease in older children.

- Tyrosinemia should be suspected in patients who exhibit signs and symptoms of liver disease, especially when associated with acute neurologic symptoms, such as excruciating pain, weakness, and paralysis.
- Early diagnosis is important because specific medical therapy will improve quality of life and delay disease progression.
- Primary mitochondrial hepatopathies are caused by a variety of defects, including mitochondrial DNA depletion, respiratory chain defects, fatty acid oxidation defects, and mitochondrial membrane enzyme defects.
 - Patients commonly have neuromuscular problems and may have marked lactic acidosis.
 - Symptoms usually develop within the first few months of life.
- Other viruses (eg, Epstein-Barr virus, cytomegalovirus, adenovirus, enterovirus) can also cause acute hepatitis.
 - Jaundice is a common presenting feature.

Jaundice in older infants and children

- In this age group, jaundice is an unusual sign and may suggest a serious clinical condition.

Unconjugated hyperbilirubinemia

- In general, unconjugated hyperbilirubinemia is rarely seen in older infants and children.
- Hemolysis: erythrocyte defects, erythrocyte enzyme defect (G6PD), disseminated intravascular coagulopathy
- Gilbert syndrome
 - A benign disorder inherited as an autosomal-dominant trait, although an autosomal-recessive pattern has also been described.
 - Jaundice does not typically develop until after puberty
 - Jaundice is usually intermittent and more evident with fasting.
 - Patients usually have mild indirect hyperbilirubinemia with otherwise normal liver function tests and no evidence of ongoing hemolysis.

Conjugated hyperbilirubinemia

Liver disease

- Viral hepatitis (hepatitis A, B, C, E)
 - Acute viral hepatitis is the most common cause of jaundice in older children.
 - Hepatitis A
 - In older children and adolescents, jaundice is a common manifestation
 - Children <5 years tend to be anicteric.
 - Rarely causes fulminant liver failure
 - Hepatitis E has a clinical course similar to that of hepatitis A.
 - Should be suspected in children with a history of recent travel to India or South Asia
 - Hepatitis B or C infection is usually anicteric and chronic in children.
- Toxins and drugs (ethanol, acetaminophen, isoniazid, phenytoin)
 - Initially suspected on the basis of circumstantial evidence
 - Classified into 3 types, according to the different clinical features
 - Hepatitic
 - Acetaminophen overdose can cause acute hepatitis with zonal hepatocyte necrosis; jaundice develops when hepatocellular damage is sufficiently severe.
 - Cholestatic
 - Cholestasis is more prominent when damage to bile duct epithelial cells results in an impaired bile flow.
 - Can be caused by many different drugs, including estrogen or oral contraceptive pills, erythromycin, cyclosporine, and haloperidol.
 - Mixed hepatitic-cholestatic
 - Most cases of drug-induced liver damage spontaneously resolve once the drug responsible for the injury is withdrawn.
- Autoimmune hepatitis (AIH)
 - Cause unknown
 - Usually progresses to cirrhosis if not promptly diagnosed and treated
 - Should always be considered in a child with jaundice associated with increased liver aminotransferase levels
 - Jaundice is present in more than one half of patients with AIH.
 - Hyperglobulinemia and autoantibodies, such as anti-nuclear antibody, anti-smooth muscle antibody, and anti-liver kidney microsomal antibody, may be found.
 - When present, anti-liver kidney microsomal antibody categorizes the disease as AIH type 2.
 - AIH type 1 usually has an insidious course.
 - Patients are likely to come to attention at an older age, some already with cirrhosis.
 - AIH type 2 may have a more fulminant course, even first exhibiting as acute liver failure.
- Metabolic liver disease (α_1 -antitrypsin deficiency, tyrosinemia, Wilson disease, mitochondrial defects)
 - *Wilson disease* is an autosomal-recessive disorder of human copper metabolism, usually found in children >5 years.
 - Mutations in the *ATP7B* gene lead to impaired biliary excretion of copper, resulting in progressive accumulation of copper in the liver and subsequently in other organs and tissues.

- Hemolytic anemia, Kayser-Fleischer rings in the eyes, and neuropsychiatric symptoms are manifestations of the disease.
- Copper deposition in liver can result in acute or chronic hepatitis, cirrhosis, or fulminant liver failure.
- Markedly increased bilirubin is typically found in patients with Wilson disease who have fulminant liver failure.
- Nonalcoholic fatty liver disease
- Acute liver damage: ischemia, hypoxia, acidosis
- TPN related
- Pregnancy related (acute fatty liver of pregnancy, preeclampsia)
- Cancer
 - Infiltrative cancers may occur rarely and can cause jaundice at any age.

Obstruction of the biliary system

- Choledochal cyst
- Cholelithiasis or choledocholithiasis
 - Most common cause of biliary obstruction in children
 - Often found in patients with an underlying hemolytic disease
 - Isolated gallstone disease can occur:
 - In infants, jaundice is the most common presentation.
 - Older children usually experience vomiting and right upper quadrant pain, with or without jaundice.
- Cholecystitis
- Diseases of the bile ducts (primary sclerosing cholangitis, AIDS cholangiopathy)
 - Primary sclerosing cholangitis is characterized by stenosis, dilatation, and fibrosis involving the intrahepatic or extrahepatic biliary tree or both.
 - Most common form of chronic liver disease in children with inflammatory bowel disease.
 - Clinical presentation is highly variable, with cholestatic jaundice developing in <50% of affected patients.

Bilirubin metabolism or transport defects

- Progressive familial intrahepatic cholestasis
- Dubin-Johnson syndrome
 - Recessively inherited disorder caused by mutations in gene encoding for the canalicular transporter for conjugated bilirubin that results in an impaired secretion of conjugated bilirubin
 - Chronic jaundice is the main clinical manifestation.
 - Serum bile acids are normal.
 - Can be precipitated by pregnancy or the use of oral contraceptives

- Rotor syndrome
 - Clinically similar to Dubin-Johnson syndrome, but involving impairment of liver storage capacity rather than a defect in bilirubin secretion
 - Inherited as an autosomal-recessive disorder
- In both Dubin-Johnson syndrome and Rotor syndrome, conjugated hyperbilirubinemia is noted without abnormalities in other liver function tests.

LABORATORY EVALUATION

- Serum bilirubin is conventionally measured by spectrophotometry based on the Van den Bergh (diazo) reaction.
 - Conjugated (direct) bilirubin reacts rapidly with diazo reagents.
 - Unconjugated (indirect) bilirubin reacts slowly.
 - Indirect bilirubin is calculated as the difference between total bilirubin and direct bilirubin fraction.
 - Direct bilirubin consists of conjugated bilirubin and δ -bilirubin.
 - High-pressure liquid chromatography can measure δ -bilirubin, as well as α -, β -, and γ -bilirubin.
- Initial laboratory studies in the evaluation of jaundice include:
 - Complete blood count
 - Useful in detecting hemolysis, indicated by the presence of anemia with fragmented erythrocytes (schistocytes) and increased reticulocytes on the smear
 - Thrombocytopenia is typically seen in patients with portal hypertension and hypersplenism.
 - Liver function tests
 - Isolated hyperbilirubinemia with otherwise normal liver function suggests hemolytic disease or bilirubin metabolism defects.
 - Coagulation profile
- Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels are the most frequently used markers of hepatocellular injury.
 - ALT is a more specific indicator of hepatocyte injury because AST may be increased with hemolysis and myocardial or skeletal muscle injury.
 - In general, marked increase in AST and ALT occurs in severe viral hepatitis, acute toxin- or drug-induced hepatic necrosis, or ischemia.
 - Mild increase of AST and ALT is seen in nonalcoholic fatty liver disease, chronic viral hepatitis, and drug toxicity.
 - Declining AST and ALT levels indicate hepatocyte recovery.
 - In the course of fulminant liver failure, if seen in association with a worsening liver synthetic function, decreasing AST and ALT levels may be an ominous sign of massive hepatic necrosis, with few viable hepatocytes remaining to further release these enzymes.

- AST and ALT are less useful in patients with chronic end-stage liver disease because they can be normal or only slightly increased in the presence of marked fibrosis of the liver.
 - Alkaline phosphatase and γ -glutamyltransferase (GGT) are 2 useful markers for intra- and extrahepatic cholestasis.
 - In most hepatobiliary diseases, both GGT and alkaline phosphatase are increased.
 - In progressive familial intrahepatic cholestasis (types 1 and 2), a normal or low GGT is observed in the presence of a high alkaline phosphatase.
 - Isolated increase of alkaline phosphatase may be seen in patients with nonhepatobiliary diseases, such as bone disorders.
 - Normal GGT values in newborn infants may be 5–8 times greater than those in adults.
 - Prothrombin time (PT) and albumin are used to evaluate hepatic synthetic function.
 - Abnormal PT results from impaired hepatic synthesis of coagulation factors I, II, V, VII, and X or deficiency of vitamin K (or both).
 - Parenteral administration of vitamin K generally normalizes a prolonged PT in patients with vitamin K deficiency associated with cholestatic jaundice but not in patients with hepatocellular disease.
 - In acute liver disease, markedly increased PT suggests the possibility of fulminant liver failure.
 - Hypoalbuminemia may be seen in patients with acute and chronic liver diseases.
 - In the early stages of acute liver disease, serum albumin may not be a reliable indicator of hepatic synthetic function because it has a long half-life (~21 days).
 - Based on clinical information and results of initial tests, further evaluation, including imaging studies, may be warranted.
 - Additional studies may include:
 - Blood and urine cultures
 - Viral serologic studies
 - Toxin and drug screen
 - Autoimmune markers
 - α_1 -antitrypsin phenotype
 - Ceruloplasmin
 - Urine succinyl acetone
 - Serum bile acids
 - In jaundiced newborns or young infants with abnormal liver function tests, TORCH titers should also be obtained.
- Suggests such causes of jaundice as:
 - Biliary atresia
 - Choledochal cyst
 - Hepatic cystic lesions
 - Cholelithiasis
 - In EHBA:
 - Can exclude other causes of cholestasis, such as choledochal cysts, gallstones, or biliary sludge.
 - Absence of gallbladder or appearance of the triangular cord sign at the hilar region is suggestive of EHBA.
 - Presence of a gallbladder on sonography does not exclude EHBA.
- Computed tomography may be preferred for
 - General anatomic information of the hepatobiliary system
 - Assessing possible noncystic hepatic lesion
 - Nuclear scintigraphy, useful in
 - Differentiating biliary atresia from other causes of neonatal cholestasis
 - Diagnosis of acute cholecystitis and chronic acalculous cholecystitis in older children
 - By calculation of gallbladder ejection fraction
 - Magnetic resonance imaging (MRI) cholangiopancreatography
 - Noninvasive study that identifies abnormalities of the intra- and extrahepatic biliary system.
 - Endoscopic retrograde cholangiopancreatography provides information similar to that of MRI.
 - Invasive and should be reserved for patients who need a possible therapeutic intervention
 - Biliary stent placement
 - Sphincterotomy

DIAGNOSTIC PROCEDURES

IMAGING

- Ultrasonography is the most useful initial imaging modality in the assessment of the intra- and extrahepatic biliary system in patients with jaundice.

- Liver biopsy provides information on the histology and architecture of the liver.
 - Percutaneous liver biopsy is most commonly used in patients with persistently abnormal liver function tests, especially when conventional laboratory and imaging studies do not lead to a firm diagnosis.
 - Use of liver biopsy to diagnose acute hepatitis or acute cholestatic jaundice is limited because the histologic changes may be nonspecific.
 - In fulminant liver failure, percutaneous liver biopsy is contraindicated because of high risk of bleeding; when needed, transjugular liver biopsy under radiographic guidance should be performed.
- EHBA
 - Percutaneous liver biopsy is an essential procedure in suspected EHBA.

- Main histopathological features observed are bile duct proliferation and fibrosis.
- Neonatal hemochromatosis
 - The diagnosis is made by punch biopsy of the lower-lip mucosa; the sample is analyzed for iron deposition in salivary glands.
- Dubin-Johnson syndrome
 - Characteristic brown to black discoloration of the liver, the result of pigment deposition in the lysosomes
- Dubin-Johnson syndrome, Rotor syndrome
 - Liver histologic findings are otherwise normal in both syndromes.

TREATMENT APPROACH

- Treatment of newborns with unconjugated hyperbilirubinemia is based on revised guideline published by the AAP.
 - Provides a framework in detecting neonatal hyperbilirubinemia and preventing kernicterus in term and near-term newborn infants
 - Emphasizes the importance of:
 - Systematic assessment of the risk of severe hyperbilirubinemia
 - Close follow-up
 - Prompt intervention when necessary

SPECIFIC TREATMENT

Direct hyperbilirubinemia

- Management should focus on correcting the underlying cause, optimizing nutrition, and controlling pruritus.
- Malabsorption of fat and fat-soluble vitamins is commonly seen in patients with cholestasis because they have impaired bile acid secretion.
- A diet high in medium-chain triglycerides should be used to promote growth in children with chronic cholestasis.
 - Medium-chain triglycerides are relatively water soluble and directly absorbed into the portal system, unlike long-chain triglycerides, which require bile acid micelles for solubilization.
- Supplementation of fat-soluble vitamins A, D, E, and K is essential.
 - Serum vitamin levels should be routinely monitored because patients may still have biochemical evidence of fat-soluble vitamin deficiency despite supplementation.

Cholestasis-associated pruritus

- Several different therapeutic agents have been used with very little success.
- Choleric agents, such as ursodeoxycholic acid and phenobarbital, increase bile flow, decreasing serum level of bile acid.
 - These agents have shown some beneficial effect in relieving pruritus.

- Other agents have been shown to reduce pruritus in some patients.
 - Cholestyramine, a bile acid-binding resin
 - Rifampin, an antibiotic used to treat tuberculosis

Liver transplantation in children

- Accepted therapy for many life-threatening liver diseases
- Whole-liver, split-liver, and living donor transplantations have been successfully used to treat both infants and older children.
- Current survival rates for children after liver transplantation are:
 - 90% at 1 year
 - 85% at 3 years
- Early referral and transfer to a liver transplant center are important to good outcome.
- EHBA with a failed Kasai procedure is the most common reason children undergo liver transplantation.
- Other indications include:
 - α_1 -antitrypsin deficiency
 - Fulminant liver failure
 - Chronic hepatitis
 - Metabolic liver disease
 - Cirrhosis of unknown origin

WHEN TO REFER

- Unexplained jaundice
- Direct hyperbilirubinemia at any age
- Jaundice with persistent or unexplained abnormal liver function tests
- Jaundice with hepatomegaly or splenomegaly

WHEN TO ADMIT

- Jaundice in an ill patient
- Poor feeding tolerance and intravenous hydration
- Need for intravenous antibiotics
- Inpatient management of underlying conditions
- Impending acute liver failure

COMPLICATIONS

- If the underlying liver condition which results in hyperbilirubinemia is not diagnosed early and treated properly, it may lead to hepatic failure

PROGNOSIS

- Prognosis depends on the underlying cause of direct or indirect hyperbilirubinemia.

PREVENTION

- Hepatitis A and hepatitis B can be prevented by vaccinating all children.

Joint Pain

DEFINITION

- *Arthralgia* is joint pain, the subjective experience of pain [referable to a bony articulation].
 - In a young child, it might be inferred from the patient's refusal to move a particular extremity or joint.
- *Arthritis* is an inflamed joint.
 - Redness
 - Warmth
 - Swelling
 - Tenderness
 - Pain with motion
 - Can be accompanied by loss of motion
- All that is arthralgia is not arthritis.

EPIDEMIOLOGY

- Juvenile idiopathic arthritis (JIA)
 - Prevalence
 - 0.1–1 child per 1000 children worldwide
 - Age
 - Systemic-onset disease is typically seen in children 1.5–2 years of age.
 - Onset of JIA can occur through late adolescence.
- Reactive arthritis (previously called *Reiter syndrome*)
 - Sex
 - More common in boys than in girls

MECHANISM

- Onset of joint pain can be sudden or indolent (over days or weeks).
 - When sudden, an associated history of a fall or direct blow to the joint suggests a traumatic cause.
- Presence of fever indicates:
 - Infectious process (eg, septic arthritis)
 - Systemic inflammatory disease (eg, systemic-onset JIA)
- Fractures and dislocations are common causes of joint pain.

HISTORY

- A complete history is indispensable in initial assessment of joint pain.
- A common symptom is loss of motion in a joint, with or without obvious swelling.
 - Further clues are time of day the stiffness occurs and its duration.
 - In JIA, patients typically experience joint stiffness when waking up in the morning (lasting 30 minutes to several hours).
 - Hypermobility syndrome or other mechanical, noninflammatory condition causes pain and stiffness at the end of a vigorous day.

PHYSICAL EXAM

- The physical examination can substantiate or alleviate suspicions raised during history taking.
- Distinguishing between arthralgia and arthritis is essential.
- In systemic-onset JIA, in addition to fever, other distinguishing signs are:
 - Rash
 - Mucous membrane involvement
 - Lymph node inflammation or enlargement
- See Differential Diagnosis for condition-specific physical examination findings.

DIFFERENTIAL DIAGNOSIS

- Differential diagnosis should begin by determining whether disease is rheumatic or nonrheumatic.
- Most rheumatic diseases cause joint pain and tend to be chronic (often with waxing and waning courses).
- Many of the nonrheumatic diseases are acute in onset and short in duration, given appropriate therapy.

JIA

- JIA is also called *Still disease*, previously called *juvenile rheumatoid arthritis*.
- Clinical presentation
 - Can be limited to ≤ 4 joints, or include a greater number
 - Usually large joints (oligoarticular disease)
 - Both large and small joints might be involved (polyarticular disease)
 - The systemic and at times initially fulminant form is called *systemic-onset disease*.
 - Marked by high, spiking fevers
 - Typical salmon-pink, maculopapular, evanescent rash
 - Lymph node, spleen, and liver enlargement
 - Subcutaneous nodules
 - Anemia
 - General malaise
 - Systemic findings can precede onset of joint involvement.
 - Arthritis must be present for ≥ 6 consecutive weeks to establish diagnosis of any of the subgroups of JIA.
 - Among patients with any subtype of JIA:
 - The clinician may glean only a history of ill-defined arthralgias and stiffness
 - Physical examination may reveal:
 - Contractures of the elbows, knees, and wrists
 - Limitation of cervical motion
 - Iridocyclitis and keratopathy

Acute rheumatic fever

- Usually involves large joints (eg, knees)
- Typically migratory
- Joints tender to palpation
- Signs of marked inflammation are commonly present, but arthralgia alone may be seen.

Ankylosing spondylitis (spondyloarthropathy)

- Can involve large joints of the lower extremities
- Typified in late adolescence by involvement of the sacroiliac joint
 - Seen on radiographs or magnetic resonance imaging
 - Pain elicited on palpation or compression over the joint
 - HLA-B27 transplantation antigen seen in 90% of patients

Reactive arthritis

- Previously called *Reiter syndrome*
- Triad of urethritis, conjunctivitis, and arthritis
- Often triggered by an episode of enteritis
- Diagnosis depends on excluding direct infectious causes of the inflammation.
- Arthritis predominantly occurs in large joints.

Psoriasis

- Characteristic involvement of the skin, or a history of psoriatic skin disease in the family
- Affected patients do not show rheumatoid factor.

Rheumatic diseases

- Systemic lupus erythematosus
 - Can cause chronic joint pain in adolescent girls
 - Joints may be stiff and painful.
 - Joints may show frank signs of inflammation.
- Dermatomyositis
 - Can cause inflamed joints in addition to muscle and skin involvement
- Scleroderma
- Mixed connective-tissue disease
- Kawasaki disease

Infectious diseases

- Acute bacterial infection (septic arthritis)
 - A medical emergency
 - The usual manifestation is rapid onset of pain in a joint, typically accompanied by fever.
 - The joint is red, warm, swollen, and exquisitely tender to palpation or with movement.
- Systemic bacterial infections
 - Notably caused by *Neisseria gonorrhoeae* and *Neisseria meningitidis*

- Can produce arthritis, although organisms not usually isolated from the joint
- Other bacterial infections that can involve the joints
 - Brucellosis
 - Leptospirosis
 - Tularemia
 - Rocky Mountain spotted fever
 - Rat-bite fever
 - Mycobacteria and fungal agents, particularly in immunocompromised individuals
 - *Borrelia burgdorferi* (Lyme disease)
 - Recurrent attacks of inflammation of the large joints (85–90% of cases involve the knee)
 - Each recurrence usually lasts 1 or 2 weeks.
 - Symptoms may persist for several months; chronic arthritis of the knee has been reported.
- Osteomyelitis: acute bone infection
 - If a long bone next to a joint (eg, the distal femur and knee) is infected
 - The patient may describe pain in the joint.
 - Sterile effusion may be present.
 - Although unusual, infection can directly invade the joint space from the bone, particularly in young children.
- Diskitis
 - Disorder characterized by back pain and tenderness over the spinous process contiguous to the involved disk space
 - Causes joint pain, sometimes with low-grade fever, but often with none
 - Often, no culture-proven cause can be found.
 - Presentation can involve sensory and motor complications.
 - Epidural abscess must be considered in the differential diagnosis.
- Congenital syphilis
 - In infants, painful bony lesions and refusal to move the involved limb (Parrot pseudoparalysis), along with other associated stigmata
 - Adolescents born with this disease can develop bilateral knee effusions (Clutton joints).
- Nonbacterial organisms that cause joint disease
 - Viruses
 - Rubella
 - Mumps
 - Chickenpox
 - Adenovirus
 - Epstein-Barr virus
 - Signs of viral syndrome (rash, fever, mucous membrane involvement) usually precede joint involvement.

- Infectious hepatitis can cause arthritis before overt hepatic involvement.
- Rubella immunization causes arthralgia and arthritis in up to 3% of recipients; sequelae are rare.

Noninfectious causes

- Inflammatory bowel disease
 - Large-joint involvement
 - Pain alone or pain with inflammation
 - Joint symptoms may precede the appearance of bowel disease.
 - Activity of the bowel disease may or may not correlate with joint flare-ups.
- Sarcoidosis
- Polyarteritis nodosa
- Marfan syndrome
- Vasculitic disorders
 - Henoch-Schönlein purpura
 - Fever
 - Abdominal pain (with or without melena)
 - Purpuric lesions of the buttocks and lower extremities
 - Warm, swollen, painful, tender joints (usually knees and ankles)
- Hematologic disorders
 - Hemophilia
 - Sickle cell disease
 - Hand-foot syndrome: type of vasoocclusive crisis that is a common initial presentation in children 1–4 years of age
- Hyperuricemia and subsequent joint disease may be seen with:
 - Leukemia (with chemotherapy producing sudden lysis of cells)
 - Hemolytic anemia
 - Glycogen storage disease
 - Lesch-Nyhan syndrome
- Polyarthritis after traumatic pancreatitis
- Infantile cortical hyperostosis (Caffey disease)
 - In infants <6 months of age
 - Fever
 - Irritability
 - Increased erythrocyte sedimentation rate
 - Tender swellings of facial, trunk, and limb bones
- Toxic (transient) synovitis of the hip

Systemic autoinflammatory diseases

- A common feature is periodic fever without infectious cause.
 - Familial Mediterranean fever
 - The cryopyrinopathies

- TRAPS (tumor necrosis factor receptor-associated periodic syndrome)
- Hyper-immunoglobulin D syndrome

Hypermobility syndrome

- Increased joint laxity with vigorous activity, especially when requiring extremes of joint flexion and extension patient can experience significant arthralgia
- Diagnosis is made by physical examination and observation ≥ 3 of these 5 signs.
 - Hyperflexion of the wrist, bringing the thumb in contact with the volar surface of the forearm
 - Hyperextension of the fingers to parallel with the forearm
 - Hyperextension of the elbow to at least -10 degrees
 - Hyperextension of the knee to at least -10 degrees
 - Hyperflexion of the spine such that with forward flexion, the palms can be placed flat on the ground with the feet together and without flexing the knees
- Arthralgia may be present in only 1 or 2 of these sites, with hypermobility only in the joints that are painful.
- All laboratory and radiologic studies are normal.

Chondromalacia patellae (patellofemoral pain syndrome)

- Knee pain, experienced as the patella moves in the patellofemoral groove, is usually related to activity.
- Results from irregularity of the cartilage on the underside of the patella

Growing pains

- Discomfort in the lower limbs and joints
- Often worse at night
- Adolescent girls with fibromyalgia syndrome can experience diffuse arthralgia, but pain is more typically muscular or periarticular.

Physical abuse

- Consider whenever signs of trauma are evident.
- Accidents representing neglect on the part of parents or guardians need to be pursued.
- Any suspicious history or circumstance demands complete investigation.

LABORATORY EVALUATION

- Erythrocyte sedimentation rate
- C-reactive protein
- Complete blood count
- Antinuclear antibody test
 - Among children with JIA, those with oligoarticular disease are most likely to have a positive result.
- Rheumatoid factor titer
 - Present in only a small subset of children with polyarticular JIA

- Serum immunoglobulin levels
- Blood cultures may yield growth of the organism, occasionally in the absence of a positive joint fluid culture.

IMAGING

- Radiographs of joints are not routinely helpful with diagnosis.
- They can be useful in evaluating surrounding soft tissue and bones.

DIAGNOSTIC PROCEDURES

- Arthrocentesis for septic arthritis and analysis of the fluid for:
 - Appearance (opaque)
 - Viscosity (usually low)
 - Mucin clot (friable)
 - Cell count (>100,000 leukocytes/mm with ≥80% polymorphonuclear cells)
 - Glucose (usually low, much less than in serum)
 - Protein (high)
 - A portion of the fluid should be Gram stained to assess for bacterial organisms.
 - Cultures can direct definitive antimicrobial therapy.
 - *Staphylococcus aureus* and *Streptococcus* organisms are likely to be the causative organisms.

TREATMENT APPROACH

- Management focuses on:
 - Subduing inflammation
 - Preserving normal range of joint motion and strength
- Septic arthritis demands immediate arthrocentesis for diagnosis and therapy.
- Systemic bacterial infection
 - After joint aspiration and establishment of strong suspicion of purulent arthritis, the child should be hospitalized and appropriate intravenous antibiotic therapy initiated.
 - Prompt, aggressive therapy usually brings about recovery without adverse side effects, although some foci, such as the hip joint, can remain persistent problems.
- Surgery is used mostly in joint reconstruction or prosthetic replacement.

SPECIFIC TREATMENT

- Nonsteroidal antiinflammatory drugs (NSAIDs) are used as initial therapy.
- For children with JIA, methotrexate plays a central role in therapy beyond NSAIDs.
- Other long-acting agents
 - Anti-tumor necrosis factor- α agents
 - Anti-interleukin-1 drugs in systemic-onset JIA
- Systemic corticosteroids are used less frequently and at lower doses than in the past.

- For patients with a single persistently active joint, intra-articular corticosteroids (eg, triamcinolone hexacetonide) can be effective.

- Growing pains
 - A bedtime dose of an NSAID can help alleviate this pain until it resolves by itself.
- Hypermobility syndrome
 - Treated with NSAIDs and reassurance
 - For some patients, exercises to increase muscle strength and tone can be beneficial.
- Chondromalacia patellae
 - Exercises that strengthen the quadriceps femoris and adductor muscles can produce marked improvement.
 - NSAIDs or analgesics (or both taken together) may also be administered.

WHEN TO REFER

- Orthopedics
 - Fracture
 - Ligamentous or cartilage injury to joint
 - Continuous pain in a joint with deformity
- Rheumatology
 - Suspicion of JIA or other rheumatologic disorder
- Infectious diseases
 - Septic arthritis
 - Lyme disease; other spirochetal infection
 - Osteomyelitis
- Hematology
 - Sickle cell disease
 - Hemophilia
- Gastroenterology
 - Joint symptoms associated with inflammatory bowel disease
- Occupational or physical therapy
 - Joint disease complicated by contractures, weakness, poor function
 - Hypermobility syndrome
- Mental health
 - Suspicion of somatization or conversion disorder

WHEN TO ADMIT

- Fracture requiring open fixation or traction
- Systemic-onset JIA with macrophage activation syndrome
- Septic arthritis
- Osteomyelitis
- Severe sickle cell pain crisis
- Inadequate response to outpatient occupational or physical therapy and to rehabilitation

FOLLOW-UP

- For ongoing joint problems, issues related to chronic pediatric disease must be addressed.
 - The child may be unable to keep up with peers in physical activity.
 - The child may need to make many health care visits or be hospitalized, which may result in school absences.
 - Environmental stress in addition to stress caused by the disease can exacerbate various chronic conditions, such as may occur in children with JIA.
 - Children should be provided with the services of a specialized social worker, counselor, or psychologist.
 - Family resources (both emotional and financial) need to be assessed and support provided when needed.

- Discussion groups or support groups composed of these children and their families can be helpful.
- Major problems of body image and feelings of lack of independence must be dealt with appropriately.

COMPLICATIONS

- Long-term psychosocial sequelae also may develop from chronic joint problems.

PROGNOSIS

- Reactive arthritis
 - Usually, recovery is seen within a few months.
 - There may be a more chronic and relapsing course that can progress to ankylosing spondylitis.

Juvenile Idiopathic Arthritis

DEFINITION

■ Juvenile idiopathic arthritis (JIA) is an uncommon collection of clinical syndromes that have the common feature of chronic childhood arthritis.

- Previously referred to as *juvenile rheumatoid arthritis* or *juvenile chronic arthritis*
- Term refers to any child <16 years who has:
 - Persistent arthritis of ≥ 1 joints
 - Condition lasting for >6 weeks
 - All other diseases have been excluded
- JIA is classified further into 7 subtypes.
 - Most patients fit into systemic-onset, oligoarthritis, or polyarthritis based on the clinical course over the first 6 months of illness.

■ Arthritis is defined as being present when:

- Intraarticular swelling or effusion is present *or*
- ≥ 2 of the following occur:
 - Joint pain or tenderness with motion
 - Limitation of joint motion
 - Increased warmth overlying the joint

■ *Arthralgia* is joint pain, which is a relatively frequent symptom in children.

■ Rheumatologic disorders with arthritis

- Juvenile ankylosing spondylitis and other spondyloarthropathies can present as a subtype of JIA at onset, especially in an older child who is human leukocyte antigen (HLA) B27 positive.
- Acute rheumatic fever has seen a resurgence in the past 2 decades.
 - Patients can experience both arthralgia and arthritis, classically characterized as migratory.
- Systemic lupus erythematosus has arthritis as 1 of its major manifestations.
 - Can be differentiated from JIA by other systemic features and specific laboratory test abnormalities
 - Sex distribution is equal in younger children, but a female preponderance is found after puberty.
- Dermatomyositis is characterized by inflammatory muscle involvement rather than by arthritis.
 - Joint inflammation and contractures may be present.
- Scleroderma is occasionally associated with arthritis.
 - Classic dermatologic and other manifestations distinguish it from JIA.

EPIDEMIOLOGY

■ Prevalence

- The most common of the pediatric rheumatic diseases
- The true incidence and prevalence are unknown.

- Best estimate of prevalence is ~0.5–1 case per 1000 children; ~40,000–100,000 children in the US have JIA at any given time.
- Systemic-onset JIA affects ~15% of children who have JIA.
- Polyarticular JIA affects 30–35% of children with JIA.
 - Subgroups include immunoglobulin (Ig) M rheumatoid factor (RF)–positive (~10% of the total) and IgM-RF–negative (~25%)
 - Positive RF in a child <7 years is rare.
- Oligoarticular JIA affects 50–60% of children with JIA.
 - 5–10% of all patients who have JIA have persistent oligoarthritis.
 - 20–25% of all children with oligoarthritis have extended oligoarthritis.

■ Age

- Peak age at onset is between 2 and 4 years of age for all subtypes taken collectively, with a smaller peak later in childhood.
- Systemic-onset JIA usually begins at an early age, although it has even been recognized in adults (adult-onset Still disease).

■ Sex

- General female predominance, but not in all subtypes
- Systemic-onset JIA is slightly more common among boys than girls.

ETIOLOGY

■ The exact cause of JIA is unknown.

■ Concept of genetic predisposition for the development of inflammatory arthritis that may be triggered by any of several events, such as trauma, infection or emotional stress

- HLA-DR5 and -DR8 in younger girls with oligoarticular JIA
- HLA-DR4 in RF-positive polyarticular JIA
- HLA-B27 in older boys with enthesitis-related JIA

■ Research is under way on:

- Immunologic abnormalities involving autoantibodies
- Cytokines
- Immunoregulation
- Function of and communication between T and B lymphocytes and antigen-presenting cells
- Precise nature of these interactions and their role in development of JIA remain unknown, but the success of specific cytokine-directed therapy (eg, etanercept, anakinra) supports involvement of proinflammatory mediators.

SIGNS AND SYMPTOMS

General

- The presence of arthritis or inflammation within the joint is an absolute criterion for diagnosing JIA.
- Younger children rarely complain of joint pain but may:
 - Become irritable
 - Stop walking or using an extremity
 - Regress in their behavior
- Other symptoms include:
 - Decreased appetite
 - Malaise
 - Inactivity
 - Morning stiffness
 - Nighttime joint pains
 - Failure to thrive
- Features that may be present in children who have chronic arthritis (varying with the subtype) include:
 - Fever
 - Rash
 - Lymphadenopathy
 - Hepatosplenomegaly
 - Polyserositis
 - Subcutaneous (rheumatoid) nodules
 - Vasculitis
 - Growth retardation
- Pattern and number of involved joints are important in classifying the disease.

Systemic-onset JIA (Still disease)

- The hallmark of systemic-onset JIA is its extraarticular manifestations.
- The eventual presence of arthritis is still necessary to confirm diagnosis.
- The systemic features may persist for months and occur or recur independently of the arthritis.
 - Daily intermittent fevers
 - Rectal temperature reaches as high as 40°C–41°C (104°F–106°F).
 - Most often in the afternoon
 - Returning to normal or subnormal levels (known as quotidian fever pattern)
 - Children frequently complain of myalgias or arthralgias when they are febrile, but they may have few symptoms when the fevers resolve.
 - Evanescent, salmon-colored rash often accompanies fevers.
 - Lesions are small macules or papules.
 - Frequently with central clearing
 - Often appear in areas of increased heat (eg, axilla)

- Mild abrasion of unaffected skin can precipitate appearance of the rash (Koebner phenomenon).
- Polyserositis in the form of pericarditis or pleuritis
 - These serosal effusions are rarely symptomatic or clinically significant.
- Enlargement of the lymph nodes, liver, and spleen may suggest the presence of cancer.
- Arthritis may occur at any time after the onset of disease.
 - In some, it appears only days to weeks after the systemic signs occur.
 - Tends to be polyarticular, involving both large and small joints
 - Can be persistent, destructive, and severe
- Clinical course is extremely variable.
 - A single systemic episode may last weeks to months, with few joint problems.
 - Multiple systemic episodes may precede development of arthritis.
 - Can be oligoarticular but is more commonly polyarticular
- Macrophage activation syndrome
 - An unusual but potentially fatal complication of systemic-onset JIA
 - Rapidly progressive and difficult to distinguish from a flare of JIA
 - Characterized by:
 - Intravascular consumption coagulopathy
 - Dramatically elevated ferritin (>10,000 ng/mL)
 - Paradoxically decreased erythrocyte sedimentation rate (ESR)
 - Decreased fibrinogen
 - Increased triglyceride levels
 - Pancytopenia
 - Hepatic failure
 - Diagnosis confirmed by bone marrow biopsy
 - Rapid intervention is necessary

Polyarticular JIA

- Systemic features in polyarticular JIA are usually mild and include:
 - Low-grade fever
 - Easy fatigability
 - Slowing of growth
 - Growth problems may be local (eg, micrognathia) or generalized
 - Can occur regardless of whether the child receives corticosteroid treatment

- Discrepancies between height and weight can help with diagnosis.
 - For example, children who have polyarticular arthritis may be of low weight for height, whereas children who have systemic-onset JIA tend to be average in weight for height.
- Chronic uveitis

■ Arthritis symptoms

- Most often chronic, symmetrical, and involving ≥ 5 joints
- Any joint can be affected.
- Nearly all children have wrist involvement; small joint involvement of hands and feet is common.

RF-positive polyarticular JIA

- Patients with IgM RF-positive polyarticular JIA are:
 - Most often >8–10 years
 - More likely to be girls than boys
 - Similar clinically to patients with adult rheumatoid arthritis
- Arthritis symptoms are:
 - Severe
 - Rapidly progressive
 - Erosive
 - Crippling
 - Subcutaneous rheumatoid nodules
 - Rheumatoid vasculitis

RF-negative polyarticular JIA

- Children with IgM RF-negative polyarticular JIA are usually younger.
- Because their arthritis starts earlier, it can lead to deformities and problems as a result of:
 - Tendency to develop flexion contractures
 - Subluxations at the involved joints
- Compared with adults, hand involvement affects interphalangeal joints more often than metacarpophalangeal joints.
- Ulnar deviation of the fingers is much less common in children.
- Ulnar deviation and subluxation at the wrist may occur.
- More frequently seen in children
 - Flexion contractures
 - Boutonniere (buttonhole) deformities
 - Radial deviation of the fingers
- Arthritis of the apophyseal joints of the cervical spine is common.
 - Can lead to rapid and significant limitation of extension and rotation
- These children are at the highest risk for local and generalized growth problems.

Oligoarticular JIA

- Involves ≤ 4 joints, most often the large (eg, knee, ankle, elbow)
- Typically asymmetrical in distribution
- Important in distinguishing this form of JIA
 - Pattern and course of joint involvement
 - Number of joints involved
- Systemic features are infrequent and mild.
- Oligoarticular JIA can be subdivided further into persistent and extended oligoarticular subtypes.
- Persistent oligoarthritis
 - Occurs classically in girls <6 years of age
 - Involves the large joints
 - Higher risk for chronic uveitis, particularly when positive for antinuclear antibodies (ANA)
 - Systemic signs and symptoms, except for uveitis, are few.
 - These children generally function well and only rarely complain of significant pain.
 - Little erosive joint damage occurs, even though patients may have ongoing arthritis for many years.
 - At risk for long-term problems, including:
 - Leg-length discrepancies (especially with asymmetrical knee joint involvement)
 - Growth centers around the arthritic knee can become more active because of the inflammatory-associated hyperemia, resulting in increased growth of that leg.
 - Muscle atrophy
 - As a result of changes in the child's biomechanics, decreased quadriceps mass on the affected side is frequently found.
- Extended oligoarthritis
 - ≤ 4 joints involved within first 6 months of disease
 - At a variable time after the initial 6 months, children develop arthritis in more joints.
 - Genetic makeup
 - Higher frequency of HLA-DR1 than in persistent oligoarthritis
 - Higher occurrence of erosive disease than in persistent oligoarthritis
 - Additionally involved joints are often:
 - Wrists
 - Fingers
 - Other smaller joints
 - Chronic uveitis still occurs, although less frequently.

Enthesitis-related arthritis

- A newer classification that includes children who previously were classified as late-onset oligoarthritis

- Complaints and findings of enthesitis (inflammation of the attachment of a tendon, ligament, fascia, or capsule to bone) are a hallmark of this group and may predate joint problems.
- Subgroup includes children with:
 - Arthritis and enthesitis *and*
 - ≥ 2 of the following:
 - Sacroiliac joint pain or inflammatory spinal pain (or both)
 - Presence of HLA-B27
 - History of relatives with HLA-B27-associated disease
 - Anterior uveitis usually associated with pain, redness, or photophobia
 - Onset of arthritis in a boy > 8 years
- More frequently occurs in the lower extremities, involving the knees and ankles; occasionally in toes (resulting in so-called sausage toe, or dactylitis)
- Patients may progress to:
 - Ankylosing spondylitis
 - Reactive arthritides
 - Arthritis associated with inflammatory bowel disease

Psoriatic arthritis

- An additional classification subtype of JIA
- Similar to enthesitis-related arthritis in that large joint inflammation, enthesitis, and dactylitis are often found
- Psoriasis must be present in the patient or in family members.
 - Thus a child can have psoriatic arthritis in the absence of skin disease.
 - Psoriatic rash can appear at some time after the onset of joint disease.
- Pitting of the fingernails or toenails can identify psoriatic arthritis in the child with characteristic musculoskeletal findings, but no skin eruption.

Undifferentiated arthritis

- Children who do not meet the criteria for ≥ 1 subtype

DIFFERENTIAL DIAGNOSIS

- Diseases to be considered in the differential diagnosis of JIA
 - Rheumatic diseases of childhood
 - Autoinflammatory diseases
 - Acute rheumatic fever
 - Systemic lupus erythematosus
 - Juvenile ankylosing spondylitis
 - Polymyositis and dermatomyositis
 - Vasculitis
 - Scleroderma
 - Mixed connective-tissue disease/overlap
 - Kawasaki disease

- Behçet syndrome
- Postinfectious reactive arthritis
- Reactive arthritis
- Reflex sympathetic dystrophy (complex regional pain syndrome type II)
- Fibromyalgia syndrome
- Infectious diseases
 - Bacterial arthritis
 - Must be considered if the child has a single inflamed joint
 - *Haemophilus influenzae* type b has decreased markedly in incidence in children < 2 years of age with universal immunization.
 - *Neisseria gonorrhoeae*, particularly in adolescence
 - Staphylococci may be found at any age.
 - Lyme disease (*Borrelia burgdorferi* infection) in endemic areas.
 - Viral or postviral arthritis
 - Parvovirus
 - Rubella
 - Hepatitis B
 - Fungal arthritis
 - Osteomyelitis
 - Postinfectious reactive arthritis
 - From a gastrointestinal bacterial infection (eg, *Shigella*, *Salmonella*, *Campylobacter*, or *Yersinia* organisms)
- Neoplastic diseases
 - Leukemia
 - Lymphoma
 - Neuroblastoma
 - Primary bone tumors
- Noninflammatory disorders
 - Trauma
 - Avascular necrosis syndromes
 - Osteochondroses
 - Slipped capital femoral epiphysis
 - Diskitis
 - Patellofemoral dysfunction (chondromalacia patellae)
 - Toxic synovitis of the hip
 - Overuse syndromes
- Hematologic disorders
 - Sickle cell disease
 - Hemophilia
- Miscellaneous
 - Inflammatory bowel disease
 - Chronic recurrent multifocal osteomyelitis

- Sarcoidosis
- Collagen (connective tissue) disorders (eg, Ehlers-Danlos syndrome, Marfan syndrome)
- Growing pains
- Psychogenic arthralgias (conversion reactions)
- Hypermobility syndrome
- Villonodular synovitis
- Foreign-body arthritis

DIAGNOSTIC APPROACH

- Because the diagnosis of JIA is based on clinical findings, history and physical examination are paramount.
- The hallmark of JIA is its chronic nature, and the best initial strategy is often careful, watchful waiting.
- The primary care physician can avoid mislabeling other transient entities as JIA by:
 - Meeting the criterion of sustained arthritis (>6 weeks)
 - Excluding other possible diseases

LABORATORY FINDINGS

- No unique or specific diagnostic laboratory tests yet exist.
- Systemic-onset JIA
 - High leukocyte count, with predominance of band forms and polymorphonuclear leukocytes
 - Most patients are anemic.
 - Thrombocytosis
 - Significant increases of acute phase reactants (eg, ESR and C-reactive protein level)
 - RF and ANA tests are rarely positive.
 - Serum immunoglobulin and complement levels are usually normal.
 - May be elevated, reflecting the degree of inflammation
 - Sometimes indicate a vasculopathy and an intravascular consumption coagulopathy
 - With intravascular consumption coagulopathy, need to rule out macrophage activation syndrome
- RF-positive polyarticular JIA
 - Cyclic citrullinated protein can be used to assess disease severity and potential for joint destruction.
 - An elevated serum level would serve as reason to institute early and aggressive therapy.
- Persistent oligoarthritis
 - Few laboratory abnormalities will be found except for positive ANA.
 - When positive, the ANA titer is typically low.
 - Mild increases in leukocyte count and ESR or low-grade anemia may be observed, but these tests are most often normal.

- HLA-DR5 gene markers appear to confer increased susceptibility for persistent oligoarthritis; HLA-DR1 and -DR4 are underrepresented in this group.

■ Enthesitis-related arthritis

- Abnormal laboratory tests are found infrequently.
- Mild to moderate increase in the ESR is common.

DIAGNOSTIC PROCEDURES

- If any question exists as to an intraarticular septic process, arthrocentesis must be performed to establish the diagnosis.

TREATMENT APPROACH

- JIA is a chronic illness, and no current mode of therapy is curative.
- The patient's management should be individualized for:
 - Disease subtype
 - Extent of activity
 - Clinical course to date
 - Family situation
- Pharmacologic therapy is only 1 aspect of treatment for children with JIA.
- Drug therapy is not yet curative but can suppress the inflammatory activity in many children.
- 5 major categories of drug therapy are available.
 - Nonsteroidal antiinflammatory drugs (NSAIDs)
 - Disease-modifying antirheumatic drugs (DMARDs)
 - Corticosteroids
 - Immunosuppressive drugs
 - Agents with immune- and cytokine-modulating effects (biological agents)
- A multidisciplinary team approach is the most effective approach.
- The goal of therapy is to attain the highest possible level of physical and psychological function for the child.
- In addition to an attentive and understanding primary care physician, the patient and family need:
 - Family counselor, social worker, and psychologist or similar mental health professional to help them adjust to this chronic illness
 - Feelings of denial, guilt, and frustration at the time of the diagnosis and throughout the course of the disease are common.
 - Siblings frequently find difficulty to cope with the special and extensive treatment the affected child may receive.
- Periodic depression and anger are frequent, especially in the early stages, and again as the patient enters adolescence.
- Poor maternal function, maternal depression, and social isolation are risk factors for poor psychosocial outcomes; a sense of control and mastery are important positive factors.

- Most children with JIA can do well in school; thus, all efforts should be made to keep them enrolled.
 - Some school adjustments may be necessary, such as different transportation or physical education (or both) and allowing extra time between classes.
 - 2 sets of books, 1 for school and 1 for home, reduces the work of carrying books.
 - The primary care physician or pediatric rheumatology team may have to advocate within the school to ensure services.
- Preparation for eventual independent living and vocations must begin in childhood to reduce potential barriers.
 - Anticipatory guidance about transitional issues should start in childhood and early adolescence.
- The child with mild disease and a hidden disability may have problems coping, adapting, and trying to accomplish unrealistic goals of a society that does not recognize the disability.
- Any chronic illness imposes many additional stresses on the entire family.

SPECIFIC TREATMENTS

NSAIDs

- NSAIDs currently approved by the US Food and Drug Administration (FDA) for use in children
 - Individual responses to NSAIDs vary widely, and if a child does not improve within 4–6 weeks, then trying a different NSAID is reasonable.
 - Salicylates
 - No longer the initial NSAIDs of choice because of concerns regarding Reye syndrome
 - Other agents have emerged that are essentially equivalent in efficacy and toxicity.
 - Indomethacin
 - Tolmetin sodium
 - Naproxen
 - Ibuprofen
 - Celecoxib
 - Meloxicam
- NSAIDs not approved by the FDA for use in children
 - Diclofenac sodium
 - Fenoprofen
 - Flurbiprofen
 - Ketoprofen
 - Phenylbutazone
 - Pirprofen
 - Piroxicam
 - Meclofenamate sodium
 - Sulindac

- NSAIDs available in liquid form for younger children who have trouble swallowing pills
 - Naproxen
 - Ibuprofen
 - Indomethacin
 - Meloxicam
- Cyclooxygenase II (COX-2)–selective inhibitors interfere only with COX-2 and decrease the prostaglandin production that mediates inflammation, in a gastroprotective manner.
 - Reduces the risk of gastric erosion or ulcer formation, or both
 - As a result of cardiovascular safety questions, many were removed from the market.
 - Celecoxib remains available in the US.
 - Meloxicam is predominantly COX-2 selective and is available in a generic preparation.

DMARDs and cytotoxic/immunosuppressive drugs

- If a child does not quickly respond to NSAID therapy alone or is in a high-risk category, more aggressive interventions are necessary.
- Moving quickly to DMARDs and/or biologic agents, as well as performing intraarticular corticosteroid injections, appears to achieve the goal of no inflammation with great effectiveness.
- Methotrexate
 - Essentially replaced intramuscular and oral gold, D-penicillamine, and hydroxychloroquine as primary second-line agent of JIA treatment
 - Competitive inhibitor of dihydrofolate reductase, which exerts both antiinflammatory and immunosuppressive effects on arthritis
 - Efficacy and dose response have been well established.
 - Hepatic, bone marrow, gastrointestinal, pulmonary, and teratogenic adverse effects may result.
 - To detect liver or hematopoietic adverse effects, laboratory monitoring every 4–8 weeks is suggested.
 - Administration of folic (or folinic) acid may decrease some of methotrexate’s adverse effects, such as nausea and oral ulcers.
- Leflunomide
 - Immunosuppressive agent that inhibits pyridine synthesis and suppresses tumor necrosis factor- α (TNF- α)–induced cellular responses
 - Shown to have beneficial effects similar to methotrexate
 - Teratogenic effects are possible
 - Requires ongoing monitoring
 - Not FDA-approved for use in treating JIA

■ Sulfasalazine

- Has seen a resurgence, but should not be used in anyone:
 - Sensitive to sulfa drugs or salicylates
 - Whose renal or hepatic function is impaired
 - Who has such conditions as glucose-6-phosphate dehydrogenase deficiency
- Adverse effects caused by sulfasalazine
 - Rashes
 - Nausea
 - Vomiting
 - Dyspepsia
 - In boys, a reversible decrease in sperm count
 - Bone marrow depression rarely occurs.

■ Other immunosuppressive agents occasionally administered in specific patients, but not currently the standard

- Intravenous immunoglobulin
- Azathioprine
- Chlorambucil
- Cyclophosphamide
- Cyclosporine
- Thalidomide

Biologic agents

- Considered standard to add a TNF- α blocker to the regimen of any child with JIA:
 - Who has not responded to previously administered DMARD therapy
 - When tapering the dose of corticosteroids is not possible without precipitating a flare of the disease
- Testing for tuberculosis is recommended before starting because these agents can interfere with immune response.
- Adverse effects
 - Injection site pain or reactions
 - Increased risk of infection
 - Possible increased risk of other autoimmune conditions or neoplasms
- Long-term effects are not yet known.
- Etanercept, adalimumab, and infliximab
 - Blocks activity of TNF- α (a major proinflammatory cytokine)
 - Etanercept and adalimumab are approved for use in children with JIA.
 - Demonstrated dramatic improvements in condition of children and adults with arthritis
 - A child who has not responded or has had an adverse effect to 1 agent may still respond to another because each is slightly different.

■ Interleukins 1 and 6 (IL-1 and IL-6) are cytokines that play a significant role in JIA treatment.

- Systemic-onset JIA is more of an IL-1- or IL-6- (or both) driven condition.
 - Often responds better to blocking these cytokines than TNF- α

■ Anakinra

- IL-1-receptor antagonist
- Proven effective in children who have not responded adequately to TNF- α inhibitors
- Should not be administered in combination with a TNF- α inhibitor or any other biologic agent

■ Abatacept

- Recently approved for treating children with JIA
- Selectively modulates the CD80/CD86:CD28 costimulatory signal required for full T-cell activation
- Demonstrated efficacy in both children and adults with arthritis who have not responded adequately to TNF- α inhibitors

■ Rituximab

- Monoclonal antibody directed against the CD20 marker on B-lymphocytes
- Currently approved for adults not responding to TNF- α blockade
- Not yet determined for use in children

Corticosteroids

- Monoclonal antibodies have rendered systemic corticosteroid use in JIA much less necessary.
- Corticosteroids remain important and effective medications, and use should follow these maxims.
 - They should be administered only when other agents have failed or when the child is seriously ill or has progressive severe chronic anterior uveitis unresponsive to local or other systemic therapy.
 - As small a dose as possible should be administered.
 - Their use should be tapered and discontinued as soon as possible.
- Corticosteroids are effective antiinflammatory agents but do not alter the course of the disease.
- Can be extremely difficult to discontinue in children with JIA
- Long-term use is associated with many serious adverse effects, including:
 - Immunosuppression
 - Osteoporosis
 - Growth retardation
- Small daily doses of prednisone may be effective in treating pain and stiffness.
- Higher doses may be needed to manage systemic features, such as pericarditis.

- High-dose intravenous pulse corticosteroid therapy can be useful in dire situations but is not more effective as chronic therapy.
- Intraarticular corticosteroids now play a larger role, especially oligoarticular JIA.
 - Can be effective in controlling acute problems associated with 1 or several active joints
 - Usually used in combination with systemic, ongoing therapy
- Children with a painful or swollen joint frequently respond to arthrocentesis and instillation of a long-acting corticosteroid preparation (eg, triamcinolone hexacetonide).
 - This procedure should not be performed >3 or 4 times per year.
 - The physician should be absolutely certain that concomitant infectious arthritis is not the cause of the acute joint problem.
 - Early use of intraarticular corticosteroids may even have the potential to modify the course of JIA.

Physical and occupational therapy

- Crucial adjuncts to:
 - Maintain strength and range of motion
 - Prevent contractures
 - Allow the best possible quality of life
- All patients should be given a home program of therapy that is reviewed and updated regularly.
- Heat therapy often helps minimize morning stiffness.
 - Warm baths or using a sleeping bag at night
- Swimming is an excellent exercise; affected children should be encouraged to swim and to participate in as many other activities as possible.
- Normal play is a form of physical and occupational therapy.
- The orthopedist's contribution ranges from the application of splints to operative tendon releases and capsulotomies.
 - Some children may require joint resurfacing or joint replacement surgery.
 - The orthopedist's perspective is an important part of disease management.

WHEN TO ADMIT

- Children with systemic-onset JIA who develop severe chest pain with shortness of breath (suggesting pericarditis with hemodynamic compromise) or a change in voice quality and difficulty breathing (suggesting cricoarytenoid arthritis)
- Children with chronic arthritis who are receiving corticosteroid therapy and develop signs of severe infection
- Children with chronic arthritis who are receiving NSAIDs and have acute anemia and melanotic stools

- Children with longstanding polyarticular arthritis complicated by multiple joint contractures and weakness and who require a period of inpatient rehabilitation (eg, physical and occupational therapy)

WHEN TO REFER

- Children with persistent oligoarticular or polyarticular joint inflammation
- Children with spiking fevers and rash but no obvious infectious cause
- Children with persistent joint pain, limp, or asymmetrical use of an extremity for which no explanation has been found

FOLLOW-UP

- Risk of uveitis decreases with time and varies by JIA subtype and age at diagnosis.
 - Prescribed intervals between examinations vary, eventually lengthening after several years if no uveitis is present (see table Frequency of Ophthalmologic Examination in Patients With Juvenile Rheumatoid Arthritis).
 - Persistent oligoarticular JIA
 - Regular ophthalmologic evaluation for uveitis, including slit-lamp examinations, should be:
 - Instituted early
 - Performed every 4–6 months
 - Continued indefinitely
 - Children with extended oligoarthritis should be monitored closely, although uveitis is more common in children with the persistent type.

Complications

- Joint related
 - Pain
 - Loss of mobility
 - Impaired growth
 - Leg length discrepancy
 - Muscle atrophy
 - Destructive arthropathy
- Uveitis
- Psychosocial effects
- Treatment side effects

PROGNOSIS

- JIA is rarely fatal, and in general the long-term prognosis is good.
- Approximately 60–75% of children will undergo remission at some point; many children will experience permanent remission.
- Most children with JIA will complete school, be gainfully employed, and raise families.

Frequency of Ophthalmologic Examination in Patients With Juvenile Rheumatoid Arthritis^{a,b}

Type	ANA	Age at Onset (yr)	Duration of Disease (yr)	Risk Category	Eye Examination Frequency (mo)
Oligoarthritis or polyarthritis	+	≤6	≤4	High	3
	+	≤6	>4	Moderate	6
	+	≤6	>7	Low	12
	+	>6	≤4	Moderate	6
	+	>6	>4	Low	12
	–	≤6	≤4	Moderate	6
	–	≤6	>4	Low	12
	–	>6	NA	Low	12
Systemic disease (fever, rash)	NA	NA	NA	Low	12

Abbreviations: ANA, antinuclear antibodies; NA, not applicable.

^a From: Cassidy J, Kivlin J, Lindsley C, et al, American Academy of Pediatrics, Section on Rheumatology and Section on Ophthalmology. Ophthalmologic examinations in children with juvenile rheumatoid arthritis. *Pediatrics*. 2006;117(5):1843–1845.

^b Recommendations for follow-up continue through childhood and adolescence.

■ Patterns of disease activity

- Persistent active arthritis and destructive arthropathy
- Active disease, then remission
- Polycyclic diseases characterized by acute flares of activity followed by temporary remissions
- Low-grade continued disease activity with little if any joint destruction

■ Oligoarticular JIA

- Children with oligoarticular arthritis and no chronic anterior uveitis have the best prognosis.
- 40–50% of children undergo complete remission.
- Persistent oligoarthritis
 - The course can be extremely variable.
 - Some children have a single episode; others may have recurrent exacerbations and remissions.
 - This group has the fewest musculoskeletal complications and more long-term remissions.
- Extended oligoarthritis
 - Fewer children in this subgroup enter a prolonged remission than do those with persistent oligoarthritis, and they fare better than children with polyarthritis-onset disease.

■ Systemic-onset JIA

- 25–30% undergo complete remission.
- Younger children with systemic-onset and polyarticular arthritis have a poorer articular prognosis.
- Poor prognostic signs include:
 - Continued presence of systemic features
 - Platelet count >600,000 cells/mm 6 months after onset
- At least one-third of these children will develop severe arthritis.

■ Polyarticular JIA

- 25–30% undergo complete remission.
- RF-negative polyarticular JIA
 - Overall better prognosis than children with RF-positive polyarticular JIA
 - Typically respond better to therapy and have a lower frequency of severe, early, crippling arthritis, but may develop significant problems

Kawasaki Disease

DEFINITION

- An acute, multisystem vasculitis of infancy and early childhood
- Characterized by:
 - High fever
 - Rash
 - Conjunctivitis
 - Inflammation of the mucous membranes
 - Erythematous induration of the hands and feet
 - Cervical adenopathy
- Formerly known as *mucocutaneous lymph node syndrome*

EPIDEMIOLOGY

- Prevalence
 - For children ≤ 8 years in the continental US
 - 32.5 cases per 100,000 in those of Asian or part Asian descent
 - 16.9 per 100,000 in blacks
 - 11.1 per 100,000 in Hispanics
 - 9.1 per 100,000 in whites
 - Recurrent cases
 - 0.3–5% in Japan
 - 1–2% in the US
- Age
 - Most common during the 2nd year of life
 - More than 80% of all cases occur in children < 5 years.
 - Uncommon beyond 9 years of age
- Sex
 - Boys are affected more commonly than girls, with a male-to-female ratio of nearly 1.5:1.
- Geographic distribution
 - Most prevalent in Japan and in children of Japanese ancestry, but distribution is worldwide
- Seasonality
 - More common in winter and spring
 - Numerous temporal clusters have been reported in the US and Japan, suggesting an infectious cause.

ETIOLOGY

- No specific cause has been established, although clinical features suggest an infectious process.
 - The most recent theory is that toxin-producing staphylococcal or streptococcal bacteria are the primary cause.
 - These agents are attractive candidates because of the similarity of Kawasaki disease to illnesses such as staphylococcal toxic shock syndrome and streptococcal toxic shock syndrome.

RISK FACTORS

- Intravenous immunoglobulin (IVIG) therapy for first episode may increase risk of recurrence within the following 12 months.
- Sibling with the disease
 - Incidence is higher in twins than in nontwin siblings.
 - Not significantly different between monozygotic twins and dizygotic twins
 - The interval between sibling cases is < 10 days in 54% of cases; onset sometimes occurs on the same day.
 - Suggests a common exposure to an infectious agent in a genetically predisposed population

SIGNS AND SYMPTOMS

Typical Kawasaki disease

Criteria

- Fever of unknown cause lasting ≤ 5 days *and*
- At least 4 of the 5 following principal features:
 - Changes in extremities
 - Acute: erythema of palms, soles; edema of hands, feet
 - Subacute: periungual peeling of fingers, toes in weeks 2 and 3
 - Polymorphous exanthem
 - Bilateral bulbar conjunctival injection without exudate
 - Changes in lips and oral cavity: erythema, lips cracking, strawberry tongue, diffuse injection of oral and pharyngeal mucosae
 - Cervical lymphadenopathy (diameter > 1.5 cm), usually unilateral
- Other illnesses with similar features must be excluded.
- Cervical lymphadenopathy is the least common of the principal features.
- Coronary artery abnormalities detected by 2D echocardiography or coronary angiography in a patient with fever for ≥ 5 days, even with < 4 criteria, fulfill the diagnosis.
- Patients with ≥ 4 criteria can be diagnosed on day 4 of illness.
- Other findings
 - Cardiovascular
 - Congestive heart failure
 - Myocarditis
 - Pericarditis
 - Valvular regurgitation
 - Coronary heart abnormalities
 - Aneurysms of medium-size noncoronary arteries
 - Raynaud phenomenon
 - Peripheral gangrene

- Musculoskeletal
 - Arthritis
 - Arthralgia
- Gastrointestinal
 - Diarrhea
 - Vomiting
 - Abdominal pain
 - Hepatic dysfunction
 - Hydrops of gallbladder
- Central nervous system
 - Extreme irritability
 - Aseptic meningitis
 - Sensorineural hearing loss
- Genitourinary
 - Urethritis/meatitis
- Other
 - Erythema
 - Induration at Bacille Calmette-Guérin inoculation site
 - Anterior uveitis (mild)
 - Desquamating rash in groin

Phases

- The course of the disease can best be described as triphasic.
- Symptoms are not all apparent simultaneously, but the timing of their appearance is remarkably constant.
- Acute phase
 - Fever
 - Oropharyngeal erythema
 - Swelling of the hands and feet
 - Polymorphous erythematous rash
 - Cervical lymphadenopathy
- Subacute phase
 - Begins after 10–12 days of the illness, when fever, rash, and lymphadenopathy fade
 - Characterized by:
 - Lip cracking and fissuring
 - Unusual desquamation of the skin, beginning at the subungual and periungual regions of the fingers and toes
 - Occurs in nearly all cases 2–3 weeks after the onset and after early signs involving the extremities have disappeared
 - May progress to complete peeling of palms and soles, but exfoliation generally does not extend to remainder of body surface
 - Onset of arthralgias or arthritis (or both), thrombocytosis, and cardiac disease
- Convalescent stage
 - Usually begins ~25 days after onset
- Characterized by:
 - Absence of clinical signs of disease
 - Persistence of residual inflammation, marked by elevated erythrocyte sedimentation rate (ESR)

Symptoms

- Fever is the most prominent symptom of the acute phase of the disease.
 - High-spiking remittent pattern in the range of 38.4°C (101.1°F) to >40°C (104°F)
 - Persists despite use of empirical antibiotics, corticosteroids, and standard doses of antipyretics.
 - Is present on average for ~12 days, although prolonged courses of up to 5 weeks have been reported; defervescence occurs over 1–3 days.
- Conjunctival hyperemia
 - Discrete engorgement of the bulbar conjunctivae blood vessels (without associated discharge, exudate, keratitis, chemosis, or pseudomembrane formation) and an anterior uveitis develop shortly after the onset of fever.
 - The cornea, lens, and retina are not involved.
- Early oropharyngeal signs include dryness and reddening of lips and of buccal and pharyngeal mucosa.
 - Absence of aphthous ulceration or hemorrhagic bullae is noticeable.
 - A “strawberry tongue” often is present.
 - Later, as intensity of the erythema subsides, lips usually become cracked and fissured.
- The most characteristic and unique feature of Kawasaki disease relates to changes that occur in the hands and feet.
 - Early on, they become diffusely indurated and swollen; overlying skin develops a woody firmness suggestive of acute scleroderma.
 - The palms and soles usually become erythematous or purplish.
 - Fusiform swelling of the fingers also occurs, which limits the child’s ability to grasp objects.
 - Feet are painful to the touch, and many children will refuse to stand or walk.
 - During convalescent phase, deep transverse grooves (Beau lines) may appear across the fingernails and toenails, presumably as a result of arrested growth during the illness.
- A polymorphous, erythematous rash appears 1–5 days after the onset of fever.
 - Usually begins on the extremities and spreads centripetally
 - The 3 most common patterns of rash are
 - Maculopapular (morbilliform)
 - Erythema multiforme-like with iris lesions
 - Scarlatiniform
 - The rash may be coalescent, producing large, irregular, raised plaques, and may be pruritic.

- Vesicles, pustules, and bullae are not seen.
 - The rash is not petechial or purpuric.
 - Rash usually fades within 1 week but occasionally persists longer or recurs.
 - Lymphadenopathy
 - Typically involves a single cervical node measuring >1.5 cm in diameter.
 - The node usually is not tender or warm and does not become fluctuant.
 - The lymph node diminishes in size with defervescence of the disease.
 - Generalized lymphadenopathy does not occur.
 - The least often seen of the major criteria
 - Occurs in only ~60% of patients in most US series.
 - Other features of Kawasaki disease may be noted.
 - Sterile pyuria occurs more often than lymphadenopathy in most US cases.
 - 10–100 white blood cells (WBCs) per high-power field may be observed on a clean-catch voided urine specimen.
 - No WBCs will be seen on a bladder aspiration specimen, because the sterile pyuria is caused by urethral inflammation or ulceration.
 - Occasionally, trace proteinuria or hematuria
 - Irritability, mild meningismus, and lethargy are seen in nearly all patients with Kawasaki disease, and nearly all probably have aseptic meningitis.
 - Cerebrospinal fluid (CSF) typically shows 25–100 WBCs/mm³ with normal amounts of glucose and protein.
 - Diarrhea is seen in approximately 50% of patients.
 - Passing 5–15 stools per day for 2–7 days during the acute or subacute phase is common.
 - Stools do not contain polymorphonuclear cells and do not test positive for occult blood.
 - Either arthralgias, arthritis, or both occur in 30–40%.
 - Large joints, particularly the knees and ankles, are involved most often.
 - Usually, no more than 2 or 3 joints will be affected.
 - Joint symptoms occur 8–12 days after the onset of disease.
 - Joint fluid, if analyzed, reveals findings similar to those of rheumatoid arthritis.
 - Pneumonia, tympanitis, photophobia, and mild liver dysfunction are observed somewhat less commonly.
 - Acute hydrops of the gallbladder, jaundice, convulsions, encephalopathy, Bell palsy, hearing loss, pancreatitis, orchitis, and pleural effusions are seen rarely but also are associated complications of Kawasaki disease.
 - Cardiovascular system findings
 - Disease mortality results from coronary artery aneurysm rupture or occlusion.
 - During the acute phase, tachycardia and gallop rhythms may appear.
 - However, the most serious manifestations of cardiac involvement occur during the subacute phase.
 - Manifestations may include:
 - Serious arrhythmias
 - Congestive heart failure
 - Pericardial effusion
 - Mitral insufficiency
 - Myocardial ischemia or infarction
 - Infants <6 months of age with Kawasaki disease
 - High risk for coronary abnormalities
 - This group is at highest risk (≥50%) for coronary artery lesions if untreated.
 - Echocardiography should be considered in any infant aged <6 months with fever of >7 days, laboratory evidence of systemic inflammation, and no other explanation for the febrile illness.
- Atypical Kawasaki disease**
- Severe or even fatal coronary abnormalities can develop after illnesses that resemble but do not fulfill the classic diagnostic features of Kawasaki disease.
 - Should be considered in:
 - Infants and children with unexplained fever for >5 days and 2 or 3 of the principal diagnostic criteria
 - Young infants may have fever only.
 - Children (<1 year and teens) with fever for >7 days, rash with or without nonexudative conjunctivitis
 - Laboratory results are similar to those of classic cases.
 - Patients may display
 - Prolonged high fever
 - Nonspecific rash
 - Arthralgia or arthritis
 - Fissuring of the lips
 - Nonexudative conjunctivitis
 - Extreme irritability
 - Atypical Kawasaki disease occasionally can produce prolonged fever for ≥5 days in the absence of other clinical criteria for the illness.
 - In other patients, unilateral cervical adenopathy refractory to antibiotic therapy indicates that atypical Kawasaki disease may be present.
 - In infants <6 months of age, atypical Kawasaki disease is likely to produce the same subtle manifestations seen in typical Kawasaki disease.
 - Usually lack full diagnostic criteria
 - Manifestations often subtle: fever, rash, and cerebral spinal fluid pleocytosis may be misdiagnosed as viral meningitis

- High risk for coronary abnormalities
 - This group is at highest risk ($\geq 50\%$) for coronary artery lesions if untreated.
 - Echocardiography should be considered in any infant aged < 6 months with fever for > 7 days, laboratory evidence of systemic inflammation, and no other explanation for the febrile illness.
- In the first days of the illness, a whole spectrum of acute febrile diseases might be considered.
- By 3–5 days after onset, certain clinical features may be singled out as compatible with other diagnoses—eg, strawberry tongue, which is suggestive of streptococcal infection.
- 2 conditions most commonly mimic Kawasaki disease: streptococcal and staphylococcal scarlet fever.
 - However, if all the signs and symptoms are considered carefully, then the diagnosis is readily apparent.
- The clinical features of Kawasaki disease and other mucocutaneous disorders are compared in the table below.

DIFFERENTIAL DIAGNOSIS

- The clinical picture of Kawasaki disease, after all major features have exhibited, is not difficult to differentiate from other mucocutaneous syndromes.

Clinical Features of Kawasaki Disease and Other Mucocutaneous Diseases

	Kawasaki Disease	Stevens-Johnson Syndrome	Streptococcal Scarlet Fever	Staphylococcal Scarlet Fever	Staphylococcal Toxic Shock Syndrome	Leptospirosis
Age (yr)	Usually < 5	Usually 3–30	Usually 5–10	Usually 2–8	Usually adolescent	Usually > 2
Fever	Prolonged	Prolonged	Variable	Variable	Usually < 10 days	Variable
Eyes	Hyperemia of ocular conjunctivae; uveitis	Catarrhal conjunctivitis; chemosis; iritis; uveitis; panophthalmitis	No change	Hyperemia of ocular conjunctivae	Hyperemia of ocular conjunctivae	Hyperemia of ocular conjunctivae; uveitis
Lips	Red, dry, fissured	Erosions; crusted, fissured, bleeding	No change	No change	Red	No change
Oral cavity	Diffuse erythema; strawberry tongue	Erythema; bullae, ulcers, pseudo-membrane formation	Pharyngitis; palatal petechiae; strawberry tongue	Pharyngitis	Erythema; pharyngitis	Pharyngitis
Peripheral extremities	Erythema of palms and soles; indurative edema; periungual, palmar, and plantar desquamation	No change	Periungual desquamation	No change	Swelling of hands and feet; dry gangrene	Gangrene of hands and feet (rare)
Exanthem	Erythematous, polymorphous	Erythematous, polymorphous; iris lesions, vesicles, bullae, crusts	Finely papular erythroderma; Pastia lines; circumoral pallor	Finely papular erythroderma; Pastia lines	Erythroderma	Erythematous, maculopapular, petechial, or purpuric
Cervical lymph nodes	Nonpurulent swelling; unilateral (frequent)	Nonpurulent swelling (occasional)	Nonpurulent or purulent swelling (frequent)	Nonpurulent or purulent swelling (occasional)	No change	Nonpurulent swelling (infrequent)
Other	Meatitis; diarrhea; arthralgia and arthritis; aseptic meningitis; rhinorrhea (uncommon); ECG changes	Malaise; cough, rhinorrhea, pneumonitis; vomiting; arthralgia; recurrent episodes	Malaise; vomiting; headache		Headache; confusion; hypotension; icteric hepatitis; diarrhea; coagulopathy; renal injury	Headache myalgia; abdominal pain; icteric hepatitis; meningitis

Abbreviation: ECG, electrocardiogram.

- Other conditions that share some aspects of Kawasaki disease include:

- Ratbite fever
- Rubella
- Rubeola
- Infectious mononucleosis
- Toxoplasmosis
- Juvenile rheumatoid arthritis
- Systemic lupus erythematosus
- Behçet syndrome
- Acrodynia (mercury poisoning)
- Febrile drug reactions, especially those caused by anticonvulsants

- The similarities between fatal Kawasaki disease and fatal infantile polyarteritis nodosa are striking.
 - Pathologically, the 2 diseases cannot be distinguished.
 - The exact relationship between them, however, is undetermined.
 - The clear differentiating feature is that Kawasaki disease rarely is fatal (<1% mortality), whereas infantile polyarteritis nodosa is a pathological diagnosis made at autopsy.

LABORATORY FINDINGS

- No pathognomonic laboratory findings
- Certain laboratory abnormalities that are seen commonly can help establish the diagnosis.
 - In the acute phase, most patients exhibit an elevated WBC count with an associated left shift.
 - WBC counts of 15,000–20,000/mm³ are common and may remain elevated for 1–3 weeks.
 - Other laboratory abnormalities commonly seen in the acute phase include:
 - Elevated ESR (mean >55 mm/hr)
 - Increased C-reactive protein (CRP) and β_2 -globulin
 - Mild normochromic, normocytic anemia
 - Slight elevations of the liver enzymes
 - Slight decrease in erythrocyte and hemoglobin levels
 - Many patients demonstrate sterile pyuria and CSF pleocytosis.
 - In weeks 2–3 of illness, patients characteristically develop significant thrombocytosis, with platelet counts averaging >700,000/mm³.
- Importantly, results of several laboratory studies are negative.
 - Routine cultures of blood, CSF, urine, throat, and lymph node aspirates reveal no growth or normal flora.
 - Serologic studies for bacterial and viral agents are negative, including the antistreptolysin titer.
 - Antinuclear antibodies, rheumatoid factor, and other autoantibodies are absent.

IMAGING

- Echocardiography
 - Should be considered in any infant <6 months with
 - Fever for >7 days
 - Laboratory evidence of systemic inflammation
 - No other explanation for the febrile illness
 - Baseline echocardiogram should be performed as soon as the diagnosis of Kawasaki disease is suspected.
 - To evaluate cardiac function and the anatomy of the coronary arteries
 - Coronary artery abnormalities usually are apparent by the 3rd or 4th week of the illness.
 - Coronary artery disease rarely, if ever, develops after 6–8 weeks, although late-onset valvular disease has been reported.
 - To assess for the presence or absence of pericardial effusion
 - May reveal:
 - Decreased left ventricular contractility
 - Mild valvular regurgitation (mitral regurgitation)
 - Pericardial effusion
 - Cases of atypical Kawasaki disease followed by typical coronary artery involvement have led to the suggestion that an echocardiography examination be performed in children with prolonged unexplained febrile illnesses associated with subsequent peripheral desquamation.
 - Although aneurysms rarely form before day 10 of the illness, perivascular brightness, ectasia, and lack of tapering of the coronary arteries can be seen in the acute stage of disease.

DIAGNOSTIC PROCEDURES

- Electrocardiography
 - In the acute phase, may reveal
 - Sinus tachycardia
 - Nonspecific ST segment and T wave changes
 - Evidence of mild left ventricular hypertrophy
 - In the subacute phase
 - Myocardial infarction patterns may be observed infrequently.

TREATMENT APPROACH

- Treatment should begin as soon as the diagnosis is established and as early as possible in the course of the illness.
- IVIG with aspirin
 - The best available therapy for preventing coronary artery abnormalities
 - Should be administered to all patients diagnosed within the first 10 days of the illness

SPECIFIC TREATMENTS

Aspirin

- Aspirin, given in high doses (80–120 mg/kg/day), reduces the length and severity of Kawasaki disease during the acute phase.
 - Aspirin used early in the course of the disease may reduce coronary artery involvement.
 - Salicylate levels should be checked to avoid toxicity.
 - Defervescence is accompanied by improvement in gastrointestinal absorption of aspirin.
 - Dosages should be reduced to 30–50 mg/kg/day after fever subsides and continued until the ESR has returned to normal.
 - Thereafter, aspirin should be prescribed because of its antithrombotic effects at 3–5 mg/kg/day until the platelet count has returned to normal.
 - If coronary aneurysms are recognized, then salicylates (3–5 mg/kg/day) should be continued until careful follow-up electrocardiograms demonstrate aneurysm resolution.

IVIG

- High-dose IVIG may prevent coronary artery lesions in Kawasaki disease.
 - 400 mg/kg/day for 4 consecutive days initially was shown to be effective, but a single dose of 2 g/kg infused over 10–12 hr has replaced the 4-day regimen.
 - No apparent difference exists in efficacy among particular IVIG products currently commercially available.
 - Patients should be monitored carefully during IVIG infusions for signs of anaphylaxis and immune hemolysis.
 - 80–90% of children treated with IVIG respond favorably with decreased fever and reduction in mucocutaneous findings.
 - Remainder have persistent or recurrent fever, with or without mucocutaneous signs.
 - If ongoing fever cannot be attributed to another cause, then the assumption should be made that Kawasaki disease is persisting or has relapsed.
 - Because fever may be viewed as a sign of continued vasculitis, retreatment with IVIG is advocated.
 - Most patients treated again after failure of a single dose of IVIG therapy will respond to retreatment.
 - Patients who remain symptomatic beyond the 10th day still may benefit from IVIG.
 - Decision to administer IVIG later than the 10th day of the illness must be individualized.

Other therapeutic options

- Corticosteroids
 - Previously believed dangerous as therapy for Kawasaki disease based on an early study in Japan in which 65% of patients treated with oral prednisolone developed coronary artery aneurysms.

- Subsequent studies have not confirmed a detrimental effect of corticosteroids, and some patients have benefited.
- If IVIG therapy fails (particularly after 2 treatments), then patients are at high risk for developing severe coronary artery complications, including death.
 - Such patients may benefit from 1–3 pulse-doses of methyl prednisolone at 30 mg/kg per dose.
 - This therapy should be reserved for patients who are clearly refractory to more established treatments (ie, failure of 2 doses of IVIG).
- Plasmapheresis and exchange transfusion have been reported to be of benefit in patients with Kawasaki disease, but these treatments are cumbersome and more involved.
- Antibiotics are not useful.

WHEN TO ADMIT

- All patients with Kawasaki disease should be admitted for treatment.

WHEN TO REFER

- Patients suspected of having atypical or incomplete Kawasaki disease
- Patients with Kawasaki disease who have not responded to 2 doses of IVIG
- Patients who have developed complications such as coronary dilatation and aneurysm.

FOLLOW-UP

- For long-term management of patients with Kawasaki disease, a risk stratification scheme may be of benefit
- Level I risk: no coronary artery abnormalities at any stage of the illness
 - The primary care physician may fully assume care after the 1-year anniversary of Kawasaki disease onset.
 - Physical activities should not be restricted.
- Level II risk: transient coronary artery ectasia followed by regression
 - A pediatric cardiologist should be consulted every 1–2 years.
 - At least 1 stress test evaluating myocardial functioning should be performed at ~10 years of age.
- Level III risk: small to medium solitary coronary artery aneurysm
 - Daily low-dose aspirin therapy
 - Annual cardiac follow-up with echocardiography and electrocardiography
 - Periodic stress tests recommended
- Level IV risk: ≥1 giant aneurysms or multiple aneurysms without obstruction
 - Low-dose aspirin therapy should be maintained.
 - Low-dose warfarin should be considered.

- Coronary angiography may be considered 6–12 months after the acute disease has resolved, to delineate coronary artery anatomy.
- Physical activities should be modified to minimize the risk of hemorrhage.
- Strenuous or competitive sports should be avoided.
- Level V risk: coronary artery obstruction (thrombosis or stenosis)
 - Daily low-dose aspirin
 - Warfarin should be considered.
 - Patients should be evaluated for indications for bypass graft surgery.
 - Mild to moderate recreational physical activities are permitted.

COMPLICATIONS

- Coronary artery aneurysm
 - The major complication of Kawasaki disease
 - Risk increased if:
 - Fever lasts for >14 days
 - Fever pattern is biphasic
 - Skin rash has biphasic pattern
 - Maximum WBC count is 30,000/mm³
 - Maximum ESR is 101 mm/hr
 - ESR or CRP does not normalize until day 30 of the illness
 - Biphasic elevation of ESR or CRP
 - Increased Q/R ratio in leads II, III
 - aVF >0.3
 - More common in
 - Boys
 - Children <1 year of age
 - Children who have a triphasic fever pattern or fever for >2 weeks when a gallop rhythm or other arrhythmia is noted or when the ESR exceeds 50 mm/hr
 - If IVIG is not administered, aneurysms occur in 15–25% of cases.
 - Usually apparent by echocardiogram during the subacute phase of the illness.
 - Most patients who have aneurysms are asymptomatic.
 - In some cases, formation of an aneurysm, particularly a giant aneurysm (>8 mm in diameter), is followed by thrombosis or rupture, resulting in a fatal myocardial infarction.
 - Some authorities treat patients with giant aneurysms with a regimen of low-dose warfarin in combination with low-dose aspirin.

- In children <7 years, a radionuclide scan may help identify areas of mild cardioischemia.
 - When echocardiography, angiography, or radionuclide scanning detects thrombi occluding a significant portion of main branches of coronary arteries, thrombolytic therapy should be instituted.

■ Myocardial infarction

- Risk increased by
 - Male gender
 - Age at onset <1 year
 - Hemoglobin <10 g/dL
 - Red blood cell count <3.5 million
 - Maximum WBC count >26,000/mm³
 - Maximum ESR >50 mm/hr
 - Cardiomegaly
 - Arrhythmia
 - Recurrence of disease
- Bypass surgery should be undertaken.

■ Hydrops of the gallbladder

- A rare complication of Kawasaki disease
- Occurs in ~3% of cases
- Seen most commonly in children who are jaundiced
- Becomes evident during the acute phase of the illness
- Is diagnosed best by ultrasound on recognition of a right upper quadrant abdominal mass
- Pathogenesis is unknown.
- Resolves spontaneously in convalescence

PROGNOSIS

- Mortality rate is 0.3%.
- Death occurs almost exclusively in children who have giant aneurysms, largely as a result of coronary artery thrombosis, massive myocardial infarction, and cardiogenic shock.
- Eighty percent of children whose aneurysms are small to moderate in size have complete resolution without apparent sequelae within 5 years.
- The remaining children may experience persisting aneurysms, coronary artery stenosis or obstruction, or aortic regurgitation.
 - Emerging evidence suggests that a portion of this last group of children may be at risk for subsequent development of significant cardiovascular disease such as coronary arteriosclerosis or persistent aneurysms, placing some at risk for sudden death from aneurysm rupture or thrombosis, cardiac arrhythmias, angina, or hypertension.
- Almost always self-limited and without complications, which should be emphasized to the parents
 - Even if coronary artery aneurysms do develop, they resolve spontaneously in >50% of patients in 2 years and 80% in 5 years.

Labial Adhesions

DEFINITION

- Labial adhesions are membranous structures that develop as a result of fusion of the adjacent mucosal surfaces of the labia minora.
- Also known as *labial agglutination* or *synechia vulvae*

EPIDEMIOLOGY

- Prevalence
 - Among preadolescent girls in a general pediatric setting, ranges from ~2% identified by inspection alone to 39% identified with inspection plus magnified photographic vulvar images
 - Found in 15.6% of girls referred to a gynecology clinic for various hymenal findings documented during well-child evaluations
- Age
 - Healthy, postpubescent young women do not develop labial adhesions.
 - Most common in prepubertal girls <5 years of age
 - Decreased in older preadolescent girls, most likely because of:
 - An increase in endogenous estrogen levels during the prepubertal period
 - Improved hygiene
 - Rare in neonates
 - Maternal estrogen is presumed to have a protective influence.

ETIOLOGY

- The exact cause of labial adhesions is not known.
 - They may be the result of fusion of the adjacent mucosal surfaces of the labia minora; the cause of this fusion is unknown.
 - Usually considered a nonspecific finding
 - Probably due to chronic irritation and inflammation of the hypoestrogenic vulva
- Triggers for chronic inflammation include:
 - Physical or chemical trauma
 - Infection (*Candida albicans*, *Enterobius vermicularis*, various bacteria)
 - Poor hygiene
 - Sexual abuse
- During healing of the irritated area, the medial edges of the labia minora adhere to each other, forming an adhesion.

RISK FACTORS

- Poor hygiene
- Physical or chemical trauma
- Infection (*Candida albicans*, *Enterobius vermicularis*, various bacteria)

- Sexual abuse
- Trauma
- Herpesvirus infection
- Episiotomy
- Chemotherapy
- Graft-versus-host disease

SIGNS AND SYMPTOMS

- Labial adhesions often are asymptomatic.
 - Discovered at routine well-child visits
 - Brought to the attention of the pediatrician by the child's caregiver
- If the adhesions partially dehisce, the child may experience
 - Spotting of a minute amount of blood
 - Irritation
- Uncommon symptoms:
 - Pain with urination
 - Vaginal pain
 - Pain with ambulation
 - Urinary retention
 - Altered urinary stream
 - Other symptoms suggestive of urinary tract infection
 - History of recurrent urinary tract infection
- The membranous structure can vary from thin and transparent to thick and fibrous.
- Any degree of labial involvement can occur, including covering of the urethral meatus.

DIFFERENTIAL DIAGNOSIS

- Conditions that may be confused with labial adhesions include:
 - Ambiguous genitalia
 - Vaginal agenesis
 - Imperforate hymen
 - Septated hymen
- Physical examination easily differentiates these entities.
 - A line of demarcation between the clitoral hood and labia minora is:
 - Present with labial adhesions
 - Not present with ambiguous genitalia secondary to androgen excess
 - In vaginal agenesis and hymenal variants, the labia are normal and unfused.
 - The characteristic findings of these entities are located in the vaginal introitus.

DIAGNOSTIC APPROACH

- The condition is diagnosed by visual inspection of the vulva.
 - Includes hymenal examination in the supine frog-leg or prone knee-chest position
- The labia majora should be gently stretched apart.
 - A membrane of variable length and thickness is seen in the midline.
 - A small opening near the clitoris allows the outflow of urine.
- A line of adhesion between the 2 nonrugated labia minora or raphae also may be seen.

LABORATORY FINDINGS

- Urinalysis and urine culture if the child has accompanying symptoms, such as
 - Pain on urination or ambulation
 - Altered urinary stream
 - Urinary retention
 - History of urinary tract infections

TREATMENT APPROACH

- If the child has no accompanying symptoms, labial adhesions should not be treated.
- Any documented urinary tract or vulvar infection should be treated accordingly.

SPECIFIC TREATMENTS

Uncomplicated

- If the child has no accompanying symptoms, labial adhesions should not be treated.
- Parents should be given an opportunity to visualize the adhesion so they are not surprised and concerned about the unusual appearance of the vulva.
- Reassurance of the benign, self-limiting nature of this condition and education about potential symptoms should be provided.

Complicated

- The first-line treatment of the complicated labial adhesion is topical estrogen.
 - Goal: to use the least amount of medication that will achieve separation of the adhesion
 - 0.625 mg conjugated estrogen cream (Premarin Vaginal Cream, Wyeth Ayerst)
 - Applied to the adhesion and labial edges with a fingertip or cotton swab
 - Gentle traction should be placed on the opposing labia during the application.
 - Specific optimal dosing and length of treatment are unknown; twice-daily application for 2 weeks is a reasonable starting point.

- Treatment produces thinning of the line of fusion.
 - Facilitates manual labial separation in the office
- Highly effective for most thin, transparent adhesions
- Less effective in dense and fibrous or long-standing adhesions
- Even dense adhesions should be treated initially with topical estrogens
- Possible adverse effects of topical estrogen
 - Breast budding and tenderness
 - Vulvar hyperpigmentation
 - Local irritation
 - All these effects are reversible on discontinuation of the medication.
- After labia are separated
 - Topical lubricant (eg, white petroleum jelly) applied daily for several months
 - To ensure complete healing and persistent separation
- Treatment with estrogen cream is considered unsuccessful if:
 - Labial separation has not occurred within 8 weeks.
 - The child suffers untoward effects from the estrogen and cannot continue using it.
- Topical anesthetic is applied to the affected area.
- Firm traction on the opposing edges of the labia minora is applied to separate the fused edges.
- Edges should be smoothly peeled away from each other.
- After separation, a lubricant should be applied to the affected area daily for several months to prevent readherence.
- Warm soaks or sitz baths in the days after separation may provide relief if vulva is irritated.
- Manual separation if estrogen therapy is unsuccessful
 - Topical anesthetic is applied to the affected area.
 - Firm traction on the opposing edges of the labia minora is applied to separate the fused edges.
 - Edges should be smoothly peeled away from each other.
 - After separation, a lubricant should be applied to the affected area daily for several months to prevent readherence.
 - Warm soaks or sitz baths in the days following separation may provide relief if the vulva is irritated.
- Surgical treatment is rarely required.
 - Surgical lysis by a pediatric urologist or gynecologist while under general anesthesia
 - For thick labial adhesions that cannot be separated by the previously described treatments or adhesions associated with complications

- The decision to treat labial adhesions with surgery is made by weighing:
 - Significance and severity of symptoms after less aggressive treatments
 - Risks of general anesthesia
- Postoperative care includes:
 - Sitz baths in the immediate postoperative period
 - Application of topical lubricant for several months

WHEN TO REFER

- A symptomatic child with persistent or recurrent labial adhesions should be referred to a pediatric urologist or gynecologist for surgical lysis if she has:
 - A history of urinary tract infections
 - Urinary retention
 - Altered urinary stream
 - Dysuria
 - Pain with ambulation
 - Failed topical estrogen therapy

PROGNOSIS

- The condition is self-limiting.
- Spontaneous resolution in affected individuals has been reported to occur in
 - 50% of cases within 6 months
 - 90% of cases within 12 months
 - 100% of cases within 18 months

PREVENTION

- Explain the value of proper hygiene of the vulva.
- Educate the parents about practices to help their child avoid recurrent labial adhesions
 - Wiping front to back after urination or defecation
 - Wearing cotton underwear
 - Avoiding application of detergents in the genital area
 - Avoiding wet, tight clothing against the vulva for prolonged periods

Language and Speech Assessment

BACKGROUND

- Each child who enters school is assumed to have a well-developed system of spoken language skills.
 - This system is the foundation for social interaction and higher levels of communication.
- Children with early language problems are at an increased risk for later reading problems.
 - In a 5-year follow-up study of 3-year-old children, as many as 50% of those with preschool articulation or phonologic disorders were receiving some type of special education by the third grade.
- Children identified in second or third grade as needing special assistance in reading, spelling, writing, and math previously exhibited:
 - Slow development of spoken words
 - Unintelligible speech at age 3 years
 - Word-finding difficulties

GOALS

- Fundamental question to ask:
 - “Is the child I am examining, who appears to be slow in speech or language development, simply at the low end of the normal continuum (and presumably will catch up without professional assistance), or is this a child who is at risk for later learning difficulties?”
 - The age at which typical children achieve spoken language milestones varies.
 - Interventionists see these children only after problems are suspected and referrals are made.
 - Speech-language pathologists
 - Occupational therapists
 - Nurses and primary care physicians are often the only trained professionals who monitor young children on a regular basis before school entry at a variety of sick and well visits.
 - Access to young children carries with it a responsibility to make early and appropriate referrals to specialists trained to perform comprehensive evaluations.

GENERAL APPROACH

- A child’s communication competency may be assessed using a validated screening instrument.
 - The emergence of certain critical speech and language abilities follows a relatively stable timetable.
 - The purpose of screening is not to diagnose but to identify children in need of further testing.
- Children who are identified as having a concern should be referred for evaluation by a developmental specialist or a speech-language pathologist.
 - Benefits of referral
 - Assurance of early intervention

- Regular and appropriate reassessment of children whose developmental status remains uncertain
- Objective baseline data for measurement of progress over time
- Delayed onset of language may be the first indication of more global developmental delays.
- Children develop communication skills long before the onset of first words.
 - Wave good-bye months before saying “bye-bye”
 - Raise their hands to be held before saying “up”
 - Shake their head before saying “no”
- Within the first year of life, the normally developing infant progresses from a reflexive newborn to a purposeful communicator.
 - Preverbal red flags may indicate potential developmental problems.
 - Failure to smile or show joyful expressions by 6 months
 - No reciprocal turn taking with sounds and facial expressions by 9 months
 - No pointing or reaching to communicate by 12 months
- Preschool speech and language development
 - By age 3 years, most children have a spoken vocabulary of >500 words.
 - Routinely speak in 3- and 4-word sentences
 - Some basic rules of grammar are finely tuned.
 - Plural, possessive, and past tense forms of words are emerging.
 - Use of pronouns, such as *I*, *me*, *you*, and *mine*, is common.
 - 3-year-olds demonstrate an appropriate understanding of *why?* questions.
 - Appreciation of cause and effect
 - The speech of a 3-year-old is highly intelligible.
 - Parents and most strangers have little difficulty understanding the child.
 - Frequent mispronunciations do not impair understanding.
 - 3-year-olds have the capacity to carry on a reasonable conversation with an adult.
 - The language of 4-year-olds approaches adult competency in grammatical skill.
 - Unlike 2- and 3-year-olds, 4-year-olds speak in complete sentences.
 - They rarely omit words from the 4- and 5-word sentences that are typically produced.

- 4-year-olds do not have as many different ways to say the same things as do older children.
 - They usually have at least one way to express all thoughts and desires.
- The vocabulary of a 4-year-old is extensive.
 - By this age, most children can:
 - Recognize and name several colors
 - Count to 10 by rote
 - Understand the prepositions *in*, *on*, *under*, *beside*, *in front*, and *in back* (understanding of *behind* at 5 years)
 - Answer complex questions, such as *How much?* *How long?* and *What if...?*
- 3- and 4-year-olds are beginning to formulate questions using mature constructions.
 - For example, *Is it broken?*
- By age 5 years, children have developed most of the language-based concepts that are important for schooling.
 - Sort and classify objects by category
 - Name all the basic colors
 - Understand the concept of time (and answer *when* questions)
 - Understand the concept of numbers up to 10 integers
 - The acquisition of individual speech sounds should be fully developed by age 5 years, with the exception of *th*.
 - Occasional mispronunciations are usually restricted to:
 - Sound blends (*truck*, *sprinkle*)
 - Difficult-to-pronounce, multisyllabic words

SPECIFIC INTERVENTIONS

Late talkers

- The term *late talker* or *slow expressive language development* refers to children who:
 - Have <50 spoken words and no word combinations by 24 months of age with otherwise normal:
 - Receptive language
 - Cognitive and social-emotional development
 - Adaptive behavior
- Research appears inconclusive regarding the long-term outcomes.
 - Some of the literature suggests that 40–50% continue to exhibit expressive language delays throughout the pre-school years.
 - 25% will exhibit problems well into elementary school.
- Positive predictors of children who will outgrow their delayed speech are:
 - Age-appropriate development in receptive language, cognitive, and self-help skills

- Lack of oral-motor concerns
- Lack of social or interactive concerns
- Appropriate play skills
- Lack of family history of speech-language disorders or learning disabilities
- The emergence of 2-word phrases is a significant milestone in language learning.
 - Rudimentary rules of grammar are first evidenced.
 - Normally developing children begin producing 2-word combinations as early as 18 months.
 - Failure to achieve this milestone by 24 months indicates a risk for later language-based difficulties.
 - Child should be referred for further testing.
 - To many parents, the child's production of *hot dog*, *choo-choo*, and *merry-go-round* represent word combinations.
 - Instead, they are simply learned labels of objects and thus considered single words.
 - Ask, "Can you give me an example of some of your child's word combinations?"
 - Helps parents give a clearer picture of the child's language abilities.
 - Common early 2-word combinations include:
 - *No juice*
 - *What that*
 - *My cup*
 - *Look, kitty*

Mispronunciation

- Children commonly mispronounce certain sounds or have problems producing particular words with difficult sound combinations.
- The mastery of speech sounds is a gradual process that takes place over 6–7 years.
- As children master various sounds and sound combinations, their speech becomes more adult-like.
- Normally developing children are easily understood by their caregivers.
 - Regardless of the frequent errors in pronunciation
 - Complaints by parents that they cannot understand their child's speech suggests a pattern of mispronunciation so unusual and unpredictable that it is not characteristic of normal mispronunciations.
- The reaction of the child regarding speech intelligibility is equally important.
 - Many children with unintelligible speech become frustrated by their inability to communicate effectively.
 - They cease talking and resort to gestures and pantomime to fulfill their communicative needs.

- Children with childhood apraxia of speech (CAS) often exhibit frustration.
 - CAS is the inability to program voluntary movements of the articulators in absence of paralysis, paresis, incoordination.
 - Such children often:
 - Have mastered only 1 or 2 speech sounds
 - Exhibit groping while attempting to search for the correct tongue placement
 - Have great difficulty imitating simple words
 - CAS is often misdiagnosed as expressive language disorder because of the child's frequent nonverbal nature.
- Repeat testing in the 7th and 11th grades
- These school screening tests should be completed at 20 dB for 1000, 2000, and 4000 Hz under earphones.
- Any child with a speech and language delay should have hearing screening using:
 - Age-appropriate method
 - Tympanometry
 - Otologic evaluation
- Sensorineural hearing losses in children should be identified as early as possible.
 - Reduces the effect of hearing loss on speech and language development

Screening for hearing loss

- Hearing screening is an integral part of any developmental evaluation.
- Normal speech and language development requires an intact auditory system.
- The Joint Committee on Infant Hearing has endorsed early detection of hearing loss and early intervention.
- A national program of universal newborn hearing screening has been implemented.
 - This program provides the opportunity for infants with significant hearing impairment to have early identification and intervention.
 - Children who fail neonatal hearing screening are given additional in-depth assessment.
 - Intervention can begin in the first 3–4 months.
- Among toddlers and preschoolers, parental concern was identified as a significant factor in the identification of 70% of children with hearing impairment.
 - Toddlers <3 years of age may be difficult to screen.
 - Should be tested using physiologic methods, such as:
 - Brainstem audiometry
 - Tympanometry
 - Screening stimuli that do not have calibrated levels or frequency information or that rely on behavioral observation are not recommended.
 - For example, rattles, music toys, other noisemakers
 - For children 3–5 years of age, play audiometry and tympanometry may be helpful.
 - In play audiometry, children are trained to provide an operant response to a sound that establishes an estimate of hearing acuity.
- The American Speech-Language-Hearing Association recommends hearing screening:
 - At birth
 - On initial entry into school
 - Annually through the third grade
- Hearing-impaired children who receive appropriate amplification and intervention before 6 months of age have significantly better language scores than those receiving intervention after 6 months.
- For the mild or moderately hearing-impaired infant:
 - Traditional hearing amplification and aural habilitation is provided by audiologists and speech-language pathologists.
- Options for severely impaired infants and children may include:
 - Referral for consideration of cochlear implant surgery
 - Specialized postoperative aural habilitation
 - Families who strongly identify with deaf culture may rightfully not choose this option for their infants and young children.

Acquired communication disorders

- Acquired communication disorders can be secondary to:
 - Stroke
 - Seizure disorder
 - Meningitis
 - Other diseases
 - Brain trauma (cause of the majority of childhood-acquired speech and language disorders)
- A brain injury often interferes with acquisition of new knowledge and skills.
 - Older children have the advantage of greater knowledge acquired before the brain injury.
 - Younger children must gain more new knowledge and skills with a brain developing with injured areas.
- Traumatic brain injury (TBI) can result in a focal or, more often, a diffuse brain injury with sequelae that include:
 - Speech disorders
 - Apraxic speech, characterized by difficulty initiating and programming speech
 - Dysarthric speech resulting from paralysis or paresis of oral or pharyngeal musculature; may contribute to a secondary swallowing or dysphagic disorder

- Communication disorders
- Swallowing problems
- Language disorders
 - Disorganized, tangential, wandering discourse
 - Imprecise language
 - Word-retrieval difficulties
 - Disinhibited, socially inappropriate language, with ineffective use of contextual cues
 - Restricted output and lack of initiation
 - Difficulty comprehending extended language in spoken or written form and detecting main ideas
 - Difficulty understanding abstract language, including indirect or implied meaning
 - Inefficient verbal learning caused by reduced memory ability
- These problems are different from the grammatical difficulties typical of children who have developmental problems.
- They are frequently misunderstood and not seen as being symptomatic of a language disorder.
- Standardized testing may not be sensitive to the social communication and language effects of TBI.
- Clinical evaluation of speech and language function is essential to determine the need for rehabilitative or specialized educational intervention.
- Children with TBI should be referred for a speech-language-cognitive assessment if any memory, learning, comprehension, or attention problems are reported.
 - Consequences of speech, language, and related cognitive function are often difficult to identify through screening procedures.
- Therapeutic intervention goals may be rehabilitative or compensatory.
 - Necessary for cognitive processing and language functioning
 - Rehabilitation of attention
 - Awareness
 - Perception
 - Memory
 - Learning
 - Organization
 - Social cognition
 - Problem solving
 - General executive system functioning
- Compensatory techniques may include:
 - Memory devices
 - Organizational patterning
 - Referent cues
- Stimulating speech programming and muscular strengthening may improve oral communication.
 - Compensatory techniques may be required in the form of augmentative communicative devices.
 - Communication boards
 - Computerized speech

WHEN TO REFER

- No smile or joyful expression by 6 months
- No reciprocal turn-taking, with sounds and facial expressions, by 9 months
- No babbling, pointing, or gestures by 12 months
- No spoken words by 15 months
- No 2-word combinations by 24 months
- Inability of parents to understand their child's speech at 30 months
- Continued poor intelligibility at 36 months of age
- Difficulty answering *why* questions by 48 months of age
- Poor ability to associate letters with their sounds by the end of kindergarten
- Parents voice concern about their child's hearing, speech, or language
- Any regression in speech, language, or social skills at any age

Leukemias

DEFINITION

- Leukemias are a heterogeneous group of disorders classified by immunophenotype and subclassified primarily on the basis of prognostic features.
- *Acute leukemias* are defined as a clonal expansion of hematopoietic progenitor cells (blasts), such that the number of these cells exceeds:
 - 25% of the total nucleated-cell population in the marrow for acute lymphocytic leukemia (ALL)
 - 20% for acute myelogenous leukemia (AML)
- *Chronic leukemia* is a hyperproliferation of mature hematopoietic elements.
 - Classified as either chronic myelogenous leukemia (CML) or chronic lymphocytic leukemia (CLL)
- *Juvenile myelomonocytic leukemia* (JMML) is a clonal disorder of early childhood.
- *Myelodysplastic syndromes* (MDS) are clonal disorders of ineffective or abnormal hematopoiesis that frequently precede AML or aplastic anemia.
- Chloromas, or granulocytic sarcomas, are solid collections (tumors) of malignant cells in patients with AML.

EPIDEMIOLOGY

- Prevalence
 - Leukemia is the most common cancer of childhood.
 - Leukemias account for one-quarter of all childhood cancers.
 - Frequency of leukemias in children
 - ALL: 80%
 - Of those with ALL:
 - Early pre-B cell: 60–65%
 - Pre-B cell: 15%
 - Mature B cell: <5%
 - Pre-T cell: 10–15%
 - AML: 16%
 - CML: 3%
 - CLL: <1%
 - Extramedullary leukemia
 - As many as 20% of patients will have evidence of disease in the central nervous system (CNS).
 - Mixed-lineage leukemia (MLL)
 - Translocations involving the *MLL* gene at 11q23 and >30 potential partner chromosomes can be found in 6% of childhood ALL cases.
 - The t(4;11)(q21;q23) mutation resulting in the *MLL-AF4* fusion product is commonly seen in infant ALL.
- Incidence
 - 40 cases per 1,000,000 children in the US annually
 - In the US, leukemia will be diagnosed in >3000 children <20 years of age each year.

- Age
 - Peak incidence is ~4 years of age.
 - Due almost entirely to ALL
 - AML is equally distributed among patients 0–10 years of age.
 - Slight increase in incidence in adolescence
 - T-cell ALL is also more common during adolescence.
 - Diagnosed in nearly 40% of children 10–18 years of age with ALL
 - JMML occurs at a median age of 1.8 years.
- Race/ethnicity
 - ALL is more common among white persons than black persons in the US.
 - AML has an equal distribution among all ethnic groups.
 - Early reports of worse outcomes for black persons with leukemia have been refuted in recent publications.
- Sex
 - Incidence of leukemia is slightly higher among boys than girls.
 - The ratio of boys with leukemia to girls with leukemia is greatest during adolescence.
 - Particularly in patients with T-cell ALL

ETIOLOGY

- The cause of most leukemias is multifactorial, including genetic, immune, infectious, and environmental factors.
 - DNA damage and inadequate DNA repair is the initial insult.
- Genetic factors
 - Predisposition to childhood leukemia may be inherited, as indicated by:
 - An association of leukemia with various constitutional chromosomal abnormalities
 - Reports of familial leukemias
 - Several reported karyotypic abnormalities in leukemia cells
 - Patients with Down syndrome (trisomy 21) have a 15-fold increased risk of leukemia compared with patients without trisomy 21.
 - Patients with autosomal-recessive chromosomal fragility disorders, such as Bloom syndrome, ataxia telangiectasia, and Fanconi anemia, have a well-documented high incidence of leukemia.
 - Concordance of both AML and ALL in monozygotic twins is estimated to be as high as 25%.
- Environmental factors
 - Risk of leukemia after exposure to ionizing radiation is well established.
 - Environmental influences in leukemogenesis are likely to be complex and multifactorial.

■ Investigators have examined the role of:

- Toxins
- Electromagnetic fields
- Pesticides
- Nitrites
- Population mixing
- Seasonal and climatic variations
- Birth weights
- Socioeconomic status
- Breastfeeding
- Maternal history of fetal loss in leukemogenesis
- Little conclusive evidence exists.

■ Equally unclear is the role of in utero and childhood infections in the pathogenesis of childhood leukemia.

■ Most studies evaluating childhood vaccination and leukemia demonstrated a protective effect.

■ MDS may occur spontaneously or after exposure to:

- Radiation
- Epipodophyllotoxin
- Alkylators

RISK FACTORS

■ Factors associated with a higher risk of leukemia

- Genetic predisposition
 - Siblings of patient with a childhood leukemia
 - Down syndrome
 - Fanconi anemia
 - Bloom syndrome
 - Ataxia telangiectasia
 - Paroxysmal nocturnal hemoglobinuria
 - Congenital hypogammaglobulinemia
 - Wiskott-Aldrich syndrome
 - Neurofibromatosis
 - Klinefelter syndrome
 - Shwachman-Diamond syndrome
- Environmental exposures
 - Ionizing radiation (therapeutic or environmental exposure)
 - Epipodophyllotoxin or alkylator-based chemotherapy

■ Extramedullary leukemia

- Greatest risk for CNS disease is in patients with:
 - T-cell ALL
 - Age <2 years
 - Monoblastic forms of AML

SIGNS AND SYMPTOMS

ALL and AML

■ Signs and symptoms are similar to common symptoms in children with benign illnesses.

■ Presenting clinical features

- Fever
 - ALL: 61%
 - AML: 34%
- Pallor
 - ALL: 55%
 - AML: 25%
- Petechiae, purpura, bleeding
 - ALL: 8%
 - AML: 33%
- Anorexia or weight loss
 - ALL: 33%
 - AML: 22%
- Fatigue, malaise
 - ALL: 30%
 - AML: 19%
- Bone or joint pain
 - ALL: 38%
 - AML: 18%
- Lymphadenopathy
 - ALL: 50%
 - AML: 14%
- Hepatosplenomegaly
 - ALL: 68%
 - AML: 55%
- Swollen gingivae
 - AML: 8%
- Cough, dysphagia
 - AML: 41%
- Recurrent infection
 - AML: 3%
- Neurologic symptoms
 - ALL: 3%
 - AML: 10%

■ Extramedullary leukemia

- CNS disease
 - Few children have symptoms of disease at diagnosis, including vomiting, headache, and lethargy.
 - Papilledema and cranial nerve palsies can be present.
 - Cranial nerve palsies typically reflect meningeal infiltration of leukemic cells rather than increased intracranial pressure.

- Painless enlargement of 1 or both testicles has been reported in <5% of boys with leukemia and is more common in ALL (particularly T-cell ALL) than AML.
- Chloromas
 - Can occur anywhere, including:
 - Skin
 - CNS
 - Bones
 - Rarely, chloromas can occur independent of or before evidence of bone marrow disease.

CML

- Typically produces leukocytosis marked by myeloid progenitor cells at all levels of differentiation, and thrombocytosis
- Hepatosplenomegaly is present in a majority of patients.
- Fatigue, weight loss, bone pain, and low-grade fevers may be present for weeks to months.
- In most patients, CML is diagnosed in the chronic phase (cytogenetic evidence of disease with <5% blasts in the marrow) or the accelerated phase (cytogenetic evidence of disease with 5–30% blasts in the bone marrow).
- Blast crisis indicates more advanced disease and is indistinguishable from AML, with the exception of the presence of the Ph chromosome.

JMML

- Hallmarks of the disease at diagnosis include:
 - Marked hepatosplenomegaly
 - Peripheral blood monocyte count $>1 \times 10^9/L$
 - Myeloid precursors in the peripheral blood
 - Chronic infections
 - Lymphadenopathy
 - Rash (eczema, xanthomas, café-au-lait spots)
 - Failure to thrive

DIFFERENTIAL DIAGNOSIS

- Differential diagnosis of individual or concurrent cytopenias/cytosis includes several common infectious and noninfectious diseases of childhood.
- Nonmalignant diseases
 - Juvenile idiopathic arthritis
 - Systemic lupus erythematosus
 - Infectious mononucleosis
 - Immune thrombocytopenia purpura
 - Aplastic anemia
 - Pertussis, paraptosis
 - Benign lymphocytosis
 - Leukemoid reaction
 - Sepsis
 - Osteomyelitis

- Malignant diseases
 - Metastatic bone marrow disease in retinoblastoma
 - Neuroblastoma
 - Ewing sarcoma
 - Rhabdomyosarcoma
 - Lymphoma
- Many more common illnesses than leukemia produce:
 - Fever
 - Rash
 - Lymphadenopathy
 - Hepatosplenomegaly
 - Mild cytopenias
 - Lymphocytosis
- Appearance of atypical and variant lymphocytes on the peripheral blood smears of children with such infections as Epstein-Barr virus, pertussis, and paraptosis often bring leukemia into the differential diagnosis.
- Such diseases as systemic lupus erythematosus and juvenile idiopathic arthritis may be associated with bone or joint pain and cytopenias that are indistinguishable from acute leukemia.
- For many diseases, eliminating leukemia from the differential diagnosis becomes of paramount importance.
 - In specific diseases that require use of corticosteroids:
 - Systemic lupus erythematosus
 - Juvenile idiopathic arthritis
 - Immune thrombocytopenia purpura
 - Hemolytic anemia
 - Infectious processes precipitating an acute asthma exacerbation
 - In these instances, if leukemia is possible or probable, referral to a hematologist may be necessary.
 - Inadvertent administration of corticosteroids may impair or delay the diagnosis of leukemia and may necessitate more intensive high-risk chemotherapy for patients with otherwise standard-risk disease.
- Mature B-cell leukemias are indistinguishable from Burkitt lymphoma with bone marrow involvement.

LABORATORY FINDINGS

General

- Leukocyte count may be normal, increased, or decreased in a patient with newly diagnosed leukemia.
 - Leukocyte count (per mL)
 - <10,000 (53% ALL, 39% AML)
 - 10,000–49,000 (30% ALL, 29% AML)
 - >50,000 (17% ALL, 32% AML)
- Anemia and thrombocytopenia are common but not always present.

- Hemoglobin (g/dL)
 - <7 (43% ALL, 41% AML)
 - 7–11 (45% ALL, 48% AML)
 - >11 (12% ALL, 11% AML)
- Platelet count (per mL)
 - <20,000 (28% ALL, 15% AML)
 - 20,000–99,000 (47% ALL, 67% AML)
 - >100,000 (25% ALL, 18% AML)
 - Coagulopathy (17% AML)
- Blasts may or may not be present on the peripheral blood smear.
- Continued close follow-up or referral to a hematologist should be guided by clinical evidence and laboratory findings.

Tumor lysis syndrome

- Other abnormal laboratory findings include measures of tumor burden and cell turnover.
 - Increased potassium
 - Increased phosphorus
 - Decreased calcium
 - Increased uric acid
 - Increased lactate dehydrogenase
- Usually most severe after administration of chemotherapy, signs of tumor lysis syndrome may be present at diagnosis because of rapid proliferation and destruction of leukemic cells.
- Patients at risk for significant electrolyte abnormalities and renal failure are those with evidence of high tumor burden, especially if an extramedullary tumor mass is present.
 - High leukocyte count
 - Massive organomegaly
 - Mature B-cell leukemia (Burkitt type)
- With appropriate preemptive management, clinically significant tumor lysis syndrome is rare in childhood leukemias.

IMAGING

- Mediastinal masses are present in 5–10% of children with leukemia, especially older boys, who are more likely to have T-cell leukemia.
- Chest radiography is necessary in all patients with suspected acute leukemia.
 - Should be performed before administration of anesthesia for any procedures
 - Radiographs of long bones frequently demonstrate evidence of leukemic infiltration of the periosteum and bone.
 - Patients with particularly high leukemic cell burdens may appear osteopenic.
 - Others may demonstrate signs of:
 - Subperiosteal new bone formation
 - Radiolucent bands in the metaphysis (leukemic lines)

- Discrete osteolytic lesions
- Growth arrest lines

DIAGNOSTIC PROCEDURES

- Cases in which the index of probability is sufficient require a more definitive bone marrow aspiration and biopsy.
- If the leukemic cell burden is sufficient to elicit clinical symptoms, findings on a bone marrow evaluation will not be subtle.
 - Identifying patients with signs and symptoms severe enough to warrant bone marrow evaluation (frequently requiring anesthesia in younger children) can be challenging.

CLASSIFICATION

Immunophenotypic classification

- Classification of leukemia by immunohistochemical or immunoflow cytometric detection of lineage-specific antigens allows precise and biologically relevant description of the leukemia cells.
- Surface and cytoplasmic antigens differentially expressed on cells of myeloid or lymphoid origin can be used to reliably distinguish AML from ALL and to subclassify within each lineage.
- Classification and immunophenotype of ALL (TdT = terminal deoxynucleotidyl transferase)
 - Early pre-B cell, CD10–
 - Common features of immunophenotype: CD10–, CD19+, CD20+, TdT+
 - Prevalence: 5.2%
 - Common in infants <1 year of age, associated with t(4;11)
 - Early pre-B cell, CD10+
 - Common features of immunophenotype: CD10+, CD19+, CD20+, TdT+
 - Prevalence: 63.1%
 - Peak incidence in early childhood
 - Pre-B cell
 - Common features of immunophenotype: CD10+/-, CD19+, CD20+, TdT+, cytoplasmic immunoglobulin+
 - Prevalence: 15.5%
 - Clinically similar to early pre-B-cell ALL
 - Mature B cell
 - Common features of immunophenotype: CD19+, CD20+, TdT+, surface immunoglobulin+
 - Prevalence: 3.9%
 - Burkitt-type leukemia, treated differently than pre-B-cell ALL
 - Pre-T cell
 - Common features of immunophenotype: CD2+, CD3+, CD7+, TdT+
 - Prevalence: 12.3%

- More common in adolescents and in boys
- Associated with high leukocyte count and bulky extramedullary disease, particularly a mediastinal mass

Classification of AML

■ French-American-British classification

- M1: AML without maturation (24%)
- M2: AML with maturation (23%)
- M3: Promyelocytic leukemia (5%)
- M4: Myelomonocytic (27%)
- M5: Monocytic (10%)
- M6: Erythroleukemia (2%)
- M7: Megakaryocytic (7%)

■ World Health Organization Classification

- AML with recurrent genetic abnormalities
 - t(8;21)(q22;q23), (*AML/ETO*)
 - AML with abnormal marrow eosinophils and *inv* 16(p13q22), or t(16;16)(p13;q22), *CBFβ/MYH11*
 - APLM1 with t(15;17)(q22;q12), (*PML/RARα*) and variants
 - AML with 11q23 abnormalities
- AML with multilineage dysplasia
 - After MDS or myeloproliferative diseases
 - No antecedent MDS or myeloproliferative disease, but dysplasia in 50% of cells
- Therapy-related AML and MDS
 - Alkylating agent, radiation related
 - Topoisomerase II-inhibitor related
- AML not otherwise categorized
 - Apply FAB categories

■ The European Group for the Immunologic Classification of Leukemias developed a scoring system of lineage specificity for different markers to distinguish AML from ALL

- The following abbreviations are used in this section: cy, cytoplasmic; mem, membrane; MPO, myeloperoxidase; TCR, T-cell receptor; TdT, terminal deoxynucleotidyl transferase.
- Biphenotypic or mixed-lineage leukemia is defined as a score = 2 in 2 separate lineages.
- Points: 2
 - B-cell ALL: cyCD79
 - T-cell ALL: cyCD3 or memCD3
 - AML: MPO
- Points: 2
 - B-cell ALL: cyCD22
 - T-cell ALL: cyCD3 or memCD3
- Points: 2
 - B-cell ALL: cyIgM
 - T-cell ALL: Anti-TCR

- Points: 1
 - B-cell ALL: CD19
 - T-cell ALL: CD2
 - AML: CD117
- Points: 1
 - B-cell ALL: CD20
 - T-cell ALL: CD5
 - AML: CD13
- Points: 1
 - B-cell ALL: CD10
 - T-cell ALL: CD8
 - AML: CD33
- Points: 1
 - T-cell ALL: CD10
 - AML: CD65
- Points: 0.5
 - B-cell ALL: TdT
 - T-cell ALL: TdT
 - AML: CD14
- Points: 0.5
 - B-cell ALL: CD24
 - T-cell ALL: CD7
 - AML: CD15

Cytogenetic and molecular markers for AML and ALL

■ Common cytogenetic abnormalities of childhood leukemias

- ALL
 - Karotype: t(12;21)(p13;q22)
 - Fusion gene: *TEL/AML1*
 - Frequency in childhood leukemia: 25–30% of ALL
 - Karotype: 11q23 abnormalities
 - Fusion gene: Multiple *MLL* fusion genes are reported.
 - Frequency in childhood leukemia: 6% of ALL
 - Karotype: t(1;19)(q23;q13)
 - Fusion gene: *E2A/PBX*
 - Frequency in childhood leukemia: 5% of ALL
 - Karotype: t(12;21)(p13;q22)
 - Fusion gene: *TEL/AML1*
 - Frequency in childhood leukemia: 25% of ALL
 - Karotype: t(9;22)(q34;q11)
 - Fusion gene: *BCR/ABL*
 - Frequency in childhood leukemia: 3–5% of ALL
 - Karotype: Hyperdiploidy
 - Fusion gene: --
 - Frequency in childhood leukemia: 30% of ALL

- AML
 - Karotype: t(8;21)(q22;q22)
 - Fusion gene: *AML1/ETO*
 - Frequency in childhood leukemia: 10–15% of AML
 - Karotype: inv16(p13;q22)
 - Fusion gene: *CBFB-MYH11*
 - Frequency in childhood leukemia: 6–12% of AML
 - Karotype: t(15;17)(q22;q21)
 - Fusion gene: *APML/RARα*
 - Frequency in childhood leukemia: 8–10% of AML
- *HOX11* over expression is a common abnormality in T-cell ALL and is identified in 5–10% of patients.
- Cytogenetic and molecular markers in ALL include:
 - Ploidy
 - Mixed-lineage leukemia (*MLL*)
 - E2A/PBX
 - BCR-ABL
 - *TEL/AML1*
- Cytogenetic and molecular markets in AML include:
 - PML/RARα
 - Core-binding factor

JMML

- Bone marrow aspiration will reveal:
 - Hypercellularity with a predominance of all stages of granulocyte maturation
 - Blast count <20%, similar to the findings in CML, with 1 key exception:
 - Patients with JMML do not harbor the Ph chromosome.
- With the exception of proving that no Ph chromosome is present, bone marrow aspiration is not diagnostic in JMML, as it is in the acute leukemias.

Myelodysplasia

- Diagnosis is based on identification of:
 - Dysplastic features in the bone marrow
 - Characteristic cytogenetic abnormalities
- Further classification is based on the number of blasts present in the marrow.
 - Used primarily to predict progression to AML

TREATMENT APPROACH

Pharmacogenetics

- Genetic polymorphisms in specific genes that are responsible for regulating drug metabolism, transport, and target expression can have a profound effect on both therapeutic and toxic responses to leukemia therapies.

- Understanding the incidence and implication of polymorphisms affecting drug metabolism and distribution will ultimately help control for individual variability in leukemia treatment protocols, with the goal of further reducing toxicity while maximizing efficacy.

Thiopurine metabolism

- 1 in 300 individuals will have 2 alleles with thiopurine S-methyltransferase (TPMT) polymorphisms, resulting in very low TPMT enzyme activity.
- 10% of individuals will have intermediate enzyme activity, resulting from 1 abnormal allele.
- Nearly 90% of the population is wild type and defined as having normal enzyme activity.
- All patients with low activity, 35% of patients with intermediate activity, and 7% of patients with wild-type activity require 6-mercaptopurine (6-MP) dose reductions.
- Higher doses of 6-MP are associated with improved outcomes, and defective TPMT metabolism is associated with a higher incidence of topoisomerase II inhibitor–induced secondary AML and a higher risk of brain tumors in patients who receive concomitant radiation therapy.
- Commercially available genotype and phenotype analysis of the TPMT enzyme helps guide current thiopurine therapy.
- Direct clinical applications of these relatively recent pharmacogenetic discoveries are clear.

Antifolate metabolism

- Antifolates remain essential in the treatment of ALL.
- Polymorphisms in methotrexate (MTX) transport, metabolism, and target expression may all effect leukemia cell sensitivity to MTX and illustrate how multiple polymorphisms may alter efficacy and toxicity of a single drug.
- Reduced folate carrier (RFC) is an active transport system for MTX.
- Decrease in RFC expression will lead to decreased MTX accumulated intracellularly.
- Though not yet correlated to RFC function, specific RFC polymorphisms are associated with a worse outcome with standard therapy for ALL.
- MTX is a tight-binding inhibitor of dihydrofolate reductase.
 - The concentration of MTX required to achieve inhibition of enzyme activity increases in direct proportion to the amount of the enzyme in target cells.
- Amplification of the dihydrofolate reductase gene is seen in 30% of patients with relapsed ALL but only 10% of patients with newly diagnosed ALL.
- Polymorphisms of other enzymes involved in MTX metabolism that are implicated in pediatric ALL include:
 - Methylene tetrahydrofolate reductase (an enzyme responsible for the reduction of 5,10-methylene tetrahydrofolate to 5-methyl tetrahydrofolate)
 - Thymidylate synthase (a target of MTX)

- In addition to the enzymes specifically involved in metabolism of MTX and thiopurines, several detoxifying enzyme systems have profound effects of a broader range of chemotherapeutic agents.
 - Cytochrome P450 enzymes are involved in the activation or inactivation of a variety of anticancer agents.
 - Polymorphisms in the cytochrome system have been implicated both in treatment efficacy and in toxicities, including vincristine neuropathies and treatment-related leukemias.
 - Implications of polymorphisms in glutathione S-transferase enzymes, glucocorticoid receptors, vitamin D receptor, and others are more controversial and not clearly defined.

SPECIFIC TREATMENTS

ALL

- Risk-stratified therapy
 - Today, risk-adapted therapies based on clinical features (age, leukocyte count, and response to induction therapies) and biological features (ploidy and mutations of known prognostic significance) are used to maximize response and cure rates while minimizing long-term side effects.
 - Importance of T cell–directed therapy is underscored by:
 - Greater sensitivity of T-lineage cancers to asparaginase
 - A new antimetabolite, ara-G (nelarabine)
 - Relative resistance of these cells to low doses of MTX
- Principles of treatment
 - Leukemia cell infiltration in marrow space and other organ systems in patients with newly diagnosed ALL may result in pancytopenia and many systemic symptoms.
 - Resolution of symptomatic disease and recovery of normal bone marrow function can only be achieved with the administration of potentially myelosuppressive and immunosuppressive chemotherapy.
 - Therapy is frequently divided into 4 phases.
 - Remission induction
 - Delayed intensification
 - Extramedullary disease treatment or prophylaxis
 - Maintenance

Remission induction

- 3 drugs are used in standard-risk patients.
 - Vincristine
 - Asparaginase
 - Corticosteroid
- In high-risk patients, the same 3 drugs are used, with the addition of:
 - Daunorubicin
- The goal is to induce complete remission.

- With current chemotherapeutic regimens, remission induction is possible in >95% of children with ALL.
- Many protocols follow an induction phase with a consolidation phase heavy in antimetabolites to secure or consolidate remission.

Delayed intensification

- A second phase of intensified chemotherapy similar to the induction and consolidations phases
- The addition of a delayed-intensification phase has led to significant improvement in survival in all patients with childhood ALL.
- Survival among patients with high-risk leukemia may be further improved by augmenting the regimen with a second delayed intensification phase.

Extramedullary disease treatment or prophylaxis

- Trials have demonstrated that CNS radiation may be reduced (to 1200–1800 cGy) or eliminated in patients with low-risk B-cell ALL with a rapid early response to induction therapy.
- Elimination of cranial radiation in patients with T-cell ALL has not proven feasible.
- Reduction in cranial radiation is designed to reduce long-term endocrine and cognitive effects and reduce the risk of secondary cancer.
- Intensified intrathecal therapy and high-dose MTX are associated with late cognitive side effects even when administered without radiation therapy.
- Optimal CNS treatment and prophylactic regimens in childhood ALL are not yet clearly defined, but current widely used strategies are associated with significantly fewer side effects than previous efforts.

Maintenance

- Unlike treatment paradigms for most cancers, successful therapy for childhood ALL includes a protracted maintenance period.
- Components of maintenance therapy vary between cooperative group studies.
- Attempts to reduce therapy to <24 months have never been successful.
- In the current Children's Oncology Group studies, boys with standard-risk ALL receive 3 years of postremission therapy.
- Boys with high-risk disease (therapy is intensified up front) and all girls with ALL receive 2 years of postremission therapy.
- Maintenance consists of:
 - Daily oral mercaptopurine
 - Weekly oral MTX
 - Monthly intravenous vincristine
 - Monthly 5-day oral corticosteroid pulses
 - Intrathecal therapy once every 3 months

- Therapy is adjusted to maximize the dose within a range that maximizes the antileukemic effect and minimizes toxicity, including myelosuppression and immunosuppression.
- Many children on maintenance chemotherapy may return to school and normal daily activities.

Infant acute lymphoblastic leukemia

- Incremental improvement in survival with intensified chemotherapy approaches has prompted several investigators to consider bone marrow transplantation in first remission for infants.
- Transplantation poses several problems, including:
 - Matched siblings are not usually available.
 - Total-body radiation is associated with significant long-term side effects in young infants.
- Continuous intensified multiagent chemotherapy may improve event-free survival for many infants, reserving the use of bone marrow transplantation only in the setting of relapse or abnormalities involving 11q23 in younger infants.

BCR-ABL

- Matched-sibling bone marrow transplantation is now recommended for children in first remission.
 - The role of specific tyrosine kinase inhibitors, such as imatinib mesylate, are currently being evaluated.

TEL/AML1

- Patients with the *TEL/AML1* translocation do very well with conventional therapy.
 - May be preferentially sensitive to protocols containing augmented therapy with asparaginase
- Patients with *TEL/AML1*-positive leukemias tend to have relapse late.
 - Salvage after relapse remains excellent.

AML

- >90% of patients achieve complete remission with cytarabine and daunorubicin in combination with either etoposide or thioguanine.
- Attempts to improve remission induction rates and long-term survival by substituting idarubicin or mitoxantrone for daunorubicin or by increasing the dose of cytarabine have largely proven to be of similar efficacy and occasionally greater toxicity.
- Alternative approaches under investigation include the introduction of monoclonal antibodies directed against CD33, a surface antigen expressed on most myeloid neoplasms.
- Intensive postremission therapies have been developed using multiagent regimens cycled every 4–6 weeks.
- No randomized head-to-head comparisons of regimens have been made.
 - None has succeeded in improving long-term, event-free survival beyond 60%.

- Allogeneic stem cell transplantation has been extensively evaluated.
 - Most studies nonrandomly assign patients with matched-sibling donors to undergo transplantation and those without sibling donors to continue with conventional chemotherapy.
 - Relapse-free survival is generally better in patients who undergo transplantation, but overall survival is comparable because of transplant-related mortality.
 - Stem cell transplantation (SCT) is currently not recommended in first remission among patients with t(8;21), t(9;11), t(15;17) and *inv* 16, all favorable cytogenetic features.

Relapsed leukemias

ALL

- Despite development of successful therapies in childhood leukemias, 20–25% of children with ALL and 50% of children with AML have relapse after chemotherapy treatment.
- In most children with relapsed leukemia, long-term, event-free survival is <50%, even with SCT.
- 2 reliable predictors of survival after relapse are:
 - Duration of the first remission (improved survival after a longer first remission)
 - Phenotype (relapse B-lineage leukemias are more curable than T-lineage leukemias)
- According to the Berlin-Frankfurt-Munster (BFM) group, patients with late relapse tend to do better with both chemotherapy and SCT.
 - Very early relapse occurs after a first remission of <18 months.
 - Early relapse occurs after a first remission of >18 months but <6 months after completion of therapy.
 - Late relapse occurs after a first remission of >18 months and >6 months after completion of therapy.
- In the Children's Cancer Study Group:
 - Bone marrow relapse occurred in 539 patients (12%).
 - CNS relapse in 194 patients (4%)
 - Testicular relapse in 56 patients (1.5%)
 - Overall 3-year survival after marrow relapse was 28% for CNS relapse and 60% for testicular relapse.
- Remission reinduction after relapse is relatively good, but overall survival remains poor owing to a lack of effective therapies.
- Most studies comparing SCT to chemotherapy approaches demonstrate an advantage to SCT.
 - These studies typically include significant selection bias (based on donor availability and response to remission reinduction).

AML

- As in ALL, hematologic relapse is the most common adverse event in patients with AML.
- Approximately 30–40% of patients who achieve remission will have relapse.
 - 25% will have residual disease after intensive induction therapy.
- Many patients with AML undergo SCT in first remission.
 - As many as 40–50% still have relapse.
 - Their relapse therapy may be severely limited or complicated by posttransplant toxicities.
- Remission reinduction rates for all patients with AML in first relapse ranges from 50–80% using multiagent chemotherapy.
- Overall survival after relapse is 30–40%.
- In ALL, a subset of patients may be found who had late relapse that may still be salvaged with conventional chemotherapy.
- The only curative alternative for patients with relapsed AML is SCT.

Acute promyelocytic leukemia

- When treated with standard AML therapy, patients fared poorly.
- Recent regimens intensifying anthracycline dose in induction and incorporating retinoic acid, mercaptopurine, and MTX into maintenance therapy have led to 5-year survival rates >80%.

CML

- Until recently, standard therapy for CML in children and adults included:
 - Hydroxyurea
 - Interferon
 - Low-dose cytarabine
- More recently, imatinib mesylate was developed as a specific inhibitor of *BCR-ABL* tyrosine kinase.

Imatinib mesylate

- Imatinib mesylate has been established as the standard of care for CML.
- ~60% of patients with disease that is refractory to interferon achieved major cytogenetic response with imatinib, with infrequent hematologic toxicities.
- Imatinib is most effective in patients with chronic-phase CML (76% major cytogenetic response rate reported) compared with the accelerated phase or blast crisis.
- Limited data are available on imatinib mesylate in children; however, preliminary data are promising.
- In the current era of imatinib mesylate therapy, once-unattainable cytogenetic and molecular remissions are not only possible but also expected.

- Durable remissions on imatinib mesylate therapy are likely to extend beyond the first year after diagnosis, making delay of transplantation possible, especially in patients without an appropriate donor and in very young children.

SCT

- The only proven curative strategy for children with CML is allogeneic SCT.

JMML

- The European Working Group of MDS in Childhood reported 5-year event-free survival in approximately 50% of children with JMML who received a transplant from matched-related and matched-unrelated donors.
- The role of conventional chemotherapy before transplantation or in patients without an appropriate donor is not clearly defined.
- Most European trials typically use mercaptopurine or no drug therapy.
- Current Children's Oncology Group trials in the US administer:
 - Cytarabine
 - Fludarabine
 - Retinoic acid
- Granulocyte-macrophage colony-stimulating factor agonists and farnesyltransferase inhibitors are currently under evaluation.

MDS

- AML that occurs after MDS is typically more difficult to treat than de novo AML.
- The only available therapy for AML includes supportive care and SCT.

WHEN TO REFER

- The role of the pediatrician does not end with the initial referral to an oncologist.
- Much of the treatment for ALL is given on an outpatient basis.
 - Patients should be seen periodically by their pediatrician throughout treatment.
- As the number of long-term survivors among patients with leukemias increases, so will the role of the general pediatrician.
 - Understanding biology, treatment, prognosis, and short- and long-term side effects of childhood leukemias is necessary for primary care physicians.
- Referral for an endocrine evaluation should be considered for all survivors of childhood leukemia with short stature.

COMPLICATIONS

- Long-term side effects of treatment need to be anticipated, monitored, and treated effectively.

Cognitive function

- Changes in cognitive function after cranial radiation are among the most well-studied side effects.
- Radiation-induced white-matter changes may result in:
 - Deficits in speed of information processing
 - Potentially progressive decrements in IQ testing
 - Poor school performance
- Age at the time of treatment and total dose of radiation administered are the most reliable predictors of late cognitive effects.
- Patients receiving cranial radiation at <5 years, and especially <3 years, are more susceptible to resultant cognitive deficiencies.
- Other significant observations include a dose-dependent effect between cognitive deficiencies after 1800, 2400, and 3600 cGy cranial radiation.
- Many recent treatment regimens attempt to:
 - Eliminate cranial radiation for patients at the lowest risk for CNS recurrence
 - Reduce the dose of radiation to 1200 or 1800 cGy for patients at highest risk for CNS recurrence
- Intensifying intrathecal therapy has proven to be effective prophylaxis against CNS recurrence while maintaining baseline long-term cognitive function.

Cardiac effects

- Anthracyclines will probably remain a crucial component of effective therapy for ALL and AML.
- Incidence and severity of cardiac toxicity relate to:
 - Cumulative dose of anthracycline
 - Concomitant use of mediastinal radiation
 - Use of cyclophosphamide or ifosfamide
 - Younger age at diagnosis
- Most current treatment regimens in childhood cancer are capped at a total cumulative anthracycline dose of 350–400 mg/m² to reduce late cardiac toxicities.
 - Most ALL treatment regimens do not approach this level.
- The following are associated (in addition to cumulative dose) with a higher risk of late cardiac toxicities.
 - Bolus infusion of anthracycline (as compared with continuous infusion)
 - Female sex
 - Young age at diagnosis
- Cardiac toxicities may affect function or rhythm, or both, and may be asymptomatic until years after completion of therapy, usually exhibiting at times requiring rapid increases in cardiac output (eg, puberty, pregnancy, weight training).
- Patients receiving high cumulative doses of anthracycline should maintain diligent follow-up, especially if echocardiographic abnormalities are detected before completion of therapy.

- Patients with no detectable abnormalities should undergo electrocardiography and echocardiography at least every 2–3 years.

Endocrine effects

- Craniospinal radiation may reduce adult standing height as a result of deficient growth of the vertebral bodies after spinal radiation and growth hormone deficiency after cranial radiation.
- For many patients, growth hormone supplementation may be necessary and effective.
- Osteoporosis after corticosteroid administration is a significant problem that may affect growth.
- Infertility is a significant concern after chemotherapy (especially with alkylator-based regimens) and radiation (especially boys who required testicular radiation).
 - Abnormal gonadal development and function may result from direct damage to the gonads after radiation or to the hypothalamic-pituitary axis after cranial radiation.
 - With higher cumulative doses of alkylators, boys (especially those in puberty at the time of treatment) are more likely than girls to be infertile.

Second malignant neoplasms

- Risk and development of a second cancer is a devastating side effect of both chemotherapy and radiation therapy for childhood ALL.
 - Risk is significantly less than that reported for other childhood cancers.
- Cumulative incidence of any second neoplasm in survivors of childhood leukemia is reportedly 1.18% at 10 years (95% confidence interval, 0.8–1.5%).
 - 7.2-fold increased risk above the general population
- Cranial radiation, relapse, and female gender have all been associated with an increased risk for developing a second cancer.
- Secondary CNS cancers are most common.
 - Secondary leukemias and myelodysplasia, soft-tissue sarcomas, brain tumors, and solid tumors are all reported.
- Deficiencies in TPMT may predispose patients to secondary brain tumors.
 - In protocols incorporating high doses of antimetabolites, the 8-year cumulative incidence of secondary brain tumors among TPMT-deficient children was 43%.
 - Patients with normal TPMT activity had an 8-year cumulative incidence of secondary brain tumors of 8.3%.
 - This exceptionally high incidence of secondary brain tumors in both groups probably reflects the concomitant use of cranial radiation and high-dose antimetabolites.
 - Identification of the possible late side effects of leukemia therapy has been key in the development of risk-stratified therapy.

- Reducing cumulative doses of agents with significant short- and long-term side effects while maintaining excellent cure rates in children with ALL has been an important accomplishment.

PROGNOSIS

■ ALL

- Leukemia cells that express aberrant myeloid markers but do not meet strict criteria for biphenotypic leukemia historically yield an inferior outcome.
- T-cell phenotype is associated with an inferior outcome, although older age, male sex, and extramedullary disease frequently associated with T-cell ALL may partly account for the greater risk for relapse.
- Identification of leukemia cells in the CNS at diagnosis continues to be an adverse prognostic feature of childhood ALL despite attempts to intensify intrathecal therapy and CNS irradiation.
- Independent of the increased incidence of T-cell ALL among boys, girls appear to do better with less therapy.
 - In recent studies that intensify therapy for boys, the differences in survival among boys and girls are still apparent, although significantly reduced.
 - The reason for these sex differences is not known.
- See table Common Prognostic Features of the Acute Leukemias.
- Response to induction therapy is predictive of outcome and used to stratify patients for more intensified therapy when necessary.
 - After 7 days of therapy, patients with <5% blasts in their marrow have event-free survival of 80%, whereas those with >25% blasts in the marrow have event-free survival of 68%.
 - Among patients with a slow early response to induction therapy, those who receive intensified therapy will have an improved outcome compared with those who remain on standard therapy.
- Addition of a delayed-intensification phase by the BFM group has led to significant improvement in survival in all patients with childhood ALL.

Common Prognostic Features of the Acute Leukemias^a

		Clinical Features	Cytogenetics
B-cell-precursor ALL	Favorable	Age between 1 and 9.99 years	t(11;22)(p13;q22), <i>TEL/AML1</i> fusion
			Hyperdiploidy (>50 chromosomes)
			Trisomies 4, 10, and 17
	Unfavorable	Age >10 years	Philadelphia chromosome
		Initial leukocyte count >50,000 cells/mcL	<i>MLL</i> rearrangements in infants
Poor response to induction therapy			
Extramedullary disease			
T-cell precursor ALL	Favorable	Good response to steroids ^b	<i>HOX11</i> overexpression
			t(11;19) <i>MLL-ENL</i> fusion
	Unfavorable	Poor early response to treatment	—
		Low-intensity chemotherapy regimens	
T-cell precursor AML	Favorable	Acute promyelocytic leukemia	t(8;21) <i>AML1-ETO</i> fusion
		AML in Down syndrome	inv(16) or t(16;16)(p13;q22)
			t(15;17)(q22;q21), <i>APML/RARα</i> fusion
	Unfavorable	Leukocyte count >100,000 cells/mcL	Monosomy 7 (7q-)
		Secondary AML or AML after MDS	

Abbreviations: ALL, acute lymphocytic leukemia; AML, acute myelogenous leukemia; MDS, myelodysplasia.

^a Adapted from: Pui CH, Schrappe M, Ribeiro RC, et al. Childhood and adolescent lymphoid and myeloid leukemia. *Hematology Am Soc Hematol Educ Program*. 2004;118–145.

^b With kind permission from Springer Science + Business Media. *Annals of Hematology*. Evolution of BFM trials for childhood ALL, 83,2004;S121–S123, Schrappe M.

- Subsequent trials in the US and Europe have confirmed the importance of postinduction intensification in the long-term survival of patients with ALL.
- Survival among patients with high-risk leukemia may be further improved by augmenting the regimen with a second delayed intensification.
- Infant ALL
 - Infants have a higher incidence of relapse, death from toxicity, and long-term side effects compared with older children.
 - Studies with intensified therapy in infants demonstrated event-free survival:
 - <10% in those <6 months of age
 - 40% in those >6 months of age.
- Early-cell ALL has poor outcome.
- Pre-B-cell ALL
 - Recent intensification of therapy has improved survival.
- Historically, T-cell ALL is associated with a less favorable prognosis.
 - Poor prognosis has largely been eradicated because of intensification of therapy for patients with T-cell ALL.
- Ploidy
 - Event-free survival in patients with hyperdiploid leukemia cells exceeds 75–90%, making it a reliable marker of a good prognosis.
 - Patients with simultaneous trisomies of chromosomes 4, 10, and 17 have a 7-year event-free survival >90%.
 - Patients with <46 chromosomes (hypodiploidy) have a worse prognosis.
 - Event-free survival for patients with 33 to 44 chromosomes is 40%.
 - For patients with <28 chromosomes, event-free survival is 25%.
- MLL
 - The t(4;11)(q21;q23) mutation resulting in the *MLL-AF4* fusion product is associated with an event-free survival of only 20–25%.
 - In children >1 year of age, the negative impact of *MLL* gene rearrangements on survival is less.
 - The t(11;19)(q23;q13.3) translocation fusing *MLL* with the *ENL* locus on chromosome 19 is associated with a favorable prognosis in T-cell ALL.

■ *BCR-ABL*

- Ph+ childhood ALL remains one of the most difficult subsets to cure.
 - Long-term, event-free survival of <50%.

AML

- Event-free survival rate in childhood AML has reached a plateau at 60% despite aggressive intensification of therapy.
- Individualized treatment regimens have worked to improve survival rates significantly in children with acute promyelocytic leukemia but have done little for other subsets of AML.
- >90% of patients will obtain complete remission with cytarabine and daunorubicin in combination with either etoposide or thioguanine.
- Allogeneic SCT
 - Relapse-free survival is generally better in patients who undergo transplantation, but overall survival is similar because of transplant-related mortality.
 - Among patients with t(8;21), t(9;11), t(15;17), and *inv* 16, all favorable cytogenetic features, SCT is currently not recommended in first remission (reviewed in 52 studies).

CML

- Survival after SCT for CML is reported to be 70–80% with a matched-sibling donor and 40–60% when unrelated donors are used.

JMML

- The natural history of JMML, if untreated, is death within a median of 1 year.
- At age >2 years, thrombocytopenia and high hemoglobin F at diagnosis are predictors of more aggressive disease.

MDS

- Life-threatening complications may occur in a minority of patients.
 - Most experience spontaneous remission within a few months.
- ~25% will develop leukemia within 1–3 years.

Limp

DEFINITION

- Abnormal gait pattern
 - Common presenting symptom in pediatric primary care offices and emergency departments
 - Most commonly associated with trauma, but has many possible benign or life-threatening causes
- Types of limp
 - Antalgic gait: shortened stance time on affected side caused by pain on weight bearing, with shortened swing phase on the contralateral side
 - Trendelenburg gait
 - Hip girdle drops on the affected side, and the trunk moves over the affected side to maintain balance.
 - If the problem is bilateral, the trunk swings from side to side.
 - Circumduction (vaulting): straight-legged walking
 - *Steppage equinus* gait: foot drop caused by peroneal nerve injury or weakness of the tibialis anterior muscle
 - Toe-walking
 - Waddling: wide-based stance

EPIDEMIOLOGY

- See Differential Diagnosis for causes of limp by age group.
- Legg-Calvé-Perthes disease (avascular necrosis of the femoral head)
 - 5 times more likely in boys than in girls
- Slipped capital femoral epiphysis (SCFE)
 - Most common among adolescents, often during or just before the pubertal growth spurt (age 10–15 years)
 - Boys are affected more often than girls (3:2).
 - Obesity and tall stature are risk factors.

MECHANISM

- Antalgic gait
 - Caused by pain on weight bearing, possibly as a result of:
 - Mechanical difficulties
 - Inflammatory processes
 - Infectious processes
 - Specific hip disorders
 - Cancer
 - Hematologic disorders
- Trendelenburg gait
 - Caused by hip abductor weakness or hip joint instability
 - Inflammatory processes
 - Infectious processes
 - Specific hip disorders

- Circumduction (vaulting)
 - Caused by joint pain/stiffness or muscle weakness
 - Inflammation
 - Infection
 - Pain
 - Leg-length discrepancy (true or functional)
- Steppage (equinus) gait: due to peroneal nerve injury or weakness of the tibialis anterior muscle (eg, Guillain-Barré syndrome)
- Toe-walking: result of real or functional leg-length discrepancy
 - Contractures
 - Muscle spasms
- Waddling: results from bilateral hip disease or neuromuscular disease
- Stooped and shuffle gaits (symmetric or asymmetric)
 - Caused by peritoneal inflammation
 - Pelvic inflammatory disease
 - Appendicitis
 - Salpingitis
 - Psoas abscess

HISTORY

- Important historical points
 - Duration of limp
 - Antecedent trauma and activity
 - Associated or preceding symptoms
 - Fever
 - Viral illness
 - Rash
 - Recurrent fevers, rash, and joint pain suggest an inflammatory process, eg, juvenile idiopathic arthritis).
 - Weight loss
 - Changes in exercise patterns
 - Possible trauma
 - If the nature or degree of child's injury does not fit the history given, nonaccidental injury should be considered and further evaluated.
- Recent vaccinations
 - Adolescent girls who receive rubella vaccination may develop transient but painful reactive arthritis 1–2 weeks after vaccination.
- History of influenza-like illness and erythematous rash with central clearing
 - Evaluate for Lyme disease.

- Physical activities
 - Athletes, especially runners
 - Stress fractures
 - Patellofemoral arthralgia syndrome
 - Overuse syndromes due to repetitive microtrauma to:
 - Tibia (Osgood-Schlatter disease)
 - Calcaneus (Sever disease)
 - Patella (patellofemoral arthralgia syndrome)
 - Sudden increase in the amount or duration of exercise is frequently associated with injury.
- Consider underlying hematologic disorders.
 - Hemarthrosis from hemophilia in a boy with a swollen, painful knee and family history of bleeding problems
 - Vasoocclusive pain crisis in a black patient with a history suggesting sickle cell disease

PHYSICAL EXAM

- Physical examination should be tailored on the basis of patient history.
 - If there is any indication of systemic illness, a complete examination should be conducted.
 - If there are no systemic signs, most of the examination can be directed toward the back and lower extremities.
 - Thigh or knee pain:
 - May be referred from a hip process
 - Requires thorough evaluation of the hip joint
- Determining the gait abnormality is crucial.
 - Observe the patient's gait with good visibility of feet, leg, and pelvis.
 - In younger children, useful information may be gained by observing the child before entering the examination room or when the child is engaged in other activities.
- Leg examination
 - To localize the cause, look for:
 - Erythema
 - Warmth
 - Bruising
 - Swelling
 - Muscle atrophy
 - Asymmetry
 - Erythema, warmth, and swelling suggest an infectious or inflammatory process of subcutaneous tissue, muscle, bone, or joint.
 - Palpation along the limb from lower spine to the toes may localize pain.
 - Pinpoint tenderness is found most often with fractures or osteomyelitis.
- If hip or upper thigh appear involved, then examine:
 - Lower spine
 - Paraspinal areas
 - Abdomen
 - Inguinal areas
- Joint examination
 - Each joint should be examined systematically for:
 - Infection or inflammation, suggested by erythema, warmth, and swelling
 - Pain
 - Range of motion (both active and passive)
 - Limited range of motion at the joint suggests an intraarticular process.
 - Infected or inflamed hip joints
 - Tend to be held in the position of most comfort (affected leg flexed, abducted, and externally rotated to decrease pressure in the hip joint), even to the extent of pseudoparalysis
 - Are painful with direct compression into the joint
 - Hip joints in particular should be assessed for both external and internal rotation.
 - Knee joint
 - Evaluate for the presence of an effusion.
 - Evaluate for patellar pain with pressure.
 - Assess stability for ligamentous injury.
 - Pain with active, but not passive, range of motion suggests a muscle or tendon injury.
- Musculoskeletal examination
 - Leg-length discrepancy (true or functional)
 - Measure both legs from the anterior superior spine of the ilium to distal end of the ipsilateral medial malleolus.
 - Developmental dysplasia of the hip (DDH) results in functional leg-length discrepancy.
 - Significantly better prognosis if diagnosed in infancy
 - In infants, asymmetric skin folds suggest a leg-length discrepancy and are a characteristic finding of unilateral DDH.
 - The Galeazzi test should be performed to evaluate for DDH or other leg-length discrepancy.
 - The patient lies supine, with ankles to buttocks, hips and knees flexed.
 - Test is positive if the knees are at different heights.
- General examination
 - General appearance
 - Temperature
 - Presence of a rash that may suggest a systemic cause
 - Bruising or scars that suggest nonaccidental injury

DIFFERENTIAL DIAGNOSIS

- Approaching a diagnosis by the type of gait abnormality allows a well-organized approach to evaluation and management.

Differential diagnosis, by disease type and gait pattern

- **A** (antalgic), **T** (Trendelenburg), **C** (circumduction), **S** (stepping), **E** (equinus)

■ Mechanical

- Soft-tissue injury, including bruising, strains, and foreign body (A)
- Skeletal fracture, including stress or overuse fracture (A)
- Toddler's fracture (A)
- Apophysitis of tibial tuberosity (Osgood-Schlatter disease) or calcaneum (Sever disease) (A)
- Chondromalacia patellae (A)
- Spondylolisthesis and spondylolysis (A)

■ Inflammatory

- Reactive arthritis, including transient synovitis of the hip (A, T, possibly C)
- Juvenile idiopathic arthritis (A, T, possibly C)
- Myositis (A, T)
- Other connective tissue disease (eg, systemic vasculitis, systemic lupus erythematosus) (A, T)
- Chronic recurrent multifocal osteomyelitis (A, T)

■ Infection

- Skeletal, including osteomyelitis and septic arthritis (A, T, possibly C)
- Diskitis (A)
- Soft-tissue infection (A, T, possibly C)
- Abdominal sepsis, including psoas abscess, appendicitis, peritonitis (A, T)
- Inguinal lymphadenitis (A)

■ Specific hip disorders

- Legg-Calvé-Perthes disease (A, T)
- SCFE (A, T)
 - May have dull aching in the hip or leg and pain occurring only with exercise
 - Diagnosis of SCFE is delayed in as many as 30% of cases, leading to increased difficulties with treatment.
- Idiopathic chondrolysis (A, T)

■ Congenital

- DDH (T)
- Congenital talipes equinovarus (E)
- Congenital short femur (C)
- Skeletal dysplasias (A, T, C)

■ Malignant disease

- Leukemia (A)
- Bone neoplasia (eg, osteoid osteoma, osteoblastoma, osteosarcoma, Langerhans cell histiocytosis) (A)
- Spinal cord tumor (A)

■ Metabolic

- Rickets (A)

■ Other

- Neurologic and neuromuscular disease (T, C)
- Hematologic disease (eg, hemophilia, sickle cell disease) (A)
- Tarsal coalitions (A)
- Chronic pain syndromes (A, C, T, S, E)
- Idiopathic or conversion disorder (usually bizarre gait) (A, C, T, S, E)

■ Further narrowing of the differential diagnosis depends on:

- Time course
- Associated signs and symptoms
- Age (see below)
- Physical examination

Causes of limp, by age

■ Toddler (1–3 years)

- Antalgic gait
 - Infection
 - Septic arthritis: hip, knee
 - Osteomyelitis
 - Diskitis
 - Trauma
 - Accidental
 - Nonaccidental
 - Toddler's fracture
 - Neoplasia
- Trendelenburg gait
 - Hip dislocation
 - Neuromuscular disease
 - Cerebral palsy
 - Poliomyelitis

■ Childhood (4–10 years)

- Antalgic gait
 - Infection
 - Septic arthritis: hip, knee
 - Osteomyelitis
 - Diskitis
 - Reactive arthritis, including transient synovitis of the hip
 - Legg-Calvé-Perthes disease
 - Tarsal coalition

- Rheumatologic disorder
- Juvenile idiopathic arthritis
- Acute rheumatic fever (ARF)
- Trauma
- Neoplasia
- Trendelenburg gait
 - Hip dislocation
 - Neuromuscular disease
 - Cerebral palsy
 - Poliomyelitis
- Adolescence (>11 years)
 - Antalgic gait
 - SCFE
 - Rheumatologic disorder
 - Juvenile idiopathic arthritis
 - Trauma: fracture, overuse
 - Tarsal coalition
 - Neoplasia
 - Trendelenburg gait
 - Neuromuscular disease
- Leukocyte count $>11,000$ cells/mm³
- Radiographic finding of >2 -mm difference between affected and unaffected hips
- If 4 or 5 of these factors are present, likelihood of septic arthritis is very high (85–99%).
- If joint sepsis is suspected:
 - Aspirate joint fluid (should be done by an orthopedic surgeon).
 - Obtain Gram stain, culture, and cell counts to guide diagnosis and treatment.
 - If gonococcal arthritis is a consideration, vaginal, anal, and throat specimens should be sent for culture.
- Additional tests for specific diagnoses
 - Lyme titers if history of:
 - Preceding erythema migrans rash
 - Fever and malaise
 - Arthritis
 - Travel or residence in a Lyme disease–endemic area
 - Rheumatologic workup, with history of:
 - Recurrent fevers, rash, and joint pain
 - Antinuclear antibody titer
 - Possibility of ARF should be evaluated with antistreptolysin O titer if:
 - Recent pharyngitis (previous 2–4 weeks)
 - Migrating arthritis
 - Rash
 - Possible chest discomfort (caused by carditis)
 - ARF is most common in children 4–9 years of age.

LABORATORY EVALUATION

- If history and physical examination suggest an infectious, inflammatory, or neoplastic cause
 - Complete blood cell count with differential
 - Erythrocyte sedimentation rate (ESR)
 - ESR <20 mm/hour: unlikely to be associated with serious infectious, inflammatory, or neoplastic causes
 - C-reactive protein (CRP) level
 - In febrile or ill-appearing patients: blood culture
 - Positive in up to 50% of cases of septic arthritis and osteomyelitis
- Tests to distinguish between hip septic arthritis (requires urgent joint drainage and parenteral antibiotic treatment) and transient synovitis (treated symptomatically)
 - Difficult because there can be significant overlap of history, physical examination findings, laboratory results, and radiologic findings
 - Leukocyte count, ESR, and CRP level all tend to be increased in septic arthritis.
 - CRP may be clinically useful as a negative predictor.
 - If the CRP level is <1.0 mg/dL, the patient probably does not have septic arthritis.
 - Septic arthritis
 - Temperature $>37^{\circ}\text{C}$
 - ESR >20 mm/hour
 - CRP level >1.0 mg/dL

IMAGING

- Radiography (plain film)
 - Useful to diagnose:
 - Fractures
 - Hip disease
 - Spinal abnormalities
 - Foot disease (eg, tarsal coalition)
 - ≥ 2 views of affected area are essential.
 - Suspected hip disease
 - Anteroposterior and frog-leg lateral (Lauenstein) views of the pelvis
 - Hips
 - Radiographic evidence of >2 -mm difference between affected and unaffected hip is associated with septic arthritis if temperature is $>37^{\circ}\text{C}$ and laboratory values are suggestive.

- SCFE
 - Characteristic appearance of ice cream falling off the cone at the affected femoral head
 - Seen best on Lauenstein (frog-leg) films, in which the displaced femoral head is more apparent
- DDH
 - Femoral head out of position and abnormal development on both sides of the joint (acetabulum and femoral head)
- Cancer (Ewing sarcoma, osteosarcoma)
- Multiple lesions of Langerhans cell histiocytosis
 - Additional imaging is needed for further assessment.
- Legg-Calvé-Perthes disease
 - Approximately 5 months after initial ischemia, antero-posterior radiographs of the pelvis show dense femoral epiphysis and apparent widening of the medial joint space.
- Osteomyelitis
 - Findings are not usually apparent until ≥ 10 days after onset of symptoms.
- Ultrasonography of hip
 - To assess for joint effusion
 - If there is significant effusion, aspiration is required to differentiate among inflammation, infection, and hemorrhage.
- Bone scintigraphy
 - Uptake of technetium-99m is increased at sites of increased blood supply or bone turnover.
 - Useful to diagnose
 - Osteomyelitis
 - Recurrent multifocal osteomyelitis
 - Diskitis
 - Stress fracture
 - Osteoid osteoma
 - Legg-Calvé-Perthes disease
 - Neoplasms
- Computed tomography in evaluation of bones
 - Tarsal coalition
 - Spondylolisthesis or spondylolysis
 - Osteoid osteoma
- Magnetic resonance imaging is useful to evaluate:
 - Intraspinal lesions (diskitis, soft-tissue neoplasms, bone marrow disease)
 - Legg-Calvé-Perthes disease (if early)

DIAGNOSTIC PROCEDURES

- Joint aspiration may be required in case of septic arthritis.
 - Aspiration of the osteomyelitis site may be performed to identify organism and to determine the sensitivity of those organisms.

SPECIFIC TREATMENT

Mechanical or musculoskeletal problems

- Unless evaluation suggests fracture or ligament damage, treat with:
 - Rest
 - Ice (in initial 48–72 hours after trauma)
 - Compression
 - Elevation
 - Mild analgesics
- If severe or persistent symptoms, orthopedic involvement may be indicated.
- Fracture, ligament, and tendon injury require appropriate orthopedic referral and treatment.

Infection

- High morbidity
- Septic arthritis
 - Surgical emergency
 - Necessitates emergent orthopedic involvement for diagnosis and therapeutic aspiration
- Septic arthritis and osteomyelitis
 - Broad-spectrum parenteral antibiotics, including coverage for methicillin-resistant *Staphylococcus* if present in the community
 - Treat until significant clinical improvement takes place.
 - Decreased ESR level
 - Decreased leukocyte count
 - Negative blood culture
 - Afebrile
 - CRP level should be monitored regularly because it decreases rapidly with effective antimicrobial treatment.
 - When the patient has clinically improved and in consultation with a pediatric infectious disease specialist, oral antibiotics can be considered 3–4 weeks if:
 - The organism is susceptible.
 - Outpatient compliance is excellent.
 - The patient is monitored closely.

Specific hip disorders

- Legg-Calvé-Perthes disease
 - Intermittent synovitis with discomfort may occur, requiring limitation of normal activity, bracing, or casting.
- SCFE
 - Treatment consists of pinning the femoral epiphysis for stabilization.

Inflammation

- Treatment of transient synovitis of the hip is symptomatic, usually requiring some limitation of activity.
 - Transient synovitis is self-limited, and full recovery is anticipated, usually within weeks.

- Arthritis (juvenile idiopathic arthritis, ARF, Lyme arthritis, and systemic lupus erythematosus)
 - Consultation with a rheumatologist may be beneficial.
 - Depending on laboratory test results, treatment consists of:
 - Antiinflammatory agents for autoimmune processes
 - Antibiotics for disseminated Lyme disease

Developmental or acquired conditions

- Referral to an orthopedist is needed for treatment.

WHEN TO REFER

- Refer if clinical, radiographic, or laboratory concern for:
 - Fracture
 - Septic arthritis
 - Osteomyelitis
 - DDH
 - SCFE
 - Neoplastic disease
 - Appendicitis or psoas abscess
 - Persistent limp of unclear cause

WHEN TO ADMIT

- Patients with septic arthritis and osteomyelitis need to be hospitalized for intravenous antibiotic administration, at least in the beginning of therapy.

FOLLOW-UP

- Patients with transient synovitis need to be followed closely because the signs and symptoms of transient synovitis and septic arthritis overlap.
 - Misdiagnosis may delay therapy for septic arthritis.

PROGNOSIS

- DDH
 - Prognosis is best in children diagnosed in early infancy and with mild dysplasia.
 - If not diagnosed early, DDH may result in a limp in an infant or toddler learning to walk.
- Legg-Calvé-Perthes disease
 - Self-limited, with resolution in 18–24 months
 - Intermittent synovitis with discomfort may occur, requiring limitation of normal activity, bracing, or casting.

Loss of Appetite

DEFINITION

- Loss of appetite (anorexia) is a common symptom in children.
- A transient loss of appetite is often associated with acute illness.
- Prolonged loss of appetite, when associated with poor weight gain or weight loss, may signify a serious or chronic illness.
- In infants, it is difficult to differentiate between loss of appetite and poor feeding.
- This is distinct from, but closely related to, failure to thrive.

MECHANISM

- Mechanisms regulating hunger and satiety are not completely understood.
- Appetite is regulated by the hypothalamus.
 - *Satiety center* in the ventromedial hypothalamus
 - *Feeding center* in the lateral hypothalamus
- Central control of appetite is influenced by:
 - Anticipation of a pleasurable meal
 - Visual and taste sensations
 - Ambient temperature
 - Changes in blood levels of glucose or other nutrients
 - Limbic signals from higher central nervous system (CNS) regions
- Initiators of satiety include:
 - Vagal input from gastric distention
 - Cholecystokinin from the intestine and CNS
 - Other humoral factors, including insulin, glucagon, endorphins
- Changes in appetite may be mediated by the interaction of hormones, with changes in leptin/ghrelin levels influencing the release of CNS neuropeptides, including neuropeptide Y, melanocyte-stimulating hormone, and the orexins.
 - Leptin
 - Produced in adipose cells
 - Appears to suppress appetite
 - Ghrelin
 - Produced by endocrine cells in the stomach and gastrointestinal (GI) tract
 - Appears to stimulate appetite
- Cytokines are key mediators of appetite suppression in both acute and chronic illnesses.
 - Interleukin-1 β and tumor necrosis factor- α have been shown to induce anorexia by acting directly on the hypothalamus.
 - Effects on the peripheral nervous system and on hormone levels also occur.
- The set point for body fat content may be individualized.

HISTORY

- Review diet and consumption history of the child and family.
- Adequate evaluation of nutritional intake requires caloric assessment.
- Assess parental expectations.
- Take a careful birth, family, medical, and medication history.
- For infants:
 - Assess for sick contacts and exposure to illness.
 - Discuss GI symptoms, such as emesis; constipation; diarrhea; and amount, frequency, and character of stools.
 - Evaluate for other indications of feeding intolerance, including rashes.
 - Compare caloric intake with estimated caloric needs.
 - Assess feeding effort and coordination.
 - If formula-feeding:
 - Discuss the proportions in which formula is constituted.
 - Estimate total caloric intake from volume of formula and caloric density of formula (standard is 20 kcal/oz).
 - If breastfeeding, assess:
 - Perceived adequacy of maternal milk production
 - Ability of infant to breastfeed
- For children and adolescents:
 - Assess intake and output.
 - Discuss whether eating leads to symptoms, such as pain, emesis, diarrhea, and fatigue.
 - Discuss quantity and type of stools.
 - Assess body image, social context, and stressors
 - Consider substance abuse
 - Consider HEADSSS assessment (home, education, activities, drugs, sexuality, suicide/depression, safety)

PHYSICAL EXAM

- Vital signs
 - Assess temperature.
 - Consider heart rate, blood pressure, and orthostatic vital signs.
 - Weigh the individual and plot on a growth chart.
 - Consider serial weights for computation of growth velocities.
 - With breastfed infants, consider weighing infant before and after feedings.
 - In children ≥ 2 years of age, compute body mass index, body mass index percentile, and weight for length/height
- Physical examination
 - Assess mental status.
 - Assess volume status and for anemia (eg, pale conjunctiva).
 - Examine oral mucosa for thrush, ulcerations.
 - Examine nose and palate.

- Assess cardiorespiratory status.
- Assess the abdomen for organomegaly.
- Look for signs of malnutrition or vitamin deficiencies (eg, lanugo).
- Look for clinical findings related to genetic disorders (eg, Down syndrome, Turner syndrome).
- Oral aphthous ulcers may be related to Crohn disease.
- Discoloration of teeth may be related to purging behaviors.
- Assess for toxidromes in adolescents.

DIFFERENTIAL DIAGNOSIS

Newborn period

- Poor oral intake by an infant developmentally capable of feeding has a broad differential diagnosis that includes:
 - Infection
 - Sepsis
 - Meningitis
 - Urinary tract infection
 - Perinatal infection
 - Oral thrush, herpangina
 - CNS abnormality or disease
 - Cardiac disease (eg, congestive heart failure, cyanotic heart disease)
 - Structural or functional craniofacial or GI abnormality (eg, choanal atresia, cleft palate, velopharyngeal insufficiency)
 - Renal failure
 - Metabolic or genetic issues (eg, inborn error of metabolism, Down syndrome, Prader-Willi syndrome)
 - Endocrine disorders (eg, congenital hypothyroidism)
 - Drug intoxication (including maternal substance abuse, perinatal administration of opioids or magnesium)

Organic disease in children and adolescents

- Infections, acute or chronic
- Neurologic causes
 - Cerebral palsy
 - Congenital degenerative disease (eg, neurodegenerative disorders, spinomuscular atrophy, muscular dystrophy)
 - Hypothalamic lesion
 - Increased intracranial pressure, including brain tumor
 - Static encephalopathy
- Cardiac causes
 - Congestive heart failure
 - Cyanotic heart disease
- GI causes
 - Significant GI disease commonly leads to poor appetite.
 - However, anorexia may result from disease that is distant from the bowel.

- Oral or esophageal lesions (eg, thrush, herpes simplex)
- Gastroesophageal reflux
- Eosinophilic esophagitis
- Dietary protein intolerance
- Bowel obstruction, especially with gastric or intestinal distention
- Short-bowel syndrome
- Inflammatory bowel disease
- Celiac disease
- Constipation
- Esophageal motility disorder (eg, cricopharyngeal dysfunction, achalasia, connective tissue disorder)

Metabolic causes

- Renal failure, renal tubular acidosis, or both
- Liver failure
- Inborn errors of metabolism
- Lead poisoning

Endocrine

Nutritional causes

- Marasmus
- Iron deficiency
- Zinc deficiency

Drugs

- Morphine
- Digitalis
- Antimetabolites
- Methylphenidate
- Amphetamines

Prolonged restriction of oral feedings, beginning in the neonatal period

Tumor

Chronic febrile conditions (eg, rheumatoid arthritis, rheumatic fever)

Psychological factors

Emotional deprivation

- Common cause of failure to thrive
- Thorough social history is essential to the evaluation.
- Early observation of parent-infant interaction in the hospital, including feeding techniques, may be helpful.
- The infant may not be interested when feedings are introduced by mouth.
 - Mother and infant may require training.
 - Typically provided by occupational therapist, physical therapist, or speech pathologist
 - The infant may require gradual advancement of an oral diet.

- Anxiety, fear, depression, or mania (limbic influence on the hypothalamus) may affect feeding.
- If meals produce discomfort (abdominal pain, nausea, diarrhea, bloating, urgency, dumping syndrome), poor feeding may be a result of avoidance.
- Anorexia nervosa
- Excessive weight loss and food aversion in athletes, simulating anorexia nervosa

LABORATORY EVALUATION

- Evaluation is guided by clinical suspicion.
- In infants, ensure that newborn screening has been performed.
- Because the differential diagnosis is broad, the workup is nonspecific.
- Studies may include:
 - Blood chemistries
 - Complete blood count
 - Blood, cerebrospinal fluid, and urine for:
 - Viral studies
 - Bacterial studies
 - Stool studies for:
 - Reducing substances
 - Collections for fat quantification
 - Guaiac
 - Serum studies
 - Ammonia
 - Liver function tests (including albumin)
 - Vitamin and mineral levels
 - Serum and urine amino/organic acid testing
 - Therapeutic drug monitoring
 - Toxin screens
 - Chromosome count
 - Specific genetic testing

IMAGING

- Imaging is guided by clinical suspicion.

DIAGNOSTIC PROCEDURES

- Diagnostic procedures may be performed as guided by clinical suspicion.
 - Upper endoscopy with biopsy
 - Colonoscopy
 - Sweat chloride testing
 - Esophageal motility testing
 - pH probes

TREATMENT APPROACH

- Serial evaluations of weight and intake are the cornerstones of assessing appetite.
- Assess parental expectations to ensure that they are realistic, especially in the setting of a normal growth pattern.
- If growth is poor, a systematic evaluation in the case of failure to thrive can be extensive.
- Includes:
 - Assessment of bone age (imaging or teeth)
 - Parental growth patterns
 - Mid-parental height
 - Nutrition
 - Environmental influences

SPECIFIC TREATMENT

- Treatment that improves symptoms may result in rapid improvement in appetite.
- In infants, lactation consultation as indicated and available
- Enlist the help of a nutritionist to plan diets and supplementation.
 - Foods more acceptable to the child
 - High-calorie milkshakes or snacks
 - Commercial high-calorie supplements
- Medications can be used to stimulate appetite.
- Occasionally, children will require feeding supplementation.
 - Consider placement of nasogastric, gastric, and jejeunal feeding tubes.

Appetite stimulants

- Cyproheptadine
 - Does not seem to affect appetite in all children treated
 - When successful, response is dramatic.
- Megestrol acetate
 - Progesterone derivative
 - Has been administered for cancer-related anorexia, primarily in adults
 - Potential side effects include adrenal insufficiency.
 - Weight gained may be largely from increased fat mass.

Feeding supplementation

- Initial nasogastric or nasoduodenal nutrient infusion
 - May be necessary to promote growth in some disorders (ie, congenital heart disease)
 - Place gastrostomy tube if prolonged supplementation is required.
- Parenteral nutrition
 - May be indicated in specific situations
 - Expertise with this modality and close supervision are required.

- Caretakers need special training if parenteral nutrition is to be provided at home.
- Refeeding after severe malnutrition requires careful consideration of potential cardiac and metabolic complications and may require inpatient monitoring.

WHEN TO REFER

- Loss of appetite without an obvious explanation, especially in association with weight loss or failure to thrive
- Anorexia nervosa

WHEN TO ADMIT

- Weight loss or lack of weight gain unresponsive to outpatient management

- To initiate enteral or parenteral feeding because of inadequate oral intake
- Significant metabolic derangements caused by prolonged malnutrition

FOLLOW-UP

- Patients with failure to thrive need close monitoring of their calorie intake and weight gain.

Lyme Disease

DEFINITION

- Lyme disease is a tickborne infectious disease.

EPIDEMIOLOGY

- Lyme disease was first recognized in 1975 after an investigation of a cluster of arthritis cases among children in Lyme, Connecticut.
- Prevalence
 - The most common tickborne infectious disease in the US
 - 23,305 cases were reported to the Centers for Disease Control and Prevention in 2005.
- Geographic distribution
 - Lyme disease has been reported in almost every state.
 - 95% of all cases are concentrated in 11 states from 3 geographic regions.
 - The Northeast from Maine to Maryland
 - The Midwest in Wisconsin and Minnesota
 - The West in Northern California and Oregon
 - The occurrence of disease corresponds with the distribution of the tick vectors *Ixodes scapularis* in the East and Midwest and *Ixodes pacificus* in the West.

ETIOLOGY

- In 1975 the black-legged deer tick *I scapularis* was implicated as the vector of this disease.
- In 1982 a spirochete, *Borrelia burgdorferi*, was detected in the midgut of the tick and identified as the etiologic agent.
- *B burgdorferi* live in mice, squirrels, and other small animals and are transmitted among these animals and to humans by the bite of the tick.
 - The tick lives for 2 years and has 3 stages: larvae, nymph, and adult.
 - A blood meal is required at each stage of development.
 - When the tick feeds on an infected animal, the spirochete is acquired; when the tick feeds again, the spirochete can be transmitted to a new host.
 - Although deer are important for maintaining the tick population, deer do not become infected by the spirochete.
- No causal relationship between maternal Lyme disease and congenital disease has been documented.
- No evidence exists to support transmission of *B burgdorferi* via human milk.

RISK FACTORS

- Most cases of human Lyme disease are acquired in June, July, or August, when the nymphal stage is most active and human outdoor activity is greatest.

SIGNS AND SYMPTOMS

- The clinical manifestations of Lyme disease vary with the time that elapses after inoculation by the tick.

- The infection has thus been divided into:
 - Early localized phase
 - Early disseminated phase
 - Late-stage disease

Early localized phase

- Erythema migrans (EM) is the most common manifestation of early Lyme disease.
- Approximately 70–80% of patients exhibit or have a history of a skin lesion at the site of the tick bite.
- Macule gradually expands over several days to a large erythematous lesion that may increase in size to ≥ 5 cm, sometimes with central clearing.
- Early lesions may not have central clearing or the characteristic target-like appearance.
- Rash may be warm but is not painful.
- Influenza-like symptoms may accompany the skin lesion, including:
 - Malaise
 - Fatigue
 - Headache
 - Arthralgia
 - Myalgia
 - Fever
 - Regional lymphadenopathy
- Cough, rhinorrhea, vomiting, or diarrhea are not typical.
- Rash typically appears within 7–14 days (range, 3–30 days) of the tick bite and, if untreated, resolves within 3–4 weeks.

Early disseminated phase

- In the absence of antimicrobial therapy, spread of the spirochete may occur, producing the disseminated phase of early Lyme disease.
- Within days or weeks, in an untreated person, early disseminated disease may produce:
 - Multiple secondary EM lesions
 - Bell palsy
 - Lymphocytic meningitis
 - Conjunctivitis
- Common systemic symptoms include:
 - Arthralgia
 - Myalgia
 - Headache
 - Fatigue
- Serum antibody to *B burgdorferi* is usually not present during this phase, as antibody is not detectable until 3–4 weeks have passed.
- The spirochete is cultured from the skin more easily during early infection than at any other time in the illness.

- Approximately 60% of untreated patients will develop monoarticular or oligoarticular arthritis, which generally involves the knees.
- Approximately 5–10% of untreated patients will develop neurologic manifestations.
 - Nervous system involvement may include:
 - Cranial neuropathy (especially unilateral or bilateral facial palsy)
 - Radiculopathy
 - Central nervous system involvement may include lymphocytic meningitis.
 - Encephalopathy associated with late-stage Lyme disease consisting of mild abnormalities of memory and cognitive function is poorly understood and is a rare occurrence.
- <5% of untreated patients will develop cardiac disease.
 - Cardiac involvement is characterized most commonly by varying degrees of atrioventricular block but may include myocarditis.
 - Hospitalization is appropriate for patients with syncope, dyspnea, or chest pain.
 - Complete heart block is usually brief, and only temporary cardiac pacing is needed.
- In untreated persons, symptoms involving the joints, central nervous system, or heart reflecting spread of the spirochete to other parts of the body may occur months after the tick bite.

Late-stage disease

- Late-stage disease most commonly produces recurrent pauciarticular arthritis that involves the knees.
- Peripheral or central nervous system involvement is rare.
- Late-stage disease is uncommon in children who receive antimicrobial therapy early in the disease.

DIFFERENTIAL DIAGNOSIS

- The same tick that transmits *B burgdorferi* also can transmit *Anaplasma phagocytophilum* (the agent of ehrlichiosis) and *Babesia microti* (the agent of babesiosis), either as a mixed infection or as a single infection.
 - Ehrlichiosis or anaplasmosis should be suspected in the appropriate epidemiologic setting in a patient with:
 - Fever
 - Chills
 - Headache
 - Thrombocytopenia
 - Leukopenia
 - Increased liver enzyme levels
 - Babesiosis in symptomatic patients may produce:
 - Fever
 - Malaise
 - Chills
 - Sweating episodes

- Additional differential diagnosis
 - Pauciarticular juvenile arthritis
 - Septic arthritis
 - Acute rheumatic fever
 - Fibromyalgia syndrome
- Other considerations
 - Aseptic meningitis caused by enterovirus infection
 - Bell palsy
 - A peripheral neuropathy not caused by *B burgdorferi*
 - Multiple sclerosis

DIAGNOSTIC APPROACH

- Some patients with Lyme disease may offer no history of a tick bite and EM.
- During summer months in an endemic area, Lyme disease should be considered in a patient who has lymphocytic meningitis or arthritis involving the knee.
- EM can be diagnosed in a person who lives in or has traveled to an endemic area and generally is a sufficient basis for a clinical diagnosis without laboratory confirmation.

LABORATORY FINDINGS

- Serologic testing in a person with typical EM is generally discouraged because of the lack of sensitivity at this early stage of disease.
 - As many as 60% of cases will have a false-negative test result at this stage.
 - However, not all patients with Lyme disease will develop EM, and many may not recall a tick bite.
- Serologic testing may be useful in the few patients in whom a diagnosis is uncertain, particularly when symptoms have been present for more than several weeks.
- A 2-tier approach to serologic testing for Lyme disease should be used with both acute- and convalescent-phase serum specimens.
 - Initial testing is conducted using an enzyme immunoassay.
 - If positive or equivocal results are obtained, then a standardized Western immunoblot for both Lyme-specific immunoglobulin M (IgM) and IgG should be performed, using the same serum specimen for tier 1 and tier 2 testing.
 - An IgM immunoblot is considered positive if 2 of 3 bands are present.
 - An IgG immunoblot is defined as positive if 5 of 10 bands are detected.
 - In endemic areas, a positive immunoblot result is not always due to an active *B burgdorferi* infection and may reflect previous infection.
 - 2-tier testing should be used because of the high sensitivity but low specificity of the commercial enzyme immunoassays used in the first step.

- Testing by immunoblot should not be performed without first performing an enzyme immunoassay.
- Laboratory testing should not be performed for people who do not have symptoms of Lyme disease.
- Testing of individual ticks is not useful for deciding whether antibiotic therapy should be initiated after a tick bite.
- Other laboratory tests that should not be used include:
 - Urine antigen assays
 - Immunofluorescence staining for cell wall-deficient forms of *B burgdorferi*
 - Lymphocyte transformation assays

CLASSIFICATION

- The infection can be classified as:
 - Early localized phase
 - Early disseminated phase
 - Late-stage disease

SPECIFIC TREATMENTS

Pharmacotherapy

- Patients with early localized or early disseminated disease who do not have neurologic or cardiac involvement should be treated for 14–21 days with doxycycline (for children ≥ 8 years of age)
 - Pregnant or lactating women should not be treated with doxycycline.
 - An advantage of doxycycline is efficacy against the agent of human granulocytic ehrlichiosis, which may be a coinfecting microbe.
- Amoxicillin should be used for children < 8 years of age and in pregnant women.
- Cefuroxime axetil is a third drug of choice for patients not able to take the above drugs.
- Clinical trials of patients with EM show resolution of symptoms in $> 90\%$ of patients treated with doxycycline, amoxicillin, or cefuroxime axetil.
- Macrolide antibiotics are less effective than other antimicrobial agents and should be reserved for patients who cannot take preferred agents.
- Intravenous ceftriaxone is not superior to oral agents, except in patients with neurologic or cardiac involvement.
- Oral antimicrobial agents are effective for treating multiple EM and uncomplicated Lyme arthritis.
- Oral agents can be used to treat most people with facial nerve palsy.
- Central nervous system involvement, such as meningitis, should be treated with parenteral antibiotic therapy.
- Although first-degree atrioventricular block usually responds to oral therapy, higher-grade blocks are usually treated with parenteral ceftriaxone or penicillin.

- Persistent or recurrent arthritis should be treated with either parenteral ceftriaxone or penicillin.
- Specific dosages and durations are given in table Treatment Regimens for Lyme Disease.

Vaccine

- In 1998 the US Food and Drug Administration (FDA) approved a vaccine against Lyme disease (LYMErix) for individuals 15–70 years of age.
- In 2002 the vaccine was withdrawn and is no longer available.

Prophylaxis after a tick bite

- Clinical practice guidelines for prevention of Lyme disease after a tick bite suggest that the following conditions be satisfied.
 - The biting tick is identified as *I scapularis*, with an estimated attachment time > 36 hours based on the size of the engorged tick.
 - Prophylaxis can be started within 72 hours of tick removal.
 - Local rates of tick infection by *B burgdorferi* exceed 20%.
 - The use of doxycycline is not contraindicated.
 - Doxycycline is the only antibiotic shown to be effective for postexposure prophylaxis.
 - No data are available to support amoxicillin use in this setting.

WHEN TO ADMIT

- Cardiac involvement
- Meningitis or encephalopathy

WHEN TO REFER

- Cardiac involvement (heart block, pericarditis, myocarditis)
 - Neurologic involvement (except isolated facial palsy in patient with definite Lyme disease)
 - Nonspecific clinical history but positive or equivocal laboratory testing
 - Persistent arthritis

COMPLICATIONS

- Chronic pauciarticular arthritis
- Heart block
- Meningitis
- Cranial neuropathy
- Radiculopathy

PREVENTION

- Ticks are most likely to be located in wooded and bushy areas with high grass.
- When walking in a tick-infested area, people should walk in the center of the path to avoid contact with grass and brush.

Recommended Treatment of Lyme Disease in Children^a

Disease Category		Drug(s) and Dose ^b
Early localized disease ^b	8 y of age or older	Doxycycline, 100 mg, orally, twice a day for 14–21 days ^c
	Younger than 8 y of age or unable to tolerate doxycycline	Amoxicillin, 50 mg/kg per day, orally, divided into 3 doses (maximum 1.5 g/day) for 14–21 days OR Cefuroxime, 30 mg/kg per day in 2 divided doses (maximum 1000 mg/day) or 1.0 g/day for 14–21 days
Early disseminated and late disease	Multiple erythema migrans	Same oral regimen as for early localized disease, but for 21 days
	Isolated facial palsy	Same oral regimen as for early localized disease, but for 21–28 days ^{d,e}
	Arthritis	Same oral regimen as for early localized disease, but for 28 days
	Persistent or recurrent arthritis ^f	Ceftriaxone sodium, 75–100 mg/kg, IV or IM, once a day (maximum 2 g/day) for 14–28 days OR Penicillin, 300 000 U/kg per day, IV, given in divided doses every 4 h (maximum 20 million U/day) for 14–28 days OR Same oral regimen as for early disease
	Carditis	Ceftriaxone or penicillin: see persistent or recurrent arthritis
	Meningitis or encephalitis	Ceftriaxone ^g or penicillin: see persistent or recurrent arthritis, but for 14–28 days

Abbreviations: IV, intravenously; IM, intramuscularly.

^aModified from: American Academy of Pediatrics. Lyme disease. In: Pickering LK, Baker CJ, Kimberlin DW, Long SS, eds. *Red Book: 2009 Report of the Committee on Infectious Diseases*. 28th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2009:434.

^bFor patients who are allergic to penicillin, cefuroxime and erythromycin are alternative drugs.

^cTetracyclines are contraindicated in pregnancy.

^dCorticosteroids should not be given.

^eTreatment has no effect on the resolution of facial nerve palsy; its purpose is to prevent late disease.

^fArthritis is not considered persistent or recurrent unless objective evidence of synovitis exists at least 2 months after treatment is initiated.

Some experts administer a second course of an oral agent before using an IV-administered antimicrobial agent.

^gCeftriaxone should be administered IV for treatment of meningitis or encephalitis.

- Insect repellent containing *N,N*-diethyl-metatoluamide (DEET) should be applied to skin and clothing.
 - DEET-containing compounds can be used for children >2 months, should not be applied to the face or hands, and should be removed from skin with soap and water once the risk of exposure is over.
- Permethrin kills ticks on contact and can be applied to clothing but should not be applied directly to skin because it is inactivated by skin lipids.
- Long pants and sleeves will help keep ticks off skin.
- Light-colored clothing makes the task of spotting ticks easier.
- Daily tick checks should be performed.
- If a tick is attached for <24 hours, the risk of acquiring Lyme disease is extremely small.
- Attached ticks should be removed as soon as possible using fine-tip forceps.
- Vaccine
 - In 1998 the FDA approved a vaccine against Lyme disease (LYMERix) for individuals 15–70 years of age
 - In 2002 the vaccine was withdrawn and is no longer available.

Lymphadenopathy

DEFINITION

- Lymphadenopathy is defined as any lymph node enlargement.
- All lymph nodes that are palpable are technically considered to be enlarged but may not be clinically significant.
- Enlargement of =1 lymph nodes is a common finding in childhood.
 - Nodes in the cervical chain, occipital, and inguinal areas drain regions that are commonly infected in childhood.
 - These nodes often are mildly enlarged (<1 cm in diameter) in children who are otherwise healthy.

EPIDEMIOLOGY

- Prevalence
 - For prevalence by age, see table Prevalence of Lymphadenopathy by Age.
- Age
 - Small occipital and postauricular nodes are common in infants but not in older children.
 - Cervical and inguinal nodes are common after age 2 years.

MECHANISM

- The lymphatic system includes:
 - Lymph nodes
 - Spleen
 - Thymus
 - Tonsils
 - Waldeyer ring
 - Appendix
 - Peyer patches in the intestine

- Potentially palpable lymph node groups and their drainage areas:
 - Occipital: posterior scalp, neck
 - Anterior auricular, parotid: lateral pinna, frontotemporal, eyelids
 - Posterior auricular: mastoid area and pinna
 - Superior (anterior) cervical: posterior scalp and neck, tongue, pharynx, larynx
 - Inferior (posterior) cervical: posterior scalp, neck, pectorals, and arm
 - Submental: apex of tongue and lower lip
 - Submaxillary: tongue, buccal cavity, lips, and cheek
 - Supraclavicular:
 - *Right*: inferior neck and mediastinum
 - *Left*: inferior neck, mediastinum, and upper abdomen
 - Mediastinal, hilar
 - *Anterior*: thymus, pericardium
 - *Posterior*: esophagus, pericardium, liver surface
 - *Hilar*: lungs
 - Axillary: greater part of arm and shoulder; superficial, anterior, and lateral thoracic and upper abdominal wall
 - Epitrochlear: hand, forearm, and elbow
 - Abdominal: abdominal organs to various mesenteric nodes and to retroperitoneal nodes
 - Inguinal, femoral: leg and genitalia
- Location of the lymphatics of the head and neck and lymph node drainage are shown in Figure 37 on page F16.

Prevalence of Lymphadenopathy by Age^a

Age	Number of Patients	Palpable Nodes									
		Occipital		Postauricular		Submandibular		Cervical		No Palpable Nodes	
		Number	(%)	Number	(%)	Number	(%)	Number	(%)	Number	(%)
0–6 mo	52	17	(32)	7	(13)	1	(2)	1	(2)	32	(62)
7–12 mo	31	8	(26)	4	(13)	1	(3)	8	(26)	16	(52)
13–23 mo	39	4	(10)	3	(7)	7	(18)	11	(28)	20	(52)
2 years	35	3	(8)	2	(6)	7	(20)	16	(45)	11	(32)
3 years	27	2	(7)	0	(0)	7	(26)	9	(33)	11	(41)
4 years	20	0	(0)	0	(0)	5	(25)	11	(55)	7	(35)

Total	223	34	(15)	17	(8)	32	(14)	68	(30)	102	(45)

^aFrom: Herzog LW. Prevalence of lymphadenopathy of the head and neck in infants and children. *Clin Pediatr (Phila)*. 1983;22:485–487.

HISTORY

- Inquire about:
 - Exposures
 - Medications
 - Weight loss
 - Fever
 - Night sweats
 - Bone pain
 - Localized infection
 - Dental abscess
 - Mastoiditis
 - Scalp infection
 - Insect bite
 - Cat scratch
 - Pharyngitis
 - Systemic diseases
 - Infectious mononucleosis
 - Juvenile idiopathic arthritis
 - HIV

PHYSICAL EXAM

- The physical examination should include all palpable nodes.
- Determine whether any lymph node or lymph node aggregate or chain is abnormal and requires further assessment.
- Abnormal lymph node: enlarged, tender, warm to touch, fluctuant, fixed to skin or underlying structures
 - Any abnormal node
 - Determine whether the node is benign, primarily inflammatory, or malignant.
 - Fluctuance and signs of inflammation surrounding a group of enlarged lymph nodes:
 - Strongly suggest an infectious cause, primarily bacterial
 - Are helpful in reaching a diagnosis, particularly if an infectious source is found distal to the node area
 - No inflammation, firm consistency, and nodes that are not mobile indicates possible cancer.
 - Lymphoma
 - Sarcoma
 - Neuroblastoma
 - Hard, fixed nodes
 - Seen more often in adults with metastatic carcinoma
 - Nodes that are more matted than hard indicative of:
 - Hodgkin disease
 - Lymphoma
 - Nodes associated with neuroblastoma, rhabdomyosarcoma, and other childhood cancers may mimic the findings in adults.

DIFFERENTIAL DIAGNOSIS

- See table Entities Associated With Lymphadenopathy for diseases associated with lymphadenopathy.
- Anatomic location of mediastinal masses and associated conditions
 - Anterior mediastinum
 - Lymphoma
 - Thymoma
 - Malignant germ cell tumor
 - Benign teratoma
 - Substernal goiter
 - Thymic hyperplasia
 - Thymic cyst
 - Mesenchymal tumors
 - Middle mediastinum
 - Lymphoma
 - Tuberculosis
 - Sarcoidosis
 - Histoplasmosis
 - Castleman disease
 - Bronchogenic cyst
 - Sarcoma
 - Posterior mediastinum
 - Neuroblastoma
 - Ganglioneuroma
 - Neurofibroma
 - Primitive neuroectodermal tumor
 - Sarcoma
 - Germ cell tumor
 - Schwannoma
 - Duplication cyst
- In hilar or mediastinal adenopathy
 - Assess promptly for neoplastic or granulomatous causes.

LABORATORY EVALUATION

- Complete blood count
 - Reactive lymphocytes
 - Infectious mononucleosis
 - Granulocytosis with a shift to the left
 - Systemic bacterial infection
 - Bicytopenia (eg, anemia, granulocytopenia, and/or thrombocytopenia)
 - Hematologic cancer, such as leukemia or lymphoma
 - Metastatic disease involving the bone marrow, such as neuroblastoma

Entities Associated With Lymphadenopathy

Infections	Generalized	Cervical	Other Regional	
Viral	Respiratory viruses (adenoviruses, picornaviruses, respiratory syncytial virus, parainfluenza, influenza, coronaviruses)		1-3+	
	Epstein-Barr virus	2-3+	3+	+
	Cytomegalovirus	2+	2+	
	Primary human herpesvirus type 6		+	2-3+ (postoccipital)
	Parvovirus B19	1-2+		2+
	Human immunodeficiency virus	2-3+	+	+
	Rubella	2+	3+	+
	Rubeola	1-2+	3+	
	Varicella-zoster	1-2+	+	+
	Herpes simplex virus		3+	1-2+ (genital infection)
	Human herpesvirus type 8	2-3+	2-3+	+
	Hepatitis A	+	2+	
Bacterial	<i>Staphylococcus aureus</i>		3+	2-3+
	Streptococcal pyogenes	+	3+	2-3+
	<i>Bartonella henselae</i> (cat-scratch disease)	+		2-3+
	<i>Bartonella bacilliformis</i> (Oroya fever, verruga peruana)	3+	3+	3+
	<i>Yersinia enterocolitica</i>	+		3+
	<i>Salmonella typhi</i>	2-3+		2+
	Tularemia	+	3+	2+
	Brucellosis	2-3+	+	+
	Anaerobic infections			
	Dental, gingival infections		2-3+	2-3+
	Postanginal sepsis		2-3+	
	Mycobacteria			
	<i>Mycobacterium tuberculosis</i>	+	2-3+	2-3+
	Atypical mycobacteria		2-3+	2-3+
	Spirochetal			
	Syphilis	2-3+	+	+
	Lyme disease			+
Leptospirosis	3+	+	+	
Rickettsia/chlamydia	Lymphogranuloma venereum			3+
	Ehrlichiosis	2-3+		
	<i>Rickettsia tsutsugamushi</i>	3+	2-3+	3+

continued

Entities Associated With Lymphadenopathy, *continued*

Infections		Generalized	Cervical	Other Regional
Protozoan	Toxoplasmosis	+	3+	+
	Malaria	+		
Parasitic (Toxocara canis, Toxocara cati, Baylisascaris pyocyonis, Trichinella spiralis, filiaris)	Myiasis	1-2+	+	1-2+
			+	1-2+
Fungal	Histoplasmosis	1-3+	+	1-2+
	Coccidiomycosis	1-3+	+	1-2+
	Tinea capitis			2-3+
Immunizations	Viral	+		+
	Typhoid	+		+
	Bacille Calmette-Guérin			1-3+
Neoplastic	Leukemia	1-2+		
	Lymphoma	1-3+	2-3+	2-3+
	Hodgkin's disease		2-3+	2-3+
	Metastatic, solid tumors (neuroblastoma, Wilms tumor, Ewing sarcoma, rhabdomyosarcoma)	1-2+		1-2+
Histiocytoses	Langerhans cell histiocytosis		1-3+	
	Malignant histiocytosis		1-2+	1-2+
	Sinus histiocytosis (Rosai-Dorfman disease)		3+	
	Hemophagocytic syndromes	1-2+	2+	
Immunologic	Deficiency syndromes	1-2+	1-2+	2-3+
	Autoimmune lymphoproliferative syndrome	2-3+		
	Serum sickness	2+	+	+
	Ommen syndrome	1-2+	+	+
	Juvenile rheumatoid arthritis	1-2+	+	+
	Atopic disease, eczema	2-3+	2+	2-3+
	Castleman disease	1-3+	3+	2-3+
Medications (phenytoin and others)		1-2+		
Storage diseases (Gaucher, Niemann-Pick disease)		2-3+		1-3+
Granulocyte defects	Chronic granulomatous disease	+	1-2+	2-3+
	Leukocyte adhesion deficiencies		1-3+	1-3+
	Chédiak-Higashi anomaly		1-3+	1-3+
Other	Kawasaki disease		2-3+	
	Hemoglobinopathic conditions	+	1-2+	
	Hemophilia with HIV	2-3+	+	+
	Sarcoidosis	2-3+	+	1-2+
	Gianotti-Crosti syndrome	3+	+	+

Entities Associated With Lymphadenopathy, continued

Infections		Generalized	Cervical	Other Regional
Other, continued	Necrotizing lymphadenitis (Kikuchi lymphadenitis, Fujimoto necrotizing lymphadenitis)	+	2-3+	2-3+
	Insect bites		+	+
	Kimura		2-3+	1-2+
	Addison disease	1-2+		
	Hyperthyroidism	1-3+		

- Nucleated erythrocytes and immature granulocytes (leukoerythroblastic blood picture) on the blood film
 - Bone marrow irritation, with premature release of blood cell precursors
 - Metastatic diseases
 - Neuroblastoma
 - Rhabdomyosarcoma
 - Immunologic vasculitis
 - Granulomas (mycobacteria) in the marrow
- Isolated leukopenia and neutropenia
 - Viral infections
 - Severe bacterial infections (particularly in infants)
- Serologic assessment
- Antigen detection
- Polymerase chain reaction
- C-reactive protein
- Erythrocyte sedimentation rate
- Anaerobic and aerobic culture of material obtained from biopsy or aspiration
 - Including special stains, eg, Worthin-Stern-Silver stain for cat-scratch disease

IMAGING

- Chest radiograph
 - The sensitivity and specificity of methods to define chest (mediastinal or hilar) lymphadenopathy are variable.
 - In 1 study of patients thought to have tuberculosis, the chest radiograph was 67% sensitive and 59% specific compared with spiral chest computed tomography (CT) with contrast.
- A variety of imaging modalities may be used, including ultrasonography, CT, magnetic resonance imaging (MRI), nucleotide or positron emission tomographic scanning, and scintigraphy.
- Specific regions studied include:
 - Abdomen
 - Retroperitoneal, periportal, and celiac nodes
 - Nodes of the splenic hilum

- Spleen
 - Ultrasonography or CT
- Abdominal and pelvic lymph nodes
 - Ultrasonography, CT, MRI

DIAGNOSTIC PROCEDURES

- Intradermal skin tests
 - When mycobacterial infection is suspected
- Biopsy
 - Should be performed at a medical center that specializes in the care of children
 - For significant adenopathy
 - If no evidence of infection or other cause exists
 - If mediastinal or hilar nodes are enlarged
 - Biopsy sample should encompass the central mass of the enlarged nodes to avoid misdiagnosis of reactive inflammation in adjacent nodes.
 - For suspicion of tuberculosis
 - Needle aspiration should be avoided to prevent spread of the infection and creating a track; excisional biopsy is required.
 - Prompt biopsy is recommended in significantly enlarged, unexplained lymph nodes.
 - Even in the absence of mediastinal or hilar adenopathy
 - Allows institution of appropriate therapy
- Fine-needle aspiration biopsy
 - Reserved for surgically inaccessible nodes; not recommended for biopsy of superficial, accessible nodes
 - May be useful for intrathoracic nodes to avoid thoracotomy
 - Acute cervical adenitis
 - Acutely inflamed, sometimes fluctuant, node demonstrates the infecting organism in two-thirds or more of cases.
 - Negative findings are not definitive.
- The pathology of Hodgkin disease, lymphoma, and other similar round-cell tumors may be difficult to establish.
 - Requires the assessment of a pediatric pathologist who has experience in these diseases

■ Precise diagnosis may require:

- Immunophenotyping
- Cytogenetic analysis
- Molecular studies of gene rearrangement
- Electron microscopy

TREATMENT APPROACH

- If a bacterial source for localized adenopathy (eg, pharyngitis, cervical nodes) is suggested, a limited course of 7–10 days of antibiotic therapy may be tried.
- Further evaluation should be carried out promptly, if the nodes have not regressed significantly after the trial.
- Treatment of neoplastic causes is, in most instances, oriented toward cure.

SPECIFIC TREATMENT

Infectious disease

- Therapy for lymphadenitis depends on the cause or most likely cause.
- Infection with group A β -hemolytic streptococci or *Staphylococcus aureus*
 - In children beyond the neonatal period who have acute localized adenitis, particularly cervical adenitis
 - Antibiotics directed at group A streptococci and penicillinase-producing strains of *S aureus*
 - Community-acquired methicillin-resistant *S aureus*
 - Treatment should include an antibiotic to cover methicillin-resistant *S aureus*.
 - For most patients, oral therapy is adequate.
 - Typical length of treatment is 10–14 days.
 - Treatment should be continued for ≥ 5 days after signs of acute inflammation have subsided.
 - For patients who have suppurative adenitis from these organisms, drainage is not only diagnostic (by culturing the exudate) but also therapeutic.
 - Parenteral antibiotic therapy is required in patients who do not respond to oral therapy.
 - Even with a drug to which the organism is sensitive
- Anaerobic infection
 - Therapy depends on location of the adenitis and type of organism.
 - Most anaerobic infections of the cervical and submental areas are associated with mouth flora; most are sensitive to penicillin.
 - Alternative therapy
 - Clindamycin
 - Amoxicillin-clavulanate
 - Metronidazole
 - Some cephalosporins

■ *Mycobacterium tuberculosis* and atypical mycobacteria may be difficult to differentiate.

- Many strains of atypical mycobacteria are resistant to the usual antitubercular chemotherapy.
- If tubercular infection is suspected, excisional biopsy may be required.
- Appropriate therapy for *M tuberculosis* should be initiated while awaiting identification and sensitivities of the organism.
 - Adenitis that is thought to be tubercular should not be incised or drained.
- Cat-scratch disease (*Bartonella* species, especially *B henselae*) is usually self-limited.
 - Some antibiotics, alone or combined, may be of clinical benefit
 - Azithromycin
 - Erythromycin
 - Rifampin
 - Trimethoprim-sulfamethoxazole
 - Doxycycline
 - Parenteral aminoglycosides
 - For markedly enlarged, tender, and fluctuant nodes:
 - Aspiration may help relieve symptoms.
 - Incision and drainage should be avoided.
- For severe primary herpes simplex virus infection with localized adenitis (unusual)
 - Treatment with oral acyclovir to shorten the clinical course

Neoplastic disease

- Effectiveness of therapy is markedly improved for:
 - Lymphocytic and myelocytic leukemia
 - Lymphomas
 - Wilms and other tumors
- For specific treatment of childhood cancer, see Cancers in Childhood.

WHEN TO REFER

- History and physical examination do not suggest an infectious cause.
- Potentially infectious nodes have not responded to a course of antibiotics.
- Mediastinal or hilar adenopathy is present.
- When biopsy is considered
 - Biopsies should be performed only at a center specializing in the care of children.

WHEN TO ADMIT

- When biopsy requires hospitalization (mediastinal or hilar biopsy)
- When biopsy results require inpatient treatment or further evaluation
- When an infection requires intravenous therapy

Macrocephaly

DEFINITION

- Macrocephaly is defined as a head circumference >2 standard deviations above the mean (approximately the 97th percentile) based on age and sex.

MECHANISM

■ Head size

- Can be influenced by different components that make up the cranial cavity
- Most common causes are:
 - Hydrocephalus
 - Enlarged brain (megalencephaly)
 - Thickened skull
 - Space-occupying lesions
- Conditions are not mutually exclusive; children may have >1 underlying factor.

■ Hydrocephalus

- Causes include:
 - Intracranial hemorrhage
 - Meningocele
 - Dandy Walker malformation
 - Aqueductal stenosis
 - Malignancy
 - Space-occupying lesions
 - Benign accumulation of extracranial fluid
- Conventionally, classified as either communicating or noncommunicating.
 - Communicating hydrocephalus, results from:
 - Impaired absorption of cerebrospinal fluid by the arachnoid villi because of meningeal irritation caused by:
 - Meningitis
 - Trauma
 - Malignant infiltration
 - Overproduction of cerebrospinal fluid from a choroid plexus papilloma (less common)
 - Noncommunicating or obstructive hydrocephalus
 - Marked by enlargement of the ventricular system proximal to the site of an obstruction
 - Obstruction may be an anatomic defect (such as aqueductal stenosis) or the result of a tumor, infection, or infiltrate.
 - Congenital aqueductal stenosis may occur sporadically or be transmitted by X-linked inheritance.
 - Hydrocephalus with Chiari type II defect is present in 80% of children with myelomeningocele.

- In Dandy Walker malformation, a cystic dilatation of the fourth ventricle with hypoplasia of the cerebellar vermis and a variety of other cranial malformations, macrocephaly is the first clinical manifestation.

- In many cases, classification of hydrocephalus as either communicating or noncommunicating may not be clear-cut.

- Hemorrhage and intrauterine infections, for example, may lead to both communicating and noncommunicating hydrocephalus.

- Intraventricular hemorrhage occurs in approximately 15% of premature infants with birth weight <1500 g.

■ Megalencephaly

• Megalencephaly—metabolic

- In metabolic megalencephaly, enlargement of the brain is caused by an inborn error of metabolism that leads to the abnormal deposition of some substrate in the brain.

- Most such inborn errors are autosomal-recessive disorders.

- Produce significant developmental delays, psychomotor regression, and an enlarging head that may cross percentiles over time

- Examples of metabolic conditions causing macrocephaly:

- Mucopolysaccharidoses

- Hurler syndrome is the most severe form of mucopolysaccharidoses

- Results from a deficiency of α -L-iduronidase

- Canavan disease

- A leukodystrophy that predominantly affects Ashkenazi Jews

- Caused by a deficiency of aspartoacylase

- Alexander disease

- A rare, mostly sporadic condition

- Characterized by abundant accumulation of glial fibrillary acidic protein in Rosenthal fibers

- Glutaric aciduria

• Megalencephaly—anatomic

- Overgrowth syndromes

- Neurocutaneous syndromes

- Achondroplasia

- Autism

- Fragile X syndrome

• Megalencephaly—idiopathic (benign)

■ Skull thickening and skull abnormalities

- Thalassemia

- Cleidocranial dysostosis and other skeletal disorders

- Space-occupying lesions
 - Vascular malformations
 - Intracranial tumors
 - Subdural effusion
 - Subdural hematoma

HISTORY

- Review previously measured head circumferences.
 - Determine whether a child has had any change in pattern or percentiles of head circumferences over time.
- A large head circumference at birth:
 - Presupposes a cause of prenatal origin
 - Necessitates a detailed prenatal history
 - Conditions that may cause congenital macrocephaly
 - X-linked aqueductal stenosis
 - Overgrowth syndromes
- An abnormally enlarging head postnatally in a child with neurodevelopmental problems is a clue to an acquired condition, such as:
 - Acquired hydrocephalus
 - A possible metabolic disorder
- History should explore:
 - Delays in developmental milestones
 - Regression in motor, language, and social skills
 - Seizures
 - Signs of increased intracranial pressure
 - Lethargy
 - Vomiting
 - Behavioral changes
- A family history of any genetic, neurologic, and developmental condition may be a red flag for similar disorders.
- A history of otherwise normal parents and siblings with large heads can be reassuring.

PHYSICAL EXAM

- Physical examination of the child with macrocephaly should focus on:
 - Accurate measurement of the head circumference and assessment of the pattern of head growth
 - Inspection and palpation of the skull
 - Comparison of the head circumference with other growth parameters
 - Presence or absence of dysmorphic features
 - Presence or absence of congenital abnormalities involving other organ systems
 - Thorough neurologic and developmental assessment, including a check for signs of increased intracranial pressure

- Monitoring of head size must be performed periodically during health care maintenance visits.
 - In the presence of a rapid enlargement in head circumference, more frequent monitoring is necessary.
 - Measurements should be plotted on the appropriate head circumference charts.
 - A disproportionately enlarged head relative to height and weight may indicate a primary neurologic disorder.
 - Measuring the size of the fontanelles and palpating sutures are important.
 - Significant hydrocephalus in infants may produce a bulging anterior fontanelle and separation of cranial sutures, which are uncommon in anatomic megalencephaly.
 - A vein of Galen arteriovenous malformation may produce a cranial bruit on auscultation.
 - Because macrocephaly is a feature of many genetic syndromes, dysmorphic features and other organ involvement should be noted.
 - Examination of the skin may reveal:
 - Café-au-lait spots
 - Axillary freckling
 - Ash-leaf spots
 - A whorled pattern of pigmentation that may indicate a neurocutaneous disorder
 - Careful neurologic examination is critical and may reveal:
 - Abnormalities in muscle tone and posture
 - Asymmetries
 - Persistence of primitive reflexes
 - Hyperreflexia
 - Developmental assessment may reveal:
 - Cognitive impairment
 - Autistic features
 - Learning disabilities
 - Behavioral difficulties

DIFFERENTIAL DIAGNOSIS

Hydrocephalus

- Enlargement of the ventricular system
- May be congenital or acquired
- Clinical presentation is influenced by:
 - Age of onset
 - Underlying condition causing the hydrocephalus
- Infants
 - Enlarging head circumference is the most obvious finding because cranial sutures have not fused.

- In older children whose sutures have fused:
 - Significant head enlargement does not occur.
 - Other signs and symptoms of increased intracranial pressure may occur.
 - Headaches
 - Vomiting
 - Papilledema
 - Hydrocephalus with intraventricular hemorrhage
 - Intraventricular hemorrhage occurs in approximately 15% of premature infants with birth weight <1500 g.
 - Although subtle changes in head circumference may be present, macrocephaly is not always evident in infants with intraventricular hemorrhage.
 - Grade III and IV hemorrhages are associated with poorer neurodevelopmental outcomes than grade I and II hemorrhages.
 - An estimated 35% and 90% of affected children, respectively, show neurologic sequelae.
 - Hydrocephalus with Chiari type II defect
 - Present in 80% of children with myelomeningocele
 - Dandy Walker malformation
 - Cystic dilatation of the fourth ventricle with:
 - Macrocephaly—commonly the first manifestation
 - Hypoplasia of the cerebellar vermis
 - Various other cranial malformations
 - Head size may be normal at birth, but acceleration in head growth is noted in the majority of children by 1 year.
 - Sometimes shows prominence of the posterior part of the skull
 - Congenital aqueductal stenosis
 - May occur sporadically or be transmitted by X-linked inheritance
 - Severe hydrocephalus may:
 - Complicate labor and delivery with cephalopelvic disproportion
 - Lead to signs and symptoms of increased intracranial pressure after birth
 - Benign accumulation of extracranial fluid
 - May be seen in many children with macrocephaly who have an unremarkable neurologic examination
 - The exact nature of fluid collection is not clearly established and is variously called:
 - Benign macrocephaly
 - External hydrocephalus
 - Benign extracerebral fluid collections
 - Benign subdural collections
 - Benign enlargement of the subarachnoid space
 - Fluid collection is most evident in the prefrontal area.
 - In some cases, there is mild nonprogressive dilation of the ventricular system.
 - Brain size is normal.
 - Normal or large head circumferences at birth
 - In succeeding months, head circumference grows to >98th percentile and then generally parallels the normal growth curves.
 - Large head size is an isolated feature; the affected child has an otherwise normal neurologic examination and age-appropriate development.
 - Transient early developmental delays may be seen, especially in the first year of life.
 - Condition appears to be self-limited, with normalization of CT findings usually by 2.5 years of age.
 - Relationship to benign megalencephaly has not been established and is not fully understood.
- ### Megalencephaly
- Benign or idiopathic megalencephaly
 - Large head
 - No significant collection of extraventricular or intraventricular fluid
 - Normal neurologic examination and developmental history
 - No signs of increased intracranial pressure
 - Family history of large head sizes in normal adult megalencephaly
 - Although these individuals have been thought to develop normally, recent evidence suggests they may exhibit mild neurodevelopmental dysfunction, such as incoordination and visual-motor weaknesses.
 - Anatomic megalencephaly
 - Usually associated with neurodevelopmental impairment
 - The brain is abnormally large because of an increase in the size and number of its cells.
 - Overgrowth syndromes
 - Generalized increase in body size with macrocephaly; usually present at birth
 - Sotos syndrome
 - Facial dysmorphism
 - Neurodevelopmental deficits, such as poor coordination and behavioral problems
 - Macrocephaly may reflect a combination of:
 - Megalencephaly
 - Ventricular enlargement
 - Midline anomalies
 - Neurocutaneous syndromes, such as
 - Neurofibromatosis
 - Tuberous sclerosis

- Hypomelanosis of Ito
- Associated with megalencephaly in addition to characteristic skin findings, intracranial conditions, and neurodevelopmental problems.
- Achondroplasia
 - Megalencephaly
 - Short stature
 - Shortened proximal arms and legs (rhizomelia)
 - Dysmorphic facial features
 - Normal intelligence
 - Risk for:
 - Hydrocephalus
 - Obstructive sleep apnea
 - Central apnea
 - Spine and joint problems
- Hurler syndrome
 - Enlarging head that quickly crosses percentiles during infancy
 - Coarse facial features
 - Frontal bossing
 - Corneal clouding
- Infantile form of Canavan disease
 - Irritability
 - Poor visual fixation
 - Head lag
 - Motor delay
- Alexander disease
 - Macroencephaly
 - Spasticity
 - Seizures
 - Developmental regression
- Autism
 - Compared with the general population, a disproportionately large number of autistic children have enlarged head circumferences.
 - The pattern of brain growth in some autistic children appears to be abnormal, with:
 - Acceleration of head growth in early childhood
 - Hyperplasia in cerebral gray matter and cerebral and cerebellar white matter
 - Slight decrease in brain volume during adolescence
 - The relationship between acceleration in head growth and concomitant developmental (social and language) regression (in approximately a third of autistic patients) remains unclear.

- Fragile X syndrome
 - Macrocephaly
 - Longish face with prominent ears
 - Joint hyperextensibility
 - Enlarged testes
 - Family history on the mother's side of:
 - Intellectual disability
 - Developmental and behavioral problems
 - Autistic behaviors

Thickening of the skull

- Hemolytic anemia (such as β -thalassemia)
 - May exhibit frontal bossing attributable to extracranial hematopoieses of skull bones
- Cleidocranial dysostosis
 - Autosomal disorder of abnormal bone formation characterized by:
 - Delayed closure of fontanelles
 - Widening of the head circumference
 - Other skeletal abnormalities

Space-occupying lesions

- Arteriovenous malformation
- Brain tumors
- Subdural effusion as a complication of bacterial meningitis in infants may produce:
 - Enlarging head circumference
 - Bulging anterior fontanelle
 - Signs of increased intracranial pressure

LABORATORY EVALUATION

- Metabolic testing
 - Available to identify many of the storage diseases
 - Recommended in a child exhibiting developmental regression
- Genetic and chromosomal testing
 - For suspected cases of genetic disorders

IMAGING

- Neuroimaging
 - Procedure of choice in evaluating for macrocephaly
- Magnetic resonance imaging
 - Most informative
 - Good for identifying:
 - Gray and white matter disease (eg, leukodystrophy)
 - Migration defects
 - Hydrocephalus
 - Posterior fossa lesions

- Computed tomography
 - Can identify:
 - Hydrocephalus
 - Intracranial calcifications
 - Hemorrhages
- Head ultrasonography
 - For infants with open fontanelles, useful in identifying:
 - Intraventricular hemorrhage
 - Hydrocephalus
 - Intracranial tumors
- Skeletal survey
 - May reveal:
 - Bone age abnormalities in the overgrowth syndromes
 - Abnormalities that may be present in the mucopolysaccharidoses
 - Bone dysplasias

TREATMENT APPROACH

- Management of macrocephaly depends on its cause.

SPECIFIC TREATMENT

Shunting

- Treatment of choice for significant and progressive hydrocephalus
- Complications are not rare and continue to be challenging in the care of these children owing to:
 - Infection
 - Obstruction
 - Malfunction
- Risks are even greater in premature infants, asymptomatic, or mildly symptomatic patients.
- Dandy Walker cysts
 - Dual shunting has been recommended to drain both the hydrocephalus and the posterior fossa cyst.

Lumbar puncture

- Serial lumbar punctures may be used as initial therapy.

Medical management

- Carbonic anhydrase inhibitors
- Other diuretics

Other

- Children suspected to have inborn errors of metabolism:
 - Should be referred for genetic evaluation, treatment, and counseling
 - Treatment for these conditions is mainly supportive and symptomatic.
 - Bone marrow transplantation and enzyme replacement therapy are promising interventions for certain disorders.
- Anatomic megalencephaly
 - The association with developmental and cognitive problems warrants early intervention and special education services.
- Benign accumulation of extracranial fluid and idiopathic megalencephaly
 - Serial measurement of the head circumference
 - Ongoing clinical assessments

WHEN TO REFER

- Head circumference >2 standard deviations above the mean
- Head circumference that is crossing percentiles or growing rapidly
- Dysmorphic features
- Abnormal neurologic examination
- Regression in developmental skills or significant developmental delay

WHEN TO ADMIT

- Signs of increased intracranial pressure or mental status change
- Shunt infection or malfunction

Malocclusion

DEFINITION

- In normal occlusion, maxillary and mandibular molars appropriately interdigitate, allowing anterior teeth to sit in correct alignment with the maxillary incisors slightly overlapping those in the mandible and resulting in a closed bite.
- Class I malocclusion
 - Maxillary and mandibular molars normally interdigitate.
 - Crowding or misalignment exists in other oral positions.
- Class II malocclusion
 - Maxillary molars are anterior to mandibular molars, allowing anterior teeth to appear to jut out over the lower ridge.
- Class III malocclusion
 - Mandibular molars are anterior to maxillary molars, giving the appearance of a protruding jaw.
- Abnormal dental occlusion may predispose individuals to health risks.
 - Dental caries
 - Periodontal disease
 - Increased susceptibility to trauma or root resorption
 - Disturbances of physiologic functioning linked to malocclusion
 - Muscular dysfunction
 - Speech defects
 - Masticatory disturbances

EPIDEMIOLOGY

- The incidence of malocclusion in school-age children and adolescents may be $\geq 90\%$.
 - The National Health and Nutrition Survey (NHANES I; 1963–1965) examined 7400 children 6–11 years of age.
 - 14.2% had severe or very severe malocclusion.
 - NHANES III survey (1988–1991)
 - 15% of adults had malocclusion severe enough to affect social acceptability and function.
- Slightly $< 60\%$ of individuals across all racial groups might benefit from orthodontic treatment.
 - Prevalence of therapy by race or ethnicity
 - 30% of white youth
 - 11% of Mexican Americans
 - 8% of black persons
 - Higher-income youths are more likely to receive orthodontic care.

MECHANISM

- Involves both genetic and environmental factors
- The cause of malocclusion is clearly identifiable in only approximately 5% of cases.

- Nasal obstruction has been linked to the development of a high-arched palate and posterior crossbite, especially when caused by enlarged tonsils or adenoids.
- Pacifiers, thumb sucking, and finger sucking play a role.
 - Children develop nonnutritive sucking habits during infancy.
 - By 4 or 5 years of age, most have stopped the practice, but as many as 5.9% continue into school age.
 - If sucking continues into the periods of mixed and permanent dentition, the potential for developing malocclusion is increased.
 - Anterior open bite, excessive overjet, posterior crossbite, and other malocclusions have been reported in association with sucking habits.
 - Children who have such habits may show no abnormalities.
 - Thumb sucking may be preferable to finger sucking because fewer physical stresses are exerted on the teeth.
 - Results of several studies of nonnutritive sucking from many countries are mixed regarding whether digit sucking is more or less deleterious than use of a pacifier.
 - Nearly all studies showed increased incidence of malocclusion among children who have prolonged sucking habits compared with those who do not.
 - Abnormal bite may revert to normal after the habit is stopped.
 - Functional exercisers, such as the Nuk nipple or pacifier, have no apparent advantage.

PHYSICAL EXAM

- Orthodontic treatment may be hindered by the fact that evaluation lacks a universally acceptable and quantitative classification system.
- Initial assessment
 - Observe both the maxillary and the mandibular arches with the child's mouth open.
 - Determine whether the teeth are crowded or have excess space between them.
 - Crowding increases over time.
 - Excess space may improve or worsen.
 - Excess space, especially between upper lateral incisors and canines, and between lower canines and first deciduous molars, is the norm in young children with primary dentition and allows room for eruption of permanent teeth.
- Posterior teeth are assessed with teeth set in the biting position.
 - The tongue should not be visible between the upper and lower teeth.
 - The presence of such a space or the contrasting problem of a deep bite (lower incisors biting on palatal gingiva) nearly always requires treatment.

- Maxillary teeth should overlap their mandibular partners slightly in the lateral plane and should be placed slightly anteriorly (~ one-half a tooth width).
- Posterior crossbites where posterior maxillary teeth are either medial or lateral to corresponding mandibular teeth rarely self-correct.
- Problems with anterior dentition
 - Readily apparent when the patient smiles
- Occasionally, ≥ 1 permanent teeth may erupt before the corresponding primary teeth have been shed.
 - Often the incisors
 - Gives a double row of teeth
 - Causes much parental concern
 - Normal tongue movements usually ensure correct final placement of the permanent teeth.

TREATMENT APPROACH

- Few data link maloccluded primary dentition with maloccluded permanent teeth.
 - Anterior crossbite may interfere with ultimate maxillary growth and tooth position.
 - Upper lateral incisors erupt behind the lower ones *or*
 - Upper posterior teeth erupt medial to the lower ones.
 - Absence of normal spacing in primary dentition almost always leads to severe crowding of the permanent teeth.
 - Children who have such conditions should be referred to an orthodontist early.
- Considerable controversy exists over whether treatment of other abnormalities, such as overbite or class III malocclusions, should:
 - Begin early during the period of mixed dentition
 - Be delayed until adolescence
- In general, 2 stages of treatment are required, so an early start may increase the total time the child wears braces without necessarily resulting in a superior outcome.
- Data supporting treatment outcomes are scanty and/or conflicting.
- Posterior crossbite should be treated during primary or early mixed stages of dentition.
 - Timely treatment establishes optimal function to normalize dental, skeletal, and neuromuscular growth.

- Anterior dentition problems
 - Open bite, with space visible between upper and lower arches, and underbite are difficult to treat.
 - Overbite (buck teeth) or anterior crossbite can be corrected easily.
- Eruption of permanent teeth before primary teeth have been shed
 - Extraction is rarely necessary.
 - Primary teeth are almost always shed by age 8 years.
- Temporomandibular joint (TMJ) dysfunction
 - Increasingly cited as a possible cause of headache and other symptoms in school-age children and adolescents
 - Some studies show a high incidence of signs referable to the TMJ, but usually without symptoms of TMJ dysfunction.
 - Joint sounds with movement or condyle position do not correlate well with symptomatic TMJ dysfunction that requires treatment.
 - There is no convincing evidence that malocclusion or orthodontic therapy is related to development of TMJ symptoms.
- Most patients seek orthodontic treatment because of malocclusion's effect on their appearance.

WHEN TO REFER

- The decision to refer is difficult because objective referral guidelines are few.
 - Treatment nearly always results in improved appearance.
 - Posterior crossbites rarely self-correct, and treatment during the stage of primary or mixed dentition may be optimal to promote normal development of the teeth, bones, and muscular structures.
 - Absence of normal dental spacing in the primary dentition requires early referral, especially if any primary tooth is lost or fails to erupt.
- Assess the patient's and family's expectations, as well as willingness to comply with the discomfort and cost of treatment, before arranging for referral.

Meningitis

DEFINITION

- Meningitis, or inflammation of the meninges, is most often caused by an infectious agent and less commonly by a chemical (medication) or cancer.
- Bacterial meningitis, also known as *pyogenic meningitis*, is often quickly fatal, making early diagnosis and treatment essential.
- *Aseptic meningitis* refers to inflammation of the meninges without the presence of visible microorganisms on routine Gram staining.
 - Not synonymous with *viral meningitis*, although the 2 terms are often used interchangeably
- Neonatal meningitis is considered separately because:
 - Agents that cause it are unique.
 - It is more often fatal than meningitis in the older child.

EPIDEMIOLOGY

- Incidence
 - Neonatal meningitis occurs in 0.2–1 per 1000 live births.
 - Between 1987 and 1997, the incidence of *Haemophilus influenzae* type b (Hib) meningitis decreased from 40 cases per 100,000 children <5 years of age to 1 case per 100,000.
 - Current annual estimates are as low as 0.1 cases per 100,000.
 - Aseptic meningitis (predominantly caused by enteroviruses) ranges from 1.5–4 cases per 100,000 population.
- Age
 - In the US
 - As many as 300–400 cases per 100,000 live births
 - 141 per 100,000 during the second month of life
 - <50 per 100,000 in the second year of life
 - Until recent years, a second peak occurred at 6–8 months, nearly 180 per 100,000 infants.
 - Due to Hib
 - Has declined dramatically since Hib conjugate vaccines were approved for use
 - The decline in Hib meningitis has converted bacterial meningitis to a disease of adults.
 - Median age at diagnosis of 25 years in 1995 compared with 15 months in 1985
 - Few reported cases of aseptic meningitis occur in persons >30 years of age.

ETIOLOGY

- Aseptic meningitis
 - Nonpolio enteroviruses cause 85% of cases in the US.
 - Fungi, parasites, reactions to medications, and atypical bacteria not well seen on Gram staining represent other causes.

Post-neonatal meningitis (after age 1 month)

- Bacterial meningitis
 - Most cases are caused by:
 - *Neisseria meningitidis*
 - *Streptococcus pneumoniae*
 - Hib
 - In regions where pneumococcal and Hib conjugate vaccines are widely used, *S pneumoniae* and Hib are the cause increasingly less often.
 - All 3 pathogens can be isolated from the throat or nasopharynx of healthy individuals.
 - Most studies of microorganism carrier states suggest that children at highest risk for disease are also the most likely to be colonized; however, does not always cause meningitis.
 - The successful meningeal pathogen must follow several sequential steps.
 - Nasopharyngeal mucosal colonization is facilitated by various microbial-binding adhesins and secreted enzymes.
 - Invasion across the epithelium, followed by survival of bacteria in the bloodstream, evading the action of alternative complement pathway
 - Finally, bacteria must invade the cerebrospinal fluid (CSF) by crossing the blood-brain barrier.
 - Meningitis may occasionally occur after head trauma.
 - Particularly fractures of the paranasal sinuses or middle ear
 - The pathogens most often associated are *S pneumoniae* and *H influenzae*.
 - Posttraumatic meningitis can recur if CSF leakage persists.
 - Meningitis can occur by direct spread from a congenital dermal sinus that communicates with the central nervous system (CNS).
 - Meningitis can develop after neurosurgery and is not uncommon after procedures performed to shunt ventricular fluid.
 - Coagulase-negative staphylococci are most often associated with shunt infections.
 - Cochlear implantation is a risk factor.

Neonatal meningitis

- Causes have changed since 1970, and clinicians should be alert to the possibility of future shifts.
 - Group B β -hemolytic streptococci (*Streptococcus agalactiae*) and *Escherichia coli* account for 50–66% of cases of neonatal meningitis.
 - *Listeria monocytogenes* for approximately 1–5%.

- Neonatal sepsis and meningitis caused by non-group D α -hemolytic streptococci and coagulase-negative staphylococci have been reported.
- Antimicrobial prophylaxis of pregnant women is now performed in the US who are found to be carrying group B β -hemolytic streptococci at term or those with fever, premature labor, prolonged rupture of membranes.

SIGNS AND SYMPTOMS

Bacterial meningitis

- Fever is usually present in bacterial meningitis.
- Absence of fever in a child with signs of meningeal irritation does not preclude the diagnosis.
- Inflammation of the meninges can be characterized by:
 - Irritability
 - Anorexia
 - Headache
 - Nausea
 - Vomiting
 - Confusion
 - Back pain
 - Nuchal rigidity
 - Photophobia
- The Kernig and Brudzinski signs can be assessed during physical examination to demonstrate meningeal inflammation.
 - Kernig sign
 - Extend the leg at the knee of the supine patient while the hip is flexed at 90 degrees.
 - When positive, the maneuver causes extensor spasm of knee and pain in hamstrings when the lower leg is extended to approximately 135 degrees.
 - Brudzinski sign
 - Flex the neck of the patient in the supine position.
 - When positive, the patient will involuntarily flex hips and knee.
 - Stiffness of neck is a sensitive (80–98%) indicator of true bacterial meningitis in children, adolescents, and adults.
- In a young infant, signs of meningeal inflammation can be minimal or absent.
 - In patients <12 months of age, absence of nuchal rigidity must not be used to exclude meningitis.
 - Distinguishing nuchal rigidity from voluntary movement and guarding can be difficult in a sick infant with irritability.
 - In this case, additional signs may be helpful: lethargy, poor feeding, restlessness.
- Lay the infant near the edge of the examining table, with the head supported by the examiner's hand but gently extended off edge of table.
 - The natural tendency for an infant in this position will be to try to lift the head.
 - The examiner can feel whether nuchal rigidity is preventing flexion of the neck rather than voluntary guarding or noncooperation.
- Signs of increased intracranial pressure may be seen.
 - Headache
 - Bulging fontanelle
- Papilledema is uncommon.
 - When present, other causes should be sought.
 - Bacterial meningitis progresses so quickly that the time needed for papilledema to develop may not be sufficient.
- Cranial nerve involvement occurs with bacterial meningitis; although often transient, it can be permanent.
- The auditory nerve is often affected.
 - Deafness
 - Disturbances of vestibular function
- Blindness is rare but has been reported.
- Children may have paralysis of extraocular or facial nerves.
- The degree of CNS derangement observed with bacterial meningitis ranges from irritability to coma.
 - Approximately 15% of children with bacterial meningitis are comatose or semicomatose at the time of hospitalization.
 - Occurs more often with *S pneumoniae* or *N meningitidis* than with Hib
 - Seizures occur before or within 1–2 days after admission in approximately 30% of patients.
 - Focal neurologic signs correlate with persistent abnormal neurologic and developmental examinations 1 year after discharge in approximately 16% of patients.
- Subdural effusions occur in approximately 50% of children with bacterial meningitis.
 - Seldom clinically significant
 - Effusions need not be sought through subdural taps or computed tomography (CT) unless focal neurologic signs or signs of increased intracranial pressure develop.
 - Infection of subdural effusions is extremely rare.
- Arthralgia and myalgia often occur, particularly in those with meningococemia.
- Vasculitis can be seen in children with any type of bacterial meningitis.
 - Petechiae and purpura are more commonly associated with meningococcal disease.
 - Children who have such rashes should be considered in imminent danger of developing septic shock.

- Clinical signs associated with neonatal meningitis are nonspecific.
 - Neonates with meningitis often have apneic episodes or feed poorly, and they can exhibit:
 - Hyperthermia or hypothermia
 - Irritability or lethargy
 - Respiratory distress or diarrhea (or both)
 - Nuchal rigidity (rarely)
 - Bulging fontanelle
- The neonate has a limited repertoire of clinical responses to disease or insult.
 - Most sick neonates therefore receive a diagnostic evaluation for sepsis, including lumbar puncture, and antimicrobial agents are initiated pending culture results.
- Cytology and chemistry of the CSF in neonates have a much broader normal range than children in other age groups, especially during first week of life.
 - Any single test result may not appear abnormal.
 - Infants who have bacterial meningitis rarely have completely normal CSF at examination.
 - During the first 24 hours of life, isolated meningitis without sepsis occurs rarely enough that lumbar puncture has sometimes been omitted for infants appearing septic on day of birth.
 - May lead to missed cases of both early-onset and late-onset meningitis
 - As many as 25% of neonates with meningitis have been found to have sterile blood cultures despite positive CSF cultures.
 - The proportion of such cases might increase as antibiotic prophylaxis is given to mothers and babies in the peripartum period.
 - In general, if possible, any infant thought to have sepsis or meningitis should undergo lumbar puncture.

Aseptic meningitis

- Infants and children who have aseptic meningitis caused by enteroviruses may exhibit the following.
 - Acute fever
 - Temperature is usually 38.0°C–40.5°C (100.4°F–105°F) for 4–5 days.
 - Irritability
 - Lethargy
 - Upper respiratory tract symptoms
 - Headache
 - Photophobia
 - Nausea
 - Vomiting
 - Rashes

- In general, a child with viral meningitis does not appear as critically ill as a child with bacterial meningitis.
 - Less likely to have meningeal signs
- Aseptic meningitis is likely when CSF pleocytosis ranges from 10–500 cells/mcL that are predominantly lymphocytes.
 - CSF protein level is mildly high, at 50–150 mg/dL.
 - CSF glucose concentration is normal.

Viral meningitis

- Early in the course of viral meningitis, polymorphonuclear neutrophils can predominate in the CSF.
 - Transition from a predominance of polymorphonuclear neutrophils to lymphocytes usually occurs rapidly.
 - Repeat lumbar puncture after 8–12 hours may show transition.
- Tuberculous and fungal meningitis generally have gradual onsets of illness over days to weeks.
- Hypoglycorrhachia (low CSF glucose level) rarely occurs with viral meningitis caused by:
 - Enteroviruses, mumps
 - Herpes simplex
 - Eastern equine encephalitis viruses
 - Hypoglycorrhachia caused by these viruses tends to result in CSF glucose concentrations that equal approximately 30% of simultaneous blood glucose concentration.
 - Bacterial meningitis usually results in CSF glucose concentrations of <30% of blood glucose.
 - CSF glucose concentration can also be low with tuberculous and fungal meningitis.
- Many physicians are reluctant to obtain specimens for viral culture because they believe that isolating viruses takes too long to affect management.
 - Diagnosis of enteroviral meningitis frequently results in discontinuation of antimicrobial therapy and early discharge from the hospital.
 - Therefore, when viral meningitis is a possibility, CSF should be cultured for viruses, as should nasopharyngeal or throat and rectal swab specimens.
 - Isolation of a virus from a site other than CSF can be misleading.
 - Taken in the context of other clinical and laboratory findings, a presumptive diagnosis often can be made when virus is isolated from ≥ 1 sites.
- Polymerase chain reaction (PCR) holds much promise as a rapid and sensitive method of diagnosing meningitis caused by:
 - Enteroviruses
 - Herpesviruses
 - Possibly other viruses

- PCR amplification of enteroviral RNA from CSF and serum appears to have good sensitivity, specificity, and predictive value.
 - Where PCR for enterovirus is available, it may substitute for viral culture in many cases.

DIFFERENTIAL DIAGNOSIS

- Signs and symptoms suggesting meningeal inflammation or increased intracranial pressure can be seen with other CNS infections.

- The most common cause of meningeal inflammation is enteroviral aseptic meningitis.

- Aseptic meningitis can also be caused by:

- Lyme disease spirochetes (*Borrelia burgdorferi*)
- *Mycobacterium tuberculosis*
- Fungi
- Parasites
- Inflammatory conditions

- Meningitis or meningoencephalitis may also be present in patients with:

- Rocky Mountain spotted fever
- Kawasaki disease
- Cat-scratch disease
- Toxic shock syndrome

- Meningitis often is associated with or occurs after:

- Mumps
- Rubeola
- Rubella
- Varicella
- Infectious mononucleosis
- Roseola
- Erythema infectiosum

- The following conditions can mimic bacterial meningitis.

- Brain abscess
- Epidural abscess
- Primary amebic meningoencephalitis
- Embolic diseases (eg, endocarditis, thrombophlebitis)
- Venous sinus thrombosis
- Space-occupying lesions
- Reactions to medications
 - Intravenous immunoglobulin
 - Intravenous monoclonal antilymphocyte antibody
 - Oral trimethoprim-sulfamethoxazole
 - Some oral nonsteroidal antiinflammatory drugs
- Ingestion of toxins (eg, lead)
- Spider bites

- Pemphigus
- Behçet syndrome

- Eosinophilic meningitis is rarely seen; the differential diagnosis includes reactions to:

- Ventriculoperitoneal shunts
- Unusual presentations of bacterial or *Toxoplasma* infection
- Parasitic roundworms

- Conditions that can simulate a clinical picture of meningitis but that usually have normal CSF findings include:

- Pharyngitis
- Retropharyngeal abscess
- Cervical adenitis
- Cervical spine arthritis or osteomyelitis
- Pyelonephritis
- Pneumonia
- Torticollis
- Tetanus
- Oculogyric crisis

- Selected causes of aseptic meningitis

- Viruses
 - Common
 - Enteroviruses
 - Arboviruses
 - Herpes simplex type 2
 - Human herpesvirus 6
 - Uncommon
 - HIV-1
 - Epstein-Barr virus
 - Lymphocytic choriomeningitis virus
 - Mumps
 - Rare
 - Adenovirus
 - Varicella-zoster virus
 - Cytomegalovirus
 - Measles
 - Rubella
 - Parvovirus B19
 - Influenza A and B
- Bacteria
 - Common
 - Pyogenic (partially treated)
 - *M tuberculosis*
 - *B burgdorferi*
 - *Mycoplasma pneumoniae*
 - *Leptospira* species

- Uncommon
 - *Treponema pallidum*
 - *Borrelia* species
 - *Bartonella henselae*
 - *Rickettsia rickettsii*
 - *Ehrlichia canis*
- Rare
 - *Chylidophila psittaci*
 - *Chlamydophila pneumoniae*
 - *Rickettsia prowazekii*
 - *Coxiella burnetii*
 - *Brucella abortus*
 - *Streptobacillus moniliformis*
- Fungi
 - Common
 - *Candida* species
 - *Cryptococcus neoformans*
 - *Histoplasma capsulatum*
 - *Coccidioides immitis*
 - Uncommon
 - *Blastomyces dermatitidis*
 - Rare
 - Various molds
- Parasites
 - Uncommon
 - *Toxoplasma gondii*
 - Neurocysticercosis
 - Rare
 - *Angiostrongylus cantonensis*
 - *Baylisascaris procyonis*
 - *Strongyloides stercoralis*
 - Free-living amoebae
- Miscellaneous
 - Common
 - Parameningeal infections
 - Kawasaki disease
 - Foreign bodies (CSF shunts)
 - CNS leukemia, tumors
 - Acute disseminated encephalomyelitis
 - Uncommon
 - Medications (trimethoprim-sulfamethoxazole, intravenous immunoglobulin, ibuprofen)
 - Systemic lupus erythematosus
- Rare
 - Sarcoidosis
 - Behçet syndrome
 - Heavy metal poisoning
- “Common,” “uncommon,” and “rare” refer to relative frequencies within each broad category of etiologic agents (eg, viruses, bacteria).
- Overall, enteroviruses cause $\geq 85\%$ of aseptic meningitis cases diagnosed in children in the US.
- Arboviruses cause approximately 5%; all other causes combined account for the remaining $\leq 10\%$ of cases.
- Syndrome of aseptic meningitis consists of a clinical picture of meningitis with CSF pleocytosis and absence of bacteria on Gram stain or culture.
 - Aseptic meningitis is usually caused by a virus; treatable causes should be considered in the differential diagnosis.
 - Nonpolio enteroviruses cause 85% of cases of aseptic meningitis in the US.
 - Mumps and polio should be considered in other areas of the world where they are still endemic.
 - Longer duration of symptoms has been associated with Lyme disease meningitis, especially if accompanied by erythema migrans or cranial neuropathies.
- West Nile virus infection may cause:
 - Aseptic meningitis
 - Meningoencephalitis
 - Acute flaccid paralysis

DIAGNOSTIC APPROACH

- The clinical situation should influence the amount of data required before a therapeutic decision is made.
- Interpretation of CSF findings in context of clinical manifestations usually differentiates bacterial meningitis from other diseases.
 - If CSF from an ill, febrile child is turbid or purulent, then antimicrobial therapy should be initiated as treatment for bacterial meningitis before further laboratory results are available.
- In partially treated meningitis, antibiotics have been provided before lumbar puncture is performed.
 - Renders Gram staining and bacterial culture less useful (because of the possibility of temporary bacterial sterilization)
- Distinguishing partially treated bacterial meningitis with false-negative CSF cultures from aseptic meningitis can be difficult.
 - Accompanying CSF laboratory studies may be of assistance.
 - Leukocyte count and differential
 - CSF protein and glucose concentrations

- Reasons for delaying lumbar puncture
 - Clinically important cardiorespiratory compromise, most often observed in the neonate
 - Signs of significantly increased intracranial pressure
 - Retinal changes
 - Altered pupillary responses
 - Increased blood pressure with associated bradycardia and hyperpnea (Cushing triad)
 - Focal neurologic signs during the physical examination
 - Infection in the skin, soft tissues, or epidural area at the site of lumbar puncture
 - Suspicion or history of bleeding disorders
 - Hemophilia
 - Severe thrombocytopenia
- In the circumstances above, blood cultures should be obtained.
 - Antibiotics are provided empirically without performing a lumbar puncture.
 - In cases of suspected increased intracranial pressure:
 - Arrangements should be made for cranial CT with and without contrast enhancement during or immediately after antibiotic administration.
 - If imaging suggests that it would be safe to proceed, then lumbar puncture may follow.
 - Performing CT routinely before lumbar puncture is not necessary in patients with suspected meningitis.

LABORATORY FINDINGS

General tests

- The initial laboratory examination should include:
 - CSF examination and culture
 - Blood culture
 - Measurement of serum electrolyte and glucose concentrations
 - Complete blood count and platelet count
 - Measurement of urine specific gravity
- If the patient has petechiae or purpura or is in shock, then the laboratory tests should include:
 - Partial thromboplastin time
 - Prothrombin time
 - Measurement of fibrinogen- or fibrin-breakdown products

CSF

- Most experts suggest that the following tests should be performed on CSF from all samples drawn by lumbar puncture.
 - Gram stain
 - Bacterial culture
 - Cell count

- Differential cell count
- CSF concentrations of total protein and glucose
- If the nucleated blood cell count of CSF is not >6 cells/mcL, the only other tests likely to be useful in diagnosing bacterial meningitis are Gram stain and culture.
- If only a small amount of CSF is obtained, the most important tests to perform are Gram stain and bacterial culture.
- If possible, blood glucose should be measured just before lumbar puncture is performed to determine the ratio of CSF to blood glucose.
 - Measuring the blood glucose level before lumbar puncture is best because stress of the procedure can temporarily increase it.
- CSF should be cultured on chocolate and blood agar plates and in broth.
 - Generally, bacterial cultures will be positive within a few days if pathogens are present.
- The causative agent may be identified by latex agglutination reactions or counterimmunoelectrophoresis to detect soluble capsular antigens in CSF, and in serum or concentrated urine if needed.
 - These tests are rapid but should not be viewed as essential; the negative predictive value does not approach 100%, and they are not that useful in directing patient care.
 - Rapid diagnostic tests are likely to be truly valuable only in patients who have received significant amount of anti-biotics ≥ 24 hours before lumbar puncture.
- Distinguishing CSF abnormalities caused by infection from those associated with traumatic lumbar puncture:
 - Common clinical practice is to use the ratio of erythrocytes to leukocytes to correct the observed CSF leukocyte count, either by subtraction or by examination of the ratio of observed to expected cells.
 - Despite this apparently sound theoretical basis, in practice, calculations are generally not helpful when deciding whether to proceed with antibiotic therapy.
 - Bacterial or viral cultures will yield a more definitive answer relatively quickly.

Representative CSF findings in neonates without meningitis

- Age: 0–7 days
 - Full-term neonates (mean range)
 - Leukocytes/mcL: 8 (1–30)
 - Polymorphonuclear neutrophils: 5% of leukocytes
 - Protein: 81 mg/dL
 - Glucose: 46 mg/dL
 - CSF/blood glucose: 0.73%
 - Preterm neonates (mean range)
 - Leukocytes/mcL: 4 (1–10)
 - Polymorphonuclear neutrophils: 7% of leukocytes
 - Protein: 150 (85–222) mg/dL

- Glucose: 72 (4–96) mg/dL
- CSF/blood glucose: not reported
- Age: 8–28 days
 - Full-term neonates (mean range)
 - Leukocytes/mcL: 6 (0–18)
 - Polymorphonuclear neutrophils: 3% of leukocytes
 - Protein: 64 mg/dL
 - Glucose: 51 mg/dL
 - CSF/blood glucose: 0.62%
 - Preterm neonates (mean range)
 - Leukocytes/mcL: 7 (0–44)
 - Polymorphonuclear neutrophils: 9% of leukocytes
 - Protein: 148 (54–370) mg/dL
 - Glucose: 64 (33–217) mg/dL
 - CSF/blood glucose: not reported

Blood cultures

- Blood cultures should be obtained for all children suspected of having bacterial meningitis.
 - Positive in 80–90% children who have not previously received antimicrobial agents and have meningitis caused by Hib, *S pneumoniae*, or *N meningitidis*

Partially treated meningitis

- Leukocyte counts in CSF, percentage of polymorphonuclear cells, and glucose and protein concentrations in patients with partially treated bacterial meningitis do not greatly differ from those in patients who were not previously treated.
- Even children who have received intravenous antibiotics for 44–68 hours have CSF findings still characteristic of bacterial meningitis.
- Cultures of CSF from pretreated children with bacterial meningitis frequently grow Hib.
 - Pneumococci and meningococci grow less often after pretreatment.
 - Some patients who have partially treated bacterial meningitis will have CSF findings indistinguishable from classic findings of aseptic meningitis.

IMAGING

- Herniation of the brain associated with meningitis has been observed before lumbar puncture and in the presence of normal cranial CT.
- Nevertheless, lumbar puncture should be performed cautiously if significantly increased intracranial pressure is suspected.
- Obtaining CT before lumbar puncture in selected patients is reasonable, especially in children or adults with a history of:
 - Immunosuppression
 - Hydrocephalus
 - Ventricular shunts

- Head trauma
- Those who have focal neurologic signs
- Those with signs of greatly increased intracranial pressure
- Radiographs may help in identifying suspected bone or joint infection in selected patients.
- Radionuclide and CT studies play a role in complicated cases of meningitis.
 - May be helpful for decisions on management later during the course of therapy
 - Useful for evaluating selected cases of prolonged (primary) or recurrent (secondary) fever
- CT should not be routinely done as a result of prolonged or secondary fever; results are unlikely to affect clinical management.

DIAGNOSTIC PROCEDURES

- When meningitis is suspected in a patient without papilloedema, lumbar puncture should be performed.
 - Opening pressure should be measured and the CSF examined immediately.
- In general, lumbar puncture should be performed whenever the diagnosis of meningitis is known or suspected.
 - Children <12 months, and perhaps those <18 months, with a first febrile seizure should undergo lumbar puncture to exclude meningitis or atypical febrile seizure.
- Herniation of the brain on removal of a small amount of CSF is rare in meningitis, especially in infants with open fontanelles.
- If lumbar puncture was not initially performed or was contraindicated, the procedure may be reconsidered after:
 - The patient has been stabilized.
 - Contraindications have been resolved.
- Lumbar puncture may be performed even 12–24 hours after initiation of antimicrobial therapy.
 - Interpretation of CSF leukocyte counts and protein and glucose concentrations may be helpful in discerning the likelihood of true bacterial meningitis.

TREATMENT APPROACH

- The severity of illness at the time the patient seeks care can predict morbidity and should dictate immediate management.
- Therapies that are crucial for all patients with bacterial meningitis
 - Fluid management
 - Possible antiinflammatory adjunctive treatments
 - Antimicrobial therapy
- Acute bacterial meningitis is always a medical emergency.
- All infants and children with an altered state of consciousness should be observed closely and need for intensive care anticipated.

- As soon as bacterial meningitis is diagnosed, intravenous administration of appropriate antimicrobial agents and possibly antiinflammatory agents should begin.
- Management of the child who is awake and has stable cardiorespiratory vital signs consists primarily of:
 - Administering antimicrobial agents and fluids and careful monitoring for:
 - Changes in level of consciousness
 - Development of seizures
 - Changes in vital signs
 - Development of the syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
- Other therapies should be considered in more critically ill children.
- Seizures should be treated with appropriate anticonvulsants.
 - An open airway that provides good oxygenation should be ensured.
- Patients who are in a profound coma or whose level of consciousness deteriorates while receiving therapy should be evaluated for complications.
 - Cerebral abscess
 - Obstructive hydrocephalus
 - Increased intracranial pressure
 - CT of the brain with and without contrast is helpful in determining the diagnosis in such cases.
- If increased intracranial pressure is a major clinical concern and treatment has been initiated or is anticipated, a neurosurgeon should be consulted and an intracranial pressure monitoring device placed.
 - All children with bacterial meningitis have some increase in intracranial pressure.
 - Monitoring devices are not required for most patients.
 - If an intraventricular catheter can be placed, then increased intracranial pressure can often be treated by removing CSF.
 - Placement of a pressure transducer affords continuous intracranial monitoring, so that mannitol and hyperventilation can be used as necessary to decrease pressure and maintain cerebral perfusion.
 - Decreased inflammation and increased cerebral perfusion probably account for the benefits reported by some investigators with dexamethasone therapy.
- Some studies have found that plasma antidiuretic hormone concentrations return to normal in patients with bacterial meningitis who receive replacement plus maintenance fluids for 24 hours.
 - Concentrations remain high in patients restricted to two-thirds of maintenance requirements.
- Dehydration probably produces appropriate increase of antidiuretic hormone, but SIADH may still occur in nondehydrated or fluid-replete children.
 - SIADH occurs in bacterial meningitis; however, no firm evidence has been found that fluid restriction prevents it.
- Maintenance fluids are believed necessary to perfuse, oxygenate, and deliver host defenses to the CNS.
- Obvious fluid deficits should be rapidly corrected.
- Serum sodium concentrations should be closely monitored several times during the first 24 hours of therapy, along with measurements of urine specific gravity.
 - If the serum sodium concentration decreases to <125 mEq/L, the test should be repeated as soon as possible.
 - If the serum sodium concentration is still <125 mEq/L, fluids should be restricted to keep the vein open until serum electrolyte concentrations have been corrected.
 - Otherwise, for bacterial meningitis, providing routine maintenance fluids at approximately 80% of maintenance rate after fluid repletion and advancing to full maintenance rates as serum sodium increases to >135 mEq/L seems to be appropriate.
- The period of fluid restriction may only need to be ≤ 1 day.

Anti-inflammatory therapy

- Use of glucocorticoids as adjunctive therapy in patients who have bacterial meningitis continues to be controversial.
 - Dexamethasone most likely improves hearing and neurologic outcomes of children with bacterial meningitis caused by Hib.
 - The usefulness of dexamethasone therapy in children with bacterial meningitis in children and adults caused by *S pneumoniae* or *N meningitidis* is less certain.
- Glucocorticoid therapy may also cause:
 - Gastrointestinal bleeding
 - Decreased penetration of antimicrobial agents into the CSF
 - Obfuscation of the clinical assessment of children's response to therapy
- Dexamethasone may be beneficial when administered before or within 1 hour of the first dose of antimicrobial agents to children ≥ 6 weeks of age with Hib meningitis.
- Dexamethasone should be considered for children who have pneumococcal meningitis, although uncertainty exists regarding benefits and risks.

SPECIFIC TREATMENTS

Fluid therapy

- Traditionally, fluids were restricted to two-thirds of total daily maintenance amount in patients who had bacterial meningitis.
 - To minimize brain edema and prevent SIADH, which has been reported to occur in 29–88% of cases of bacterial meningitis.

Antimicrobial therapy

- Empirical guides to therapy are primarily based on age because knowing which causative agent is present at the time of diagnosis of bacterial meningitis is difficult.
 - Adjustment to therapy can be made as conjugate vaccination history and results of CSF Gram stain and culture are confirmed.

Empirical therapy for bacterial meningitis pending culture and susceptibility data

- Age: 0–1 mo
 - Likely pathogens
 - *Streptococcus agalactiae*
 - *E coli*
 - *Listeria monocytogenes*
 - Antimicrobial agent
 - Ampicillin + cefotaxime or ampicillin + aminoglycoside
- Age: 1–3 mo
 - Likely pathogens
 - *S agalactiae*
 - *L monocytogenes*
 - *S pneumoniae*
 - *N meningitidis*
 - Hib
 - Antimicrobial agent
 - Ampicillin + (cefotaxime or ceftriaxone) plus vancomycin
- Age: 3 mo–21 yr
 - Likely pathogens
 - *S pneumoniae*
 - *N meningitidis*
 - Hib (if not vaccinated)
 - Antimicrobial agent
 - (Ceftriaxone or cefotaxime) plus vancomycin

Specific therapy

- Pathogen: *S agalactiae*
 - Therapy: Ampicillin or penicillin G for 14–21 days; first 3 days, add gentamicin
- Pathogen: *L monocytogenes*
 - Therapy: Ampicillin for 14–21 days; first 3 days, add gentamicin
- Pathogen: *S pneumoniae*
 - Therapy
 - Penicillin MIC <0.1 mcg/mL and ceftriaxone or cefotaxime MIC ≤.5 mcg/mL: penicillin G or ampicillin for 10–14 days
 - Penicillin MIC ≥0.1 mcg/mL and ceftriaxone or cefotaxime MIC ≤0.5 mcg/mL: ceftriaxone or cefotaxime for 10–14 days

- Penicillin MIC ≥0.1 mcg/mL and ceftriaxone or cefotaxime MIC 1.0 mcg/mL: (ceftriaxone or cefotaxime) + vancomycin for 10–14 days
- Penicillin MIC ≥0.1 mcg/mL and ceftriaxone or cefotaxime MIC ≥2.0 mcg/mL: (ceftriaxone or cefotaxime) + vancomycin ± rifampin for 10–14 days

■ Pathogen: *N meningitidis*

- Therapy
 - Penicillin G for 7 days
 - Alternatives: ampicillin, ceftriaxone, cefotaxime

■ Pathogen: Hib

- Therapy
 - Ceftriaxone or cefotaxime for 10 days
 - Alternative: ampicillin if isolate is susceptible

Antimicrobial dosage, in mg/kg/day

- Ampicillin
 - 0–7 days: 150–200 divided every 8 hr
 - 8–28 days: 200–300 divided every 6 hr
 - Infants and children: 200–300 divided every 6 hr
- Cefotaxime
 - 0–7 days: 100 divided every 12 hr
 - 8–28 days: 200 divided every 8 hr
 - Infants and children: 200–300 divided every 6 hr
- Ceftriaxone
 - 0–7 days: Not recommended
 - 8–28 days: 80–100 divided every 12–24 hr
 - Infants and children: 80–100 divided every 12–24 hr
- Gentamicin
 - 0–7 days: 5 divided every 12 hr
 - 8–28 days: 7.5 divided every 8 hr
 - Infants and children: 7.5 divided every 8 hr
- Penicillin G
 - 0–7 days: 100,000–150,000 Units divided every 12 hr
 - 8–28 days: 150,000–200,000 U divided every 6 hr
 - Infants and children: 300,000–400,000 U divided every 4–6 hr
- Rifampin
 - 0–7 days: 10 divided every 12 hr
 - 8–28 days: 20 divided every 12 hr
 - Infants and children: 20 divided every 12 hr
- Vancomycin
 - 0–7 days: 20 divided every 12 hr
 - 8–28 days: 30 divided every 8 hr
 - Infants and children: 40–60 divided every 6 hr

Antimicrobial selection

- Dexamethasone can decrease CSF penetrance (and thus the activity) of vancomycin, and some experts therefore advise that:
 - Dexamethasone should be omitted altogether *or*
 - Rifampin *plus* vancomycin *plus* a third-generation cephalosporin should be used with dexamethasone.
- Up to 40% of pneumococcal isolates may be resistant to penicillin at some level.
 - Many also are resistant to third-generation cephalosporins.
 - Therefore, infants and children suspected of having bacterial meningitis caused by pneumococci should receive vancomycin in addition to either ceftriaxone or cefotaxime.
- As soon as the antimicrobial susceptibility of an isolate is known, vancomycin should be discontinued if the isolate is susceptible to penicillin or if it is nonsusceptible to penicillin but still susceptible to third-generation cephalosporins.
 - Vancomycin is continued with ceftriaxone or cefotaxime for isolates found to be nonsusceptible to both penicillin and the third-generation cephalosporins.
 - Rifampin is added to the combination in some circumstances.
 - Consultation with an infectious diseases subspecialist is suggested.
- In areas with low prevalence of penicillin-nonsusceptible pneumococci, providing a third-generation cephalosporin alone (without vancomycin) for empiric therapy is reasonable.
 - Especially when examination of the CSF Gram stain shows absence of gram-positive cocci
 - Suspected or proven Hib disease may be treated reliably with either ceftriaxone or cefotaxime.
 - Ampicillin may be used only if the isolate is known to be susceptible.
 - Disease caused by *N meningitidis* is treated with:
 - Penicillin G at high doses *or*
 - Ampicillin *or*
 - A third-generation cephalosporin
- Meningitis caused by *N meningitidis* is usually treated for 7 days.
 - That caused by Hib is treated for 10 days.
 - That caused by *S pneumoniae* is treated for 10–14 days.
 - A 7-day course of antimicrobial therapy for uncomplicated Hib and *S pneumoniae* meningitis may also be effective.
 - Chloramphenicol is now rarely used in the industrialized world.
 - If an alternative agent beyond ampicillin or third-generation cephalosporins is required, then meropenem may be administered.
 - Consultation with an infectious diseases specialist is suggested.

Assessment of therapeutic success

- Most failures are caused by:
 - Inadequate therapy with the correct antimicrobial agent
 - Resistant organisms
 - Long delay in diagnosis
- Repeat lumbar puncture performed after therapy is completed does not reflect the adequacy of therapy or predict likelihood of recurrence.
 - Usually not indicated
 - Delay in sterilizing the CSF beyond 24–36 hours has been associated with adverse outcomes; therefore, another lumbar puncture may be performed at that time.
 - Repeat lumbar puncture at 24–48 hours is indicated if drug-resistant *S pneumoniae* is present, especially if dexamethasone is administered.

Neonatal meningitis

- Principles of antimicrobial therapy are the same as for infants and children.
 - Because organisms are different, antimicrobial selection must be adjusted.
- The ideal antimicrobial agent would be effective against:
 - *E coli* and other enteric organisms
 - Group B β -hemolytic streptococci and other gram-positive organisms
- Cefotaxime and ceftriaxone are extremely active against organisms that usually cause neonatal meningitis, with the exception of *L monocytogenes*.
 - Ceftriaxone has a much longer serum half-life than cefotaxime.
 - Ceftriaxone is highly protein bound and can displace unconjugated bilirubin from albumin, and thus is generally not used in:
 - Premature infants at risk for kernicterus
 - Term infants with hyperbilirubinemia
 - No formal comparison has been made of these newer agents with the historical regimen of ampicillin plus an aminoglycoside, such as gentamicin.
- Cefotaxime plus ampicillin (to empirically treat *Listeria*) should be used to treat suspected neonatal meningitis.
 - Some authorities would add gentamicin as a third agent if gram-negative enteric meningitis were thought likely.
- Some enteric pathogens, such as *Pseudomonas aeruginosa* and Enterobacteriaceae, readily become resistant to third-generation cephalosporins.
 - These antibiotics should not be used empirically for all cases of suspected sepsis in neonates.
 - Choice of empiric ampicillin with gentamicin remains appropriate when the CSF appears normal.
- Intraventricular antimicrobial therapy
 - Its role remains uncertain, and it may even be harmful.

- Other therapeutic considerations are the same for neonates as for infants and children with bacterial meningitis.
 - No data support use of dexamethasone in infants <6 weeks of age.
- Head circumference should be measured serially to detect early signs of hydrocephalus.
- Conflicting data have been reported regarding whether intravenous immunoglobulin is helpful.
 - At present, it does not have a defined role.

Aseptic meningitis

- Mainly supportive
- Meningoencephalitis caused by herpes simplex or varicella-zoster viruses should be treated with acyclovir.
- Aseptic meningitis caused by 1 of the other less common organisms may require specific therapy.
- Pleconaril, an antienteroviral agent, has been evaluated in both adults and children with enteroviral meningitis.
- This or other similar drugs may be useful in the future, but clinical development of pleconaril has been halted at present.

WHEN TO ADMIT

- All patients with suspected or proven meningitis should be hospitalized for evaluation and management.
- Patients with bacterial meningitis should be transferred to a facility experienced in management of critically ill children, with availability of consultation by pediatric critical care, infectious diseases, neurologic, and neurosurgical subspecialists, which is especially important for newborns with neonatal meningitis.
 - Treatment must begin at the referral hospital, however.
- Infants and toddlers with viral meningitis may continue to be hospitalized at primary care level hospital; transfer to a referral facility may be required for complicated cases (eg, uncertainty in diagnosis, slow resolution, presence of immune compromise).
- Older children and adolescents with viral meningitis do not always require hospitalization if the CSF evaluation strongly suggests that bacterial disease is not present, if adequate hydration and pain control can be undertaken at home, and if follow-up with the physician can be ensured.

WHEN TO REFER

- All patients with bacterial meningitis should be treated in consultation with pediatric infectious disease subspecialists, and pediatric neurologic, critical care, and neurosurgical subspecialists should be available if required.
- Patients with viral meningitis may be managed by the primary care physician, unless unusual features or complications are present (eg, immune compromise, unexpected severity, slow resolution of illness, possibility of nonviral aseptic meningitis).

- Patients with neonatal meningitis should be referred to pediatric infectious diseases, newborn medicine, and neurologic subspecialists.

COMPLICATIONS

- Early in the course of bacterial meningitis, the following may occur:
 - Increased intracranial pressure
 - Septic shock
 - Disseminated intravascular coagulation
 - Cardiorespiratory arrest
- Subdural effusions occasionally cause seizures or focal neurologic deficits.
 - In such cases, fluid should be removed by subdural taps.
 - Such effusions are rarely infected directly.
 - Subdural empyemas are occasionally reported.
- SIADH can also complicate bacterial meningitis.
 - Thus the patient should be monitored carefully for this complication.
 - If it occurs, fluid should be sharply restricted.
- Brain abscess is extremely rare after bacterial meningitis, except in neonates with meningitis caused by *Citrobacter* or certain *Enterobacter* species.
- Complications of neonatal meningitis are similar to those seen among older infants but are perhaps more common.
 - Hydrocephalus
 - Deafness
 - Blindness

PROGNOSIS

- Encephalitis mortality
 - Despite the appropriate use of bactericidal antibiotics, the mortality rate for bacterial meningitis remains 5–10%.
 - Case-fatality rate for neonates generally ranges from 20–25%.
 - In general, mortality is lower for full-term infants than for low-birth-weight infants (<2500 g).
 - The case-fatality rate may approach 50% in low-birth-weight infants with gram-negative enteric meningitis.
 - The case-fatality rate falls to approximately 5% for neonates who survive the first 24 hours.
 - Mortality of bacterial meningitis varies by pathogen.
 - 21% for *S pneumoniae*
 - 3% for *N meningitidis*
 - 6% for Hib
- Approximately 15–25% of survivors will have long-term morbidity, including:
 - Developmental delay
 - Seizure disorder

- Spasticity
 - Hearing loss
 - Approximately 65% of survivors of coliform meningitis are normal 3–7 years after illness.
 - Approximately 15–30% have mild to moderate neurologic sequelae.
 - 5–10% have major sequelae.
 - Approximately 50% of group B β -hemolytic streptococcal meningitis survivors are normal.
 - 20% have mild to moderate sequelae.
 - 15–30% have major sequelae, such as:
 - Hydrocephalus
 - Seizures
 - Profound intellectual disability
 - As many as 80% of neonates who have gram-negative enteric meningitis caused by either *Citrobacter* or certain *Enterobacter* species will develop single or multiple brain abscesses.
 - Unusual in meningitis caused by any other organism
 - Routine follow-up with cranial CT is indicated for neonates with meningitis or sepsis caused by *Citrobacter* species or *Enterobacter sakazakii*.
 - All infants recovering from meningitis should have careful audiologic testing and close evaluation for attainment of developmental milestones.
 - Outcome of aseptic meningitis relates to both the causative agent and the child's age.
 - Patients with enteroviral meningitis usually recover completely.
 - However, some studies have reported low intelligence and delayed speech development after enteroviral meningitis in very young infants.
 - In light of these findings, the prognosis for an infant <3 months of age is somewhat guarded.
 - The child's development should be monitored carefully.
 - In general, when encephalitis accompanies aseptic meningitis, the clinical course is more severe and the chance of sequelae increases.
 - Predicting long-term sequelae for an individual child is difficult at the time of hospital discharge.
 - Some children who are apparently normal are later found to have hearing or learning deficits or develop a seizure disorder.
 - Conversely, some children expected to have a dismal prognosis based on abnormal neurologic examinations make remarkable gains.
 - The practitioner should be guardedly optimistic with family while remaining sensitive to possible sequelae.
 - Hearing should be tested formally before discharge from the hospital.
 - Most sensorineural hearing loss can be detected at this time.
 - The rate of persistent bilateral or unilateral sensorineural hearing loss is:
 - 31% after pneumococcal meningitis
 - 10.5% after meningococcal meningitis
 - 6% after Hib meningitis
 - In young infants, auditory brainstem response or otoacoustic emissions testing is necessary for screening.
 - In older toddlers and children, conditioned response, play, or conventional audiometry may be performed.
 - Current thinking asserts that much of the hearing loss in meningitis occurs soon after infection.
 - This may explain why not all studies have shown reduction of hearing loss by dexamethasone therapy.
 - Timing of other neurologic sequelae is less certain.
- ## PREVENTION
- Some contacts of patients who have *N meningitidis* or Hib meningitis are at increased risk for the disease and should therefore receive prophylaxis.
 - Whether all contacts of patients who have Hib meningitis should receive prophylaxis remains controversial.
 - The AAP recommends that rifampin be provided to all household contacts, including adults, in households that have ≥ 1 contact <4 years of age whose immunization status against Hib is incomplete
 - Definition of complete immunization depends on the age of the individual involved.
 - A household contact is:
 - Anyone who resides with the index patient or
 - A nonresident who has spent ≥ 4 hours a day with index patient for 5 of the 7 days before the patient was hospitalized
 - Prophylaxis for all household contacts, regardless of age, is provided in households with a child <12 months of age.
 - Prophylaxis for nonhousehold contacts of Hib disease does not appear to be necessary.
 - The index patient should receive rifampin either during or at completion of treatment for Hib or meningococcal meningitis, unless ceftriaxone was used for treatment.
 - Many authorities still recommend that the index patient should receive rifampin either during or at completion of treatment for Hib or meningococcal meningitis.
 - The 1990s marked the beginning of conjugate vaccine era.
 - With widespread use, these vaccines have dramatically decreased the incidence of invasive Hib disease.

- Similarly, use of pneumococcal and meningococcal polysaccharide-protein conjugate vaccine promises a marked decrease in invasive pneumococcal and meningococcal infection.
- 1 of 3 Hib conjugate vaccines or 1 of 3 Hib conjugate-containing combination vaccine products is routinely provided to US infants beginning at 2 months of age.
- Pneumococcal conjugate vaccine is recommended for routine universal administration to infants and children <2 years of age.
- Pneumococcal conjugate vaccine is also suggested for high-risk children 2–5 years of age, including children with:
 - Sickle cell disease
 - Functional or anatomic asplenia
 - Immunosuppression
 - Cancer
 - Chronic renal disease
 - Chronic cardiopulmonary disease
 - CSF leaks
 - Diabetes
- At present, tetravalent meningococcal polysaccharide conjugate vaccine is routinely used only for children and adults at high risk of disease, including:
 - Young adolescents 11–12 years of age
 - Teens on entry to high school (15 years)
 - College freshmen (especially those living in dormitories)
 - Certain travelers
 - Those with sickle cell disease, functional or anatomic asplenia, immunosuppression, CSF leaks
- Meningococcal conjugate vaccine is:
 - Used as an adjunct to chemoprophylaxis in outbreak control
 - Undergoing clinical trials for safety and immunogenicity in US children as young as 2 years

Meningococemia

DEFINITION

- Meningococemia is a consequence of infection with *Neisseria meningitidis* and a classic example of fulminant bacterial sepsis.

EPIDEMIOLOGY

- Incidence
 - Approximately 2600 cases of meningitis and sepsis are reported annually in the US.
 - Meningococcal infection the leading cause.
- Prevalence
 - The Centers for Disease Control and Prevention reported 1.1 cases of meningococcal disease per 100,000 people between 1992 and 1996.
 - Invasive meningococcal disease is relatively uncommon.
 - ~5–30% of adolescents and adults in nonepidemic conditions are colonized.
- Age
 - Highest incidence of disease consistently found in infants
 - Peak attack rate for infants is 15.9 cases per 100,000 population.
 - 20–25% of all cases of meningococcal disease occur in children <2 years.
 - Second smaller peak of disease is found in adolescents and young adults.
- Geographic distribution
 - *N meningitidis* causes both epidemic and endemic disease worldwide.
- Seasonal occurrence
 - Varies with the seasons
 - Winter and spring peak time of disease in the US
- Special populations
 - Subgroups, such as military recruits, can have rates of invasive meningococcal disease as high as 80%.
 - High carriage rates in household contacts of infected patients
- Serogroups of meningococcus
 - Historically, the majority of cases of invasive meningococcal disease in the US have been caused by serogroup B meningococcus.
 - In the mid-1990s
 - Organisms of serogroup B and C were each identified in approximately 35% of cases.
 - Serogroup B
 - 40% of disease occurred in children <2 years.
 - Serogroup C
 - 57% of disease occurred in persons between 2 and 30 years of age.

– Serogroup Y

- Accounted for 26% of isolates
- Associated with older age groups and the clinical syndrome of pneumonia

ETIOLOGY

- *N meningitidis*
 - An aerobic gram-negative coccus found only in the human nasopharynx
 - Spread from person to person via respiratory droplets or direct contact with secretions
 - Thirteen serogroups have been identified on the basis of the antigenic structure of the capsular polysaccharide.
 - Five are responsible for the majority of human disease: serogroups A, B, C, Y, and W-135.
 - Additional methods of typing outer membrane proteins and lipooligosaccharides have led to classifications of serosubtypes, serotypes, and immunotypes that are useful in epidemiologic investigations.

SIGNS AND SYMPTOMS

- Early symptoms (first 12 hours) (see table Cumulative Proportion of Children Developing Clinical Features During the Course of Meningococcal Disease)
 - Leg pain
 - Thirst
 - Diarrhea
 - Abnormal skin color (pallor)
 - Breathing difficulty
 - Cold hands and feet
- Classic symptoms
 - Hemorrhagic rash
 - Neck pain or stiffness
 - Photophobia
 - Bulging fontanelle
 - Irritability or lethargy (~50%)
 - Vomiting (~35%)
 - Shock (~42%)
- Late symptoms
 - Confusion or delirium
 - Seizure
 - Unconsciousness
- Less frequent symptoms
 - Delirium
 - Headache
 - Coryza
 - Diarrhea
 - Myalgia
 - Hypothermia

Cumulative Proportion of Children Developing Clinical Features During the Course of Meningococcal Disease^a

		Fatal Cases (n=103)	Nonfatal Cases (n=345)	Overall (95% Confidence Interval)	Median Hour of Onset
Early Symptoms	Leg pain	22.3%	38%	36.7% (28–47)	7
	Thirst	41.7%	40.6%	40.7% (31–50)	8
	Diarrhea	54.4%	44.6%	45.2% (36–56)	9
	Abnormal skin color	73.8%	53.9%	55.1% (45–65)	10
	Breathing difficulty	75.7%	58.0%	59.1% (50–69)	11
	Cold hands and feet	81.6%	75.7%	76.1% (67–85)	12
Classic Symptoms	Hemorrhagic rash	94.2%	88.4%	88.8% (82–95)	13
	Neck pain or stiffness	94.2%	91.6%	91.8% (86–97)	13
	Photophobia	94.2%	92.5%	92.6% (87–97)	15
	Bulging fontanelle	94.2%	93.0%	93.1% (88–98)	15
Late Symptoms	Confusion or delirium	94.2%	95.1%	95.0% (90–99)	16
	Seizure	96.1%	95.4%	95.4% (91–99)	17
	Unconsciousness	97.1%	95.9%	96.0% (92–99)	22

^a From: Thompson MJ, Ninis N, Mayon-White R, et al. Clinical recognition of meningococcal disease in children and adolescents. *Lancet*. 2006;367(9508):397–403. Copyright © Elsevier 2006.

■ Rash

- Type and duration provide important information about the course and prognosis of the disease.
- Tender, pink maculopapular rash
 - Seen early in the infection
 - Similar to that seen in rubella, secondary syphilis, or disseminated gonorrhea
 - Can appear on any part of the skin
 - Often fades rapidly with treatment
 - Patients who have this type of manifestation are less likely to have a fulminant course.
- Generalized petechial rash (see Figure 38 on page F16)
 - Usually associated with meningococcal disease (see Figure 39 on page F16)
 - Initially, lesions are discrete and 1–2 mm in diameter.
 - Most prominent on the distal extremities, including the palms and soles
 - Found in clusters where clothing puts pressure on the skin
 - Scrapings of lesions reveal the organism approximately 70% of the time.
- Ecchymotic or purpuric rash
 - Meningococemia is the most common cause of purpura.
 - Most ominous manifestation of meningococcal disease
 - A centrifugal distribution is usually present in cases of fulminant meningococemia (see Figure 40 on page F16).

- Patients with purpura fulminans have a 20–50% mortality rate.
- The case-fatality rate also is significantly higher in a febrile child with purpura or petechiae that have been present for <12 hours.

DIFFERENTIAL DIAGNOSIS

- Other infectious and noninfectious diseases that manifest in petechiae or purpura include:
 - Viruses
 - Varicella-zoster virus
 - Cytomegalovirus (congenital infection)
 - Variola virus
 - Coxsackievirus
 - Echoviruses
 - Colorado tick fever virus
 - Rubella virus
 - Measles virus
 - Alpha viruses (eg, Ross River fever)
 - Lassa virus
 - Marburg viruses
 - Nonviral agents
 - *Rickettsia typhi* (murine typhus)
 - *Rickettsia prowazekii* (epidemic typhus)
 - *Rickettsia rickettsii* (Rocky Mountain spotted fever)
 - *Ehrlichia canis*

- *Mycoplasma pneumoniae*
- *Streptococcus pyogenes* (scarlet fever)
- *Streptococcus pneumoniae*
- Enterococcal and viridans group streptococci (endocarditis)
- *Neisseria gonorrhoeae*
- *Neisseria meningitidis*
- *Moraxella catarrhalis*
- *Haemophilus influenzae*
- *Streptobacillus moniliformis* (rat-bite fever)
- *Pseudomonas aeruginosa* (erythema gangrenosa)
- *Yersinia pestis* (plague)
- *Bartonella henselae* (cat-scratch disease)
- *Treponema pallidum* (congenital syphilis)
- *Borrelia* species (relapsing fever)
- *Trichinella spiralis* (trichinosis)
- *Toxoplasma gondii* (congenital toxoplasmosis)
- Miscellaneous
 - Henoch-Schönlein purpura
 - Immune thrombocytopenic purpura
 - Kawasaki disease
 - Serum sickness
 - Poisons
 - Erythema multiforme
 - Erythema nodosum
 - Systemic lupus erythematosus
- In a clinical study of >200 children in an emergency department with a nonblanching rash:
 - 11% were found to have meningococcal disease
 - Children with meningococemia were more likely to:
 - Be judged ill by the investigators
 - Have fever >38.5°C
 - Have a purpuric rash
 - Have a capillary refill time of >2 seconds
- In a similar study:
 - 15% of children with fever and hemorrhagic rash had documented invasive meningococcal disease.
 - 45% did not have a specific diagnosis identified.
 - Presumably most of these had self-limited viral illnesses.
 - The following were highly associated with a diagnosis of invasive meningococcal disease:
 - Poor general condition
 - Presence of nuchal rigidity
 - >2-mm maximal diameter of skin hemorrhages
 - Generalized distribution of the rash
- These 2 studies confirmed absence of meningococcal disease in children with petechial rashes confined to the area of superior vena cava distribution (above the nipple line).

DIAGNOSTIC APPROACH

- Symptoms of meningococcal disease are nonspecific.
- Clinicians must maintain a high index of suspicion.
- Median time between onset of symptoms and hospitalization for pediatric patients is 13–22 hours.
- Early recognition of meningococemia is challenging, but it is an important determinant of survival.
- The majority of children with invasive meningococcal disease have an illness with symptoms and signs lasting only a few hours to a day.
 - In general, the children have no significant medical history.
 - Approximately 25% may report a recent respiratory illness.
- Physical examination of a child or adolescent with suggested meningococemia:
 - Should be performed expeditiously and with close attention to vital signs and skin findings.
 - The following need to be evaluated to determine the presence of shock:
 - Adequacy of respiration
 - Central and peripheral circulation
 - Mental status
- Frequent reassessments are warranted.

LABORATORY FINDINGS

- Initial laboratory tests should include:
 - Blood culture
 - Complete blood count and differential
 - Partial thromboplastin time
 - Prothrombin time
 - Measurement of fibrin breakdown products
 - Serum chemistries

DIAGNOSTIC PROCEDURES

- Lumbar puncture should be performed in a stable patient to:
 - Examine the cerebral spinal fluid for organisms
 - Obtain cultures
 - Assess the prognosis
- In an unstable patient, lumbar puncture should be deferred.

TREATMENT APPROACH

- Patients with signs and symptoms of invasive meningococcal disease should have aggressive monitoring and treatment as soon as the diagnosis is reasonably thought to be present.
- Do not withhold antibiotic therapy while waiting to obtain cerebrospinal fluid.
- Treatment regimen for children with meningococemia includes:
 - Antibiotics

- Invasive monitoring of:
 - Hemodynamic function
 - Neurologic function
 - Respiratory function
- If the patient must be transported to a pediatric intensive care unit:
 - Blood should be drawn.
 - Antibiotics should be given.
 - Intravenous access should be secured.
 - The patient should be attended during transport by a physician prepared to treat shock.
 - The disease may worsen when endotoxin is liberated after antibiotic therapy.

SPECIFIC TREATMENTS

Antibiotics

- Recommended regimen
 - Aqueous penicillin G 250,000 U/kg of body weight/day in 4–6 divided doses.
 - A small number of meningococcal isolates with intermediate susceptibility to penicillin have been identified in the US.
 - No resistance to penicillin has been reported.
 - Alternative antibiotics if penicillin allergy is present
 - Ceftriaxone
 - Cefotaxime
 - Chloramphenicol
 - Continue antibiotic therapy for 5 afebrile days or 7 days total.
 - Rifampin (10 mg/kg per dose given twice a day for 2 days)
 - Prescribed at the end of the course of penicillin
 - Eliminates carriage of the organism from the nasopharynx
 - Not necessary if the patient has been treated with a third-generation cephalosporin (also effective in eliminating carriage)

Supportive therapy and critical care

- Aggressive supportive therapy in a pediatric intensive care setting
- Invasive monitoring of hemodynamic, neurologic, and respiratory function
- Mechanical ventilation to treat respiratory failure
- Maintenance of optimal plasma expansion with intravenous fluids
 - First step in stabilizing the circulatory system
 - Large amounts of fluid may be needed because of capillary leak associated with endotoxic shock.
 - Multiple transfusions with platelets and fresh-frozen plasma may be necessary to correct coagulopathy.

- Several studies have demonstrated that myocardial dysfunction precedes shock in adult and pediatric patients with meningococcal sepsis.
 - Believed to be caused by endotoxemia
 - Use of inotropic agents is recommended to:
 - Reverse myocardial depression
 - Improve tissue perfusion
 - Supportive measures for severe purpura
 - Treatments aimed at relieving the ischemic complications associated with vasculitis
 - Prevention of gangrenous necrosis
 - Mechanism of action is thought to be vasodilatation of partially occluded vessels via sympathetic blockade.
 - Continuous epidural anesthesia may help in improving perfusion of the lower extremities.
 - If there is no evidence of coagulopathy, an anesthesiologist can perform this type of regional block with an indwelling catheter in the caudal space.

Experimental therapies

- Systemic thrombolytic therapy with recombinant tissue plasminogen activator
 - Used in a limited number of patients in an attempt to dissolve microthrombi and restore organ and tissue perfusion
 - Risks of bleeding complications caused by this intervention have not been fully evaluated.
 - Not recommended for use outside of a research setting
- Topical administration of nitroglycerin
 - Reported to be useful in restoring blood flow to limited areas of skin and superficial tissues
 - No notable adverse effects
 - Has not been systematically studied
- Plasmapheresis
- Whole-blood exchange
- Extracorporeal membrane oxygenation
- Continuous venovenous hemodiafiltration
 - Designed to interrupt the disease process pathophysiology via interference with both endotoxin and the secondary mediators of inflammation induced by endotoxin
 - Studies have shown a correlation between plasma levels of endotoxin or tumor necrosis factor and multiorgan failure or disease severity.
- Recombinant human bactericidal-permeability-increasing protein (rBPI₂₁)
 - N-terminal fragment of a human protein naturally found in the azurophilic granules of polymorphonuclear leukocytes.
 - In a preliminary trial of rBPI₂₁ in children who had severe meningococemia, mortality was reduced compared with historical controls.

- A large, randomized, placebo-controlled trial of this product in children with invasive meningococcal disease demonstrated:
 - Lower incidence of multiple and severe amputations
 - Improved functional outcome
 - Less need for blood product support
 - No substantial benefit in mortality
 - On the basis of this study, the product remains in clinical development.
 - Not available for general use
 - Reports have associated purpura fulminans induced by sepsis with:
 - Acquired deficiencies of the natural anticoagulation factor proteins C and S and deficiency in the activation pathway for protein C
 - Drotrecogin alfa (activated) is an activated protein C compound licensed for use in adults with severe sepsis and organ dysfunction.
 - Although efficacy has been demonstrated in adult populations, a recent pediatric trial of this compound was halted because of:
 - Concerns over lack of benefit
 - Increased number of intracranial hemorrhages in patients receiving the product
 - High-dose steroids
 - Use in children with meningococcal disease remains controversial.
- Thought to be caused by an allergic phenomenon with immune complex deposition rather than a direct invasion of the heart or joints by the organism
 - Allergic arthritis and pericarditis
 - Late in onset
 - More common in adults than in children
 - Symptoms are usually self-limited.
 - Specific therapy is generally not required.
 - Drainage of pericardial or joint fluid occasionally is necessary.
 - Complement deficiency
 - Not a true complication
 - Reported in approximately 15% of adolescents and children who have meningococcal disease
 - Creates high risk for recurrent episodes of invasive infection
 - Screening with a total hemolytic complement assay should be considered in any pediatric patient with meningococemia.
 - Several studies have shown an association between meningococcal disease and influenza and other viral respiratory infections.
 - The exact nature of the interaction is not clear.
 - 50% of cases of invasive meningococcal disease are associated with meningitis.
 - Approximately 35% of cases of invasive meningococcal disease are classified as sepsis without central nervous system involvement.

WHEN TO ADMIT

- A febrile child who has purpura or petechiae present for <12 hours should be managed as a medical emergency.

COMPLICATIONS

- 15–40% of patients develop a complication of infection that may be categorized broadly as suppurative, neurologic, ischemic, or allergic.
 - Suppurative complications
 - Subdural effusions
 - Subdural empyema
 - Acute suppurative arthritis
 - Occur in approximately 9% of children
 - Neurologic sequelae
 - Deafness is the most common (2–6%).
 - Ischemic complications
 - Gangrenous necrosis of the skin or extremities
 - Require skin grafting or amputation
 - Percentage of survivors varies from 3–20%.
 - Arthritis and pericarditis
 - Most common sequelae
 - Reported in 4–10% of pediatric cases
- ## PROGNOSIS
- The majority of children who survive meningococcal disease recover completely.
 - Overall mortality in meningococcal disease is 5–15%.
 - Children with the severe form of the disease can progress from a state of good health to death in hours, regardless of whether meningitis is present.
 - Occult or chronic meningococemia is occasionally detected.
 - Subgroups of patients (eg, those with fulminant meningococemia) can have fatality rates as high as 50–80% despite aggressive intensive care therapy.
 - Investigators have attempted to predict the outcome for individual patients who have meningococcal disease on the basis of laboratory and clinical data.
 - These scoring systems are used to:
 - Determine which patients might benefit from more aggressive or experimental therapies
 - Help evaluate the usefulness of newer treatments
 - In 1966 Stiehm and Damrosch developed a prognostic score.
 - Patients who had ≥ 3 of the following signs or symptoms had fatality rates of $\geq 85\%$, and scores were then validated.
 - Presence of petechiae for <12 hours before admission
 - Shock

- Absence of meningitis
- Normal or low leukocyte counts
- Normal or low erythrocyte sedimentation rates
- Glasgow Meningococcal Septicemia Prognostic Score
 - Designed for rapid bedside assessment without the need for multiple laboratory tests
 - Maximum score 15
 - Blood pressure <75 mm Hg systolic, age <4 years and <85 mm Hg systolic, age >4 years: 3 points
 - Skin to rectal temperature difference >3°C: 3 points
 - Modified Glasgow Coma Scale score <8 or deterioration of at least 3 points in 1 hour: 3 points
 - Clinical deterioration in hour before scoring: 2 points
 - Absence of meningitis: 2 points
 - Extending purpuric rash or widespread ecchymoses: 1 point
 - Base deficit (capillary or arterial) >8.0: 1 point
 - The scale was tested retrospectively in 123 children with meningococemia.
 - A score ≥10 had a positive predictive value of 87.5% and a negative predictive value of 100%.
 - Scoring systems are used to determine
 - Which patients might benefit from more aggressive or experimental therapies
 - Usefulness of newer treatments

PREVENTION

- Natural immunity can be developed by colonization with:
 - Pathogenic and nonpathogenic *Neisseria*
 - Other gram-negative organisms that have similar capsular polysaccharides
- Antimicrobial chemoprophylaxis is an integral component in the control of invasive meningococcal disease.
- Studies have demonstrated that household, child care, and preschool contacts of patients who have invasive disease have a rate of infection approximately 100–800 times that of the general population.
 - 50% of secondary cases occur within 5 days of the index case.
 - 70% occur within 1 week.
- Rifampin
 - Highly effective in eliminating carriage of the meningococcus from the nasopharynx
 - AAP recommends that all household, child care, or preschool contacts or anyone directly exposed to a patient's secretions be given rifampin within 24 hours of recognizing the primary case.
 - For children ≥1 month of age: 10 mg/kg per dose (maximal adult dose is 600 mg) every 12 hours for 2 days

- For infants <1 month of age: 5 mg/kg per dose every 12 hours for 2 days
- Not recommended for use in pregnant women
- Alternative chemoprophylactic agents
 - Ceftriaxone
 - For children <15 years of age: 125 mg IM in a single dose
 - Dilute with 1% lidocaine to decrease pain at the injection site.
 - For adolescents ≥15 years of age: 250 mg IM in a single dose
 - Not recommended for widespread chemoprophylactic use
 - A single 250-mg IM dose is safe for pregnant women.
 - Ciprofloxacin
 - Can be used in older adolescents and young adults
 - Has the advantage of being administered as a single oral 500-mg dose
 - For patients ≥18 years of age: 500 mg orally in a single dose
 - Not recommended for anyone <18 years
 - Not recommended for widespread chemoprophylactic use
 - Not approved for children or pregnant women
- Vaccination
 - Licensed for use in January 2005 for individuals 11–55 years of age
 - The Centers for Disease Control and Prevention's Advisory Committee on Immunization Practices recommend adding meningococcal conjugate vaccine to the routine immunization schedule for all children at age 11–12 years.
 - Vaccine contains purified capsular polysaccharide of serogroups A, C, Y, and W-135 conjugated to diphtheria toxoid.
 - The conjugated protein elicits a T cell–dependent antibody response and induces immunologic memory.
 - In a trial comparing meningococcal polysaccharide vaccine with the new conjugate meningococcal vaccine among >800 children age 11–18 years who received conjugate vaccine:
 - 82–97% of children achieved ≥4-fold increases in serum bactericidal antibody titers.
 - 98.6–99.8% achieved protective levels to all 4 serogroups.
 - Adverse reactions were mild and infrequent, usually limited to local reactions and fever.
- Group B meningococcal disease
 - No vaccine available
 - Group B capsule not strongly immunogenic in humans
 - Has been found to share cross-reacting antigens with human neural tissue
 - Attempts to create vaccine by using outer membrane proteins are ongoing.
 - Studies aimed at evaluating the immunogenicity and safety of the new meningococcal conjugate vaccine in younger age groups are under way.

Meningoencephalitis

FOUNDATION

- Infection of the meninges and underlying brain parenchyma can be classified as septic or aseptic.
 - Septic
 - Traditionally termed *bacterial meningitis*
 - Characterized by high fever, coma, and purulent cerebrospinal fluid (CSF)
 - Aseptic
 - Aseptic meningitis
 - Encephalitis
 - Most often caused by viruses, but occasionally caused by parasites, spirochetes, rickettsia, and prions

EPIDEMIOLOGY

- Incidence of meningoencephalitis is unknown.
 - Centers for Disease Control and Prevention tallied 2840 cases of arboviral encephalitis (367 children) in 2004.
 - Approximately 75,000 cases of aseptic meningitis occur annually.
 - Difficulty in identifying the specific agent in each suspected case makes precision impossible.
- Polio
 - In the US, occurs primarily in:
 - Immigrant children
 - Immunodeficient children
 - In small communities of unimmunized children
 - Continues to cause epidemics in developing countries where clean water and sewage treatment facilities are lacking
- Herpes simplex virus (HSV)
 - HSV encephalitis has a bimodal age distribution.
 - One-third of cases occur in childhood.
- Arbovirus meningoencephalitis
 - Typically occurs in epidemics during the summer and early fall
- Rabies
 - 50,000 deaths estimated worldwide
 - Frequently in children who are bitten by rabid dogs
 - In the US, pediatric rabies infections are attributed most often to rabid bats, raccoons, and cats.
- West Nile virus (WNV)
 - 2866 West Nile neuroinvasive cases were reported in 2003.
 - 8% were fatal.
 - Cases of WNV encephalitis have been reported in children.
- Measles virus
 - Causes meningoencephalitis in approximately 1 in 1000 cases

- In 2003, 56 confirmed measles cases were reported in the US.
- Varicella-zoster virus (VZV)
 - In US, more deaths occur as complication of varicella infection than from all other disorders for which immunizations exist.
- Congenital rubella syndrome
 - Cases have declined from 57,686 in 1969 to 271 in 1999.
 - Rubella in US now primarily affects infants born to foreign-born women.
- Rocky Mountain spotted fever (RMSF)
 - In one study, 81% of 16 patients with RMSF were children.
 - In summer of 2003, 3 fatal cases of RMSF were reported in children.
- Congenital toxoplasmosis
 - An estimated 400–4000 cases occur each year.
- Congenital syphilis
 - In 2003, 413 cases related to absent or late prenatal care were reported.
 - Rate has sharply declined in recent years.
 - Congenital syphilis is more common in the southern US.
 - Possibly because of more women with inadequate prenatal care.
- New-variant Creutzfeldt-Jakob disease (CJD)
 - Related to bovine spongiform encephalopathy (BSE), which is endemic in the United Kingdom

ETIOLOGY

- Enteroviruses
 - Common cause of aseptic meningitis in infants
 - May also cause encephalitis
 - Nonpolio enteroviruses include:
 - Coxsackieviruses A and B
 - Echoviruses
 - Progression to meningoencephalitis is uncommon with most enteroviral infections.
 - When it does occur, it is usually mild, self-limited disease.
 - May infect a fetus transplacentally
- HSV
 - Neonatal infection results from passage through an infected birth canal.
 - In neonate, HSV may produce:
 - Cutaneous disease
 - Meningoencephalitis
 - Disseminated disease
- Arboviruses
 - Arboviral infections caused by *Bunyavirus* species and togavirus are transmitted to humans by arthropods.

- Other viral diseases transmitted by vectors
 - Colorado tick fever is a reovirus transmitted by rodent arthropods.
 - Lymphocytic choriomeningitis (arenavirus) is transmitted directly to humans by infected laboratory or domestic rodents.
- WNV
 - Principally transmitted by *Culex* mosquitoes
 - Occurs mostly in older adults; cases of intrauterine transmission and possible transmission through breastfeeding have occurred
- Rabies
 - Transmitted by bite, scratch, or droplet from infected wild animal (eg, raccoon, bat) or unimmunized domestic animal
 - Rabies has been documented after transplantation.
- Common childhood viral infections can occasionally cause meningoencephalitis.
 - Rubella
 - Adenovirus
 - Influenza
 - Cytomegalovirus (CMV)
 - Epstein-Barr virus (infectious mononucleosis)
 - Measles
- VZV
 - May cause mild encephalitis or a focal cerebellitis with prominent ataxia
- AIDS
 - Noteworthy for meningoencephalitides caused both by HIV and by unusual organisms, such as:
 - *Toxoplasma gondii*
 - *Candida albicans*
 - Epstein-Barr virus
- Fungi, spirochetes, and parasites
 - Nonviral causes of meningoencephalitis include infectious and noninfectious conditions associated with CSF pleocytosis.
 - Amebic meningoencephalitis may result from swimming in freshwater rivers or lakes infected with *Naegleria*.
 - RMSF
 - Transmitted by *Dermacentor* ticks
 - Toxoplasmosis
 - Causes cerebral calcifications, microcephaly, and seizures
 - Resulting from transplacental infection by the protozoa *T gondii* to the fetus
 - Transmitted to humans through ingestion of inadequately cooked meat or ingestion of oocysts from cat feces

- Prions
 - Transmissible spongiform encephalopathies include:
 - Kuru
 - Children of the Fore tribe of New Guinea
 - BSE
 - Cattle
 - CJD
 - Humans
 - CJD has been transmitted to children through administration of cadaveric growth hormone.

RISK FACTORS

- The developing nervous system may be more susceptible to viral infection.
 - Pediatric patients are thus more likely to sustain serious sequelae.
- WNV
 - Risk for WNV encephalitis increases with age and immunosuppression.
 - Possible transmission through breastfeeding has occurred.
 - However, mothers should continue breastfeeding even in areas with WNV transmission.
 - Most women infected with WNV during pregnancy have delivered apparently healthy infants, although exceptions have been reported.
- Susceptibility to new-variant CJD may be highest in teenagers.

SIGNS AND SYMPTOMS

General features

- Most viruses spread via the bloodstream to the choroid plexus and from there to brain parenchyma.
 - Rabies and HSV travel in a retrograde manner via peripheral nerves.
- The course of meningoencephalitis depends on virulence of the organism.
 - Typically, children with aseptic meningitis have:
 - Intense headache
 - Meningismus
 - Photophobia, but a clear sensorium
 - In contrast, amoebae, fungi, and the viruses causing Eastern equine encephalitis, HSV, or rabies may cause:
 - Cerebral or brain stem dysfunction
 - Seizures
 - Increased intracranial pressure
 - Death

■ Presenting signs and symptoms produced by viruses are often protean and include:

- Fever
- Chills
- Myalgia
- Headache

■ Differences in seasonal occurrence, clinical course, and outcome allow differentiation of some disorders.

■ Encephalitis may produce focal neurologic findings.

- If the spinal cord is involved, the patient may have:
 - Symmetrical limb paralysis
 - Transverse sensory symptoms
 - Bowel and bladder dysfunction

■ Viral infection of the central nervous system may be occult.

- CSF pleocytosis may or may not be present in meningoencephalitis.

Specific viruses

■ HSV commonly produces a necrotizing encephalitis.

- Mothers of infected infants often have no symptoms of herpes infection during or before gestation.
 - Makes diagnosis of neonatal infection more difficult
- Herpes simplex encephalitis is classically heralded by temporal lobe seizures and olfactory hallucinations.

■ VZV and Epstein-Barr virus

- May infect cerebellum, producing an acute ataxia

■ Congenital syphilis

- Rash develops on palms and soles in many instances.

■ Arboviruses

- California virus encephalitis
 - Suspect in a child living in a known endemic region with signs of fever and cerebrocortical dysfunction.
 - The course is usually mild, with a fatality rate <5%.
- Western equine encephalitis
 - Primarily in infants
 - More severe syndrome than California virus
- Eastern equine encephalitis has a predilection for infants and young children.
- St Louis encephalitis occurs most often in epidemic form.
 - Produces illness in adults more often than in children
- The virus that causes Colorado tick fever produces dengue-like illness.

■ Rabies

- Long incubation period

■ Measles viruses

- Meningoencephalitis within 4–7 days after onset of rash
 - The severity of neurologic illness (including irritability, drowsiness, and ataxia) does not seem to be related to the intensity of systemic illness.

■ Rubella

- Mild febrile exanthem of childhood with prominent arthralgia
- As many as one-half of individuals are asymptomatic.
- Infection during first trimester of pregnancy may result in congenital rubella syndrome.
- A child affected with rubella in utero may be infectious for ≥ 12 months.

■ Mumps meningoencephalitis

- May occur without parotitis, before the appearance of parotitis, or after it has resolved

DIFFERENTIAL DIAGNOSIS

■ Laboratory tests require time to establish diagnosis of meningoencephalitis.

- The clinician must consider the differential diagnosis carefully.

■ Metabolic encephalopathy resulting from Reye syndrome or from lead, alcohol, or other toxins

- Can be ruled out by appropriate laboratory investigations

■ Brain abscess

- The clinical course is usually slower.
- Focal findings may be prominent.
- History of sinus infection, bronchiectasis, or congenital heart disease may be elicited.

■ Myelitic form of viral nervous system infection may be mimicked by mass lesion or Guillain-Barré syndrome.

■ Congenital lymphocytic choriomeningitis mimics congenital toxoplasmosis or CMV infection with chorioretinopathy, hydrocephaly, or microcephaly.

DIAGNOSTIC APPROACH

■ Every attempt should be made to identify the offending organism to:

- Help determine prognosis
- Document potential epidemic outbreaks

LABORATORY FINDINGS

■ Typical CSF alterations among patients with meningoencephalitis consist of:

- Mild pleocytosis
- Slight increase in protein level
- No alteration in glucose concentration

- Erythrocytes in the CSF may indicate hemorrhagic brain necrosis.
 - Commonly seen with HSV infections and Eastern equine encephalitis
- Predominance of mononuclear cells in CSF is the exception in acute bacterial meningoencephalitis.
 - May be present with:
 - Syphilis
 - Lyme disease
 - Listeriosis
 - Tuberculosis
- Polymerase chain reaction
 - Powerful tool in identifying enterovirus, mumps virus, CMV, VZV, and other viruses
 - Polymerase chain reaction of CSF in patients with herpes simplex encephalitis is 98% specific and 94% sensitive.
 - Rapid-screening test for Epstein-Barr virus (Monospot) is available at most hospitals.
- Typical CSF findings in meningoencephalitis and bacterial meningitis
 - Viral meningoencephalitis
 - Leukocytes
 - Initial predominance of polymorphonuclear neutrophils, followed by shift to mononuclear cells
 - Range, 0–2000 cells/mm³
 - Glucose
 - >50% of serum concentration
 - Protein
 - Mild to moderate increase
 - Range, usually <200 mg/dL
 - Gram stain
 - Negative
 - Bacterial meningitis
 - Leukocytes
 - Predominantly neutrophils
 - Range, 0–200,000 cells/mm³
 - Protein
 - Marked increase
 - Range, usually >150 mg/dL
 - Gram stain
 - Usually reveals bacteria

IMAGING

- Magnetic resonance imaging
 - Viral encephalitis shows:
 - Diffuse scattered or confluent areas of T2-weighted hyperintensities that are isointense or hypointense on T1-weighted imaging

- In more severe cases, increased intracranial pressure (ventricular compression) or cerebral cortical enhancement
- Temporal lobe enhancement or necrosis may be evidence of HSV infection.

DIAGNOSTIC PROCEDURES

- Electroencephalography
 - Periodic pattern in infant with partial motor seizures and signs of meningoencephalitis is diagnostic of HSV encephalitis.
- Biopsy
 - Newborns with cutaneous vesicles thought to have herpes simplex meningoencephalitis need not undergo brain biopsy to establish the diagnosis.
 - Attempts should be made to isolate the virus from throat, eye, or cutaneous lesions or from blood, urine, stool, and CSF.

TREATMENT APPROACH

- Treatment of patient with meningoencephalitis is supportive and includes:
 - Reducing high intracranial pressure
 - Providing respiratory support
 - Treating seizures
 - Maintaining fluid and electrolyte balance
 - Two-thirds of infants with aseptic meningitis develop inappropriate secretion of antidiuretic hormone.
- Corticosteroids have not proved useful in treating meningoencephalitis and may blunt host defenses.

SPECIFIC TREATMENTS

HSV infection

- Specific treatment of acute viral infections of the nervous system is indicated in herpes simplex infections of the central nervous system.
 - Although it is nephrotoxic, acyclovir is the drug of choice.
 - Generally well tolerated by neonates and children with renal dysfunction

CMV infection

- Ganciclovir has been approved for use in CMV infections.
- α -Interferon has been used as prophylaxis against CMV in immunocompromised children, but not as adjunct therapy in meningoencephalitis.

HIV infection

- 17 HIV drugs are currently available, including:
 - Nucleoside and nonnucleoside reverse transcriptase inhibitors
 - Protease inhibitors
 - Fusion inhibitors

- Intravenous immunoglobulin may be of benefit.
 - Known to contain viral antibodies for specific viral infections
 - Nonspecific immunoglobulin preparations have been used as replacement therapy or as adjuncts to treatment of meningoencephalitis in immunodeficient patients.
 - Immunoglobulin therapy for overwhelming viral sepsis remains controversial.

VZV infection

- α -Interferon has been used as prophylaxis against VZV in immunocompromised children.
 - Not as adjunct therapy in meningoencephalitis

WHEN TO ADMIT

- Patients with meningoencephalitis who have increased intracranial pressure, intractable seizures, and altered mental status must be admitted

WHEN TO REFER

- Patients with meningoencephalitis who have increased intracranial pressure, intractable seizures, and altered mental status must be managed with the help of infectious diseases and critical care medicine specialists.

ONGOING CARE

- Every child who has a documented or suspected viral nervous system infection must be carefully monitored.
 - Auditory aftereffects
 - Visual aftereffects
 - Cognitive aftereffects
 - These children are at risk for cerebral cortical dysfunction.

COMPLICATIONS

- The more benign meningoencephalitides of infancy (ie, those caused by enteroviral infection)
 - May result in substantial reductions in head circumference, intelligence, and learning ability
- California encephalitis
 - Causes emotional or learning disorders in 15% of affected children
- Epstein-Barr virus
 - Focal epilepsy may be a sequelae of a mild encephalitis caused by Epstein-Barr virus.
- Measles
 - An unusual syndrome of dementia and myoclonic seizures can develop in school-aged children many years after measles infection or immunization.
 - Results from persistent measles infection known as *subacute sclerosing panencephalitis*
 - Syndrome of subacute measles encephalitis has also been reported in immunosuppressed individuals.

PROGNOSIS

- Eastern equine encephalitis
 - Usually fatal
 - Patients who survive are severely impaired.
- Western equine encephalitis
 - Associated with complete recovery in adults
 - Causes death in 20% of children
 - Has a high prevalence of neurologic sequelae among survivors
- HSV necrotizing encephalitis
 - 50–70% of untreated cases are fatal.
 - Two-thirds of patients who survive have neurologic sequelae.
- Measles meningoencephalitis
 - Mortality approximates 10%.
 - As many as one-half of survivors may have neurologic sequelae.
- Rabies
 - Has highest case fatality of any infection
 - Invariably produces meningoencephalitis
 - All but 1 of the reported cases of rabies encephalitis have been fatal.
- Mumps meningoencephalitis
 - Mild illness that generally has a good prognosis
- RMSF
 - Case-fatality rate may be as high as 30%.

PREVENTION

- Prevention is the most cost-effective method of reducing morbidity and mortality caused by viral meningoencephalitis.
- Immunization
 - Has reduced, but not eliminated, poliomyelitis
 - Has made rubella, mumps, and measles meningoencephalitis uncommon
 - Repeat measles immunizations of older children should reduce the incidence of measles encephalitis and subacute sclerosing panencephalitis further.
- Use of varicella vaccine may reduce incidence of VZV infections.
- Prohibition of beef products in cattle feed has reduced incidence of both new-variant CJD and BSE.
- Mosquito and other insect controls

Microcephaly

DEFINITION

- *Microcephaly* refers to having a head size ≥ 2 standard deviations below the mean (below the third percentile).
 - Norms based on age and sex
 - May be neurologically normal, especially if very close to the third percentile curve
 - Head size >3 standard deviations below the mean (~ 0.2 percentile) is probably associated with neurologic impairment.
- *Micrencephaly* refers to having a small brain.
 - Leads to a small head size
- Compare with *craniosynostosis*—premature closure of sutures (with normal brain growth).

EPIDEMIOLOGY

- Prevalence
 - By definition, approximately 2.5% of all children are microcephalic.

MECHANISM

- Microcephaly is a clinical finding, and the mechanism for development of microcephaly depends on its cause.
- Possible causes include:
 - Small brain/abnormal brain development
 - Genetic syndromes
 - Intrauterine environment
 - Infections (meningitis)
 - Severe malnutrition
 - Traumatic brain injury, including shaken baby syndrome
 - Craniosynostosis

HISTORY

- Medical history, including
 - Previous infections, such as meningitis
 - Results of neuroimaging studies
- Review of systems, including:
 - Feeding difficulties
 - Seizures
- Family history
 - Construct a pedigree, noting genetic syndromes, miscarriages, and microcephaly.
- Prenatal history
 - Explore potential toxin exposure (alcohol, drugs).
 - Review maternal health during pregnancy.
 - Review records and assess the likelihood of intrauterine infections.
 - Review records and assess the likelihood of placental insufficiency.

- Discuss psychosocial factors, including history of prenatal care and maternal education.
- Developmental history
 - Include a chronology of developmental milestones.
 - Assess the child's current function and behavior.
 - Note any developmental regression.

PHYSICAL EXAM

Vital signs and anthropometrics

- Measure stature, weight, and head circumference.
 - Perform these at each well-child visit.
 - Measure head circumference with a flexible, nonstretchable tape.
 - Measure above the supraorbital ridges and across the occipital prominence.
 - This occipitofrontal circumference correlates with brain volume.
 - Consider repeating suspicious measurements yourself.
 - Plot measurements on standardized charts.
 - Centers for Disease Control and Prevention growth charts from 2000 include curves for the 3rd and 97th percentiles.
 - Adjust head circumference for prematurity until approximately 2 years of age.
 - In infants with birth weight <1000 g, use corrected age until 3 years of age (or until growth has caught up to normal).
 - Use charts specific to special populations when indicated (eg, Down syndrome, Williams syndrome, achondroplasia, very-low-birth-weight infants)
 - For children >36 months, may use head circumference curves developed by Nellhaus
 - Measuring over time allows early identification of when percentiles are crossed, even if measurements are still within normal ranges.
 - Disproportionately small head circumference, with respect to stature and weight, may indicate a central nervous system condition.
 - Measure head circumferences of other family members as possible.
 - Evaluate heart rate, respiratory rate, and blood pressure for Cushing triad (bradycardia, irregular respirations, hypertension).
- ### Physical examination
- Inspect and palpate skull, looking for asymmetry and bony ridges.
 - Bony ridges may suggest craniosynostosis.
 - Examine for features of genetic conditions.
 - Characteristic facies (eg, Seckel syndrome, Down syndrome, de Lange syndrome)

- Evidence of involvement of other organ systems, such as:
 - Ocular abnormalities (eg, colobomas, cataracts)
 - Congenital heart disease
 - Genitourinary abnormalities (eg, cryptorchidism)
 - Examine for neurologic abnormalities indicative of potential central nervous system malformation
 - Pupils, extraocular muscles, visual fields, smell, and cranial nerve functions
 - Funduscopic examination for papilledema
 - Assess for asymmetries, abnormalities in muscle tone, posture, strength, and reflexes.
- ### DIFFERENTIAL DIAGNOSIS
- Asymptomatic familial microcephaly
 - Small head size in context of normal development, normal neurologic examination, and family history
 - Genetic causes (primary microcephaly)
 - Small brain/abnormal brain development
 - Microcephaly vera (“true microcephaly”)
 - Brain size usually 3 standard deviations below the mean
 - Brain architecture grossly normal
 - Patients almost always have mental retardation but have otherwise unremarkable neurologic examination.
 - May see sloping forehead and prominent ears
 - Microcephaly with severe neurologic impairment (seizures, spasticity, and/or global developmental delays)
 - More common than microcephaly vera
 - Neuroimaging may identify abnormal brain architecture
 - Genetic syndromes
 - Miller-Dieker lissencephaly (17p; deletion/mutation of *LIS1* gene)
 - Small smooth brain/lissencephaly, facial dysmorphism, severe mental retardation
 - Seckel syndrome (multiple possible loci: 3q, 18, 14q; autosomal recessive)
 - Low birth weight, intrauterine growth restriction
 - Growth delays after birth resulting in short stature
 - Bird-headed appearance (“beak-like” protrusion of nose, abnormally large eyes, narrow face, malformed ears, small jaw)
 - Varying degrees of intellectual disability
 - Rubinstein-Taybi syndrome (22q, 16p; autosomal dominant; mutation in CREB binding protein)
 - Characteristic facial features, moderate to severe mental retardation, broad thumbs and toes
 - Other findings may include coloboma, cataract, congenital heart disease, renal abnormalities, and cryptorchidism.
 - Trisomy 21
 - Distinct facial features, congenital heart anomalies, and growth retardation
 - Trisomy 13
 - de Lange syndrome (multiple possible loci: 5p, Xp, 10q; mutation in cohesin complex)
 - Growth retardation; hirsutism; and unusual facial features, such as synophrys and low anterior hairline
 - Microcephaly is almost always present at birth.
 - Rett syndrome (X chromosome; mutation in gene encoding MECP2)
 - Condition of decelerating head growth, almost exclusively in females; majority of cases appear to be sporadic
 - Developmental regression, autistic features, and unusual hand mannerisms (hand-wringing and hand-washing movements)
 - Environmental causes (secondary microcephaly)
 - Intrauterine environment/perinatal time frame
 - Teratogens
 - Fetal alcohol syndrome
 - Intrauterine growth restriction
 - Small palpebral fissures, smooth philtrum and thin upper lip
 - Heart and eye defects
 - Behavioral and cognitive deficits
 - Maternal metabolic disease
 - Untreated maternal phenylketonuria and hyperphenylalaninemia may produce findings similar to those of fetal alcohol syndrome: facial dysmorphism, intellectual disability, and heart defects.
 - Intrauterine infections (eg, TORCH [toxoplasmosis, other agents, rubella, cytomegalovirus, and herpes simplex])
 - Maternal health problems
 - Intrauterine irradiation
 - Hypoxic-ischemic encephalopathy
 - Severe perinatal asphyxia is an important cause of acquired microcephaly
 - Normal head circumference at birth, but head growth decelerates
 - May be detected as early as 6 weeks of age; these infants develop significant neuromotor and cognitive deficits.
 - Infections
 - Meningitis
 - Severe malnutrition
 - Traumatic brain injury, including shaken baby syndrome

- Craniosynostosis (multiple sutures; problem of skull, not brain)
 - Head circumference may be small at birth, or head growth may abruptly cease during infancy.
 - Asymmetric skull with bony ridging in the areas of fused sutures
 - Increased intracranial pressure may be present.

LABORATORY EVALUATION

- Laboratory evaluation is guided by clinical suspicion.
- In children with possible intrauterine infection
 - Test for perinatal infections
 - Toxoplasmosis
 - Rubella
 - Cytomegalovirus
 - Syphilis
 - HIV
 - Herpes
 - Ophthalmologic and audiologic evaluations
- If a genetic syndrome is suspected, perform a focused evaluation, consulting experts in genetics as needed.
 - Karyotype
 - Genetic testing is available for:
 - Miller-Dieker syndrome
 - Rett syndrome

IMAGING

- Neuroimaging may help to identify abnormal brain architecture, such as:
 - Holoprosencephaly
 - Lissencephaly
 - Schizencephaly
 - Pachygyri
 - Polymicrogyri
 - Heterotopias
 - Midline defects (agenesis of corpus callosum)
- Imaging modalities include:
 - Magnetic resonance imaging (MRI)
 - Use when the following are suspected.
 - Gray and white matter disease
 - Migration defects, such as lissencephaly, pachygyria, and polymicrogyria
 - MRI is limited in its ability to study bone and calcifications.
 - Computed tomography
 - Use when the following are suspected.
 - Intracranial calcifications due to intrauterine infections
 - Skull abnormalities, as seen with premature fusion of cranial sutures
 - Ventricular system abnormalities

- Radiography of the skull
 - Can demonstrate intracranial calcifications
 - Can show characteristic bone findings in craniosynostosis
 - Cannot detect abnormalities in brain structure
- Ultrasonography
 - Useful in infants because of open fontanelles

TREATMENT APPROACH

- Treatment is largely supportive, with targeted therapies to address functional disabilities.
- Refer to early intervention and special education services as needed.

SPECIFIC TREATMENT

- Children with microcephaly may have multiple medical issues; treatments depend on the individual.
- There is a reported risk of cardiac arrhythmia with use of succinylcholine in children with Rubinstein-Taybi syndrome.

WHEN TO REFER

- Head circumference >2 standard deviations below the mean (especially >3 standard deviations)
- Deceleration of head growth
- Dysmorphic features
- Abnormal neurologic examination and development
- Regression in motor, language, and social skills
- Seizures
- Suspected craniosynostosis

WHEN TO ADMIT

- Signs of increased intracranial pressure
- Mental status changes

FOLLOW-UP

- Children with microcephaly may require close follow-up for developmental issues.

PREVENTION

- Prevention
 - Appropriate prenatal care
 - Maternal education and nutrition
 - Avoidance of teratogenic substances
 - Screening for intrauterine infections
 - Management of maternal health conditions
- Genetic counseling may be offered to parents if genetic disorders are identified.

Mononucleosis and Epstein-Barr Infections

DEFINITION

- Epstein-Barr virus (EBV) is a member of the herpesvirus group.
- EBV infections can produce infectious mononucleosis.

EPIDEMIOLOGY

- Prevalence
 - Infection with EBV is extremely common.
- Age/socioeconomics
 - EBV antibodies are developed in:
 - 70–90% of children from low socioeconomic groups by 5 years of age
 - 40–50% of children from high socioeconomic groups
 - Primary infections that do not occur until adolescence and young adulthood are much more likely to produce infectious mononucleosis.
 - Annual incidence (~1 in 2,500 students) of infectious mononucleosis is highest among white high school and college students.
- Geographic distribution
 - In Africa, a strong association exists between infection with EBV and development of Burkitt lymphoma and nasopharyngeal carcinoma.
 - This association is less clear in Western countries, where infection with EBV occurs at a later age.
 - In the US, interest in EBV infection centers on the typical clinical syndrome: infectious mononucleosis.
 - Studied for emerging relationship with an increasing number of tumors, noted for the most part in immunocompromised patients
- Transmission
 - In a study of families that have a childhood index case of infectious mononucleosis, seroconversion occurred in 34.6% of susceptible siblings over several months.
 - The rate of transmission of the EBV infection was relatively low and slow.
 - Development of infectious mononucleosis was high (55.6%) in sibling contacts who showed seroconversion.
 - Secondary infection in typical college settings is even lower.

ETIOLOGY

- Infection follows entry of the EBV into the oropharynx.
 - Recovery from this site can be documented up to 16 months after illness.
- EBV establishes latency in the epithelial cells of the oropharynx.
 - Virus is periodically shed from this site throughout an individual's lifetime.

RISK FACTORS

- Transmission from one individual to another appears to occur most often through mixing of saliva.
 - Described as the *kissing disease*
- In the absence of such contact, transfer of infection is unlikely.

SIGNS AND SYMPTOMS

- In childhood, EBV infection is usually inapparent clinically or characterized by a nonspecific, uncomplicated episode of upper respiratory tract infection or pharyngitis.
- The incubation period is 2–6 weeks (usually 20–30 days).
- Classic signs of infectious mononucleosis
 - Fever
 - Sore throat
 - Lymphadenopathy
- This constellation of symptoms and signs may be preceded by vague symptoms of:
 - Fatigue
 - Malaise
 - Anorexia
- Infectious mononucleosis is the result of a systemic viral infection.
 - Virtually every organ system may be involved.
- Clinical manifestations compatible with infectious mononucleosis include:
 - Fever
 - Usually not higher than 103°F (39.5°C)
 - Lymphadenopathy
 - Most striking feature of the illness
 - Can be limited to the cervical nodes
 - Can involve virtually all lymph node groups
 - Postero-cervical adenopathy is noted most frequently.
 - The lymph nodes are not tender and do not demonstrate other signs of inflammation.
 - Sore throat/tonsillopharyngitis
 - Can be excruciating
 - Frequently accompanied by tonsillar exudate and a palatal enanthem or a grayish necrosis of the tonsillar surfaces in adolescents
 - Splenomegaly
 - Some patients do not have any palpable splenic enlargement.
 - Hepatomegaly
 - Liver enzyme levels are elevated in virtually all patients.
 - Frequency of jaundice is low.
 - Rhinitis, cough

- Rash
 - In approximately 20% of children
 - Erythematous
 - Petechial
 - Erythema multiforme–like
 - Urticarial
 - Scarlatiniform
 - In 70–90% of young adult patients treated with ampicillin and can appear after the medication has been discontinued
- Abdominal pain
- Eyelid edema
 - In approximately 25%
- Severity of illness is extremely variable.
 - Some individuals may have relatively few manifestations of infection.
 - Others will demonstrate virtually all symptoms.
- Clinical manifestations last approximately 2–3 weeks.
 - Peak involvement during the second week

DIFFERENTIAL DIAGNOSIS

- Massive enlargement of the spleen should suggest an alternative diagnosis.
- EBV-negative infectious mononucleosis
 - Symptoms similar to those of EBV infection can be produced by:
 - Rubella
 - Hepatitis
 - Toxoplasmosis
 - Cytomegalovirus
 - Human herpesvirus-6
 - Adenovirus infections
 - Systemic lupus erythematosus
 - Drug reactions
 - Negative EBV titers and heterophil antibody responses strongly suggest one of these other agents or conditions as the cause.
 - In hepatitis:
 - Heterophil test can give a false-positive result.
 - Liver enzyme levels generally are much more elevated than those seen with infectious mononucleosis.
 - Results of serologic tests for hepatitis will be positive.
 - Rubella titers in rubella infection will be positive.
 - Cytomegalovirus can be cultured from urine as the cause of illness.

- Illnesses that mimic infectious mononucleosis but lack serologic confirmation of EBV should be classified as heterophil-negative infectious mononucleosis rather than atypical mononucleosis.
 - Cause of most of these cases is unknown.

DIAGNOSTIC APPROACH

- Diagnosed by the presence of a triad of findings
 - Clinical
 - Hematologic
 - Serologic
- Minimal hematologic features should include:
 - Lymphocytosis $\geq 50\%$ of all leukocytes
 - Atypical lymphocyte count $\geq 10\%$ of all leukocytes

LABORATORY FINDINGS

- General laboratory findings usually include a decrease in the number of granulocytes and platelets.
- Paul-Bunnell antibody, a heterophilic immunoglobulin (Ig)M antibody produced by humans during infection, is the cornerstone of laboratory diagnosis.
 - Will be present in $\leq 50\%$ of children < 4 years
 - Among school-age children and young adults, detectable 80–90% of the time during the second week of clinical illness
 - Heterophil response will be brief and minimal or will occur late in the illness.
 - Shows negative results early in the course of the illness
 - Commercial diagnostic kits rely on differential adsorption to detect the heterophil antibody.
 - Readily available and easy to use in a physician's office
 - 96–99% sensitive
 - Give a result in 2 minutes
 - False-positive results have been reported in cases of:
 - Rubella
 - Hepatitis
 - Serum sickness
 - Drug reactions
 - Systemic lupus erythematosus
 - Improper use of the kit
 - Inaccurate interpretation of the agglutination reaction
 - Magnitude of the heterophil antibody titer does not correlate with clinical severity.
 - Repeat testing, once a positive test result is obtained, provides no additional information beyond that gained from clinical assessment.
- If heterophil test results are negative and infection is strongly suspected, confirmation of EBV infection should be sought by other serologic tests.

Interpretation of Epstein-Barr Virus Serology^{a,b}

	Heterophil Antibody	Epstein-Barr Virus Antibodies			
		VCA-IgM	VCA-IgG	EA	EBNA
No infection	–	–	–	–	–
Acute infection	+/-	+	+ (>1:320)	+/-	–
Past infection	–	–	+ (1:80–1:160)	+/-	+

Abbreviations: EA, early antigen; EBNA, IgG antibody to Epstein-Barr nuclear antigen; VAC-IgG, IgG antibody to viral capsid antigen; VCA-IgM, IgM antibody to viral capsid antigen.

^a From: Sumaya CV, Ench Y. Epstein-Barr virus infectious mononucleosis in children. I. Clinical and general laboratory findings. *Pediatrics*. 1985;75(6):1003–1010.

^b Other patterns may occur in an individual patient; the above profile is for a typical individual.

- Patients who have negative heterophil test results will have antibodies against specific components of the virus if EBV is the cause of illness.
- A variety of antibodies directed against various portions of EBV can be detected.
- 4 different antibodies define the EBV serologic profile.
 - IgG antibody to the viral capsid antigen (VCA-IgG)
 - IgM antibody to viral capsid antigen (VCA-IgM)
 - IgG antibody to early antigen (EA)
 - IgG antibody to Epstein-Barr nuclear antigen (EBNA)
 - Includes 2 patterns: diffuse and restricted
 - These antibodies usually appear in an individual who acquires a primary EBV infection.
 - The pattern of antibody responses can help determine the date of EBV infection onset.
 - In most cases, an individual develops a VCA-IgM antibody (or VCA-IgG antibody) response in the acute period after an EBV infection.
 - IgG antibodies to the VCA persist for life.
 - VCA-IgM tends to disappear in 2–3 months.
 - Height of the VCA-IgG response decreases as the acute infection resolves.
 - Serial measurements of antibody titers are not clinically beneficial.
 - EA response peaks at 3–4 weeks into the illness.
 - Initially thought to persist only for several months
 - Was considered a good marker for an acute or recent infection
 - Recent evidence suggests that the EA response may persist for years in some children and may not develop at all in others.
 - EBNA antibody response usually appears several weeks to months after a primary infection.
 - Thought to be a marker for a past or convalescent infection
- Must be interpreted in light of the clinical situation
 - A large number of children develop this response in the acute phase of their infection.
 - 10–20% of individuals never develop detectable levels of antibody to EBNA.
- Children who acquire EBV infections typically develop antibodies in the same sequential pattern.
 - Not all patients follow the same pattern.
- Clinical judgment remains important in the interpretation of such findings.
- Interlaboratory variability in results of EBV antibody testing has been observed.
 - Reliability of tests is suspect in some cases.
 - If both heterophil test and specific serologic findings are negative, a non-EBV infectious mononucleosis–like illness should be suspected.
- The table above provides an interpretation of EBV serology.

TREATMENT APPROACH

- Most patients who have infectious mononucleosis recover uneventfully.
- Physicians need do little except:
 - Establish the diagnosis.
 - Explain the nature of the illness.
 - Reassure parents.
- No specific therapy is indicated.
- Patients should rest to the extent that they believe necessary.
- As long as the patient can consume adequate amounts of fluids and calories, hospitalization is unnecessary.
- To minimize the danger of splenic rupture, ambulatory patients should avoid strenuous physical exercise or contact sports for 1 month or until the spleen is no longer palpable.
- Patients who have a late-onset heterophil antibody response appear to have a prolonged convalescence.
- Accounts are rare but increasing of infectious mononucleosis episodes that are severe or fatal or result in significant long-lasting problems.

- Most of these patients had some form of immunological abnormality.
 - X-linked lymphoproliferative syndrome
 - Renal or bone marrow transplant
 - Chédiak-Higashi syndrome
- Definitive management of these patients remains unclear.

SPECIFIC TREATMENTS

Corticosteroids

- Corticosteroids are of unproved value in treating this illness.
 - Should not be used routinely merely to make the patient feel better
- Controlled studies documenting efficacy are lacking.
- Most clinicians believe that their use is justified in treating:
 - Severe hemolytic anemia
 - Significant airway obstruction secondary to tonsillar hypertrophy
 - Thrombocytopenia
- Some authorities suggest using corticosteroids if neurologic involvement is significant.
 - Proof of efficacy is not available.
- High-dose, short-term courses of steroids have been used with dramatic improvement typically noted over 24–72 hours.
 - Dexamethasone: 0.25 mg/kg every 6 hours
 - Methylprednisolone: 1 mg/kg every 6 hours
 - Oral prednisone: 40 mg/day

Antiviral agents

- Acyclovir has good activity against EBV in vitro.
 - Has not been shown to be beneficial in several clinical trials
 - At this time, routine use is not recommended.
- Several antivirals (acyclovir, ganciclovir, vidarabine) and immunomodulating agents (interferon- γ , interferon- α , interleukin-2) have been used in severe EBV infections.
 - Varying degrees of success
- Pharyngitis of infectious mononucleosis can be indistinguishable from that of streptococcal pharyngitis, and culture specimens of the pharynx should be obtained.
- Patients who have positive culture findings should be treated accordingly.
- Clinician should avoid using ampicillin or amoxicillin when EBV infection is suspected.
 - Rash develops in most young adults with EBV infection who receive this drug.
- Ampicillin effect has not been well demonstrated in young children with infectious mononucleosis.

Experimental approaches

- Approaches under investigation for the treatment of EBV-associated lymphoproliferative disease include:
 - Bone marrow transplantation
 - Treatment with monoclonal antibodies
 - Infusions of donor peripheral leukocytes

WHEN TO ADMIT

- Hospitalization may be necessary in the presence of:
 - Airway compromise
 - Splenic rupture
 - Neurologic complications
 - Severe hemolytic anemia
 - Thrombocytopenia

WHEN TO REFER

- Consultation with appropriate subspecialists for the complications listed below would be warranted.
 - Airway compromise
 - Splenic rupture
 - Neurologic complications
 - Severe hemolytic anemia
 - Thrombocytopenia

FOLLOW-UP

- Many patients with chronic fatigue syndrome date the onset of their illness to an episode of infectious mononucleosis.
- Virologic and clinical studies have confirmed that active EBV infection is not responsible for the illness.
- At present, no single infectious or other cause has been identified for chronic fatigue syndrome.

COMPLICATIONS

- Death occurs in approximately 1 in 3000 cases.
 - True complication and death rates during this illness are uncertain.
 - Many reports do not include strict diagnostic criteria for infectious mononucleosis.
- Relative frequencies (approximate) of more common complications associated with this illness from one study
 - Pneumonia—5%
 - Severe airway obstruction—3.5%
 - Seizures—4%
 - Meningitis, encephalitis—2%
 - Peripheral facial nerve paralysis—1%
 - Guillain-Barré syndrome—1%
 - Thrombocytopenia with hemorrhages—3.5%

- Hemolytic anemia—1%
- Bacteremia—1%
- Recurrent tonsillopharyngitis—3%
- Jaundice—2%
- Glomerulonephritis —1%
- Orchitis—1%
- Abdominal pain is an infrequent symptom of this illness.
 - Its appearance, particularly if severe and in the left upper quadrant, should alert the clinician to the possibility of impending or actual splenic rupture.
- Fatal cases of Reye syndrome associated with serologic evidence of EBV infection have been reported.
- EBV infection and cancer
 - Some have speculated that EBV infection might be oncogenic in the US.
 - Some cases of leukemia occurring shortly after the onset of infectious mononucleosis have been reported.
 - No other evidence exists to support this speculation.
 - The association between EBV and classic Burkitt lymphoma is not as strong in the US as in Africa.
- The EBV genome can be detected in approximately 50% of Reed-Sternberg cells found in patients with the mixed cellularity form of Hodgkin lymphoma.
 - Whether EBV is a causal agent, or even a cofactor, is unknown.
- EBV has also been associated with several lymphoreticular cancers in patients with AIDS.
 - Malignant B-cell lymphoma
 - Colonic lymphoid hyperplasia
- EBV has been associated with:
 - Oral hairy leukoplakia
 - Lymphoid interstitial pneumonitis in individuals with AIDS
- The precise relationship between EBV and cancer remains unknown and is the subject of intense investigation.

PREVENTION

- Secondary infection in typical college settings is low.
 - Strict isolation of the patient is unnecessary.
 - Separation of drinking and eating utensils should suffice.

Mood Disorders

DEFINITION

- Mood disorders include major depressive disorder, dysthymic disorder, adjustment disorder, bipolar affective disorder, and cyclothymic disorder.
- Major depressive disorder requires ≥ 2 weeks of depressed mood more than one-half of the time and 4 additional depressive symptoms.
- Dysthymic disorder may have periods of depression interspersed with normal mood.
- Adjustment disorder is a mild, self-limited disturbance of mood that follows a serious life stressor.
- Manic symptoms with dysthymia is diagnosed as bipolar affective disorder.
- Manic symptoms with major depression is diagnosed as cyclothymic disorder.

EPIDEMIOLOGY

- Age
 - Relatively rare in prepubertal children; point prevalences range from 1.8–2.9%
 - Incidence is 3–4 times more common in adolescence.
 - Approximately 3–8% experience depression.
 - Bipolar disorder is diagnosed in 1–2%.
 - Bipolar spectrum is diagnosed in 5–7%.
 - Rate of bipolar disorder is twice as high in adolescents as in prepubertal children.
- Sex
 - Sex ratio for affectively ill prepubertal children approaches unity.
 - Depression among adolescents is 2–3 times more common among girls than boys.
 - Earlier onset of puberty may be associated with an increased risk of depression, especially in girls.

ETIOLOGY

- Childhood depression is associated with:
 - Serotonergic and noradrenergic neurotransmission abnormalities, as demonstrated by altered response to neuroendocrine challenges
 - Structural and functional alterations in the prefrontal cortex and the limbic system
- Genetics
 - Adoption, twin, and linkage studies support a genetic component.
 - Genetic epidemiologic studies suggest that depression results from an interaction between genetic vulnerability and accumulated stressful life events.

RISK FACTORS

- Depression
 - Family history
 - ≥ 1 parent with a history of depression
 - Earlier age of onset of depression in parent(s)
 - Family history of bipolarity or recurrent unipolar disorder
 - Previous psychiatric disorder and family history of depression predispose to the development of depression following bereavement.
 - Age
 - In girls, early onset of puberty may be a risk factor.
 - Severe stressors, such as physical or sexual abuse
 - Exposure to family and community violence
 - Anxiety disorders
 - Medications
 - Antihypertensive agents
 - Steroids
 - Phenobarbital
 - Chronic illnesses
 - Epilepsy
 - Inflammatory bowel disease
 - Juvenile-onset diabetes

SIGNS AND SYMPTOMS

Criteria for diagnosis of a major depressive episode

- ≥ 5 of the following symptoms during the same 2-week period, representing a change from previous functioning (must have 1 of first 2):
 - Depressed mood most of the day, nearly every day, indicated by either:
 - Subjective report (eg, feels sad or empty)
 - Observation by others (eg, appears tearful or irritable)
 - Markedly diminished interest or pleasure in most or all activities most of the day, nearly every day, by:
 - Subjective account
 - Observation made by others
 - Significant weight loss without dieting, or weight gain (change in body weight $>5\%$ in 1 month), or decrease or increase in appetite nearly every day
 - Consider failure to make expected weight gains as weight loss.
 - Insomnia or hypersomnia nearly every day
 - Psychomotor agitation or retardation nearly every day:
 - Observable by others, not merely subjective feelings of restlessness or being slowed down
 - Fatigue or loss of energy nearly every day

- Feelings of worthlessness or excessive or inappropriate guilt
 - May be delusional nearly every day
 - May not merely be self-reproach or guilt about being sick
- Diminished ability to think or concentrate, or indecisiveness nearly every day, either by:
 - Subjective account
 - Observations of others
- Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, suicide attempt, or specific plan for committing suicide
- Symptoms do not meet criteria for a mixed episode.
- Symptoms cause clinically significant distress or impairment in social, occupational, or other important areas.
- Symptoms are not due to physiologic effects of:
 - A substance (eg, a drug of abuse, a medication)
 - General medical condition (eg, hypothyroidism)
- Symptoms are not better accounted for by bereavement (ie, after the loss of a loved one).
- Symptoms persist for >2 months or are characterized by marked functional impairment, morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation.

Criteria for diagnosis of dysthymic disorder

- Depressed mood most of the day, for more days than not
 - In children and adolescents, mood can be irritable or depressed.
 - Duration must be ≥ 1 year.
- Presence, while depressed, of ≥ 2 of the following:
 - Poor appetite or overeating
 - Insomnia or hypersomnia
 - Low energy or fatigue
 - Low self-esteem
 - Poor concentration or difficulty making decisions
 - Feelings of hopelessness
- During the 1-year period of the disturbance, the person has never been free of the above symptoms for ≥ 2 months at a time.
- No major depressive episode during 1 year of the disturbance
 - Disturbance is not better accounted for by chronic major depressive disorder or by major depressive disorder in partial remission.
 - After the initial year of dysthymic disorder, episodes of major depressive disorder may be superimposed.
 - Both diagnoses may be given when the criteria for a major depressive episode are met.
- Patient has never had a manic, mixed, or hypomanic episode, and criteria for cyclothymic disorder have never been met.
- The disturbance does not occur exclusively during the course of a chronic psychotic disorder (eg, schizophrenia or delusional disorder).
- Symptoms are not due to the physiologic effects of:
 - A substance (eg, a drug of abuse, a medication)
 - A general medical condition (eg, hypothyroidism)
- Symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Criteria for diagnosis of adjustment disorder with depressed mood

- Development of emotional or behavioral symptoms in response to an identifiable stressor(s) within 3 months of the onset of the stressor(s)
- Clinically significant symptoms or behaviors, evidenced by either:
 - Marked distress in excess of what would be expected from exposure to the stressor
 - Significant impairment in social or occupational (academic) functioning
- The disturbance does not meet the criteria for another specific axis I disorder and is not merely an exacerbation of a preexisting axis I or axis II disorder.
- Symptoms do not represent bereavement.
- Once the stressor (or its consequences) has terminated, the symptoms do not persist for more than an additional 6 months.

Criteria for diagnosis of bipolar disorder

- Past or current history of a manic episode, characterized by:
 - Distinct period of abnormally and persistently elevated, expansive, or irritable mood, lasting ≥ 1 week (or any duration where hospitalization is necessary)
 - During the period of mood disturbance, ≥ 3 of the following have persisted (4 if the mood is only irritable) and have been present to a significant degree.
 - Inflated self-esteem or grandiosity
 - Decreased need for sleep (eg, feels rested after only 3 hours of sleep)
 - More talkative than usual, or pressure to keep talking
 - Flight of ideas or subjective experience that thoughts are racing
 - Distractibility (ie, attention too easily drawn to unimportant or irrelevant external stimuli)
 - Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation
 - Excessive involvement in pleasurable activities that have a high potential for painful consequences (unrestrained buying sprees, sexual indiscretions)
- Symptoms do not meet criteria for a mixed episode.
- Mood disturbance includes either:
 - Marked impairment in academic functioning or in usual social activities or relationships with others

- Necessity for hospitalization to prevent harm to self or others
- Psychotic features
- Symptoms are not due to the direct physiologic effects of:
 - A substance (eg, a drug of abuse, a medication)
 - Other treatment
 - General medical condition (eg, hyperthyroidism)

Criteria for diagnosis of cyclothymic disorder

- For ≥ 1 year, numerous periods with hypomanic symptoms and numerous periods with depressive symptoms that do not meet criteria for a major depressive episode
- During the 1-year period, the patient has not been free of the above symptoms for ≥ 2 months at a time.
- No major depressive episode, manic episode, or mixed episode has been present during 1 year of the disturbance. The symptoms are not better accounted for by schizoaffective disorder and are not superimposed on:
 - Schizophrenia
 - Schizophreniform disorder
 - Delusional disorder
 - Psychotic disorder not otherwise specified
- Symptoms are not due to the direct physiologic effects of:
 - A substance (eg, a drug of abuse, a medication)
 - A general medical condition (eg, hyperthyroidism)
- Symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

DIFFERENTIAL DIAGNOSIS

- Within depressive disorders, the main differential diagnosis is among the triad of dysthymia, depression, and adjustment disorder with depressed mood.
 - Dysthymia
 - More chronic and intermittent depression than major depression
 - The 2 disorders can coexist (so-called double depression).
 - Adjustment disorder with depressed mood
 - Less severe mood disturbance
 - Fewer symptoms
 - Self-limited compared with dysthymia or major depression
 - If a life stressor precedes a syndrome of depression, the presence of the stressor does *not* invalidate the diagnosis of major depressive disorder.
- Symptoms of bereavement may be hard to distinguish from depressive symptoms.
 - Depression is diagnosed if bereavement is associated with:
 - Functional impairment
 - Suicidal ideation

- Psychotic features
- Feelings of worthlessness
- Prolonged course
- Other psychiatric disorders that may have associated mood disturbances
 - Learning disabilities or attention-deficit/hyperactivity disorder (ADHD)
 - Patients may have poor self-esteem and feel demoralized.
 - Depression should not be diagnosed in these patients unless they meet the criteria for the syndrome.
 - Poor concentration is characteristic of both ADHD and depression.
 - ADHD usually has an earlier onset and is not associated with anhedonia or social withdrawal.
 - Anxiety disorder
 - Children are often dysphoric when separated from their parents.
 - In the absence of premorbid depression, reunion with the parent relieves the dysphoria.
 - Patients who are anorectic, particularly if malnourished, may show a markedly depressed affect.
 - Depression should not be diagnosed until nutritional status has been normalized.
 - Abusers of drugs and alcohol often show disturbances of mood.
 - Mood disorder may antedate and even predispose the individual to substance abuse.
 - Mood disorder is often secondary to substance abuse and subsides within a month of detoxification.
 - Distinguishing depression from chronic medical illness can be difficult.
 - Depression may be higher in certain illnesses.
 - Chronic illness may affect sleep, appetite, and energy similarly to depression.
 - Feelings of guilt, worthlessness, hopelessness, and suicidal thoughts are unlikely to be attributable to the illness itself.
 - If present, strongly suggest a depressive disorder
 - Mania
 - Abuse of stimulants (eg, cocaine, amphetamine) can mimic symptoms of mania.
 - The irritability of mania also can be seen in depression.
 - Distinguishing depression from mania rests on whether the preponderance of associated symptoms is more consistent with mania or with depression.
 - Euphoria, increased energy, and increased sexuality are much more common in patients with bipolar disorder than in those with unipolar (ie, only experiencing depression) disorder.

- Irritability, anger, and poor judgment also may be prominent features of conduct disorder.
 - Lack of changes in energy, sleep, sexuality, and thought patterns generally exclude mania as a diagnosis.
- Features of ADHD may suggest mania, but patients with mania are more likely to:
 - Have mood swings and alterations in sleep and appetite
 - Show hypersexuality and inappropriate joking and punning
- Severe clinical deterioration of a patient with an attention-deficit disorder after a trial of stimulants suggests bipolar disorder.
 - Particularly with some of the manic clinical features mentioned earlier or with a positive family history of mania
- Sexually abused children
 - May show sexually provocative behavior and depressed mood
 - However, euphoria or increased energy in the absence of bipolar disorder is rarely seen.

DIAGNOSTIC APPROACH

- Both child and parent usually contribute important information used in diagnosing depression.
 - The child is likely to be the most accurate reporter of symptoms referring to an internal state, such as:
 - Depressed mood
 - Anhedonia
 - Guilt
 - Worthlessness
 - Suicidal thoughts
 - The parent may be able to note externally validated symptoms, such as:
 - Irritability
 - Decline in school performance
 - Listlessness
 - Withdrawal from social and other pleasurable activities
 - Weight loss
- Mood disorder is classified on the basis of 3 factors:
 - Severity
 - Course
 - Presence or absence of mania
- Suspicion for depression should be high when the patient exhibits substantial alteration of mood with evidence of a decline in function.
- Important in identifying mood disorder is to recognize that the depressed mood may be described as grouchy, mad, or bored rather than sad.
- A brief self-report, the *Mood and Feelings Questionnaire*, can be useful in identifying which children have depression and need more specialized treatment.

TREATMENT APPROACH

- Mood disorders are best managed by collaboration among a pediatrician, mental health specialist, and child psychiatrist.
- Generally, psychiatric intervention has 3 components.
 - Psychoeducation
 - Psychotherapy
 - Pharmacotherapy
- Most patients with mood disorder can be managed as outpatients.
- Family psychoeducation approaches depression as a chronic illness, aiming to instruct the family about the nature and course of the illness.
 - This is likely to improve adherence with treatment.
 - May reduce the rate of relapse
 - Psychoeducation reduces the tensions of living with a person with mood disorder by altering familial expectations.
 - Parents' accepting the illness and making appropriate expectations of the patient and of themselves
 - Psychoeducation should enable the child and family to:
 - Identify early signs of recurrence
 - Seek treatment before recurrent disorder becomes severe and chronic
 - Identification and treatment of parental depression are critical.
 - Evidence suggests that parental depression may prolong the child's depressive episodes and interfere with recovery.
- Depressed patients with a family history for bipolar disorder should be treated initially with psychotherapy.
 - If they require an antidepressant, they should be monitored closely for emergent manic symptoms.
 - Other side effects include:
 - Drowsiness
 - Extrapyrarnidal symptoms
 - Galactorrhea
 - More rarely, tardive dyskinesia
- Treatment for bipolar disorder includes:
 - Mood stabilizers for prophylaxis and acute treatment of manic or depressive episodes
 - Encouragement of continued treatment after normalization of mood
 - Psychoeducation for the patient and family is key.

SPECIFIC TREATMENTS

Cognitive-behavioral therapy (CBT) for depression

- Brief CBT (3 months) is more efficacious than credible alternative treatments (family, supportive, or relaxation therapies) for adolescent depression.
- Group CBT is helpful both for treating depression and for preventing depression in at-risk youth.
- Combination of CBT and medication
 - Results in highest remission rate and a trend toward lower rates of suicidal adverse events
 - In more severe depression, may be no better than fluoxetine alone
- Interpersonal psychotherapy is efficacious in treating adolescent depression.
 - Has not been compared with antidepressant medication

Pharmacologic treatment for depression

Selective serotonin reuptake inhibitors (SSRIs)

- Somewhat effective
 - The strongest data support the use of fluoxetine.
 - The only SSRI with US Food and Drug Administration (FDA) approval for treatment of pediatric depression
- Standard approach
 - The equivalent of 10 mg of fluoxetine for 1 week, then increase to 20 mg for 3 more weeks
 - If the patient does not show an adequate clinical response to increase, the dose is increased to 40 mg.
- Adolescents who do not respond to the first SSRI
 - The standard is to try another SSRI at an adequate dose for 6–8 weeks.
 - Establishing adherence and ruling out possible medical problems, such as hypothyroidism that might contribute to lack of response, are important.
 - If patient shows partial response, consider augmentation with lithium, which is effective in adults.
 - If there is complete lack of response, switch to another type of agent, such as bupropion.
 - Addition of psychotherapy may enhance treatment response.
- The FDA has determined that SSRIs are associated with an increased risk of suicidality (ie, suicidal ideation and behaviors) compared with placebo.
 - Recommends close monitoring for clinical response and adverse events during the early phase of treatment
 - Weekly for the first month
 - Every other week for the next 2 months
 - Monthly thereafter

- This adverse effect emerges early in treatment.
 - Most often characterized by new-onset or worsening suicidal ideation; a suicidal threat; or much more rarely, a suicide attempt
- In the FDA's review of clinical trials involving ≥ 4300 pediatric patients, no suicides occurred.
 - The rate of emergent or worsening suicidality was, on average, 4% in the antidepressant group and 2% in the placebo group.
- Although many more patients will benefit from SSRIs than will experience suicidality, SSRIs should be prescribed only:
 - When patients and families understand the risks and benefits, *and*
 - The physician can monitor progress and side effects on a regular basis.
- 2–5% of patients treated with SSRIs develop manic symptoms.
 - Expansive mood
 - Racing thoughts
 - Increased energy
 - Decreased need for sleep
 - Increased risk taking
 - Risk is higher in younger patients and in persons with a positive family history for bipolar disorder.

Tricyclic antidepressants

- An older type of antidepressant
- Should not be prescribed as a first-line treatment because:
 - Not efficacious for treating pediatric depression
 - Are potentially lethal in overdose

Pharmacologic treatment for bipolar disorder

- If the patient is exhibiting acute mania, administer either:
 - Lithium *or*
 - Anticonvulsant mood stabilizers (divalproex or carbamazepine) *or*
 - Atypical neuroleptics (risperidone and quetiapine)
- If the patient is exhibiting psychotic mania
 - Lithium, divalproex, or carbamazepine combined with an atypical neuroleptic agent is recommended.
 - If the patient has partial response to monotherapy, adding a second agent from the above group is recommended.
- Treatment of depression in a patient with bipolar disorder requires relieving depression and prophylaxis against mania.
 - Mood stabilizers and atypical neuroleptics have some antidepressant properties.
 - Depressed patients with bipolar disorder often require the addition of an antidepressant.
 - This should always be prescribed *after* adequate coverage with a mood-stabilizing agent.

- Family interventions to improve communication, problem solving, and coping with having a bipolar family member may improve outcome.
- Mood-stabilizing agents have significant medical complications requiring close management.
 - Lithium
 - Causes weight gain; acne; hypothyroidism; and, rarely, renal damage
 - Therapeutic levels are between 0.6 and 1.0 mEq/L.
 - Should be monitored to assess compliance and prevent toxicity
 - Monitor every 4–6 months for hypothyroidism.
 - Monitor renal function annually with a blood urea nitrogen test, creatinine test, urinalysis, and creatinine clearance test.
 - Divalproex
 - Causes weight gain, can affect hepatic and hemopoietic function, and has been associated with polycystic ovarian disease
 - Requires periodic assessment of liver function and blood and platelet counts
 - Carbamazepine
 - Less frequently used because of its greater sedative effects and risk of hemopoietic side effects
 - Atypical neuroleptics typically cause weight gain.
 - Before prescribing, weight, body mass index, fasting blood glucose level, and lipid levels should be documented.
 - Weight and body mass index should be monitored closely.
- Lamotrigine
 - Anticonvulsant that has been demonstrated to be helpful for treating and preventing adult bipolar depression
 - Has not yet been carefully studied in children
 - Has a very benign side effect profile except, for the rare but very serious complication of Stevens-Johnson syndrome
 - For this reason, practitioners titrate this medication very slowly and monitor carefully for rashes.

WHEN TO ADMIT

- Inpatient admission is suggested if patient is:
 - Psychotic *or*
 - Acutely suicidal *or*
 - Acutely manic or in a mixed state *or*
 - Abusing substances *or*
 - Unresponsive to outpatient intervention

WHEN TO REFER

- Consider referring patients who have either:
 - Chronic, complex, or severe disorder, exhibited by:
 - Comorbidity
 - Suicidality
 - Psychosis
 - Bipolar-type depression

FOLLOW-UP

- After termination of CBT or pharmacotherapy, risk of relapse is high.
- Patient should continue treatment at a lower frequency of contact for 6 months after recovery is achieved.
 - For CBT, this consists of monthly visits or booster sessions.
 - For pharmacotherapy, continue treatment at same dose for at least 6 months after recovery.
 - Critical in treating early-onset depression because getting depressed patients well is not enough; keeping them well is crucial.

PROGNOSIS

- Untreated major depressive disorder lasts an average of 7.2 months.
- Untreated dysthymic disorder lasts an average of 45.9 months.
- Patients with both major depressive disorder and nonaffective morbidity (eg, additional diagnoses of conduct disorder, attention-deficit disorder) may have a prolonged course, as do depressed youth whose parents also are depressed.
- Recurrence of depression
 - 40% of depressed children experience recurrence within 2 years.
 - Nearly 75% have recurrence within 5 years.
 - Earlier age of onset and co-occurrence of a preexisting dysthymic disorder increase risk for major recurrences.
- Compared with nondepressed peers, depressed adolescents show greater risk of:
 - Academic, occupational, and interpersonal impairment
 - Tobacco and substance abuse
 - Obesity
- Residual social impairment may be related to unresolved depression.
 - However, many adverse outcomes are due to risk factors seen for depression and other conditions (eg, abuse, family discord, parental substance abuse).
- Depression confers increased risk for completed and attempted suicide, in both male and female adolescents.
- Girls are more likely to attempt suicide, but boys are more likely to complete suicide.

Muscular Dystrophy

DEFINITION

- Muscular dystrophies are a group of slowly progressive inherited diseases with specific patterns of muscle wasting and weakness.

EPIDEMIOLOGY

- Duchenne dystrophy
 - Most common pediatric muscular dystrophy
 - Prevalence: 1:3500 male births
- Becker dystrophy
 - Prevalence: 1:35,000 male births
- Myotonic dystrophy
 - Prevalence: 1:8000 all births
- Facioscapulohumeral dystrophy
 - Prevalence: 1:20,000 of all births
- Fukuyama-type congenital muscular dystrophy
 - Prevalence: 1:18,000 of all births
- Congenital muscular dystrophy
 - Prevalence unknown
- Emery-Dreifuss muscular dystrophy
 - Prevalence: 1:100,000 of all births

ETIOLOGY

- Duchenne dystrophy
 - Due to absence of dystrophin
 - A large cytoskeletal protein that attaches to the inner surface of the muscle fiber membrane as part of a complex of glycoproteins
 - Also part of the inner membrane structure of smooth and cardiac muscle and of certain cells in the central nervous system and in specialized connective tissues, such as the myotendinous junctions
 - X-linked recessive; *XP21* region encodes for the protein dystrophin
 - Large deletions occur in approximately two-thirds of cases.
 - Additionally, smaller point mutations occur in ~30% of patients.
 - No consistent relationship exists between the size of the gene mutation and clinical severity.
- Becker dystrophy
 - Marked deficiency of dystrophin
 - X-linked recessive; *XP21* region encodes for the protein dystrophin
 - Large deletions occur in more than two-thirds of cases.
 - Additionally, smaller point mutations occur in ~15% of patients.

- Myotonic dystrophy
 - Autosomal-dominant; chromosome 19
 - Abnormal expansion of CTG trinucleotide repeat in the 3' nontranslated region of a gene coding for a serine/threonine kinase
- Facioscapulohumeral dystrophy
 - Autosomal dominant; most cases localize to chromosome 4
 - Deletion of a variable quantity of 3.3-kb tandem repeats at *4q35*
- Fukuyama-type congenital muscular dystrophy
 - Autosomal recessive; chromosome 9, *q31-33* region for most cases
 - 3-kb insertion of 3' noncoding region of gene encoding fukutin; mutation-caused instability of messenger RNA for fukutin
- Congenital muscular dystrophy
 - Autosomal recessive; chromosome 6*q22-23* region, laminin $\alpha 2$ gene
 - Complete (or partial) loss of merosin (laminin $\alpha 2$) in both muscle and skin
- Emery-Dreifuss muscular dystrophy
 - X-linked recessive form *Xq28* and autosomal-dominant form *1q21.3*
 - The X-linked form involves gene for emerin and dominant form gene for lamins A and C.

SIGNS AND SYMPTOMS

Duchenne dystrophy

- Slowly progressive muscle-wasting disease marked by symptoms that develop before 5 years of age
 - Presents typically at 2–4 years of age
- Early symptoms
 - Cannot run or keep up with peers
 - Can take only 1 step at a time
 - Weakness of forward head flexion that persists beyond infancy
 - Accompanied by slowed motor development
 - Muscles affected early in course of disease are:
 - Proximal hip and shoulder girdle
 - Anterior neck
 - Abdominal
- Progressive gluteal and shoulder girdle muscular weakness
 - Widened stance
 - Lumbar lordosis
 - Forward thrusting of abdomen
 - Winging of scapulae

- Patients:
 - Never run normally
 - Put their hands on their knees to rise from the floor (see Figure 41 on page F17) and to assist in climbing steps
 - Have difficulty keeping up with peers
 - More apparent as children enter nursery school and kindergarten
 - May appear clumsy, or fall more easily
 - Complain of tiredness and calf cramps
- Mild cognitive deficits are common.
 - The patient may appear to be intellectually disabled; thus, the diagnosis of Duchenne dystrophy may be overlooked.
- Hip and knee extensor weakness develops gradually in middle childhood.
 - Patients often toe-walk to use the power of the gastrocnemius to help stabilize knee extension.
 - Reliance on calf muscles during ambulation contributes to typical hypertrophy of calf muscles.

Becker dystrophy

- Presentation is similar, but onset is later and symptoms are milder.
- Fatigue or marked thigh weakness
- Trouble climbing steps
- Occasional calf or thigh cramps

Myotonic dystrophy

- Congenital form
 - Floppy infant
 - Poor suck
 - Weak respiratory effort
 - Talipes
- Childhood form
 - Bifacial weakness
 - Slurred speech
 - Impaired hearing
 - Intellectual disability

Facioscapulohumeral dystrophy

- Congenital form (rare)
 - Bifacial weakness
 - Ophthalmoparesis (sometimes)
 - Occasionally floppy
 - Deafness
- Childhood form (more common)
 - Mild facial weakness
 - Weakness of scapular fixator muscles

Fukuyama-type congenital muscular dystrophy

- Develops in infancy
- Floppy infant

Congenital muscular dystrophy

- Develops in infancy
- Floppy, contractures

Emery-Dreifuss muscular dystrophy

- Onset in middle to late childhood
- Mild elbow contractures
- Mild weakness of triceps, biceps, and scapular fixator muscles
- Occasionally presents as isolated cardiomyopathy
- Can produce severe cardiac complications that require urgent treatment
 - Cardiac symptoms may prompt medical evaluation before muscle weakness or contractures occur.

DIFFERENTIAL DIAGNOSIS

- Awareness that there are a variety of uncommon muscular dystrophies helps parents and patients understand that differential tests may be necessary to establish the specific diagnosis, prognosis, and plan of treatment.

Muscular dystrophies

- Duchenne dystrophy
- Becker dystrophy
- Myotonic dystrophy
- Facioscapulohumeral dystrophy
 - Rare in infancy, occasional in childhood, usually seen in adults
 - Early-onset cases of facioscapulohumeral dystrophy may resemble Duchenne dystrophy.
 - Facioscapulohumeral dystrophy causes only a mild to moderate increase in creatine kinase (CK) or creatine phosphokinase.
- Fukuyama-type congenital muscular dystrophy
- Congenital muscular dystrophy
- Emery-Dreifuss muscular dystrophy
 - Clinically and genetically distinct from, but occasionally confused with, Becker dystrophy
 - Presents with the triad of:
 - Joint contractures that begin in early childhood
 - Slowly progressive muscle weakness
 - Cardiac involvement
- Limb-girdle muscular dystrophy (see tables Autosomal-Dominant Forms of Limb Girdle Muscular Dystrophy [LGMD 1A-D] and Autosomal-Dominant Forms of Limb Girdle Muscular Dystrophy [LGMD 2G-I])

Autosomal-Dominant Forms of Limb Girdle Muscular Dystrophy (LGMD 1A-D)^a

Characteristic	LGMD 1A	LGMD 1B	LGMD 1C	LGMD 1D
Age at onset	18–35 yr	4–38 yr (half of the cases in childhood)	~5 yr	<25 yr
Gene location (chromosome)	5q31	1q21.2	3p25 ^b	6q23
Protein	Myotilin	Lamin A/C	Caveolin 3	Unknown
Serum creatine kinase	Normal or 2–5× normal	Normal or 2–5× normal	Often >10× normal	22–5× normal
Muscle biopsy	Fiber size variation; moth-eaten fibers; increased internal nuclei; occasional necrotic and regenerating fibers	Fiber size variation; increased internal nuclei; mild endomysial fibrosis; occasional necrotic and regenerating fibers	Similar findings to 1A and 1B; absence or deficiency of caveolin 3 on immunocytochemistry	Similar findings to 1A and 1B
Clinical features	Proximal weakness; occasional dysarthria; slow progression; Achilles tendon contractures; may show anticipation	Cardiac disturbances prominent; proximal weakness; slow progression; may be allelic to autosomal dominant locus for Emery-Dreifuss dystrophy	Proximal weakness; calf hypertrophy; muscle pain on exertion; variable progression; muscle cramps	Cardiac conduction disturbances prominent; proximal weakness; problems worse in boys

^a Each of these has been described in a single family. Linkage analysis has excluded other known LGMD loci, but new causative genes have not yet been identified.

^b Mutations alter the scaffolding domain of the protein.

Autosomal-Recessive Forms of Limb Girdle Muscular Dystrophy (LGMD 2G-I)

Characteristic	LGMD 2G	LGMD 2H	LGMD 2I
Age at onset	9–15 yr	1–27 yr	Early childhood to 27 yr (61% <5 yr)
Genetics	Chromosome 17q12; mutation found in the gene encoding the sarcomeric protein telethonin	D487N homozygous mutation in the <i>TRIM 32</i> gene, 9q31-0.34-1 coding for a E3 ubiquitin ligase responsible for posttranslational regulation of protein levels	Chromosome 19q13.3 fukutin-related protein gene
Serum creatine kinase	Usually <5× normal; may be >10× normal early in the disease	From near normal to 20× normal	Markedly increased, 5–70× normal
Muscle biopsy	Rimmed vacuoles in some patients	Mild dystrophic changes (fiber size variation, degeneration/regeneration); fiber splitting, internal nuclei; endomysial fibrosis	Dystrophic changes; type I fiber predominance; reduced staining for merosin (α2 chain of lamin)
Clinical features	Anterior tibialis weakness early in the course in some patients	Proximal lower limb weakness; weakness of facial muscles with flat smile; slow progression (patients remain ambulatory through midadulthood)	Severe limb girdle weakness; cardiac failure (30–50%) and respiratory failure (30%)

- Occurs during childhood or in the teens, and on superficial evaluation, resembles Duchenne dystrophy
- Most forms progress more slowly than Duchenne dystrophy, and prognosis differs.

Other diseases with similar presentation to muscular dystrophies

- Variants of spinal muscular atrophy
 - Spinal muscular atrophy produces no increase or only mild increase in creatine phosphokinase.
 - Hypertrophy of calf muscles
- Cerebral palsy
 - Pattern of walking and presence of mild cognitive deficits can lead to an incorrect diagnosis of cerebral palsy.
 - Misdiagnosis delays effective treatment
- Myasthenia gravis
 - More rapid development of weakness
 - Ptosis, ophthalmoparesis, and facial weakness
- Inflammatory myopathy
 - More rapid development of generalized weakness
 - Skin rash
- Chronic demyelinating polyneuropathy
 - Absence of ankle reflexes
 - More generalized weakness
 - More rapid course
 - No marked increase of CK
 - Abnormally slowed nerve conductions
- Hypothyroidism
 - Symptoms usually more generalized
 - May be identified by blood tests
 - Does not cause high CK levels that occur in Duchenne dystrophy
- Carnitine deficiency
 - Symptoms usually more generalized
 - May be identified by blood tests
 - Does not cause high CK levels that occur in Duchenne dystrophy

The floppy infant

- Floppy infants can have markedly increased serum CK levels.
 - Newborns or infants with Duchenne dystrophy also have a marked increase in CK, but they are not floppy.
- The floppy infant without an infectious, toxic, or metabolic disorder that causes muscle destruction to account for marked increase of serum CK level:
 - Usually has one of the severe childhood autosomal-recessive forms of congenital muscular dystrophy:
 - Fukuyama-type muscular dystrophy
 - Congenital muscular dystrophy

- Certain congenital myopathies may be marked by floppiness.
 - These infants do not have significantly increased CK levels.

DIAGNOSTIC APPROACH

- Complete history
 - Almost always distinguishes muscular dystrophy from other conditions that cause proximal weakness without sensory findings in childhood
- In suspected cases, serum CK should be measured first.
 - A marked increase is suggestive of a muscular dystrophy.
 - Detailed discussion of natural history of Duchenne dystrophy or procedures for screening at-risk family members for carrier status is premature and best initiated after neurologic consultation and specific diagnostic data are available.
- The clinician should refer the patient for further evaluation to a neurologist skilled in the care of patients with neuromuscular disease.

LABORATORY FINDINGS

- A continuously updated list of laboratories and tests available for genetic diagnosis of the muscular dystrophies can be found at GeneTests.

Duchenne dystrophy

- Serum creatine phosphokinase level 10× above normal
- If suspicion is high, perform DNA screening first.
 - If negative, perform muscle biopsy.
- Leukocyte DNA testing
 - DNA is screened for deletions, which are found in 60–70% of patients.
 - If a deletion is found, deletion tests are performed in at-risk family members.
 - If no deletion is found, DNA sequencing for point mutation should be performed.

Becker dystrophy

- Serum creatine phosphokinase level 5–10× above normal
- Leukocyte DNA testing
 - DNA is screened for deletions, which are found in 60–70% of patients
 - If a deletion is found, deletion tests are performed in at-risk family members.
 - If no deletion is found, DNA sequencing for point mutation should be performed.

Myotonic dystrophy

- Serum creatine phosphokinase level ranges from normal to 2–5× above normal.

■ Leukocyte DNA testing

- Southern blot analysis is performed to identify abnormally large expansion of CTG repeats in the gene; most childhood cases show abnormal CTG repeat enlargements (eg, 500–4000 repeats), whereas normal alleles have 5–30 repeats.
- If normal, polymerase chain reaction is performed to search for smaller expansion of the repeat.

■ Facioscapulohumeral dystrophy

- Serum creatine phosphokinase level 2–5× above normal
- DNA analysis is available to identify the 3.3-kb deletions.
 - Should perform before obtaining muscle biopsy if clinical suspicion is high

■ Fukuyama-type congenital muscular dystrophy

- Serum creatine phosphokinase level >10× above normal

■ Congenital muscular dystrophy

- Serum creatine phosphokinase level >10× above normal
- Genetic testing available at select laboratories for some forms of congenital muscular dystrophy

■ Emery-Dreifuss muscular dystrophy

- Serum creatine phosphokinase level 5–10× above normal
- Genetic testing is available at selected laboratories.

DIAGNOSTIC PROCEDURES

■ Duchenne dystrophy

- Muscle biopsy
 - Active myopathy
 - Absence of dystrophin
 - Severe reduction in dystrophin-associated proteins
 - Helps distinguish among many of the autosomal-dominant and autosomal-recessive forms of limb-girdle muscular dystrophy that are clinically similar to Duchenne dystrophy
- Electrodiagnostic testing
 - Normal nerve conduction

■ Becker dystrophy

- Muscle biopsy
 - Moderately active myopathy
 - Absence or deficiency of dystrophin
 - Reduction in dystrophin-associated proteins
- Electrodiagnostic testing
 - Normal nerve conduction; mildly myopathic electromyogram (EMG)

■ Myotonic dystrophy

- Muscle biopsy
 - Increased central nuclei atrophy of type I fibers
 - Ringbinden
 - Subsarcolemma masses

■ Electrodiagnostic testing

- Normal nerve conduction
- Myotonic discharges are present in children and adults but are often absent in infants (EMG should be performed on the mother).

■ Facioscapulohumeral dystrophy

- Muscle biopsy
 - Nonspecific myopathy
 - Up to 30% have mononuclear inflammation.
- Electrodiagnostic testing
 - Normal nerve conduction; EMG occasionally myopathic, often within normal limits

■ Fukuyama-type congenital muscular dystrophy

- Muscle biopsy
 - Mixture of necrotic and regenerating fibers, fibrosis, and an increased number of small fibers
- Electrodiagnostic testing
 - Normal nerve conduction; myopathic EMG

■ Congenital muscular dystrophy

- Muscle biopsy
 - Dystrophic changes with adipose and connective tissue replacement
 - Often prominent inflammatory infiltrates
- Electrodiagnostic testing
 - Normal nerve conduction; myopathic EMG

■ Emery-Dreifuss muscular dystrophy

- Muscle biopsy
 - Mild to moderate active myopathy
 - Occasional atrophic type I fibers
- Electrodiagnostic testing
 - Normal nerve conduction; EMG often normal in early stages

TREATMENT APPROACH

■ Duchenne dystrophy

- Goals
 - Maintain ambulation for as long as possible.
 - Optimize development of the patient's cognitive abilities.
 - Anticipate complications.
- Develop an individualized care plan for each stage of disease.
 - The patient and family need to work closely with physicians, schoolteachers, physical educators, and physical and occupational therapists to develop a plan.

- Muscular Dystrophy Association clinics offer multiple services to patients.
 - Orthopedic care, physical therapy, occupational therapy, and neurologic care are coordinated by a neuromuscular specialist.
 - Typically, services are provided in a clinic financed partly by the Muscular Dystrophy Association.
 - Role of primary care physician remains critical.
 - The pediatrician usually provides routine care of upper respiratory infections, as well as treatment for other common medical problems.

SPECIFIC TREATMENTS

Duchenne dystrophy

- Prednisone is the only effective therapy.
 - Administered daily to maintain or stabilize muscle strength and function
 - Muscle strength begins to increase after only 10 days of treatment; maximal response after 3 months of therapy.
 - Muscle mass increases 10% after 3 months of treatment.
 - Rate of muscle breakdown declines in association with maintenance of normal rate of muscle protein synthesis.
 - Treatment is preferably monitored by or coordinated with a specialized neuromuscular center.
 - Appears to maintain respiratory muscle power even in late stages of disease
 - Has reduced number of patients who develop respiratory failure
 - Has decreased need for: tendon release surgery, long-leg bracing, spinal stabilization surgery for scoliosis
 - The mechanism responsible for beneficial effect is unknown.
 - Side effects
 - Most common
 - Excessive weight gain
 - Mood disturbances (more aggressive, more tearful)
 - Cushingoid facial appearance
 - Serious side effects are uncommon, but may include:
 - Compression fractures of the spine
 - High blood pressure
 - Gastrointestinal bleeding
 - Severe infections
 - Diabetes
 - Some patients develop small, dot-shaped cataracts.
 - Some patients experience decreased linear growth
 - Probably helps maintain ambulation

- Azathioprine immunosuppressive therapy
 - Has been used, but confers no beneficial effect
- Lightweight long-leg bracing
 - Often helpful by 10–12 years of age
 - Prolongs weight-bearing and ambulation, both of which delay the development of joint contractures and scoliosis
- Gene therapy
 - Discovery of the gene in Duchenne dystrophy has raised hopes that direct gene therapy, by either local injection or viral vector, will prove feasible.
- Other advances in research include:
 - Stem cell therapy
 - Treatments to “read through” certain types of mutations

WHEN TO ADMIT

- Before surgery
 - For medical, cardiology, and pulmonary consultations
- After surgery
 - For 24 hours (or longer, depending on type of surgery) to monitor cardiac and pulmonary function
- For evaluation and management of pneumonia or respiratory insufficiency, especially in:
 - Nonambulatory patients with Duchenne dystrophy
 - Patients with advanced cardiomyopathy with cardiac failure

WHEN TO REFER

- Neuromuscular clinic or specialist
 - When diagnosis of Duchenne dystrophy is strongly suspected (eg, symptoms and high CK levels)
 - To facilitate workup
 - Once diagnosis is confirmed
 - A neuromuscular specialist should take responsibility for initial description of course of Duchenne dystrophy and treatment options.
- Genetic counselor
 - After the diagnosis of Duchenne dystrophy is established
 - Offered to family members of patients, especially at-risk carrier women
- Cardiologist
 - After the patient with Duchenne dystrophy becomes wheelchair bound
 - To obtain a baseline cardiologic evaluation
 - In late stages of disease for monitoring of cardiac function and management of cardiomyopathy
 - Before surgery

■ Pulmonologist

- Pulmonary consultation before and after general anesthesia is integral part of any elective surgery.
 - Includes training patient and home care providers in use of assisted coughing techniques and nasal bilevel positive airway pressure to:
 - Hasten recovery after general anesthesia
 - Decrease likelihood of postoperative pneumonia
- After the patient with Duchenne dystrophy becomes wheelchair bound
- To obtain a baseline pulmonary evaluation
- In late nonambulatory stage of disease
 - To monitor and manage respiratory failure

■ Orthopedic surgeon

- Can help guide timing of use of long-leg bracing
- Can discuss possible need for surgery to lengthen Achilles tendons
- Can monitor severity of contractures, as well as degree of spinal curvature
 - Orthopedic consultation is especially important in early nonambulatory stage of Duchenne dystrophy, when contractures and spinal curvature become prominent.
- After the patient with Duchenne dystrophy becomes wheelchair bound
- To obtain a baseline orthopedic consultation
- For consideration of scoliosis surgery
- For release of heel cord contractures

■ Physical and/or occupational therapist

- Patients usually receive this care in their schools.
- During ambulatory stage of Duchenne dystrophy, to develop a heel cord stretching program and an individualized exercise program
- In the late ambulatory stage of Duchenne dystrophy, when the patient may appear to be close to becoming wheelchair limited
- To be fitted with adaptive equipment and long-leg braces
- To evaluate and manage contractures

■ Dietitian

- During ambulatory stage of Duchenne dystrophy
 - Particularly in patients receiving corticosteroid treatment
- To help manage weight gain
- To establish healthy eating patterns

■ Neuropsychologist

- During ambulatory and nonambulatory stages of Duchenne dystrophy
 - Patients are at risk for emotional, cognitive, and behavioral problems.

- For patients:
 - With borderline intellectual abilities
 - With cognitive or behavioral abnormalities
- For patients and family members who need end-of-life counseling

FOLLOW-UP

■ Monitoring for side effects of prednisone

- Patients are seen every 3 months for:
 - Weight check
 - Blood pressure check
 - Pulse check
 - Forced vital capacity check
 - Urinalysis
 - Assessment of neuromuscular functioning
- Each visit includes measures to help guide the physician in adjusting the dose of prednisone.
 - Timed function tests
 - Time needed to travel 30 feet, to arise from supine to standing position, and to climb 4 standard steps
 - Muscle strength evaluation
 - Shoulder abductors
 - Elbow flexors and extensors
 - Knee extensors
 - Hip flexors and extensors
- Blood count and serum electrolyte levels are measured at 6-month intervals.

COMPLICATIONS

■ See table Complications and Treatment of Muscular Dystrophies.

Duchenne dystrophy

- In middle and late nonambulatory stages, minor medical problems can provoke major complications.
 - Contractures and scoliosis
 - Develop when the patient becomes wheelchair bound
 - Do not appear at a specific age
 - Depend on patient's functional status
 - Usually begin to develop at ankles and elbows (flexion)
 - Respiratory problems
 - Mild cold may lead to atelectatic pneumonitis and acute respiratory insufficiency.
 - Chronic constipation can produce respiratory compromise in later stages due to abdominal distention and upward pressure on diaphragm.
 - An effective regimen to maintain regular bowel movements becomes important in routine care.

Complications and Treatment of Muscular Dystrophies in Childhood

Characteristic	Duchenne Dystrophy	Becker Dystrophy	Myotonic Dystrophy	Facioscapulohumeral Dystrophy	Fukuyama-Type Congenital Muscular Dystrophy	Congenital Muscular Dystrophy: Primary Deficiency of Merosin	Emery-Dreifuss Muscular Dystrophy
Muscle weakness	Treatment with prednisone slows or stabilizes muscle strength; lightweight long-leg bracing maintains ambulation in later stages.	No controlled studies of prednisone treatment; bracing is helpful in late stages.	No specific therapy; braces for foot drop; children can usually participate in gym in school.	No specific treatment; patients should avoid lifting with arms fully extended and abducted; braces are sometimes needed.	No specific treatment; bracing and physical therapy are useful in some patients.	Same as Fukuyama-type congenital muscular dystrophy	No specific treatment; skeletal muscle weakness often is relatively mild compared with cardiac problems and does not limit function.
Respiratory problems	Forced vital capacity is monitored (in later stages, atelectatic pneumonia is common); colds are treated aggressively; if signs of respiratory failure develop, nasal or oral ventilation should be considered.	Uncommon until late stages; management then as with Duchenne dystrophy	For congenital cases, ventilation is often needed; the prognosis for survival is poor if the patient is ventilator dependent at >4 weeks of age; otherwise management is as for Duchenne dystrophy.	Uncommon	As with Duchenne dystrophy; patients often die of respiratory failure late in childhood or in early teens.	Same as Fukuyama-type congenital muscular dystrophy	Mild other than symptoms related to cardiac dysfunction
Cardiac problems	Occasionally, cardiomyopathy leads to congestive heart failure; afterload-reducing therapy often helps; patient should be monitored for intracardiac clots.	Occasionally, severe cardiomyopathy develops; treatment is the same as for Duchenne dystrophy.	Occasionally, tachyarrhythmias or heart block develops in childhood forms, and pacemaker treatment is indicated.	Uncommon	Uncommon	Uncommon	Frequent cardiac conduction defects; atrial paralysis, cardiac arrest, and sudden death are common; pacemaker treatment and preventive therapy for cardiac emboli are often necessary.
Orthopedic problems	Achilles tendon contractures respond to stretching in early stages; later tendon release surgery is often necessary; contractures at the hips, knees, elbows, and wrists usually develop after the patient becomes wheelchair bound; scoliosis often develops when patients stop ambulating; spinal stabilization surgery helps maintain use of the arms.	Uncommon; contractures are much less common than in Duchenne dystrophy.	Talipes deformity requires treatment with stretching and orthotic support; occasionally, surgery is necessary.	Occasionally, knee effusion and low back pain develop as a result of weakness; conservative care measures are effective; in late stages, surgery to stabilize the scapula may be performed, but surgery is uncommon.	Contractures develop in 70% of patients by 3 months of age at the ankles, knees, and hips.	Contractures, especially feet and hips	Contractures, especially in the elbows and ankles, occur early and respond somewhat to physical therapy; surgical release of Achilles tendon may be necessary; some patients develop a rigid spine syndrome, for which no effective therapy is available.

Complications and Treatment of Muscular Dystrophies in Childhood

Characteristic	Duchenne Dystrophy	Becker Dystrophy	Myotonic Dystrophy	Facioscapulohumeral Dystrophy	Fukuyama-Type Congenital Muscular Dystrophy	Congenital Muscular Dystrophy: Primary Deficiency of Merosin	Emery-Dreifuss Muscular Dystrophy
Nervous system problems	Increased incidence of cognitive and behavioral problems; some patients improve with small doses of methylphenidate.	Uncommon	Intellectual disability is common, especially in congenital cases, and special classroom care is needed; hearing deficits are common and may require hearing aids; facial weakness, dysarthria, and hearing problems exaggerate the impression of intellectual disability.	Uncommon; in rare cases, the infant-onset form of the disease occurs in association with hearing loss, retinal disease, or both.	Generalized or focal seizures occur in most patients; anticonvulsant therapy is necessary; intellectual disability is common; most patients have microcephaly, polymicrogyria, pachygyria, and heterotopias.	Intellectual disability is common; magnetic resonance imaging of head shows increased signal from white matter on T2-weighted images; occipital agyria	Caused only by stroke from heart block or cardiac emboli
Gastro-intestinal problems	Constipation is common, especially late in the disease; careful dietary monitoring, stool softeners, and good water intake (urine specific gravity 1.007–1.010) are usually effective; occasionally acute gastric dilation occurs; it resolves over 2–3 days with nasogastric tube decompression of the stomach and intravenous hydration.	Uncommon	Spastic colon-type symptoms with abdominal pain are common; occasionally, these symptoms improve with antimyotonia therapy with mexiletine; eating small portions at each meal diminishes tendency to aspirate.	Uncommon	Uncommon	Uncommon	Uncommon

- Respiratory insufficiency often develops in late stages.
 - Forced vital capacity declines, usually into the range of 600–1000 mL.
- Management options include nasal ventilation rather than positive pressure ventilation via tracheostomy.
- Assistive cough devices (insufflator-exsufflator) may be helpful in speeding recovery from episodes of bronchitis and pneumonia.
- Ventilatory care usually is coordinated among pediatrician, neuromuscular specialist, pediatric pulmonologist, and patient and family.
- Cardiac problems
 - In late stages, patients occasionally develop cardiomyopathy.
 - Chest radiography reveals a dilated heart.
 - Cardiac ejection fraction decreases to 10–20% of normal.
 - Heart failure often exacerbated by coexisting respiratory insufficiency
 - Ventricular or atrial clots (or both) may be present.
 - Long-term anticoagulant therapy is necessary.
- Gastrointestinal system: acute gastric dilation
 - Infrequent complication occurring in late stages of disease
 - Typically occurs in association with idiopathic metabolic acidosis
 - Responds rapidly to nasogastric tube decompression of stomach and intravenous hydration
- Caution must be used with intravenous repletion of potassium.
 - In late stages of disease, the patient's muscle mass is considerably diminished and is not available to buffer an acute rise in extracellular potassium.
- Cause of gastric dilation is unknown.
 - Probably results, along with chronic intestinal hypomotility (constipation), from deficiency of dystrophin in smooth muscle of gastrointestinal tract.
- Treatment
 - Good hydration
 - Balanced dietary intake
 - Regular bowel habits

PROGNOSIS

Duchenne dystrophy

- Without prednisone treatment, most patients will become wheelchair bound between 10 and 12 years of age.
- With close follow-up, patients have been kept stable or have had only mild progression of muscle weakness for periods exceeding 5 years.

Becker dystrophy

- Patients can ambulate beyond age 15 years.

Fukuyama-type congenital muscular dystrophy

- Slow improvement up to 6–8 years of age, then a decline

Nephritis

DEFINITION

- *Nephritis* refers to noninfectious inflammation of the kidney parenchyma, which may involve primarily the glomerulus (glomerulonephritis), the interstitium (interstitial nephritis), or both.
- Acute glomerulonephritis
 - Most commonly, acute poststreptococcal glomerulonephritis (APSGN)
 - Henoch-Schönlein purpura (HSP) is small-vessel vasculitis that most often affects children.
 - Rapidly progressive glomerulonephritis (RPGN) is a variant of acute glomerulonephritis characterized by:
 - Symptoms of acute nephritis
 - Relentless progression to renal failure over days or weeks
- Chronic glomerulonephritis is associated with variety of conditions.
 - Immunoglobulin (Ig)A nephropathy (Berger disease)
 - Benign familial hematuria
 - Alport syndrome
 - Nephritis of systemic lupus erythematosus (SLE)
 - Membranoproliferative glomerulonephritis (MPGN), also called *mesangiocapillary glomerulonephritis*, is a chronic inflammatory disease of the kidney with poor prognosis.
 - Interstitial nephritis
 - Inflammation of the interstitium
 - Much less common than glomerular inflammation

EPIDEMIOLOGY

- Poststreptococcal nephritis
 - May happen at any age, but peak incidence at age 7 years
 - Slight predominance among boys
 - Geography
 - Following streptococcal pharyngotonsillitis, more common in temperate regions
 - Following streptococcal skin infections, more common in tropical and subtropical climates
- Acute glomerulonephritis
 - Of 487 children <15 years of age who underwent renal biopsy, 43% had glomerulonephritis.
 - Only 8.4% of these had a classical nephritic picture with hematuria, hypertension, oliguria, edema, and reduced glomerular filtration rate.
- SLE nephritis
 - Seen mainly in young women during childbearing years
 - 20% of cases involve children.
- IgA nephropathy
 - Males affected more often than females
 - Less frequent in black persons than in white persons

- Primary MPGN
 - Average age of onset, approximately 9 years

ETIOLOGY

- APSGN
 - Consequence of immune response to a nonrenal infection with some strains of group A β -hemolytic streptococci
 - Types 12 and 49 are the strains most commonly associated with nephritis.
 - Risk of nephritis may differ according to site of infection and the particular M type.
- Nonstreptococcal acute glomerulonephritis
 - Viruses suspected of causing acute glomerulonephritis include:
 - Varicella
 - Echovirus 10
 - Coxsackieviruses
 - Viruses that cause infectious mononucleosis
 - Measles
 - Mumps
- RPGN
 - Most cases are the result of glomerular disease.
 - May be caused by:
 - Acute interstitial nephritis stemming from pyelonephritis
 - Hypersensitivity to certain drugs
- SLE may cause acute glomerulonephritis.
- IgA nephropathy
 - Cause is unknown
 - Abnormal glycosylation of the hinge region of the IgA antibody molecule is a possible mechanism.
- Benign familial hematuria
 - Inherited as an autosomal-dominant trait
- Alport syndrome
 - Inherited as an X-linked-dominant trait in 80–85% of cases
 - Caused by a mutation of the gene encoding the α -5 chain of type-IV collagen
 - The particular type of mutation may influence the severity of the clinical expression of the disease.
 - X-linked Alport syndrome with leiomyomatosis
 - Due to deletions involving the contiguous genes encoding the α -5 and α -6 chains of type-IV collagen
 - Autosomal-recessive Alport syndrome
 - Related to mutations in the genes encoding the α -3 and α -4 chains of type-IV collagen on chromosome 2
 - Autosomal-dominant Alport syndrome
 - Linked to the region of chromosome 2 containing the genes encoding the α -3 and α -4 chains of type-IV collagen

- **MPGN**
 - Cause usually unknown
 - Some forms are associated with immune complex deposition in the glomeruli.
 - Type-1 MPGN
 - Thought to be mediated by immune complex formation and deposition, with activation of the classical pathway of complement
 - Types 2 and 3
 - Complement consumption is thought to be the result of the presence of circulating autoantibodies (nephritic factors [NFs]) that stabilize C3 convertases activating the alternative (NF₂) and terminal (NF₁) pathways of complement activation, respectively.
- **Interstitial nephritis**
 - Often caused by an immune reaction to drugs

RISK FACTORS

- Streptococcal pharyngotonsillitis, especially in temperate regions
- Streptococcal skin infections, especially in tropical and subtropical climates
- SLE

SIGNS AND SYMPTOMS

General

- Periorbital or pretibial edema
- Changes in eye grounds
- Uremic odor to the breath
- Pleural or pericardial friction rubs
- Ascites
- Costovertebral angle tenderness
- Joint swelling or tenderness
- Vasculitic rashes
- Hematuria, microscopic or macroscopic
- Proteinuria
 - Proteinuria can range from mild to nephrotic range.
 - The finding of hematuria and proteinuria together strongly suggests underlying glomerular inflammation.
- Erythrocyte casts in the urine

Acute glomerulonephritis

- Abrupt onset of:
 - Hematuria
 - Often grossly visible as tea-colored or cola-colored urine
 - May be microscopic only
 - Erythrocyte casts and dysmorphic erythrocytes, although several urine samples may have to be examined
 - Proteinuria

- Hypertension
- Edema
- **APSGN**
 - Characteristically occurs:
 - 8–14 days after pharyngeal infection *or*
 - 14–21 days after a skin infection
 - Two-thirds of patients exhibit macroscopic hematuria.
 - Usually oliguria
 - Rarely, anuria
 - Edema that is usually periorbital and, rarely, severe
 - Signs of congestive heart failure
 - Hypertension
 - If severe, may produce headache, drowsiness, vomiting, personality and visual changes, and convulsions
 - Anorexia
 - Pain in the abdomen or flank are common, although palpation of the abdomen usually does not reveal significant findings.
 - Costovertebral angle tenderness

HSP nephritis

- Palpable purpuric lesions
- Arthritis
- Abdominal pain
- Gastrointestinal bleeding
- Not all manifestations need be present at the same time.

IgA nephropathy

- Characteristically, sudden onset of painless gross hematuria concomitant with an infection, usually of the respiratory tract
 - May be associated with flank pain
 - Usually clears within a few days to a week as the infection resolves
 - Frequently recurs with subsequent infections
 - Microscopic hematuria may persist with or without proteinuria between episodes.
 - Urine may clear totally.
- Some patients may have nephrotic syndrome or acute renal failure at presentation.

Benign familial hematuria

- Persistent asymptomatic microscopic hematuria in the absence of:
 - Hearing loss
 - Proteinuria
 - Progressive renal impairment

Alport syndrome

- Persistent microscopic hematuria is found early in all affected male patients.

- Most female patients have intermittent microscopic hematuria.
- Macroscopic hematuria is often seen at time of respiratory infection.
 - In up to 70% of male patients
 - In 33% of female patients
- Proteinuria in males; nephrotic range in approximately 30%
- Sensorineural hearing loss
 - Progressive starting with high frequencies
 - Affects male patients more than female patients
- Eye abnormalities in approximately 50% of patients
 - Anterior lenticonus
 - Retinal abnormalities
 - Corneal ulcerations
- Two-thirds of patients with the autosomal-recessive form develop hearing loss.
- Half the carriers of the abnormal gene also have microscopic hematuria.

SLE nephritis

- Initial symptoms may be vague; a high index of suspicion is warranted.
- Initially may have constitutional, cutaneous, or musculoskeletal symptoms, such as:
 - Fever
 - Malaise
 - Rash
 - Arthritis
- Isolated hematuria
- Hematuria with proteinuria
- Nephrotic syndrome
- Hypertension
- Rapidly progressive renal failure

MPGN

- Hematuria in 60–100%
- Hypertension in 42–67%
- Decreased renal function in 17–50%
- Nephrotic syndrome in 50–67%
 - Some may not have significant hematuria.

DIFFERENTIAL DIAGNOSIS

- Nonstreptococcal glomerulonephritis
 - No effective way to differentiate from other nephritides that progress to renal failure, except observation of clinical course

- Glomerulonephritides with low complement levels
 - APSGN
 - Failure of complement levels to normalize by 8 weeks suggests another form of nephritis, such as MPGN, nephritis of chronic infection, or SLE nephritis.
 - SLE nephritis
 - MPGN
 - Nephritis of chronic infection
 - Cryoglobulinemia
- RPGN with immune complex
 - Postinfectious reaction
 - Streptococcal infection
 - Visceral abscess
 - Other
 - Collagen-vascular disease
 - SLE
 - HSP
 - Mixed cryoglobulinemia
 - Primary renal disease
 - IgA nephropathy
 - MPGN
 - Unknown cases (ie, idiopathic)
- RPGN with no immune deposit
 - Unknown cause
 - Vasculitis
 - Microscopic polyangiitis
 - Wegener granulomatosis
 - Hypersensitivity vasculitides
 - Hemolytic-uremic syndrome
- RPGN with anti-glomerular basement membrane antibody
 - With lung hemorrhage (Goodpasture syndrome)
 - Without lung hemorrhage
 - Complicating membranous nephropathy
- Acute glomerulonephritides characterized by no or mild renal failure
 - More common
 - APSGN
 - HSP with nephritis
 - IgA nephropathy is difficult to differentiate morphologically from HSP.
 - Has led to speculation that HSP is a form of IgA nephropathy with systemic findings
 - Postinfectious (nonstreptococcal) glomerulonephritis
 - Interstitial glomerulonephritis
 - Radiation nephritis

- Less common
 - Acute episodes in patients with chronic glomerulonephritis
 - Hemolytic-uremic syndrome (milder cases)
 - MPGN (some)
 - SLE nephritis (some)
- Only a family history of lack of progressive renal impairment, deafness, and eye findings distinguishes benign familial hematuria from early Alport syndrome.
- IgA nephropathy
 - Simultaneous onset of upper respiratory tract infection with gross hematuria helps differentiate this from APSGN, in which delay between infection and hematuria is the rule.
 - Absence of a rash, abdominal pain, and arthritis helps differentiate from HSP nephritis.

DIAGNOSTIC APPROACH

- If nephritis is suspected:
 - Blood pressure should be monitored carefully and frequently and compared with normal values for sex, age, and height percentile.
 - Weight should be measured.
 - Significant weight gain might suggest fluid retention.
 - Poor growth with crossing height percentiles with inappropriate weight gain or loss might suggest a chronic renal disorder.
- Follow up with appropriate laboratory, imaging, and biopsy studies.

LABORATORY FINDINGS

General

- Initial laboratory evaluation should include:
 - Urinalysis with microscopy
 - Serum electrolytes
 - Blood urea nitrogen
 - Creatinine
 - Calcium
 - Phosphorous
 - Albumin
 - Liver enzymes
 - Complete blood count with platelets
 - Complement levels
 - Decreased levels of the third component of complement (C3) and on occasion, fourth component (C4) can help narrow the differential diagnosis by distinguishing the hypocomplementemic nephritides from those with normal complement levels.
 - Antinuclear antibody

- Antistreptolysin O or other antibodies to streptococcal antigens
- For SLE nephritis, Wegener granulomatosis, microscopic polyangiitis, and some cases of membranoproliferative glomerulonephritis or membranous nephropathy:
 - Anti-double-stranded DNA
 - Antineutrophil cytoplasmic antibodies
 - Hepatitis B and C serologic tests
- Urine culture should be obtained if unclear diagnosis versus pyelonephritis

Acute glomerulonephritis

- Leukocytes on microscopy and positive test for leukocyte esterase are often found and suggest inflammation.

APSGN

- Urine usually tea colored and opaque
- Urine specific gravity generally increased
- Proteinuria
 - Usually parallels degree of hematuria
 - Rarely reaches the nephrotic range (>40 mg/m² per hour or >3.5 g/day in older children and adults)
- Microscopic urine examination
 - Usually reveals erythrocytes and leukocytes, and granular or cellular casts
 - Identifiable erythrocyte casts and dysmorphic erythrocytes may or may not be present, so serial urine specimens may need to be examined.
- Serum complement levels
 - Reduced C3 in 80% of patients
 - Early in the course, reduced C4 in 50%
- Erythrocyte sedimentation rate usually elevated
- In severe oliguria, azotemia and acidosis may be seen.
- Plasma volume usually expanded, causing decrease in serum protein, hemoglobin, and hematocrit
- Antistreptolysin O titer
 - Elevated in 80% of patients
 - Increases in titer are less common in patients who have skin infection or who receive early treatment with antibiotics.
- Other streptococcal antibodies (antihyaluronidase, antideoxyribonuclease B) are present in 80–90% of patients.

IgA nephropathy

- Findings are often normal except for abnormal urinalysis

Benign familial hematuria

- All laboratory results usually normal except for urinalysis
- Presence of hematuria in otherwise asymptomatic family members suggests the diagnosis.

Alport syndrome

- Laboratory findings:
 - Reflect degree of renal impairment
 - May vary from normal early on to advanced renal failure as disease progresses
- Blood urea nitrogen and creatinine levels become elevated with advancing disease.
- Serum electrolytes may become abnormal.
- Hypoalbuminemia may occur in some patients who develop nephrotic syndrome.
- Serum complement level is usually normal.

SLE nephritis

- Antinuclear antibodies positive in most
- Anti-double-stranded DNA positive in many patients with renal involvement
- Serum complement components frequently decreased
- Renal disease may be characterized by:
 - Elevation of serum urea and creatinine levels
 - Decrease in serum albumin levels in the setting of nephrotic-range proteinuria
- Findings on urinalysis vary greatly.
 - Isolated hematuria
 - Hematuria with proteinuria
 - Nephrotic-range proteinuria
- Pyuria reflects the underlying glomerular inflammation.
- Erythrocyte, leukocyte, and renal tubular epithelial cell casts frequently seen
- Coombs-positive anemia
- Leukopenia
- Thrombocytopenia
- Antiphospholipid antibodies; risk factor for thrombotic complications

MPGN

- Serum C3 is depressed in 67–75% of patients.
- Blood urea nitrogen and creatinine values may be elevated.
- Albumin level may be low in severe cases.
- Anemia is common.
- Electrolyte disturbances if renal insufficiency is present
 - Urinalysis most commonly shows both hematuria and proteinuria.
 - Proteinuria may reach the nephrotic range.
 - Hematuria may be macroscopic.
 - Cellular casts are a common finding.

Interstitial nephritis

- Peripheral eosinophilia may or may not be seen.
- If present, urinary eosinophils are demonstrated on Hansel stain.

IMAGING

- APSGN
 - Chest radiography in patients with significant fluid retention and hypertension may reveal:
 - A large heart with prominent pulmonary vasculature
 - Pulmonary edema
 - Rarely, pleural effusions
 - Ultrasonography is nonspecific, usually revealing bilaterally enlarged echogenic kidneys.

DIAGNOSTIC PROCEDURES

- Alport syndrome
 - Renal biopsy may help establish diagnosis if family history is unclear or in patient with a new mutation.
- RPGN
 - Although characteristic clinical and laboratory features may suggest specific causative factors, renal biopsy often is indicated to diagnose and to determine extent of disease.
- Interstitial nephritis
 - Renal biopsy is often necessary to confirm the diagnosis.

SPECIFIC TREATMENTS**APSGN**

- Most often resolves spontaneously
 - Must be aggressive in treating symptoms that occur in the acute phase of the illness
 - Hypertension
 - Mild hypertension may resolve spontaneously.
 - More severe hypertension should be controlled with quick-acting antihypertensive agents.
 - Oliguria and resulting vascular overload
 - Diuretics
 - Pulmonary edema
 - Encephalopathy
 - Control of severe hypertension often requires either:
 - Intravenous sodium nitroprusside
 - Labetalol
 - Nicardipine
 - Fenoldopam
 - Oral minoxidil
 - Slower-acting, less potent antihypertensive drugs are not good initially but can be substituted once blood pressure has been acutely stabilized.
 - Occasionally, a patient develops acute renal failure severe enough to require dialysis.
 - A 10-day course of antibiotics is usually given to eradicate any remaining group A β -hemolytic streptococci and prevent transmission of the organism.

- Close contacts should be screened for streptococcal infection and treated if present.

RPGN

- Treatment depends on particular diagnosis, which is often determined by kidney biopsy.
- Plasmapheresis may be helpful in resistant forms of RPGN.
 - Anti-glomerular basement membrane antibody disease
 - Atypical forms of hemolytic-uremic syndrome
 - Thrombotic thrombocytopenic purpura

Other

- Fulminant SLE nephritis, MPGN, IgA nephropathy, HSP nephritis
 - Methylprednisolone pulses frequently are given initially, followed by oral or intravenous alkylating agents.
- IgA nephropathy
 - Suggested regimens for poor prognostic indicators
 - Long-term, alternate-day prednisone, with or without methylprednisolone pulses
 - Mycophenolate mofetil
 - Control of hypertension is essential
- Benign familial hematuria
 - No treatment is indicated.
- Alport syndrome
 - Treatment is supportive, with medical management of hypertension and complications of renal insufficiency.
 - Dialysis or transplantation is instituted when medical management is no longer sufficient.
 - Audiologic screening can identify hearing impairment early for timely implementation of hearing-augmentation services.
- SLE nephritis
 - High-dose corticosteroid therapy is the mainstay of treatment but is associated with considerable morbidity.
 - Pulse methylprednisolone is used to treat rapidly progressive lupus glomerulonephritis.
 - Oral or pulse intravenous cyclophosphamide frequently is recommended for treatment of World Health Organization class III, IV, and sometimes V renal disease.
 - Azathioprine and mycophenolic acid have been used as steroid-sparing agents.
 - Mycophenolic acid may allow decreasing exposure to, or even substitute for, cyclophosphamide, thus preventing significant side effects, particularly on fertility.
 - Cyclosporine
 - Variable results
 - Renal biopsy should be performed before therapy is begun.
 - Patients are managed best by a team trained in dealing with all aspects of this disease.

■ MPGN

- Treatment is controversial.
- High-dose, long-term, alternate-day prednisone therapy showed renal survival of 82% at 10 years and 56% at 20 years.
- Some differences in clinical course and response to treatment may be seen according to the type of MPGN.

WHEN TO ADMIT

- Severe hypertension
- Renal failure with significant electrolyte disturbances
- Congestive heart failure from volume overload
- Oliguria or anuria
- Rapidly progressive renal failure

WHEN TO REFER

- Acute glomerulonephritis with significant complications
- Acute glomerulonephritis that is not following a typical course expected of APSGN
- Failure of complement level to normalize within 6–8 weeks in suspected acute glomerulonephritis
- Rapidly progressive course
- Glomerulonephritis with the development of nephrotic syndrome
- Persistent hematuria and proteinuria
- Persistent hypertension
- Elevated creatinine level for age
- Family history of renal failure or deafness
- Any chronic glomerulonephritis

PROGNOSIS

- APSGN
 - Nephrotic-range proteinuria or extensive crescents by biopsy portend a poor prognosis.
 - >95% of children recover.
 - For most children, the critical period is early in the illness, when potentially fatal hypertension or fluid overload presents a danger.
 - Some patients with severe involvement, evidenced by nephrotic-range proteinuria or the presence of extensive glomerular crescents on biopsy, have some residual damage or may progress to end-stage renal failure.
 - Recurrences of APSGN are rare.
- IgA nephropathy
 - 10–30% are anticipated to progress to renal failure over the course of several decades.
 - Progression is related to:
 - Higher amounts of proteinuria
 - Presence of hypertension

- Renal insufficiency at presentation
- Severity of histologic changes found on kidney biopsy
- Alport syndrome
 - Renal disease and hearing loss are progressive.
 - Families carrying large DNA deletions or stop codons leading to truncated proteins may be at risk for more severe disease than those with mutations leading to an amino acid substitution.
 - 3–4% of patients receiving a kidney transplant develop anti-glomerular basement membrane nephritis, leading to loss of the transplanted kidney in 75% of cases.
- SLE nephritis
 - Renal survival in childhood lupus nephritis ranges from 29–71% at 10 years.
 - Patients with World Health Organization class IV diffuse proliferative glomerulonephritis have the poorest renal outcome.
 - Predictors of poor renal prognosis
 - Sclerosis on biopsy specimens
 - Hypocomplementemia
 - Decreased renal function
 - Nephrotic-range proteinuria
 - Persistent hypertension
- MPGN
 - 50% reach end-stage renal failure within approximately 11 years of diagnosis.
 - 90% reach end-stage within 20 years.
 - Poor prognostic indicators
 - Nephrotic-range proteinuria
 - Renal insufficiency
 - Hypertension
 - Sclerosis on biopsy examination
 - Type 1 MPGN has a better prognosis than the other 2 types.
- Interstitial nephritis
 - The combination of interstitial nephritis with severe glomerulonephritis has a much more guarded prognosis, since combined involvement reflects greater severity of renal disease.
 - Interstitial inflammation tends to heal by fibrosis, damaging segments of the remaining kidney.

Nephrotic Syndrome

DEFINITION

- Syndrome with clinical findings of:
 - Heavy proteinuria
 - Hypoalbuminemia
 - Edema (often frank anasarca)
 - Hyperlipidemia
- Nephrotic syndrome may result from underlying systemic disease or manifest as a primary idiopathic renal disorder.

EPIDEMIOLOGY

- Incidence
 - Idiopathic nephrotic syndrome in children seen in 2–7 cases per 100,000 children annually
- Sex
 - 2:1 ratio of male to female children
 - Affects male to female adolescents and adults equally
- Children 3 months to 16 years
 - 76% have minimal change nephrotic syndrome (MCNS).
 - Occurrence peaks between 2 and 5 years of age.
 - 7–25% have focal segmental glomerulosclerosis (FSGS).
 - 2–5% have diffuse mesangial hypercellularity or mesangial proliferation.
 - 7% have membranoproliferative glomerulonephritis (MPGN).
 - 1% have membranous nephropathy.
 - Adolescents are more likely than younger children to have a more aggressive cause, such as FSGS, MPGN, or membranous nephropathy.
- Race
 - Black and Hispanic adolescents are more likely than white adolescents to have FSGS and to progress to end-stage renal disease.
 - In a predominantly black and Hispanic population of nephrotic adolescents:
 - 55% had FSGS.
 - 20% had MCNS.
 - 7% had MPGN.

ETIOLOGY

- Filtration barriers are variably altered, depending on the severity and nature of the underlying disease process.
 - Examples of alterations in the filtration barrier include:
 - Loss of negative charge seen in MCNS
 - Altered organization of glomerular basement membrane components in Alport syndrome
 - Mutations of genes encoding proteins associated with glomerular podocytes
- Changes in barriers allow passage of large quantities of plasma proteins into the urine, which may lead to a decrease of proteins in the blood.

- Development of edema has been explained by massive loss of plasma proteins, in particular albumin, in the urine.
 - Development of hypoalbuminemia leads to decreased plasma oncotic pressure and leakage of fluid from the vascular space into the interstitium.
 - Subsequent decrease in circulating blood volume
 - Stimulates the renin-angiotensin-aldosterone system
 - Leads to avid sodium retention
 - Produces a nonosmotic stimulus for vasopressin secretion and free-water reabsorption
 - This scenario does not explain edema formation in all nephrotic patients.
 - In patients who experience remission, diuresis often begins as proteinuria is resolving but before plasma albumin levels normalize.
 - Primary sodium retention has been demonstrated with onset of proteinuria (but before development of hypoproteinemia) in some experiencing relapse.
 - Would lead to expansion of vascular volume and development of edema

RISK FACTORS

- Disease processes associated with FSGS lesions
 - Diabetic nephropathy
 - Sickle cell disease
 - HIV nephropathy
 - Glomerulonephritides
 - IgA nephropathy
 - MPGN
 - Lupus nephritis

DIAGNOSIS

SIGNS AND SYMPTOMS

- Gradual or more acute edema and inappropriate weight gain
 - Periorbital edema when arising in the morning
 - Resolves during the day
 - Often mistaken for allergy
 - Clothing may be tight.
 - Socks may leave indentations in the skin of shins and ankles.
- The abdomen may be distended, and a fluid wave may be discernible on examination.
- Breath sounds may be decreased at lung bases due to accumulation of pleural fluid.
- May see:
 - Gallop on auscultation of the heart
 - Rales over the lung fields
 - Hepatomegaly

- Boys may develop significant scrotal swelling.
- Girls may develop labial swelling.
- Decreased frequency of urination
 - Dark, amber-colored, concentrated-appearing urine
 - Urine appears to foam when voided.
- Hypertension (in 16%)
 - Marked hypertension suggests underlying glomerulonephritis.
- Specific changes due to nephrotic syndrome
 - MCNS, also known as *lipoid nephrosis* or *nil disease*, is the most common pathologic diagnosis in nephrotic children.
 - Hematuria in approximately 13%
 - Hypertension in 10–20%
 - Relapses are common, but long-term prognosis is excellent.
 - Membranous nephropathy
 - Rare in children and adolescents (1% of children with nephrotic syndrome)
 - Spontaneous remissions occur in most, but remission may not occur for several years.
 - 13% of affected children progress to end-stage renal failure.

DIFFERENTIAL DIAGNOSIS

- Causes of primary nephrotic syndrome
 - MCNS
 - FSGS
 - Mesangial hypercellularity
 - MPGN
 - Membranous nephropathy
- Causes of secondary nephrotic syndrome
 - Inherited diseases
 - Congenital nephrotic syndrome (see below)
 - Diffuse mesangial sclerosis
 - Alport syndrome
 - Nail-patella syndrome
 - Lowe syndrome
 - Vasculitides
 - Lupus nephritis
 - Henoch-Schönlein purpura nephritis
 - Wegener granulomatosis
 - Goodpasture syndrome
 - Postinfectious
 - Poststreptococcal
 - HIV
 - Hepatitis B and C
 - Malaria

- Syphilis
- Intrauterine infections
- Other viruses and bacteria
- Drugs and toxins
 - Nonsteroidal antiinflammatory drugs
 - Gold
- Diabetes mellitus (rare in children)
- Mutations of certain genes are implicated in the development of hereditary forms of the nephrotic syndrome.
 - Congenital nephrotic syndrome presents in the first 3 months of life.
 - Finnish type is an autosomal-recessive disorder caused by mutations in the *NPHS1* gene encoding nephrin, or the *NPHS2* gene encoding podocin (podocyte membrane protein).
 - Diffuse mesangial sclerosis
 - May be part of Denys-Drash syndrome
 - Onset in first months of life with rapid progression to end-stage kidney failure, male pseudohermaphroditism, and Wilms tumor
 - Associated with mutations of the *WT1* gene
 - Podocin mutations
 - Some are associated with a steroid-resistant, autosomal-recessive form of FSGS in older children with a rapid progression to renal failure.
 - Mutations in the *ACTN4* gene encoding α -actinin result in an autosomal-dominant form of FSGS, with onset during early childhood and slow progression to renal failure.

LABORATORY FINDINGS

- Urinalysis is the first test to be done in a child with edema.
 - Significant proteinuria
- Significant microscopic hematuria or gross hematuria
 - Up to 25% of children with primary nephrotic syndrome will have 3–5 erythrocytes per high-power field.
 - Glycosuria suggests underlying tubular injury and may be seen with FSGS.
- Blood urea nitrogen and creatinine values are generally normal or only slightly increased in primary nephrotic syndrome.
- Serum total protein and albumin levels are low.
- Mild hyponatremia may be present
- Total calcium levels are low; ionized calcium levels are usually normal.
- Serum cholesterol level is usually increased.
- Third component of complement (C3) is generally normal.
 - A low level suggests MPGN, poststreptococcal glomerulonephritis, or lupus nephritis.

- Tests to quantify urinary protein losses
 - 24-hour urine collection
 - Nephrotic-range proteinuria = urinary protein excretion >40 mg/m² per hour or 1 g/m² per day in children
 - In incontinent children, urine protein-to-creatinine ratio on a random urine sample
 - Ratio (mg/mg) $>2:1$ on a random urine sample is considered nephrotic.
 - Urinary protein quantification is helpful for monitoring the response to treatment of children with resistant forms of nephrotic syndrome.

IMAGING

- Chest radiography
 - Usually shows small cardiac silhouette and, in severe cases, pleural fluid
 - Cardiomegaly may be seen in patients with increased intravascular volume.

TREATMENT APPROACH

- Clinical response to corticosteroids is informative in determining long-term outcome.
 - 85% respond to a trial of prednisone.
 - 75% respond within 2 weeks of initiating therapy.
 - 94% respond by 4 weeks.
 - Biopsy findings do not predict which children with MCNS will be corticosteroid resistant or which with FSGS will be responsive.
 - Patients who achieve remission on steroids (whether they have MCNS or FSGS) do not progress to renal failure if they remain responsive to corticosteroid therapy.
- Children age 1–6 years (most likely to have MCNS) with new onset of typical, pure nephrotic syndrome should be given a trial of corticosteroids.
 - Depending on the treatment regimen, 36–61% of children will have a relapse within first year of initial episode.
 - Relapse = urine tests $\geq 2+$ for protein on 3 consecutive days
 - Relapses are usually triggered by intercurrent illnesses or allergies.
 - Parents can be taught to use albumin test sticks or sulfosalicylic acid at home to monitor urinary protein excretion.
- Children who have relapse while corticosteroids are being tapered or within 2 weeks of completing a course of corticosteroids are considered corticosteroid dependent and may develop toxicity.
 - Second-tier therapies for difficult cases should be discussed with a pediatric nephrologist.

- Children who fail to respond to initial or subsequent courses of corticosteroids have corticosteroid-resistant nephrotic syndrome and a more guarded prognosis.
 - Consult with a pediatric nephrologist for consideration of a renal biopsy and more aggressive treatment.
- Salt intake should be restricted in edematous children.
- Water intake should be restricted only if:
 - Significant hyponatremia develops.
 - Edema is intractable.
- Diuretics should be used judiciously.
- Treatment of membranous nephropathy is controversial.
 - High rate of spontaneous remission
 - Consider treatment with high-dose corticosteroids (oral or intravenous), alone or combined with cytotoxic agents, if the patient has:
 - Renal insufficiency
 - Persistent heavy proteinuria
 - Hypertension
 - Sclerosis on biopsy
- Treatment for congenital nephrotic syndrome
 - Supportive, but must be aggressive
 - Until kidney transplantation can be done, treatment may include:
 - Intensive nutritional support
 - Nephrectomy
 - Maintenance on dialysis

SPECIFIC TREATMENTS

Corticosteroids

- Prednisone, 2 mg/kg daily or 60 mg/m² daily (maximum, 60–80 mg/day) for 4–6 weeks
 - Usually given in divided doses
 - Can also be given as a single morning dose
 - Followed by single dose of 1.3 mg/kg or 40 mg/m² for an additional 4–6 weeks given in the morning on alternate days
 - Decreased frequency of relapses in the first year and a lower total steroid dose if:
 - Daily prednisone is given initially for 6 weeks
 - Followed by 6 weeks of alternate-day prednisone
 - Tapered off over an additional 4 weeks
- Treatment of relapse
 - Prednisone, 2 mg/kg daily or 60 mg/m² daily until urine is free of protein for 3 consecutive days
 - Dose then changed to 40 mg/m² on alternate days for 4 weeks
 - Tapered off over an additional 4 weeks

■ Complications of corticosteroid therapy

- Development of cushingoid features
- Cataract formation
- Glaucoma
- Gastritis
- Peptic ulcer disease
- Pancreatitis
- Hypokalemia
- Hypertension
- Increased risk of infection
- Behavioral changes
- Growth delay if treatment is prolonged

Other pharmacologic agents

■ Angiotensin-converting enzyme inhibitors or angiotensin-receptor blockers

- Can be tried in resistant nephrotic syndrome, even in the presence of normotension
- High doses of angiotensin-converting enzyme inhibitors may decrease progressive sclerosis.

■ Diuretics

- Furosemide, alone or in combination with a thiazide diuretic, is used to treat clinically significant edema.
- Intravenous albumin followed by intravenous furosemide when edema is severe:
 - Interferes with ambulation
 - Compromises respiratory status
 - Causes tissue breakdown
- Renal function and urine output are fairly well maintained.
- Patients must be monitored closely during infusion for signs of intravascular overload.
 - Rales
 - Cardiac gallop
 - Hepatomegaly
- Treatment can be used in the severely edematous, corticosteroid-resistant nephrotic patient in whom cyclosporine therapy is being considered for improvement of renal perfusion and prevention of acute renal failure.

Secondary/tertiary/complementary treatment for difficult cases

- Cyclophosphamide, chlorambucil
 - Can induce prolonged remission
- Intravenous nitrogen mustard
 - Can be considered in noncompliant patients
- Cyclosporine or tacrolimus
 - Can be used as a corticosteroid-sparing agent in patients who do not respond to an alkylating agent

- Can cause acute and chronic renal injury
 - Acute renal failure can occur in severely nephrotic patients on cyclosporine who have markedly decreased intravascular volume.

■ Methylprednisolone infusions

■ Levamisole

- Has been used to decrease corticosteroid doses in patients who experience frequent relapse

■ Mycophenolate mofetil

- Some success as a corticosteroid-sparing agent
- Side effects include:
 - Bone marrow suppression
 - Gastrointestinal upset

■ Angiotensin-converting enzyme inhibitors

■ Angiotensin-receptor blockers

■ Nonsteroidal antiinflammatory drugs

- Used to decrease proteinuria in resistant nephrotic syndrome
- Can lead to acute renal failure in children with significantly decreased intravascular volume
- Can cause salt retention and edema
- Risk of renal failure, especially in patients with decreased intravascular volume

■ Complications of cytotoxic agents (eg, cyclophosphamide, chlorambucil, nitrogen mustard)

- Increased risk of infection
- Cancer
- Sterility
 - With higher doses than those typically used for nephrotic syndrome
 - After repeated or prolonged courses
- Hemorrhagic cystitis (cyclophosphamide)
 - Encourage large fluid intake and frequent voiding.
- Induction of seizures (chlorambucil)

WHEN TO ADMIT

- Initial episode for teaching of parents, especially if complications are present
- Anasarca interfering with ambulation or compromising ventilation
- Pleural effusions or ascites interfering with ventilation
- Signs of volume overload (congestive heart failure)
- Infection (eg, severe cellulitis, peritonitis)
- Significant hypertension
- Significant electrolyte abnormalities
- Compromised renal function
 - May require dialysis to manage edema, electrolyte disturbances, and uremia

WHEN TO REFER

- Complicated nephrotic syndrome
- Outside the expected age range (<1 year or >10 years of age)
- Accompanied by signs of glomerulonephritis (renal insufficiency, hypertension, hematuria, hypocomplementemia)
- Refractory edema
- Frequently relapsing nephrotic syndrome
- Corticosteroid-dependent nephrotic syndrome
- Corticosteroid-resistant nephrotic syndrome

COMPLICATIONS

- Infections
 - Spontaneous bacterial peritonitis
 - Sepsis
 - Cellulitis
 - Pneumonia
 - Children with recurrent nephrotic syndrome should receive multivalent pneumococcal vaccination.
 - *Staphylococcus pneumoniae* and gram-negative bacteria are responsible for most infections in nephrotic syndrome.
 - Predisposing factors for the development of bacterial infections
 - Tissue edema
 - Immunosuppressive therapies
- Thromboembolism
 - Deep-vein thrombosis
 - Pulmonary embolism
 - Renal-vein thrombosis
 - Arterial thrombosis
 - Contributory factors include:
 - Increased plasma levels of procoagulant factors
 - Urinary loss of inhibitors of coagulation
 - Thrombocytosis

- Predisposition to thrombus formation may be exacerbated by decreased intravascular volume, especially in the face of vigorous forced diuresis.

■ Hyperlipidemia

- In unremitting nephrotic syndrome, increased plasma lipids may contribute to cardiovascular morbidity; treatment of lipid abnormalities should be considered.

PROGNOSIS

- Approximately 25% of children who have relapse follow a frequently relapsing course, ie, either:
 - 2 relapses within 6 months of completing a course of corticosteroids *or*
 - 3 relapses within 1 year
- Prognosis of congenital nephrotic syndrome
 - Depends on the underlying cause
 - Guarded for congenital nephrotic syndrome of the Finnish type, with significant morbidity and mortality from complications
 - Malnutrition
 - Infection
 - Thrombotic events caused by massive protein losses
- Membranous nephropathy, poor prognostic factors
 - Persistent heavy proteinuria (>8 g/day for >6 months)
 - Hypertension
 - Increased creatinine
 - Significant scarring on biopsy

Nervousness

DEFINITION

- Feelings, such as anxiety or nervous stomach, that occur as symptoms without any readily discernible underlying pathophysiologic abnormality
- Nonspecific symptoms may be associated with another condition, eg:
 - Anorexia
 - Restlessness at night
 - Sluggishness
 - Overactivity
- A physical problem, with a variety of possible causes, is implied but often not at the root of the complaint.

MECHANISM

- Nervousness may have a physical cause.
 - Caffeine consumption
 - Endocrine disorder
 - Allergy
- Nervousness may result from:
 - Emotional distress
 - Psychological distress

HISTORY

- Complete history and thorough physical examination are needed.
 - The problem is difficult to define; thus adequate time is more important than urgency for:
 - Complete history
 - Thorough physical examination
 - Discussion of the problem in depth
- Ask what accompanies the nervousness.
 - Anorexia
 - Restlessness at night
 - Sluggishness
 - Overactivity
- Inquire about:
 - Caffeine ingestion (colas and coffee)
 - Use of drugs
- Evaluate concomitant findings that may indicate:
 - Attention-deficit disorder with or without hyperactivity
 - Anxiety disorder, such as separation anxiety or school phobia
 - Somatization of depression
 - Autism*
 - Childhood psychoses*
 - Obsessive-compulsive and manic-depressive disorders*
 - Panic attacks*
 - Tourette syndrome*

- More serious psychiatric problems, denoted with an asterisk (*), are rarely defined by families as nervousness alone.

PHYSICAL EXAM

- Even if the patient has no physical disorder, other problems may be evident.
 - Emotional tension
 - Restlessness, agitation
 - Fearful apprehension
 - Acute uneasiness
 - Undue excitability
 - Excessive irritability

DIFFERENTIAL DIAGNOSIS

- Nervousness is often part of the constellation of symptoms from:
 - Endocrine disorders
 - Hyperthyroidism
 - Hypoglycemia
 - Addison disease
 - Disorders associated with pruritus
 - Dermatitis
 - Pinworm infestation
 - Allergy
 - Disorders associated with palpitations
 - Mitral valve prolapse
 - Paroxysmal tachycardia

LABORATORY EVALUATION

- Laboratory investigations need to rule out conditions that cause nervousness.
 - Hyperthyroidism
 - Hypoglycemia
 - Addison disease
 - Pinworm infestation
 - Allergy
 - Mitral valve prolapse
 - Paroxysmal tachycardia

TREATMENT APPROACH

- If a conscientious search for biopsychosocial cause is unsuccessful, nervousness becomes even more difficult to manage.
- If the physician cannot provide the necessary time and effort, refer the patient to ease the morbidity associated with symptoms.

WHEN TO REFER

- Persistent, recurrent symptoms unresponsive to repeated physician reassurance
 - Unremitting symptoms that interfere with family, school, and social functioning
-

Neurocutaneous Syndromes

DEFINITION

- A heterogeneous group of conditions in which abnormalities of skin and nervous system predominate
- Prototypical neurocutaneous conditions
 - Neurofibromatosis
 - Tuberous sclerosis
 - Von Hippel-Lindau disease
- Several other genetic or developmental anomaly syndromes share the phenotypic association of cutaneous and neurologic abnormalities.
 - Sturge-Weber syndrome
 - Ataxia-telangiectasia
 - Incontinentia pigmenti
 - Hypomelanosis of Ito
 - Epidermal nevus syndromes
- Neurofibromatosis (NF) is divided into 7 types.
 - NF-1 and NF-2 are different conditions with only minimal overlap.
 - Both are autosomal-dominant disorders with high penetrance but variable phenotypic expression.
 - NF-1 (von Recklinghausen disease)
 - A complex disorder with neurologic, cutaneous, skeletal, vascular, and endocrinologic abnormalities
 - Neurofibromas are benign tumors that:
 - Appear in late childhood
 - Grow in response to hormonal changes
 - Proliferate with age
 - May compromise local function by mass effect
 - NF-2
 - A tumor syndrome defined by the presence of bilateral vestibular schwannomas
 - Also known as *multiple inherited schwannomas*, *meningiomas*, and *ependymoma syndrome*
 - NF-3 (mixed) and NF-4 (variant)
 - Autosomal dominant
 - Resemble NF-2
 - More cutaneous NFs
 - Greater risk of optic gliomas, neurilemmoma, meningiomas
 - NF-5 (segmental)
 - Skin lesions are located on a single body segment (eg, leg)
 - Somatic mosaicism
 - NF-6
 - Café-au-lait macules (CALMs)
 - CALM is only disease manifestation
 - Requires 2 generations to diagnose
 - NF-7
 - Late-onset
 - Symptoms manifest in the 20s
 - Not known whether it is heritable
- Tuberous sclerosis complex (TSC), or Bourneville disease
 - Autosomal dominant multisystem disorder
 - Characterized by perturbed cellular growth and differentiation in the brain, heart, kidneys, skin, eyes, and other tissues
- Sturge-Weber syndrome (SWS), or encephalotrigeminal angiomas
 - Rare sporadic disorder
 - Characterized by:
 - Upper facial port wine stain (PWS)
 - Ipsilateral ocular abnormalities
 - Ipsilateral leptomeningeal angiomas
 - Only 1 or 2 of the triad features may be present.
 - Leptomeningeal involvement is defining element.
- Von Hippel-Lindau disease (VHL) is an autosomal-dominant multiorgan familial cancer syndrome.
 - Subtype 1
 - High risk for hemangioblastoma, renal cell carcinoma, pancreatic cyst or tumor
 - Low risk for pheochromocytoma
 - Subtype 2a
 - High risk for hemangioblastoma, pheochromocytoma
 - Low risk for renal cell carcinoma, pancreatic cyst or tumor
 - Subtype 2b
 - High risk for hemangioblastoma, renal cell carcinoma, pheochromocytoma, pancreatic cyst or tumor
 - Subtype 2c
 - High risk for pheochromocytoma
 - Low risk for hemangioblastoma, renal cell carcinoma, pancreatic cyst or tumor
- Ataxia-telangiectasia (A-T), or Louis-Bar syndrome
 - Autosomal-recessive progressive neurodegenerative disorder

EPIDEMIOLOGY

- NF
 - Prevalence
 - NF-1 occurs in ~1 in 3500.
 - NF-2 occurs in ~1 in 40,000.
 - No race or gender predilection has been found.
 - Approximately one-half of cases of each condition represent new mutations.

- Age
 - NF-2
 - Average age at onset of symptoms is ~20 years.
 - Average age at diagnosis is 28 years.
 - 18% of patients show symptoms before age 15 years.
- TSC
 - Prevalence
 - Approximately 1 in 6000
- SWS
 - Prevalence
 - ~1 in 50,000 live births
 - No gender predilection has been found.
- VHL
 - Prevalence
 - 1 in 40,000 live births
 - Inherited in 80% of patients; 20% represent new mutations.
 - >90% penetrance by age 65 years
- A-T
 - Prevalence
 - 1 in 40,000 in the US
 - 1 in 300,000 in the UK

ETIOLOGY

- NF-1
 - Loss of function mutation in the neurofibromin tumor suppressor gene is thought to be responsible for most clinical features.
- NF-2
 - Precise mechanism of tumor formation is uncertain.
- TSC
 - Results from mutations in 1 of 2 genes:
 - *TSC1* encodes hamartin.
 - *TSC2* encodes tuberin.
 - Mutations of *TSC1* are more common in familial cases.
 - Seem to result in less severe disease
- SWS
 - Thought to result from:
 - Failed regression of the cephalic venous plexus
 - Only a few case reports have suggested familial occurrence.
 - Appears to result from somatic mosaicism
 - Supported by discordance between monozygotic twins
- VHL
 - Almost all patients with VHL have germ-line mutations in the VHL gene (found on chromosome 3) and secondary somatic mutations (Knudson's 2-hit hypothesis)

- Subdivided into 2 major categories based on the type of mutation
 - Type 1 disease: mutations are premature termination mutations or deletions, not associated with significant risk for pheochromocytoma.
 - Type 2 disease: characterized by missense mutations; pheochromocytoma is a predominant tumor in type 2 disease.
- A-T
 - Caused by mutations in the *ATM* (A-T, mutated) gene
 - Loss of *ATM* function leads to:
 - Accumulation of defective DNA
 - Inability to repair or eliminate genetically defective cells
 - Defective DNA repair explains the sensitivity to ionizing radiation.
 - Inability to remove damaged cells has been postulated as a cause of many of the diverse abnormalities in A-T.
 - Cancer has been linked to genomic instability.

SIGNS AND SYMPTOMS

NF-1

- Characteristic lesion is the neurofibroma.
 - Proliferation of Schwann cells and fibroblasts
- Small neurofibromas appear as:
 - Pink to flesh color to brown papules
 - Soft, spongy texture (see Figure 42 on page F17)
 - Gentle downward pressure can cause these lesions to sink through the underlying dermis and create a dimple (see Figure 43 on page F18).
- Size and number vary greatly.
- Slight predilection for trunk involvement, but neurofibromas can occur anywhere on the body.
- Plexiform type (seen in ~50% of patients)
 - Variant of neurofibroma
 - Can be large
 - Can cause considerable disfigurement
 - Highly variable masses
 - Sometimes soft and spongy in texture, other times feels like a bag of rope
 - May have surface hyperpigmentation or remain flesh-colored
 - Overlying skin
 - May be somewhat thickened
 - May exhibit increased hair growth
 - Often produce soft tissue masses
 - Figure 44 on page F18 shows plexiform neurofibroma on a breast.

- Earliest features often are CALMs.
 - Tan, oval macules
 - Smooth margins
 - No surface texture change
 - Remain flat
 - No increased hair growth
 - May vary in size and shape
 - May increase in number and size with age
 - Figure 45 on page F18 shows multiple CALMs on an infant, with coincidental gray Mongolian spot.

NF-2

- Characteristic vestibular schwannomas lead to progressive deterioration of hearing.
- Patients may develop:
 - Intracranial or spinal meningiomas
 - Ependymomas
 - Astrocytomas
 - Neurofibromas
 - Schwannomas of the cranial, spinal, and peripheral nerves
 - Cutaneous schwannomas (with minimal clinical impact)
- Ependymomas and astrocytomas are seen in up to 33% of patients.
- Peripheral schwannomas may arise from any nerve (see Figure 46 on page F18).
 - May produce pain or sensory or motor dysfunction
- Patients may develop peripheral neuropathy not related to tumor growth.
- Seizure disorders are uncommon.
- Cognitive impairment is not a feature.
- Ocular findings include:
 - Juvenile posterior subcapsular lens opacities
 - Retinal hamartomas
 - Cortical wedge opacities

TSC

General

- Classic triad includes:
 - Seizures
 - Intellectual disability
 - Facial angiofibromas
- Seizures and facial lesions occur frequently.
- Mental function often is normal or only slightly impaired.
 - ~50% of patients with TSC have normal intelligence.
 - ~30% have profound intellectual disability
- Hallmark of TSC is the development of hamartomas in the various organ systems involved.

- An international consensus conference in 1998 revised diagnostic criteria, based on new understanding of disease and its underlying pathophysiological features.

- Major criteria
 - Facial angiofibroma or forehead plaque
 - Ungual or subungual fibroma
 - >3 hypomelanotic macules
 - Connective tissue nevus (Shagreen patch)
 - Cortical tuber
 - Subependymal nodule
 - Subependymal giant-cell astrocytoma
 - Multiple retinal hamartomas
 - Cardiac rhabdomyoma
 - Renal angiomyolipoma
 - Lymphangiomyomatosis
- Minor criteria
 - Dental enamel pits
 - Hamartomatous rectal polyps
 - Bone cysts (radiographic evidence sufficient)
 - Cerebral white matter migration lines
 - Gingival fibromas
 - Retinal achromic patch
 - Nonrenal hamartomas
 - Multiple renal cysts
 - Confetti skin lesions

Diagnosis for TSC

- Definitive: 2 major, or 1 major + 2 minor criteria
- Probable: 1 major criterion + plus 1 minor criterion
- Possible: 1 major or ≥ 2 minor criteria

TSC has no pathognomonic feature.

Individual features may occur in isolation.

- Primary care physician must consider the diagnosis of TSC only if:
 - >1 organ system is involved.
 - Different lesion types occur in a single system.

Central nervous system manifestations (CNS) are the most common and often most disabling aspect of TSC.

Neurologic features include:

- Seizures
- Cognitive disability
- Behavioral disturbances

Seizures

- Occur in 80–90% of patients
- All types of seizures except classic absence seizures have been reported.

■ Infantile spasms

- Seen in approximately one-third of infants.
 - The presenting feature in 70% of cases
 - Thorough description of the clinical and electroencephalographic findings in infantile spasms is found in Seizure Disorders.
 - Children with infantile spasms are likely to have cognitive disability, corresponding to increased cortical hamartoma (tuber) burden.

Cognitive impairment

- Seizure onset and severity are closely associated with severity of cognitive impairment.
 - Early onset of seizures or infantile spasms is associated with poor cognitive outcome.
- Most patients with TSC and cognitive disability have epilepsy.
 - Many patients with TSC and seizures have normal intellect.
- Presence of ≥ 7 cortical tubers on magnetic resonance imaging (MRI) confers a 5-fold increase in risk of moderate to profound cognitive impairment.
 - A few patients with multiple tubers and normal intellect have been reported.
- Autism spectrum disorder is more common in TSC.
 - Estimates of prevalence range from 17–68%.
 - Autism spectrum disorder is much more common in children with global cognitive impairment in TSC (>60%), compared with only 6% among TSC children with normal cognitive function.
 - Almost all children with autism spectrum disorder and TSC have epilepsy.
 - Patients with autism and TSC do not exhibit the male preponderance seen in autism without TSC.
 - TSC is found in up to 4% of children with autism spectrum disorder.
 - TSC is the underlying genetic condition in 14% of children with autism and seizures.

Behavioral abnormalities

- Behavioral abnormalities include:
 - Severe temper tantrums
 - Restlessness
 - Impulsivity
 - Attention deficit with hyperactivity
 - Self-injury
 - Anxiety
 - Depression
- Among children with TSC and a history of infantile spasms and autism, 69% exhibit behaviors disruptive to the family by age 5 years.
- Anxiety disorder is seen in up to 59% of adults.
- Depression is seen in 35% of adults.

- Learning disabilities have been noted frequently in TSC.
 - No systematic studies are available to date.

Neuropathology

- Neuropathologic findings responsible for many of the symptoms of TSC include:
 - Tubers
 - Subependymal nodules
 - Subependymal giant cell astrocytomas
- Cortical tubers are nodular areas of gray and white matter dysplasia.
 - Often seen on the apex of a gyrus
 - Tubers are present in >95% of patients with TSC.
 - Tubers have been noted as early as 20 weeks' gestation.
 - Known to persist throughout life
 - No risk of malignant degeneration exists.
 - Tubers function as epileptogenic foci.
- Subependymal nodules are present in up to 80% of patients with TSC.
 - Arise from the lateral and 3rd ventricle walls
 - Often protrude into the lumen
 - Can be present before birth
 - Sometimes may be noted on imaging studies during infancy
- Subependymal giant cell astrocytomas may be symptomatic.
 - Occur in up to 14% of patients with TSC
 - Seem to arise from subependymal nodules
 - Continue to grow during childhood
 - May produce focal neurologic deficits or obstructive hydrocephalus

Cutaneous manifestations

- Skin findings are the most consistent features of TSC.
 - Hypomelanotic macules
 - Found in >90% of patients with TSC
 - Formerly known as *ash leaf spots*
 - May be present at birth (see Figure 47 on page F18)
 - In lighter-skinned individuals, may be visible only with a Wood lamp
 - Usually larger than 1 cm
 - Have a characteristic leaf shape: oval with 1 blunt end and 1 pointed end
 - At least 3 lesions must be visible for diagnostic significance.
 - Hypomelanotic macules
 - Seen most commonly on the trunk, but may occur anywhere
 - Fine, stippled hypopigmentation on the extremities is known as *confetti lesions*.
 - When hypomelanotic macules occur on hair-bearing surfaces, associated poliosis (white hair) may be found.

- Facial angiofibromas
 - Noted in 70–75% of individuals
 - Formerly known as *adenoma sebaceum*
 - Small, discrete, shiny pink to reddish papules develop by ~5 years of age.
 - Increase in number and size into the teenage or early adult years (see Figure 47 on page F18)
 - Initially distributed over the malar areas
 - Often spread to chin and nasolabial folds during puberty
- Forehead plaques
 - Flesh-colored to erythematous fibrotic plaques on the forehead or frontal scalp in ~19% of patients.
 - Appear later than angiofibromas
- Shagreen patches (see Figure 48 on page F18)
 - Connective tissue nevi seen in 20–50% of patients
 - Flesh-colored
 - Slightly raised
 - Irregularly shaped plaques
 - Prominent follicles
 - Cobblestone texture
 - Most often on the lower back
 - Usually noted in later childhood
- Ungual and subungual fibromas
 - Firm flesh-colored to red papules that develop beside or beneath the nails
 - Lesions under the nail may appear as a longitudinal ridge or groove.
 - Toenail involvement is more common.
 - Typically appear during puberty

Cardiac manifestations

- Cardiac rhabdomyomas are present in one-half to two-thirds of infants with TSC.
- Usually remain asymptomatic and decrease in size over time
- Often multiple
- Often diagnosed on prenatal ultrasound

Ocular manifestations

- Retinal hamartomas
 - Seen in 50–87% of patients with TSC
 - Most remain asymptomatic.
 - May be bilateral in up to 50%
 - Three clinical types include
 - Raised mulberry-like calcified nodule
 - Flat translucent gray patch
 - Transitional lesion with mixed features
- Factors that may lead to loss of vision include:
 - Involvement of the macula
 - Enlargement of the hamartoma

- Vitreous hemorrhage
- Retinal detachment
- Other ocular findings may include:
 - Retinal pigment anomalies
 - Strabismus
 - Cataracts
 - Colobomas
 - Iris depigmentation
 - Eyelid angiofibromas

Renal manifestations

- Renal lesions occur in 80% of patients.
- May include angiomyolipoma, cysts, and renal cell carcinoma (RCC)
- Prevalence increases with age.
- Angiomyolipomas develop in 55–75% of patients >10 years.
- Bilateral and multiple tumors are common.
- Small lesions may remain asymptomatic.
- Lesions >4 cm pose risks of:
 - Severe hemorrhage
 - Hypertension
 - Renal insufficiency
- Renal cysts occur in ~17% of children and 47% of adults.
- Solitary epithelial cysts are the most common.
- ~3–5% of patients with TSC will develop polycystic kidney disease as a contiguous gene deletion syndrome.
 - *TSC2* gene is adjacent to the adult polycystic kidney disease gene *PKD1* on chromosome 16.
 - Polycystic kidney disease may lead to renal insufficiency in late adolescence.

Pulmonary manifestations

- Symptomatic lymphangiomyomatosis occurs in 1–2%, almost exclusively in young women.
- Radiographic evidence of lymphangiomyomatosis may be seen in 26–39% of women.
- Main clinical findings include:
 - Spontaneous pneumothorax
 - Dyspnea
 - Cough
 - Hemoptysis

Vascular manifestations

- Arterial dysplasia seen most often in renal angiomyolipomas
- Also has been reported with basilar artery and aortic aneurysms

Dental manifestations

- Gingival fibromas occur in ~50% of adults with TSC.
- Almost all patients with TSC have dental enamel pits in permanent teeth.

- Dental pits rarely cause problems.
- Extensive fibromas may result in malocclusion or abnormal tooth eruption.

SWS

General

- Exhibits at birth
- Upper facial capillary malformation (PWS), involving the area of skin innervated by the ophthalmic (V1) division of the trigeminal nerve
 - Area includes:
 - Forehead
 - Brow ridge
 - Upper eyelid
 - Possibly the lower eyelid
 - Lower areas of the face (V2 or V3 distributions) also may be involved.
 - No apparent significant risk of SWS exists in the absence of V1 involvement.
 - Unilateral PWS is the rule.
 - Only 10–30% have bilateral PWS.
 - With unilateral facial PWS, the risk of SWS is ~8%.
 - If bilateral PWS is present, the risk is much higher.
 - One of the more useful clinical clues seems to be eyelid involvement, a significant predictor of disease.
 - PWSs are pink to red blanching macules to patches with variable irregularity of the borders (see Figure 49 on page F19).
 - They are capillary malformations.
 - Remain fixed in location
 - Show no tendency to evolve or involute over time
 - Growth should be commensurate with the child's growth.
 - With age, the PWS may thicken and darken, becoming somewhat cobblestoned by adulthood.

Ocular manifestations

- May include:
 - Glaucoma
 - Vascular anomalies of the globe
 - Conjunctiva
 - Episclera
 - Retina
 - Choroid
 - Buphthalmos
 - Iris heterochromia
 - Retinal detachment
 - Retinal pigment degeneration
 - Cataract
 - Optic disc coloboma

- Glaucoma is the most common ocular problem.
 - Occurs in up to 70% of patients
 - Usually ipsilateral to the PWS
 - May be bilateral, even if the PWS is unilateral
 - Glaucoma may develop from birth to the 5th decade.
 - Median age at onset is 5 years.
 - Develops in infancy to early childhood in 60%
 - Development in infancy, when the globe is more sensitive to increased intraocular pressure, may lead to:
 - Increased corneal diameter
 - Buphthalmos
 - Iris heterochromia
 - Choroidal hemangioma ipsilateral to the PWS is seen in up to 71% of patients.
 - Over time, retinal changes can lead to visual field defects and vision loss.

Neurologic manifestations

- Neurologic features may include:
 - Seizures
 - Focal neurologic deficits
 - Developmental delay
 - Progressive intellectual disability
 - Headaches
- Seizures are the most common neurologic problem.
 - Occur in 75–83% of patients
 - ~75% of seizure disorders develop in the first 2 years of life.
 - Partial motor seizures are the most common type (40%).
 - Generalized tonic-clonic, atonic, and absence seizures may also occur.
 - Infantile spasms may be the presenting seizure type.
 - Seizures tend to worsen with age, becoming more frequent, severe, and complex
 - Seizures may be provoked by febrile episodes.
 - Status epilepticus may occur in up to one half of these children.

Developmental and behavioral problems

- Developmental delays are seen in up to one-half of patients.
 - Early milestones often normal
 - Decline in function noted over time
 - Some of the cognitive decline occurs during periods of encephalopathy after prolonged or severe seizures.
 - Others experience decline in function as a result of recurrent strokelike episodes.
 - Factors that seem to correlate best with developmental delay and its severity are presence of:
 - Bilateral cerebral lesions
 - Degree of cerebral atrophy

- Presence of intractable seizures
- Multiple seizure types
- Early onset of seizures (controversial)
- In the absence of seizures, cognitive development is normal.
- 85% of patients with seizure onset after age 4 years have normal intelligence.
- Psychological manifestations of SWS may include:
 - Attention-deficit/hyperactivity disorder (ADHD)
 - Irritability
 - Social problems
- Inattentive and oppositional behaviors may be noted.
- ~85% of patients who have cognitive disability exhibit emotional or behavioral problems.
 - Aggressive behavior toward others
 - Self-abuse
- Headache, including migraine, is seen in 30–45%.
 - Median age at onset is 8 years.
 - Migraines may be associated with:
 - Visual aura
 - Visual field defects

VHL

General

- Most common tumors
 - Cerebellar
 - Spinal
 - Retinal hemangioblastomas
- Other associated tumors
 - Renal cysts
 - RCC
 - Pheochromocytoma
 - Pancreatic cysts
 - Neuroendocrine tumors
 - Endolymphatic sac tumors of the inner ear
 - Cystadenomas of the epididymis or broad ligament

CNS manifestations

- CNS hemangioblastomas are the most common tumors in VHL (21–72%).
 - Occur most commonly in the cerebellum (63%)
 - Followed by the spinal cord (32%) and
 - Brainstem (5%)
 - Mean age at presentation is 33 years.
 - Tumors may develop in childhood through the 4th decade of life.
 - Slow-growing benign tumors produce symptoms largely by mass effect or obstructive hydrocephaly.

- Cerebellar tumors may present with:
 - Headache
 - Nausea
 - Vomiting
 - Vertigo
 - Slurred speech
 - Broad-based gait
- Clinical signs may include:
 - Papilledema
 - Nystagmus
 - Ataxia
 - Dysmetria
- Spinal hemangioblastomas may produce:
 - Back pain
 - Numbness
 - Pain or weakness in arms or legs
 - Posterior column proprioceptive defects
 - Bowel and bladder dysfunction
- CNS hemangioblastomas tend to exhibit alternating periods of growth and stability.
 - Low-level chronic symptoms may worsen acutely during a critical growth phase.

Ocular manifestations

- Retinal hemangioblastomas (capillary hemangiomas) develop in more than one-half of patients with VHL.
 - Most have solitary tumors
 - Approximately one-third have multiple lesions.
 - One-half of patients have bilateral retinal tumors
 - Most develop in the 2nd to 3rd decade of life.
 - Mean age at diagnosis is 25 years.
 - Retinal tumors may develop at any time from infancy to the 9th decade.
 - Patients may experience painless loss of visual acuity or visual field defects.
 - They may remain asymptomatic.
 - Exudation or hemorrhage from the hemangiomas may lead to:
 - Macular edema
 - Retinal detachment
 - Secondary changes in the anterior chamber may lead to:
 - Glaucoma
 - Cataract

Renal manifestations

- Renal cysts are seen in approximately one-half of patients.
- Often multiple and bilateral
- May remain asymptomatic

- Stable lesions may not require intervention.
- RCC develops in 75% of patients by age 60.
- RCC is seen in patients with type 1 or type 2b disease.
 - Usually develops after 20 years of age
 - Often earlier than with sporadic renal carcinoma
 - Lesions often are multiple and bilateral.
 - Tumors may be associated with cysts.
 - May have better 10-year survival than sporadic RCC
 - Symptoms may include:
 - Hematuria
 - Flank pain
 - Flank mass
 - By the time symptoms develop, metastases are present in 30–50% of patients.

Endocrine system

- Pheochromocytoma occurs in 10–24% of persons with type 2 disease.
 - May be the only manifestation of VHL (type 2c)
 - VHL accounts for ~20% of all pheochromocytomas.
 - Mean age at presentation is 27 years.
 - Tumors may be present even before age 10 years.
 - Pheochromocytoma in VHL differs from sporadic tumors by:
 - Occurring at an earlier age
 - Developing multiple, bilateral, and extraadrenal tumors
 - Only 5% of VHL pheochromocytomas are malignant.
 - Clinical features may include:
 - Hypertension (paroxysmal or sustained)
 - Palpitations
 - Sweating
 - Flushing
 - Headache
 - Tachycardia
 - Pallor
 - Nausea
 - Pancreatic cysts or tumors occur in ~90% of patients with VHL.
 - Rarely cause disease
 - Benign adenomas occur in ~12% of patients with VHL.
 - ~5–10% of patients with VHL develop neuroendocrine islet cell tumors.
 - May be multifocal
 - May metastasize in 10–20% of patients
 - Average age at diagnosis of pancreatic lesions is 41 years.
 - Islet cell tumors may be seen as early as 10 years of age.
 - Most pancreatic lesions are asymptomatic.
 - Found during routine imaging surveillance.

- ~10% will develop endolymphatic sac tumors.
 - Cystadenomas arising from the inner ear labyrinth ectoderm may cause:
 - Deafness
 - Tinnitus
 - Vertigo
 - Facial nerve and vocal paralysis may result from progressive tumor growth.
- Cystadenomas may develop in the epididymis in men and the uterine broad ligament in women.
 - Usually asymptomatic

A-T

- Consanguinity is common.
- Characteristic features
 - Progressive decline in cerebellar function
 - Oculocutaneous telangiectasia
 - Immunodeficiency
 - Susceptibility to cancer
 - Sensitivity to ionizing radiation
- Infants are normal.
 - Begin to walk at approximately 12 months of age
 - By age 2–3 years, develop unsteady gait and staggering
- By age 10 years, most require wheelchairs for mobility; they have slow reflexes and tend to fall.
- Ocular apraxia develops in early childhood.
 - Difficulty with voluntary eye movement
 - May be confused with absence seizures in infants
 - Dysarthric speech often is present early in childhood.
 - Can be difficult to assess
- Telangiectasias (tortuous dilated capillaries) develop several years after the onset of neurologic symptoms on:
 - Bulbar conjunctiva
 - Nasal bridge
 - Ears
 - Neck
 - Knuckles
 - Antecubital and popliteal fossae
- Immunodeficiency varies.
 - May be severe in approximately one-third of patients.
 - Many patients have reduced numbers of T lymphocytes with poor mitogen response.
 - Low serum levels are noted despite normal to high numbers of B cells.
 - Immunoglobulin (Ig) E (80% of patients)
 - IgG₂ (80%)
 - IgA (60%)
 - IgM levels vary widely, at times rising enough to create a hyperviscous state

- Some patients exhibit poor immune response to pneumococcal polysaccharides.
- Patients with severe immunodeficiency may develop recurrent sinopulmonary infections.
- Opportunistic organisms are not a problem in patients with A-T.

DIFFERENTIAL DIAGNOSIS

NF-1

- CALMs are often the earliest presenting feature.
 - Up to 25% of normal individuals may have 1–3 CALMs.
 - Up to 40% of people with > 6 CALMs never progress to NF-1.
- Multiple CALMs may be present in the following conditions:
 - NF-1
 - Clinical features
 - Axillary freckling
 - Cutaneous NFs
 - Plexiform NFs
 - Lisch nodules
 - Optic glioma
 - Bony abnormalities
 - Positive FH
 - Present in 95% of patients with NF-1; must have >6 CALMs (>5 mm before puberty; >15 mm after puberty)
 - Watson syndrome
 - Other clinical features
 - Pulmonic stenosis
 - Intellectual disability
 - Axillary freckling
 - Axillary freckling only in NF-1 and Watson syndrome type 1
 - McCune-Albright syndrome
 - Other clinical features
 - Polyostotic fibrous bony dysplasia
 - Precocious puberty
 - Hyperthyroid
 - Cushing syndrome
 - Usually large-segment CALM with irregular border (*coast of Maine*).
 - Russell-Silver syndrome
 - Other clinical features
 - Short stature
 - Skeletal asymmetry
 - Abnormal pubertal development

- Bloom syndrome
 - Other clinical features
 - Malar facial erythema and telangiectasia
 - Photosensitivity
 - Long, narrow face with prominent nose
 - Short stature
 - Hypogonadism
 - Malignancy risk
 - Facial photosensitivity with multiple CALMs triggers evaluation
- Tuberous sclerosis
 - Other clinical features
 - Hypopigmented macules
 - Facial and periungual angiofibromas
 - Seizures
 - Intellectual disability
 - Renal and cardiac hamartomas
 - Hypopigmented macules more common; mixture very concerning for tuberous sclerosis complex
- Noonan syndrome
 - Other clinical features
 - Hypertelorism
 - Webbed neck
 - Short stature
 - Leg lymphedema
 - Pulmonic stenosis
 - Hypogonadism

TSC

- Does not have a pathognomonic lesion
- Fulfillment of diagnostic criteria is of paramount importance.
- Facial angiofibromas once were considered diagnostic.
 - Now known to occur in multiple endocrine neoplasia syndrome type 1

SWS

- Isolated (ie, nonsyndromic) facial PWS
 - Unilateral forehead PWS has no underlying syndrome in 92% of patients.
 - Bilateral PWS has a much higher likelihood of association with SWS.
- Wyburn-Mason syndrome
 - Rare disorder consisting of retinal and CNS arteriovenous malformations associated with upper facial PWS.
 - Symptoms include:
 - Headaches
 - Seizures
 - Focal neurologic deficits

- Retinal hemorrhage
- Subarachnoid hemorrhage

VHL

- CNS hemangioblastomas create symptoms by mass effect.
- Similar to many other tumors, cysts, and obstructive hydrocephalus
- Evaluation of mass effect with neurologic symptoms should reveal characteristic radiologic findings of hemangioblastomas.
- Differential diagnosis of retinal capillary hemangiomas
 - VHL
 - Orange-red circumscribed tumors
 - Pair of prominent vessels
 - Stellate macular exudates
 - Retinal or subretinal exudates
 - Coat disease
 - Diffuse retinal vascular anomaly
 - Retinal or subretinal exudates
 - Wyburn-Mason syndrome
 - Dilation and tortuosity of retinal arteries and veins, but no intervening hemangioma
 - No retinal or subretinal exudates
 - Retinal cavernous hemangioma
 - Cluster of small dilated vessels around central vein
 - Lacks prominent feeder vessels
 - No retinal or subretinal exudates
 - Vasoproliferative tumor of the retina
 - Pink to yellow retinal tumor
 - Lacks dilated feeder vessels
 - Lacks stellate macular exudates
 - Retinal or subretinal exudates (nonstellate)
- Differential diagnosis of renal cysts includes the diagnosis of polycystic kidney disease.
- Pheochromocytoma may occur sporadically or in the setting of
 - VHL
 - Multiple endocrine neoplasia 2a or 2b with associated medullary thyroid carcinoma
 - Neurofibromatosis
 - Succinate dehydrogenase subunit mutations

A-T

- A-T
 - Early ataxia, oculomotor apraxia, progressive neurologic decline
 - Increased α -fetoprotein
 - Cancer risk

- Immune deficiency
- Sensitivity to radiation
- Ataxia-telangiectasia–like disorder (*hMRE11* mutation)
 - Ataxia early
 - No telangiectasia
 - No increase in α -fetoprotein
 - No cancer risk
 - No immune deficiency
 - Sensitivity to radiation
- Nijmegen breakage syndrome
 - Microcephaly, intellectual disability
 - No telangiectasia
 - No increase in α -fetoprotein
 - Cancer risk
 - Immune deficiency
 - Sensitivity to radiation
- Ataxia oculomotor apraxia I
 - Early ataxia, progressive neurologic decline
 - No telangiectasia
 - No increase in α -fetoprotein
 - No cancer risk
 - No immune deficiency
 - No sensitivity to radiation
- Ataxia oculomotor apraxia II
 - Late-onset ataxia
 - No telangiectasia
 - Increased α -fetoprotein
 - No cancer risk
 - No immune deficiency
 - No sensitivity to radiation

DIAGNOSTIC APPROACH**NF-1**

- Cannot be diagnosed clinically until ≥ 2 of the major diagnostic criteria are met:
 - >6 café-au-lait spots
 - >5 mm in prepubertal child
 - >15 mm after puberty
 - Axillary or inguinal freckling
 - ≥ 2 neurofibromas of any type or = 1 plexiform neurofibroma
 - Optic pathway glioma
 - ≥ 2 Lisch nodules
 - Characteristic bony lesion: sphenoid wing dysplasia, or thinning of the cortex of long bones—with or without pseudoarthrosis
 - First-degree relative with NF-1

■ History

- Should include age-appropriate questions about:
 - Development
 - Language and learning
 - Socialization
 - Self-esteem
- Family history is of paramount importance in the initial evaluation of a child with CALMs only.

■ Physical examination

- Should start with a thorough skin survey for CALMs
- Thorough examination of the entire skin surface should also reveal the presence of plexiform neurofibromas.
 - May be present at birth
 - May develop in the 1st few years of life

■ Evaluation for possible NF-1 depends on age.

- Many features develop over time.
- CALMs are present at birth and will increase in size and number for the first 5–7 years.
- Bowing of the long bones (especially tibia) and cutaneous plexiform neurofibromas typically are visible within the 1st year of life.
- Axillary (see Figure 50 on page F19) and inguinal freckling, optic gliomas, and scoliosis may not be apparent until age 7 years.
- Cutaneous neurofibromas and iris Lisch nodules usually appear during or after the teenage years.

NF-2

■ History should include

- Vision or hearing changes
- Tinnitus
- Vertigo
- Gait disturbances
- Decreased facial sensation
- Facial weakness or twitching
- Hoarseness
- Dysphagia
- Headaches

■ Family history of NF-2 is crucial for diagnosis

■ Definite NF-2

- Bilateral vestibular schwannomas *or* 1st degree relative with NF-2 *plus*
 - Unilateral vestibular schwannomas or any 2 of the following:
 - Meningioma
 - Schwannoma
 - Glioma
 - Neurofibroma
 - Juvenile posterior subcapsular cataract

■ Probable NF-2

- Unilateral vestibular schwannoma *plus* multiple meningiomas *or* any 2 of the following:
 - Meningioma
 - Schwannoma
 - Glioma
 - Neurofibroma
 - Juvenile posterior subcapsular cataract
- *Or* any 2 of the following:
 - Schwannoma
 - Glioma
 - Neurofibroma
 - Juvenile posterior subcapsular cataract

■ Physical examination should focus on

- Vision
- Hearing
- Cranial and peripheral nerve function
- Younger patients often have
 - Headache
 - Tinnitus
 - Cranial nerve symptoms
 - Skin or spinal tumors before the onset of hearing loss
- Eye examination should assess the presence of lens opacities.
- Cranial nerve examination should specifically address:
 - Trigeminal nerves
 - Facial nerves
 - Auditory nerves
- Neurologic examination should assess:
 - Balance
 - Gait
 - Deep tendon reflexes
- At the skin examination, the physician should note the presence of:
 - Neurofibromas
 - CALMs
 - Cutaneous schwannomas
 - Present in approximately one-half of patients.
 - May be subcutaneous nodules or plaques with thickened texture and occasional hair growth
 - May be surface pink to flesh-colored papules (see Figure 46 on page F18)

TSC

■ History

- In infants, seizures often are the 1st symptom.
- Any infant with new-onset seizures should have a detailed history, including:

- Skin lesions
- Developmental milestones
- Family history
- Initial examination should include:
 - Wood lamp examination of the entire skin surface
 - Funduscopic examination for hamartomas
 - Thorough neurologic examination

SWS

- Infants with facial PWS on the forehead and eyelids should be evaluated for the possibility of SWS.
- Evaluation should include ophthalmologic examination.
 - If eye findings or any other typical clinical features such as seizures are present, then neuroimaging is mandatory.
- Routine MRI may be performed even in the absence of seizures.
- History
 - Earliest manifestation is the PWS present at birth.
 - Relevant history in a child with facial PWS includes:
 - History of seizures
 - History of eye or vision problems
 - Concerns about development
 - Older children should be asked about:
 - Headaches
 - Vision changes
 - Episodes of weakness
 - School progress
- Physical examination
 - Should include a thorough eye examination.
 - Clues to early glaucoma
 - Difference in sizes of cornea or globe
 - Iris heterochromia
 - Presence of PWS on eyelids should be noted.
 - Auscultation of the orbits, fontanelles, and temples should be performed to detect bruits.
 - Funduscopic examination may reveal the characteristic “ketchup stains” of choroidal angiomas.
 - Tortuous vessels or colobomas should be noted.
 - Neurologic examination should search for focal deficits.
 - Developmental evaluation is important.
 - Particularly if the child has a seizure history
 - Observation of an infant should specifically address the presence of a head turn or early handedness.
 - Potential clues to visual field cuts

VHL

- Diagnosis established in a patient who has:
 - 1 characteristic tumor and positive family history
 - Hemangioblastoma *plus* 1 other tumor when the family history is negative

History

- Most important historical information is family history
 - 80% of cases are familial
- Changes in vision
- Development of neurologic symptoms
 - Clumsiness
 - Broad-based gait
 - Hearing loss
 - Slurring of speech
 - Pain
 - Numbness or weakness in limbs
- Loss of bowel or bladder control after complete toilet training
- Hematuria or flank pain
- Heart palpitations
- Flushing
- Sweating spells
- Episodic nausea and vomiting
- Physical examination should include:
 - Blood pressure evaluation
 - Thorough eye examination
 - Thorough neurologic examination with particular attention to cerebellar and spinal functions
 - Observation of gait
 - Test of balance
 - Observation of deep tendon reflexes
 - Test for sensation

A-T

- Earliest manifestation of A-T is the ataxia.
 - Begins as broad-based gait or staggering
 - Evident by age 2–3 years
- Any other history should focus on:
 - Additional neurologic symptoms
 - Developmental milestones
- Family history should include:
 - Neurologic problems
 - Consanguinity in the family
- Examination should focus on neurologic findings.
 - Include cerebellar function
 - Difficult to assess in young children
 - Voluntary visual tracking of objects will often reveal the early development of oculomotor apraxia.
 - In older children, telangiectasia may be noted on:
 - Bulbar conjunctiva
 - Skin of the neck
 - Face

- Ears
- Extremity flexures
- Examination also should include:
 - Thorough lymph node examination
 - Abdominal evaluation for hepatosplenomegaly

LABORATORY FINDINGS

NF-1

- Routine laboratory testing is unnecessary.
- In cases of uncertain diagnosis, test for gene mutations.
 - Complementary series of analyses is available, including:
 - Premature truncation test
 - Heteroduplex analysis
 - Fluorescent in situ hybridization assay
 - This tiered analysis provides a sensitivity of 95%.

NF-2

- Should always include formal audiologic testing for sensorineural hearing loss
- Once the diagnosis is established, audiometry should be repeated every 6–12 months.
 - Annual screening appropriate for:
 - Children at risk
 - Asymptomatic children with a detected mutation
- Genetic testing for the mutations is available on a clinical basis.
 - Sensitivity is low:
 - 34% in sporadic mutations
 - 54% if familial
 - High false-negative rate

TSC

- Once diagnostic criteria are fulfilled, molecular testing can be performed to determine the specific mutation.
- 15–20% of patients who fulfill TSC diagnostic criteria have no identifiable mutations.
- Clinical gene testing is available by using combined techniques such as:
 - Denaturing high-performance liquid chromatography
 - Heteroduplex analysis
- Mutation detection rate is only 85%, even with combined methods.

SWS

- Routine laboratory testing is not useful.

VHL

- Should begin with molecular testing for the specific mutation
 - Phenotypic profile and tumor risk are directly related to the types of mutation.

- Subsequent laboratory evaluation for patients with type 2 disease should consist of:
 - Annual screening for plasma or urine catecholamines and metanephrines
 - Begin at age 10 years

A-T

- Serum α -fetoprotein
 - Increased in >95% of patients
 - Serum α -fetoprotein increase is only useful after age 2 years
 - Some unaffected children have persistent mild increases beyond the neonatal period.
- Karyotyping rarely is normal in A-T.
 - Often shows translocations between chromosomes 7 and 14
- Quantitative immunoglobulins may show low levels of:
 - IgE
 - IgA
 - IgG2
- IgM is normal or high.
- Quantitative T- and B-cell numbers reveal:
 - Low levels of T cells
 - Normal to slightly high levels of B cells
- Radiosensitivity test currently available is the colony survival assay.
 - Uses the patients' transformed lymphocytes.
 - Requires ~3 months to complete
- Gene testing is not useful unless the family mutation is known.
 - *ATM* is a huge gene with 66 exons and >400 known mutations
 - None with a frequency >3%
- Measurements of the ATM protein from the transformed lymphocyte cell line also is possible by immunoblotting.

IMAGING

NF-1

- Routine neuroimaging usually is not undertaken.
- Evidence of scoliosis or long bone anomaly merits plain-film radiography.
 - Scoliosis may require MRI or computed tomography (CT) to:
 - Define the extent
 - Help map surgical intervention
- Head MRI is indicated for evaluation of:
 - Focal neurologic changes
 - New-onset seizures
 - Severe headaches

- Vision changes
- Proptosis
- Short stature
- Rapid change in head circumference
- Plexiform lesions
- Severe cognitive deficits
- Precocious or delayed puberty
- Cranial MRI is indicated to evaluate for possible optic pathway glioma once symptoms have developed.
 - Routine imaging before symptom onset is not indicated.
 - Once optic gliomas are diagnosed, MRI should be obtained:
 - Every 2 years
 - With any symptom change to age 10 years
- One unusual finding is the presence of unidentified bright objects on T2-weighted sequences of cranial MRI.
 - These lesions are present in 60–90% of children, but only ~30% of adults.
 - Their significance is uncertain.
 - Controversial evidence suggests that some learning disabilities correlate with presence and specific locations of unidentified bright objects.
- MRI is useful to assess for radiculopathy.
 - Neurofibromas have a propensity to develop along or within the spine, often impinging on nerve roots.
- MRI is the mainstay of evaluation of plexiform neurofibromas.
- Development of pain, or any focal neurologic deficit, warrants an MRI.
 - Particularly important if pain develops in a plexiform neurofibroma, where pain may herald malignant change.
- Positron emission tomographic (PET) scanning may be of more value in distinguishing benign from malignant lesions.
- Imaging is useful in evaluation of cerebrovascular disease and renal artery stenosis.

NF-2

- Routine screening MRI of the brain is required for any patient with:
 - Unilateral vestibular schwannoma
 - Multiple intracranial or spinal tumors
 - 1st-degree relative with NF-2
 - Child with meningioma
- Any child at risk for NF-2 should have a screening brain MRI annually beginning at age 7 years.
- Gadolinium-enhanced MRI with thin cuts through the internal auditory canals for assessment of vestibular schwannomas
- Spinal MRI should be considered if any symptoms or neurologic deficits are noted.

TSC

- Initial imaging studies include:
 - Brain studies (MRI or CT)
 - Echocardiography
 - Renal ultrasound
- Cortical tubers are best evaluated by MRI.
- Subependymal nodules may be seen in infancy on MRI as T1-weighted hyperintense nodules.
 - By age 1 year, the subependymal nodules contain calcium and may be visualized with CT scanning.
- MRI may be useful to identify subependymal giant cell astrocytomas.
 - Radiologic distinction from subependymal nodules is difficult.
- Renal lesions in older children and adults may be evaluated by ultrasound, CT, or MRI.
- Chest CT is indicated for all women with TSC to evaluate for possible pulmonary lymphangiomyomatosis.

SWS

- Leptomeningeal enhancement, with or without cortical atrophy, is the radiologic hallmark of SWS.
 - Gadolinium-enhanced MRI is the most sensitive imaging modality to evaluate for leptomeningeal angiomas.
 - Leptomeningeal involvement is ipsilateral to the PWS.
 - May be seen before calcifications develop
 - Calcification of adjacent gyri may give the classic “tram track” appearance seen on CT and even plain-film radiographs.
 - Involvement of the parietal and occipital lobes often is noted before frontal or temporal findings.
 - PET and single-photon emission CT may reveal areas of altered metabolism and hypoperfusion.
- Choroidal hemangioma almost always is associated with leptomeningeal lesions.
 - Makes CNS imaging mandatory
- Choroidal angiomas are best visualized with MRI.

VHL

- MRI with gadolinium contrast is the modality of choice for most features of VHL.
- Hemangioblastomas of the cerebellum are usually subpial in location.
 - May appear as a solid enhancing mass with or without surrounding fluid space
 - May appear as a more complex tissue or fluid mass
 - Spinal hemangioblastomas are solid enhancing intramedullary masses, frequently associated with a surrounding fluid filled syrinx that enlarges and displaces the cord.
- Renal cysts may be found on MRI, ultrasound, or CT.

A-T

- Imaging is limited.
- Cranial MRI will reveal gradual cerebellar atrophy, which is almost always noted by age 10 years
- Imaging with radiation should be considered carefully because of these patients' extreme radiosensitivity.
- Adult female patients and carriers should be screened for breast cancer with regular examinations and ultrasound.
 - Do not use mammograms.

DIAGNOSTIC PROCEDURES

- TSC
 - Should include an electrocardiogram, as well as echocardiogram, because of risk for dysrhythmias
 - Especially in infants or children with evidence of cardiac rhabdomyomas
- SWS
 - Evaluation of seizures should include electroencephalography.
 - Typical findings include:
 - Asymmetry, with background slowing and reduced voltage in the affected hemisphere
 - Asymmetry becomes more prominent with the progressive cerebral atrophy.

TREATMENT APPROACH**NF-1**

- Management should focus on the organ system involved, given the wide variability of expression.
- Genetic counseling should be provided for all NF-1 families.
 - Affected individuals have a 50% chance of transmission with each pregnancy.
- Careful attention should also be paid to the long bones of the lower leg.
 - Congenital tibial dysplasia is an early finding in up to 5% of children with NF-1.
 - Any curvature or nodularity of the tibia is worrisome, as is any length discrepancy.
- Head circumference should be monitored at each visit.
 - ~50% of children with NF-1 have macrocephaly.
- Thorough developmental evaluation should be undertaken at each visit and repeated at regular intervals, with preschool attention to:
 - Language
 - Visual motor skills
 - Learning
- Examination of the back for evidence of scoliosis should start by age 2 years.
 - Scoliosis appears at an earlier age in NF-1.
 - Severe dystrophic form of kyphoscoliosis can appear between 3–5 years of age.
- Regular blood pressure assessment should begin by age 2 years.
- Ophthalmologic evaluation should be obtained annually to age 10 years.
 - Assess for the presence of optic pathway glioma
 - Grade-1 pilocytic astrocytomas
 - Present in ~15% of children with NF-1 under age 10
 - May produce proptosis, strabismus, papilledema, or vision loss
 - If the optic chiasm is involved, hypothalamic extension can produce an endocrinopathy.
 - Results in precocious or delayed puberty
 - Development of precocious puberty should prompt evaluation for an optic glioma.
 - Other ocular findings may include:
 - Congenital ptosis
 - Orbital asymmetry (result of sphenoid wing dysplasia)
- School-aged children should be assessed for:
 - Limb asymmetry
 - Long bone bowing
 - Scoliosis
 - Cutaneous neurofibromas
- School performance should be addressed, with particular attention to:
 - Learning disabilities
 - ADHD
 - Self-esteem
 - Socialization
- Teens should be assessed for:
 - Limb asymmetry
 - Scoliosis
 - Neurofibromas
 - Hypertension
 - Iris hamartomas (Lisch nodules)
 - Tan to brown papules that usually appear in the teenaged years
 - Found in slit-lamp ophthalmologic evaluation
 - Have minimal impact other than support of diagnosis
 - Complaint of pain
 - Particularly pain associated with focal neurologic deficit or arising from a plexiform tumor
 - Should be thoroughly evaluated by examination and imaging studies.
 - School performance
 - Socialization
 - Self-esteem

NF-2

- Most important aspect is early diagnosis so surgery to preserve hearing can be performed.
- Advanced tumors may prevent the preservation of hearing.
 - May lead to complete deafness
 - Creates need for either cochlear or auditory brainstem implants
 - Cochlear implants seem to be better than auditory brainstem implants.
- Once a diagnosis is made, the child should be evaluated by:
 - Ophthalmology
 - Otolaryngology
 - Audiology
 - Imaging

TSC

- 2 basic principles
 - Establishing correct diagnosis
 - Long-term follow-up for later manifestations
- Genetic counseling is mandatory for families and patients.
 - Disorder is autosomal dominant
 - Affected individuals have a 50% risk of affected offspring.
 - Germ-line mutations occur in ~2% of patients.
 - Seemingly unaffected parents with a single affected child have ~2% risk of having another affected child.
- Older children should be screened for:
 - Seizure disorder
 - Developmental delay
 - Autism spectrum disorders

SWS

- Seizure control is the most important aspect of management.

VHL

- Once a diagnosis is established, tumor screening and regular imaging and ophthalmologic examinations are indicated.
 - First-degree relatives should be screened for tumors.
- Annual eye examinations, including dilated funduscopy, should begin by age 6 years.
- Annual cranial and spinal MRI should begin by age 10–11 years.
- Abdominal imaging for kidneys and possible pheochromocytoma should begin by age 15–18 years.
 - May consist of ultrasound, CT, or MRI
 - MRI is best modality for finding all the possible intra-abdominal tumors.
- Hearing loss or tinnitus should be evaluated.
 - By MRI with thin sections through the ear structures
 - By formal audiologic examination

A-T

- Most important aspects of therapy include:
 - Family and patient counseling
 - Support
 - Rehabilitation
 - Assistance with the progressive ataxia

SPECIFIC TREATMENTS**NF-1**

- Neurofibromas present unique management issues.
 - Smaller lesions may become painful or may interfere with activities as a result of location.
 - Plexiform lesions can be disfiguring.
 - Numerous or large lesions may exert a profound effect on self-esteem and socialization.
 - Surgical excision may be necessary for problematic tumors.
- Sudden development of pain or focal neurologic deficit in plexiform tumors may represent malignant degeneration.
- Malignant peripheral nerve sheath tumors (formerly called *neurofibrosarcoma*) develop in 5–13% of patients, with devastating effect.
 - Often multicentric
 - Metastasize quickly
 - Usually fatal within a year
- Other malignant tumors are seen with an overall incidence 3% higher than the general population, including:
 - Leukemia, especially juvenile myelomonocytic leukemia
 - Rhabdomyosarcoma
 - Pheochromocytoma (an adult-onset tumor)
 - Carcinoid (an adult-onset tumor)

NF-2

- Screening examinations, audiometry, and imaging should be repeated at least annually starting at age 7 years.
- Children of a parent with NF-2 should have:
 - Annual ophthalmologic examinations starting in infancy
 - Neurologic and audiometric examinations annually from age 7 years
- Most patients should be encouraged to learn sign language as preparation for possible future complete hearing loss

TSC

- Treatment of epilepsy in TSC is the same as in other forms of epilepsy, with 1 exception:
 - Infantile spasms in TSC do not respond as well to adrenocorticotropic hormone as infantile spasms without TSC.
 - Irreversible γ -aminobutyric acid transaminase inhibitor vigabatrin is much more effective.
 - Response rates up to 96% in infants with TSC and infantile spasms

- Vigabatrin is not currently approved by the US Food and Drug Administration because of potential severe ophthalmic toxicity.
- Vigabatrin may be considered despite its toxicity because of potentially devastating cognitive impact of uncontrolled infantile spasms.

SWS

- Seizure control
 - Prophylactic anticonvulsant therapy may be useful for infants with extensive intracranial disease.
 - Carbamazepine and oxcarbazepine are useful first-line anticonvulsants for SWS.
 - Other options include
 - Valproic acid
 - Topiramate
 - Phenobarbital
 - Phenytoin
 - Vigabatrin
 - Refractory seizures in SWS may lead to consideration of seizure surgery.
 - Hemispherectomy has been found to be effective in reducing refractory seizures.
 - Fevers should be treated aggressively to prevent the triggering of seizures.
- Hydration status should be monitored.
 - Especially during gastrointestinal illness
 - Dehydration may create intravascular sludging and further compromise the cerebral circulation.
- Antipyretic agents should be given prophylactically with immunizations.
- Iron-deficiency anemia should be corrected.
- Low-dose aspirin is suggested for prevention of stroke-like episodes.
- Prevent headaches through avoidance of:
 - Fatigue
 - Sleep deprivation
 - Stress
 - Minor head trauma
 - Ibuprofen is useful in management of common headaches.
 - Migraines may require sumatriptan.
- Glaucoma may be managed medically in most patients with:
 - β -adrenergic blockers
 - Carbonic anhydrase inhibitors
 - Surgical approaches are not usually required.
- PWSs may be treated effectively with pulsed dye laser.

VHL

- Surgical excision generally is considered the best treatment for most symptomatic VHL tumors.

- CNS hemangioblastomas that remain stable and asymptomatic may be followed by serial imaging.
- Proper management for asymptomatic but radiologically progressive lesions is a matter of debate.
- Spinal hemangioblastomas and large or symptomatic intracranial tumors usually are resected.
- Small retinal lesions are often treated with laser photocoagulation.
 - Larger lesions may require
 - Cryotherapy
 - Brachytherapy
 - Vitreoretinal surgery
- Screening for eye lesions is of critical importance.
- Small renal tumors (<3 cm) are often followed by serial imaging.
 - Larger lesions may be addressed by partial nephrectomy.
 - Radical nephrectomy is rarely indicated.
- Symptomatic pheochromocytomas require excision.

A-T

- Speech, physical, and occupational therapy should be obtained early.
 - Speech therapy may help with:
 - Communication
 - Swallowing difficulties
 - Physical and occupational therapy can help with:
 - Mobility
 - Safety
 - Daily living skills
- Careful monitoring is crucial for the recurrent infection and cancer risks.
- Recurrent sinopulmonary infections should be treated aggressively.
 - Aspiration should be anticipated.
- Emotional support is crucial for:
 - Depression
 - Anger
 - Isolation

WHEN TO ADMIT

- NF
 - Sudden neurologic decline
 - Uncontrollable seizures
- TSC
 - Sudden neurologic deterioration
 - Intractable seizures
 - Gross hematuria
 - Heart failure or dysrhythmia

- SWS
 - Refractory seizures
- VHL
 - Hypertension crisis with pheochromocytoma
 - Sudden neurologic deterioration
- A-T
 - Severe pulmonary infection, especially if respiratory distress is present
 - Severe aspiration event

WHEN TO REFER

- NF-1
 - Pediatric ophthalmologic evaluation beginning in the first year
 - Neurologic evaluation if seizures are difficult to manage
 - Neurodevelopmental testing if evidence of:
 - Learning disability
 - ADHD
 - Speech delay
 - Surgical referral for symptomatic neurofibromas, renovascular hypertension
- NF-2
 - Hearing loss
 - Gait or balance difficulty
 - Headache
 - Tinnitus
- TSC
 - Ophthalmologic screening
 - In infancy if TSC is suspected
 - Neurologic screening
 - When seizures are hard to manage or progressive
 - Surgery
 - Symptomatic or progressive renal lesions >4 cm
 - Neurodevelopmental testing
 - At diagnosis
- SWS
 - Ophthalmologic evaluation
 - Any infant with forehead and eyelid PWS
 - Neurologic evaluation
 - Difficult seizure management
- VHL
 - Ophthalmologic examination
 - By age 6 years

- Neurologic examination or neurosurgery
 - On detection of CNS tumors
- General surgery
 - On detection of intraabdominal tumors
- A-T
 - Neurologic examination
 - On development of ataxia
 - Speech therapy
 - On development of speech or swallowing difficulty
 - Physical and occupational therapy
 - Before ataxia becomes severe

FOLLOW-UP

TSC

- Neurobehavioral assessment and monitoring
 - Routine formal testing should be performed at age-appropriate levels in:
 - Infancy
 - Preschool
 - Early school age
 - Periodically into adulthood
 - Identify cognitive and behavioral issues as early as possible.
 - Any regressive behavior or new cognitive dysfunction should prompt urgent reevaluation.
- Brain and abdominal imaging should be performed at least every 3 years.
 - More often if lesions exhibit progressive growth or if any acute change in symptoms occurs:
 - Sudden neurologic or cognitive decline
 - Hypertension
 - Hematuria
 - Annual brain MRI is suggested to age 21 years.
 - Annual renal imaging is suggested for monitoring of angiomyolipomas.
 - Serial renal ultrasound is adequate if maximal lesion size is <4 cm.
 - Larger renal lesions should be assessed by Doppler or MRI or magnetic resonance angiography for abnormal vasculature.
 - Chest CT is indicated for all women with TSC to evaluate for possible lymphangiomyomatosis.
 - Women with lung lesions should have annual pulmonary function tests.

COMPLICATIONS

NF-1

- Optic pathway gliomas develop in 15–20% of patients at a mean age of 4.2 years.
 - Annual ophthalmologic monitoring from the 1st year of life and continue to age 10 years, checking for:
 - Vision change
 - Afferent pupillary defect
 - Change in fundoscopic examination findings
 - Other ocular findings may include:
 - Congenital ptosis
 - Congenital glaucoma
 - Pulsating exophthalmos
 - If optic pathway glioma is present, MRI evaluation should be repeated every 2 years until age 10 in addition to annual ophthalmologic examination.
 - Precocious or delayed puberty may be a later clinical sign of optic glioma extending from the chiasm into the hypothalamus and should prompt reevaluation and MRI.
- Hormonal surges
 - Should be discussed with preteens and teens
 - Factors likely to cause increases in both size and number of neurofibromas
 - Oral contraceptives
 - Puberty
 - Pregnancy
- Neurodevelopment
 - Headaches occur in 20% of patients.
 - Usually migraines that respond well to standard therapy such as amitriptyline or topiramate
 - Seizures occur in 4–10%.
 - Management should be directed toward the specific seizure type.
 - Hearing loss, usually unilateral, occurs in ~10% of patients.
 - Various learning disabilities are observed in 35–65% of children:
 - Math and reading comprehension problems
 - Visual perception deficits
 - Delays in both gross- and fine-motor skills
 - Speech and language delays in ~50%
 - ADHD is common, occurring in ~50%.
 - Various behavioral problems, often in association with a comorbid diagnosis of ADHD
 - Anxiety
 - Depression
 - Social problems
- Aggression
- Unusual behaviors
- Vascular disease is more common and may include:
 - Congenital heart defects
 - Hypertension
 - Occlusive arterial disease
 - Aneurysms
 - Arteriovenous fistulae
- Hypertension
 - In young children as a result of renal artery stenosis in 1% of patients
 - In adults as primary hypertension or associated with pheochromocytoma
 - Workup should include:
 - Renal angiography in children
 - Urine catecholamine levels in adults
- Bone abnormalities
 - Range from skeletal dysplasia to nonossifying fibroma to short stature to kyphoscoliosis
 - Long bone dysplasia (especially tibial) may be seen during the first year of life.
 - May present as bowing or, rarely, pseudoarthrosis (nodule at the site of a healing pathological fracture)
 - Pseudoarthrosis occurs in only 3%.
 - Nonossifying fibromas occur in late childhood to the teen years.
 - May lead to pathological fracture, particularly in the femur, tibia, and humerus
 - Scoliosis is seen in 10%.
 - May develop earlier than in the general population
 - Aggressive dystrophic form may develop between 3–7 years of age

TSC

- Heart failure in infancy
- Various dysrhythmias
 - Wolff-Parkinson-White syndrome
- Renal cell carcinoma is a less common but potentially severe complication.
 - Lifetime risk is the same in TSC as in the general population
 - Average age of onset is 28 years in TSC.
 - Average onset is 52 years in general population.
 - Overall morbidity of renal lesions is predominantly related to angiomyolipomas.
- Symptomatic lymphangiomyomatosis
 - Often progressive
 - Leading cause of death among women with TSC

SWS

- Some patients may develop sudden stroke-like episodes of weakness, even in the absence of seizures.
 - May be transient
 - May leave permanent hemiplegia
- Hemianopsia may develop in up to one half of patients.

VHL

- Major causes of death are:
 - Renal cell carcinoma
 - Complications from CNS hemangioblastomas

A-T

- Patients with A-T are at higher risk (one third) for developing cancer.
 - In children, acute lymphoblastic leukemia predominates.
 - Other lymphoid tumors include
 - B-cell non-Hodgkin lymphoma
 - T-cell lymphoma
 - Hodgkin disease
 - Older children sometimes develop
 - T-prolymphocytic leukemia
 - Adults tend toward nonlymphoid cancers such as
 - Breast
 - Stomach
 - Ovarian
 - Liver
 - Uterus
 - Melanoma
 - Basal cell skin cancer
 - Women who are *ATM* mutation carriers have a 5-fold increase in risk of breast cancer compared with the normal population.
 - ~15% of patients with A-T die of lymphoid malignancies during childhood.
- Patients with A-T are susceptible to injury by ionizing radiation and radiomimetic chemotherapeutic drugs.
 - Because of the inability to repair defective DNA, this susceptibility complicates therapy for the various malignancies.
 - Exposure to these agents poses life-threatening risk to patients with A-T.

PROGNOSIS**NF-1**

- Life expectancy is approximately 10–15 years shorter compared with the general population.
- Malignancy and vascular disease are the leading causes of death.

TSC

- Large numbers of tubers are associated with worse overall prognosis.
 - Infantile spasms
 - Cognitive impairment
 - Difficult seizure control
- Presence and number of subependymal nodules do not seem to correlate with severity of neurologic symptoms.
- With any type of seizures, better control seems to improve prognosis.
 - Seizures become refractory to treatment in up to 50% of children with TSC.

SWS

- Earlier onset may predict worse outcome.
 - Poor seizure prognosis
 - More difficult seizure control
 - Higher risk of cognitive impairment
- No definite link exists between age at onset and neurologic outcome.
- Bilateral leptomeningeal angiomas (7–26% of patients) has poor neurologic prognosis.

VHL

- Visual prognosis is better when ocular lesions are detected before development of symptoms.

A-T

- Life expectancy varies.
- Survival into the 6th decade is likely.
- Leading causes of death are:
 - Malignancy
 - Infection
 - Pulmonary failure
 - From combined recurrent infection and recurrent aspiration

Nonconvulsive Periodic Disorders

DEFINITION

- A variety of paroxysmal nonepileptic disorders occurring in children with a wide range of clinical features that mimic seizures
- Distinguishing these from seizures is important so that the child is not treated inappropriately with anticonvulsants.
 - Syncope (fainting) is an acute and transient loss of consciousness caused by reduced cerebral perfusion.
 - Benign paroxysmal vertigo is a disorder characterized by brief attacks of vertigo.
 - Shuddering attacks or shivering episodes are a benign movement disorder.
 - Benign neonatal sleep myoclonus is sleep-related myoclonus (jerking of limbs) in neonates.
 - Night terrors or sleep terrors are a sleep disorder with some features that mimic partial complex seizures.
 - Narcolepsy is a sleep-wake disorder characterized by excessive and inappropriate periods of sleep during the day.
 - Interrupts activities
 - Does not diminish in response to adequate amounts of sleep at night
 - Naps may last from a few minutes to >1 hour.

EPIDEMIOLOGY

- Breath-holding spells (infantile syncope)
 - 2 types: cyanotic and pallid
 - Prevalence
 - ~5% of children
 - Age
 - Episodes typically begin between 6 and 18 months of age.
 - Spells may begin in the first few weeks of life.
 - Frequency of episodes ranges from once a year to several times daily.
- Syncope
 - Prevalence
 - Relatively common
 - Age
 - Particularly seen among teenagers
- Benign paroxysmal vertigo
 - Age
 - Symptoms usually appear within the first 3 or 4 years of life.
 - Frequency of episodes varies from 1 episode every few months to several weekly.
- Shuddering attacks
 - Prevalence
 - Occurs in many children at one time or another

- Age
 - Episodes may start as early as a few months of age or not until later in childhood.
- The number of episodes usually declines gradually.
- Night terrors
 - Prevalence
 - Occur in up to 6% of children
 - Age
 - A peak incidence in late preschool and early school-age children
- Narcolepsy
 - Prevalence
 - Estimated at 0.02–0.05%
 - Age
 - Onset usually occurs in the second decade.
 - Has been reported in children as young as 3 years
 - Sleep studies show that with narcolepsy rapid eye movement (REM) sleep occurs within 15 minutes of sleep onset.
 - In healthy patients, 90 minutes of non-REM sleep precede the first REM period.

MECHANISM

- Syncope
 - Postural hypotension can precipitate an episode.
 - May occur after a sudden change from a sitting or reclining position to a standing position
 - Common provoking stimuli
 - Emotional upset
 - Fright
 - Overheating
 - Cardiac disorders may cause syncope by reducing cardiac output and causing cerebral hypoxia.
 - Arrhythmias
 - Aortic stenosis
 - Severe cyanotic heart disease
 - In rare cases, episodes of syncope have been reported with:
 - Swallowing
 - Coughing
 - Urinating
 - Defecating
 - Clonic movements after the initial episode occur as a result of cerebral ischemia rather than epileptiform discharges from the brain.

■ Shuddering attacks

- The pathophysiologic mechanism is unclear.
- Attacks have been postulated to be an expression of an essential tremor.

■ Breath-holding

- Cyanotic
 - Evaluation of children who have severe cyanotic breath-holding spells has shown an underlying autonomic system dysregulation.
 - This may contribute to the pathophysiologic features of the episodes.
- Pallid
 - A vasovagal phenomenon
 - The precipitating event induces a vagally mediated asystole, which then leads to cerebral ischemia.
 - The clonic jerks are caused by cerebral hypoxia and are not caused by epileptiform discharges from the brain.

■ Night terrors

- Caused by a rapid partial arousal from deep, slow-wave sleep
- Night terror triggers include:
 - Febrile illness
 - Sleep deprivation

HISTORY

■ A thorough history is often all that is needed to make the diagnosis.

- A few patients may require more extensive evaluation.

■ Breath-holding spells

- The most important features of the evaluation are:
 - History of the episode
 - Surrounding events
 - Familial incidence of breath-holding spells is high; parents should be questioned about episodes in other family members.

■ Syncope

- Obtain a description of the event by the patient and an observer.

DIFFERENTIAL DIAGNOSIS

■ Breath-holding spells can be divided into 2 types: cyanotic and pallid.

- Cyanotic
 - More common than the pallid form
 - Usually precipitated by frustration or anger
 - During spells, children cry vigorously and then hold their breath in expiration.

- Apnea is followed by cyanosis, with opisthotonic posturing and loss of consciousness.
- Recovery is usually quick, with return of respiration and consciousness within 1 minute.

• Pallid

- Usually provoked by sudden fright or minor injuries
- The child gasps or cries briefly and then abruptly becomes quiet.
 - The child loses consciousness, has pallor, and becomes limp.
 - The child may develop clonic jerks.
 - The child may fall and hit the occiput.

■ Syncope

- Patients have presyncopal symptoms that may include:
 - Light-headedness
 - Anxiety
 - Sweating
 - Nausea
 - Generalized numbness
 - Visual changes described as constriction or darkening of vision
 - Observers notice marked pallor and clammy skin.
- Presyncopal symptoms are followed by loss of consciousness and slumping to the floor.
 - Once the patient is recumbent and cerebral perfusion is restored, consciousness returns within a few seconds.
 - If patient is held with the head above the body and cerebral perfusion is not restored, clonic movements may occur.
 - Patients may be tired but are not disoriented or confused after an episode of syncope.

■ Benign paroxysmal vertigo

- Characterized by abrupt onset
 - The child appears fearful and cannot maintain normal posture and gait.
 - The child may seek support and clutch the parent, then abruptly sit down or fall.
 - In severe cases, the child may be limp and incapable of using the extremities.
 - Pallor and diaphoresis are usually apparent.
 - Vomiting and nystagmus sometimes occur.
- An episode typically lasts <30 seconds.
 - In rare cases, may last a few minutes
 - A brief period of postural instability may follow that usually resolves within a few minutes.
 - Consciousness is not altered during the episode.
 - The child rarely feels sleepy afterwards.

- History and physical examination usually differentiate from:
 - Brain stem lesions
 - Posterior fossa tumors
 - Epilepsy
- Benign neonatal sleep myoclonus
 - Myoclonic jerks begin in the first month of life, sometimes as early as the first day.
 - Myoclonus presents only during quiet sleep and disappears when the infant awakens.
 - Jerks occur every 2–3 seconds for several minutes and have been reported to last up to 12 hours.
 - Jerking movements may begin bilaterally or start in 1 extremity, then progress to involve the other extremities.
 - Neonatal sleep myoclonus is differentiated from seizure disorder by:
 - History of episodes during sleep only
 - Normal electroencephalogram
- Night terrors
 - Affected children often have a family history of either night terrors or another sleep disorder.
 - Episodes usually occur during the first 2 hours after falling asleep.
 - Child sits up in bed abruptly and screams or talks unintelligibly.
 - If the child's eyes are open, they have a glazed look.
 - During the episode, the child appears to be hallucinating and does not respond to parents.
 - Response of the sympathetic nervous system includes tachycardia and diaphoresis.
 - In some cases, the child may sleepwalk.
 - Episode usually lasts 10 minutes; the child then relaxes and abruptly falls back to sleep.
 - On awakening, the child does not remember the episode.
 - Nightmares should be differentiated from night terrors.
 - Nightmares occur during REM sleep.
 - Nightmares are associated with easy arousal and recall of the content, or at least the occurrence of the nightmare.

LABORATORY EVALUATION

- Laboratory evaluation is seldom needed for any of these disorders.
- Narcolepsy
 - A strong association exists between narcolepsy and the human leukocyte class II antigen DQB1*0602.
 - Human leukocyte antigen typing may be helpful but is not diagnostic.
 - Neuropeptides may be absent on cerebrospinal fluid studies.

DIAGNOSTIC PROCEDURES

- Syncope
 - If atypical features are present, electroencephalography or a cardiac evaluation, including Holter monitoring, may be appropriate.
 - Absence of a precipitating factor
 - Confusion after the episode
 - Evaluation with tilt-table testing can be helpful for children who have unexplained syncope.
- Narcolepsy
 - Sleep studies are important in diagnosing narcolepsy.

TREATMENT APPROACH

- In general, the approach with the majority of the nonconvulsive periodic disorders is to:
 - Educate the parents about the disorder
 - Reassure parents that disorder will not lead to intellectual disability or epilepsy
 - Explain that most of the disorders are time-limited and will resolve on their own
- Narcolepsy is the exception.
 - It is a lifelong disorder that must be accurately diagnosed and subsequently treated.

SPECIFIC TREATMENT

Breath-holding spells

- Treatment is directed mainly at reassuring the family of the benign nature of the episodes.
- Emphasize that the episodes are not seizures and do not lead to intellectual disability or epilepsy.
- Anticonvulsants should not be used.
 - They are not effective in treating either cyanotic or pallid breath-holding spells.
- Cyanotic episodes
 - Often precipitated by temper tantrums, anger, and frustration
 - Advice about behavior management may be helpful.
- Pallid breath-holding spells
 - Anemia has been described as a contributing factor.
 - Treating anemia may reduce the incidence of the episodes.
 - Atropine is effective for pallid breath-holding episodes; however, its use is rarely warranted.

Syncope

- Teach the patient and family about managing an episode.
- When patients have presyncopal symptoms:
 - They should sit or lie down as soon as symptoms begin to prevent progression to loss of consciousness.
 - If the patient loses consciousness, place the child in a recumbent position, with the head lower than the trunk.

- Parents should be cautioned against picking up a child who has fainted, as this may prolong the period of unconsciousness.

Benign paroxysmal vertigo

- In most cases, no treatment is necessary.
- Anticonvulsants are not effective.
- Antihistamines have been used in some patients who have frequent episodes.
 - Some have noted an apparent reduction in the number of episodes.
 - Assessing the effect of therapy accurately is difficult because frequency of attacks varies.

Shuddering attacks

- In most cases, no treatment is necessary.
- If episodes are severe and interfere with activities, treatment with propranolol may be helpful.
- Anticonvulsants are ineffective and should not be used.

Benign neonatal sleep myoclonus

- No treatment is necessary.
- Reassure parents that these infants do not subsequently develop epilepsy or cognitive delay.

Night terrors

- The nature of the episodes should be explained to the parents.
- Parents tend to try to wake and reassure the child.
 - Attempts to awaken the child are not helpful and may increase agitation.
- Parents should be told that the child is not aware of their presence.
- If the child is sleep deprived as a result of night terrors, parents should take steps to increase the amount of sleep the child is getting.
- If night terrors persist despite adequate sleep:
 - A sleep study may be needed to evaluate for obstructive sleep apnea, which can trigger night terrors.
- In most cases, no medication is indicated.
 - If episodes are frequent or severe, medications may be helpful.
 - Benzodiazepines
 - Imipramine
 - L-5-Hydroxytryptophan

Narcolepsy

- Central nervous system stimulants help reduce the frequency of naps.
 - Methylphenidate
 - Modafinil

- Tricyclic medications are used to treat cataplexy and the other associated symptoms.
 - Imipramine

WHEN TO REFER

- If a diagnosis cannot be made by history and physical examination
- If a need exists for subspecialty expertise

WHEN TO ADMIT

- Admission may be necessary if the child needs video electroencephalographic monitoring to evaluate an episode.

COMPLICATIONS

- Narcolepsy
 - In addition to the excessive daytime sleep, patients often have:
 - Cataplexy, a transient partial or complete loss of tone
 - Often triggered by an emotional reaction, eg, laughter or fright
 - The individual does not lose consciousness.
 - Sleep paralysis
 - Occurs as the patient falls asleep or awakens
 - Characterized by the inability to move or speak
 - Hypnagogic hallucinations
 - Occurs while falling asleep
 - Can be auditory or visual
 - May be very frightening to a child

PROGNOSIS

- Breath-holding spells (either cyanotic or pallid) have an excellent prognosis.
 - Most children outgrow such episodes by school age.
- Benign paroxysmal vertigo attacks usually stop spontaneously over a few years.
 - Some children may later develop migraine headaches.
- Benign neonatal sleep myoclonus usually diminishes gradually during the first 6 months of life.
 - Rarely lasts >3 years
- Narcolepsy is a lifelong condition that needs to be monitored and treated.

Obesity and Metabolic Syndrome

DEFINITION

- Definitions of *overweight* and *obesity* are based on body mass index (BMI).
 - BMI = weight in kilograms divided by height in meters squared
 - Approximates a person's body fat
 - Correlates well with medical complications associated with obesity
 - Easily calculated from standard measurements obtained during health care visits
 - In children, body fat changes throughout development, so BMI percentile must be used.
- For children and adolescents in US, terms *at risk for overweight* and *overweight* have been used instead of *overweight* and *obese*.
 - At risk for overweight: BMI between the 85th and the 95th percentiles for age and sex
 - Overweight: BMI at or above the 95th percentile
- In 2007 an expert committee consisting of representatives from 15 national health care associations recommended changing to different terminology.
 - When BMI is between the 85th and 94th percentile, "overweight" should replace "at risk of overweight."
 - When BMI is at or above the 95th percentile, "obesity" should replace "overweight."
- Metabolic syndrome (syndrome X)
 - Cluster of metabolic abnormalities that leads to cardiovascular disease and increased risk of mortality

EPIDEMIOLOGY

- Prevalence of obesity
 - Has dramatically increased worldwide in developed and underdeveloped countries
 - Only the very poorest geographic areas, where food scarcity is widespread (eg, Haiti and sub-Saharan Africa), have yet to be affected.
 - In US in last 2 decades
 - 3-fold increase in obesity in children age 12–19 years
 - Doubling of obesity in children age 6–11
- Age
 - Children and adolescents age 6–19 years: 16% have a BMI >95th percentile.
 - Children age <5 years: >10% have a BMI >95th percentile.
- Ethnicity
 - Between 1986 and 1998, black and Hispanic youth showed increases in obesity prevalence more than double that of non-Hispanic white youth.

- Geographic factors
 - Children living in southern states showed greater increases in obesity prevalence than those in northern and western states.
- Socioeconomic status (SES)
 - Poverty is a risk factor for obesity in non-Hispanic white adolescents.
 - No SES-obesity relationship has been found in Hispanic children.
 - Higher SES is associated with higher rates of overweight and obesity in black persons.
- Sex
 - Risk for obesity varies by ethnicity.
 - Hispanic boys are more likely than Hispanic girls to be overweight.
 - Black girls are more likely than black boys to be overweight.
- Prevalence of metabolic syndrome
 - Increasingly recognized in children and adolescents as prevalence of overweight rises in these age groups
 - Data from the National Health and Nutrition Examination Survey (1988–1994) estimates the prevalence of metabolic syndrome to be as high as 30% in obese adolescents 12–19 years of age.
- Costs
 - The current epidemic of obesity poses a significant threat to health care systems already struggling with escalating costs.
 - The US Surgeon General predicted that costs related to obesity will overtake those of tobacco.
 - Based on alarming increased expenses associated with obesity and related conditions
 - Current costs for obese patients exceed by 36% those of patients who are not obese.
 - Medication expenses are 77% higher for obese compared with non-obese individuals.
 - Obesity is associated with increased numbers of medical diagnoses and medications.
 - Leading to increased medical costs comparable to 20 years of aging
 - These figures do not attempt to capture costs of psychological morbidity.

ETIOLOGY

- Weight gain is caused by a positive energy imbalance.
 - Increased caloric intake, decreased energy expenditure, or a combination of the 2
 - A sustained positive balance of 100 calories per day leads to weight gain of 10 lb/year.

- Overweight and normal-weight children do not differ by metabolic rate.
 - Overweight adolescents have higher total daily energy expenditures and resting energy expenditures than adolescents who are not overweight.
 - Overweight children need to eat more to maintain their higher body weight.
- Leptin
 - Hormone that acts on hypothalamus to regulate hunger and satiety
 - Serum levels correlate with adiposity in children and adults.
 - Whether increased adiposity results in decreased leptin production or whether primary leptin deficiency is followed by weight gain is unclear.
 - Leptin resistance or deficiency results in increased food intake in animal models.
 - The role of hormones and neurotransmitters in human energy regulation remains poorly understood.

RISK FACTORS

- Genetic and family influences
 - The rapid increase in obesity over the past 20 years demonstrates the significance of lifestyle and societal influences.
 - Shared family conditions support the importance of causal environmental factors.
- Family environment and food preferences
 - Children of overweight parents are more likely than children of normal-weight parents to prefer high-fat foods.
 - Children with higher BMI consume less at breakfast and more at dinner than their normal-weight peers.
 - Skipping breakfast is associated with poorer food choices and increased risk for obesity.
 - Families who eat meals together consume less fried food and carbonated beverages and more fruits and vegetables.
- Recent environmental changes may be related to population-level increases in obesity.
 - Urbanization
 - Increased reliance on motorized transport
 - Less outdoor play time
 - Technologic advances
 - Easy access to calorie-dense foods
- Eating behaviors
 - Overeating in response to environments that interfere with normal regulatory mechanisms
 - Extremes of parental behavior (neglect and overinvolvement)
 - Use of food to comfort children
 - Prompting children to finish what is on their plate may impair the ability to self-regulate appetite and satiety.

- Food insecurity
 - Malnutrition during gestation and early infancy is associated with both stunting and obesity.
 - Possible mechanisms
 - Excess deposition of fat in subsequent times of nourishment
 - Preference for high-fat foods, overeating when food is plentiful
 - Individuals may develop increased sensitivity to hunger- and satiety-related hormones and neurotransmitters, resulting in fat deposition in response to early life stress.
- American diet
 - Large portion sizes
 - Greater intake of calorie-dense beverages and juice
 - Increases in consumption of fast-food
 - School lunches (usually contain >30% of calories from fat)
 - Vending machines in schools
- Parental obesity
 - For children <3 years of age, parental weight is a better predictor of adult obesity than the child's actual weight.
 - This effect lessens with age; toward adolescence, the child's weight becomes an equal predictor at school age and a more important predictor.
 - Overweight and normal-weight children with 1 obese parent are at twice the risk of adult obesity.
- Smaller family size
- Single-parent families
- Parental neglect
- Overparenting
- High prepregnancy maternal BMI
- Higher birth weight
- Servings of sugar-sweetened beverages
- Television time >3 hours per day is associated with a higher average BMI.

SIGNS AND SYMPTOMS

- Clinical manifestations of metabolic syndrome
 - Obesity
 - Excess body fat
 - Increased visceral fat
 - Central fat distribution
 - Insulin resistance
 - Dyslipidemia/hypertriglyceridemia
 - Hypertension
 - Glucose intolerance or non-insulin-dependent diabetes mellitus

DIFFERENTIAL DIAGNOSIS

- Primary medical causes of obesity are rare.
- Endocrine and genetic causes of obesity often cause short stature or cognitive impairment.
 - Hypothyroidism
 - Associated with short stature
 - Weight gain, fatigue, constipation, cold intolerance, myxedema
 - Testing: thyroid-stimulating hormone, free thyroxine
 - Cushing syndrome
 - Short stature
 - Central obesity, hirsutism, moon face, plethora, hypertension
 - Testing: dexamethasone suppression test
 - Pseudohypoparathyroidism
 - Short stature
 - Short metacarpals, subcutaneous calcifications, dysmorphic facies, intellectual disability, hypocalcemia, hyperphosphatemia
 - Testing: urinary cyclic adenosine monophosphate after synthetic parathyroid hormone infusion
 - Growth hormone deficiency
 - Short stature
 - Fatigue
 - Testing: evoked growth response, insulinlike growth factor-1 (IGF-1)
 - Down syndrome
 - Short stature
 - Dysmorphic facies, intellectual disability
 - Testing: karyotyping
 - Turner syndrome
 - Short stature, web neck
 - Testing: karyotyping
 - Prader-Willi syndrome
 - Cognitive impairment
 - Hypogonadism, small hands and feet
 - Testing: FISH *15q11* microdeletion (70% of cases)
 - Bardet-Biedl syndrome
 - Cognitive impairment
 - Retinitis pigmentosa, renal abnormalities, polydactyly, hypogonadism
 - Testing: *BBS1* gene
 - Biemond syndrome
 - Cognitive impairment
 - Iris coloboma, hypogonadism, polydactyly
 - Testing: clinical

- Alstrom syndrome
 - Cognitive impairment
 - Retinitis pigmentosa, diabetes mellitus, and hearing loss
 - Testing: *ALMS1* gene

DIAGNOSTIC APPROACH

- The Centers for Disease Control and Prevention provides age- and sex-specific growth curves for BMI.
- Electronic medical records allow routine calculation and plotting of BMI when height and weight data are entered.

LABORATORY FINDINGS

- Centers for Disease Control and Prevention and AAP recommendations for evaluating obese children (BMI >95%)
 - Cholesterol panel (including low-density lipoprotein cholesterol, high-density lipoprotein cholesterol, and triglycerides)
 - Fasting plasma glucose
- The American Diabetes Association recommends fasting glucose test for children with BMI between 85th and the 95th percentile if:
 - They have a family history of diabetes mellitus or obesity *or*
 - They have signs of insulin resistance, including acanthosis nigricans, polycystic ovary syndrome (PCOS), or hirsutism
- Hemoglobin A_{1C} is sometimes used to screen patients who cannot comply with fasting before laboratory testing.
- Insulin levels
 - Not recommended for evaluating obesity
 - Can be low to high at time of presentation of type 2 diabetes
 - Do not alter medical management
 - Helpful when uncertainty exists as to whether patient has type 1 or type 2 diabetes mellitus
- Liver function tests
 - At baseline
 - Before pharmacologic management for type 2 diabetes
 - Before surgical intervention for obesity
- Other studies
 - Ordered only as indicated by history or physical examination
- Laboratory tests, by indication
 - Thyroid function tests
 - When symptoms of hypothyroidism are present
 - Luteinizing hormone, follicle-stimulating hormone, total and free testosterone; consider pelvic ultrasonography
 - Menstrual irregularity
 - Acne
 - Hirsutism (PCOS)

- Genetic consultation, karyotype
 - Short stature
 - Dysmorphic features
 - Cognitive impairment
- When to test for diabetes
 - Patient is obese, with BMI >95th percentile
 - BMI between the 85th–95th percentile with any of the following:
 - Family history of type 2 diabetes
 - Native American, black, Hispanic, Asian, Pacific Islander
 - Signs of:
 - Insulin resistance
 - Acanthosis nigricans
 - Hypertension
 - Dyslipidemia
 - PCOS
- Metabolic syndrome
 - Insulin resistance (decreased β -cell count)
 - Elevated fasting insulin levels
 - Fasting insulin level >15 mg/dL
 - Peak insulin level >150 mg/dL
 - Dyslipidemia/hypertriglyceridemia
 - Low high-density lipoprotein cholesterol
 - Increased free fatty acids
 - Glucose intolerance or non-insulin-dependent diabetes mellitus
 - Fasting plasma glucose level >126 mg/dL
 - 2-hour plasma glucose level >200 mg/dL (oral glucose tolerance test)

IMAGING

- Plain-film radiography
 - For deformity, hip or knee pain (slipped femoral capital epiphysis or Blount disease)
- Head computed tomography and lumbar puncture to evaluate:
 - Headache
 - Visual changes
 - Papilledema

TREATMENT APPROACH

- Preventing secondary comorbidity and disability is the principal goal in treating overweight children and adolescents.
- Obesity should be approached as a chronic condition that requires permanent lifestyle changes to achieve optimal body weight.

- Prescribing a treatment plan without engaging the child and family can lead to frustration, impairing future attempts at weight control.
- Enhancing the therapeutic relationship can begin with a question to the parent.
 - “Have you ever struggled with your weight?”
 - The answer reveals the family’s perception of body weight as an indicator of health and well-being and the parent’s empathy for child.
- Readiness to change can be assessed by asking the child and parent 3 questions:
 - “How concerned are you about your weight (your child’s weight)?”
 - “Do you think that you can improve your body fitness (your child’s body fitness)?”
 - “Do you think that your family can change eating and physical activity patterns?”
- Once the patient and family are ready to begin a treatment plan, the clinician should assist in setting realistic goals.
- Weight maintenance rather than weight loss is usually the first step.
 - The objective is to decrease the rate of weight gain and allow the child to achieve healthier body mass.
 - Learning healthy eating and activity habits improves health over time.
 - Focusing on health and healthy behavior changes allows gradual and long-term change.
 - Fad diets and very-low-calorie regimens are not recommended because they cannot be maintained.
 - Children with acute comorbid conditions, such as sleep apnea, may be managed medically on a very-low-calorie diet, usually in an inpatient treatment program.
- Recommendations for weight maintenance or weight loss are based on:
 - Level of overweight/BMI
 - Age
 - Existence of complications
 - Setting goals for weight maintenance or weight loss may be based on BMI, age, and complications.
- Role of pediatrician
 - Intervene early.
 - Assess the family’s readiness to change.
 - Educate the family about medical complications of obesity.
 - Involve the family and caregivers in the treatment program.
 - Aim for permanent dietary and activity change.
 - Avoid short-term diets or exercise programs aimed at rapid weight loss.
 - Teach the family to monitor eating and activity.

- Assist the family in making small, gradual changes.
- Encourage and empathize.
- Avoid criticism.

SPECIFIC TREATMENTS

Pharmacologic approach

- Weight loss
 - No evidence exists that pharmacologic agents for weight loss are safe and effective for children.
- Hyperlipidemia
 - Lipid-lowering medication is considered if behavioral modifications are unsuccessful.
- Metabolic syndrome
 - Evidence for short- and long-term efficacy of pharmacologic treatment of metabolic syndrome in youth remains sparse.
 - Studies of oral hypoglycemics (specifically metformin) in adolescents have demonstrated reductions in blood glucose but have shown little effect on insulin resistance or lipid abnormalities.

Counseling

- May be necessary for the family of a child who is seriously obese (>99th percentile) or has medical complications

Bariatric surgery

- May be considered in severely obese adolescents (BMI >40 kg/m²) with all of the following:
 - Nearly complete skeletal maturity
 - Significant medical complications
 - Inability to change weight or obesity-related comorbid conditions despite dietary and exercise modifications for 6 months
- After evaluation by a multidisciplinary team, surgery can be performed by surgeons experienced in gastric bypass.
- The major challenge is how to give informed consent or assent about the consequences of both obesity and the alternative of bariatric surgery.
 - The procedure changes the individual's ability to eat and may have unforeseen long-term consequences.
 - On the other hand, obesity may be life threatening.

Dietary modifications

- Drink water, sugar-free beverages, or milk with no more than 1% fat.
- Use cooking spray instead of frying.
- Make cut-up fruits and vegetables accessible.
- Serve appropriate portions and limit seconds to fruits and vegetables.
 - Meat: size of palm
 - Starch: 1/2 cup

- Review school lunch menu with the child to pick healthy options.
- Pack a lunch with 4 oz of lean meat, whole-grain bread, fruit or vegetable, and milk.
- Limit restaurant dining to once per week or less.
- Limit fast food to rarely.
- Eat meals together, and turn off the television while eating.
- Schedule at least 20 minutes for each meal.
 - Eating slowly helps to avoid overeating.
- Eat regular meals.
 - Skipping meals can lead to overeating.
- Remove snack foods, chips, cookies, and desserts from the house.
- Allow occasional treats.
- Make salads with vegetables, not eggs, meat, bacon, or cheese.
 - Toss the family salad to decrease amount of dressing.

Recommendations for increasing physical activity

- Limit television and video games to no more than 1–2 hours per day.
- Engage in active family activities (biking, walking after dinner, swimming, going to zoo/museum).
- Dance to your favorite music.
- Walk with a friend rather than talking on the telephone.
- Walk while you talk on the telephone.
- Engage in team sports.
- Take classes: dance, martial arts, or swimming.
- Strategies for toddlers and preschool-age children
 - Engage in outdoor play every day.
 - Engage in active indoor play, soft balls, jumping, or bouncing balls.
 - Buy active toys rather than computer games or videos.
- Strength training
 - Overweight children often find this rewarding and benefit psychologically and physically.
 - Given their body mass, they may be stronger than peers.
 - It does not require aerobic endurance or agility.

Parenting skills for weight loss

- Find reasons to praise the child's behavior.
- Avoid using food as a reward.
- Establish daily family meal and snack times, as well as physically active family time.
- Determine what food is offered and when.
- Allow child to decide whether to eat.
- Offer only healthy options.
- Remove temptations (snack food in home).
- Walk instead of driving.

- Take the stairs.
- Decrease television-viewing time.
- Be a role model in diet and physical activity.
- Be consistent.

Metabolic syndrome

- Treatment is aimed primarily at weight reduction and treating component diagnoses: hypertension, diabetes, and hyperlipidemia.
- Behavioral and dietary modifications are first-line therapy.
- Metformin may be helpful as an adjuvant therapy.

WHEN TO ADMIT

- The morbidly obese patient with BMI >40 kg/m² may need to be hospitalized for a low-calorie weight reduction program.

WHEN TO REFER

- Refer to a pediatric obesity center for acute complications, such as:
 - Pseudotumor cerebri
 - Sleep apnea
 - Obesity hypoventilation syndrome
 - Orthopedic problems

FOLLOW-UP

- A key role for child health professionals is monitoring.
 - BMI should be calculated and plotted at each health care maintenance visit.

COMPLICATIONS

- Obesity is associated with medical comorbid conditions in many organ systems.
 - Some problems are apparent after a relatively short duration of excess body fat.
 - Other complications do not arise for decades.
 - Obesity is responsible for childhood appearance of diseases previously seen only during adulthood, most notably type 2 diabetes mellitus.
- Cardiovascular
 - Hypertension
 - Systolic blood pressure >95th percentile for sex, age, and height
 - Diastolic hypertension increases with BMI.
 - Prevalence of hypertension is 3 times greater in overweight children than in their normal-weight peers.
 - Underdiagnosed in children
 - Blood pressure norms change with height, age, and sex.
 - Technical difficulties, including use of a wrong-size blood pressure cuff, can cause errors.

- Dyslipidemia
 - High-density lipoprotein cholesterol level <40 mmol/L, low-density lipoprotein cholesterol level >130 mmol/L, total cholesterol level >200 mmol/L

■ Endocrine

- Type 2 diabetes
- Increased insulin resistance
- PCOS
 - Menstrual irregularities
 - Hirsutism
 - Acne
 - Insulin resistance
 - Hyperandrogenemia
- Metabolic syndrome (hypertension, dyslipidemia, insulin resistance)

■ Gastrointestinal

- Nonalcoholic steatohepatitis
 - Increased aminotransferase levels
 - May progress to fibrosis or cirrhosis
- Gallbladder disease
 - Obesity may account for 50% of cases in adolescents.
- Obstructive sleep apnea
 - Snoring, apnea, restless sleep, behavioral problems

■ Orthopedic

- Slipped capital femoral epiphysis
 - Hip or knee pain, decreased mobility of hip
- Blount disease
 - Tibia vara; severe bowing of the tibia
- Osteoarthritis
 - May present in adolescence

■ Neuromotor

- Pseudotumor cerebri
 - Headaches, vision changes, papilledema

■ Oncologic

- Endometrial cancer
- Breast cancer
- Colon cancer
- Increased prevalence with adult obesity

■ Chronic inflammation

- Adiponectin (anti-inflammatory peptide): reduced in obese individuals
 - Low levels correlate with high BMI, as well as elevated levels of plasma triglycerides and free fatty acids.
- Levels of the proinflammatory peptides tumor necrosis factor- α and interleukin-6 are elevated in obese patients.
 - Interleukin-6 stimulates liver to produce C-reactive protein; this may be a link to coronary disease.

- A linear relationship exists among BMI and C-reactive protein and interleukin-6 levels.

■ Psychiatric

- Anxiety
- Low self-esteem
- Depression
- Difficult to assess whether depression or low self-esteem is cause of weight gain or if weight gain is cause of depression
- The effects of obesity on child and adolescent mental health are still not well understood.
 - During early childhood, body weight is not associated with self-esteem.
 - As children approach adolescence, self-esteem is lower in overweight children than in normal-weight peers.
- Poor emotional and social functioning is self-reported by 12- to 14-year-old overweight girls.
- Adolescent girls concerned about weight also report more depressive symptoms.
 - Depressed adolescents are at increased risk for developing persistent obesity.
- Overweight youth are likely to report physical but not emotional problems, even though some studies show that they may be socially excluded.
- Assessing affect and mental health status is advisable.

PROGNOSIS

- Early childhood obesity often resolves.
 - Optimism is warranted in early years.
- By adolescence, nutritional and activity patterns are more difficult to change, and families have less influence.
- Obesity remains an emotionally charged issue, creating more difficulties for the family and clinician than do more purely medical problems.
- Blood pressure can decrease with as little as 5–10 pounds of weight loss.
- The age at which the child becomes obese is related to how likely the child is to be obese in adulthood.
 - Children who are obese from 6–11 years
 - 50% of girls and 30% of boys will be obese as adults, compared with 18% of age-matched peers.
 - Obesity during adolescence
 - >60% will maintain obesity into adulthood.
 - Obese adults who became obese during childhood
 - More likely than those who become obese during adulthood to have severe obesity (BMI >40 kg/m²)
- Overweight and normal-weight children with 1 obese parent are at twice the risk of adult obesity compared with children without an overweight parent.
 - Overweight 10–14 year olds with ≥1 obese parent: 80% will remain obese as adults.

PREVENTION

■ Prevention of childhood obesity

- Crucial to public health
- Requires concerted effort of:
 - Public health officials
 - Government at all levels
 - Schools
 - Health care system

■ Clinicians should educate families about importance of healthy nutrition and physical activity from earliest years.

- Healthful nutrition begins with breastfeeding.
 - Associated with lower childhood obesity risk
 - Exclusive breastfeeding is recommended for first 4–6 months of life.
- Consideration of nutrient quality and caloric content
 - Reserve calorie-laden foods with little nutritional value for occasional treats.
 - Plan meals and snacks based on fruits, vegetables, and grains.
 - Include appropriate portion sizes of meat and dairy products
 - Should supply fewer calories than fruits, vegetables, and grains
 - Low-fat milk is recommended for most children after age 2 years.
 - Children should be encouraged to drink water to quench thirst.
 - Reserve highly sugared beverages for occasional treats.
 - Fruit juice in moderation
 - Healthy desserts
 - Fruit
 - Yogurt
 - Cookies made with oatmeal
 - Occasional puddings made with milk and eggs
 - Ice cream
 - Using lower-fat alternatives is suggested for cardiovascular health.
 - Attention to portion size is important.
- Encourage physical activity.
 - Children whose parents are physically active are more likely to be physically active.
 - Clinicians can encourage families to plan opportunities for physical activity as a parental responsibility.
 - Children should engage in ≥60 minutes of physical activity on most, preferably all, days.
 - Children who participate in organized sports should be encouraged to be physically active on days without organized activities.

- Pediatricians can reinforce the importance of daily physical activity and to resist reliance on organized sports for all of a child's physical activity.
- Older children and adolescents may benefit from strength training.
- Increased physical activity should be accompanied by decrease in sedentary activities.
 - Limiting television/other recreational screen time to <2 hours per day is recommended.
 - The AAP recommends no television for children <2 years.
- Parents should strive to be role models in their eating and activity habits.
 - Child health professionals can begin to talk to parents about healthy nutrition and activity during the first year of life.
 - Themes can be revisited at annual health care maintenance visits.
- Monitoring
 - Tracking growth trajectories and explaining patterns to parents is an essential component of primary prevention.
 - Children with increasing BMI percentiles may be at risk for obesity.
 - Health care professionals can help families evaluate nutritional and activity patterns and make adjustments.

Obstructive Uropathy and Vesicoureteral Reflux

DEFINITION

■ Obstructive uropathy

- Impairment of urinary flow that causes:
 - Proliferation and myofibroblastic transformation of interstitial fibroblasts
 - Expansion of extracellular matrix
 - Loss of renal tubular cells
 - Decreased numbers of nephrons
- These changes may affect the kidney and cause:
 - Sodium wasting
 - Hyperkalemic acidosis
 - Nephrogenic diabetes insipidus
 - Renal insufficiency
 - Renal failure
- Effects on renal growth, development, and function depend on the timing, severity, and duration of urinary obstruction.
 - Early renal development: dysplasia and arrest of renal development with persistence of fetal architecture
 - Later development: dilatation of collecting system (ie, hydronephrosis)
 - Complete obstruction (such as from urethral atresia) has more detrimental effects on renal development and function than partial obstruction.

■ Vesicoureteral reflux (VUR)

- Occurs when urine in bladder flows in a retrograde manner into upper urinary tracts

EPIDEMIOLOGY

■ Obstructive uropathy

- Leading cause of renal failure in children <2 years
- Accounts for 17% of cases of kidney transplants in children
- Incidence of prenatal hydronephrosis: 1:100 to 1:500 (half of all abnormalities detected by prenatal ultrasonography)
- Prevalence of the causes of prenatal hydronephrosis
 - Transient physiologic–nonpathologic: 50–70%
 - Ureteropelvic junction (UPJ) obstruction: 10–40% (male-to-female ratio of 2:1)
 - VUR: 10–30%
 - Ureterovesical junction (UVJ) obstruction: 5–20% (more common in boys)
 - Multicystic dysplastic kidney: 2–5%
 - Posterior urethral valves (PUVs): 1–5%

- Other (ureterocele, ectopic ureter, duplex system, urethral atresia, prune belly, polycystic kidney disease, and renal cysts): <1%
 - Ureteroceles: More common in girls (female-to-male ratio of 7:1)
 - Ectopic ureter: Only 15% of cases occur in boys.

■ VUR

- Prevalence
 - No urinary tract infection (UTI) or urologic anomalies: 0.4–1.8% of pediatric population
 - With UTI: 30–50%
 - With prenatal hydronephrosis: 25%
 - With parents who have VUR: 50–67%
 - With sibling who has VUR: 33–50%
- Race
 - Significantly fewer black persons than white persons
- Sex
 - Much lower in boys than girls
 - In infants <1 year, proportions of boys and girls are more equivalent.
 - In children with UTI, the ratio of girls to boys is about 4:1
 - In infants evaluated for prenatal hydronephrosis, the ratio of boys to girls is about 1:4.

ETIOLOGY

■ VUR

- May arise from maldevelopment or delayed maturity of the UVJ (primary reflux)
- May result from distortion of UVJ by changes in bladder caused by other conditions
 - PUVs
 - Neurogenic bladder (secondary reflux)
- Appears to be heritable

RISK FACTORS

■ VUR

- Association between VUR and renal abnormalities, termed *reflux nephropathy*
 - Renal scarring associated with intrarenal reflux of infected urine (common in older children with primary reflux)
 - Congenital nephropathy associated with VUR but without infection (common in infants with primary reflux)
 - Nephropathy associated with VUR and impaired urinary flow (common in children with secondary reflux)

- Incidence is low in children with mild hydronephrosis detected on prenatal ultrasonography and increases with moderate and severe grades.
- Strong genetic component

SIGNS AND SYMPTOMS

■ Obstructive uropathy

- UTI
- Abdominal mass
- Hematuria
- Urinary stone
- Poor urinary stream
- Incontinence
- Failure to thrive
- Renal insufficiency or failure
- Anemia
- Sudden onset of hypertension

■ VUR

- UTI
 - Fever
 - Vomiting
 - Failure to thrive
 - In older children
 - Flank pain
 - Dysuria
- Gross hematuria
- Prenatal hydronephrosis
- Family history of reflux
- Hypertension
- Renal insufficiency or failure

DIFFERENTIAL DIAGNOSIS

Obstructive uropathy (hydronephrosis)

■ Unilateral

- UPJ obstruction
 - Urine flow from the renal pelvis into the proximal ureter is impaired.
 - Intrinsic obstruction results from luminal narrowing of the UPJ, with or without kinking.
 - Extrinsic obstruction is caused by compression of the ureter by anomalous renal vasculature.
 - It is more commonly found in older children and adults.
 - Most common cause of obstructive uropathy in children, second only to transient, physiologic nonpathologic hydronephrosis as the most common cause of antenatal hydronephrosis

- UVJ obstruction, also called *obstructed megaureter*
 - Urine flow from the distal ureter into bladder is impaired.
 - Primary obstruction: due to deficiency of smooth muscle in intravesical ureter
 - Secondary obstruction: results from extrinsic compression of ureter by thick bladder wall in such states as PUVs or neurogenic bladder
 - Accounts for about 8% of children who had symptoms, such as infection, hematuria, or pain, and hydroureteronephrosis on imaging studies
 - Accounts for 23% of newborns with prenatally diagnosed hydronephrosis and is the third most common cause of prenatal hydronephrosis (first: transient, physiologic nonpathologic hydronephrosis; second: UPJ obstruction)
 - Contralateral renal anomalies occur in about 9% of cases.
- Ureterocele
 - Cystic dilatation of the intravesical submucosal ureter, usually associated with stenotic orifice that impairs urinary flow into bladder
- Ectopic ureter
 - Inserts into a site other than the bladder trigone
 - Boys: sites above urinary sphincter
 - Girls: sites above or below sphincter
 - Often obstructive in boys; may not be obstructive in girls
- Polycystic kidney disease
- Extrarenal pelvis
- Unilateral vesicoureteral reflux
- Transient physiologic–nonpathologic

■ Bilateral

- Posterior urethral valves
- Urethral atresia
- Prune belly syndrome
- Megacystis-megaureter syndrome
- Vesicoureteral reflux
- Polycystic kidney disease

■ Uncommon causes

- Megacalycosis
- Renal cyst
- Urachal cyst
- Ovarian cyst
- Hydrocolpos
- Sacrococcygeal teratoma
- Bowel duplication
- Duodenal atresia
- Anterior meningocele

- Not all children with prenatal hydronephrosis have obstructive uropathy.
 - Most have transient or physiologic hydronephrosis that often resolves during pregnancy or after birth and have no clinical sequelae.

VUR

- Differentiating between UTI and other causes of sepsis may be difficult, particularly in young infants.
- VUR is diagnosed after evaluation for UTI, prenatal hydronephrosis, or family history of reflux.

DIAGNOSTIC APPROACH

- Not all children with prenatal hydronephrosis require extensive radiologic evaluation.
 - If hydronephrosis persists during pregnancy, postnatal ultrasonography (US) after 48 hours is indicated.
 - Earlier US for:
 - Bilateral moderate to severe hydronephrosis
 - Solitary kidney
 - Oligohydramnios
 - Giant hydronephrosis

LABORATORY FINDINGS

- Fetal intervention for obstructive uropathy
 - Obtain serial measurements of urine electrolytes to assess fetal renal function.
 - Increased urine sodium, chloride, and osmolality suggest renal damage or dysplasia.

IMAGING

Obstructive uropathy

- US
 - The first test should be renal and bladder US.
 - Hydronephrosis is almost always present but should not be interpreted as a sign of significant obstruction because US cannot adequately assess renal function and drainage of upper urinary tract.
 - Increased echogenicity and marked parenchymal thinning may portend poor renal function but are not sensitive or specific.
 - US may help differentiate the cause of obstructive uropathy.
 - Presence of dilated ureter on US suggests that obstruction occurs distal to the UPJ.
 - UVJ obstruction
 - Ectopic ureter
 - Ureterocele (visualized as cystic mass inside bladder)
 - PUV (thick wall bladder and dilated posterior urethra)

- Voiding cystourethrography (VCUG)
 - Will identify vesicoureteral reflux, which may cause hydronephrosis itself but is associated with other diagnoses of obstructive uropathy:
 - UPJ obstruction
 - Ureterocele
 - PUV
 - Will help delineate bladder (eg, ureterocele) and urethral (eg, PUV) anomalies
- Radionuclide renography
 - Can assess renal function
 - ^{99m}Tc dimercaptosuccinic acid (DMSA) renography
 - Most accurate for renal function and renal scarring
 - ^{99m}Tc diethylenetriaminepentaacetic acid and ^{99m}Tc mercurioacetyltriglycine diuretic renography
 - Less accurate for renal function
 - Can assess drainage
 - Quantitatively measure degree of obstruction
- Diuretic renography
 - Done only in children ≥ 2 months of age (because of tubular function maturation) who have moderate or severe hydronephrosis
- Intravenous pyelography
 - Alternative study to assess renal function and anatomy
 - Use in children is limited because of radiation exposure and presence of bowel gas, which interferes with visualization of urinary tract.

VUR

- US
 - To evaluate for UTI or prenatal hydronephrosis
 - Cannot confirm presence or absence of reflux because severe reflux may be present without significant hydronephrosis
 - Has limited ability to detect renal abnormalities, such as dysplasia and scarring
- VCUG
 - Remains principal method of detecting and quantifying degree of VUR
 - Performed in children with history of moderate or severe hydronephrosis observed on prenatal US
 - Additional indications include the following findings on prenatal US.
 - Dilated ureter
 - Abnormal bladder wall thickness
 - Renal echogenicity
 - Renal parenchymal thinning
 - Decreased amniotic fluid volume

- Performed by:
 - Placing a urethral catheter into bladder
 - Instilling contrast agent
 - Obtaining images of bladder and kidneys during filling and voiding
- VUR is diagnosed when contrast instilled into the bladder is detected in ureter or upper urinary tract.
- Helps identify other bladder and urethral anomalies that may cause secondary reflux
 - PUVs
 - Ureterocele
 - Bladder diverticula
 - Neurogenic bladder
- Conventional fluoroscopic VCUG captures images at fixed time points and may miss episodic reflux.
- Especially in infants, a fill-void cycle should be repeated at least once to improve sensitivity.

■ Radionuclide cystography

- Radioisotope is placed in bladder; bladder, kidneys, and ureters are continuously monitored.
- Continuous imaging causes increased sensitivity in detecting reflux compared with fluoroscopic VCUG.
- Exposes patient to less radiation than does conventional VCUG
- Poor resolution of anatomic details (eg, grade of reflux and associated urethra, bladder abnormalities)
- Used for follow-up studies (after VCUG is done to identify and characterize reflux)

■ DMSA scan

- Accurately assesses renal development
- Evaluates for renal scarring from UTI

■ Intravenous pyelography

- Once used to assess renal parenchymal abnormalities
- Replaced by renal scintigraphy as gold standard because of increased sensitivity of DMSA scans in detecting renal scarring

■ Renal scintigraphy

- For children with VUR who have ≥ 1 episode of UTI and those with at least grade III VUR

CLASSIFICATION

■ International Reflux Study classification system for vesicoureteral reflux

- Grade I
 - Reflux into ureter: distal segment only
 - Reflux into calices: none
- Grade II
 - Reflux into ureter: without tortuosity
 - Reflux into calices: without distention

- Grade III
 - Reflux into ureter: with minimal tortuosity
 - Reflux into calices: with mild distention
- Grade IV
 - Reflux into ureter: with moderate tortuosity
 - Reflux into calices: with moderate distention
- Grade V
 - Reflux into ureter: with severe tortuosity
 - Reflux into calices: with severe distention

TREATMENT APPROACH

■ Goals for treating obstructive uropathy

- Preserve renal function
- Prevent associated complications
 - UTI
 - Pain
 - Stone formation

SPECIFIC TREATMENTS

Obstructive uropathy

■ UPJ obstruction

- Surgical correction for patients with:
 - Severely dilated renal pelvis (anteroposterior >2 cm on US)
 - Decreased renal function (relative renal function $>40\%$)
 - Marked obstructed pattern on renography
 - UTI
 - Renal colic
 - Pulmonary compromise from giant hydronephrosis
- Procedures
 - Removal of stenotic or adynamic UPJ
 - Transposing ureter anterior to lower pole-crossing vessels
- Patients with moderate to severe hydronephrosis but preserved renal function may be managed without surgery.

■ UVJ obstruction

- Symptomatic patients seeking care for UTI, pain, or nausea and vomiting
 - Removal of distal adynamic segment of ureter with or without ureteral tapering
- Asymptomatic patients (ie, diagnosed by evaluation of prenatal hydronephrosis)
 - Observation and prophylactic antibiotics allow spontaneous regression of obstruction, do not compromise renal function, and minimize risk of UTI.
- Infants diagnosed in evaluation for prenatal hydronephrosis
 - Surgical correction

- Lower urinary tract obstruction
 - For suspected PUV, catheter drainage is needed until diagnosis is confirmed and surgical correction performed.
 - Before surgery:
 - Stabilize pulmonary status (particularly in newborns diagnosed in utero with oligohydramnios).
 - Correct associated metabolic abnormalities.
 - Treat UTI.
 - Procedures
 - Endoscopic fulguration of PUV relieves bladder outlet obstruction in most patients.
 - Vesicostomy or alternative treatment (eg, ablation with Fogarty balloon) in very small or premature infants because endoscopic instruments are too large
- Ureterocele and ectopic ureter
 - Surgical correction is usually needed.
 - Urgently for symptomatic patients
- Fetal intervention
 - Indicated only for cases in which:
 - Pulmonary or renal dysfunction can be identified.
 - Severe oligohydramnios occurs without associated renal dysplasia, poor renal function, or associated chromosomal anomalies.
 - The goal is to prevent pulmonary hypoplasia and preserve renal function.
 - Procedures
 - Open fetal surgery
 - Percutaneous vesicoamniotic shunt placement
 - Fetoscopic surgery

VUR

- Medical therapy should be instituted, with the goal of preventing following long-term complications.
 - Renal scarring
 - Hypertension
 - Renal insufficiency or failure
- See Prevention for discussion of antibiotic prophylaxis.
- Indications for surgical correction
 - Recurrent UTI during antibiotic prophylaxis
 - Lack of adherence to medical regimen
 - Low probability of spontaneous resolution of reflux (eg, in older children with higher-grade reflux)
 - New renal scar formation during prophylaxis
 - Anatomic abnormalities, such as a paraureteral diverticulum
- Overall rate of surgical correction: 13–20%
- Procedures
 - Transurethral (endoscopic)
 - Much lower morbidity and shorter recovery time than open surgery but lower success rates
 - Laparoscopic
 - Open
 - High success rate (98%), but often requires a few days of hospitalization and subsequent recovery time

WHEN TO ADMIT

- All patients with significant metabolic abnormalities and electrolyte imbalances.
- Patients with urosepsis
- Patients with markedly impaired renal function

WHEN TO REFER

- All patients with obstructive uropathy should be managed in collaboration with pediatric nephrologists and pediatric urologists.
- All patients with VUR should be managed with pediatric nephrologists.
 - Pediatric urologists should be consulted if surgery is indicated.

FOLLOW-UP

- Ureterocele and ectopic ureter
 - Long-term follow-up is needed to evaluate renal function and look for recurrent obstruction.
 - Since hypertension and proteinuria can develop in patients with renal insufficiency or dysplasia, yearly blood pressure and urinalysis are indicated in all patients with obstructive uropathy.
- VUR
 - Monitor children for long-term complications, such as reflux nephropathy
 - About 10% of children with renal scarring will develop hypertension.
 - About 10% of children with reflux nephropathy will develop end-stage renal disease, and 90% will have diminished glomerular filtration rate.
 - Measure blood pressure and urinary protein periodically if renal scarring is present.
 - Monitor pregnant patients with history of VUR and reflux nephropathy because of increased rates of the following.
 - Pyelonephritis
 - Toxemia
 - Preterm delivery
 - Fetal growth retardation
 - Fetal loss
 - Decreased maternal renal function

COMPLICATIONS

- Lower urinary tract obstruction
 - Children with PUV and renal insufficiency:
 - Cannot concentrate urine to a specific gravity >1.015, leading to excessive fluid loss
 - May develop renal salt wasting and metabolic acidosis with hyperkalemia
 - May develop severe dehydration and cardiovascular compromise with minor gastrointestinal illness
 - Bladder dysfunction is often associated with PUV despite adequate relief of obstruction.
 - VUR occurs in approximately 30–75% of children with PUV.
- Fetal intervention is associated with a high complication rate.
 - Premature labor
 - Inadequate drainage or migration of shunt
 - Perforation of fetal bowel or bladder
 - Chorioamnionitis
 - Iatrogenic gastroschisis
 - Bleeding

PROGNOSIS**Obstructive uropathy**

- UPJ obstruction
 - Hydronephrosis often resolves, but it may take several years.
 - Declining renal function may occur, necessitating surgery.
 - In most cases, renal function is recovered after surgery, suggesting small risk to obstructed kidney from conservative management.
- UVJ obstruction
 - Most symptoms resolve spontaneously.
 - Surgery is indicated in infants who are diagnosed during evaluation for prenatal hydronephrosis and have greatly decreased renal function at onset.
 - Renal function after surgery is preserved but never normalizes.
- Lower urinary tract obstruction
 - After treatment of PUV, postobstructive diuresis may develop with urine output as high as 15 mL/kg per hour.
 - Pay careful attention to fluid balance after relief of distal obstruction.
 - Renal insufficiency and failure can occur in up to 50% of patients with PUV.
 - In some patients with PUV, the ability to hold large urine volumes at high intravesical pressures can lead to:
 - Increased upper tract dilatation
 - Increased pressure
 - Progressive renal compromise

- Early treatment reduces incidence of bladder and renal dysfunction
 - Anticholinergic medications
 - Intermittent catheterization
 - Nighttime drainage

■ Fetal intervention

- Success varies.
- Normal amniotic fluid volume is restored.
- Lung development improves.
- Renal outcome does not significantly improve.

VUR

- Usually resolves spontaneously without surgical intervention
 - Spontaneous resolution rate depends on:
 - Reflux grade: low-grade more likely to resolve than high-grade
 - Grades I and II, 70–80% resolution rate; grade III, 50%; grades IV and V, <30%
 - Laterality
 - Bilateral high-grade VUR tends to resolve less often than unilateral high-grade VUR.
 - Sex
 - Tends to resolve more slowly in girls than boys
 - Mode of presentation
 - High-grade VUR detected after evaluation for prenatal hydronephrosis tends to resolve more quickly than that detected after evaluation for UTIs.
 - In patients with sibling reflux, the rate of resolution is similar to that of probands, with grade the primary determining factor.
- Voiding dysfunction
 - Can impede resolution of reflux
 - Can worsen reflux severity with time
 - Ascertain symptoms for dysfunctional voiding (eg, urinary urgency and incontinence) and begin treating with timed voiding, anticholinergic therapy, or both.
- Constipation
 - Can increase risk of UTI
 - Can delay resolution of VUR
 - Treat aggressively to decrease risk of UTI and improve voiding function
- Fetal intervention
 - Favorable prognosis for good renal function is associated with following laboratory values.
 - Sodium <100 mEq/L
 - Chloride <90 mEq/L
 - Osmolality <210 mOsm/kg
 - β_2 -Microglobulin <508 mmol/L

PREVENTION**■ VUR**

- Screening for reflux in families with VUR is indicated.
- Goal: identify affected children early and decrease risk of long-term complications
- Screening US
 - For older siblings or offspring with no history of UTI
- Screening with radionuclide cystography
 - For siblings or offspring <5 years of age
 - For older siblings with history of UTI or hydronephrosis or evidence of parenchymal thinning on US
- Predicting which children will and will not develop renal scarring is impossible.
- Antibiotic prophylaxis
 - Can prevent UTI and prevent VUR complications
 - Age <3 months
 - Amoxicillin, 25 mg/kg once a day
 - Cephalexin, 25 mg/kg once a day
 - Age ≥3 months
 - Trimethoprim, alone or with sulfa, 2 mg/kg once a day
 - Nitrofurantoin, 1–2 mg/kg once a day (not to exceed 100 mg/day)
 - Should be maintained until VUR has resolved spontaneously or after surgical correction
 - Can be used as long as no breakthrough UTIs or compliance issues occur
 - Length of therapy varies depending on parental preference and likelihood of reflux resolution.
 - When reflux resolution seems unlikely, consider stopping antibiotics and correcting the reflux.
 - Most providers use monotherapy; little evidence suggests that alternating antibiotic prophylaxis is more effective than monotherapy.
 - In teenagers with reflux, an antibiotic trial is reasonable, but chance of resolution is somewhat lower.
 - Consider observing children >7–8 years of age with persistent low-grade VUR, but no recent UTIs, while they are no longer receiving antibiotic prophylaxis because their risk of renal scarring is low.

Ocular Trauma

DEFINITION

- Accidental injury to the eye is a major public health issue accounting for permanent visual loss and monocular blindness.
- Severe trauma in children can present significant developmental and emotional challenges, especially if a cosmetic defect is present.

EPIDEMIOLOGY

- Prevalence
 - 5% of all eye injuries result in permanent visual loss.
 - Trauma accounts for 40% of all cases of monocular blindness.
- Sex
 - Boys are 3 times more susceptible than girls.

ETIOLOGY

- Common sources of injury
 - Sports-related injuries
 - Baseball (most common)
 - Basketball
 - Tennis
 - Hockey
 - Motor vehicle crashes
 - Falls
 - Projectiles
 - BB guns
 - Knives
 - Rocks
 - Other children
- Nontraumatic causes of subconjunctival hemorrhage
 - In newborns, small, bilateral hemorrhages, presumably from the pressure of uterine contractions
 - Severe coughing, such as that caused by pertussis or forceful vomiting
 - Viral conjunctivitis
 - Can be hemorrhagic
 - Usually associated with chemosis (edema of the conjunctiva) and symptoms of irritation and mild discharge
 - Blood dyscrasias (rarely), such as leukemia
 - Hemorrhage usually bilateral

RISK FACTORS

- Lack of eye protection
 - Most severe injuries occur in children with no eye protection.
 - Mandatory eye protection in organized sports, such as hockey, has significantly reduced eye injuries.

SIGNS AND SYMPTOMS

Physical examination

- If the history is clear and reliable (eg, the child was poked in the eye with a finger), more directed examination is possible.
- External inspection and observation is helpful to characterize the severity of the injury.
- If a full-thickness injury through the eyeball is apparent, further examination is best left to an ophthalmologist.
- If index of suspicion for a serious injury or foreign body is high and the patient is uncooperative, examination under sedation or anesthesia may be necessary.
- Important signs include:
 - Swelling or bruising of lids
 - Lacerations of lids or face
 - Proptosis or enophthalmos
 - Foreign bodies and possible entrance sites
 - If a foreign body is likely, eversion of the upper lid is required to inspect the palpebral conjunctiva properly.
 - Conjunctival hemorrhage
- Obvious globe laceration with prolapse of intraocular contents may be visible by inspection alone.
- If the globe appears intact, palpation of the orbital rim can be performed to check for fracture of orbital or facial bones.

Ocular motility

- Ocular motility should be evaluated to ensure full range of motion in all gaze positions.
 - Limited movement can result from:
 - Orbital hemorrhage or swelling
 - Orbital fractures
 - Cranial nerve palsies
 - Direct muscle trauma
 - Diplopia generally results from limited motility, although young children may not verbalize this symptom.

Pupils

- Round and equally reactive
 - Greatly reduces (but does not eliminate) likelihood of severe, vision-threatening injury
- Irregularity in size or shape
 - Can result from blunt trauma with damage to the pupillary sphincter
 - Can result from a full-thickness laceration of the cornea or sclera

Anterior segment

- Initial assessment of anterior chamber can be performed simply with penlight examination or direct ophthalmoscope.
- Without a slit lamp, it is possible to detect:
 - Conjunctival hemorrhages
 - Corneal or conjunctival lacerations

- Foreign bodies
- Anterior chamber depth
- Iris and pupillary irregularities
- If a slit lamp is available, the primary care physician should evaluate for smaller conjunctival or corneal lacerations.
 - Depth of laceration
 - Presence of foreign bodies not visible with penlight
 - Presence of erythrocytes or leukocytes in anterior chamber
 - Cataract formation or dislocation of lens

Fundus

- Detailed fundus examination can be difficult in a child without pupillary dilatation.
- Red reflex should be observed, looking for asymmetry.
 - Absence or asymmetry of the red reflex can indicate:
 - Vitreous hemorrhage
 - Cataract formation
 - Hyphema
 - Corneal abrasion or irregularity and corneal foreign body can be appreciated as an opacity in the red reflex.

Specific ocular injuries

Eyelid and lacrimal injury

- The anterior segment must be examined to exclude globe injury.
- Eyelid injuries (see Figure 51 on page F19)
 - Lacerations medial to the lacrimal puncta
 - High risk of disrupting lacrimal drainage system
 - Failure to recognize and treat a canalicular laceration can result in chronic tearing, particularly if the lower canaliculus is involved.
 - Dog-bite injuries often involve the lacrimal system.
 - Lacerations of the upper lid that are deep enough to expose orbital fat
 - Risk of damage to the levator muscle
 - Failure to recognize levator involvement can result in posttraumatic ptosis, which may require additional surgery.

Chemical injury

- After irrigation, more detailed examination should be performed.
- Examiner should note degree of conjunctival injection.
 - Lack of hyperemia, particularly in perilimbal area, may be a sign of ischemia.
 - Permanent damage to stem cells can significantly impair the patient's ability to regenerate corneal epithelial loss.
- The cornea should be examined for clarity.
 - Hazy or edematous cornea is a sign of serious injury.
- The examiner should instill fluorescein to check for corneal abrasions.

Thermal injury

- Ocular involvement from thermal injury
 - Can be isolated
 - Is often seen in the setting of severe facial burns
- Globe injury
 - Typically mild because of the protective blink reflex
 - Can be severe if the blink reflex is impaired or if loss of consciousness occurs
- Severe lid involvement can lead to contracture and cicatricial changes, resulting in corneal exposure and ulceration.

Subconjunctival hemorrhage

- May cause significant discoloration (see Figure 52 on page F19)
 - Various color changes may occur while blood is being resorbed.
 - Several days to weeks may elapse before hemorrhage has completely disappeared.
- Surrounding blood often masks conjunctival laceration.
 - A small, superficial laceration often does not require repair.
 - Examine to ensure that no underlying laceration of sclera or other trauma to the eye has occurred.

Corneal abrasion

- Extreme pain and sensitivity
 - Only in rare situations of neurotrophic disease are corneal abrasions relatively asymptomatic.
 - Abrasions may be linear or patchy and can be of any size (see Figures 53 and 54 on page F19).
- Photophobia
- Blepharospasm
- Conjunctival injection
- Mild lid swelling
 - Lids must be opened well enough to gain view of the entire cornea.
 - Fine, linear abrasions in the superior cornea may easily be missed and often are a sign of a foreign body lodged in the superior tarsal conjunctiva.

Conjunctival and corneal foreign bodies

- Conjunctival foreign bodies
 - Typically produce irritation and discomfort
 - Mild to moderate conjunctival injection
 - Lids should be forcefully opened, if necessary, for direct examination of the bulbar conjunctiva.
 - If this area appears normal, attention should be turned to the tarsal conjunctival surfaces (see Figure 55 on page F20).
 - Lower-lid eversion can be accomplished readily with gentle inferior traction.

- Upper-lid eversion can be much more difficult, especially if the child is very young or uncooperative.
 - The lashes are grasped and lid stretched minimally.
 - A cotton-tipped applicator shaft is placed horizontally along superior margin of the tarsal plate.
 - The lid is then reflected over applicator for inspection.
- Once conjunctival foreign body has been identified, topical anesthetic should be administered, and a cotton tip used to remove it gently.
- If conjunctival foreign body is not identified, cotton tip may be used to sweep the upper and lower conjunctival fornices for small foreign particles.
- Finally, fluorescein should be administered to check for corneal abrasions.
- Multiple, fine vertical abrasions of superior aspect of the cornea are highly suggestive of a foreign body of the upper tarsal conjunctiva.
- Corneal foreign bodies
 - 2 types
 - Particle resting on the surface of the epithelium
 - Particle that has penetrated epithelium and is embedded in the anterior stroma (more common)
 - Normal blink and secondary movement of the tears usually will expel a nonembedded particle or move it to a conjunctival surface.
 - Lids should be opened to gain full view of the cornea and a light source used.

Hyphema

- The presence of blood in the anterior chamber
 - Results when enough force is transmitted to the globe to cause rupture of blood vessels located within the iris root (see Figure 56 on page F20) and ciliary body
- Can be of varying severity
 - Microhyphema: floating erythrocytes in the aqueous fluid without layering
 - 8-ball hyphema: blood filling the entire anterior chamber
 - Most cases are in between and are described by percentage of the anterior chamber occupied by layered blood.
- Readily identified with a light source and good exposure of the anterior segment

Traumatic iritis

- Iritis, or anterior uveitis: inflammation of the iris and ciliary body
 - Occurs in trauma or in a nontraumatic setting, eg, in association with autoimmune disorders
 - Causes blurry vision, pain, and significant photophobia
- The eye usually is quite injected, and the pupil may not constrict briskly.
- If diagnosis is suspected, referral to an ophthalmologist is indicated.

Traumatic mydriasis

- A mid-dilated pupil noted on examination of a patient after a blunt, traumatic event
 - Can be a result of small ruptures or tears of the iris sphincter muscle
 - The pupil cannot constrict normally.
- Injury may involve only part of sphincter muscle, giving a slightly irregular appearance to the pupil.
- Care must be taken to rule out possibility of a ruptured globe.
- Ophthalmologist often can identify free pigment cells released into the anterior chamber.
- Unless true associated inflammation or iritis exists, treatment usually is not indicated.

Ruptured globe

- Open-globe injuries occur primarily in adults.
- Pediatric open-globe injuries are caused by penetrating injury (79%), blunt trauma (13%), and perforating injury (8%).
 - Penetrating injuries are most common in boys.
 - Blunt trauma is the primary cause of ruptured globe in girls.
- Blunt trauma
 - Motor vehicle crashes
 - Air bag, paintball, and fist injuries
 - External signs
 - An irregular pupil
 - A deep anterior chamber
 - A subconjunctival hemorrhage
 - Conjunctival chemosis
- Anterior segment penetration
 - Lid laceration
 - Conjunctiva laceration
 - Subconjunctival hemorrhage
 - Scleral laceration with uveal prolapse
 - Corneal laceration with iris prolapse
 - Cataract
- Most common rupture locations are at limbus and posterior to the eye muscle insertion.
- Associated clinical findings in an open-globe injury include:
 - Vision loss
 - An afferent pupillary defect
 - Retinal detachment
 - Optic disc edema
- In many cases, diagnosis is evident from initial inspection with a penlight.

- Further assessment can include:
 - Dilated ophthalmic examination
 - Intraocular pressure (IOP) measurement
 - In most instances, the IOP is <8 mm Hg.
 - IOP is safest with applanation tonometer or Tono-Pen.
 - A Schiøtz tonometer should not be used, because the weight of the tonometer may cause an expulsive hemorrhage.
 - Intraocular foreign body should be considered based on the mechanism of injury.
 - The presence of a hyphema or vitreous hemorrhage may preclude visualizing an intraocular foreign body.
 - Retinal tear or detachment is commonly associated with intraocular penetration.
- Orbital trauma**
- Primary care evaluation includes assessment of:
 - Visual acuity
 - Motility
 - Pupils
 - Anterior segment
 - Intraocular pressure
 - Proptosis or enophthalmos should be noted.
 - Emergent ophthalmologic evaluation is needed for:
 - Marked decrease in vision
 - Relative afferent pupillary defect
 - Elevation of IOP
 - Blunt or penetrating trauma may cause intraorbital hemorrhage.
 - Traumatic orbital hemorrhage in a child is unusual.
 - Iatrogenic hemorrhage is well reported with preoperative peribulbar and retrobulbar anesthetic injections.
 - Hemorrhage causes anterior displacement of the globe.
 - Blindness may be caused by a marked elevation of the IOP or tension on the optic nerve.
 - To relieve tension on the globe, a lateral canthotomy of the upper and lower lids may be performed at the bedside.
 - Blunt trauma to midface and orbital rim may cause a fracture of the orbital wall.
 - Inferior floor is the most common site, with medial wall second.
 - Associated facial fractures are frequent, most commonly a zygoma-malar fracture.
 - Diplopia is common.
 - A defect in the orbital floor may allow prolapse of orbital fat, leading to enophthalmos.
 - Vertical restrictive strabismus may be caused by prolapse of inferior rectus into floor defect or bony impingement on muscle.
 - Reduced vision can occur secondary to:
 - Retrobulbar hemorrhage
 - Optic neuropathy
 - Optic nerve impingement
 - Retinal detachment
 - Rupture of the globe
 - Decreased facial sensation inferior to orbital rim may indicate damage to the infraorbital nerve.
 - Midfacial trauma may be associated with traumatic optic neuropathy.
 - Neurologic findings with facial trauma may include:
 - Cranial nerve palsies
 - Optic neuropathy
 - Examination of traumatic optic neuropathy may demonstrate:
 - Decreased vision
 - An afferent pupillary defect
 - Decreased color vision
 - The optic nerve may appear normal or edematous.
- Abusive trauma**
- Eye injuries may be present in up to 40% of pediatric abusive injury.
 - Retinal hemorrhage associated with shaking injury is a primary concern, but many other signs of trauma may involve the eyes.
 - Cranial nerve palsies
 - External lid trauma
 - Anterior and posterior segment injuries
 - Orbital injury
 - Sexually transmitted infections
 - *Chlamydia* and gonorrhea conjunctivitis
 - *Phthirus pubis* on the lashes
 - Münchhausen syndrome by proxy has been reported in connection with recurrent conjunctivitis.
 - Violent, repetitive, abusive acceleration-deceleration injury may cause:
 - Retinal hemorrhages
 - Retinal schisis
 - Retinal folds
 - Cranial nerve palsy
 - This type of injury typically occurs in children <3 years but has been seen in children as old as 8 years of age.
 - Retinal hemorrhages
 - Occur at multiple layers of the retina
 - Vitreous
 - Preretinal
 - Nerve fiber layer
 - Intra- and subretinal layers

- Are associated with abusive head trauma
- Nerve fiber layer heme is the most common type.
- Distribution of hemorrhages
 - Primarily around the optic nerve and macula
 - Often distributed to the periphery of the retina
- Retinal heme has been reported in:
 - 60–72% of abusive head trauma
 - 0–20% of nonabusive head trauma
- Bilateral involvement is more common in abusive injury, but unilateral hemorrhages are well reported in known shaking injuries.
- Abusive head trauma is associated with much more severe retinal hemorrhages.
- Brain findings include:
 - Subdural bleeding (93%)
 - Cerebral edema (44%)
 - Subarachnoid bleeding (16%)
 - Parenchymal bleeding (8%)
- Forceful vomiting does not commonly cause retinal hemorrhaging.
- Cardiopulmonary resuscitation has been reported to cause few retinal hemorrhages around the optic nerve.
- Falls from <1.5 meters are not likely to cause serious neurologic trauma.
- Retinal folds associated with severe shaking injury are perimacular along vascular arcades.
 - The presence of perimacular folds most likely indicates a shaking injury, although there are reports of retinal folds with known severe accidental injury.
 - Macular holes and peripheral retinoschisis (separation of the layers of the retina) have been noted.
 - Retinal folds and peripheral retinoschisis are indicative of severe neurologic trauma.
 - The vitreous gel of the eye is tightly adherent to retina at the macula, optic nerve, and periphery in a child.
 - Adherence creates tractional forces on the retina with repetitive acceleration-deceleration injury.
- Shaken baby syndrome
 - Hemorrhages usually resolve within 4 weeks but have been reported to last up to 4 months.
 - Retinal hemorrhages often resolve without serious visual effects unless the macula is involved (see Figure 57 on page F20).
 - Macular holes and macular scar tissue may result in visual loss.
 - Severe visual impairment or blindness may occur with significant neurologic trauma and cortical damage, optic atrophy, or retinal detachment.
 - Abusive head trauma combined with retinal heme offers a poor neurologic prognosis.

- History and associated physical findings aid in establishing the cause of the trauma.
 - Patients often exhibit physical findings inconsistent with variable caregiver histories.
 - If abuse is suspected, then dilated fundus examination by an ophthalmologist is mandatory.

DIFFERENTIAL DIAGNOSIS

- Shaken baby syndrome
- Preseptal edema caused by an orbital hemangioma
- Preseptal ecchymosis caused by neuroblastoma
- Ruptured vascular malformation
- Other causes of retinal hemorrhage confused with shaken baby syndrome include:
 - Zellweger syndrome
 - Glutaric aciduria type 1
 - Hermansky-Pudlak syndrome

DIAGNOSTIC APPROACH

History

- An accurate and detailed history can suggest mechanism and nature of injuries.
 - History can be difficult to obtain if an adult or other reliable observer did not witness the injury.
 - Details obtained from smaller children may not always be reliable.
 - In such instances, the primary care physician must verify that physical findings are consistent with the history.
- Certain historical details are particularly helpful.
 - Is there potential for chemical injury?
 - If so, then treatment must be delivered immediately, before obtaining a full history and performing an examination, to minimize damage from an acid or alkali burn.
 - Use pH indicator paper to determine the nature and extent of acid or alkali injury.
 - A small strip can be quickly placed in the conjunctival sac.
 - Normal pH of the eye is 6.8–7.4.
 - If pH paper is not readily available, then time should not be wasted in obtaining it.
 - Has a severe head injury or other nonocular injury occurred that may require attention?
 - Significant head trauma can be associated with:
 - Globe rupture
 - Traumatic optic neuropathy
 - Cranial nerve palsies
 - Orbital fractures
 - Cortical visual damage

- Is the injury blunt or sharp in nature?
 - A sharp injury is more likely to be penetrating, resulting in a full-thickness laceration through the cornea or sclera.
 - A severe blunt impact can also lead to globe rupture as a result of globe compression and increased intraocular pressure.
- Is there the possibility of a foreign body?
 - Superficial (in the eyelid, cornea, or conjunctiva)
 - Intraocular
 - Intraorbital
 - Injury associated with flying debris, metallic fragments, projectiles, or any broken object is high risk for a retained foreign body.
- Once details surrounding mechanism of injury have been obtained, additional history taking should focus on:
 - Ocular history (eg, presence of amblyopia)
 - Medical history
 - Medications and allergies
 - Date of the last tetanus immunization

Vision testing

- Examination should begin with an age-appropriate assessment of vision.
- Verbal children
 - Acuity is measured with letter charts or with letter matching (such as the HOTV chart) if the child cannot name the letters.
 - Acuity testing should be performed with proper optical correction, if applicable.
 - Care should be taken to ensure that normal eye is fully occluded when testing the injured eye.
 - If the child cannot see the largest target on the chart (usually 20/200 or 20/400), alternative methods are used.
 - Ability to count fingers (recorded as “count fingers at x feet”)
 - Ability to perceive hand motion (recorded as “hand motion at x feet”)
 - Ability to perceive light (recorded as “light perception” or “no light perception”)
- Preverbal children
 - Assessed by ability to fix and follow a small object or toy
 - Each eye should be tested separately.
 - Decreased vision in the injured eye is suggested by:
 - Inability to follow smoothly with one eye compared with the other
 - Attempts to look around the occlusion of the normal eye

Physical examination

- Pupils
 - Ideally, the reaction of each pupil to light (direct and consensual) is checked with the child fixating at a distant target.
 - The swinging flashlight test is performed to check for the presence of afferent pupillary defect, or Marcus Gunn pupil.
 - Alternately shine the light source into each eye.
 - Both pupils should normally stay constricted as a result of direct and consensual response to light.
 - Paradoxical dilatation of the illuminated pupil indicates presence of an afferent pupillary defect resulting from optic nerve or extensive retinal injury.
 - Anterior segment
 - If a slit lamp is available, more detailed and accurate examination is possible in a cooperative child.
 - Primary care physician should evaluate for smaller conjunctival or corneal lacerations.
 - Depth of laceration
 - Foreign bodies that might not be visible with a penlight
 - Presence of erythrocytes or leukocytes in the anterior chamber
 - Cataract formation or dislocation of the lens
 - Once penlight, slit-lamp, or both examinations have been completed, fluorescein solution or strips and cobalt-blue filter or lamp should be used to check for abrasions, lacerations, or foreign bodies that might otherwise go undetected.
 - Posterior segment
 - Any child who is thought to have posterior segment injury or unexplained vision loss should have dilated fundus examination by an ophthalmologist with the aid of indirect ophthalmoscope.
 - Corneal abrasion
 - Diagnosis of a corneal abrasion may be facilitated by the instillation of a topical anesthetic followed by fluorescein.
 - Use of a cobalt-blue filter will then easily highlight areas of epithelial loss.
 - Traumatic iritis
 - Floating leukocytes in the anterior chamber are visualized under the high magnification of a slit lamp, confirming the diagnosis.
- ### IMAGING
- Orbital trauma
 - Radiologic evaluation of the orbit to delineate the size of the floor defect
 - Ultrasonography or computed tomography for orbital or intraocular foreign body

- Shaken baby syndrome
 - On computed tomography, severe shaking injury may be associated with:
 - Cerebral edema only
 - Subdural bleeding
 - Normal brain
- Radiologic evaluation of the optic canal for a displaced fracture is paramount after orbital trauma.

TREATMENT APPROACH

- Chemical injury
 - Immediate management to prevent serious complications
 - Treatment should be administered before arrival, either by the caregiver or by emergency medical services.
 - Should be tailored to injury but often includes an antibiotic drop or ointment and artificial lubricants
 - Corneal abrasions associated with chemicals should not be patched, so that tears and natural blinking can eliminate residual chemical.
- Thermal injury
 - Immediate irrigation to cool ocular surface
- Corneal and conjunctival abrasions
 - Treat with artificial lubricants and topical antibiotics
 - Initial treatment of lid injury consists of topical antibiotic ointment.
 - Severe injury may require subsequent skin grafting to prevent lid malposition and exposure.
 - Most abrasions heal quickly, particularly in children.
 - Treatment is aimed at keeping the patient comfortable and preventing infection.
- Hyphema
 - Usually treated with a topical corticosteroid drop to reduce associated inflammation, and a topical cycloplegic agent
 - Initial management involves placing a protective shield over the eye to avoid further injury; shielding may be continued.
 - Bed rest (often advised)
 - If hyphema is worrisome and the child is too young to cooperate with restricted activity, hospitalization may be indicated.
 - Restriction of activity is particularly important in the first 2–5 days after injury, when clotted blood may start to resorb and cause rebleeding of injured vessels.
 - In many instances, rebleeding can be more visually devastating than original injury.
 - Patients should be instructed to limit activities until seen by a specialist.
- Traumatic iritis
 - Topical corticosteroid and cycloplegic agent if inflammation is severe

SPECIFIC TREATMENTS

Eyelid

- Initial treatment consists of topical antibiotic ointment.
- Superficial lacerations to eyelid can be closed.
 - 6-0 nylon suture, removed in 5–7 days
 - 6-0 plain suture if the child might be uncooperative for suture removal
- Severe injury may require subsequent skin grafting to prevent lid malposition and exposure.
- Lacerations involving the lid margin
 - Should be repaired by an experienced surgeon to ensure that the smooth contour of the lid margin is maintained
 - Poor closure or reapproximation can result in a notch along lid margin, with cosmetic and functional consequences.
- Lacrimal injury
 - Requires referral and surgical repair with tube placement in the lacrimal drainage system
 - Removal of the tube several months later
- Laceration of upper lid that exposes orbital fat
 - Surgical exploration is required:
 - To repair any involvement of the levator muscle
 - To close the laceration

Chemical injury

- Eye(s) should be irrigated with up to 2 L of a pH-neutral solution, such as buffered saline.
 - A lid speculum may be used to keep lids open if necessary.
 - Alternatively, irrigating contact lens can be used.
 - Care must be taken to ensure flow of saline is adequate; a steady drip will not be sufficient.
- Once irrigation is completed, pH indicator paper can be used to determine whether the pH of the eye has returned to normal.
 - The conjunctival fornices should be examined to check for residual chemical agent.
 - A cotton-tipped applicator may be used to gently remove any precipitate, and the area should be reirrigated.

Thermal injury

- Immediate irrigation to cool the ocular surface

Traumatic optic neuropathy

- Standard treatment is intravenous corticosteroids for 1–3 days after injury.
 - Dose, time, and efficacy are controversial.

Ruptured globe

- If rupture is suspected:
 - Bed rest
 - Antiemetics, if required
 - Shield placed over eye
- Ophthalmology consultation is required for operative repair.

Foreign body

- Topical anesthetic and cotton-tipped applicator can be used to dislodge the particle gently, with care not to debride epithelium in the process.
- In many instances, removal of an embedded object will require referral to an ophthalmologist.
- Management of intraocular foreign body is based on injury.
 - Copper or iron is toxic to the retina and requires urgent removal.
 - Plastic, graphite, lead, and aluminum are better tolerated in the eye than either copper or iron.
 - If the child can sit at a slit lamp, ophthalmologist may be able to use a fine needle, forceps, or burr to remove the foreign body.
 - Younger or uncooperative children usually require sedation or general anesthesia.
 - Removal by a retina specialist with a vitrectomy is the treatment.

Corneal and conjunctival abrasions

- Antibiotic ointment or drop 2–4 times a day until abrasion has healed
- Nonsteroidal antiinflammatory eyedrops may be used as an adjunct to reduce pain, particularly in older children.
- Pressure patch
 - Antibiotic ointment is instilled with soft oval gauze taped over the eye to keep it shut.
 - Patch and antibiotic are then replaced after 24 hours, or decision is made to discontinue use.
 - Prolonged patching is discouraged for young children because of the possibility of amblyopia or strabismus.
 - Placement of a patch may provide additional patient comfort and may be particularly useful if a child tends to rub the eye excessively.
 - No evidence has been found to suggest the abrasion will heal more quickly.
- Some ophthalmologists believe that allowing natural tears, which contain immunoglobulin A, lysozyme, and other antiinfective agents, to stream over the cornea with normal blinking may result in improved healing and decreased risk of infection.
- Whichever method is used, the patient should be monitored closely, usually within 1 to 2 days.
- Delayed healing may suggest:
 - Foreign body
 - Ulcer
 - A different pathologic process (eg, herpes keratitis)

Orbital trauma

- A large defect or bony muscle impingement may require early surgical treatment, but treatment of a globe injury is primary.

- Most floor fractures do not require immediate surgery.
 - Lid edema, proptosis, and diplopia may resolve in the first week.
 - If diplopia persists or enophthalmos is significant, then repair of the orbital floor defect can be done safely up to 4 weeks after the injury.
- Bone impingement into the optic nerve requires urgent neurosurgical intervention.

WHEN TO ADMIT

- Hyphemas
- Ruptured globe
- Abusive trauma

WHEN TO REFER

- Lacerations
 - Involving the lid margin
 - Medial to the lacrimal puncta
 - Deep lacerations of the upper lid
- Canalicular injury
- Levator muscle injury
- Corneal abrasion
- Removal of corneal foreign bodies
- Hyphema
 - Because of potential vision-threatening complications, all hyphemas, regardless of size, should be referred to an ophthalmologist.
- Traumatic iritis
- Traumatic mydriasis
- Ruptured globe
- Abusive trauma
- Chemical injury
 - Refer to an ophthalmologist within 24 hours, particularly with moderate to severe injuries, which can result in permanent vision loss from corneal scarring, corneal vascularization, and other sequelae.

FOLLOW-UP

- Foreign body
 - Antibiotic drop or ointment typically is prescribed for a few days after removing a surface foreign body, particularly if:
 - The source was organic
 - The disturbance occurred in the corneal epithelium
 - Follow-up
 - Not necessarily indicated for a simple conjunctival foreign body
 - Required in cases of corneal involvement

COMPLICATIONS

- In addition to the obvious visual consequences, severe trauma can present significant developmental and emotional challenges, especially if a cosmetic defect is present.
- Amblyopia can develop after injury in children <8 years of age, placing additional physical and psychological burdens.
- Hyphema
 - Corneal bloodstaining
 - Glaucoma
 - Patients with sickle cell anemia or trait are at greater risk for visual compromise from optic neuropathy or central artery occlusion at lower pressures.
 - Amblyopia
- Traumatic iritis
 - Iris synechiae
 - Glaucoma
 - Cataract formation

- Ruptured globe
 - Spontaneous or induced expulsive hemorrhage
 - Retinal detachment
 - Endophthalmitis
 - Incidence of associated endophthalmitis after open-globe injury has been reported to be 6.8%.
- Corneal and conjunctival abrasions
 - Severe lid involvement can lead to contracture and cicatricial changes, resulting in corneal exposure and ulceration.

PROGNOSIS

- Ruptured globe
 - The visual prognosis is worse with blunt than with penetrating trauma.

PREVENTION

- Eye protection for appropriate activities
-

Odor (Unusual Urine and Body)

DEFINITION

■ Unusual odors may be a chief complaint, symptom, or sign and provide clues in diagnosis of many specific conditions.

■ Unusual odors may emanate from:

- Breath
- Urine
- Skin
- Sputum
- Vomitus
- Stool
- Vagina

■ *Bromhidrosis* refers to malodorous and offensive sweat.

- Caused by decomposition of products from the apocrine, eccrine, and sebaceous glands
- Apocrine bromhidrosis begins after puberty with a characteristic acrid or sweaty odor.
- Eccrine bromhidrosis results from bacterial interaction with moist keratin.
 - Associated with hyperhidrosis, obesity, intertrigo, and diabetes mellitus
 - Aggravated by hot weather and occurs primarily in the soles, palms, and intertriginous areas

■ *Halitosis* is offensive odor emanating from the mouth or air-filled cavities (nose, sinuses, or pharynx).

- May be physiologic or pathologic and has numerous causes

MECHANISM

■ Axillary odor

- Aerobic diphtheroids act on apocrine secretions.
- Bacterial decomposition of androsterone is a possible cause.
- Axillary hair appears to retain and spread odor.
- Possible explanations for osmidrosis axillae (unusually strong axillary odor)
 - Apocrine androgen metabolism
 - Bacterial alteration of sweat
 - Abnormally large and numerous apocrine glands

■ Vaginal odor may be caused by:

- Vulvar secretions
- Vaginal wall transudates
- Exfoliated cells
- Cervical mucus
- Fluids from endometrium and uterine tubes
- Metabolic products of vaginal microflora
- Odor during menses is usually rated as the most offensive (but normal).

- The rotten fish smell of vaginal discharge is associated with bacterial vaginosis, caused by trimethylamine.

■ Mouth odor

- Halitosis is exacerbated by infrequent eating and drinking, which have a flushing action.
- Acutely, it may accompany variety of respiratory tract and gastrointestinal infections.
- When inhalation or ingestion of a toxic substance is suspected, odor may provide a clue to the substance involved.

■ Foot odor

- Eccrine bromhidrosis results from the breakdown of keratin and lipids by diphtheroids.
 - Fatty acid metabolites may be the agents responsible for the odor.
- Tinea pedis (athlete's foot)
- Pitted keratolysis
 - White plaques and shallow pits on the plantar surface
 - Various gram-positive bacteria and dermatophytes have been identified.
 - Odor is related to breakdown products (such as thiols and thioesters) of the microorganisms within the stratum corneum.
- Each of these conditions may be exacerbated by occlusive footwear and a hot, humid climate.

■ Metabolic abnormalities

- Unusual odor of urine, sweat, and other body fluids may be caused by accumulation of odoriferous metabolic precursors or byproducts.

■ Foreign body retained in an orifice

- Focal foul smell can be from retention of a foreign body in:
 - Vagina (eg, tampons, diaphragms)
 - Auditory canals
 - Nostrils
- May also be related to generalized body odor because odoriferous substances in a retained foreign body can be absorbed and then secreted in sweat

HISTORY

■ When approaching the differential diagnosis of unusual odors, a thorough history and physical examination must first be conducted.

■ If unusual body odor is the chief symptom, a history of present illness helps.

- Questions may include:
 - When did you first notice the odor?
 - What does it smell like?
 - Does it smell like anything familiar?
 - What is the quality?

- What is the intensity?
 - Does it seem to come from a certain part of the body?
 - Does bathing or cleaning make it better?
 - Are there any associated symptoms, such as vomiting, weight loss, or lethargy?
 - Do other members of the family have similar odors?
 - Do any family members have metabolic or infectious diseases?
 - Have you seen any insertion of a foreign body in the nose, ear, anus, or vagina?
 - Has your child taken any oral or topical medications, vitamins, herbal supplements, or toxins?
 - How has the odor affected the child and family?
- Reporting by the patient of intermittent unusual odor that is never detected by others may indicate temporal lobe epilepsy with olfactory manifestations.

PHYSICAL EXAM

- The examiner should:
- Note the character of the odor.
 - Physicians and patients may vary in their ability to detect certain odors and whether they are offensive.
 - If the practitioner notices a clearly offensive body odor, but the patient or parent does not, anosmia should be considered.
 - Determine the patient's stage of pubertal development.
 - Check for other signs or symptoms during a complete examination with the child unclothed.
 - Attempt to localize the odor to a particular body site.
- Metabolic disorders should be suspected in infants with unusual body odor, especially if the infant appears ill, malnourished, or ketotic.

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis of unusual odors is extensive.
- Includes numerous systemic, metabolic, toxic, and infectious diseases
 - Can become more focused after thorough history and physical examination

Characteristic odors, metabolic disease, associated symptoms

- Cat urine
- 3-hydroxy-3-methylglutaryl-coenzyme A lyase deficiency
 - Malaise, hypoglycemia, hepatomegaly, transaminitis, mild acidosis
- Sweaty feet, acrid
- Glutaric aciduria type II
 - Hypoglycemia, hypotonia, hepatomegaly, respiratory distress
- Isovaleric acidemia
 - Vomiting, dehydration, coma, mild to moderate intellectual disability, aversion to protein foods
- Swimming pool
- Hawkinsinuria (4-hydroxyphenylpyruvate dioxygenase deficiency)
 - Failure to thrive, hepatomegaly, anemia, irritability
- Boiled cabbage
- Hypermethioninemia
 - Usually asymptomatic; some develop intellectual disability, dystonia
 - Tyrosinemia (odor may be like rancid butter)
 - Liver failure
- Fruity, acetone-like, decomposing apples
- Ketoacidosis (eg, from starvation or insulin deficiency)
 - Vomiting, dehydration, altered mental status, lethargy
- Maple sugar, burnt sugar, caramel
- Maple syrup urine disease (mitochondrial branched-chain α -keto dehydrogenase complex deficiency)
 - Severe form
 - Acidosis
 - Feeding difficulty, vomiting
 - Lethargy
 - Seizures
 - Coma leading to death in the first months of life
 - Intermediate form
 - Mild acidosis
 - Intellectual disability, developmental delay
 - Ophthalmoplegia
 - Intermittent form
 - Episodic ataxia and lethargy that may progress to coma
- Tomcat urine
- Multiple carboxylase deficiency
 - Failure to thrive, hypotonia, vomiting, seizures, rash
- Dried celery, malt, hops; yeast, beer
- Oasthouse urine disease (methionine malabsorption syndrome)
 - Diarrhea, intellectual disability, spasticity, attacks of hyperpnea, fever, edema
- Musty; similar to a mouse, horse, wolf, or barn
- Phenylketonuria
 - Vomiting, progressive intellectual disability, microcephaly, eczema, decreasing pigmentation, seizures, spasticity
- Dead/rotting fish
- Trimethylaminuria
 - Usually asymptomatic, except for odor

Infections that can be identified by their associated odors

■ Respiratory and ear, nose, and throat infections

- Candidiasis: sweet, fruity
- Diphtheria: sweet
- Intranasal foreign body: foul, putrid
- Lung abscess, empyema, fetid bronchitis: putrid breath or sputum
- *Pseudomonas* infections, otitis externa: foul cerumen
- Rubella: fresh-plucked feathers
- Tonsillitis, gingivitis, trench mouth: severe halitosis
- Tuberculous lymphadenitis (scrofula): stale beer
- Typhoid fever: fresh-baked brown bread
- Yellow fever: butcher shop

■ Skin infections

- Candida (skin): heavily sweet
- Decubitus ulcer: foul
- Diphtheria (skin): sweet
- Erythroderma: rancid
- Hidradenitis suppurativa: lingering, pungent
- Pitted keratolysis (gram-positive bacteria and dermatophytes): cheesy, sweaty, rotten smell from feet
- *Pseudomonas* skin infection (burns): musty, fruity, grape-like, wet corn tortillas
- Syphilis (condyloma latum): foul
- Tinea capitis: mousy, mouse urine

■ Genitourinary infections

- Bacterial vaginosis: fishy vaginal discharge
- Genital warts (condyloma acuminatum): foul
- Urinary tract infection with urea-splitting bacteria: ammoniacal urine
- Vaginal foreign body, vaginitis: foul vaginal discharge

■ Gastrointestinal infections

- Rotavirus gastroenteritis: full
- Shigellosis: rancid stool

■ Neurologic infections

- *Cryptococcus* meningitis: alcohol smell to cerebrospinal fluid

Recognizable odors on the breath indicating ingestion of poisonous substances or toxins

- Bitter almond: cyanide (chokecherry, apricot pits), jetberry bush
- Burned rope: marijuana
- Camphor: naphthalene (mothballs)
- Carrots: water hemlock (cicutoxin)
- Coal gas: carbon monoxide
- Disinfectant: phenol, creosote

- Fishy: zinc or aluminum phosphide
- Fruity, acetone or decomposing apples: lacquer, salicylates, chloroform
- Fruity, alcohol: alcohol (ethanol, isopropyl alcohol), phenol, acetone, amyl nitrite (poppers)
- Fruity, pearlike: chloral hydrate, paraldehyde
- Garlic: arsenic; also phosphorus, tellurium, parathion, malathion, dimethyl sulfoxide, selenium
- Glue: toluene, solvents (huffing)
- Rotten eggs: hydrogen sulfide mercaptans, disulfiram, dimethyl sulfate, *N*-acetylcysteine
- Severe bad breath: amphetamines
- Shoe polish: nitrobenzene
- Stale tobacco: nicotine
- Violets: turpentine
- Wintergreen methyl salicylate

Odors that can indicate disease or abnormal conditions

■ Breath

- Musty fish, raw liver, feces, rotten eggs, or newly mown clover (*Fetor hepaticus*) (caused by mercaptans, such as dimethyl sulfide): liver failure
- Fruity, acetone-like, decomposing apples (caused by ketones): ketoacidosis
- Sweet: portacaval shunt, portal vein thrombosis
- Feculent, foul
 - Esophageal diverticulum
 - Intestinal obstruction

■ Vomitus

- Fecal: peritonitis

■ Urine

- Fishy (caused by dimethylamine and trimethylamine): uremia
- Stale water: acute tubular necrosis

■ General

- Sour or musty bread: pustular psoriasis
- Putrid: scurvy

■ Skin

- Heavy: psoriasis (pustular)
- Foul, unpleasant: skin diseases with protein breakdown (pemphigus)
- Unpleasant, pungent, heavy: trans-3-methyl-2-hexanoic acid, may be elevated in patients with schizophrenia

■ Feces: foul

- Malabsorption
- Melena (gastrointestinal bleeding)

■ Skin and nasal cavity

- Fetid, putrid: nasal foreign body

LABORATORY EVALUATION

- Infants with odor and other findings suggesting underlying metabolic disorder may need appropriate laboratory evaluation based on the suspected metabolic disease.
- In most cases with suspected metabolic disorder, the evaluation begins with, but is not limited to, checking serum glucose, liver enzymes, and liver function tests.

DIAGNOSTIC PROCEDURES

- Gas-liquid chromatography allows more precise identification of odors.
- Artificial noses or bioelectronic noses have been used to detect:
 - Tuberculosis
 - *Helicobacter pylori* infection
 - Urinary tract infections
 - Bacterial vaginosis
 - Diabetes

TREATMENT APPROACH

- Once an odor is identified and evaluated, a proper diagnostic and treatment plan can begin.
- Treatment is based on the underlying condition.

SPECIFIC TREATMENT

- Osmidrosis axillae or axillary apocrine bromhidrosis can be treated by:
 - Topical interventions
 - Surgical excisions
- Conditions associated with foot odor may respond to combination of:
 - Moisture control
 - Topical antibiotics
 - Antifungal agents

WHEN TO REFER

- Infants with odor and other findings suggesting underlying metabolic disorder
 - A specialist in metabolic diseases should be consulted.
 - An appropriate diet should be started while a more thorough metabolic evaluation is being completed.

WHEN TO ADMIT

- Infants with odor and other findings suggesting underlying metabolic disorder and have symptoms/signs of failure to thrive, hypoglycemia, and other complications

Osteochondroses

DEFINITION

- Juvenile osteochondroses are related to irregular mineralization resulting from necrosis followed by regeneration of bone tissue.
- Sites of osteochondroses
 - Femoral head
 - Legg-Calve-Perthes disease: aseptic necrosis secondary to interruption in blood supply
 - Tibial tuberosity
 - Osgood-Schlatter disease: avulsion of part of patellar ligament and attached fragments from tuberosity
 - Tibial shaft, proximal tibial physis
 - Rickets: softened metaphyses of long bones from vitamin D deficiency
 - Tibia vara: failure of cartilage to transform to bone at the medial aspect of the epiphysis
 - Tarsal navicular bone
 - Köhler disease: aseptic necrosis secondary to interruption in blood supply
 - Metatarsal heads 2, 3, or 4
 - Freiberg disease: aseptic necrosis leading to susceptibility to functional trauma, such as running and jumping
 - Vertebrae, especially lower thoracic
 - Scheuermann disease: cartilage plates covering vertebral bodies thin from intervertebral disk swelling, leading to narrowed disk spaces, and impeded anterior longitudinal growth, resulting in kyphosis
 - Distal radial epiphysis
 - Madelung disease
 - Lunate
 - Kienbock disease: aseptic necrosis

EPIDEMIOLOGY

- Legg-Calve-Perthes disease
 - Onset in early school-age years
 - Occurs in boys 4 times more frequently than in girls
 - Usually unilateral; in the <10% where both hip joints are involved, involvement is successive not concurrent
 - Surgery or orthotic devices can be used to encourage proper reformation of a spherical femoral head.
- Tibial tuberosity (Osgood-Schlatter disease)
 - Onset is earlier in girls than boys, because ossification of tibial tuberosity occurs earlier.
 - Incidence is higher in boys than in girls.
 - ~25% of cases with bilateral involvement
- Tibia vara (Blount disease)
 - Obesity appears to be a factor in adolescent-onset tibia vara, which is more common in boys of African descent.

- Köhler disease of the tarsal navicular bone
 - Seen primarily in boys between 3 and 7 years of age
- Freiberg disease (aseptic necrosis of the metatarsal head)
 - Girls are affected more often than boys.
- Kienbock disease (aseptic necrosis of lunate bone)
 - Right hand (the usual working hand) is involved more frequently than the left.
 - Boys are affected more frequently than girls.
- Scheuermann disease
 - Common cause of kyphosis in teenagers, occurring in ~5% of this population

ETIOLOGY

- Juvenile osteochondroses are related to irregular mineralization resulting from necrosis followed by regeneration of bone tissue.
- Exact causes and mechanisms are not known.
- Possible contributors include endogenous stress, ischemia, and genetic factors.

RISK FACTORS

- Excessive endogenous mechanical stress appears to play a role.
 - The degree of deformity and disability depends on the duration and degree of stress to which softened fibrous parts are subjected.
 - Excessive stress can lead to disordered cellular or local microvascular growth.
- Inherited tendencies to hypercoagulability may cause vascular thromboses in the osteochondroses.

SIGNS AND SYMPTOMS

- Legg-Calve-Perthes disease
 - Often presents with intermittent limp, especially after exertion
 - May be associated with hip and ipsilateral knee pain
 - The hip may develop adduction flexion contracture, with discomfort on internal rotation.
 - The acute phase generally lasts for 1 or 2 weeks.
 - Followed by the active phase, which can last for 12–40 months, during which no clinical signs or symptoms are evident.
- Osgood-Schlatter disease
 - Local pain and tenderness in the region of the knee, particularly the tuberosity
 - Pain is most severe at the end of active flexion or extension of knee.
 - If present for several months, the tuberosity enlarges, and a bony prominence may be found on its anterior aspect (see Figure 58 on page F20)

- **Tibia vara (Blount disease)**
 - Consider with bowing of the legs that persists or progresses beyond 2 years of age.
- **Köhler disease of the tarsal navicular bone**
 - Pain is localized to inner aspect of the midtarsal part of the foot, and the foot is held in a slight varus position.
 - The child walks on the outer side of the foot or in a flat-footed manner.
 - Skin over the navicular bone may be warm, red, and swollen, with tenderness to palpation.
- **Freiberg disease (aseptic necrosis of metatarsal head)**
 - Pain occurs in the region of the affected metatarsal while the child is walking.
 - Plantar pressure or abrupt release of pressure elicits tenderness in the area of affected metatarsal.
 - Swelling occurs over the dorsum of the involved metatarsophalangeal joint.
 - Plantar flexion becomes limited.
 - The transverse arch of the involved foot becomes flattened.
 - Callus develops on the plantar surface of the foot, overlying the involved metatarsal head.
- **Kienbock disease (aseptic necrosis of lunate bone)**
 - Pain is experienced on movement of the wrist; in long-standing cases, pain may be present at rest.
 - Swelling over the dorsum of the wrist, with tenderness over the affected bone
- **Scheuermann disease**
 - Aching pain aggravated by physical exertion in the affected portion of the vertebral column
 - The affected area is tender to palpation.
 - Assuming a stooping position often will increase the pain.
 - Within 1 year or so, kyphosis easily is apparent as a round back deformity.
 - In many cases, the pain is so minor that the complaint is that of poor posture.

DIFFERENTIAL DIAGNOSIS

- See Extremity Pain.

IMAGING

- When indicated, the first diagnostic imaging study in all the cases below is radiography.
 - **Legg-Calve-Perthes disease**
 - Early in the course of disease, radiography shows widening of hip joint, and occasionally, metaphyseal demineralization.
 - During the active phase, may see increased radiodensity in the femoral head ossification center caused by resorption of dead trabecular bone

- **Osgood-Schlatter disease**
 - The best view is one with the knee rotated inward, giving a tangential view of the tibial tuberosity.
 - Soft-tissue swelling, opaque patellar ligament, and fragmented tuberosity are seen.
- **Köhler disease of the tarsal navicular bone**
 - Lateral radiographs of the feet show a very narrowed, wafer-like, irregular navicular ossification center, with increased radiopacity and loss of trabecular markings.
- **Freiberg disease (aseptic necrosis of the metatarsal head)**
 - A deformed, broadened metatarsal head is seen.
- **Kienbock disease (aseptic necrosis of lunate bone)**
 - Flattened fragmented lunate bone seen with variable radiodensity
- **Scheuermann disease**
 - Narrowing of anterior disk spaces is seen, with defects on surfaces of adjacent vertebrae.

TREATMENT APPROACH

- Treatment is aimed at the underlying disease entity.

SPECIFIC TREATMENTS

Legg-Calve-Perthes disease

- During the remolding phase (after active phase of first 1–2 weeks, for next 12–40 months), care is directed toward maintaining the femoral head abducted and internally rotated in relation to the acetabulum.
- Surgery or orthotic devices can be used to encourage proper reformation of a spherical femoral head.

Osgood-Schlatter disease

- Treatment is directed at decreasing stress on the tubercle until the tuberosity fuses with the tibial metaphysis.
- Fusion occurs at approximately 15 years of age in girls and 17 years in boys.
- Management depends on the degree of pain.
 - In most cases, it is sufficient to restrict strenuous activities involving deep-knee bending and jumping.
 - In some instances, casting may be required to completely immobilize the knee.

Rickets

- Treatment with vitamin D will produce radiographic evidence of healing within a few weeks with eventual straightening of bones.

Tibia vara (Blount disease)

- Most children whose Blount disease persists or develops beyond 6 years of age require osteotomy.

Köhler disease of the tarsal navicular bone

- The disease process is self-limiting; surgical intervention is to be avoided.
- The process of revascularization and reconstruction occurs over 1–3 years.
- Orthotic pads can be used to absorb weight and pressure forces until healing occurs.

Freiberg disease (aseptic necrosis of the metatarsal head)

- High heels should not be worn, and long walks should be avoided until symptoms subside.
- Nonsteroidal antiinflammatory drugs can be used for symptomatic relief.

Kienbock disease (aseptic necrosis of lunate bone)

- Treatment includes wrist immobilization.
- On occasion, fusion of the lunate with adjacent wrist bones is required for stabilization and pain relief.

Scheuermann disease

- Most children require only careful observation.
- Treatment is aimed at preventing further deformity, occasionally using casting or bracing.
- Rarely, spinal fusion is necessary when progression is rapid or pain is persistent and severe.
- Rare instances of myopathy have occurred.

WHEN TO ADMIT

- For surgical intervention

WHEN TO REFER

- When uncertain of diagnosis
- When treatment requires orthopedic assessment or intervention

Osteomyelitis

DEFINITION

- Infection of bone that can be acute or chronic
- Chronic osteomyelitis may occur if:
 - Infection is indolent.
 - Diagnosis is delayed.
 - Treatment does not completely eradicate infection.
- Chronic multifocal osteomyelitis is a recurring inflammatory disease not typically associated with infection that can mimic bacterial osteomyelitis.

ETIOLOGY

- *Staphylococcus aureus* is most likely to cause hematogenous osteomyelitis in all age groups.
- Other possible pathogens include:
 - Coagulase-negative staphylococci
 - Gram-negative organisms
 - *Haemophilus influenzae* type b is currently very rare but previously occurred frequently in preschool-age children.
 - Other unusual organisms can become pathogens.
- In newborns, other frequent pathogens include:
 - Group B streptococcus (*Streptococcus agalactiae*)
 - Gram-negative bacteria, such as *Escherichia coli*
 - Fungal pathogens, especially *Candida* species, in infants who have been in the neonatal intensive care unit and who have had vascular lines in place
- In older infants or children, the most common pathogens are:
 - *S aureus*
 - Group A streptococcus (*Streptococcus pyogenes*)
 - *Streptococcus pneumoniae* occurs mostly in children <2 years.
 - *Kingella kingae* occurs in young children.
- The most common pathogens in children with hemoglobinopathies are:
 - *Salmonella* species
 - *S aureus*
- Unusual pathogens reflect the source of contamination.
 - *Pseudomonas aeruginosa* commonly follows foot puncture wounds through a sneaker.
 - *Aeromonas* infections may occur after trauma to bare feet while walking in river water.
- Multiple pathogens, including anaerobes, may be present, especially if the wound has been contaminated with dirt.

RISK FACTORS

- Trauma
 - Open fracture
 - Orthopedic surgery, especially placement of a foreign body, such as the insertion of pins or screws into bone

- Adjacent soft-tissue infection
- Hemoglobinopathies
 - Bone infarcts can occur with sickle cell crisis.

SIGNS AND SYMPTOMS

- Chronic osteomyelitis
 - Symptoms may have been present for months.
 - Nonspecific malaise
 - Poor appetite
 - Nonspecific pain may be elicited in the area of the bone.
- Acute osteomyelitis
 - Bone pain and fever
 - Child who had open fracture or bone surgery and develops fever and new pain or drainage at the same site.
 - A child with a fracture, either open or closed, who has new or worsening pain under a cast should have the cast removed and the area evaluated for infection.
- Infection causing bacteremia
 - History of high fever spike before the onset of pain may be described.
 - Signs of bacteremia
 - Chills and high fever
 - Malaise
 - Acute illness
- Vital signs
 - May be normal, especially with chronic infection
 - May be abnormal if child is bacteremic
 - Fever (may be low grade) is often present.
- Local signs
 - Localized pain is almost always present
 - Tenderness is often exquisite; in younger children, a new limp or absence of movement of an arm or leg may be noted.
 - Inflammation, including swelling, redness, and warmth is present over the involved bone; this can be confused with cellulitis.
 - Characteristically, the child is reluctant to move the adjacent joint and, when a lower extremity is involved, may refuse to bear weight.
 - In the young infant, the loss of active movement in an extremity may be confused with a neurologic problem.
 - Erythema is often present over the infected bone, in addition to tenderness to palpation or movement.
 - If associated arthritis occurs, pain on movement of the joint may be prominent.
 - Chronic osteomyelitis can result in a spontaneously draining sinus.
- Gastroenteritis and *Salmonella* infection may present with new fever and bone pain.

DIFFERENTIAL DIAGNOSIS

- Trauma
 - If fever is not prominent, osteomyelitis is likely to be confused with trauma or other conditions not caused by infection.
- Intraabdominal infection, especially in the area of the psoas muscle
 - Hip or femur pain can be confused with intraabdominal infection.
 - Missed appendicitis can result in a phlegmon, causing a limp that can be confused with osteomyelitis of the femur.
- Osteomyelitis, septic arthritis, and juvenile idiopathic arthritis
 - All could be signalled by limp.
 - Careful abdominal examination is necessary in a child who limps.
- Back pain and diskitis
 - Diagnostic considerations must include vertebral body infection, with or without nearby epidural abscess and diskitis.
- Leukemia
 - Bone pain can be a presenting symptom of leukemia.
 - Abnormal blood count with anemia, low leukocyte count, or thrombocytopenia signal possible leukemia.
- Lymphoma or other cancer
 - Can be confused with osteomyelitis caused by cat-scratch disease
- Bone tumors
 - Can cause nonspecific bone pain and lytic bone lesions on radiograph
 - To differentiate from chronic osteomyelitis, biopsy and culture the bone.
- Septic arthritis
 - May coexist with osteomyelitis, especially in infants
 - Requires prompt treatment
- Cellulitis
 - Difficult to differentiate from osteomyelitis because of erythema over the infected bone
- Chronic multifocal osteomyelitis
 - Can only be diagnosed over time by observing recurring disease, usually with cultures that are negative for acute infection

DIAGNOSTIC APPROACH

- Careful examination seeking focal areas of tenderness is necessary in the young child who may not be able to describe pain adequately.
 - Ask about trauma, fracture, or orthopedic surgery.
- Infants with signs and symptoms of septic arthritis of the hip must always be evaluated for accompanying osteomyelitis of the femur.
 - If the child is >1 year of age, infection tends to be held in place by the metaphysis.
 - After infancy, infection is most likely to spread into the diaphysis and down the bone.
- Blood culture and a needle aspirate of the infection site are the most helpful procedures.
 - If history and examination fit the diagnosis and a blood culture is positive, therapy can be started without bone aspiration.
- Evaluation for related arthritis is crucial, given that joint infections can progress rapidly and need adequate drainage to avoid damage to the joint.

LABORATORY FINDINGS

- Complete blood count and smear review
 - The leukocyte count may be elevated in acutely ill children with bacteremia.
 - Very low leukocyte counts occur with sepsis.
 - Anemia, low leukocyte count, or thrombocytopenia in the absence of disseminated intravascular coagulation should raise concern for leukemia or other cancer.
- Erythrocyte sedimentation rate
 - May be normal at first, but almost always becomes elevated in acute osteomyelitis
- C-reactive protein
 - Usually elevated early
- Blood cultures
 - Helpful in identifying the presence of bacteremia and the cause of the infection
 - Positive in 40–50% of cases
 - If infection with tuberculosis is suggested because of history or setting, cultures for acid-fast bacteria should be included and tuberculin skin testing added.
- All tests can produce normal findings, especially early in the infection.

IMAGING

- Radiography
 - Early: no bone changes seen
 - Earliest detectable signs are blurred soft-tissue planes secondary to edema spreading into fatty tissues.
 - Bone changes are apparent 7–10 days or longer after onset of symptoms.
 - Nonspecific periosteal reaction; lytic lesions occur later
 - In chronic osteomyelitis, shows extensive disease, usually along the diaphysis of the bone; bone changes may need to be differentiated from cancer by history and ultimately, cultures and biopsy.

- Radiographs should always be obtained to exclude other abnormalities, such as fracture or a malignant lesion.
- Magnetic resonance imaging (MRI) is better than skeletal scintigraphy (technetium bone scan).
 - Provides excellent views of bone and soft-tissue anatomy
 - Reveals subperiosteal abscesses that require surgical intervention; frequently produces false-negative results
 - Presence of a subperiosteal abscess is diagnostic for acute osteomyelitis that has broken through the metaphyseal cortex.
 - MRI is the imaging technique of choice when pelvic or spine osteomyelitis is suspected.
- Bone scans
 - Not useful in neonates because of low bone mineralization
 - Provide limited information regarding soft-tissue involvement, subperiosteal space, and bone marrow edema
 - Results may be normal in up to 20% of children during first days of illness.
 - Cancer, cellulitis, trauma, and bone infarction can affect specificity.
 - 3-stage scans improve sensitivity
 - Require large amounts of radiation but no sedation or general anesthesia
 - Can be useful in cases in which multiple sites of osteomyelitis are suspected
 - Less sensitive and specific than MRI, and often difficult to interpret
- Ultrasonography
 - Can detect a subperiosteal abscess
 - May help guide needle aspiration of an infected bone
 - Can help evaluate a nearby joint for an effusion present with an associated arthritis

DIAGNOSTIC PROCEDURES

- Aspiration
 - Confirms diagnosis
 - Can determine the necessity for operative decompression if frank pus is obtained
 - May alleviate pain caused by pressure from an abscess
 - Provides a specimen for pathogen identification by culture and material for immediate Gram stain
 - Aspiration of the subperiosteal space and of the metaphysis for culture is indicated to obtain culture identification of the pathogen.
 - When blood cultures are pending
 - Whenever a collection of pus exists

TREATMENT APPROACH

- Acute osteomyelitis should be aggressively treated to decrease the risk of chronic osteomyelitis.
- Chronic infection requires surgical drainage or debridement and is more difficult to eradicate.
 - Antibiotics for up to 1 year
- Surgery
 - Should be prompt
 - Antibiotics should be started as soon as culture material is obtained.
- Once blood cultures and needle aspiration have been performed, intravenous antibiotics should be given empirically.
- Antibiotics
 - Should be adjusted once cultures and sensitivities are available, narrowing the spectrum to cover the pathogen
 - Should be continued for 4–8 weeks, using clinical response and sedimentation rate to guide length of therapy
 - Oral antibiotics can be considered to finish the course of therapy, if:
 - An oral agent is available that has good bone penetration.
 - An oral agent has excellent activity against the pathogen.
 - Oral medicine is palatable.
 - The child has a social situation that will guarantee compliance.
 - The switch to oral therapy should not occur before clinical response to IV therapy, including:
 - Absence of fever
 - Return to normal function
 - Decrease or normalization of inflammatory markers
 - Oral antibiotics often require 2–3 times the usual dose, making gastrointestinal tolerance a requirement.
- Abscess
 - Must be drained surgically when detected or suspected
 - Lack of pus should suggest that the site of aspiration may have been inaccurate, or that pus may be present but too thick to pass through even a large-bore needle.

SPECIFIC TREATMENTS

Pharmacologic therapy

- After the newborn period, in a previously well child thought to have hematogenous osteomyelitis, give a penicillinase-resistant penicillin or first-generation cephalosporin unless:
 - The child is severely ill.
 - The child has signs of bacteremia and sepsis.
 - If the child has sepsis, vancomycin should be considered because of the increasing incidence of methicillin-resistant *S aureus* (MRSA).

- Therapy should cover all likely pathogens.
 - In newborns, initial therapy should always include coverage against Gram-negative enterics.
 - Oxacillin and gentamicin
 - Vancomycin and ceftazidime
 - When concern about MRSA infection exists
 - For coagulase-negative staphylococci
 - Neonates who have been in a neonatal intensive care unit and who have been on antibiotics should be treated most broadly, pending culture results.
- Antifungal agents are not usual unless blood culture or other epidemiologic data suggest the presence of a fungal infection.
- Children with sickle cell hemoglobinopathies are at special risk for *Salmonella* species in addition to *S aureus*.
 - Treat with cefuroxime or with vancomycin and ceftriaxone or cefotaxime, pending culture results.
- If pseudomonas infection is suspected or there is contamination with dirt (eg, after a puncture wound of the foot), initial treatment should be either:
 - Ceftazidime
 - A carboxypenicillin or acylureidopenicillin combined with an aminoglycoside, such as piperacillin-tazobactam and gentamicin or ceftazidime and gentamicin
 - Piperacillin-tazobactam is appropriate to treat *S aureus* while cultures are pending.
- Clindamycin
 - Often used in cases of allergy to β -lactams or to treat MRSA isolates that are sensitive
- Linezolid
 - Should not be used empirically
 - May be helpful in patients with β -lactam allergies and as a drug that can be used orally to treat a serious infection
 - Side effect of thrombocytopenia limits its long-term use.

WHEN TO ADMIT

- Children with acute osteomyelitis require admission to the hospital for rapid evaluation and to initiate treatment.
- Initial evaluation can begin as an outpatient, before diagnosis is established.
 - Complete blood count, blood culture, and radiography
 - The physician must follow up closely and consider hospitalization as soon as the diagnosis becomes likely.

WHEN TO REFER

- Diagnosis requires thorough evaluation and usually includes consultation with radiology and orthopedic surgery.
 - Radiologist can help focus the radiologic evaluation effectively.
 - Early consulting with orthopedic surgeon helps expedite aspiration of the bone or open drainage.
- Infectious disease specialists may help:
 - To organize the evaluation
 - To start therapy
 - With follow-up with children who are discharged on home intravenous therapy and who have chronic disease

COMPLICATIONS

- Chronic osteomyelitis can result in lifelong disability related to recurrences and, rarely, to cancer.
- Chronic osteomyelitis may result in bone loss and areas of devascularized bone, which separate and create sequestrum or pieces of dead bone in the shaft of the long bones.
 - If this occurs, surgery will be required to treat the infection.
 - A Brodie abscess has a capsule that can develop in the bone; it appears to be the result of walled-off chronic infection.

Otitis Media and Otitis Externa

DEFINITION

- *Otitis media* means “inflammation of the middle ear.”
- *Acute otitis media* (AOM) is the presence of inflammatory fluid in the middle-ear space, accompanied by acute onset of local findings, such as erythematous and/or bulging tympanic membrane, distorted landmarks and light reflex, and a tympanic membrane that is not mobile on insufflation.
- *Otitis media with effusion* (OME), or *serous otitis media*, describes inflammatory fluid in the middle-ear space in an asymptomatic child or in a child with mild upper respiratory tract symptoms.
- *Recurrent otitis media* has generally been used to refer to the occurrence of:
 - ≥3 episodes of AOM in 6 months
 - 4 episodes in 1 year
 - Recurrent otitis media should not be confused with chronic otitis media, which may be used to describe OME that:
 - Lasts >3 months
 - Is a suppurative middle-ear process that fails to respond to initial antibiotic therapy
- Otitis externa (OE) is an inflammatory process that involves structures of the outer ear, specifically the external auditory canal.
- Malignant OE is a complicated form of OE that can develop in immunocompromised children and those with severe malnutrition.

EPIDEMIOLOGY

Otitis media

- Age
 - By the age of 1 year, 62% of children have experienced ≥1 episode of AOM.
- Sex
 - More common in boys
- Socioeconomics
 - More common in children of low socioeconomic status
- Race
 - Incidence rates in white and black children are similar.
- Otitis media is the most common reason that children in the US receive antibiotics.
 - >90% of all antibiotic use in the first 2 years of life is attributable to the treatment of otitis media.
 - By the age of 7 years, between 65% and 95% of children will have been treated for ≥1 episode of otitis media.
- Each year in the US, >\$3.5 billion is spent on the treatment of otitis media.

Otitis externa

- Common finding in children
- Especially prevalent during the warm-weather months

ETIOLOGY

Otitis media

- Otitis media is an inflammatory process of the upper respiratory tract.
- Usually results from a viral infection
 - As viruses infect the respiratory mucosa, edema can lead to eustachian tube dysfunction.
 - Inflammatory fluid and pathogenic respiratory bacteria that reflux into the middle-ear space do not drain normally.
 - This process leads to formation of an abscess in the middle ear.
- In studies of children with AOM, specimens of middle-ear fluid:
 - Were positive for bacteria approximately 70% of the time
 - The most frequently identified pathogens are:
 - *Streptococcus pneumoniae*
 - *Haemophilus influenzae*
 - *Moraxella catarrhalis*
 - Group A β -hemolytic streptococcus and *Staphylococcus aureus* (including methicillin-resistant strains) are much less common.
 - Rarely, *Mycoplasma pneumoniae* is detected.
 - Not often enough to affect the empirical selection of an antibiotic for treatment
 - Respiratory viruses, such as respiratory syncytial virus (RSV), influenza viruses, and parainfluenza viruses, are also recovered often from middle-ear aspirates, either in addition to bacteria or in isolation.
 - RSV has a tendency to infect the mucosa of the middle ear.
 - Probably contributes substantially to the development of otitis media in children

OE

- Multifactorial in etiology
- Involves interaction between the host and environmental factors, including:
 - Trauma to the external auditory canal
 - Presence of a foreign body
 - Repeated ear cleansing
 - Prolonged exposure to standing water in the ear canal
 - For example, following swimming or bathing (swimmer's ear)
 - High environmental temperature and humidity
 - Increased sweating
 - Allergy
 - Stress

- Inflammation may be:
 - Focal, at the site of trauma or an infected hair follicle
 - Diffuse, as is the case with swimmer's ear
- When inflammation is focal and associated with infection, the organism is often *S aureus*.
 - Can lead to furuncle formation at the site of the inflammation
- The most common organism associated with diffuse inflammation is *Pseudomonas aeruginosa*.
 - Hydrophilic bacterial species
- Infection is often polymicrobial.
- Enteric bacilli and fungi are less common causes.

Malignant OE

- Necrotizing infection of the external auditory canal
- Often begins as minor trauma to the canal
- Usually caused by *P aeruginosa*
- Rapidly spreads to involve:
 - Soft tissue
 - Cartilage
 - Nerves and the temporal bone
- Leads to osteomyelitis of the base of the skull

RISK FACTORS

- Several environmental factors increase the risk for otitis media.
 - Exposure to tobacco smoke
 - Use of a pacifier
 - Formula feeding (not breastfeeding)
 - Feeding in a lying-down position
 - Attendance at child-care centers
 - Particularly those serving large numbers of children
- Children at high risk for AOM include those with:
 - Craniofacial anomalies that alter the normal air and fluid dynamics of the middle-ear space, eg, cleft palate
 - Allergic rhinitis
 - Immunodeficiencies
 - Certain ethnic groups, such as:
 - Native Americans
 - Alaskan Natives
- A mild hereditary predisposition to recurrent otitis media appears to exist.
 - Some of the variation in presentation and incidence is explained by genetic factors.
 - Familial and individual environmental factors account for the remainder.

SIGNS AND SYMPTOMS

Otitis media

- In the classic case of AOM, a young child with a history of a recent upper respiratory tract infection develops acute onset of:
 - New fever
 - Ear discomfort or pain
- Other symptoms include:
 - Otorrhea
 - Distortion of the tympanic membrane (bulging, erythema, opacity, limited mobility)
- In children old enough to localize pain, the affected ear is often obvious.
- In younger children, discomfort may be more generalized, exhibited by unexplained crying or irritability.
- Examination may reveal other signs of upper respiratory infection, such as:
 - Rhinorrhea
 - Cough
 - Conjunctival injection

OE

- Children complain of ear pain.
- May report pain with chewing
 - Because of proximity of the temporomandibular joint to the external auditory canal
- May report difficulty hearing
 - Result of swelling within the external auditory canal and conductive hearing loss
- Examination reveals tenderness with manipulation of the pinna or pressure on the tragus.
- Insertion of otoscope into the external auditory canal can be painful and should be undertaken carefully.
- Within the canal, focal erythema and swelling may be seen at the site of trauma or folliculitis.
- If inflammation is diffuse, swelling of the entire canal renders a boggy appearance.
- Edema and the presence of inflammatory debris may prevent complete visualization of the tympanic membrane.
- The tympanic membrane should appear normal in OE, unless coexistent otitis media is present.

Malignant OE

- Pain is severe.
- Discharge from the external canal is copious.

DIAGNOSTIC APPROACH

- Concern is growing that overdiagnosis of otitis media and liberal use of antibiotics for treatment have contributed to the rapid emergence of antibiotic-resistant bacteria.
 - Particularly penicillin-resistant *S pneumoniae*
- Accurate diagnosis is critical to appropriate management.
- Diagnosis is based on recognition of:
 - Characteristic clinical context
 - Physical findings on pneumatic otoscopic examination
- Diagnosis of AOM is confirmed using pneumatic otoscopy.
 - To perform this technique, the child must either cooperate or be restrained in a comfortable position that allows manipulation of the pinna and insertion of otoscope into the external auditory canal.
 - Cleanse the external auditory canal for clear visualization of the tympanic membrane.
 - Cerumen or foreign bodies should be removed using a cerumen spoon or gentle irrigation with warm water.
 - The largest speculum that will fit into the external auditory canal at a depth of one-third inch to one-half inch should be attached to pneumatic otoscope.
 - Permits visualization of the largest possible area and ensures a relatively airtight seal for insufflation
 - AOM is present when:
 - Distortion (usually bulging) of the tympanic membrane is noted on direct visualization.
 - In some cases, the tympanic membrane may be retracted rather than bulging.
 - Restricted movement of the tympanic membrane, indicative of fluid in the middle ear, is noted with gentle insufflation and exsufflation using the squeeze bulb attached to the otoscope.
 - Erythema of the tympanic membrane alone is not sufficient to diagnose AOM.
 - Possibly the incidental result of fever or crying
 - Occasionally, a child with AOM experiences spontaneous rupture of the tympanic membrane.
 - Leads to marked improvement in ear pain
 - Otorrhea is evident on examination.
- OME may be an incidental finding on physical examination.
 - Decreased mobility of the tympanic membrane
 - Signs of acute inflammation seen in AOM are absent.

LABORATORY FINDINGS

- In AOM, some experts advocate making a specific bacteriologic diagnosis (see Diagnostic Procedures).

DIAGNOSTIC PROCEDURES

- Tympanocentesis or carbon dioxide laser-assisted myringotomy
 - Used to obtain middle-ear fluid for culture and sensitivities
 - Not necessary for routine diagnosis of AOM
 - Useful in specific clinical situations in which identification of the organism to guide therapeutic decisions is a high priority
 - Episodes of AOM that do not respond to empirical antibiotic therapy
 - Children who experience frequent recurrences despite seemingly appropriate therapy
 - Children who are young and particularly toxic in appearance
- Cultures of other areas of the upper respiratory tract are useful for research.
 - Do not assist in the management of individual episodes of AOM
 - The same organisms usually are recovered from the nasopharynx as from middle-ear fluid.
 - The presence of an organism from nasopharyngeal culture does not prove presence in the middle ear.
- Tympanometry is a technique for documenting tympanic membrane compliance.
 - Can be used to document objectively presence of fluid in the middle-ear space
 - Does not add to information obtained on carefully performed pneumatic otoscopy.
 - Can be useful for monitoring the course of an episode of OME over time

TREATMENT APPROACH

- Otitis media is usually self-limited.
 - As viral illness resolves, eustachian tube function is restored.
 - The middle-ear space drains normally.
- Acute symptoms generally resolve spontaneously within a few days.
- Middle-ear effusions can persist for weeks after an episode of AOM.
 - 60% of middle-ear effusions resolve spontaneously within 3 months.
 - 85% resolve within 6 months.
- Persistence of middle-ear effusions (or OME) after an episode of AOM has raised concern about:
 - Conductive hearing loss that accompanies these effusions
 - Impact on speech and language development, especially in younger children
- Effusions are sterile.
 - In the absence of other acute signs and symptoms, they do not require antibacterial therapy.

SPECIFIC TREATMENTS

Management of AOM

- Whether an episode of AOM should be treated with antibiotics is a matter of ongoing discussion.
 - The 2004 AAP and American Academy of Family Physicians practice guidelines delineate very specific criteria for:
 - Patients who should receive antibiotic therapy
 - Patients who are candidates for observation
 - Clinical experience should be used to determine which course of therapy is most appropriate when patients do not quite fit criteria.
 - The modest benefits of antibiotic therapy must be weighed against the negative impact of widespread antibiotic use and its effect on producing antibiotic-resistant species of organisms, such as *S pneumoniae*.
 - In some areas of the US, 40% of strains of this organism are resistant to penicillin.
- Several guiding principles should be observed when selecting patients to be treated with antibiotics.
 - The diagnosis should be clear.
 - Presence of fever, upper respiratory symptoms, or a middle-ear effusion are not sufficient indications without objective findings on pneumatic otoscopy
 - Antibiotics should not be prescribed without a clear diagnosis.
 - Younger patients may benefit more from empirical antibiotic therapy than older children.
 - Positive effects of antibiotic administration have been more prevalent in children <2 years.
 - Possibly because of their more limited immune response to encapsulated organisms
 - Uniquely susceptible individuals, such as those with immunodeficiencies or those with craniofacial anomalies, are at increased risk of complications or protracted course of illness.
 - These patients warrant a lower threshold for treatment.
 - Observation of a patient off antibiotic therapy for 48–72 hours is now considered an acceptable management option in low-risk patients >6 months of age.
 - If symptoms have not resolved spontaneously within 48–72 hours:
 - Reexamination is indicated.
 - Prescription of antibiotics is appropriate if objective findings of AOM are still present.
- An effective antibiotic with the narrowest spectrum should be chosen.
 - Antibiotics for treatment of this common condition include:
 - Penicillins
 - First-, second- and third-generation cephalosporins
 - Macrolides
 - Carbacephems
 - In the absence of specific microbiological information, selection of empirical antibiotic therapy should be guided by:
 - Knowledge of the most common bacterial pathogens identified in middle-ear aspirates of children
 - Efficacy of the antibacterial agent (based on minimal inhibitory concentration and pharmacokinetic and pharmacodynamic data) against these organisms
 - In population-based studies of children with AOM, the most common organisms isolated were *S pneumoniae*, *H influenzae*, and *M catarrhalis*.
- High-dose amoxicillin is the recommended first-line choice.
 - Inexpensive
 - Good spectrum of activity against target organisms, including strains of *S pneumoniae* with intermediate resistance to penicillin
 - Studies of amoxicillin treatment of AOM show cure rates of 85–94% based on clinical criteria.
 - Treatment should be administered for 10 days.
 - Shorter courses of 5–7 days may be acceptable in low-risk patients (older children with uncomplicated histories).
- If fever, ear pain, and objective findings of AOM persist despite ≥72 hours of therapy, then a change of antibiotic may be warranted.
 - Second-line agents, such as second- or third-generation cephalosporins or amoxicillin plus clavulanate
 - Cover β -lactamase-producing strains of *H influenzae* and *M catarrhalis*
 - Penicillin-resistant *S pneumoniae*
 - Clindamycin only provides coverage for resistant gram-positive organisms.
 - Alternative agent if otitis is proven to be secondary to a resistant strain of *S pneumoniae*
 - For patients who develop hives or anaphylaxis to β -lactam antibiotics, azithromycin may be used.
 - This drug has decreased activity against:
 - Penicillin-resistant strains of *S pneumoniae*
 - β -Lactamase-producing strains of *H influenzae*
- No proven benefit has been found from use of:
 - Antihistamine or decongestant preparations
 - Steroids
 - Nonsteroidal antiinflammatory drugs
- Topical Auralgan otic solution is somewhat effective in reducing acute ear pain.

Management of OME

- OME presents a different therapeutic challenge.
 - The goal of therapy is to limit potential long-term detrimental effects on speech and language development.
 - Weak associations have been found between OME and abnormal speech and language development in children <4 years.
 - Problems with attention and expressive language delay have been found in older children.
 - Associations may be the result of environmental influences that predispose patients to both OME and developmental delays.
 - The effects of treating OME on these outcomes are not well established.
- Medical therapies for OME have produced unsatisfactory results.
 - Very limited scientific evidence exists.
 - A few experts believe that empirical antibiotic therapy either early or later, when the effusion has persisted for ≥ 3 months, may hasten resolution of the effusion.
 - Most experts strongly discourage this practice, given increasing rates of antibacterial resistance.
 - No role exists for:
 - Steroid medications
 - Antihistamine or decongestant preparations
 - Tonsillectomy
 - Adenoidectomy
 - The most effective therapy is surgical insertion of tympanostomy tubes.
 - Placement of tympanostomy tubes evacuates middle-ear effusion and restores near-normal hearing.
 - The effect on long-term speech and language outcomes is unclear.
 - Laser-assisted myringotomy may soon replace tympanostomy tube placement.
- Adenoidectomy is used in the management of patients with OME.
 - May be effective in a select group of children
 - Chronically infected adenoids are thought to serve as a reservoir of pathogenic organisms, leading to tubal edema and malfunction and persistent OME.
 - Removal of enlarged adenoids has been shown to improve effusion resolution.
 - Adenoidectomy and myringotomy plus ventilation tube insertion is recommended therapy for:
 - Children with severe ear disease
 - Children undergoing replacement of a second set of ventilation tubes

Management of recurrent otitis media

- Occurrence of ≥ 3 episodes of AOM within 6 months or of 4 episodes within 1 year satisfies many experts' definition of recurrent otitis media.
 - Therapy is controversial.
 - Studies have shown that long-term administration of prophylactic antibiotics (usually either amoxicillin or trimethoprim plus sulfamethoxazole) can reduce incidence of subsequent episodes of AOM.
 - The effect is modest.
 - To improve outcome in 1 child, 9 must be treated with daily medication, and prophylactic antibiotics contribute to the development of resistant organisms.
 - Use of prophylactic antibiotics is currently not recommended for management of recurrent otitis media.
 - Controlling environmental risk factors, such as exposure to tobacco smoke and attendance at large child-care centers, is a more desirable approach.
- Tympanostomy tube placement or laser-assisted myringotomy should be considered in the management of recurrent otitis media.
 - This approach may be justified when recurrent AOM complicates OME and is accompanied by hearing loss.
 - Frequent episodes of AOM (without OME) that respond to appropriate antibiotic therapy are not an indication.
 - AOM tends to occur less frequently in children who have had tympanostomy tubes placed.
 - Requires administration of anesthesia
 - Tubes may not remain in place for a sufficient duration to have a measurable impact on health of an individual child.
- Strategies that show promise for prevention of future episodes of otitis media
 - Use of conjugated vaccine against *S pneumoniae*
 - Widespread use of influenza vaccine in healthy children
 - Development of an effective vaccine against RSV

Care of the child with tympanostomy tubes

- Tympanostomy tube placement is the most common surgical procedure performed in children.
 - Examination of the child with tympanostomy tubes should show a patent tube traversing the pars flaccida.
 - A tympanic membrane that contains a tympanostomy tube is not intact.
 - Mobility is affected.
 - Pneumatic otoscopy cannot be used as a reliable indicator of AOM.

- Tympanostomy tubes are usually extruded naturally some time after insertion.
 - Some otolaryngologists recommend actively removing tympanostomy tubes that have been in place for ≥ 2 years to prevent complications, such as chronic perforation or tympanosclerosis.
 - If a tympanostomy tube is visualized in the external canal and is no longer seated within the tympanic membrane, it may be removed with a cerumen spoon under direct visualization.
- Otorrhea is common in children with tympanostomy tubes.
 - Otorrhea associated with other symptoms of upper respiratory infection may indicate the presence of AOM.
 - Treat accordingly.
 - When otorrhea occurs in isolation, it may respond to topical application of an otic solution containing:
 - Neomycin
 - Polymyxin B
 - Hydrocortisone
 - Otorrhea is no more common in children with tympanostomy tubes who swim or submerge their heads in a bathtub than in those who do not.
 - Use of topical antibiotics or earplugs does not reduce incidence of swimming-related otorrhea.
 - Children with tympanostomy tubes who do not dive to depths >6 feet or swim in potentially contaminated water (such as a pond) require no special precautions to swim.
 - Use of earplugs or molds may increase drainage from the ears.

Management of OE

- When OE is accompanied by furuncle formation, incision and drainage may be necessary.
 - Diffuse OE usually responds to 4 times-a-day application of a topical otic solution containing:
 - Neomycin
 - Polymyxin B
 - Hydrocortisone
 - With the patient lying on the unaffected side, 5 drops of this solution are instilled into the affected ear.
 - The patient should remain in position for 5–10 minutes after instillation to ensure that the medication has come in contact with affected skin.
 - Insertion of a cotton wick can prolong this contact.
- OE can be prevented by keeping the external auditory canal dry.
 - Avoid vigorous cleaning of the canal that can lead to superficial trauma.

Management of malignant OE

- Treatment requires administration of intravenous antibiotics.
- Occasionally, surgical intervention is required.

WHEN TO ADMIT

- Admit any patient with severe otitis media who has:
 - Toxic appearance
 - Malignant OE
 - Suppurative complications of otitis media
- Hospitals provide:
 - Institution of prompt, effective intravenous antibiotic therapy
 - Evaluation for possible surgical intervention

WHEN TO REFER

- Otitis media with effusion
 - If, at 3 months, middle-ear effusions are persistent and bilateral, refer for audiologic testing.
- Care of the child with tympanostomy tubes
 - Occasionally, a granuloma may develop at the site of tympanostomy tube insertion.
 - May lead to bleeding from the external auditory canal
 - Patients should be referred to an otolaryngologist for intervention.
- Patients with recurrent or chronic otitis media and persistent otitis media with effusion (present for ≥ 3 months) should be referred for ear, nose, and throat evaluation.
- Infectious diseases consultation should be obtained in patients with the following conditions.
 - Suppurative complications of otitis media
 - Recurrent or chronic episodes of otitis media unresponsive to standard therapy
 - Patients with unusual or multiple antibiotic resistant organisms isolated from middle ear fluid
 - Patients with chronic suppurative otitis media unresponsive to conventional therapy
 - Patients with malignant OE
- In many of these conditions, a team approach with both ear, nose, and throat and infectious diseases referrals should be used for optimal management of the patient's condition.

FOLLOW-UP

- Acute otitis media treatment
 - Most children who respond satisfactorily to treatment do not require specific follow-up.
 - As long as a child is asymptomatic, the main reason for follow-up is to document resolution of a middle-ear effusion that may contribute to conductive hearing loss.

- Only 50% of middle-ear effusions resolve by 6 weeks after initial presentation.
- Follow-up for an otherwise healthy and asymptomatic child should be scheduled no sooner than 6 weeks post-diagnosis, if at all.
- An effusion that is persistent at 6 weeks does not warrant specific intervention other than perhaps checking for resolution again in 6 more weeks.
- Documented OME
 - Follow-up at 3 months is reasonable, assuming that acute symptoms have not intervened.
 - If hearing is normal, then further observation to allow spontaneous resolution is appropriate.
 - If a conductive hearing loss at a threshold ≥ 20 dB is documented at 3-month follow-up, consideration should be given to tympanostomy tube placement or laser-assisted myringotomy to drain the effusions and restore hearing.
 - Use of these procedures for OME in otherwise healthy children with normal hearing is not recommended.

COMPLICATIONS

Otitis media

- Conductive hearing loss resulting from chronic middle-ear effusions associated with otitis media may contribute to speech and language delay in some children.
- Overuse of antibiotics to treat otitis media is thought to contribute significantly to the emergence of antibiotic-resistant bacteria.
- Suppurative complications of otitis media are:
 - Mastoiditis
 - Intracranial extension of infection
 - Lateral sinus thrombosis
- Suppurative complications are rare.
 - Occur much less frequently than in the era before routine antibiotic treatment of AOM
 - The incidence of these complications has declined in areas of the world where routine antibiotic treatment of AOM is less common.
 - Factors other than early antibiotic treatment may have contributed to this trend.

- Early signs and symptoms associated with suppurative complications include:
 - Mastoid tenderness
 - Persistent fever associated with chronic tympanic membrane perforation
 - Persistent and severe headache
 - Severe otalgia
 - Retroorbital pain on the side of the affected ear
 - Vertigo
 - Mental status changes
 - Nystagmus
 - Other focal neurologic signs can signal intracranial extension of suppurative otitis media.
 - Facial paralysis
 - Meningismus
 - Papilledema

Malignant OE

- Stenosis of the external auditory canal
- Auricular cartilage deformity
- Tympanic membrane necrosis
- Sensorineural hearing loss

PROGNOSIS

- Most otitis media is self-limited and resolves spontaneously in several days.
- Malignant OE
 - Development of facial paralysis indicates a poor prognosis.

PREVENTION

- Exclusive breastfeeding early in life has a protective effect.
- Immunizations with influenza and pneumococcal vaccines
- Avoiding passive smoke exposure
- Using appropriate feeding positions (not feeding in lying down position)
- Treating allergic rhinitis appropriately
- Treating the underlying cause, such as cleft palate

Parasitic Infections

DEFINITION

- Disease caused by any 1 of a variety of parasites, including protozoa, nematodes, trematodes, and cestodes

EPIDEMIOLOGY

Leishmaniasis

- Endemic areas for cutaneous form
 - Mediterranean basin
 - Middle East, including Iraq
 - Southern Asia
 - Parts of Africa
 - Ethiopia
 - Yemen
 - Kenya
 - Central and South America
 - Texas
- Visceral form
 - Disease involves different age groups depending on parasite species and geographic distribution.
 - India: affects adolescents and young adults
 - Sudan and East Africa: affects young men
 - Mediterranean basin and northern China: affects infants and young children
 - Latin America (rare): affects primary infants and young children

Chagas disease

- Areas from the southern US to southern Argentina
 - Highest prevalence in Brazil, Argentina, and Venezuela
 - In the US, infection is common in immigrants from Central and South America
- Most infections occur in poor, remote rural areas or areas with poor sanitation.
- Prevalence
 - 16–18 million people in endemic areas are infected.
 - An estimated 100,000 chagasic Latin Americans are living in the US.

African trypanosomiasis

- Transmission occurs in areas between the latitudes of 15 degrees north and 20 degrees south, with temperatures between 20°C and 30°C (distribution of the tsetse fly).
- Rare in children because of limited exposure

Giardiasis

- Prevalence
 - 20–30% in developing countries to 2–7% in the developed world
- Incidence in US
 - Approximately 2.5 million new cases annually

- Most cases occur in children in the first 5 years of life.
 - Children attending child care centers
 - Prevalence among children who attend child care centers can be as high as 35%.
 - Internationally adopted children
 - Tend to be older than those in child care centers and to have additional parasitic infections
- Peak incidence is in late summer and early fall.

Amebiasis

- Incidence
 - Worldwide, 40–50 million people develop colitis or extraintestinal disease annually, with 40,000 deaths.
- Prevalence
 - Developing countries have high prevalence rates, up to 50% in certain developing areas.
 - Related to poor hygiene, inadequate water sanitation, and human waste that is used to fertilize crops
- In developed countries
 - Mainly seen in migrants from and travelers to endemic countries

Amoebic meningoencephalitis

- Primary amoebic meningoencephalitis (PAM)
 - Disease in previously healthy children and young adults
 - The responsible organism is found in warm bodies of water.
 - Human-made lakes and ponds
 - Hot springs
 - Thermally polluted streams, rivers, and healing swimming pool waters
- Granulomatous amoebic encephalitis (GAE)
 - Disease in immunocompromised patients
 - The responsible organism is identified in:
 - Soil
 - Various water sources
 - Air conditioners
 - Contact lens fluid

Cryptosporidiosis

- Common in developing countries that have increased crowding and poor sanitation
- Prevalence
 - 1–3% of immunocompetent patients with diarrhea in developed countries
 - 7–10% of immunocompetent patients in developing countries
 - 3 cases per 100,000 in the US and 6 per 100,000 persons in Canada
 - Higher in children than in adults

- Cause of outbreaks

- Contaminated drinking water
- Contaminated apple cider
- Playing in contaminated water at a water park
- Contaminated food (less frequent)
- Person-to-person transmission at child care centers (attack rates of 30–60%)

- **Isosporiasis**

- Common in tropical/subtropical regions of Central and South America, Africa, and Southeast Asia
- In the US, seen in homosexual men

- **Cyclosporiasis**

- Worldwide
- From ingesting contaminated food or water
- Eating infected fruit, herbs, and vegetables

- **Toxoplasmosis**

- Worldwide distribution
- Highest incidence in countries where consumption of raw meat is common (US and Western countries)
- Common in regions with warm, humid climates, including tropical areas

- **Malaria**

- Incidence
 - 350–500 million clinical episodes of malaria occur every year, resulting in ≥ 1 million deaths.
- Most cases are in sub-Saharan Africa.
 - Most occur in African children <5 years of age.
- *Plasmodium falciparum*
 - Causes most severe disease
 - Predominant malarial parasite in tropical Africa, Southeast Asia, and Oceania
- *Plasmodium vivax*
 - Predominant in Southeast Asia
 - Causes most malaria infections worldwide
- *Plasmodium malariae*
 - Least common
 - Produces long-lasting infections

- **Babesiosis**

- In Europe
 - Affected patients usually those who have undergone splenectomy
 - Cases have been reported from Yugoslavia, France, Germany, Spain, Sweden, Ireland, Great Britain, and the former Soviet Union.

- In the US

- Most cases occur in the northeastern part of the country, including islands and coastal areas near Massachusetts, New York, New Jersey, and Rhode Island and areas in Connecticut.
 - Cases from other states have also been reported.
- Most cases occur between May and August.
- Most infected patients are immunocompetent.
- Cases also reported in other parts of the world.
 - Taiwan
 - Canary Islands
 - Egypt
 - South Africa
 - Mexico
 - China

- **Trichuriasis**

- Worldwide, but most frequently found in tropical/subtropical areas and areas of poor sanitation
- Infection is common in warm, humid areas.
- In US, most common in Latin immigrant children in rural areas of the southeastern states

- **Strongyloidiasis**

- Worldwide, but particularly common in the tropical/subtropical regions
- In US, most common in the southeastern states
- Disease is most frequent among white men.

- **Hookworm infections**

- Worldwide

- **Cutaneous larva migrans**

- Most cases occur in tropical/subtropical areas of Africa, Southeast Asia, the Caribbean, and Central and South America.
- In US, most cases occur in the southeast.

- **Pinworm infections**

- Infections are more prevalent in temperate and cold climate regions than in the tropics.

- **Enterobiasis**

- Infections occur across socioeconomic levels but are more common in close, crowded conditions.

- **Toxocariasis**

- Humans acquire infection by ingesting soil contaminated with infective eggs of the parasites, shed by dogs.
- Endemic in areas where dogs are present
 - Estimates suggest that 20% of dogs and 98% of puppies are infected.

- Most reported cases of toxocariasis occur in the US.
 - Highest rates of transmission are in the southern US, particularly in rural areas
 - Infection can be acquired in urban areas.
- Most affected patients are children 1–4 years of age.

Lymphatic filariasis

- Hot, humid climates
- Most cases worldwide
 - Sub-Saharan Africa
 - China
 - India
 - Indonesia
- Most affected patients are 15–44 years of age.

Onchocerciasis

- Tropical Africa
- Central and South America
- Arabian peninsula, mainly Yemen

Schistosomiasis

- Each species of *Schistosoma* has a specific geographic distribution.
 - Sub-Saharan Africa: *Schistosoma haematobium*, *Schistosoma mansoni*, and *Schistosoma intercalatum*
 - Brazil, Venezuela, the Caribbean, and the Arabian peninsula: *S. mansoni*
 - Eastern Mediterranean: *S. haematobium*
 - China, Indonesia, the Philippines: *Schistosoma japonicum*
 - Cambodia and Laos: *Schistosoma mekongi*
- Persons most commonly infected
 - School-age children
 - Women
 - Persons involved in water-related occupations, such as irrigation, fishing, and farming
 - Most cases among travelers to Africa
 - Particularly if they swim in Lake Malawi and the Zambezi River

Taeniasis and cystercercosis

- *Taenia* species have worldwide distribution, with higher prevalence in areas with the custom of eating undercooked beef or pork.
 - *Taenia saginata*
 - Some new independent states of the former Soviet Union
 - The Near East
 - Central and Eastern Africa
 - Europe
 - Southeast Asia
 - South America

- *Taenia solium*
 - Mexico
 - Central and South America
 - Africa
 - Southeast Asia
- In US, human infections are usually found in immigrants from areas with high disease prevalence or travelers to endemic areas.
- In US, cysticercosis can be acquired from patients or immigrants from endemic area who have adult-stage *T. solium* infection in the intestine.

Hydatid disease

- *Echinococcus granulosus*, seen practically worldwide
 - Predominantly in rural livestock-raising areas
 - South and Central America
 - Middle East
 - Some sub-Saharan countries
 - Central Asia
 - Southern Europe
 - Former Soviet Union
 - In US
 - Most human infections are seen in immigrants from areas with high disease prevalence.
 - Sporadic transmission in some states
 - California
 - Arizona
 - New Mexico
 - Utah
 - Alaska
- *Echinococcus multilocularis*
 - Northern and Central Europe
 - Russia
 - Western China
 - Certain areas of North America
 - Northern Africa
 - Incubation period of cyst is 5–15 years; average age at its manifestation is 55 years.
- *Echinococcus vogeli* and *Echinococcus oligarthrus* are seen in Central and South America and have only rarely been associated with human infection.

Diphyllobothriasis

- Infestation occurs worldwide.
- High prevalence where there is a common culinary habit of eating undercooked or raw fish
 - Scandinavia
 - Newly independent states of the former Soviet Union

- North America (in US, mostly in the Southeast)
- Latin America
- Asia

Hymenolepiasis

- Infections most common in children because they are prone to fecal-oral contamination.
- Prevalence
 - Highest prevalence is among institutionalized school-age children in developing areas of the world.
 - In US, a 4% infection rate has been reported among schoolchildren in the rural Southeast.

ETIOLOGY

Protozoal infections

- Leishmaniasis
 - Cutaneous, mucocutaneous, and visceral forms
 - Caused by protozoa of the genus *Leishmania*, and transmitted by the sandfly
 - Dogs and rodents are considered reservoir hosts.
- Chagas disease (American trypanosomiasis)
 - Caused by the flagellated protozoan parasite *Trypanosoma cruzi*
 - Transmitted to humans by blood-sucking insect vectors of the family Reduviidae (*cone-nose*, *kissing*, or *assassin bug*)
 - Organisms enter the host at the site of bite wound or through intact mucous membranes of the eye or mouth.
 - Parasite can also be transmitted by:
 - Blood transfusion
 - Organ transplantation
 - Transplacentally
 - Ingestion of the vector
 - Vector's excretion
 - In the laboratory from handling blood from infected people or laboratory animals.
- African trypanosomiasis
 - Caused by *Trypanosoma brucei*
 - 2 subspecies infect humans.
 - *T brucei gambiense* is the cause of West African sleeping sickness.
 - *T brucei rhodesiense* is the cause of East African sleeping sickness.
 - Transmitted by the tsetse fly
- Giardiasis
 - *Giardia intestinalis* (syn *Giardia duodenalis* or *Giardia lamblia*) is a flagellated binucleated protozoan, intestinal parasite.
 - Humans acquire giardiasis directly by ingestion.
 - Ingesting cysts by hand-to-mouth transfer of fecally contaminated material from an infected person
 - Ingesting contaminated water or food
- Amebiasis
 - Caused by *Entamoeba histolytica*
 - *E histolytica* cysts can be ingested with contaminated food or drink and survive the gastric barrier.
 - Cysts transform into trophozoites that:
 - Lodge in the submucous layer of the cecum and rectosigmoid
 - Transform into cysts, which are passed in the stool
 - Can invade the bowel wall, producing ulcers and causing destruction and tissue necrosis
 - May disseminate to the liver, lungs, pericardium, or the brain through the bloodstream, causing abscesses
- Amoebic meningoencephalitis
 - Free-living amoebas that cause 2 distinct clinical manifestations
 - PAM: acute, fulminant disease caused by *N aegleria fowleri*
 - GAE: chronic and slowly progressive disease caused by *Acanthamoeba* and *Balamuthia* species
- Cryptosporidiosis
 - Caused by *Cryptosporidium*, an intracellular coccidian protozoan parasite
 - Humans acquire infection by ingesting thick-walled oocysts.
 - Infection is generally limited to the superficial parts of the small intestine.
 - In immunocompromised patients infection, may:
 - Spread to involve the biliary tree and the pancreas
 - Disseminate to extraintestinal sites, mainly the respiratory tract
 - Causes diarrhea and inflammatory changes in the gastrointestinal (GI) tract
- Isosporiasis
 - Humans acquire infection by ingestion of sporulated oocysts in contaminated food or water.
 - Oocysts are released into the intestinal lumen.
- Cyclosporiasis
 - Caused by the coccidian protozoan parasite *Cyclospora cayatanensis*
- Toxoplasmosis
 - Caused by *Toxoplasma gondii*
 - Cats are definite hosts; humans and other mammals are intermediate hosts.

- Humans acquire infection by ingesting cysts in raw or undercooked meat or oocysts in material contaminated by cat feces.
- Other causes of infection
 - Contamination of drinking water supplies
 - Blood transfusion
 - Stem cell or solid organ transplantation
- Congenital toxoplasmosis
 - Follows a primary infection in the mother during pregnancy
 - Newborns are most frequently infected when maternal infection is acquired during third trimester.
 - In rare instances, the fetus may be infected after *Toxoplasma* reactivation in immunocompromised mothers, including those with HIV.
- Malaria
 - 4 species of plasmodia infect humans.
 - *P falciparum*
 - *P vivax*
 - *P malariae*
 - *Plasmodium ovale*
 - Transmitted from person to person by the bite of the female *Anopheles* mosquito.
 - Infected cells lyse and release waste products and toxic factors into the bloodstream which act to produce fever and rigor
- Babesiosis
 - Caused by a tick bite
 - Results in ischemic damage in different organs, including liver, spleen, heart, and brain
- Nematode infections**
- Trichinellosis
 - Caused by the roundworm *Trichinella* in infected meat (mainly pork, but also beef and wild game)
- Trichuriasis
 - Caused by *Trichuris trichiura* (whipworm)
 - Humans acquire infection by ingesting eggs.
 - Larvae are released in the intestine and develop over 2–3 weeks into adult worms.
- Strongyloidiasis
 - Caused by:
 - *Strongyloides stercoralis*
 - Less frequently by *Strongyloides fulleborni*, which causes infantile protein-losing enteropathy with high mortality rates
 - Humans acquire infection by skin contact with infective (filariform) larvae in soil or other material contaminated with human feces.
 - Disease may range from asymptomatic eosinophilia in healthy people to life-threatening disseminated infection with septic shock in immunocompromised patients.
- Hookworm infections
 - The 2 most common hookworms are *Ancylostoma duodenale* and *Necator americanus*.
 - Humans acquire infection after percutaneous penetration of larvae.
 - *A duodenale* may also be acquired by the oral route or human milk.
- Cutaneous larva migrans
 - Caused by the infective larvae of the cat and dog hookworms *Ancylostoma braziliense* and *Ancylostoma caninum*
 - Infection occurs among individuals with direct skin contact to infective larvae.
- Pinworm infections
 - Disease is caused by the nematode *Enterobius vermicularis*.
 - Humans acquire infection by ingesting eggs from the same host (autoinfection) or from another person.
 - Direct anus-mouth contact
 - Eating contaminated food
 - Contaminated hands and fomites
 - Contaminated clothing, linen, toilet seats, and baths contribute to spread among families and close contacts.
 - Eggs hatch in the intestine into larvae, and adult worms develop over several weeks.
 - Female adult worms travel at night from the GI tract and migrate through the rectum to lay eggs onto the perianal skin.
- Ascariasis
 - Caused by *Ascaris lumbricoides*, the largest roundworm that infects humans
 - Human infection occurs by ingesting eggs from contaminated soil.
 - Larvae hatch in the intestine, penetrate the intestinal wall, and migrate to the right side of the heart, lungs, and bronchial tree; they ascend to the pharynx and are swallowed to mature into adult worms in the small intestine.
- Toxocariasis (visceral larva migrans)
 - Caused by the dog ascarid, *Toxocara canis*, and less frequently by the cat ascarid, *Toxocara cati*.
 - Humans are unusual hosts for *T canis* and *T cati*.
 - The parasite fails to mature in humans and remains alive in the body for months to years.
 - Humans acquire infection by ingesting soil contaminated with infective eggs of the parasites.

■ Lymphatic filariasis

- Caused by 3 species of filarial nematodes
 - *Wuchereria bancrofti* (accounts for 90% of cases)
 - *Brugia malayi*
 - *Brugia timori*
- Humans acquire infection by bites of mosquitoes that contain larvae; larvae travel to the lymphatic vessels, where they mature into adult worms.
- Female adult worms release microfilariae in the bloodstream.

■ Onchocerciasis (river blindness)

- Caused by the filarial nematode *Onchocerca volvulus*
- Disease is transmitted by various species of the blackfly *Simulium*, distributed along turbulent waters.
- Blackflies suck microfilariae from human skin and subcutaneous tissue.
- Infective larvae develop inside the blackfly and are released in the skin when a human host is bitten.
- Adult worms develop from larvae inside the skin, subcutaneous tissue, or fascia over approximately 1 year.
 - Adult worms live curled up in nodules under the skin and subcutaneous tissue.
- Female worms produce microfilariae in the skin; their migration is responsible for skin lesions.

Trematode infections

■ Schistosomiasis

- Caused by the trematode *Schistosoma*
- Snails are an intermediate host, infected by schistosome eggs.
- Cercariae are released from snails and penetrate the skin of humans exposed in fresh water.
- After skin penetration, cercariae become schistosomulae.
- Schistosomulae travel via blood vessels and lymphatics to the right side of the heart and pulmonary circulation and then the arterial circulation; they are carried to the mesenteric and splanchnic arteries, and finally the portal circulation, where they mature to adult forms.
- Mature worms migrate to their final habitat in the mesenteric vein (*S. mansoni* and *S. japonicum*) or the vesical veins (*S. haematobium*).
- Eggs laid by female worms are transported to other organs or traverse the circulation through adjacent tissue to the lumen of the intestine or the urinary bladder.
- Skin penetration by cercariae induces a delayed-type hypersensitivity reaction leading to dermatitis.
- Host response to eggs is formation of granulomas and by infiltration of cells around the eggs.

Cestode infections

■ Taeniasis and cystercercosis

- Taeniasis
 - Caused by the adult worm of *T. solium* and *T. saginata*
 - People are infected by eating undercooked beef (*T. saginata*) or pork (*T. solium*) that contains cysticerci in the muscle.
 - Inside the intestine, proctoscopies are released from the cysticerci and attach to the intestinal wall with suckers and hooks.
 - The proctoscopies become the head of the tapeworm, which later develop by forming proglottids and maturing into adult tapeworms over 2 months.
- Cysticercosis
 - Caused by the larval stage of only *T. solium*
 - Infection occurs after embryonated eggs are ingested, which can be either from eating food contaminated with human feces or by autoinfection.
 - Inside the human intestine, the oncospheres hatch, penetrate intestinal wall, and migrate via circulation or lymphatic channels to various tissue sites.
 - Cysticerci may develop in any organ, most commonly the brain, subcutaneous tissue, eye, and liver.

■ Hydatid disease (echinococcal disease)

- Caused by the tapeworm of the genus *Echinococcus*
- Eggs are ingested by the human/intermediate host, and under appropriate conditions, they hatch and release oncospheres in the small intestine.
- The oncosphere penetrates intestinal mucosa and migrates through circulatory or lymphatic system into various visceral organs, mainly lungs and liver.
- In the visceral organ, the oncosphere develops into a fluid-filled cyst, enlarges, and differentiates into the metacestode or hydatid cyst.
- Infection is usually from contamination of the environment (water, cultivated vegetables) and direct contact with infected pet dogs through the fecal-oral route.
 - Fecal-oral transmission occurs mostly in children.
- Direct human-to-human transmission does not occur.

■ Diphyllbothriasis

- Caused by *Diphyllbothrium* (fish tapeworm or broad tapeworm)

■ Hymenolipiasis

- Caused by *Hymenolepis nana* (dwarf tapeworm)
- Infection is usually acquired by ingesting food or water contaminated with human or rodent feces.

RISK FACTORS

■ Giardiasis

- Hypochlorhydria
- Previous gastric surgery
- Reduced gastric acidity
- Cystic fibrosis
- Chronic pancreatitis
- Risk of infection and transmission are highest among:
 - Children age 12–36 months
 - Children not yet toilet trained
 - Young adults with homosexual activity (because of direct contact with infectious cysts)
 - Travelers in former Soviet Union, South/Southeast Asia, tropical Africa, western South America, and Mexico

■ Babesiosis

- Risk factors for severe infection
 - Age >40 years of age
 - Asplenia
 - HIV infection
 - Immunosuppressive therapy, including corticosteroids
 - Disease is particularly overwhelming in patients without a spleen.

■ Cryptosporidiosis

- Risk factors for prolonged/severe course
 - AIDS
 - Immunoglobulin (Ig)A deficiency
 - Hypogammaglobulinemia
 - Immunosuppressive treatment

■ Toxoplasmosis

- Presence of a domestic cat

SIGNS AND SYMPTOMS

Leishmaniasis

■ Cutaneous form

- Skin lesion on an exposed area of the body, mostly the face and extremities
 - Itchy papule surrounded by erythema and induration; progresses to become a nodule
 - May have accompanying satellite lesions and adjacent adenopathy resembling sporothroid nodules
- Moist cutaneous form
 - Shallow ulcer with raised borders may develop.
 - May progress slowly, leading to an open sore as large as 5 cm in diameter with a granular center
 - Takes 3–12 months to heal and leaves a depressed scar

- Dry cutaneous form
 - No ulcers form.
 - The papule heals to a scar over a longer period, which may extend to 1 year or more.
- Diffuse cutaneous leishmaniasis
 - Seen in patients with underlying immune disorders, particularly cellular immunodeficiency
 - The primary lesion is a localized papule with surrounding satellite lesions.
 - Dissemination to multiple nodules on the face and extremities
 - Lesions slowly progress and may last for years.

■ Mucosal form

- Lesions occur months to years after the primary cutaneous lesion heals.
- Lesions commonly involve nose, mouth, soft palate, and larynx.
 - Usually begins with nasal congestion and ulceration
 - The cartilage of the nose is commonly involved, leading to nasal septal perforation.
 - Formation of granulomas and secondary bacterial infections are common.

■ Visceral form (kala-azar, which means *black fever*)

- Amastigotes spread from macrophages at the site of inoculation to the liver, spleen, bone marrow, and sometimes lymph nodes.
- Typical manifestations
 - Fever
 - Anorexia
 - Malaise
 - Weight loss
 - Hepatomegaly
 - Splenomegaly (spleen is massively enlarged)
 - Skin hyperpigmentation occurs commonly in Indian patients.
 - Jaundice (less common)
 - Guillain-Barré syndrome (less common)

Chagas disease

- Bite wounds are frequently found at the lateral canthus of the eye, mucocutaneous border of the lips, and exposed areas of face and upper extremities.

■ Acute phase

- Local inflammatory reaction commonly occurs at site of parasite inoculation.
- Chagoma (erythematous, firm, nodular swelling at the bite site) or Romaña sign (unilateral periorbital edema with conjunctivitis and ipsilateral preauricular lymphadenopathy) may be present when the portal of entry is lateral canthus of the eye.

- Generalized infection with fever
- Malaise
- Headache
- Generalized lymphadenopathy
- Hepatosplenomegaly
- Edema
- Some degree of acute myocarditis, generally present in all symptomatic cases; can be fatal
- Meningoencephalitis may follow and is usually associated with high mortality rate.
- In congenital infection, may see:
 - Hepatosplenomegaly
 - Jaundice
 - Skin hemorrhage
 - Neurologic signs, especially in premature infants
- Latent or indeterminate phase
 - 1–3 months after acute disease
 - Asymptomatic
- Chronic phase
 - Chronic heart failure
 - Severe cardiomegaly
 - Ventricular conduction defects
 - Various types of arrhythmia
 - Palpitations
 - Dizziness
 - Syncope
 - Dyspnea
 - Chest pain
 - 8–10% of all patients have a variable degree of changes in motility or severe dilatation of the digestive tract.
 - Extreme enlargement of the colon is slightly more common than the esophagus.
 - Difficulty swallowing
 - Regurgitation
 - Severe constipation
 - Abdominal pain
 - Neurologic symptoms in a minority of patients
 - Paresthesia or anesthesia
 - Convulsions
 - Alteration of homeostatic equilibrium
- West African
 - Milder, chronic course associated with lymph node and CNS invasion
- Trypanosomal chancre usually develops a few days after inoculation.
 - Indurated, erythematous, painful lesion that develops at the bite site
 - Usually resolves within 3 weeks
- During dissemination of parasite
 - Fever
 - Headache
 - Generalized malaise
 - Papular skin lesion
 - Generalized lymphadenopathy, especially in the posterior cervical triangle (Winterbottom sign)
 - Mild hepatosplenomegaly
 - Generalized weakness
 - Dyspnea
 - Chest pain
 - Anemia
 - Arthralgia
 - Cachexia
 - Local swelling of the joints, hands, or feet
- As parasite invades CNS (sleeping sickness stage)
 - Severe headache
 - Irritability
 - Personality and behavioral change
 - Gradual loss of cognitive function
 - Alteration in motor function
 - Psychiatric manifestations
 - Sleep disorders
 - Somnolence
 - Inappropriate episodes of sleeping
 - Nocturnal insomnia
 - Signs and symptoms of congestive heart failure

Giardiasis

- Most infections are asymptomatic.
- Symptomatic children may have acute self-limited infection or chronic infection associated with malabsorption.
- Acute symptoms
 - Last 2–4 weeks; may be intermittent
 - Acute watery diarrhea
 - Malaise
 - Abdominal pain, cramps
 - Bloating

- Flatulence
- Foul-smelling and fatty stools
- Nausea
- Fatigue
- Chronic symptoms
 - Chronic diarrhea with steatorrhea
 - Marked weight loss
 - Failure to thrive/growth retardation
 - Rash
 - Urticaria
 - Aphthous ulcers
 - Reactive arthritis
 - Iridocyclitis
 - Retinal arteritis

Amebiasis

- Usually asymptomatic
- Symptoms, when present, range from mild to severe.
 - Abdominal pain
 - Diarrhea
 - Bloody stools
 - Weight loss in 50% of patients
 - Fever
- Amoebic liver abscess
 - Most common extraintestinal manifestation of amebiasis
 - Less common in children than in adults
 - Symptoms usually appear within 8–20 weeks (5 months after return from endemic area in 95% of patients)
 - Longer lags have been reported.
 - In the US, most diagnosed patients are from a country where amebiasis is endemic or have traveled to such an area.
 - Pain in the right upper quadrant
 - Fever
 - Anorexia
 - Fatigue
 - Diarrhea (in fewer than one-third of patients)
 - Jaundice is uncommon.

Amoebic meningoencephalitis

- PAM
 - Bifrontal headaches that do not respond to analgesia
 - Fever (temperature 38°C–41°C)
 - Alteration in sense of taste or smell, with or without rhinitis, may be noted early.
 - Emesis
 - Seizures
 - Lethargy

- Nuchal rigidity
- Cerebellar ataxia
- Dysfunction of the third, fourth, and sixth cranial nerves

■ GAE

- Disease of immunocompromised and debilitated individuals; chronic and insidious
- Hemiparesis
- Personality changes
- Seizures
- Neck stiffness
- Headaches
- Fever
- Sinusitis
- Otitis media
- Cutaneous lesions
- Corneal ulcers

Cryptosporidiosis

- Varies from asymptomatic infection to severe enteritis and fatal dehydration
- Acute diarrhea (frequent, watery, foul-smelling, nonbloody stools)
 - Resolves spontaneously in 1–20 days
 - Occasionally, healthy infants may develop chronic and persistent diarrhea, leading to malnutrition and growth retardation.
- Malaise
- Nausea
- Anorexia
- Fatigue
- Abdominal cramps
- Weight loss
- Fever
- Vomiting
- Clinical manifestations of cryptosporidiosis in patients with AIDS include:
 - Cholecystitis
 - Cholangitis
 - Hepatitis
 - Pancreatitis
 - Respiratory cryptosporidiosis is seen mainly in patients with AIDS; symptoms include:
 - Cough
 - Dyspnea
 - Fever
 - Expectoration
 - Chest pain

- Biliary cryptosporidiosis is exclusively seen in patients with AIDS; symptoms include:
 - Right upper quadrant pain
 - Fever
 - Nausea and vomiting with or without diarrhea

Isosporiasis

- Diarrhea
 - Self-limited and resolves spontaneously in days to weeks
 - Typically watery
- Fever
- Malaise
- Vomiting
- Headache
- Abdominal pain
- Weight loss

Cyclosporiasis

- Profuse, watery diarrhea
 - Intermittent and prolonged
- Fatigue
- Anorexia
- Abdominal cramps and bloating
- Nausea
- Vomiting
- Fever
- Myalgia
- Weight loss

Toxoplasmosis

- Congenital disease
 - Most (70–90%) congenitally infected infants are asymptomatic.
 - Clinical manifestations at birth include:
 - Hepatosplenomegaly
 - Lymphadenopathy
 - Hydrocephalus or microcephaly
 - Seizures and neurologic deficits
 - Chorioretinitis
 - Rash
 - Jaundice
- Acquired disease
 - Usually asymptomatic
 - Cervical lymphadenopathy
 - Fever
 - Myalgia
 - Fatigue

- In some, infectious mononucleosis–like manifestations
 - Sore throat
 - Fever
 - Malaise
 - Adenopathy
 - Splenomegaly
 - Rash

■ Disease in immunodeficient patients

- Localized infections
 - Encephalitis
 - Meningoencephalitis
 - Fever
 - Headache
 - Deterioration in mental status
 - Seizures
 - Hemiparesis
 - Abnormal speech
 - Pneumonitis
 - Myocarditis
 - Pericarditis
 - Hepatitis
- Ocular disease/chorioretinitis
 - Bilateral in congenital form and unilateral in acquired form
 - Nystagmus
 - Blurred vision
 - Photophobia
 - Central vision loss

Malaria

- Attacks occur:
 - Every second day with *P falciparum*, *P vivax*, and *P ovale*
 - Every third day with *P malariae*
 - These classic patterns are rarely observed.
- Combination of influenza-like symptoms
 - Fever
 - Chills
 - Sweats
 - Headaches
 - Nausea and vomiting
 - Body aches
 - General malaise
 - Anemia
 - Enlarged spleen

- Severe malaria
 - Cerebral malaria
 - Abnormal behavior
 - Impairment of consciousness
 - Seizures
 - Coma
 - Other neurologic abnormalities
 - Severe anemia
 - Pulmonary edema
 - Acute respiratory distress syndrome

- Congenital malaria
 - Fever
 - Severe anemia
 - Hepatosplenomegaly

Babesiosis

- Gradual onset of malaise, fatigue, and anorexia
- Followed by fever with:
 - Chills
 - Sweats
 - Myalgia
 - Headache
 - Vomiting
- Less commonly
 - Conjunctival injection
 - Meningismus
 - Altered sensorium
 - Nonproductive cough
- Symptoms may last for several weeks or sometimes months.
- In immunodeficient patients
 - Hemolytic anemia
 - Jaundice
 - Dark urine

Trichinellosis

- 1–7 days after infection
 - Asymptomatic or GI symptoms
 - Nausea
 - Vomiting
 - Diarrhea
 - Constipation
 - Abdominal pain
- Muscle stage (lasts 1–5 weeks or longer)
 - Myalgia; may mimic rheumatic pain
 - Eyelid edema
 - Eosinophilia
 - High and prolonged fever

- Weakness
- Malaise
- Headache
- Subconjunctival hemorrhages, retinal hemorrhages
- Splinter hemorrhages under fingernails
- Facial flushing
- Urticarial or macular rashes
- Hoarseness
- Dyspnea
- Dysphagia

Trichuriasis

- Often present with other helminthic/protozoal infections
- Diarrhea
- Heavy infection symptoms
 - Mucoid bloody stools with abdominal pain and tenesmus (trichuris dysentery syndrome)
 - Rectal prolapse
 - Colonic obstruction and perforation
 - Finger clubbing

Strongyloidiasis

- Usually asymptomatic
- Peripheral eosinophilia may be the only symptom.
- Cutaneous reactions when larvae penetrate skin, especially on feet
 - Edema
 - Rash
 - Severe pruritus
- Pulmonary migration of larvae
 - Dry cough
 - Wheezing
 - Tachypnea
 - Hemoptysis
 - Pneumonitis or Loeffler-like syndrome (acute transient pneumonitis)
- If adult worms are in the GI tract:
 - Abdominal pain
 - Vomiting
 - Diarrhea
 - Malabsorption/failure to thrive
- Larvae in perianal skin
 - Pruritic lesions in the perianal area, buttocks, and upper thighs
- Infants with *S. fulleborni* infection may develop swollen belly syndrome.
 - Marked abdominal distention
 - Ascites, pleural effusions

■ Hyperinfection in immunocompromised patients

- Gram-negative bacteremia and sepsis

Hookworm infections**■ Symptoms and signs correlate with the stage of infection.****■ Early findings**

- Itching
- Focal eruptions with or without edema
- Enlargement of adjacent lymph nodes (ground itch)
- Mild respiratory symptoms, cough
- If severe, Loeffler syndrome may develop.

■ Intestinal phase

- Abdominal pain
- Nausea
- Vomiting
- Increased flatulence
- Diarrhea
- Constipation
- Symptoms of anemia

Cutaneous larva migrans**■ Erythematous pruritic papule at site of skin entry, usually lower extremities****■ Days or weeks later, dermal skin rash (creeping eruption)**

- Pruritic, elevated serpiginous tract that elongates several mm/day
- May become vesiculated and secondarily infected by bacteria

■ Rarely, dry cough and Loeffler-like syndrome**Pinworm infections****■ Most infections are asymptomatic.**

- However, the most common symptom is perianal itching (pruritus ani), mainly at night.
 - Less frequently, pruritus vulvae as a result of aberrant migration to genital tract

■ Other rare manifestations

- Salpingitis
- Urethritis
- Vaginitis
- Pelvic peritonitis

■ Patients with a heavy worm burden

- Abdominal pain
- Nausea
- Vomiting

Ascariasis**■ Usually asymptomatic****■ Loeffler syndrome occurs 1–2 weeks after ingestion of the eggs.**

- Fever
- Eosinophilia
- Urticaria

■ Patients with ascariasis

- Abdominal discomfort
- Nausea
- Vomiting
- Diarrhea
- Malnutrition
- Intestinal obstruction

■ Worm migration into the biliary tree

- Biliary colic
- Cholecystitis
- Ascending cholangitis
- Biliary strictures and hepatic abscesses
- Pancreatitis
- Appendicitis

■ Migration may occur through body orifices, such as the mouth, nose, anus, and lacrimal duct.**Toxocariasis****■ Most patients who are lightly infected are asymptomatic.****■ Symptomatic children with toxocariasis usually experience:**

- Fever
- Leukocytosis with eosinophilia
- Hypergammaglobulinemia
- Hepatomegaly
- Splenomegaly and lymphadenopathy

■ Allergic manifestations are possible.

- Urticaria
- Rhinorrhea
- Asthma

■ Constitutional symptoms may be present.

- Anorexia
- Weakness
- Failure to gain weight
- Myalgia
- Arthralgia
- Nighttime sweats

■ Neurologic symptoms are less frequent.

- Irritability
- Seizures

- Myocarditis
- Congestive heart failure
- Pleural effusion
- Eosinophilic ascites
- Meningoencephalitis
- Ocular involvement, usually without other systemic involvement
 - Unilateral solitary posterior retinal lesion
 - Granulomatous mass or multiple lesions may be seen
 - Lesions are painless; some are asymptomatic and are found incidentally during routine retinal examination.
 - Strabismus
 - Visual impairment
 - Unilateral loss of vision
 - Leukocoria

Lymphatic filariasis

- Usually asymptomatic
- Most common acute symptoms in the early stages are:
 - Lymphangitis and lymphadenitis
 - Fever
 - Headache
 - Myalgia
 - Pain in the affected extremities
 - Male genital area effects
 - Acute epididymitis
 - Orchitis
 - Funiculitis
- During chronic stage
 - Elephantiasis (lymphedema)
 - Recurrent superimposed bacterial infections
 - The skin over affected extremity becomes thick and warty.
 - Tropical pulmonary eosinophilia in a small proportion of patients
 - Nocturnal paroxysmal respiratory symptoms, such as cough and wheezing

Onchocerciasis

- Dermatitis
 - Intensely pruritic and may develop into an erythematous papular rash
- Subcutaneous nodules
 - Vary from a few millimeters to several centimeters
 - Can be discrete or clustered
 - Tend to occur over bony prominences
 - Secondary bacterial infection may cause acute inflammation or abscess formation.

- Lymphadenitis
- Ocular lesions
- Skin papules and depigmentation in chronic infections
- Hydroceles
- Elephantiasis
- Hanging groins
- Ocular involvement
 - Punctuate keratitis
 - Sclerosing keratitis
 - Iridocyclitis
 - Chorioretinitis
 - Optic neuritis

Schistosomiasis

- Maculopapular eruption may develop at the site of cercarial skin penetration.
 - Few hours or up to 1 week after infection
- Eosinophilia 4–8 weeks after exposure
 - Fever
 - Headache
 - Generalized myalgia
 - Hepatomegaly
 - Bloody diarrhea
 - Splenomegaly (30% of patients)
 - Cough
 - Aseptic meningitis
- If GI tract involvement
 - Colicky pain
 - Diarrhea
 - Occasionally, constipation
 - Blood, either gross or occult, may appear in stools.
 - Colonic or rectal stenosis
- If liver involvement
 - Hepatomegaly
 - Late stages: esophageal varices, bleeding, and splenomegaly
- If genitourinary involvement
 - Microscopic hematuria, early stages
 - Moderate to severe lesions in the urinary tract

Taeniasis

- Often asymptomatic
- Main symptom is intermittent passage of the proglottids.
 - Either with the stool or spontaneously
- Nausea, diarrhea, and abdominal pain or discomfort

Cysticercosis

- In infants, the initial manifestation of neurocysticercosis is generalized seizures.

■ Cysticercal encephalitis

- Fever
- Headache
- Vomiting
- Impaired consciousness
- Reduced visual acuity
- Seizures

■ Extranuclear cysticercosis

- Some patients may notice small palpable nodules that may become inflamed, or patients may experience muscle pain.

Hydatid disease

- Although most infections are acquired during childhood, clinical manifestations do not develop until adulthood because of the slow-growing nature of the cyst.

■ Symptoms seen in adults include:

- Hepatic enlargement/right upper quadrant pain
- Nausea
- Vomiting
- Pulmonary hydatidosis
 - Chronic cough
 - Chest pain
 - Pleuritis
 - Dyspnea

Diphyllobothriasis

- Usually asymptomatic, especially in younger children
- Abdominal pain
- Nausea
- Vomiting
- Diarrhea
- Weight loss
- Fatigue
- Numbness
- Dizziness
- Allergic symptoms
- Intestinal obstruction if worm burden is massive

Hymenolipiasis

- Usually asymptomatic
- Symptoms of heavy infection are:
 - Abdominal pain
 - Nausea
 - Vomiting
 - Diarrhea
 - Anorexia
 - Weakness
 - Irritability
 - Headache

DIAGNOSTIC APPROACH

Leishmaniasis

- Diagnosis is made by identification of parasites in tissue biopsy samples or in aspirate.
- Serologic tests may be helpful in diagnosing visceral and mucosal leishmaniasis but not cutaneous disease.
 - False-positive results may occur with other diseases, such as trypanosomiasis, tuberculosis, leprosy, and malaria.

Chagas disease

- Acute phase
 - Diagnostic test of choice is detection of parasites in a blood specimen.
- Chronic phase
 - Diagnosis is usually made by immunodiagnostic tests or isolation of parasite.

African trypanosomiasis

- Diagnosis is made by microscopic detection of trypomastigotes in specimens from various sites.
 - Chancre fluid
 - Blood
 - Bone marrow
 - Lymph node aspirates
 - Cerebrospinal fluid (CSF)

Giardiasis

- Routine blood tests are not helpful in diagnosing giardiasis.
- The mainstay of diagnosis is demonstrating cysts or trophozoites by direct stool examination for ova and parasites.
 - Cysts are more likely to be seen in formed stools.
 - Frequent loose stools increase yield of identifying trophozoites.
 - 3 stool samples should be collected and examined every other day.
- Duodenal fluid sampling may be warranted.
 - If clinical suspicion is high and stools are negative

Amebiasis

- Stool examination from 3 fresh stool samples from separate days
- Liver amoebic abscesses are usually diagnosed on the basis of:
 - Clinical presentation
 - Recognition of epidemiologic risk factors
 - Serologic testing
 - Noninvasive imaging studies

Amoebic meningoencephalitis

■ PAM

- Neuroimaging studies may be normal early in disease but may show signs of increased intracranial pressure later.
- Laboratory studies (including CSF examination and wet mount)

■ GAE

- Neuroimaging
- CSF examination
- Corneal scrapings to look for cysts, and culture

Cryptosporidiosis

■ Diagnosis depends on microscopic identification of oocysts in:

- Stools
 - The laboratory should be alerted to potential diagnosis of cryptosporidiosis to perform specific staining of samples.
- Aspirated fluid
- Tissue samples

Cyclosporiasis

■ Diagnosis is made by microscopic examination of stool specimens.

Toxoplasmosis

- If suspected, the patient should undergo complete clinical evaluation, including ophthalmologic, neurologic, and auditory examination (see Laboratory Findings and Imaging).
- After delivery, infants should be evaluated for congenital toxoplasmosis if:
 - The mother had a primary infection, *or*
 - The mother is HIV infected and has serologic findings suggestive of past infection
- In patients with ocular involvement, the diagnosis is based on classic eye findings and serologic testing.
- Clinical and laboratory data should be carefully correlated during patient evaluation and management.

Malaria

■ Most commonly used diagnostic tools

- Microscopic diagnosis
 - Thick smears are more sensitive, but cannot be used to differentiate among species
- Rapid diagnostic tests are based on immunochromatographic techniques.
- Diagnosis can be difficult in nonendemic areas.
 - Health care providers are not familiar with the disease.
 - Laboratory workers may fail to detect parasites in blood smears.

Trichinellosis

■ The diagnosis should be suspected in patients with:

- Suggestive clinical history (consumption of inadequately cooked meat, particularly pork)
- Eosinophilia

■ The presence of symptoms in other patients who ate the same food makes the diagnosis stronger.

Strongyloidiasis

■ Diagnosis is made by detecting rhabditiform larvae in stool specimens.

■ When stool samples are not diagnostic, examination of duodenal fluid for larvae should be considered.

Hookworm infections

■ Diagnosed by identifying eggs in stools

- Stool smears are often negative in early stages of infection.

Cutaneous larva migrans

■ Most cases are diagnosed clinically, with no further diagnostic evaluation needed.

Pinworm infections

■ Stool examination for ova and parasites is not helpful in establishing the diagnosis.

■ The test of choice is the use of the cellophane tape swab.

- Alternatively, sterile pinworm collector kits are commercially available.

Ascariasis

■ Diagnosis is made by demonstrating characteristic eggs in stools by direct microscopy.

- Eggs may not appear in the stools until after ≥ 40 days of infection.

■ Imaging studies may demonstrate worms if there is:

- Intestinal obstruction
- Hepatobiliary or pancreatic ascariasis

Toxocariasis

■ Definitive diagnosis requires demonstration of larvae in tissue sections but is rarely needed.

■ Diagnosis is usually based on clinical findings and serologic testing.

Lymphatic filariasis

■ Diagnosis is made by demonstrating microfilariae on peripheral blood smears obtained between 10PM and 2AM.

- If blood cannot be obtained at night, a dose of diethylcarbamazine (DEC) can be provided to stimulate filaria release, followed by blood draw 1 hour later.

■ If microfilariae cannot be demonstrated on blood smears:

- Fine-needle aspirate or biopsy of the involved lymph node or epididymis may demonstrate worms or microfilariae.

- Serologic tests are helpful once microfilariae are no longer detectable.
- Chronic filariasis (lymphedema) is usually diagnosed on clinical grounds.

Onchocerciasis

- Diagnose by identifying microfilariae in direct histologic examination.
- Surgical excision of a skin nodule can be diagnostic and therapeutic.
 - Adult worms are found in these nodules.
- Ocular lesions
 - Diagnosed by slit-lamp examination, which may reveal microfilariae in the cornea or anterior chamber of the eye

Taeniasis

- Diagnosis is made by microscopic identification of eggs or proglottids in stool.
 - May not be possible during the first 3 months of infection

Cysticercosis

- Definitive diagnosis is made by demonstrating the cysticercus in the involved tissue.
- Demonstration of eggs or proglottids in stool specimen may support the diagnosis, but does not prove it.
- For neurocysticercosis, magnetic resonance imaging (MRI) and computed tomography (CT) are the most reliable imaging techniques.

Hydatid disease

- Diagnosis is usually made by a combination of imaging studies and serologic testing.
- History of exposure to possible animal hosts in an endemic area in a patient with a cystic, masslike lesion may help support diagnosis.

Diphyllobothriasis

- Diagnosis is made by microscopic identification of eggs or proglottids in stool.
- Pernicious anemia and vitamin B₁₂ deficiency provide clues to diagnosis.

Hymenolipiasis

- Diagnosis is made by demonstrating eggs in stool specimens.

LABORATORY FINDINGS

Leishmaniasis

- Staining for *Leishmania* parasites (intracellular amastigotes, Leishman-Donovan bodies)
 - Wright
 - Giemsa
 - Hematoxylin and eosin

- Culture of tissue or peripheral blood on special media (Novy-MacNeal-Nicolle medium) if available
 - Days to several weeks may be needed.
- Leishmanin skin test (Montenegro test) for diagnosis of cutaneous leishmaniasis
 - Usually positive in the ulcerative phase, which occurs 1–3 months after infection
 - Not helpful for diagnosing visceral disease
 - A positive skin test may indicate an old rather than acute infection.
 - Not approved for use in the US.
- Serologic tests
 - May be helpful for visceral and mucosal leishmaniasis but not cutaneous disease
 - False-positive results may occur with trypanosomiasis, tuberculosis, leprosy, and malaria.
- Laboratory findings
 - Leukopenia
 - Anemia
 - Thrombocytopenia
 - Hypoalbuminemia
 - Hypergammaglobulinemia
 - Reversal of the albumin-globulin ratio may be seen.
- Nucleic acid–based techniques (DNA hybridization and polymerase chain reaction [PCR])
 - To identify parasite sequence in tissue samples and peripheral blood
 - Especially useful in diagnosis of visceral leishmaniasis and in aspirates that are negative for parasites by microscopy
 - PCR is highly sensitive but not routinely available.

Chagas disease

- Acute phase: detection of parasites in blood specimen
 - Thin and thick blood smears stained with Giemsa for parasites
 - Direct wet mount of fresh blood sample or buffy coat for parasites
- Chronic phase: Diagnosis is usually made by immunodiagnostic tests or isolation of the parasite.
 - Available tests
 - Indirect fluorescent antibody (IFA) test
 - Complement fixation
 - Enzyme immunoassay (EIA)
 - In US, IFA and complement fixation tests are available at the Centers for Disease Control and Prevention (CDC).
 - Sensitivity and specificity of these serologic tests are highly variable.
 - 2 different, independently performed methods should be used to confirm the diagnosis of Chagas disease.

- Serologic tests may cross-react with other conditions, such as:
 - Leishmaniasis
 - Malaria
 - Syphilis
 - Infectious mononucleosis
 - Tuberculosis
 - Leprosy
 - Collagen vascular diseases
- Isolation of parasite can be accomplished by:
 - Culture in special media *or*
 - Mouse inoculation *or*
 - Xenodiagnosis
 - Reduviid insects are fed the infected patient's blood, and their gut contents are examined 4 weeks later for the parasites.
 - The animal inoculation method is unreliable and should be performed only after repeated culture attempts have failed to isolate the organism.
- Molecular methods, such as PCR, are available as an investigational diagnostic tool.

African trypanosomiasis

- Giemsa stain and wet preparation to look for trypanosomes
- Concentration technique may be used with body fluid specimen examination to increase sensitivity.
- Isolation of parasite by rat or mice inoculation is a sensitive test.
 - Use is limited to *T. brucei rhodesiense*.

Giardiasis

- Staining of fresh stool sample (or sample preserved in polyvinyl alcohol or merthiolate-formalin) with:
 - Iodine *or*
 - Trichrome *or*
 - Giemsa *or*
 - Iron hematoxylin
- Cysts and trophozoites may be identified in saline wet mount.
- If organisms are not found on direct examination of 3 stool specimens, feces should be checked for *Giardia* antigens.
 - Several commercial kits are available that use enzyme-linked immunosorbent assay (ELISA) or IFA.
 - Sensitivity is 95–99% and specificity 95–100% compared with stool microscopy.

Amebiasis

- Serologic testing
 - Infection with *E. histolytica* results in development of antibodies; *Entamoeba dispar* infection does not.

- 10–35% of uninfected individuals in endemic areas have antiamebic antibodies as a result of previous, often undiagnosed, infection with *E. histolytica*.
 - Negative serologic result in these populations helps exclude disease.
 - Positive serologic result is not particularly helpful because it does not distinguish between acute infection and past exposure to parasite.
- Fecal and serum antigen detection assays
 - Quick and easy tests
 - Ability to differentiate between strains
 - Greater sensitivity than microscopy
 - Potential for diagnosis in early infection and in endemic areas where serologic testing is less useful
- PCR techniques can detect *E. histolytica* in stool specimens.
 - PCR-based techniques are the most sensitive and specific methods.
 - Not widely available

Amoebic meningoencephalitis

- PAM
 - Increased leukocyte count
 - Hyperglycemia
 - Glycosuria
 - CSF examination
 - Pleocytosis with polymorphonuclear neutrophil predominance
 - Increased CSF protein
 - Normal or decreased glucose
 - Motile amoebas may be seen on wet mount; preferably, use unrefrigerated CSF collected within 30 minutes of the evaluation.
 - Culturing amoebas on nonnutrient agar plated with *Escherichia coli* is the definitive way to diagnose.
- GAE
 - Diagnosis is made by finding amoebas in tissue sections, either:
 - Stained with hematoxylin and eosin *or*
 - IFA staining with rabbit antiameoba sera
 - Cysts of infecting amoebas can be recognized in corneal scrapings that have been stained with calcofluor white.
 - *Acanthamoeba* can also be cultured onto nonnutrient agar with bacteria for identification.

Cryptosporidiosis

- Modified Kinyoun acid-fast stain of ≥ 3 stool samples
 - Stool samples are usually concentrated by either the sucrose flotation or the formalin acetate method.
- Immunofluorescent staining that uses monoclonal antibodies and ELISA kits can be used to detect oocysts in stool and tissue specimens.

Isosporiasis

- Diagnosis is made by finding oocysts in stool using special stains.
 - Kinyoun acid-fast or modified acid-fast stain
 - Alternatively, specific fluorescent techniques may be used.
- Oocysts may also be detected in duodenal fluid aspirates.

Cyclosporiasis

- Staining of samples for oocysts
 - Modified Ziehl-Nelson or Kinyoun acid-fast staining
- Fluorescent microscopy reveals autofluorescence of the cell wall of *Cyclospora* oocysts.

Toxoplasmosis

- The most definite test for diagnosis of toxoplasmosis is isolation of the organism from infected tissue or body fluids by either inoculation into laboratory animals or by tissue culture.
 - However, these techniques are not routinely available.
- The primary method currently used for diagnosis is based on detecting specific antibodies and monitoring immune response.
- Molecular methods involving PCR for detecting *Toxoplasma* DNA in tissue and fluid samples have been used.
- ELISA tests
 - Serum IgG usually becomes positive 4–8 weeks after infection.
 - Remains positive indefinitely
 - Paired sera should be tested simultaneously 3 weeks apart to document an increase in titers of ≥ 4 -fold.
 - Serum IgM levels should also be tested simultaneously with IgG.
 - ELISA IgM tests are more sensitive than the IFA test.
 - IgM test may remain positive for 6 months, and false-positive results can occur.
 - In newborns, serum levels of IgA and IgE for *Toxoplasma* can also be tested.
 - These become negative sooner than IgM test, giving more precise information about the timing of infection.
 - However, anti-*Toxoplasma* IgA and IgE tests are available only at *Toxoplasma* referral laboratories.
- Definitive diagnosis of congenital toxoplasmosis during pregnancy can be made by testing amniotic fluid.
 - Detecting *Toxoplasma* in amniotic fluid by either DNA PCR or tissue culture or mouse inoculation is considered diagnostic.
 - Similarly, fetal blood sampling to isolate *Toxoplasma* from fetal leukocytes and to test for IgM antibody may also be used.

- In infant with suspected toxoplasmosis:
 - Diagnosis is confirmed serologically by demonstrating:
 - Positive IgM or IgA
 - Higher infant IgG titer than the mother, *or*
 - Persistently positive IgG beyond 1 year of age
 - CSF should be analyzed for cells, protein, glucose, *Toxoplasma* antibodies, and PCR.
 - Serum samples should be evaluated for IgG, IgM, IgA, and IgE antibodies for *Toxoplasma*.
- Diagnosis of toxoplasmosis in older children and adults who are immunocompetent relies on identification of a positive IgM titer or a 4-fold increase in IgG titers after 3 weeks.
- Classic histopathologic findings in tissue samples, such as lymph nodes, strongly supports the diagnosis.
 - Identification of proliferating organisms on histology provides a definite diagnosis.
- Isolation of *Toxoplasma* from tissue or body fluid by culture or identification of nucleic acid material by DNA PCR is definitive.
- In immunocompromised patients, including those with HIV infection, serologic testing may not be reliable.

Malaria

- Examine peripheral blood smears.
- Serologic testing (IFA test or ELISA) does not detect current infection.

Pinworm infections

- Cellophane tape swab
 - Adhesive part of tape is applied to skin and then onto a glass slide and examined by light microscopy.
 - Higher diagnostic yield if specimen is obtained at night or early morning
- Commercially available test kits work on the same principle.
- Examination of multiple samples may be needed.

Ascariasis

- Usually a single stool sample is sufficient to confirm the diagnosis.
- Adult worms are sometimes passed in stool and provide a clue to diagnosis.
- Eosinophils and occasionally *Ascaris* larvae may be demonstrated in sputum samples.

Lymphatic filariasis

- Diagnosis is made by demonstrating microfilaria on peripheral blood smears obtained between 10 PM and 2 AM.
 - If blood cannot be obtained at night, a dose of DEC can be provided to stimulate filaria release, followed by blood draw 1 hour later.

■ Serologic tests

- Helpful once microfilariae are no longer detectable
- Enzyme immunoassays may cross-react with other helminthic infections.
- Antifilarial IgG4 antibody detection: good index of the intensity and duration of filarial exposure in endemic areas.
- Filarial antigen can be detected by monoclonal antibodies.
 - Filaremic patients are more likely to have positive results than those who are not.

- DNA probes/PCR assays have been developed but not routinely available.

Babesiosis

- Diagnosis is made by demonstrating the organism in thick and thin smears prepared for Wright and Giemsa staining.
 - Presence of a cluster of 4 small merozoites (“tetrads”) in erythrocytes
 - Multiple parasites may be present in a single cell.
 - Occasional presence of 3 chromatin dots in a single parasite
- Serologic testing if blood smears are nondiagnostic
 - IFA test (available in reference laboratories)
- PCR is more sensitive than blood smear.

Trichinellosis

- Serologic tests are usually used to make the diagnosis.
 - ELISA (most sensitive)
 - IFA test
 - Latex agglutination
 - Only helpful after the second week of infection
 - Testing of paired acute and convalescent serum is diagnostic.
 - Eosinophilia usually appears during second week of the muscle phase and can be as high as 70%.
 - Creatine kinase and lactate dehydrogenase concentrations may be high.
 - Ig levels may be high.
- The definitive diagnostic test is finding larvae in muscle biopsy samples.
 - Only occurs after first week after ingestion

Trichuriasis

- Diagnosed by detecting typical ova on direct stool examination
 - Eggs have a typical barrel shape, 3-layer shell, and transparent bipolar plugs.
 - Eggs can be quantified by Kato-Katz smear.
 - Number of eggs per gram of stool can be used to assess worm burden.

Strongyloidiasis

- Examining multiple specimens and using stool concentration procedures may increase yield.
- In disseminated infection, rhabditiform larvae may be recovered from:
 - Stools
 - Sputum
 - Bronchoalveolar lavage
 - Pleural fluid
 - Peritoneal fluid
 - Spinal fluid
- Serologic testing (available at reference laboratories)
 - Highly sensitive and specific, but false-negative results in immunocompromised patients

Hookworm infections

- Stool concentration techniques may be needed if infection is light.
 - Repeat stool examinations may also be needed.
- Species identification can be accomplished by PCR.

Toxocariasis

- Serologic testing used to confirm diagnosis
 - ELISA is the most frequently used test, with high sensitivity and specificity.
 - Western blot and immunofluorescence tests are also used.
- Total leukocyte count may be as high as 30,000 cells/mm³, with up to 80% eosinophils.
- Hypergammaglobulinemia with high IgE levels
 - Sometimes 10–15 times normal levels
- Increased isohemagglutinins to A and B blood groups
- During the pulmonary phase, eosinophils may be detected in respiratory secretions.
- With CNS involvement, the CSF may show eosinophils.

Onchocerciasis

- Peripheral eosinophilia is common.

Schistosomiasis

- Nonspecific laboratory tests
 - Peripheral eosinophilia
 - Anemia
 - Hypoalbuminemia
 - Hypergammaglobulinemia
- Diagnosis may be made by demonstrating eggs in stool or urine samples.
 - 3 specimens may be needed.
 - Egg excretion peaks at noon to 3PM.
- Serologic tests (available at reference laboratories)
 - Not useful in differentiating old infection from reinfection

Taeniasis

- The egg is indistinguishable microscopically from egg of other tapeworm species, especially *Echinococcus*.
- Species determination is made by microscopic examination of the gravid proglottids and rarely the scolex, if available.

Cysticercosis

- Serologic test of choice for confirming diagnosis is the CDC immunoblot assay with purified *T solium* antigens
 - 100% specificity
 - 50–97% sensitivity
- The other test is EIA.
 - Lower sensitivity and specificity
 - Can cross-react with other helminthic infections, such as echinococcosis and filariasis

Hydatid disease

- Eosinophilia seen in <25% of cases
- Serologic testing (EIA or indirect hemagglutination)
 - More reliable in diagnosing *E multilocularis* than *E granulosus* infection
 - Immunoelectrophoresis or immunoblot assay as specific confirmatory test
 - Both false-positive and false-negative results can occur.
 - Children usually have less antibody response and more frequently have a negative result.
 - Cyst in the liver elicits more antibody response than cyst in the lung.
 - Cyst in the brain, eye, or spleen almost always yields negative serologic findings.
 - Cyst in bone typically elicits a serologic response.

Diphyllobothriasis

- The infected person usually passes a large number of eggs in stool that can be demonstrated without a concentration technique

Hymenolipiasis

- Eggs are apparent in stool specimens
 - Detection of light infection may require a concentration technique and repeated examination.
- Peripheral blood eosinophilia may be present.

IMAGING

- Amoebic meningoencephalitis
 - PAM
 - Neuroimaging studies may be normal early in the disease but may show signs of increased intracranial pressure later.
 - Meningeal enhancement of the basilar region is frequently reported.
 - Severe brain edema is late finding and indicative of poor outcome.

- GAE
 - Neuroimaging may reveal space-occupying lesions resembling abscesses, tumors, or hemorrhagic infarction.

Toxoplasmosis

- In congenital toxoplasmosis
 - CT of the brain should be performed to rule out brain calcification or hydrocephalus.
- To detect congenital toxoplasmosis during pregnancy:
 - Serial ultrasonographic examinations to assess brain ventricular size or other signs of infection can be performed.

Ascariasis

- Imaging studies may demonstrate worms if there is:
 - Intestinal obstruction
 - Hepatobiliary or pancreatic ascariasis

Hydatid disease

- Ultrasonography
 - Most widely used, and wide availability
 - Sensitivity is 90–95%.
 - Allows cyst classification based on biological activity (active, transitional, or inactive), which helps guide the choice of treatment
- CT
 - Higher sensitivity than ultrasonography
 - Better than ultrasonography in detecting extrahepatic cysts and cyst complications

Cysticercosis

- MRI
 - Allows good visualization of ocular, ventricular, and subarachnoid cysts
 - Demonstrates degree of edema and inflammation, as well as viability of the cysticercus
- CT
 - Better than MRI for detection of granuloma or calcification

DIAGNOSTIC PROCEDURES**Leishmaniasis**

- Skin samples obtained by:
 - Punch biopsy
 - Scraping or needle aspiration of the nonnecrotic edge
- Other samples
 - Bone marrow aspirate and biopsy
 - Needle aspirate and biopsy of lymph node, liver, or spleen
 - The highest yield for diagnosis is splenic aspirate, but this test is considered too invasive.

■ Giardiasis

- Duodenal fluid sampling
 - Entero-Test, in which the patient swallows a gelatin capsule that contains a string (string test)
 - Examination of fresh specimens for motile trophozoites is diagnostic.
- Duodenal biopsy is considered the last resort for diagnosis.
 - Rarely required

■ Isosporiasis

- Parasites may be found in biopsy specimens from the small intestine.

■ Cutaneous larva migrans

- If biopsy is performed, then eosinophils will be demonstrated in tissue samples.
 - However, the parasite can rarely be seen.

■ Lymphatic filariasis

- If microfilariae cannot be demonstrated on blood smears, fine-needle aspirate or biopsy of involved lymph node or epididymis may demonstrate worms or microfilariae.
 - Lymph node biopsies may worsen the obstructive manifestations of filariasis and should not be routinely done

■ Trichinellosis

- Muscle biopsy
 - Number of larvae per gram of muscle may be used as guide of severity of infection.
 - Specimens should be either:
 - Fresh and compressed between 2 microscope slides *or*
 - Digested by artificial gastric juice to increase yield
- PCR testing to detect *Trichinella*-specific DNA in muscle biopsy specimens is used but not readily available.

■ Strongyloidiasis

- Duodenal fluid can be obtained by the Entero-Test or by endoscope.

■ Schistosomiasis

- Rectal or bladder biopsy may be needed (most sensitive) if stool or urine smears are negative.

■ Onchocerciasis

- Identify microfilariae in direct histologic examination of:
 - Skin snips
 - Biopsy samples
 - Lymph node biopsy sample

■ Hydatid disease

- Cyst aspiration or biopsy is usually reserved for cases with an uncertain diagnosis because of potential anaphylaxis reaction or spread of infection.
- If needed, aspiration is usually performed under ultrasonographic or CT guidance along with benzimidazole treatment to minimize the risk of spreading.

TREATMENT APPROACH

■ Leishmaniasis

- Treatment decisions should be individualized.
- In general, all patients with visceral and mucosal leishmaniasis should be treated.
- Most patients with cutaneous leishmaniasis will heal spontaneously, but consider treatment if:
 - Lesion is cosmetically important (eg, on the face)
 - Lesions are multiple
 - Lesions are enlarging
 - Lesions overlie joints
 - May be caused by *Leishmania braziliensis* or other species that may disseminate to nasopharyngeal mucosa

■ Chagas disease

- Provide specific treatment for:
 - Acute and indeterminate phases of infection
 - Congenital infection
 - Reactivation of infection associated with immunosuppression
 - Infection associated with transfusion or organ transplantation

■ Giardiasis

- Treatment not warranted for asymptomatic patients
- To prevent spread, therapy may be provided to children attending child-care centers.
- Treatment may be provided to carriers in close contact with patients who have hypogammaglobulinemia or cystic fibrosis.

■ Amebiasis

- *E dispar* and *Entamoeba moshkovskii* infections do not require treatment.

■ Amoebic meningoencephalitis

- Treatment should be in centers where neurologic, neurosurgical, and infectious disease experts are available.
- Consultation with the CDC is advisable.

■ Cryptosporidiosis

- In immunocompetent patients, supportive care, including hydration and nutritional support, may be adequate.

■ Toxoplasmosis

- Treatment is not indicated in immunocompetent patients unless clinical symptoms are severe or complications occur.
- Immunocompromised patients with acute infection should be treated even if asymptomatic.
- Infected pregnant women and neonates, whether symptomatic or not, should be treated as soon as diagnosed.
- Patients with chorioretinitis are treated when symptoms are present or progressive.

■ Malaria

- Malaria must be recognized promptly to treat the patient in time, to prevent cerebral malaria and to prevent further spread of infection in the community.
- Malaria is a nationally notifiable disease.
 - All cases should be reported to the state health department, which forwards them to the CDC.
- 3 main factors should be considered.
 - Infecting *Plasmodium* species
 - Clinical status of patient
 - Drug susceptibility of the infecting parasites, determined by geographic area where infection was acquired
- If malaria is suspected and cannot be confirmed, or if the diagnosis is confirmed but species determination is not possible, then antimalarial treatment effective against *P falciparum* must be initiated immediately.

■ Cutaneous larva migrans

- Disease is usually self-limited, but specific treatment may be needed.

■ Toxocariasis

- Treatment is suggested only for symptomatic patients and those with systemic forms of the disease.

■ Cysticercosis

- Appropriate management depends on:
 - Location of cyst
 - For neurocysticercosis, treatment not generally provided to an asymptomatic patient with a nonviable single parenchymal cyst that is evidently destroyed by the host immune response.
 - Viability of cyst
 - In children with viable cysticercus with minimal or no surrounding inflammatory response, cysticidal agent should be provided to prevent further perilesional damage and to reduce the risk of developing chronic seizures.
- Host immune response
- Presence or absence of symptoms

SPECIFIC TREATMENTS

Leishmaniasis

■ Drugs of choice are the pentavalent antimonials.

- Sodium stibogluconate (Pentostam) and meglumine antimonate (Glucantime)
- Common side effects
 - Nausea
 - Vomiting
 - Myalgia
 - Headache

– Malaise

– High hepatic and pancreatic enzymes

• More severe/dose-dependent side effects

– Leukopenia

– Thrombocytopenia

– Behavioral changes

– Electrocardiographic abnormalities (ST-segment changes, QT prolongation, and arrhythmias)

– Cardiac toxicity and sudden death may occur with higher-than-recommended doses.

■ Amphotericin B is increasingly used for visceral leishmaniasis.

• Side effects

– Infusion-related reactions and nephrotoxicity

• Liposomal amphotericin B (AmBisome) is better tolerated and distributes well to the reticuloendothelial system but is expensive.

■ Pentamidine isothionate is an alternative treatment.

• Significant side effects

– Hypotension

– Hypoglycemia

– Nausea

– Vomiting

– Headache

– Electrolyte disturbances (hyperkalemia, hypomagnesemia, and hypocalcemia)

■ Topical paromomycin

• Partially effective in treatment of Old World cutaneous leishmaniasis when risk of mucosal spread is low

■ Parenteral paromomycin has been used as adjunctive therapy with antimonial therapy in the treatment of visceral leishmaniasis.

■ Miltefosine

• Oral formula

• Shows promise in treating cutaneous and visceral leishmaniasis

■ Oral fluconazole may speed healing of cutaneous lesions caused by *Leishmania major*.

■ Other drugs used with limited efficacy

• Itraconazole

• Allopurinol

• Dapsone

■ Local treatments, such as thermotherapy and cryotherapy, are sometimes used for cutaneous leishmaniasis.

• Unreliable in patients with New World lesions as a result of the risk of mucosal dissemination

Chagas disease

- Benznidazole and nifurtimox
 - Benznidazole is not available generally in the US but may be obtained through a compounding pharmacy.
 - Nifurtimox is available in the US under an investigational new drug protocol from the CDC drug service.
 - Side effects are dose dependent.
 - Hypersensitivity reactions
 - Bone marrow suppression
 - Peripheral neuropathy
- Pacemakers are implanted in patients with symptomatic heart block.
- Balloon dilation of the esophagogastric junction may be performed in patients with megaesophagus.
- Fecaloma and atonic segment of megacolon can be removed surgically.

African trypanosomiasis

- West African form
 - Pentamidine isethionate during hemolymphatic stage
 - In late-stage disease with CNS involvement, the drug of choice is melarsoprol or eflornithine.
- East African form
 - Suramin during hemolymphatic stage
 - Melarsoprol during late disease with CNS involvement
- Suramin and eflornithine are available only as investigational new drugs from the CDC's drug service.
 - Patients should be monitored closely for possible adverse reactions.

Giardiasis

- Metronidazole
 - Cure rate of 80–95%
 - Common side effects
 - Metallic taste in mouth
 - Nausea
 - Headache
 - Dizziness
- Nitazoxanide
 - Shorter course is as effective as a longer course of metronidazole.
 - Has advantage of treating other intestinal parasites, such as *Cryptosporidium*
- Alternative medications: furazolidone and quinacrine
 - Furazolidone well tolerated and results in a cure rate of 72–100%
 - Quinacrine has high cure rate (90–95%) but adverse effects
 - GI upset
 - Nausea

- Vomiting
- Abdominal pain
- Rarely, dermatitis, jaundice, and toxic psychosis
- No longer available in US

Amebiasis

- Antibiotic therapy with metronidazole followed by the intraluminal agents iodoquinol or diloxanide furoate
- If the patient's disease is slow to respond to metronidazole or if the patient has relapse after therapy:
 - Aspiration or a prolonged course of metronidazole, or both, should be considered.
- Asymptomatic *E histolytica* infection should be treated with an intraluminal agent.
 - Because of potential risk of invasive disease and risk of spread to household members

Amoebic meningoencephalitis

- PAM
 - Intravenous or intrathecal amphotericin B
- GAE
 - For encephalitis caused by *Acanthamoeba*, no optimal antimicrobial therapy has been developed.
- Multiple drugs have been used in both PAM and GAE infections with varying degrees of success.
 - Amphotericin B
 - Azithromycin
 - Fluconazole
 - Flucytosine
 - Pentamidine isethionate
 - Sulfa drugs
- Amoebic keratitis
 - Treatable with ≥ 1 drugs topically
 - Drugs of choice are:
 - Chlorhexidine gluconate (component of germicidal soaps)
 - Polyhexamethylene biguanide (disinfectant and swimming pool cleaner)

Cryptosporidiosis

- Nitazoxanide
 - Treatment for children ≥ 1 year of age
 - Treatment for adults with diarrhea caused by cryptosporidiosis or giardiasis
- Paromomycin
 - With or without azithromycin has been used in HIV-infected patients
 - Concurrent immune therapy, such as oral administration of human immunoglobulin, hyperimmune bovine colostrum, and bovine transfer factor, has demonstrated some benefit.

- Total parenteral nutrition may be needed in HIV-infected patients with chronic diarrhea and weight loss.

- Fluid and electrolyte management of affected patients is essential.
- Nutritional supplements containing medium-chain triglycerides may be helpful.
- Milk and dairy products should be avoided.

Isosporiasis

- Trimethoprim-sulfamethoxazole (TMP-SMX) for 10 days
 - Should not be provided to infants <2 months because of risk of kernicterus
 - Patients with AIDS may require maintenance courses with TMP-SMX or pyrimethamine-sulfadoxine to prevent relapses.
- Pyrimethamine
 - May be provided for patients who cannot tolerate TMP-SMX
- Ciprofloxacin
 - May be effective, but should not be provided to people <18 years of age

Cyclosporiasis

- TMP-SMX
 - In patients infected with HIV, a prolonged course may be needed.
 - Secondary prophylaxis with TMP-SMX for months may also be needed in these patients.

Toxoplasmosis

- Pyrimethamine-sulfadiazine
 - Lifelong daily maintenance therapy is needed in patients with AIDS.
 - Supplemental leucovorin (folinic acid) is provided to prevent bone marrow toxic effects.
 - For congenital toxoplasmosis, pyrimethamine and sulfadiazine (with folinic acid supplements) should be continued for a prolonged period, often for 1 year.
- Clindamycin and pyrimethamine
 - For patients who are allergic to sulfa drugs
- Ocular toxoplasmosis
 - Corticosteroids provided in addition to pyrimethamine and sulfadiazine
- Patients with CNS disease
 - Corticosteroids provided in addition to pyrimethamine and sulfadiazine in selected patients

Malaria

Uncomplicated (nonsevere) malaria

- See table Chemotherapy for Uncomplicated Malaria for chemotherapy for uncomplicated cases.

Severe malaria

- Treatment should be parenteral administration of quinidine gluconate, with continuous infusion until:
 - The patient can take oral medication and
 - Parasite density is <1%
- Therapy should be combined with doxycycline, tetracycline, or clindamycin.
- Monitor the patient closely in an intensive care unit.
- Consult the CDC regarding treatment of severe cases.

Artemisinin derivatives

- In China and Southeast Asia, artemisinin derivatives, such as artemether and artesunate, are replacing quinine.
 - These agents can be administered orally or rectally.
 - Some concerns about possible neurotoxicity and a high rate of recurrence have been raised.
 - Thus these drugs should be used when malaria resistance to quinine is suspected.
 - Should be administered for a minimum of 3 days and followed up with mefloquine to ensure a cure rate >90%

Supportive measures to optimize management

- Closely monitor fluid and electrolytes status.
- Treat the convulsions with phenobarbital or diazepam.
- Be vigilant about hypoglycemia.
- Correct anemia with packed red blood cell transfusions
 - The CDC recommends that exchange transfusion be considered when parasite density is >10% or severe complications.
- Gram-negative sepsis must be suspected whenever patients experience shock.
 - Appropriate antibiotic therapy should be initiated after blood cultures are obtained.

Self-treatment

- Self-treatment course of atovaquone-proguanil can be provided to travelers who:
 - Do not receive antimalarial drugs for prophylaxis
 - Are on a less-than-effective regimen
 - May be in remote areas when they develop fever
- Travelers should be advised that self-treatment is not considered a replacement for seeking prompt medical help.

Babesiosis

- Clindamycin plus or alquinine or atovaquone plus azithromycin for treatment of symptomatic infection
- Exchange transfusion
 - Consider in fulminant cases with severe hemolysis and high-grade parasitemia. (>10%)

Chemotherapy of Uncomplicated Malaria^a

	Route	Drug	Dosage
All <i>Plasmodium</i> Species Except Chloroquine-Resistant Species	Oral drug of choice	Chloroquine phosphate	10-mg base/kg (max 600-mg base), then 5-mg base/kg 6 hr later, then 5-mg base/kg at 24 and 48 hr
	Parenteral drug of choice	Quinidine gluconate	10-mg/kg loading dose (max 600 mg) in normal saline over 1–2 hr, followed by continuous infusion of 0.02 mg/kg/min until oral therapy can be started
OR		Quinine dihydrochloride for <i>P falciparum</i> acquired in areas of chloroquine resistance	20-mg/kg loading dose in 5% dextrose over 4 hr, followed by 10 mg/kg over 2–4 hr every 8 hr (max 1800 mg/day) until oral therapy can be started
	Oral drug of choice	Atovaquone-proguanil	<5 kg: not indicated 5–8 kg: 2 pediatric tablet once a day × 3 days 9–10 kg: 3 pediatric tablet once a day × 3 days 11–20 kg: 1 adult tablet once a day × 3 days 21–30 kg: 2 adult tablet once a day × 3 days 31–40 kg: 3 adult tablet once a day × 3 days >40 kg: 4 adult tablet once a day × 3 days
OR		Quinine sulfate	30 mg/kg/day in 3 doses × 3–7 days
PLUS		Doxycycline	4 mg/kg daily in 2 doses × 7 days
OR		Quinine sulfate	30 mg/kg daily in 3 doses × 3–7 days
PLUS	Alternatives	Clindamycin	20 mg/kg daily in 3 doses × 7 days
		Mefloquine	15 mg/kg followed 12 hr later by 10 mg/kg
OR		Artesunate	4 mg/kg daily × 3 days
PLUS		Mefloquine prevention of relapses: <i>P vivax</i> and <i>P ovale</i> only	15 mg/kg followed 12 hr later by 10 mg/kg
		Primaquine phosphate	0.6-mg base/kg × 14 days

^a Modified in part from: American Academy of Pediatrics. Malaria. In: Pickering LK, Baker CJ, Long SS, McMillan JA, eds. *Red Book: 2006 Report of the Committee on Infectious Diseases*. 27th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2006:435–441.

Trichinellosis

- Mebendazole and albendazole have comparable efficacy.
 - Both drugs are ineffective for larvae in the muscles.
- Coadministration of corticosteroids (eg, prednisone)
 - Indicated in severe cases, especially with cardiac and CNS involvement

Trichuriasis

- Mebendazole is the drug of choice.
 - Alternatives are:
 - Albendazole
 - Ivermectin

- Nitazoxanide (not yet approved by the US Food and Drug Administration for this indication)

Strongyloidiasis

- Ivermectin is the drug of choice.
 - Alternatives are thiabendazole and albendazole.
 - In the past, thiabendazole was the preferred medication.
 - Lower cure rates have been reported with the use of thiabendazole or albendazole compared with ivermectin.
- In immunocompromised patients with hyperinfection or disseminated disease, prolonged or repeat courses of treatment (or both) may be needed.

Hookworm infections

- May need to correct malnutrition and anemia, including iron supplementation
- Drugs of choice are:
 - Albendazole
 - Mebendazole
 - Pyrantel pamoate

Cutaneous larva migrans

- Topical thiabendazole should be provided if available.
 - An alternative is albendazole or ivermectin.

Pinworm infections

- Drugs of choice are:
 - Mebendazole
 - Pyrantel pamoate
 - Albendazole
- Reinfection rates are high, and subsequent treatment may be needed.

Ascariasis

- Treat with either:
 - Albendazole, mebendazole, or ivermectin
 - Experience with these 3 drugs is limited in children <2 years of age.
 - Limited data suggest that these drugs are safe.
 - However, risk and benefits of treating ascariasis should be considered in this age group.
- Pyrantel pamoate and nitazoxanide are also effective.
- Patients with suspected intestinal or biliary obstruction:
 - Should be treated with conservative management to alleviate obstruction
 - Followed by albendazole, mebendazole, or ivermectin
- Surgery
 - If medical therapy is not successful in relieving obstruction or if complications exist (eg, volvulus peritonitis or perforation)
 - During laparotomy for obstructive cases, the small bowel should be milked down to the cecum, avoiding incision of bowel wall.
 - Endoscopic retrograde cholangiopancreatography is used to extract worms in hepatobiliary cases.

Toxocariasis

- Albendazole and mebendazole
- Corticosteroids are indicated for patients with severe cardiac and CNS involvement.
- Ocular involvement
 - Anthelmintic therapy, surgery, corticosteroids, or a combination of these
 - DEC is an alternative.

Lymphatic filariasis

- The drug of choice is DEC.
 - Systemic side effects
 - Headache
 - Anorexia
 - Nausea
 - Vomiting
 - Lymphadenitis and transient lymphedema
 - Systemic reactions if heavy load
 - May want to initiate low-dose treatment at first
- A single oral dose of ivermectin has been shown to be effective.
- Combination therapy of single doses of DEC and ivermectin may be more effective than single doses alone.
- Surgical and cosmetic therapy may be needed in some patients with chronic filariasis.
- Decongestive physiotherapy may be helpful in some cases of lymph edema.
- Bacterial superinfections, most commonly caused by *Staphylococcus* and group A *Streptococcus*, should be treated appropriately.

Onchocerciasis

- The drug of choice is ivermectin.
 - Does not kill adult worms, and therapy is not curative
 - Improves dermatitis and prevents ocular lesions
- DEC
 - No longer drug of choice because of high incidence of severe Mazzotti reactions
- Surgery
 - Surgical excision of the lesions (nodulectomy), particularly on the head, can reduce microfilarial load and decrease risk of ocular complications.
- *Wolbachia* endosymbiotic bacteria have emerged as a target for treatment with doxycycline.
 - Doxycycline should not be provided to children <8 years of age.

Schistosomiasis

- Praziquantel is drug of choice.
- Alternative treatments are:
 - Oxamniquine for *S mansoni*
 - Metrifonate for *S haematobium*

Taeniasis and cysticercosis**Taeniasis**

- Praziquantel
 - Drug of choice for the treatment of taeniasis from both *T solium* and *T saginata*
 - Highly effective in eradicating the adult stage (intestinal stage) of the tapeworm

- Niclosamide
 - An alternative agent
 - Not available commercially in the US

Cysticercosis

- In general, albendazole is preferred over praziquantel because of its higher cysticidal activity and lower cost.
- An anticonvulsant agent is usually provided to patients with:
 - Seizures
 - Multiple cysts but no history of seizure, because of risk of seizures after treatment starts
- Cysticercal encephalitis
 - The initial goal is to reduce inflammation and cerebral edema with a corticosteroid or an immunosuppressive agent.
 - Treatment with a cysticidal agent should be deferred until clinical signs of encephalitis have subsided and imaging studies demonstrate improvement of brain edema.
 - A small cyst located in the lateral ventricle can be treated effectively with an anthelmintic agent.
 - A ventriculoperitoneal shunt should be placed before treatment begins in patients with hydrocephalus.
 - If the cyst is in the fourth ventricle, is attached to the middle cerebral artery, or is compressing the optic chiasm, surgery should be performed before the cysticidal agent is administered.
 - Patients with subarachnoid cysts or a large cyst in the fissures should be treated for ≥ 30 days.
- Intraocular subretinal cyst
 - Treatment with albendazole combined with a corticosteroid is effective.
 - An intraocular cyst located in the vitreous chamber should be removed surgically.
 - An ophthalmologic examination should be performed in all cases to rule out intraocular cyst before initiating treatment.
- Symptomatic subcutaneous or muscular lesions
 - Treatment with antiinflammatory medication may be provided.
 - Surgical excision of a solitary subcutaneous or intramuscular cyst may be considered if symptoms persist.

Hydatid disease

- Surgery
 - Most common treatment modality
 - The goal is complete removal of the cyst, which may lead to a cure.
- Nonresectable cysts
 - Treatment with an anthelmintic agent (albendazole [preferred] or mebendazole) usually provides improvement and sometimes a cure.

- Response to treatment depends on the size and location of the cyst.
 - Cysts inside bone generally respond less well to drug therapy.
- PAIR treatment (puncture, aspiration, injection, and reaspiration)
 - Percutaneous drainage of cyst with a needle or catheter, followed by instillation of a protoscolicide agent and reaspiration of cyst content
 - Should be provided only to children >3 years of age
- Long-term treatment with albendazole and mebendazole has been demonstrated to inhibit growth of cyst in alveolar infection.
 - Sometimes leads to a cure

Diphyllobothriasis

- Praziquantel is the drug of choice.
 - An alternative agent, niclosamide, is no longer available in the US.
- Patients with clinical or laboratory evidence of vitamin B₁₂ deficiency should be treated with cobalamin injections and oral folic acid.

Hymenolipiasis

- Praziquantel is the drug of choice.
- Close family members, especially siblings, may also need treatment.

WHEN TO ADMIT

- All patients with systemic symptoms caused by primary infection or as a complication of parasitic infection should be hospitalized.

WHEN TO REFER

- If the physician is not well versed in taking care of children with parasitic infections, referral to an infectious disease specialist is prudent.

FOLLOW-UP

- Leishmaniasis
 - Patients receiving antimonials should have complete blood counts and electrocardiographic monitoring at baseline and weekly thereafter.
- African trypanosomiasis
 - Patients taking suramin or eflornithine should be monitored closely for possible adverse reactions.
- Hookworm infections
 - Repeat stool examination should be performed 2 weeks after treatment.
 - If positive, then additional treatment should be considered.

■ Schistosomiasis

- Patients treated with praziquantel in the first 4–8 weeks of exposure should be retreated in 1 or 2 months.
- Reexamination of stool or urine 1 month after treatment should be performed to assess efficacy of treatment.
 - If patients continue to shed eggs, treat again.

■ Cysticercosis

- Patients with neurocysticercosis should be monitored with a brain imaging study after completion of treatment.

■ Hymenolipiasis

- Stool examination should be repeated 2–4 weeks after treatment to document cure.
 - Especially in patients with many worms

COMPLICATIONS

Leishmaniasis

■ Cutaneous form

- Secondary bacterial infection is common.

■ Visceral form

- Secondary bacterial and mycobacterial infections, including tuberculosis

■ Patients with thrombocytopenia may develop:

- Epistaxis
- Gingival bleeding
- Other hemorrhagic manifestations

■ If patients go untreated

- Disseminated intravascular coagulation
- Pulmonary or intestinal superinfections

■ Patients infected with HIV and stem cell and solid organ transplant recipients are:

- At risk of reactivation of latent infection and disseminated disease

■ Post-kala-azar dermal leishmaniasis after recovery in patients from visceral disease:

- Indicates reversal to dermal form
- Lesions occur predominantly on the face, extremities, and upper trunk.

Trypanosomiasis

■ Death from meningitis, heart failure, and other complications

Giardiasis

■ *G intestinalis* uncommonly spreads from the duodenum to other organs.

- Hepatitis
- Cholangitis
- Pancreatitis

Amebiasis

- Extension or rupture into lung, pleural space, peritoneum, or pericardium may complicate the course of amoebic hepatic abscess.

Cryptosporidiosis

- The biliary tract is affected in 10–30% of HIV-infected patients.
 - Can lead to sclerosing or acalculous cholangitis

Trichinellosis (severe)

- Fatal myocarditis with subsequent heart failure and cardiac arrhythmias
- Encephalitis
- Meningitis
- Focal neurologic deficits
- Bronchopneumonia
- Nephritis

Amoebiasis

- Fulminant colitis with bowel necrosis leading to perforation and peritonitis
 - Rare, but associated with mortality rate >40%
- Other rare complications
 - Ameboma (a nodular, tumorlike focus of proliferate inflammation in the wall of the colon)
 - Toxic megacolon
 - Local perforation
 - Peritonitis
 - Extraintestinal extension
- Complications of amoebic hepatic abscess
 - Jaundice
 - Extension or rupture into the lung, pleural space, peritoneum, or pericardium

Toxoplasmosis

- Rare complications of primary toxoplasmosis infection
 - Hepatitis
 - Pneumonitis
 - Myocarditis
 - Pericarditis
 - Encephalitis
- Complications of congenital toxoplasmosis infection
 - If untreated, a large proportion of infants may develop late-onset sequelae, such as:
 - Chorioretinitis: Relapses are frequent, and vision loss may occur.
 - Learning disabilities
 - Intellectual disability months to years later

- Other complications of congenital ocular involvement
 - Chorioretinal scars
 - Microphthalmia
 - Cataract
 - Retinal detachment

Babesiosis

- Vascular injury may also cause renal insufficiency.

Trichuriasis

- Colitis results from chronic infection.
 - May mimic inflammatory bowel disease
- Colonic obstruction and perforation may occur.
- Chronic infection in children may also be associated with malnutrition, growth retardation, and cognitive abnormalities.

Ocular larva migrans

- Chronic endophthalmitis
- Retinal detachment
- Keratitis
- Uveitis
- Iritis
- Vitreous abscess
- Optic neuritis
- Retinal tracks with larvae

Pinworm infections

- Bacterial superinfection may develop in the perianal region.

Schistosomiasis

- Genitourinary lesions include obstructive lesions that may eventually lead to chronic renal failure or bladder carcinoma.
- Schistosome eggs may occasionally embolize to other organs with subsequent granuloma formation.
 - Skin
 - Lungs
 - Brain
 - Adrenal glands
 - Skeletal muscles
- Neurologic complications
 - Transverse myelitis occurs with either *S mansoni* or *S japonicum* infection.
 - Seizures, either focal or generalized, have been reported in patients infected with *S japonicum*.
 - Focal neurologic deficits may rarely occur.

Cysticercosis

- After treatment initiation, patients may develop a treatment reaction, usually with an inflammatory reaction in the surrounding tissue.
 - Severe headache and vomiting

- Reaction can be minimized by administration of dexamethasone 2–3 days before treatment initiation and during treatment with a cysticidal agent.

Hydatid disease

- Possible complications from surgical procedures or PAIR are spreading of the infection and allergic or anaphylaxis reaction.
 - These can be minimized by perioperative administration of anthelmintic agents against echinococcal cysts.

Lymphatic filariasis

- Hydrocele and chyluria result from obstructed lymph drainage in the genital area and urinary bladder, respectively.
- Other complications of lymphatic obstruction include chylothorax and chylous ascites.

Diphyllobothriasis

- Because *Diphyllobothriasis latum* can compete with the human host for vitamin B₁₂, chronically infected people may develop pernicious anemia as a result of vitamin B₁₂ deficiency.

PROGNOSIS

- Chagas disease
 - In the acute phase, children <2 years of age who develop heart failure or meningoencephalitis have a high mortality rate.
 - Patients in the chronic phase with digestive tract involvement generally have a good prognosis.
 - Prognosis is usually poor among chronic-phase patients with heart failure.
- Amoebic meningoencephalitis
 - PAM
 - Even with combined therapy, survival has been the exception.
- Cryptosporidiosis
 - In immunocompromised patients, particularly those infected with HIV
 - Cryptosporidiosis frequently takes a severe and protracted course.
 - Can lead to significant malnutrition and wasting, dehydration, and death
- Strongyloidiasis
 - Patients may remain infected for decades.

PREVENTION

Leishmaniasis

- Travelers to endemic areas should use personal-protection measures to prevent bites by the sandfly.
 - Long-sleeve shirts, pants, and socks
 - Insect repellents

- Limit exposure to the fly from dusk to dawn.
- Bed nets

Giardiasis

- Personal hygiene is the most important way to prevent spread.
- In child care centers, strict hand washing and appropriate diaper disposal
- Symptomatic children should be excluded from child care centers.
- *Giardia* cysts are resistant to the usual chlorination levels and are not easily killed in cold water.
 - Cysts can be killed by boiling or heating water to $\geq 70^{\circ}\text{C}$ for 10 minutes.
 - Travelers, hikers, and campers should be advised to ensure safe drinking water.
 - Heat or boil water *or*
 - Chemically disinfect *or*
 - Filter (high-quality filtration units are effective)

Amoebic meningoencephalitis

- Effective levels of chlorine in water used in swimming pools and spas
- Avoidance of swimming in warm, stagnant, and possibly feces-contaminated waters
- Compliance with procedures for contact lens care

Cryptosporidiosis

- Effective hand washing and appropriate disposal of infected material
- Contact precautions are suggested for diapered and incontinent children.
- Infected people should not use public recreational water when they have diarrhea and for ≥ 2 weeks after resolution of symptoms.
- Boiling water intended for drinking for 1 minute kills *Cryptosporidium*.
 - Alternatively, filtration devices with particle-size ratings of 1–5 μm removes *Cryptosporidium*.

Toxoplasmosis

- General prevention measures
 - Hygienic practices during cat contact
 - Prevention of consuming raw meat
 - Deep freezing and cooking meat, particularly ham and lamb, to an internal temperature of 65.5°C – 76.6°C or until no longer pink kills cysts.
 - All fruits and vegetables should be washed thoroughly.
 - Pregnant women and immunocompromised individuals should avoid contact with cats, cat litter, or soil contaminated by cat feces.
 - Stress wearing gloves and hand washing in such settings.

- Cats may be prevented from acquiring infection by restricting their outdoor activities and feeding them commercially prepared cat food.
- Because oocysts are not infective until 36–48 hours or longer after passage, daily cleaning of cat litter boxes is a simple and effective control measure.

■ Prophylactic therapy

- Children with HIV or AIDS with severe immunosuppression and positive *Toxoplasma* IgG antibodies
 - The drug of choice is TMP-SMX.
 - Alternative therapies: dapsone plus pyrimethamine (with supplemental folinic acid) or atovaquone
- To prevent recurrence of toxoplasmosis in immunosuppressed patients with prior *Toxoplasma* encephalitis:
 - Pyrimethamine plus sulfadiazine plus folinic acid
 - Alternatively, clindamycin plus pyrimethamine plus folinic acid for patients who cannot tolerate sulfa drugs

Malaria

- To prevent recurrence when treating *P vivax* and *P ovale*
 - Antimalarial drugs that target the liver stage (eg, primaquine) should be added.
 - Patients should be checked for glucose-6-phosphate dehydrogenase deficiency before being given primaquine.
- Reducing population of *Anopheles* mosquitoes
- Avoiding bites by parasite-carrying mosquitoes (vector control)
- Providing antimalarial drugs prophylactically
- Detailed guidelines about chemoprophylaxis of malaria for travelers to endemic areas are available (www.cdc.gov/travel/).

Chemoprophylaxis by geographic area

- Begin 1 week before arrival in area, except doxycycline and atovaquone-proguanil, which should be started 1–2 days before arrival, to allow time to develop blood concentrations of the drug/permit evaluation for adverse reactions; medications should be continued after departure from endemic areas.
- Areas with chloroquine-sensitive *Plasmodium* species
 - Chloroquine phosphate: 5-mg base/kg once a week; up to adult dose of 300-mg base
- Areas with chloroquine-resistant *Plasmodium* species
 - Atovaquone-proguanil
 - 5–10 kg: 1–8 tablets once a week
 - 11–20 kg: 1 pediatric tablet/day
 - 21–30 kg: 2 pediatric tablets/day
 - 31–40 kg: 3 pediatric tablets/day
 - >40 kg: 1 adult tablet/day

- Or mefloquine
 - 11–20 kg: 0.25 tablet once a week
 - 21–30 kg: 0.5 tablet once a week
 - 31–45 kg: 0.75 tablet once a week
 - >45 kg: 1 tablet once a week
- Or doxycycline: 2 mg/kg per day, up to 100 mg/day
- Alternatives: primaquine: 0.6-mg base/kg daily
- Or chloroquine phosphate: 5-mg base/kg once/week, up to 300-mg base, *plus*
- Proguanil
 - 2–6 yr: 100 mg once a day
 - 7–10 yr: 150 mg once a day
 - >10 yr: 200 mg once a day

Babesiosis

- Avoid tick-infested areas.
 - Particularly from May to September
- Wear clothing that covers arms, legs, and other exposed areas.
 - Tuck pants into socks or boots.
- Tick and insect repellents that contain *N,N*-diethyl-metoluamide (DEET) may be considered.
 - Repeat applications may be needed.
- Tick-toxic agents, such as permethrin, may be sprayed on clothes and shoes but not the skin.
- Inspect bodies of self and children, as well as all clothing, for ticks after possible exposure.
 - Exposed hairy areas, including the scalp and behind the ears, should be thoroughly inspected.
- If a tick is found:
 - Grasp with a tweezers close to the skin and gently pull out straight.
- Pets should be inspected for ticks daily.

Trichinellosis

- Prevent by thorough cooking of pork and game meat.
 - Heat at a temperature of 77°C.
- Freezing is also effective in killing larvae in meat.
 - Freezing at –15°C for 3 weeks (available in home freezers)
 - Freezing pork meat at –23°C for 10 days

Trichuriasis

- Proper disposal of human fecal material may be the most effective control measure.

Strongyloidiasis

- Proper disposal of human fecal material
- Screening
 - Consider in patients with immunodeficiency if history of living in or traveling to endemic areas.
 - Especially those receiving corticosteroids or with human T-lymphotropic virus type 1 infection

- Screening of immigrants or returned travelers from endemic areas should also be considered before initiating immunosuppressive therapy.

Hookworm infections

- Proper disposal of human feces

Pinworm infections

- Hand hygiene is essential.
- Morning bathing is suggested for all infected persons.
- Prevention of autoinfection
 - Avoid scratching the perianal area.
 - Wash the hands before eating.
 - Keep fingernails short.
 - Frequently change and wash underwear, bed linen, and clothing.
 - Shaking of bed linen should be avoided.
 - Treating all family contacts should be considered if there are repeated symptomatic infections.

Ascariasis

- Sanitary disposal of human feces is essential to prevent soil contamination.
 - Particularly near children's play areas
- Mass deworming programs with a single dose of mebendazole or albendazole have been used in some communities endemic for ascariasis.

Toxocariasis

- Correct underlying causes of pica in children.
- Cat and dog feces should be properly disposed of.
- Sandboxes not in use should be covered.
- Anthelmintic therapy for puppies and kittens at 2, 4, 6, and 8 weeks may prevent secretion of eggs in feces and subsequent potential transmission.

Onchocerciasis

- Prevent blackfly bites in endemic areas.
 - Bites during the day
 - Insect repellents and protective clothing are suggested.

Schistosomiasis

- Sanitary disposal of human waste
- Travelers should be advised to avoid contact with fresh water in lakes or streams.
- Artemether, an antimalarial agent, has been suggested for use as a prophylactic agent.
 - Kills schistosomula (the migrating larvae) in the first 21 days in the body
 - When administered every 2 weeks, kills all immature schistosomes
 - Should be avoided in malaria-endemic areas because of risk of emergence of resistance

Pectus Excavatum and Pectus Carinatum

DEFINITION

- Pectus excavatum
 - A congenital syndrome characterized by a concave depression of the sternum
 - Phenotypically, the appearance resembles a funnel chest.
 - Concavity often is asymmetric, with the right side usually more depressed than the left.
 - Severity of the concavity can range from a mild depression to a profound indentation.
- Pectus carinatum
 - The second-most common chest wall abnormality
 - Characterized by a protuberance of the sternum that mimics a pigeon's chest

EPIDEMIOLOGY

- Pectus excavatum
 - The most common congenital chest wall deformity
 - Affects approximately 1 in 400 live births
 - Accounts for ~90% of chest wall defects
 - 80% of children with pectus excavatum are boys.
- Pectus carinatum
 - Accounts for <5% of chest wall defects

ETIOLOGY

- Pectus excavatum
 - Results from excessive growth of the costal cartilage, which displaces the sternum posteriorly
 - Defect may be exaggerated by rapid skeletal growth during adolescence.

RISK FACTORS

- For pectus excavatum
 - Family history

SIGNS AND SYMPTOMS

Pectus excavatum

- Typically becomes problematic as children reach early adolescence
 - Embarrassment over cosmetic appearance of the chest
 - Many patients describe having social anxiety, problems with body image, and depression.
 - Respiratory impairment from the defect
- Defect can progress from barely noticeable to extremely prominent in the span of a few years.
 - Severity usually does not increase after age 18.
 - Rapid growth during adolescence tends to make deformity more pronounced.

- Most patients do not exhibit symptoms.
 - Some may have decreased chest excursion and diminished inspirations, causing:
 - Decreased exercise tolerance
 - Easy fatigability
 - Frequent respiratory tract infections
 - Chest pain (unusual)
- Auscultation of the chest may reveal diminished inspiration or a cardiac murmur, especially in the presence of mitral valve prolapse.
- Patients tend to have *pectus posture*:
 - Rounded shoulders
 - Protuberant abdomen
- Pectus excavatum is associated with:
 - Asthma
 - Bronchial atresia
 - Bronchomalacia
 - Down syndrome
 - Marfan syndrome
 - Mitral valve prolapse ($\leq 30\%$)
 - Noonan syndrome
 - Osteogenesis imperfecta
 - Poland syndrome
 - Rett syndrome
 - Rickets
 - Scoliosis (15%)
 - Turner syndrome
 - Wolff-Parkinson-White syndrome

Pectus carinatum

- Usually a symmetric, midline deformity
- Only infrequently associated with cardiovascular compromise

DIAGNOSTIC APPROACH

- Pectus excavatum
 - Thorough history and physical examination, with attempt to rule out associated disorders that may have been undiagnosed
 - Severity is measured by the Haller index: CT scan–measured transthoracic diameter divided by sternovertebral diameter.
 - An index of >3.5 is considered to be a severe defect.
 - Even indices <2.5 can cause significant cardiopulmonary impairment.
 - Repair usually is considered for defects with an index of >1.5 – 1.7 .

IMAGING

■ Pectus excavatum

- Transthoracic echocardiogram
 - May reveal diminished cardiac output from decreased stroke volume and mitral valve prolapse

DIAGNOSTIC PROCEDURES

■ Pectus excavatum

- Pulmonary function tests tend to demonstrate a restrictive pattern.

TREATMENT APPROACH

■ Pectus excavatum

- Nonoperative measures are aimed at decreasing symptoms, but generally are only minimally effective.
 - Patients can be taught to increase breathing efforts to increase diaphragmatic excursion and oxygen exchange.
 - Improvement in posture can improve air exchange.
 - External braces can help correct posture but have been largely associated with only minimal correction.
 - Some authorities have advocated the use of continuous external vacuum.
- Repair should be performed in patients with:
 - Cardiopulmonary impairment
 - Pain
 - Concerns about cosmesis resulting in poor body image
- The best time for repair is uncertain; however children should undergo surgical repair between 12–18 yr of age, when old enough to:
 - Understand the nature, consequences, and magnitude of the surgery
 - Understand the level of pain that might be experienced postoperatively and accept a temporary limitation of activity
- Although the surgery can be performed later, it should not be delayed too long, to take advantage of the pliable chest wall of the growing adolescent.

■ Pectus carinatum

- Open surgical repair similar to that used for pectus excavatum

- A minimal open repair has been described for both the excavatum and carinatum deformities.

SPECIFIC TREATMENTS

Pectus excavatum

■ Two methods of surgical repair

- Ravitch method (1949)
 - Transverse incision is made over the middle portion of the sternal defect.

- Dissection is performed below the level of the pectoralis fascia and muscles.
- Costal cartilage of ribs 1–8, on each side of the sternum, is resected, proceeding from the costochondral junction to the costosternal junction.
- Transverse osteotomy of the sternum is performed at the level of the third costal cartilage.
- Lower sternum is then repositioned to correct the deformity, and pectoralis muscles are reattached to the midline.
- Despite its extensive nature, this repair has been associated with good long-term outcome.
- Nuss procedure (1987)
 - Less invasive
 - Elevates the sternal depression without cartilage resection
 - Bilateral incisions are made at the anterior axillary line at the level of the greatest depression of the pectus defect.
 - Incision is made in the fourth intercostal space, and a thoracoscope is introduced.
 - Under direct vision, a pectus bar is passed across the chest.
 - Bar then is flipped anteriorly to raise the sternum.
 - Bar remains in place for 2 to 3 years to allow for proper remodeling of the costal cartilage.
 - This process is slower in the older patient because of the decreased rate of growth.
 - Bar is removed as an outpatient procedure.
 - The method has been associated with equivalent cosmetic results and may be more cost effective because it has a shorter operating time.
- Adequate analgesia typically is the most troublesome problem in the postoperative period.
 - Epidural patient-controlled analgesia catheter greatly reduces pain after the procedure.
 - The epidural catheter usually is required for several days, and is the main reason the patient remains in the hospital.

Pectus carinatum

- Typically, open Ravitch repair method (as for pectus excavatum) is performed to correct deformity.
- Thoracoscopic techniques also are used.
- Some investigators have advocated the use of conservative measures as an alternative to surgical repair, such as:
 - External braces applying constant pressure

WHEN TO REFER

■ Pectus excavatum

- Patients may be referred to pulmonologists and cardiologists to manage the pulmonary and cardiac complications until the defect is corrected surgically at 12–18 years of age.

COMPLICATIONS

■ Pectus excavatum

- Complications with the Ravitch repair method include:
 - Impairment of growth of the chest wall
 - Possible constriction of the thorax
- Complications with the Nuss repair method include
 - Displacement of the bar
 - Modifications in technique and increased surgeon experience have led to low rates of bar migration.
 - No cases of cardiac perforation have occurred with the use of thoracoscopy during the procedure.

PROGNOSIS

■ Pectus excavatum

- Long-term outcomes have shown both types of repair to be effective.
- Almost all patients report satisfaction with cosmetic results.

- Pain and decreased exercise intolerance generally improve after surgery.
- Many asymptomatic patients with normal preoperative pulmonary function test and cardiac echo report significant improvement in their exercise tolerance and endurance, although they had not previously reported presurgical limitations.
- Advent of a minimally invasive technique has changed the approach to a patient with this deformity.
 - Children who previously lived with psychological issues because of poor body image or physical limitations (or both) can now undergo a safe and effective operation with minimal morbidity.
 - Number of patients referred for surgical repair is likely to increase.

Pertussis (Whooping Cough)

DEFINITION

- A highly contagious, bacterial respiratory infection
 - Caused by *Bordetella pertussis*, an aerobic gram-negative coccobacillus
 - Characterized by paroxysms of intense coughing and a protracted clinical course lasting several weeks

EPIDEMIOLOGY

- Incidence
 - 300,000 pertussis-related deaths annually worldwide
 - Before availability of pertussis vaccines, almost 300,000 cases and 10,000 deaths annually in the US.
 - 11,647 cases were reported in the US in 2003, with an annual incidence of 4.0 cases per 100,000 population.
 - Epidemic peaks occur every 3–5 years.
 - In highly immunized populations as well as in infants who have not received 3 doses of vaccine
 - Overall number of cases is likely underestimated because the infection is often underdiagnosed in adolescents and adults.
- Prevalence
 - A very common cause of prolonged cough in adolescents and adults
 - Accounts for 12–32% of cases of cough lasting 2 weeks or longer
- Age
 - By the late 1980s, infants <1 year of age had the highest age-specific incidence, which declined with increasing age.
 - Since the early 1990s, a marked increase has occurred in reported cases in children aged 10 years and older.
 - Between 2001 and 2003, children aged 10–19 years accounted for 33% of all reported cases; 23% of cases occurred in individuals ≥20 years of age.
 - Between 2001 and 2003 infants <1 year accounted for 23% of all cases.
 - Severe paroxysmal cough ending in the inspiratory *whoop* is most often seen in infants and young children, who experience the most severe manifestations.
 - Annual incidence by age
 - Infants <1 year: 55.2 per 100,000 population
 - Ages 10–19 years: 7.7 per 100,000
 - Adults: 1.1 per 100,000
- Geographic distribution
 - Disease is endemic, with all 50 states reporting cases annually.
- Seasonality
 - Most cases in the US occur between June and October.

ETIOLOGY

- *Bordetella pertussis* is a highly contagious organism.
 - 80–90% secondary attack rates among susceptible household contacts
 - Acquired through direct transmission from close respiratory contact
- Subclinical or mild illness commonly occurs in fully or partially immunized, and naturally immune individuals.
- Immunity
 - Wanes within 3–5 years of vaccination or natural infection
 - Often undetectable at 12 years after vaccination or natural infection
 - Thus neither vaccination nor natural disease provides long-lasting immunity.
- Adults and adolescents with pertussis serve as
 - Important reservoirs for infection
 - Index cases for younger infants and children

SIGNS AND SYMPTOMS

Infants and children

- 3 stages of illness, each lasting at least 2 weeks
- Classic stages are evident most commonly in unimmunized infected young children.
 - In partially or totally immunized children, stages are shortened and may be atypical.
 - Neonates do not have an apparent catarrhal phase.
- Incubation period of 7–10 days
- *Catarrhal* phase
 - Nonspecific upper respiratory tract symptoms with:
 - Rhinorrhea
 - Lacrimation
 - Mild cough
 - Conjunctival injection
- *Paroxysmal* stage
 - Intermittent dry hacking cough
 - Repetitive series of forceful coughs within a single expiration
 - Sudden massive inspiratory respiratory effort often occurs at the end of cough paroxysm, resulting in a high-pitched *whoop*.
 - Between attacks, patient appears comfortable, without apparent distress.
 - Very young infants often lack the characteristic *whoop* and exhibit episodes of:
 - Gagging
 - Gasping
 - Apnea

- Bradycardia
- Cyanosis

■ Convalescent stage

- Diminishing severity and frequency of paroxysms
- Continued intermittent coughing for weeks to months, often exacerbated by subsequent intercurrent respiratory illness

■ Physical examination is usually normal, except for evidence of the forcefulness of their cough and posttussive emesis.

- Conjunctival hemorrhage
- Upper body petechial lesions

■ Fever

- Characteristically absent at all stages
- If present, suggests secondary bacterial infection

Adolescents and adults

■ Usually does not have distinct phases.

■ Persistent (>21 days) cough, indistinguishable from other respiratory infections, can be the only symptom.

■ Paroxysmal nature of the cough is present in approximately 70–99% of infected individuals.

■ Other features include:

- Inspiratory whoop
- Posttussive emesis
- Choking
- Sleep disturbed by cough

■ Positive predictors of confirmed pertussis include:

- History of prolonged duration of violent cough (median, 43 days)
- Longer duration of cough illness (median, 56 days)
- Posttussive emesis

■ Adults with pertussis do not have fever

DIFFERENTIAL DIAGNOSIS

In infants

■ Respiratory viral illnesses

■ Infection with *Chlamydia trachomatis* and with other *Bordetella* species

■ Bacterial pneumonia

■ Foreign body aspiration

■ Reactive airway disease

■ Adenovirus

- Can produce clinical syndrome of:
 - Prolonged paroxysmal cough
 - Posttussive emesis
 - Inspiratory whoop

- Presence of associated features commonly found with adenovirus can help distinguish clinically

- Pharyngitis
- Conjunctivitis

■ Respiratory syncytial virus (RSV)

- A common cause of upper and lower respiratory tract infection in neonates and infants
- Dual infection with RSV and *B pertussis* can occur.
 - Apnea is a common complication of both infections.
- Predominantly lower respiratory tract signs (wheezing), fever, and ongoing symptoms between cough episodes more suggestive of RSV

■ *Chlamydia trachomatis*

- A common cause of afebrile pneumonia in young infants
- Infants with chlamydial infection usually have:
 - Staccato rather than paroxysmal cough
 - Lower respiratory tract signs such as tachypnea and rales
 - Frequent history of neonatal conjunctivitis

■ *Bordetella parapertussis* and rarely *Bordetella bronchiseptica*

- Characteristically cause a less protracted illness

■ Bacterial pneumonia caused by *Staphylococcus aureus* and *Streptococcus pneumoniae*

- Not difficult to distinguish based on the clinical manifestations
 - High temperature
 - Ill appearance
 - Respiratory distress
- These agents can secondarily complicate pertussis infection.

In the older child, adolescent, and adult

■ Adenoviral infection

■ *Mycoplasma pneumoniae*

- Common cause of prolonged cough and may be difficult to distinguish
- Suggested by presence of systemic symptoms such as:
 - Headache
 - Sore throat
 - Rales on auscultation of the chest
 - Chest radiograph that characteristically appears worse than the appearance of the patient would indicate

■ *Chlamydia pneumoniae*

■ Reactive airway disease

■ Upper respiratory tract infection

■ Concurrent outbreaks have been reported.

DIAGNOSTIC APPROACH

- Definitive diagnosis of pertussis is problematic.
- A complete history is by far the most important aspect of the evaluation of the infant or child with possible pertussis.
- Clinical diagnosis can be supplemented by:
 - Physical examination
 - Laboratory studies
 - Radiographic studies
- Physical examination usually normal
- Diagnosis may be missed if attention is not paid to historical description of coughing paroxysms.
- Cough paroxysms in a young infant should be witnessed by a medical professional before a disposition is planned.

LABORATORY FINDINGS

- Culture
 - Isolation of the organism by culture is the diagnostic standard.
 - Highly dependent on appropriate specimen collection, transport, and isolation technique
 - Culture is obtained from the posterior nasopharynx using a calcium alginate or Dacron-tipped (not cotton-tipped) swab.
 - Specimen should be immediately inoculated onto Regan-Lowe medium and incubated for 7 days.
 - Semisolid transport media is available if specimen cannot be inoculated immediately onto solid media.
 - Even in ideal conditions, sensitivity of culture is suboptimal.
 - Most likely to be positive early in the illness (catarrhal and early paroxysmal phase) in unimmunized children
 - Greatly diminished when obtained late in the illness, in immunized individuals, and in those who have received macrolides or sulfonamides
- Polymerase chain reaction (PCR) testing
 - Nasopharyngeal specimens
 - Appears to be more sensitive than culture, including in individuals who are mildly symptomatic and in those who have been treated with macrolides.
 - Sensitivity highly dependent on the age of the patient; likely a reflection of past immunization and immune responses
 - 60–70% sensitive in infants and young children
 - <10% sensitive in older children and adults
 - PCR also can detect *B parapertussis*.
- Direct fluorescent antibody testing for pertussis antigens
 - Nasopharyngeal specimens
 - Plagued by poor sensitivity when compared with culture
 - Requires experienced laboratories for accuracy
 - Rarely used today

- Serologic testing for detection of antibodies to components of *B pertussis* in acute and convalescent samples
 - The most sensitive mode of diagnosis
 - Used extensively in epidemiologic studies and vaccine trials
 - Not readily available
 - Results are difficult to interpret in immunized individuals
 - Not helpful for the diagnosis of pertussis

IMAGING

- Chest radiography in infants and children
 - Commonly normal
 - May reveal:
 - Perihilar infiltrates
 - Pneumothorax
 - Pneumomediastinum

TREATMENT APPROACH

- Supportive care is the mainstay of management.
- Hospitalization is indicated for most infants <6 months of age
 - To assess for life-threatening events associated with paroxysms, such as:
 - Apnea
 - Bradycardia
 - Hypoxia
- Hospitalization provides:
 - Continuous cardiorespiratory monitoring
 - Vigilant suctioning of the nasopharynx
 - Oxygen therapy if needed
 - Careful attention to feeding and hydration
 - Monitoring and treatment of acute complications
- A macrolide antibiotic is indicated for proven or suspected pertussis to:
 - Eliminate the organism from the nasopharynx
 - Limit spread to others
- If administered early, this therapy can reduce duration and severity of symptoms.
- These agents have little influence on clinical course of pertussis unless use is started early in the catarrhal phase.

SPECIFIC TREATMENTS

Macrolide agents

- Erythromycin traditionally has been antibiotic of choice.
- Newer macrolide agents—clarithromycin and azithromycin—are:
 - As effective in persons aged 6 months and older
 - Better tolerated
 - Associated with fewer and milder adverse effects

- Based on these data, the Centers for Disease Control and Prevention developed guidelines recommending that erythromycin, clarithromycin, and azithromycin be used for the treatment of pertussis in persons aged 1 month and older.
- Although studies evaluating the safety and efficacy of the newer macrolides for infants younger than 6 months are limited, their use is encouraged based on:
 - In vitro effectiveness
 - Demonstrated safety in older infants and children
 - More convenient dosing schedule
- Erythromycin therapy is associated with infantile hypertrophic pyloric stenosis.
 - Thus azithromycin is the preferred macrolide in infants younger than 1 month.
 - Limited data to date have not documented an association between azithromycin and infantile hypertrophic pyloric stenosis.

Antimicrobial treatment and postexposure prophylaxis by age group

- <1 month
 - Azithromycin 10 mg/kg/day as single daily dose for 5 days
- 1–5 months
 - Azithromycin 10 mg/kg/day as single daily dose for 5 days *or*
 - Erythromycin 40–50 mg/kg/day in 4 divided doses for 14 days *or*
 - Clarithromycin 15 mg/kg/day in two divided doses for 7 days
- Infants 6 months and older and children
 - Azithromycin 10 mg/kg/day as single dose on day 1 then 5 mg/kg/day (maximum 500 mg) on days 2–5 *or*
 - Erythromycin 40–50 mg/kg/day (maximum 2 g/day) in 4 divided doses for 14 days *or*
 - Clarithromycin 15 mg/kg/day in 2 divided doses (maximum 1 g/day) for 7 days
- Adults
 - Azithromycin 500 mg as single daily dose on day 1, then 250 mg/day on days 2–5 *or*
 - Erythromycin 2 g/day in 4 divided doses for 14 days *or*
 - Clarithromycin 1 g/day in 2 divided doses for 7 days
- Treatment of parapertussis is the same as for pertussis.

Care of household and other close contacts

- A macrolide should be given promptly to all household and close contacts (eg, those in child care).
- Chemoprophylaxis
 - Significantly reduces but does not eliminate risk of pertussis
 - Should be given to close contacts regardless of age and immunization status

- Should be given to health care workers with definite or likely exposure
- Antimicrobial agents that should be used for postexposure prophylaxis are the same as for treatment.
- Trimethoprim-sulfamethoxazole
 - An alternative treatment or prophylactic option for patients who cannot tolerate macrolides
 - Contraindicated in infants younger than 2 months

WHEN TO ADMIT

- Strongly consider in any young infant younger than 6 months suspected of having pertussis
- When complications such as apnea, bacterial pneumonia, bradycardia, or pulmonary hypertension exist
- When the infant has an oxygen requirement or when the infection is interfering with feeding

COMPLICATIONS

- Secondary bacterial pneumonia is the most common complication.
 - Occurs in ~5% of all reported cases
 - Causes most pertussis-related deaths
- Infants <6 months have highest rate of hospitalization (69%), secondary bacterial pneumonia (13%), and seizures (2%).
- Important complications include:
 - Apnea
 - Bradycardia
 - Dehydration
 - Pulmonary hypertension
 - Pneumothorax
 - Central nervous system changes
 - Retinal hemorrhages
- Complications are much more common in infants.
- In adults, morbidity includes:
 - Pneumonia
 - Otitis media
 - Sinusitis
 - Rib fracture
 - Pneumothorax
 - Pneumomediastinum
 - Weight loss
 - Urinary incontinence

PROGNOSIS

- Young infants have the highest incidence of morbidity and mortality.
 - 91% of pertussis-related deaths occur in children <6 months

PREVENTION

- AAP recommends universal immunization with pertussis vaccines for children <7 years of age.
 - Vaccination of all children starting in infancy has resulted in >97% decrease in incidence of pertussis in the US.
- Currently available acellular vaccines have been shown to be 75–90% effective and well tolerated.
 - Purified subunit vaccines
 - Combination vaccines with diphtheria and tetanus toxoids (diphtheria-tetanus-acellular pertussis [DTaP])
- AAP recommends that a total of 5 doses of pertussis vaccine be administered to every child before school entry, unless contraindicated.
 - First dose at 2 months of age
 - 2 subsequent doses at intervals of 2 months
 - Fourth dose at 15–18 months
 - Fifth dose at 4–6 years
- Because of the role that adolescents and adults play in transmission, studies have evaluated efficacy and safety of acellular pertussis vaccines in these age groups.
 - Adverse reactions to these vaccines among adolescents and adults have been mild.
 - Although these vaccines appear well tolerated in trials to date, concern exists about the possibility of more severe limb swelling in individuals vaccinated with booster doses of acellular vaccines after primary immunization with the same acellular vaccines.
 - However, limb swelling does not appear to be a problem in those who received whole-cell vaccine as their primary immunization.
 - Thus adolescents and adults who previously received acellular vaccines will need to be observed closely when given booster doses to determine the frequency and severity of such reactions.
- AAP recommends that adolescents aged 11–18 years receive acellular pertussis vaccine combined with tetanus and reduced diphtheria toxoid (Tdap).
 - Single dose of Tdap instead of tetanus and diphtheria toxoids (Td) vaccine for booster immunization for adolescents 11–18 years of age.
 - The preferred age for Tdap immunization is 11–12 years.
 - Adolescents 11–18 years of age who have received Td but not Tdap are encouraged to receive a single dose of Tdap.
- An interval of at least 5 years between Td and Tdap is suggested.
- Intervals <5 years can be used, particularly in settings of:
 - Increased risk
 - Complicated disease
 - Danger of transmitting infection to vulnerable contacts

Petechiae and Purpura

DEFINITION

■ Petechiae

- Small (1–3 mm), red, nonblanching macular lesions caused by intradermal capillary bleeding

■ Purpura

- Larger, typically raised lesions resulting from bleeding within the skin

EPIDEMIOLOGY

- May occur at any age

MECHANISM

- Petechiae and purpura result from a wide variety of underlying disorders.

- Petechiae are caused by intradermal capillary bleeding.
- Purpura result from bleeding within the skin.

HISTORY

- Evaluation begins with a complete history.

- Can readily eliminate a majority of disorders from the differential diagnosis

- Special attention to:

- Recent trauma
- Bleeding history
- Medication use
- Symptoms consistent with:
 - Infection
 - Malignancy
 - Autoimmune disorders
 - Rheumatologic disorders

PHYSICAL EXAM

■ Petechiae

- Small (1–3 mm), red, nonblanching macular lesions

■ Purpura

- Larger
- Typically raised lesions
- Can vary somewhat in color
 - Based on the age of the lesion as the blood within the skin is metabolized
- Do not blanch
- May occur anywhere on the body

- Physical examination should determine:

- If skin findings are isolated
- If evidence of a more generalized process is present

- Particular physical findings to evaluate include:

- Hepatosplenomegaly
- Lymphadenopathy

- Arthritis
- Arthralgias
- Findings consistent with an acute viral syndrome

DIFFERENTIAL DIAGNOSIS

General

- Neither petechiae nor purpura are pathognomonic of a specific disorder.

- Petechiae and purpura must be evaluated according to:

- Overall context of the patient
- Severity and extent of lesions
- History and age of the patient

- Clinician must entertain a broad differential diagnosis:

- Hemostasis
- Infection
- Autoimmune disorders
- Trauma
- Malignancy
- Other rare causes

- Underlying pathophysiological mechanism may be defined by:

- Age at presentation
- Overall appearance
- Extent of the lesions

- Scant petechiae on the face of an otherwise well-appearing newborn after a vaginal delivery are likely caused by the trauma of passing through the birth canal.

- Newborn with diffuse petechiae warrants further evaluation.

- If the child appears ill:

- Sepsis must be strongly considered.

- If the child appears well:

- Platelet disorder should be considered.

- With petechiae or purpura the possibility of a hemostatic defect is always a concern.

- For isolated petechiae, the clinician must consider a primary platelet disorder:

- Low platelet number
- Platelet dysfunction

- Purpura may result from a platelet disorder or other coagulation defect.

- Can be classified as primary or as a secondary phenomenon from an underlying disease

- Platelet disorders can be classified as disorders of:

- Platelet production
- Platelet survival (destruction)
- Platelet function

- Clinician must consider thrombocytopenia as the proximate cause.
- Normal platelet count is 150,000–450,000/mm³.
- Low platelet counts
 - >80,000: child will be hemostatically normal as long as platelet function is not altered.
 - 50,000–80,000: increased bleeding with trauma is likely, but spontaneous bleeding would be unusual.
 - 20,000–50,000: a mild bleeding diathesis is expected.
 - <20,000, spontaneous mucosal bleeding can occur.
 - <10,000: spontaneous severe bleeding is a danger.

Infectious causes of petechiae and purpura

- Mechanism by which a variety of viruses cause thrombocytopenia is not clear.
 - May involve:
 - Decreased platelet production
 - Immune-mediated destruction
 - Live-virus vaccinations can cause moderate thrombocytopenia.
 - Varicella
 - Measles
 - Cytomegalovirus has been implicated in thrombocytopenia.
 - Treatment of cytomegalovirus has not affected the outcome of patients monitored for chronic thrombocytopenia.
 - Parvovirus has been associated with:
 - Isolated thrombocytopenia
 - Pancytopenia
 - Dengue fever and other viral hemorrhagic fevers are known to cause thrombocytopenia.
 - Patients may develop petechiae and purpura as a result.
 - Rickettsial diseases such as Rocky Mountain spotted fever may produce a petechial rash.
 - Alterations of the endothelial lining of blood vessels cause:
 - Thrombi formation
 - Platelet destruction
 - Thrombocytopenia and disseminated intravascular coagulation (DIC) may develop.
 - Malaria can cause either mild or profound thrombocytopenia; mechanisms are not well defined.
 - HIV has been associated with thrombocytopenia resulting from bone marrow suppression.
 - Poor production
 - Immune-mediated destruction
- Platelet consumption is common in children with bacteremia and sepsis before frank DIC has developed.

- In an ill-appearing child with petechiae or purpura:
 - Infectious causes must be considered.
 - Appropriate antibiotics administered based on likely pathogens
- Bacterial meningitis must be considered for the febrile child with petechiae or purpura.
- Purpura fulminans has been associated with
 - Viral infections
 - *Streptococcus*
 - *Meningococcus*
- Microscopic thromboses in arterioles result in
 - Purpura
 - Infarction
 - Bleeding within the skin and subcutaneous tissue
- These lesions may coalesce and become necrotic.
 - Patients typically develop full DIC.

Disorders of platelet production: malignancy and bone marrow failure syndrome

- Most patients with petechiae or purpura have a benign process.
 - The greatest concern for clinician and parents is malignancy.
- History must rule out the classic signs and symptoms of malignancy:
 - Fevers
 - Night sweats
 - Weight loss
 - Lymphadenopathy or other masses
 - Pallor
 - Malaise
 - Bone pain
 - Anorexia
- Many of these symptoms overlap with those seen in infectious and autoimmune processes.
- Petechiae or purpura in the setting of hepatosplenomegaly or impressive lymphadenopathy would put leukemia high on the differential diagnosis.
- Other marrow infiltrating malignancies must be considered.
 - Chest radiograph should be obtained immediately.
 - Patients may have occult but massive mediastinal lymphadenopathy.
- Petechiae and purpura may be the presenting signs in patients with bone marrow failure secondary to nonmalignant processes.
 - Abnormal hematopoiesis usually causes *pancytopenia*, defined as alteration of more than one cell line, or even all cell lines.

- Bone marrow failure may occur secondary to:
 - Infectious processes
 - Viral
 - Bacterial with sepsis
 - Medication use, notably a variety of antibiotics and anticonvulsants
 - Profound nutritional deficits
 - Rare bone marrow failure syndromes
 - Fanconi anemia
 - Myelodysplastic disease
 - Wiskott-Aldrich syndrome
- Indicated to rule out malignancy and define abnormal hematopoiesis
 - Bone marrow aspiration
 - Biopsy

Disorders of platelet function: primary platelet disorders

- Petechiae and purpura may result from a primary platelet disorder.
- Qualitative disorders result from platelet dysfunction.
 - Absolute platelet number is normal.
 - Platelets lose normal hemostatic function.
 - In most instances, platelet dysfunction is acquired from medication use.
 - Classic example is aspirin, which causes irreversible inhibition of cyclooxygenase within platelets.
 - Other causes of acquired platelet dysfunction
 - Uremia
 - Liver disease
 - Mechanisms of poor platelet function in these settings are not clear.
- von Willebrand disease
 - Typically produces mucocutaneous bleeding
 - Should be considered in patients who have:
 - Petechiae and purpura
 - Normal platelet count
 - No other obvious systemic disease
 - Most common bleeding disorder
 - Affects ~1% of the population.
 - Establish the diagnosis with:
 - Coagulation screening
 - Factor VIII and von Willebrand factor assays
- Variety of rare platelet function disorders
 - Can be considered in patients with:
 - Normal platelet number
 - Bleeding
 - Petechiae or purpura

- Can be diagnosed with:
 - Specialized platelet aggregation studies
 - Morphologic study of platelets
- These disorders are rare.

- Hematology consultation should be made to define disorders such as:

- Glanzmann thrombasthenia
- Bernard-Soulier syndrome
- Hermansky-Pudlak syndrome
- Chédiak-Higashi syndrome

Disorders of platelet survival (destruction)

- Isolated thrombocytopenia in an otherwise well child may lead to petechiae or purpura as the chief complaint.
- Idiopathic (or immune) thrombocytopenic purpura is a diagnosis of exclusion.
 - Produces profound isolated thrombocytopenia and petechiae or purpura
 - Few other findings on physical examination
 - Laboratory workup should be normal except for thrombocytopenia.
 - No other blood cell line is affected.
 - Microscopic review of the blood reveals platelets that are too few in number but large in size.
 - Indicates that they are young
 - Platelet lifespan is reduced to minutes or hours rather than the normal several days.
 - Incidence is highest in children 2–8 years of age.
 - Formerly, clinicians performed bone marrow aspirates to rule out malignancy or other bone marrow failure syndromes.
 - Most now believe that the diagnosis can be made clinically.
 - Bone marrow studies rarely are indicated.
- Typically, one-third of the total body platelet mass is sequestered within the spleen at any time.
 - Whatever the cause of increased spleen size, mild thrombocytopenia may result.
 - Common causes of hypersplenism include:
 - Liver disease
 - Variety of infections, such as Epstein-Barr virus, malaria
 - Metabolic diseases, such as Gaucher disease
 - Hypersplenism alone does not typically cause platelet counts <50,000.
 - Alternative explanations should be considered for patients with moderate–severe thrombocytopenia.

- Henoch-Schönlein purpura
 - Autoimmune vasculitic syndrome
 - Produces purpura in most patients
 - Classic distribution is on the buttocks and legs.
 - May be more disseminated
 - Other findings in Henoch-Schönlein purpura
 - Arthritis
 - Arthralgias
 - Abdominal pain
 - Renal impairment
- Hemolytic-uremic syndrome
 - Produces a constellation of findings:
 - Thrombocytopenia
 - Hemolytic anemia
 - Renal failure
 - Associated with a variety of infections, most notably *Escherichia coli* O157:H7
- Thrombotic thrombocytopenic purpura
 - Distinct syndrome rarely seen in children
 - Shares some clinical features with hemolytic-uremic syndrome
 - Findings include:
 - Purpura
 - Thrombocytopenia
 - DIC
 - Hemolytic anemia
 - Elevated lactate dehydrogenase
- Giant vascular malformations may cause intravascular destruction of platelets.
 - Kasabach-Merritt syndrome is classic example of a giant hemangioma causing severe thrombocytopenia secondary to platelet destruction.
 - Lesions usually are readily apparent.
 - Multiple smaller vascular malformations that are more difficult to define may cause platelet destruction.
 - Thrombocytopenia or altered hemostasis may be associated with rare vascular disorders and connective tissue syndromes, such as
 - Hereditary telangiectasias
 - Ehlers-Danlos syndrome
 - Marfan syndrome
 - Osteogenesis imperfecta

LABORATORY EVALUATION

- History and physical examination dictate the appropriate laboratory evaluations.
- At minimum
 - Complete blood count with platelets and differential count
 - Prothrombin time and partial thromboplastin time
- If the history or physical examination is consistent with a malignancy, the following should be obtained immediately:
 - Complete blood count
 - Screening coagulation studies
 - Comprehensive metabolic panel
 - Liver function tests
 - Lactate dehydrogenase
 - Uric acid
 - Manual differential count of the peripheral blood
- Absence of leukemic blasts on a peripheral blood smear does *not* rule out leukemia.
- Diagnosis of leukemia can be made if peripheral blasts are present.
 - Having few or no peripheral blasts seen on routine microscopy is not uncommon for patients with leukemia.
- Isolated profound thrombocytopenia is not likely to result from a malignancy.
- When >1 cell line on a blood count is abnormal, bone marrow process must be considered.
- Laboratory findings consistent with malignancy include:
 - Elevated lactate dehydrogenase
 - Elevated uric acid
 - Abnormal serum electrolytes
 - May result from tumor lysis even before therapy is started

WHEN TO REFER

- Platelet count <100,000/mm³
- Diffuse petechiae or purpura
- Focal petechiae
- Purpura not clearly associated with trauma
- Evidence of >1 cell line abnormality on complete blood count

WHEN TO ADMIT

- Toxic-appearing patient
- Moderate to severe bleeding
- Concern for poor adherence

Pharyngitis and Tonsillitis

DEFINITION

- *Pharyngitis* implies inflammation of throat with or without presence of exudate.
- *Tonsillitis*, *tonsillopharyngitis*, and *pharyngotonsillitis* are used when tonsils are affected.

EPIDEMIOLOGY

- Prevalence
 - Acute pharyngitis is a very common diagnosis in pediatric practice.
 - Exceeded only by otitis media and viral upper respiratory tract infections
 - Most common diagnosis requiring treatment with antibiotics in school-age children
- Seasonality
 - Pharyngitis caused by coxsackievirus A and echovirus is common in late summer or early fall.
- Relative prevalence of infectious agents
 - Adenoviruses account for up to 23% of cases.
 - Epstein-Barr virus (EBV) is a copathogen of group A β -hemolytic *Streptococcus* (GABHS) in 5–10% of cases.
 - Herpes simplex viruses
 - Studies in a college-aged population showed that herpes simplex virus types 1 and 2 account for 5.7% of pharyngitis cases.
 - GABHS
 - Not fully recognized as a frequent cause of pharyngitis with possibility of subsequent rheumatic fever until the 1940s
 - In children <3 years, GABHS is the cause of tonsillopharyngitis in <3% of cases.
 - In children >3 years, GABHS is the cause of 15–20% of pharyngitis episodes.
 - Ingestion of GABHS-contaminated food has led to outbreaks of pharyngitis.
 - *Corynebacterium diphtheriae*
 - Now rare in North America
 - Still being reported in some developing countries
 - *Haemophilus influenzae* type b (Hib)
 - As many as 20% of sampled tonsils have Hib infection.
 - In recent years, most infants in the US have Hib immunization.
 - Because of immunization, the organism may be less likely to play a role in pathogenesis of acute tonsillitis and pharyngitis.
 - *Arcanobacterium haemolyticum*
 - Causes ~7% of tonsillopharyngitis cases in adolescents and young adults

- *Mycoplasma pneumoniae*
 - In school-age children, as much as 5% of pharyngitis may be caused by this organism.

ETIOLOGY

Viruses

- Pharyngitis and tonsillitis are most commonly caused by viral agents.
 - Associated with upper respiratory tract symptoms, such as conjunctivitis, nasal congestion, and rhinorrhea
- Adenoviruses
 - At least 12 different types have been found to cause pharyngitis in children and adolescents.
 - Cause both nasopharyngitis and tonsillitis
 - Adenovirus type 3 causes the unique clinical illness pharyngoconjunctival fever.
- Enteroviruses
 - Coxsackievirus A and echovirus have been shown to cause pharyngitis.
 - Various strains of coxsackievirus A and B cause herpangina.
- EBV
 - Etiologic agent of infectious mononucleosis
 - Frequently causes a severe exudative pharyngitis
- Other viruses (though pharyngitis is usually not the primary manifestation of the illness) include:
 - Herpes simplex virus
 - Influenza
 - Parainfluenza
 - Respiratory syncytial virus
 - Human metapneumovirus
 - Measles
 - Coronavirus
 - Rhinoviruses

Bacteria

- Many primary care physicians associate pharyngitis and tonsillitis with bacterial origins.
 - However, GABHS and other bacterial agents are highly unlikely causes.
- GABHS is the most frequent bacterial cause.
 - GABHS can be divided into M and T serotypes, which have been associated with:
 - Rash of scarlet fever (GABHS T4)
 - Development of rheumatic fever (GABHS M3 and M18)
 - Pharyngitis caused by GABHS characteristically begins after a 2- to 5-day incubation period.
 - Usually after exposure to another individual who has the infection

- Spread occurs by way of respiratory secretions.
- Fomites have occasionally been shown to be vectors.
 - Shared silverware
 - Household cats (but not dogs)
- Other groups of *Streptococcus* (B, C, F, and G) have been associated with pharyngitis.
- *Neisseria gonorrhoeae*
 - Acquired from oral sex
 - Seek as cause of pharyngitis in sexually active adolescents or sexually abused children.
- Hib
 - Possible involvement of Hib organism in pharyngitis and tonsillitis (controversial)
 - Evidence suggests that it may contribute to infection in some children, especially those with recurrent tonsillitis.
- *Mycoplasma pneumoniae*
 - Causes mild pharyngitis in children
 - Associated with a laryngotracheitis or progressing to bronchitis or pneumonia
- Other bacteria include:
 - *C diphtheriae*
 - *A haemolyticum*
 - *Actinomyces*
 - *Chlamydia trachomatis*
 - *Chlamydia pneumoniae*
 - *Yersinia enterocolitica*
 - *Coxiella burnetii*
 - *Francisella tularensis* (oropharyngeal tularemia)
 - *Mycoplasma hominis*

Fungi

- *Candida* infection
 - Uncommon cause of pharyngitis in the healthy host
 - Can be seen in immunocompromised patients and in those taking corticosteroids

RISK FACTORS

- Exposure to cigarette smoke
 - Smoke itself has not been reported to cause pharyngitis or tonsillitis.
 - A significant association has been found between parental smoking and incidence of tonsillectomy in children.
 - Children of smokers also had a much higher frequency of attacks of acute tonsillitis compared with children in a smoke-free environment.

SIGNS AND SYMPTOMS

- A clinical complaint of sore throat indicates some degree of pharyngitis.

Viral causes

- Nasopharyngitis and tonsillitis caused by adenoviruses can be exudative.
- Pharyngoconjunctival fever
 - Cough
 - Myalgias
 - Conjunctivitis
- Herpangina
 - Typified by pharyngitis associated with small, shallow, ulcerated areas on soft palate and peritonsillar
 - Coxsackievirus A and echovirus
 - Often accompanied by respiratory symptoms
- EBV
 - White, shaggy membrane on tonsils and palatal petechiae
 - In older children, EBV infection is accompanied by:
 - Fever
 - Adenopathy
 - Malaise
 - Swelling of the eyelids
 - Hepatosplenomegaly
- Herpes simplex virus
 - Most oral colonization and covert infection with herpes simplex virus type 1 is asymptomatic.
 - Virus can cause painful gingivostomatitis and pharyngitis in ~1% of infected children.

Bacterial causes

- GABHS
 - Sudden onset of:
 - Fever
 - Sore throat
 - Dysphagia
 - Other associations include headache and abdominal pain.
 - Examination of throat reveals an erythematous pharynx and tonsillar area.
 - Often with exudate present
 - Small petechiae (enanthem) are sometimes seen on uvula and soft palate.
 - Cervical lymph nodes are usually enlarged and tender.
 - Symptoms can last for 4–5 days.
 - Gradually subsiding when no antibiotic therapy is instituted
 - Key findings
 - Red throat or tonsils and/or exudative tonsils
 - Swollen and usually tender anterior cervical nodes
 - Fever
 - Scarlet fever rash

- *N gonorrhoeae*
 - Exudative tonsillitis is rarely seen with pharyngitis caused by *N gonorrhoeae*.
- *C diphtheriae*
 - Characteristic gray pseudomembranous exudate over the posterior pharynx and tonsils
- *A haemolyticum*
 - Physical findings are identical to those seen with GABHS infection.
 - Includes a scarlatiniform rash present in ~20% of cases
 - Sore throat may persist until patients are treated with antibiotics.

DIFFERENTIAL DIAGNOSIS

- Sore throats are common in children.
 - May be sole finding in an illness
- Streptococcal infections should be considered in children >3 years who have pharyngitis.
 - Even if no exudate is present
 - Pharyngitis associated with nasal, chest, or cold symptoms is much more likely to be a viral illness.
- In atypical pharyngitis, either in duration or severity, suspect:
 - Infectious mononucleosis
 - 1 of the rarer bacterial causes
 - Including those that are sexually transmitted
- Peritonsillar abscess or cellulitis also may cause a sore throat.
 - Thorough examination will reveal:
 - Swelling extending into the soft palate
 - Deviation of the uvula
 - Change in tonal quality of the voice
- Postnasal drip from viral respiratory tract infection or allergies has been thought to irritate the posterior pharynx.
 - This finding is not well documented.
- Allergies may lead to chronic inflammation of the mucous membranes, which might include the pharynx.
 - Pharyngitis would be infrequent as the sole manifestation.
- Epiglottitis
 - Diagnosis that must not be missed
 - Can be life threatening
 - The child with epiglottitis:
 - Has severe throat pain
 - Rapidly becomes ill
 - Appears to have a toxic condition
 - Experiences respiratory distress accompanied by stridor or a croupy cough
- Kawasaki disease
 - Unknown cause

- Occurs mostly in preschool children who have:
 - Pharyngitis associated with erythema and fissuring of the lips
 - Palmar and pedal edema
 - Erythema
- An association with staphylococcal toxin has been postulated, as have other viral and bacterial etiologies.

- Oral thrush
 - In otherwise healthy children, severe mouth pain can occur.
 - May be interpreted as a sore throat
- Pharyngitis may be associated with other inflammatory conditions of the mucous membranes.
 - Herpes gingivostomatitis
 - Herpangina
 - Stevens-Johnson syndrome

DIAGNOSTIC APPROACH

- The major step is to establish whether GABHS is the responsible pathogen.
 - Almost all children >3 years need to be examined to rule out GABHS as the cause.
 - Multiple studies have shown that streptococcal pharyngitis cannot be distinguished purely on clinical grounds.

LABORATORY FINDINGS

Rapid streptococcal test and cultures

- Traditional method for determining whether cause of pharyngitis or tonsillitis is viral or GABHS: obtain a throat swab and perform a culture.
 - With availability of rapid streptococcal tests, the process was made simpler.
 - Allows a result to be obtained in minutes rather than waiting 1–2 days
 - Strict federal guidelines for office laboratories require certification for use of these rapid tests.
 - Most clinicians now perform a rapid streptococcal diagnostic test on all patients whose pharyngitis is suggestive of GABHS.
- Various rapid streptococcal tests claim differing levels of specificity and sensitivity.
 - Appear to be specific (95–98%)
 - Sensitivity can be as low as 70–85%.
 - Some cases of GABHS are not detected.
 - Positive rapid streptococcal test result is a sufficient indication to treat the patient.
- Culture should be sent if:
 - Rapid test result is negative, but high index of suspicion exists that GABHS is the causative agent.

- Throat culture is not necessary:
 - If little clinical evidence of pharyngitis or tonsillitis can be found in a child with sore throat
 - In patients with manifestations highly suggestive of viral infection
 - Coryza
 - Conjunctivitis
 - Cough
 - Hoarseness
 - Herpangina
 - Stomatitis
 - Sindbis virus
- Some individuals are *Streptococcus* carriers.
 - They may be found to be positive for *Streptococcus* infection during a viral illness.
 - An asymptomatic *Streptococcus* carrier does not need to be treated.
 - When symptoms are present, most physicians treat these individuals.
 - Difficult to ascertain that GABHS is not the cause of illness
 - Performing pre- and post-illness rapid streptococcal tests or cultures on every child who presumably has GABHS pharyngitis is impractical.
 - All those who test positive are treated.

Serologic tests

- If EBV infection is suspected, a heterophile antibody or specific EBV test can be ordered.
 - Ascertain with the reference laboratory whether an immunoglobulin (Ig)G or IgM test has been performed.
 - A positive heterophile test result may confirm only that children were exposed sometime in their life to EBV.
 - Tests of specific IgG and IgM antibody to various components of EBV are available.
 - Usually expensive and slow to produce results
 - Less-than-ideal test to determine cause of acute pharyngitis
- Serologic tests exist to determine recent streptococcal infections.
 - Rarely helpful in evaluating for acute pharyngitis
 - Antistreptolysin-O titer is used more commonly in diagnosing rheumatic fever.
 - Documents recent exposure to streptolysin with production of antibody

Leukocyte count

- Only real value in performing is if infectious mononucleosis is suspected
 - Patients with acute EBV infection tend to have relative lymphocytosis.
 - 10–20% atypical lymphocytes

- The leukocyte count may be a helpful diagnostic study.
 - Combine with heterophile or specific EBV antibody test for children who have severe pharyngitis and are culture negative for GABHS

TREATMENT APPROACH

- Pharyngitis caused by viruses generally is treated symptomatically with:
 - Saline gargles
 - Throat lozenges
 - Analgesics, such as acetaminophen
- When GABHS has been documented, either by positive rapid *Streptococcus* test or by culture, antibiotics are indicated primarily to prevent subsequent development of rheumatic fever.
 - Early antibiotic treatment will shorten duration and severity of symptoms by 24–36 hours.
 - Patients should be kept out of school and avoid close contact with family and friends for only 24 hours.
 - Numerous studies have shown that they become culture negative after just 24 hours of antibiotic therapy.
- Controversy exists over whether to begin antibiotics for presumptive GABHS pharyngitis while waiting for culture results.
 - Rheumatic fever can be prevented even if treatment is started as late as the ninth day of symptoms.
 - The decision to begin therapy immediately rests with the individual physician who knows the circumstances.

SPECIFIC TREATMENTS

Antibiotic therapy

GABHS

- The presence of GABHS mandates early antimicrobial therapy.
 - Start within 9 days of onset of symptoms
- Various antibiotic regimens have been used for GABHS pharyngitis or tonsillitis
 - Standard therapy has been a 10-day oral course of potassium penicillin or amoxicillin given 2 or 3 times a day.
 - Alternatively, intramuscular benzathine penicillin G may be given as a single injection.
 - These injections are often painful not only initially, but also for a few days afterward.
 - Patients allergic to penicillin may be given:
 - Erythromycin or a cephalosporin for 10 days *or*
 - Azithromycin for 5 days
 - Shorter courses of newer antibiotics have been studied and shown to be effective in eradicating GABHS from the pharynx.
 - Their efficacy in preventing rheumatic fever is not clear, although presumed.

- Cephalosporins have been shown to be superior to penicillin in eradicating GABHS from pharynx.

Other bacteria

- Gonococcal pharyngitis
 - 1 intramuscular injection of ceftriaxone is recommended.
 - In young children with this diagnosis, sexual abuse must be investigated.
- *A haemolyticum*
 - Clarithromycin
 - Erythromycin
 - Azithromycin
- Other possible bacterial causes of pharyngitis are treated with appropriate antibiotics, once the causative organism has been determined.

Corticosteroids

- Administration of corticosteroids to decrease pain in acute exudative pharyngitis has been studied in adults and found to provide some benefit.
- Use in children is not recommended
 - Except in rare situations, such as infectious mononucleosis infection with imminent airway obstruction

Tonsillectomy

- Parents often raise the question of tonsillectomy after a child has multiple episodes of pharyngitis or tonsillitis.
 - Tonsillectomy is not indicated in children with recurrent pharyngitis except:
 - In cases of documented recurrent, frequent streptococcal infection
 - In those who develop peritonsillar abscess

WHEN TO ADMIT

- Toxic appearance (suspected toxic shock syndrome)
- Peritonsillar abscess
- Retropharyngeal abscess
- Acute rheumatic fever

WHEN TO REFER

- Suspected peritonsillar abscess
- Suspected retropharyngeal abscess
- Recurrent GABHS (5 episodes in 1 year) for tonsillectomy

FOLLOW-UP

- The physician must be aware of the possibility of peritonsillar or retropharyngeal abscess or cellulitis.
 - Should reexamine the throat of any patient who is not improving

COMPLICATIONS

- Most cases of pharyngitis present no unusual complications.
 - Many are viral.
 - Resolve with or without therapy
- Acute tonsillopharyngitis may progress to a peritonsillar abscess.
 - Infection begins with the typical signs and symptoms of pharyngitis, such as:
 - Sore throat
 - Dysphagia
 - Fever
 - Usually in an older child who often has a history of recurrent tonsillitis
 - Systemic symptoms may develop.
 - Malaise
 - Poor appetite
 - Chills
 - Mild dehydration
 - Symptoms progress rapidly to more severe pharyngeal symptoms.
 - Difficulty in swallowing and speaking
 - The child has a toxic appearance.
 - Trismus almost always occurs.
 - The characteristic signs are:
 - Muffled (hot potato) voice, trismus, and major leukocytosis
 - Needle aspiration can be performed only if the abscess is within the superior pole.
 - The success rate of needle aspiration compares favorably with that of incision and drainage in these type cases.
 - Computed tomography and intraoral ultrasonography are quite reliable in distinguishing abscesses from cellulitis alone.
 - Initial antimicrobial therapy is clindamycin *plus* a third-generation cephalosporin, such as:
 - Ceftriaxone
 - Cefotaxime
 - Ceftazidime
 - Routine tonsillectomy along with or after medical management is recommended.
- Other suppurative complications can also develop, such as:
 - Cervical adenitis
 - Acute otitis media
 - Sinusitis
 - Pneumonia

- Hematogenous spread of a bacterial organism is possible, which can result in:
 - Bacteremia
 - Joint, bone, or meningeal infection
- Rheumatic fever is the major complication of streptococcal pharyngitis.
 - Can be life threatening
 - Occurs some time after the acute throat infection
 - The incidence of rheumatic fever is low in North America.
 - Still occurs and has been seen in increasing numbers
- Acute glomerulonephritis is possible after streptococcal throat infections.
 - Much more likely after streptococcal skin infections
- Some evidence has shown association between GABHS infection and obsessive-compulsive disorders and tic behavior in children.
 - This clinical entity is termed *pediatric autoimmune neuropsychiatric disorder associated with group A streptococcal infection* (PANDAS).
 - Documentation is largely anecdotal.
 - Includes the observation that these children have high concentrations of antibody to streptococcal antigens
 - Small series have noted improvement in obsessive-compulsive disorder behavior or tics when these children are GABHS positive and treated with penicillin.
 - Many still question the authenticity of PANDAS.

PREVENTION

- History of parental smoking should be sought.
 - If history exists, advise measures to reduce the child's exposure to cigarette smoke.

Phimosis

DEFINITION

- *Phimosis*: unretractile foreskin

EPIDEMIOLOGY

- Prevalence
 - Problems and questions related to the foreskin of young boys are frequently seen in pediatric practices.
 - Most of the referrals made to urologists are for boys with physiologic phimosis.
 - True phimosis is uncommon: ~1 case per 1,000 boys
 - Rate obtained after looking at pathologic specimens after circumcision
 - Individuals with evidence of inflammation were counted as true phimosis.
- Age
 - In children, balanitis occurs most frequently between the ages of 2 and 5 years.

ETIOLOGY

- Pathologic phimosis is believed to have several different causes.
 - Chronic nonspecific inflammatory process
 - Repeated infections that cause scarring and stricture
 - Forcible premature retraction of the foreskin, causing scarring and adhesions
 - Balanitis xerotica obliterans (BXO): a chronic dermatitis
 - Unknown etiology
 - Causes pathologic phimosis
- Balanoposthitis
 - Most common causative organisms are:
 - *Staphylococcus*
 - Coliforms
 - *Pseudomonas*
 - *Candida*
 - Potential cause is *Streptococcus*
 - Can cause a thin purulent discharge in the preputial-glanular sulcus (but not from the urethra)
 - Associated with a red, glistening glans
 - Sexually transmitted infections (gonorrhea and chlamydia) must be considered when purulent discharge from the urethra is present.
 - Presence of sexually transmitted infections in the absence of purulent discharge is extremely unlikely in a prepubertal boy.

RISK FACTORS

- Risks for nonspecific balanitis include:
 - Poor hygiene
 - Trauma
 - Irritation from soaps or detergents

SIGNS AND SYMPTOMS

Phimosis

- Can be either physiologic or pathologic
- At birth, most boys have physiologic phimosis.
 - Inner surface of the foreskin is developmentally fused to the glans penis.
- Over time, desquamation and glanular secretions allow gradual separation of the foreskin.
- Smegma
 - The epithelial debris generated during desquamation
 - Sometimes can be seen under the foreskin as pearls
 - Requires no intervention
- Accumulations are released as the foreskin becomes more retractile.
 - May be mistaken for infection
- Retractability increases yearly.
 - By 1 year of age, 50% of uncircumcised boys have retractile foreskins.
 - By age 3, 90%
 - By age 6–7, 92%
 - By adolescence, 99%
- Lack of clear diagnostic criteria makes it difficult to distinguish pathologic from physiologic phimosis.
 - *Physiologic phimosis* is described as unretractile foreskin that is supple and unscarred.
 - On attempted retraction, foreskin lies flat against the penis and is effaced.
 - Tip opens as a flower (see Figure 59 on page F21).
 - Young boys may exhibit preputial adhesions where part of the foreskin does not completely retract.
 - No visible constricting ring
 - Not pathologic
 - Resolves on its own
 - In *pathologic phimosis*, margin between foreskin and glans is rolled and thickened.
- BXO
 - Histologically resembles lichen sclerosus et atrophicus

Paraphimosis

- Occurs when the foreskin is retracted, is not replaced immediately, and becomes trapped behind corona
 - May happen during cleaning
 - May occur during procedures such as catheterization
- Fibrous ring at the base of the corona causes venous congestion.
 - Leads to:
 - Extreme penile pain
 - Swelling of the glans with a collar of swollen foreskin at the coronal sulcus

Balanitis or balanoposthitis

- Characterized by:
 - Erythema
 - Edema of prepuce that produces purulent discharge from the preputial orifice
 - Edema can involve some of the penile shaft.
- Patients may complain of dysuria.
- Condition usually occurs when the prepuce is wholly or partially retractable.

LABORATORY FINDINGS

- Sexually transmitted infections
 - Appropriate diagnostic tests (DNA probes) should be obtained.

TREATMENT APPROACH

- Treatment approach depends on whether the phimosis is thought to be physiologic or pathologic.
 - Watchful waiting results in resolution of most cases of physiologic phimosis.
 - Treatment alternatives if child is believed to have pathologic phimosis include:
 - Topical corticosteroid cream
 - Surgery
- Choice regarding which patients should be referred and receive therapy may be unclear.
- Little agreement exists in the literature.
- Circumcision should be undertaken for:
 - BXO
 - Phimosis resistant to corticosteroid therapy
 - Voiding problems
 - Recurrent balanitis
 - Urinary tract infections
- Ballooning of the foreskin during micturition is not, by itself, a reason for circumcision.
- Most cases of phimosis probably are physiologic and will resolve spontaneously over time.

- Some urologists question whether true phimosis can exist before age 5 and question whether any treatment need be initiated.
- Others use the age of 3 years as an upper limit and initiate a trial of corticosteroid creams (if no indication for surgery) at that time.
- Argument in favor of treating children who are younger (>3 but <5 or 6):
 - Most noninvasive therapy (topical corticosteroids) is more successful in younger children than older children.
 - Compliance is greater at that age because parents are able to apply the cream.
 - When older children become responsible for cream application, compliance and success decrease.

SPECIFIC TREATMENTS**Phimosis**

- Topical corticosteroid creams
 - Multiple studies have investigated the use of topical corticosteroid creams.
 - 4- to 8-week course of therapy has been found to be approximately 85% effective.
 - High-potency corticosteroid creams such as 0.05% betamethasone have been studied the most.
 - Medium-potency topical corticosteroid (clobetasone butyrate 0.05%) has been shown to have similar resolution rates.
 - Lower-strength corticosteroid may be an option.
 - Creams are applied to the tip of the prepuce and down to its junction with the glans.
 - Twice a day for 4–8 weeks
 - Corticosteroids are believed to be therapeutic by
 - Decreasing any potential inflammation between the foreskin and glans
 - Thinning the skin, making it more supple
 - Topical corticosteroid therapy has multiple advantages over more traditional surgical management:
 - Less invasive
 - Avoids risks of surgery: bleeding, deformity, meatal stenosis
 - No anesthesia risks
 - Cost effective—25% the cost of surgery
 - Preservation of prepuce may be desired for social and cultural reasons.
 - Neurologically complex and erogenous tissue
 - Avoids potential emotional problems
 - Some boys who undergo circumcision at an older age may develop severe emotional problems.

■ Surgery

- Surgical alternatives include dorsal slit surgery or circumcision
- Dorsal slit procedure involves making a single slit dorsally in the foreskin.
 - Preserves the prepuce
 - Allows easy retraction of the foreskin
 - Surgery is less involved than circumcision.
 - Cosmetic result is not as satisfactory as with circumcision.
 - Can be complicated by scarring
- Circumcision is more commonly used.
- Forced premature retraction of the foreskin is *never* recommended.
 - May lead to significant adhesions and scarring
 - Painful
 - Traumatic

Paraphimosis

- Paraphimosis is a urologic emergency.
- Goal of treatment is to replace the foreskin in its normal position.
 - In early stages, the foreskin may be replaceable manually without sedation.
 - As condition progresses, anesthesia may be required:
 - Penile block
 - Sedation
 - General anesthesia
- Gentle persistent pressure is used to decrease edema and allow reduction of foreskin.
 - Ice packs or a compressive elastic dressing decrease swelling.
 - Sometimes, to relieve swelling
 - Incision must be made in the fibrous ring.
 - Multiple punctures must be made in the glans.

Balanoposthitis

- Local hygienic measures
 - Sitz baths
 - Gentle cleaning
 - 1% hydrocortisone cream
- If irritation does not resolve, treatment with antimicrobials may be necessary.
- Circumcision usually is considered only for recurrent episodes.

WHEN TO ADMIT

- Paraphimosis
 - Failure of manual reduction with vascular compromise of the glans
- Balanoposthitis
 - Systemic infection or sepsis
 - Inability to urinate
 - Vascular compromise of the glans

WHEN TO REFER

- Phimosis
 - Failure of topical corticosteroids
 - BXO
 - Parents desire circumcision
 - Association with urinary tract abnormalities/obstructive uropathy
- Paraphimosis
 - Failure of manual reduction
- Balanoposthitis
 - Recurrent episodes

COMPLICATIONS

- Paraphimosis
 - If no treatment is initiated, ischemia and necrosis of the glans can result.

Phobias and Anxiety

DEFINITION

■ Phobia

- Extreme and persistent fear of an object, event, or situation that in reality is not dangerous to the individual
- The feared object, event, or situation would not be of concern to most people.
- Phobias are divided into 3 categories.
 - Specific phobia
 - Social phobia
 - Agoraphobia (often associated with panic disorder)

■ Specific phobia

- Fears related to a single stimulus for ≥ 6 months
- Categories of feared stimuli commonly include:
 - Animals
 - Insects
 - Certain situations (eg, health care or dental care procedures)
 - Objects in the natural environment
- Exposure to the feared stimulus or even thoughts of the feared stimulus result in an immediate anxiety response.
 - Physiologic (tachycardia, sweating)
 - Cognitive (thoughts of being harmed)
 - Emotional reactivity (crying, tantrums)

■ Social phobia

- More complex and potentially more disabling diagnosis than a specific phobia
- Often begins in late childhood or early adolescence
- Characterized by evident fear of social or performance situations for ≥ 6 months
- The child has fears of doing or saying something that will be socially inappropriate and thus humiliating.
- Typical situations that trigger fears include:
 - Reading aloud in front of class
 - Making a telephone call
 - Joining conversation with peers
 - Going to parties
 - Ordering at restaurants
- Such children limit contacts.
- At risk for social immaturity and stigmatization by other children

■ Agoraphobia

- Fear of being in places from which:
 - Escape may not be possible
 - Help might not be available
- Often begins in late adolescence

- May be associated with:

- Panic disorder
 - Fears of panic
 - Fears of embarrassing happenings
- Individuals often progressively limit outside activities.
 - Persistent and disabling if left untreated

EPIDEMIOLOGY

■ Prevalence

- In a large-scale population studies of adults, phobias and other anxiety disorders are the most frequent psychiatric disorders occurring in the general population.

■ No comparable studies of the frequency of psychiatric disorders in childhood or adolescence have been conducted.

■ Most common specific phobias occurring in children and adolescents involve:

- Animals
- Insects
- Objects in the natural environment
 - Storms
 - Water

■ Other common phobias of closed spaces (*claustrophobia*) and heights (*acrophobia*) are much less frequent in children.

- Tend to have their origins in adulthood

■ Other common phobias are associated with:

- Injury
- Blood
- Health care
 - Injections
 - Other invasive medical procedures

■ Age

- Phobias are common in all age groups.
 - In Rutter's Isle of Wight Study, ~2.5% of children had disabling specific fears or phobias.
 - A more recent community study found specific phobias in 2.6% of children.
 - In a study of children and adolescents with anxiety disorders, except for separation anxiety disorders, specific phobias and social phobias were extremely common.
- Likely to begin before the age of 7 years

ETIOLOGY

■ Various theoretic speculations about the cause of phobias

- Early theories postulated unconscious conflicts as the source.
- Others suggest phobias are learned responses in the context of a child's experience.

- In recent years, increased emphasis has been placed on the way in which factors affect the development of childhood anxiety disorders.
 - Genetic influences
 - Temperamental predispositions
 - Parental functioning
 - Practices
- A multidimensional understanding of the cause of such childhood disturbances is crucial to best practices in diagnostic and treatment approaches.

SIGNS AND SYMPTOMS

Relevant history

- A complete history will usually help define possible diagnoses in the primary care setting.
- Further assessment should be prompted by reports of:
 - Fearful behavior
 - Symptoms of anxiety
 - Development of avoidance behavior or compulsions
 - Repetitive, purposeful, intentional behaviors in response to fears or obsessions
- Some important areas to screen include:
 - Onset of symptoms, including review of recent life changes (deaths, births, moves)
 - Specific history of symptoms and associated behaviors
 - Circumstances in which symptoms occur
 - Responses of parents, teachers, peers, and others to symptoms
 - Review of the patient's general pattern of psychosocial development
- Children, and more commonly adolescents, may recognize that their fear is irrational.
 - May invent another reason for avoidance behavior
 - The possibility of a traumatic experience with the phobic object should be explored.
 - Frightening experience
 - Being lost
 - Threatened
 - Abused
- Social anxiety can sometimes produce depressive symptoms that mask anxiety symptoms.
 - Use of a brief screening instrument can help the primary care physician identify anxiety symptoms.
 - Depending on the level of impairment, the primary care physician can decide whether to:
 - Intervene
 - Consult
 - Refer to a mental health specialist

- Practitioners should review available screening instruments to determine which best fits their practice.
- Consultation with mental health care provider can help selection.
- Self-report for Childhood Anxiety Related Emotional Disorders
 - 41 items
 - Takes an average of 5 minutes to complete
 - Can be used with children age ≥ 8 years
- The Liebowitz Social Anxiety Scale—Child Adolescent Version screens for social anxiety symptoms.
 - 24 items
 - Takes an average of 10–20 minutes to complete
 - Can be used with children age ≥ 7 years
- Providing results of initial screening and assessment to mental health care specialist is helpful.
 - Especially if the primary care practitioner has an established relationship with the patient
- Children do not typically realize their fears are unreasonable.
- In extreme cases, panic may occur for adolescents.
- The degree to which avoidance or anticipatory anxiety occurs is often a critical factor in parents' seeking help.

Physical

- Thorough physical examination should be completed if physical problems are likely.
- Producing symptoms similar to anxiety
 - Hypoglycemia
 - Hyperthyroidism
 - Pheochromocytoma
- Withdrawal from some abused substances may be associated with episodes of severe anxiety.
- Side effects from prescribed medications may produce similar symptoms.
- Key symptoms of phobias include avoidance of the fear-provoking object or situation and fear often associated with:
 - Sweating
 - Tachycardia
 - Difficulty in breathing
 - Light-headedness or dizziness
- According to the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)*, children may express anxiety by:
 - Crying
 - Tantrums
 - Clinging
 - Freezing

DIFFERENTIAL DIAGNOSIS

Phobias and development

- Some fears are common and expected at various developmental levels.
 - Stranger anxiety
 - Seen at ~8 months of age
 - Decreases around the middle of 2nd year
 - Toddlers are commonly fearful of being left alone or with babysitters.
 - Preschool children are afraid of the dark.
 - Parents often do not consult physicians about these common fears.
- Many children have fears that meet criteria for a diagnosis of specific phobia, but then disappear without specific intervention.
 - Avoidance behavior associated with a phobia may interfere with:
 - Usual activities
 - Productive social relationships
 - Animal phobias may prevent a child from:
 - Playing with neighbors
 - Attending after-school activities
 - When a particular specific phobia disappears spontaneously, consequences linger.
 - Missed opportunities
 - Embarrassment
 - Interference with social development
- Social phobias commonly occur in adolescence as the importance and impact of peer interactions emerges.
 - Teenagers turn toward peers to help with identity development.
 - This process can be interrupted if adolescent has intense fears about social interactions.

Psychiatric disorders

- As defined by the *DSM-IV-TR*, other psychiatric disorders have overlapping symptoms.
- Separation anxiety disorders
 - Children are afraid of leaving parents or others to whom they are attached.
 - Fear something may happen to parents when they are not present
 - Fear of the dark, animals, or objects
 - Unlike a specific phobia, the added fear of separation from loved ones exists.
 - School phobia or school refusal is a specific manifestation.

- Selective mutism
 - Persistent failure to speak in certain social situations
 - The child will talk in other situations.
 - Rare
 - Usually occurs by 5 years of age
 - Lasts for ≥ 1 month
 - Typically lasts a few months
 - Disorder can last several years (uncommon).
 - Should not be diagnosed if the child is encountering a significant transition
 - First month of a school term
 - Recent immigration to a new country
 - Should be diagnosed only in a child who has demonstrated ability to speak at the appropriate developmental level in more familiar social situations
 - Social anxiety and social avoidance associated with social phobia may be present in children with selective mutism.
 - In this case, both diagnoses would be appropriate if the child's symptoms meet the criteria for social phobia.
- Generalized anxiety disorders
 - The essential feature is excessive or unrealistic anxiety or worry for ≥ 6 months.
 - Worries are considered uncontrollable by the patient.
 - Significantly interfere with daily functioning
 - Phobias are often present.
 - Global disorder with fewer focused fears
- Obsessive-compulsive disorder
 - Avoidance behaviors are associated specifically with the content of obsession, rather than a feared stimulus.
 - Dirt
 - Contamination
 - May develop to neutralize or prevent the occurrence of anxiety or worry
 - Repetitive, purposeful, intentional behavior
- Posttraumatic stress disorder
 - Develops subsequent to experiencing a traumatic stressor
 - Symptoms include:
 - Reexperiencing the trauma
 - Flashbacks
 - Witnessing a similar event
 - Frightening dreams
 - Repetitive play in which the child expresses themes or aspects of the trauma
 - Restricted affect

- Acute stress disorder may be diagnosed if disturbances related to the trauma persist.
 - Minimum of 2 days
 - Maximum of 4 weeks
 - Occur within 4 weeks of the traumatic event
 - Hypochondriasis
 - Distinguishing between specific phobia (blood-infection-injury type) and hypochondriasis depends on the presence or absence of disease conviction.
 - People with hypochondriasis are preoccupied with fears of having a disease.
 - Individuals with a specific phobia fear contracting disease.
 - Do not believe it is already present
 - Vasovagal fainting response is typical for a phobia of the blood-infection-injury type.
 - Not common for hypochondriasis
 - Additional psychiatric factors
 - Avoidance behaviors or phobias may be present with:
 - Other anxiety disorders
 - Depressive disorders
 - Substance abuse
 - Psychotic disorders
 - Symptoms of these other disorders are typically the focus of treatment.
 - Tend to produce more distress and impairment of daily functioning than symptoms of phobias
- TREATMENT APPROACH**
- Treatment of phobias includes:
 - Thorough assessment
 - Initial intervention
 - Short-term follow-up
 - If phobia persists:
 - Further assessment
 - Potential consultation
 - Referral to a mental health specialist
 - The primary care physician should inform the patient and parents of diagnosis and treatment.
 - Parents need to be partners in treatment.
 - Without intending to do so, parents can reinforce and perpetuate symptoms by allowing the child to avoid the feared stimulus.
 - Family therapy can provide additional treatment opportunities by:
 - Offering education to parents about the diagnosis
 - Strengthening the child's coping skills
 - Improving familial support
 - Helping the family cope with any recent life transitions
 - Addressing best-parenting practices
 - When evaluating and treating patient, developmental issues should be considered.
 - Children may exhibit phobic behaviors, such as a fear of the dark.
 - Common
 - Likely to be self-limited
 - Provide a nightlight and use simple cognitive self-control strategies.
 - Relaxation
 - Visualizing a pleasant scene
 - Teaching the child positive self-statements, such as, “I am brave; I can take care of myself in the dark.”
 - More likely, the phobia will abate spontaneously over time.
 - Systematic desensitization can be difficult to establish because of:
 - Complexity of anxiety-provoking stimuli
 - Social immaturity of patient
 - Range of psychotherapeutic interventions may be used to promote socialization and improve social skills
 - Cognitive-behavioral individual therapy
 - Family therapy
 - Group therapy with age-appropriate peers
 - In vivo exposure with response prevention
 - Most effective treatment for agoraphobia with and without panic attacks
 - Effectiveness ranges from 60–70%
 - Booster sessions for symptoms of panic are usually necessary.
 - Anticipatory guidance plays an important role in:
 - Recognizing
 - Diagnosing
 - Treating
 - In many instances, the child would rather avoid discussing fears.
 - In some cases, parents may not recognize avoidant and anxious behavior as something that should be reported.
 - Routine screening for fears that might interrupt or impair normal development should be included when treating children and adolescents in primary care.
 - Well-child visits provide a good opportunity for such screening.

SPECIFIC TREATMENTS

Cognitive-behavioral therapy

- Patients typically treated by a mental health specialist with systematic desensitization.
 - Approach includes a combination of progressive exposure to feared stimulus using:
 - Hierarchy of fears (ranked by the patient according to level of anxiety)
 - Relaxation techniques
 - As anxiety occurs in response to actual feared (in vivo) or imagined (in vitro) stimulus, relaxation techniques are invoked and stimuli removed.
 - The feared stimulus will gradually become paired with a relaxed state instead of an anxious state.
- Other behavioral approaches used by mental health specialists can enhance the effectiveness of systematic exposure, including use of:
 - Behavioral contracts
 - Modeling procedures
- Getting a child to participate in deliberate exposure to a feared stimulus is often difficult for parents.
 - Contracts can increase the patient's compliance by using specific contingencies to reinforce positively desired behavior toward the feared stimulus.
 - Contracts can ensure treatment plans are followed consistently outside of the office by patient and family.
 - Modeling includes direct observation of the desired behavior.
 - Not avoiding feared stimulus
 - Demonstrated by practitioner, family members, or peers
 - Initially show a comparable level of fear, which they are able to overcome

Psychopharmacologic therapy

- Psychiatric consultation is typically considered when:
 - The child is in so much distress ability to function is significantly impaired.
 - The condition prevents success with cognitive-behavioral treatment.
- Medications are usually used in combination with behavioral interventions.

- Medications of choice for majority of children and adolescents
 - Anxiolytics
 - Antidepressants

Other therapy

- Social phobia and agoraphobia are difficult to treat.
 - Often require psychological treatment and pharmacotherapy

WHEN TO ADMIT

- If a comorbid condition exists that is threatening the safety of the patient or others, psychiatric admission may be necessary to stabilize the patient.

WHEN TO REFER

- Psychological consultation is indicated if initial treatment does not result in symptom relief.
- May result in a need for further assessment, including referrals for:
 - Cognitive-behavioral psychotherapy
 - Psychiatric consultation
 - Both
- Maintaining collaboration with referral sources helps coordinate treatment planning.

PROGNOSIS

- Most phobias in children and adolescents seem to respond to treatment.
- Lack of controlled studies creates difficulty in attributing remission clearly to treatment.
- Follow-up studies are limited.
 - Those that exist suggest a positive long-term outcome.
 - Adults seeking treatment for phobias and other anxiety disorders often report onset of a phobia or similar symptoms during childhood or adolescence that diminished or disappeared for some time.
- The prognosis for children and adolescents with social phobia is less clear.
 - Experience suggests that these disorders are less likely to remit spontaneously or as a consequence of treatment.
 - Agoraphobia has a more guarded prognosis than social phobia.

Pinworm Infestations

DEFINITION

- Pinworm is a condition caused by an infestation with *Enterobius vermicularis*.

EPIDEMIOLOGY

- Prevalence
 - *E. vermicularis* infestation is exceptionally common.
 - Adults are often infested.
 - Can be found in at least 30% of children worldwide
 - Finding pinworms in all members of a family is not uncommon.
 - Infestation rates may approach 100% in:
 - Day care centers
 - Boarding schools
 - Institutions
- Socioeconomic factors
 - Good sanitation and advanced socioeconomic status are feeble deterrents.

ETIOLOGY

- *E. vermicularis*
 - A white, threadlike worm that lives primarily in the cecum and adjacent bowel
 - Gravid female worm
 - Approximately 1 cm long
 - Migrates to perianal area to deposit up to 10,000 eggs
 - Dies shortly thereafter
 - Infestation would be self-limited were it not for reinfestation.
 - Eggs are:
 - Approximately 50 × 30 μm
 - Oval
 - Flat on 1 side
 - Thin shelled
 - Become infective in approximately 6 hours
- Eggs are hardy and may survive for weeks in:
 - Dirt
 - House dust
 - Clothing
 - Bed sheets
- Survival is enhanced by:
 - Lower temperature
 - Inhalation or swallowing
- Pets may carry eggs in their fur.

- Once ingested, the eggs hatch in the upper small intestine.
 - Worms mature while migrating to the lower ileum and ascending colon.
 - Cycle from ingestion to deposition of eggs is ~4–6 weeks.
 - Adult worms may live up to 13 weeks.
 - The worm burden within an individual may reach the hundreds.
 - In an infested population, most individuals would be harboring few parasites.

RISK FACTORS

- Inadequate hand washing after contact with perianal area

SIGNS AND SYMPTOMS

- One-third or more of infestations are asymptomatic.
- Signs and symptoms include:
 - Localized perianal pruritus (most commonly reported symptom)
 - Restlessness
 - Fitful sleep
 - Secondary excoriation
 - Serratitis
 - Genitourinary symptoms
 - Migrating pinworms may enter the vagina or urinary tract in female patients.
 - Granulomatous reaction (rare)
 - Granulomas-containing worms have been an incidental finding in the:
 - Gut
 - Vulva
 - Cervix
 - Fallopian tubes
 - Peritoneum
 - Bladder
 - Appendicitis and eosinophilic colitis (rare)
 - Inflammation associated with the parasite has been found in these conditions.
 - Lack of abdominal symptoms supports the notion of minimal gastrointestinal abnormality with this parasite.

DIAGNOSTIC APPROACH

- Diagnosis is dependent on identifying either adult worms or eggs.
 - Eggs are seldom found in feces even using concentration techniques.
 - The best way to make a diagnosis is to use the cellophane tape technique.
-

LABORATORY FINDINGS

- Cellophane tape technique to visualize pinworm eggs
 - When the child awakens in the morning, press the adhesive side of a 2-inch strip of clear cellophane tape against the perianal skin using a tongue depressor.
 - Commercially produced kits are available for this purpose.
 - Tape is then placed on a microscope slide with the adhesive side down.
 - Eggs are naturally transparent.
 - Staining with lactophenol cotton blue enhances detection.
 - A single test should detect at least 50% of infestations.
 - 3 will detect 90%.
 - 5 will detect virtually 100%.

TREATMENT APPROACH

- Eradication is extremely difficult because of:
 - Ubiquity, infectivity, and persistence of the parasite
 - High level of infestation in symptomatic patients
- Vigorous pursuit of a permanent cure may provoke needless turmoil and anxiety in the family.
- The most important aspects of treatment:
 - Humility on the part of the physician
 - Reassurance of the family

SPECIFIC TREATMENTS

Pharmacologic treatment

- Reasonable to treat either a confirmed individual patient or the entire family
 - Single dose of either mebendazole (100 mg for all ages) or albendazole (400 mg for all ages)
 - Extremely effective and has virtually no side effects
 - Pyrantel pamoate administered as a single dose of 11 mg/kg (maximum 1 g)
 - Effective
 - Transient headache and abdominal symptoms have been reported.
- Treatments are effective against adult worms only.
 - Therapy is usually repeated in 2 weeks to eradicate emerging parasites.

General measures

- Clipping the fingernails (a repository for eggs)
- Frequent hand washing
- Daily morning showers
- Tight-fitting cotton underpants
- Bland ointment (eg, petroleum jelly) applied to the perianal region to limit dispersal of eggs
- Cleaning floors in sleeping areas thoroughly, particularly in cases of recurrence
- Washing clothing and bedding at the time of treatment

Plagiocephaly

DEFINITION

- *Plagiocephaly* means “oblique head” (Greek origin).
 - Term is used to describe any abnormality in the shape of the head, irrespective of its cause.
- *Posterior deformational plagiocephaly (PDP)* is a condition in which flattening of the occiput occurs as a result of mechanical factors that affect the malleable growing skull in utero or during early infancy.
 - Also referred to as *benign positional molding*, *posterior plagiocephaly*, and *occipital plagiocephaly*

EPIDEMIOLOGY

- Prevalence
 - Before 1992, when more than 70% of infants were placed in the prone position during sleep, PDP was estimated to be present in 1 in 300 live births.
 - After the *Back to Sleep* campaign was initiated by the AAP, PDP has been on the rise, with a 2004 study showing PDP in almost 1 in 68 infants.
 - More common on the right side because of the right-sided sleep position preference of most infants.
 - Almost 85% of neonates have left occipital anterior presentation during birth, which causes pressure on the infant’s right occiput and left forehead by the mother’s pelvis and lumbosacral spine.
- Sex
 - More common in boys, probably because male infants have larger heads and because boys tend to be less flexible
- PDP is first noticed by parents and health care providers when the infant is 2–3 months of age.
 - Severity of PDP peaks at 4 months
 - Resolves gradually over time.
 - In two-thirds of cases, PDP resolves by 2–3 years of age.
 - Resolution is observed to be slow in children with limited head rotation and low activity level.

ETIOLOGY

- Abnormalities in skull shape
 - May develop prenatally *or*
 - May develop postnatally during the first 2 years of life
- Whether PDP begins prenatally or is an acquired phenomenon remains controversial.
- Some investigators believe that many infants who develop PDP are born with mild flattening of the occiput that initially goes unnoticed.
 - Worsens as the infant continues to sleep on the flat side in the position of comfort
 - Termed *positional plagiocephaly*

- Deformity present from birth is usually the result of in utero conditions such as:
 - Small maternal pelvis
 - Uterine abnormalities
 - Large baby
 - Multiple gestations
 - Oligohydramnios or polyhydramnios
- Some researchers believe constrictive and restrictive uterine environment leads to conformational changes in the skull and fusion of the sutures.
- Others believe that the uterine environment simply causes severe molding and leads to flattening.

RISK FACTORS

- Primiparity
- Prolonged labor
- Assisted delivery
- Frequently associated with PDP:
 - Supine sleeping position
 - Congenital torticollis
 - Some theories suggest that torticollis develops as a result of PDP.
 - Prolonged periods in car seats and infant carriers
 - Prematurity
 - Infants maintained in 1 position for prolonged periods on ventilator support
 - Neurologic conditions such as hydrocephalus
 - Movement of bones and sutures as a result of volume changes from hydrocephalus
 - Limitations imposed by the draining devices and shunt
 - Position of baby’s crib in relation to the room’s major light source.
 - Infants usually look toward a light source when in the supine position.

SIGNS AND SYMPTOMS

- PDP is first noticed by parents and health care providers when the infant is 2–3 months of age.
- Severity peaks at 4 months and then resolves gradually over time.
- Infants with PDP exhibit preferential head position and turn the head only to 1 side.
- When head is viewed from above:
 - Frontal prominence is observed on the same side as the occipital flattening.
 - Ear on that side is anterior as compared with the other ear.

- Other craniofacial abnormalities that may be observed on the affected side are:
 - Prominent mandibular sulcus with mandibular tilt
 - Uplifted lower helix
 - Smaller ear
 - Unilateral epicanthal fold
 - Most have 1-sided occipital bald spots.

DIFFERENTIAL DIAGNOSIS

- Distinguishing lambdoid synostosis from PDP in infants with flat posterior plagiocephaly is critical because of differences in management.
 - Rarely, clinically differentiating between them may be difficult.
- Lambdoid synostosis is a rare condition that occurs in ~2% of all cases of craniosynostosis.
 - Head is trapezoid shaped.
 - Ear is displaced inferiorly and posteriorly.
 - Posterior basal skull is tilted, with prominence of mastoid process present on the same side.
 - Facial deformity is absent or minimal.
- PDP
 - Head is shaped like a parallelogram.
 - Significantly greater protrusion of the forehead on the same side of the occipital flattening than with lambdoid synostosis.
 - Ear on flattened side is displaced anteriorly.
 - Facial deformity
- Presence of torticollis must be ruled out in every case of flattened occiput because of its greater association with PDP.
 - Primary care physician should perform both passive and active head rotations and check for tightness of the sternocleidomastoid muscle.
 - Eye on the side of torticollis appears to be incompletely open as a result of the vertical displacement of soft tissues of the cheek.
 - Mothers of infants with torticollis note that they have difficulty feeding the infant from both breasts because the infants have trouble turning their heads.

DIAGNOSTIC APPROACH

- Diagnosis of PDP in infancy is made primarily based on history and physical examination.
- If the infant has a normal, rounded head at birth and after a few weeks or months develops an occipital flattening, then the most likely diagnosis is PDP.

IMAGING

- Imaging studies usually are not required.
- In the past, skull radiographs were used to rule out lambdoid suture synostosis.
 - Ultrasound examination of the lambdoid suture also has been shown to be useful in ruling out lambdoid suture synostosis.
- Three-dimensional CT scans have been shown to be sensitive in diagnosing common and rare causes of posterior plagiocephaly.

TREATMENT APPROACH

- Early recognition and intervention improves outcome.
 - If not treated appropriately, then quality of life may be reduced.
- In most patients, the head shape improves with changes in head position or helmet therapy.
- Definitive treatment guidelines have not been developed.
- Early treatment is successful in most cases of mild to moderate PDP.
- Treatment started after 12 months does not produce significant benefits.

SPECIFIC TREATMENTS

Initial management

- Early treatment is similar to preventive measures.
- Educate parents about changing the infant's head position frequently.

Neck motion exercises

- If the infant is found to have torticollis, parents should be taught neck motion exercises to use with the baby.
 - First exercise is used to stretch the sternocleidomastoid muscle.
 - Place one hand on the infant's upper chest.
 - Rotate infant's neck with the other hand so chin touches the shoulder.
 - Hold infant's head in this position for 10 seconds.
 - Then rotate head to the other side and hold in that position for an additional 10 seconds.
 - Second exercise stretches the trapezius muscle.
 - Infant's head is tilted so that the ear touches the shoulder and is held in that position for 10 seconds.
 - Same process is followed on the other side.
- Parents should perform these neck exercises with every diaper change, with 3 repetitions of each exercise.
 - ~2 additional minutes per diaper change are required for these exercises.
- Infant should be referred for physical therapy for stretching exercises if these exercises fail to improve torticollis within 2–3 months.

- If no improvement is evident, or if plagiocephaly worsens after 2 months of repositioning and physical therapy, infant should be referred to a pediatric neurosurgeon or a craniofacial surgeon for further management.

Helmets

- Skull-molding helmets have been used for reshaping affected skull.
- Must be used in the age range of 4–12 months because of the malleability of the infant's skull during this period.
- Ideally, therapy is begun at 4–6 months of age; may be continued until 12–14 months of age.
- Head growth remains normal during helmet therapy; helmet works by symmetrically shaping the cranial growth.
- Use of helmets is more beneficial for:
 - Patients with severe deformity
 - Infants with mild to moderate severity who are resistant to position changes and physical therapy
- No consensus exists on use of helmets.
- Disagreement exists on cost effectiveness of helmets.
- AAP states that helmets are beneficial in the treatment of PDP after position changes and exercise have failed.
- Helmets used for treating PDP are considered to be class II neurologic devices and are regulated by the US Food and Drug Administration.
- Information on the approved orthotics can be obtained at www.fda.gov.

Surgery

- Rarely needed
- May be indicated in severe cases in which infants have been presented late for management, missing the window of opportunity for success with repositioning, physical therapy, or helmet therapy
- Craniotomy
 - Does not provide superior results as far as a cosmetic outcome is considered
- Associated with significant morbidity

WHEN TO ADMIT

- Surgical correction of PDP

WHEN TO REFER

- After position change and physical therapy have failed to correct PDP
- In severe cases
- When the patient who has PDP is >12 months
- When lambdoidal craniosynostosis is a possibility

COMPLICATIONS

- Uncorrected or improperly treated PDP can lead to marked psychosocial developmental sequelae.

PROGNOSIS

- In two-thirds of cases, PDP resolves by 2–3 years of age.
- Resolution is slow in children with limited head rotation and low activity level.
- In most cases, early implementation of repositioning and neck exercises yields considerable response over a 2- to 3-month period.
- The ipsilateral temporomandibular joint is pushed anteriorly in patients with PDP, and the mandible develops asymmetrically.
 - Positional and helmet therapy improve the head shape but not the position of the temporomandibular joint or the asymmetry of the mandible.
- PDP also causes forehead and facial shifts that may lead to asymmetric positioning of eyes and bilateral astigmatism.
 - Fitting corrective glasses on an asymmetric head is difficult.
- Cognitive and psychomotor development has been observed to be mildly delayed in patients with PDP.
 - Whether delays can be corrected with therapy is not known.
 - Whether delays are the cause or the effect of PDP is not known.
 - Long-term follow-up of patients with PDP has shown persistence of developmental delay.

PREVENTION

- In most infants, PDP can be prevented by:
 - Alternating supine head position during sleep
 - Periodically changing position of the crib to require the child to look away from the flattened side to see parents or to look at a light source
- AAP has recommended a certain amount of prone positioning, or *tummy time*, while the infant is awake and being observed.
 - May help prevent development of a flat occiput
 - May also facilitate development of upper shoulder girdle strength necessary for timely attainment of certain motor milestones
 - Theories suggest that prone position prevents PDP by correcting or preventing infants' positional preferences.
- Parents and health care professionals should be educated on different techniques to reduce the risk for development of PDP.
 - Caregivers should be encouraged to change the head position of a sick newborn whenever possible.
 - Caregivers should be encouraged to:
 - Provide care from alternate sides of the crib
 - To reposition the infant from head to foot periodically
- Breastfed infants are less likely to develop PDP because alternate head positioning is promoted.
 - Parents should be advised to use alternate arms during each bottle feeding.

Pneumonia

DEFINITION

- Pneumonia is defined by the presence of infiltrates on a chest radiograph.
- In less-developed parts of the world, evidence of retractions along with tachypnea leads to a clinical diagnosis of pneumonia.

EPIDEMIOLOGY

- Incidence varies according to age:
 - Infants and toddlers are infected more commonly than older children.
 - In children ≤ 5 years of age, incidence is 30–45 episodes per 1000 children per year.
 - In children aged 5–9 yr, incidence is ~ 16 –20 cases per 1000 children per year.
 - In older children and adolescents, incidence is 6–12 cases per 1000 patients per year.

ETIOLOGY

- Pneumonia results from:
 - Overwhelming load of pathogenic organisms
 - Breach of host defense mechanisms
- Causes vary depending on patient's age.
- In the neonatal period, acute pneumonia is caused by bacteria that may cause sepsis and meningitis.
 - Group B *Streptococcus* (GBS) causes a severe lower respiratory tract infection.
 - Major morbidity and mortality
 - Infections from GBS have been found in infants up to 8 months of age.
 - Approximately 75% develop infection by 2 months of age.
 - Other organisms include:
 - *Escherichia coli*
 - *Klebsiella pneumoniae*
 - Other enteric gram-negative bacteria
 - *Listeria monocytogenes* must be considered.
 - Less frequently, the following may be implicated in episodes of lower pulmonary infections:
 - Nontypeable *Haemophilus influenzae*
 - Other strains of *Streptococcus*
 - *Enterococcus* spp
 - Rarely, anaerobic bacteria may be found.
 - Infection with *Chlamydia trachomatis* leads to pneumonia with significant auscultatory findings.
 - Conjunctivitis frequently precedes or accompanies respiratory infection in infants who have been colonized during delivery.

- Bacterial causes beyond the neonatal period
 - *Streptococcus pneumoniae* is the most important pathogen.
 - Highest number of cases
 - Greatest potential for complications
 - Pneumococcus may be the etiologic agent in 25–38% of cases.
- Other bacterial pathogens associated with acute lower respiratory infections in toddlers and young children include:
 - *H influenzae* type B
 - Nontypeable strains of
 - *H influenzae*
 - *C trachomatis*
 - *Mycoplasma pneumoniae*
 - *Moraxella catarrhalis*
- Cases of severe group A β -hemolytic streptococcal pneumonia have been reported.
 - Often with marked comorbidity
 - Pleural effusion
 - Empyema
 - Shock
- Among school-aged children and adolescents
 - *M pneumoniae* is the major treatable cause.
 - *Chlamydia pneumoniae* may cause pneumonia.
 - *S pneumoniae* may be the cause.
 - *Legionella pneumophila* may be a rare cause.
- Children < 5 yr of age are at risk for viral pneumonias.
 - Respiratory syncytial virus (RSV) infects almost all toddlers by the age of 3 yr.
 - 1% are ill enough to require hospitalization.
 - Other viral etiologies that may be seen in the first years of life include:
 - Parainfluenza virus
 - Influenza
 - Adenovirus
 - Human metapneumovirus has been shown to cause bronchiolitis that may be similar to that caused by RSV.
 - Influenza also may cause significant respiratory illness within all pediatric age groups.
 - Infants are at risk during yearly influenza outbreaks.
 - Multiple pathogens may be found in the same patient.
 - Viral infections, with consequent epithelial loss and inflammation, may lead to secondary bacterial infections.
 - 16–50% of patients may harbor more than one pathogen.

RISK FACTORS

- Exposure to environmental tobacco smoke and air pollutants
 - Associated with >190,000 cases of pneumonia per year in the US among persons in the youngest age groups
- Malnutrition
- Immune deficiency
- Loss of normal cellular components of the immune system (polymorphonuclear leukocytes and alveolar macrophages) caused by either acquired or congenital immune deficits
- Severe developmental delay
- History of prematurity
- Chronic lung disease

SIGNS AND SYMPTOMS

- During the neonatal period, signs and symptoms may be nonspecific.
 - Infants may have:
 - Fever
 - Irritability
 - Altered feeding patterns
 - Cough
 - Tachypnea or apnea
 - Findings on examination may include:
 - Retractions
 - Nasal flaring
 - Grunting
 - Auscultation may reveal:
 - Crackles
 - Decreased breath sounds
 - Occasionally wheezing, especially if the cause is viral
- Among older children
 - Indicators include:
 - Tachypnea
 - Cough
 - Fever
 - Crackles
 - Respiratory distress
 - Complaints of pleuritic chest pain may accompany pneumonia, and help localize attention to the chest.
 - Abdominal pain may be associated with acute lower respiratory tract infections.
 - Milder cases of pneumonia may be associated with findings in the upper respiratory tract:
 - Pharyngitis
 - Hoarseness
 - These symptoms are especially likely in illnesses caused by *Mycoplasma* and *Chlamydia* organisms.

LABORATORY FINDINGS

- Sputum sample
 - If the patient is able to provide a good specimen
 - Producing sputum samples often is difficult for children.
- Nasopharyngeal or throat culture specimens
 - Use for diagnosis of childhood pneumonia is not supported by the Canadian Medical Association or the British Thoracic Society.
- Blood cultures
 - Positive only ~10% of the time
- Serologic testing
 - May be useful
 - Often yields results (based on acute and convalescent titers) only after patient has recovered from acute illness
- Direct antigen testing
 - Currently available for influenza A, influenza B, and RSV
 - To assist in determining viral etiologies
- Because of the effectiveness of therapies against influenza, consideration should be given to obtaining nasal or respiratory secretions for testing.

IMAGING

- Radiographs of the chest
 - Radiographic patterns may be helpful in suggesting whether the infection is bacterial or viral.
 - Bacterial process
 - Lobar involvement
 - Pleural effusions
 - Pneumatoceles
 - Pulmonary abscess
 - Viral etiology
 - Bilateral perihilar infiltrates
 - Increased interstitial markings
 - Mycoplasmal infection
 - Focal or interstitial infiltrates
- Repeat chest radiographs should be obtained in 3–6 wk after diagnosis for documenting resolution.
 - Lack of radiologic resolution may suggest:
 - Congenital lung malformation
 - Foreign body
 - Neoplastic process

DIAGNOSTIC PROCEDURES

- Bronchoalveolar lavage
 - May help define therapeutic choices

- Useful for patients with:
 - Significant respiratory distress
 - Clinical picture that fails to fall into a readily recognized category
- May allow the discontinuation of certain antimicrobial drugs and alleviates risk of adverse reactions and cost associated with these agents.
- Bronchoscopy with lavage
 - Particularly valuable in patients with immune defects
 - May be performed quickly with minimal morbidity in almost any child
 - Should be considered early in the illness, before therapy with multiple antibiotics has been initiated
 - Increases yield of the test
 - May not be available to every practitioner

TREATMENT APPROACH

- For unhospitalized patients
 - Oral antibiotics
- For patients admitted to the hospital
 - Parenteral antibiotics

SPECIFIC TREATMENTS

Antimicrobials

- For young, hospitalized infants, ampicillin *and* either an aminoglycoside or a third-generation cephalosporin
 - Combination provides good coverage for specific organisms frequently seen in the neonatal period:
 - GBS
 - Gram-negative enteric bacteria
 - *Listeria* organisms
- Older infants and toddlers requiring hospitalization may be treated with intravenous cefuroxime or cefotaxime.
 - Many of these illnesses are caused by pneumococci and are increasingly resistant to β -lactam antibiotics.
 - If illness worsens significantly while patient is receiving either of these antibiotics, consideration should be given to therapy with vancomycin.
 - Treatment failures are uncommon in spite of penicillin-resistant strains of *S pneumoniae*.
- For children with severe illness, additional antibiotic coverage with erythromycin or a newer macrolide may be considered.
 - These antibiotics may be first-line choices for the treatment of pneumonia (*M pneumoniae* and *C pneumoniae*) in school-aged children and adolescents.
- Patients with less severe illness may be treated with the same antibiotics.

Parapneumonia effusions

- Video-assisted thoracoscopic drainage
- Thoracostomy tube placement

Lung abscesses

- Imaging studies show an irregularly shaped cavity with an air-fluid level inside.
 - Prolonged antibiotic therapy will resolve this complication.

WHEN TO ADMIT

- Clinical assessment is most important in determining whether hospitalization is needed.
- Admission is indicated if:
 - Child is <8 wk
 - Child is in significant respiratory distress, indicated by:
 - Grunting
 - Nasal flaring
 - Retractions
 - Hypoxia is present.
 - Child appears toxic.
 - Family cannot adequately assess and care for child.
 - Normal hydration status cannot be maintained.
 - Child cannot be brought back for reassessment after outpatient therapy.
 - Pneumonia is recurrent.

WHEN TO REFER

- Child continues to have fever 48 hours after starting appropriate antibiotic therapy.
- Child develops a pleural effusion.
- Child develops a lung abscess.

COMPLICATIONS

- Infections of the lower respiratory tract have varying morbidity and mortality when comparing illness in developed and developing countries.
- Combined effects of malnutrition and inadequate immunization may cause much more severe respiratory disease for children.
 - Particularly for those without access to advanced therapy to treat underlying infection and subsequent complications
- Many more deaths are caused by pneumonia in the developing world.
- *S pneumoniae*
 - Patients may be gravely ill.
 - Sepsis and meningitis possible

- Overuse of antibiotics has led to development of pneumococci with reduced antibiotic susceptibility.
 - *S pneumoniae* resistant to penicillins and advanced-generation cephalosporins
 - Resistance to other antibiotics may occur.
 - Resistance genes often are plasmid-borne and may be transferred between bacteria.
- Despite appropriate antimicrobial therapy, complications are seen.
 - Parapneumonic effusions may occur in 40–60% of pneumonia cases.
 - Initially result from inflamed pleural surfaces caused by underlying infection
 - Later, fibrin levels increase along with increased numbers of inflammatory cells.
 - May allow previously thin fluid to organize and become a thick rind, compromising lung function
- Lung abscesses are seen intermittently during the evolution of pediatric pneumonia.

PREVENTION

- Routine use of conjugated pneumococcal vaccine has lessened the incidence of *S pneumoniae* infections, including those of the lung parenchyma.

Pneumothorax and Pneumomediastinum

DEFINITION

- Pneumothorax is a collection of air in the potential space between the parietal and visceral layers of the pleura.
- Pneumomediastinum is a condition in which air is present in the mediastinum.

EPIDEMIOLOGY

- Pneumothorax and pneumomediastinum are uncommon events in healthy children.
- Primary spontaneous pneumothorax
 - The incidence of primary spontaneous pneumothorax in children is not known.
 - In adults, the estimated incidence is:
 - 7.4–18 cases per 100,000 population per year among men
 - 1.2–6 cases per 100,000 population per year among women
- Secondary spontaneous pneumothorax
 - The pediatric incidence has not been reported.
 - The adult estimated incidence is:
 - 6.3 cases per 100,000 population per year among men
 - 2 cases per 100,000 population per year among women
- Traumatic pneumothorax
 - In 1 report of children with blunt trauma, 38% had associated pneumothorax, hemothorax, or both.
 - In children with penetrating thoracic trauma, 64% had associated pneumothorax, hemothorax, or both.
- Iatrogenic pneumothorax
 - Rates of pneumothorax caused by mechanical ventilation have decreased in all age groups.
 - The observed rate of iatrogenic pneumothorax in hospitalized children was recently reported as 0.06 per 1000 discharges.
 - Some reports note an incidence of iatrogenic pneumothorax that exceeds that of spontaneous pneumothorax.
- Neonatal pneumothorax
 - Incidence depends on:
 - Gestational age
 - Birth weight
 - Presence of lung disease
 - Spontaneous pneumothorax is present in 1–2% of live births.
 - Most are term infants.
 - Incidence increases with prematurity.
 - Approximately one-half of affected infants have symptoms.
 - A history of delivery-room resuscitation efforts or infant aspiration of meconium or blood often exists.

- Pneumothoraces are very common in critically ill ventilated neonates.
 - Incidence increases with prematurity.
- Pneumothorax in an infant with neonatal respiratory distress syndrome has been associated with mortality rates exceeding 60%.
- Familial cases of spontaneous pneumothorax in neonates have been described.

- Pneumomediastinum
 - Uncommon in the pediatric population
 - Usually self-limited
 - Often go undetected
 - The actual incidence is difficult to ascertain.

ETIOLOGY

- Spontaneous pneumothorax
 - Usually related to underlying lung disease (76–100%)
 - Precipitating factors
 - Foreign body ingestion, particularly children age 6 months to 6 years
 - Exposure to loud music
 - Illicit drug use
 - Attempted jugular or subclavian vessel injection (mainlining)
 - Cavitating septic thromboemboli
 - Forceful exhalation of crack smoke into another individual's respiratory tract (shotgunning)
 - Deep inhalation and Valsalva maneuvers while smoking marijuana
 - Emesis and coughing
- Traumatic pneumothorax
 - Causes of blunt thoracic trauma include:
 - Vehicle-pedestrian injuries
 - Motor-vehicle crashes
 - Falls
 - Child abuse
 - The leading causes of penetrating thoracic trauma are:
 - Gunshot
 - Stab wounds
- Iatrogenic pneumothorax caused by diagnostic or therapeutic interventions, including:
 - Transthoracic needle aspiration
 - Central venous catheter insertion
 - Thoracocentesis
 - Barotrauma or volutrauma related to mechanical ventilation

■ Pneumomediastinum

- The 3 main causes are:
 - Alveolar rupture
 - Perforation or rupture of esophagus, trachea, or main bronchi
 - Dissection of air from the neck or the abdomen
- The most common cause is bronchospasm related to respiratory tract infection.
- Often associated with exaggerated Valsalva maneuvers during:
 - Cough
 - Emesis
 - Hiccupping
 - Heavy lifting
 - Straining at stool
 - Illicit drug inhalation
 - Sports activities
- Has been noted in situations in which external pressure changes occur, such as:
 - Scuba diving
 - Air travel
- Other causes include:
 - Marked decreases in interstitial pressure, eg, with hyperpnea from diabetic ketoacidosis
 - Barotrauma or volutrauma secondary to mechanical ventilation or manual resuscitative ventilation
 - Foreign body ingestion, especially in children <6 years
- Trauma
- Child abuse
- Blunt thoracic trauma, such as motor-vehicle crashes
- Isolated facial trauma
- Tracheobronchial and esophageal rupture

RISK FACTORS

■ Primary spontaneous pneumothorax

- The typical patient is:
 - Tall
 - Thin
 - Male
 - Age 10–30 years
- Smoking increases the risk of primary spontaneous pneumothorax:
 - 9-fold among women
 - 22-fold among men
- Risk is increased in various inherited disorders, such as:
 - α_1 -Antitrypsin deficiency
 - Marfan syndrome
 - Ehlers-Danlos syndrome

■ Pneumomediastinum

- Asthma

SIGNS AND SYMPTOMS

Pneumothorax

■ History

- Patients often note abrupt ipsilateral pleuritic chest pain, with or without acute dyspnea.
- Pleuritic pain may be more prevalent in primary spontaneous pneumothorax.
- Dyspnea is typically severe in secondary spontaneous pneumothorax.
 - Patients have decreased cardiopulmonary reserve at baseline.
- Symptoms associated with primary spontaneous pneumothorax often resolve within 24 hours.
 - Unlike the progressive course of secondary spontaneous pneumothorax
- Respiratory symptoms might be vague in young children.
- Parents may note sudden dyspnea and irritability.

■ Physical examination

- Findings in primary spontaneous pneumothorax are variable and depend on:
 - Pneumothorax size
 - Patient age
- Most commonly, vital signs demonstrate tachycardia and tachypnea.
- Patient with pneumothorax occupying <15% of the hemithorax may have a normal physical examination.
- Hypoxemia caused by small primary spontaneous pneumothorax is uncommon in older children.
 - Most have adequate alveolar reserve to preserve oxygenation.
- Smaller children are often hypoxemic.
- Underlying lung function is normal.
- Hypercarbia does not typically develop in patients with primary spontaneous pneumothorax.
- Patients with secondary spontaneous pneumothorax often have hypoxemia and hypercarbia.
- As size pneumothorax increases, characteristic signs include:
 - Diminished or absent breath sounds
 - Hyperresonance to percussion on the involved side
 - Chest asymmetry
- Neonates may have severe respiratory distress with marked:
 - Tachypnea
 - Grunting
 - Retractions
 - Cyanosis

- Pneumothorax can be rapidly life threatening in infants with:
 - Respiratory distress syndrome
 - Other underlying lung disease
- Such infants may have cardiorespiratory instability and progress to cardiac arrest.
- Detection of pneumothorax by physical examination in infants can be difficult because of small thorax size.
- Shift of the apical heart impulse away from side of the pneumothorax has been reported to be a reliable sign.
- Iatrogenic pneumothorax should be suspected in:
 - Any patient who becomes more dyspneic after medical or surgical procedure known to be associated with the development of pneumothorax
 - Any patient treated with positive pressure ventilation who:
 - Experiences sudden clinical deterioration
 - Demonstrates unexplained increase in peak and plateau pressures or decreased tidal volume
- Tension pneumothorax is life threatening and requires immediate attention.
 - Heralded by:
 - Hypotension
 - Profound hypoxemia
 - Tracheal deviation in the setting of diminished breath sounds

Pneumomediastinum

- History and physical findings
 - Healthy young people do not often have severe symptoms or physical examination findings.
 - Patients may have:
 - Chest pain
 - Cough
 - Dyspnea
 - Dysphonia
 - Dysphagia
 - Neck pain
 - Examination will often reveal subcutaneous cervical emphysema with crepitance.
 - Less commonly, the physician may hear the Hamman sign.
 - Mediastinal crunching sound synchronized with systole

DIFFERENTIAL DIAGNOSIS

- Pneumomediastinum
 - Spontaneous esophageal perforation (Boerhaave syndrome)
 - Mediastinitis
- In young infants, neonatal pneumothorax must be differentiated from congenital lobar emphysema.

DIAGNOSTIC APPROACH

■ Pneumomediastinum

- The term *spontaneous pneumomediastinum* is applied to younger patients with no obvious precipitating event.
- Care must be taken to evaluate for penetrating injury.
- Air can enter the mediastinum from penetrating neck or chest wall injury.

IMAGING

Pneumothorax

- Routinely diagnosed by chest radiography
 - Preferably with the patient in an upright position
 - The main radiologic feature is a white visceral pleural line, separated from the parietal pleura by avascular collection of gas (see Figure 60 on page F21).
 - In many instances, no pulmonary vessels are visible beyond the visceral pleural edge.
 - In films in which the patient is in an upright position, the accumulation of gas is primarily in an apicolateral location.
 - In supine views, more pleural gas is needed for definitive diagnosis of pneumothorax.
 - Pleural gas accumulates in a subpulmonic location, outlining:
 - Anterior pleural reflection
 - Costophrenic sulcus (*deep sulcus sign*)
 - Anterolateral border of the mediastinum
- Computed tomography (CT) can detect pneumothoraces that do not appear on radiograph (occult pneumothoraces).
 - Often not practical in the initial workup
 - In young infants, neonatal pneumothorax must be differentiated from congenital lobar emphysema.
 - Can appear as an expanded radiolucent pulmonary segment
 - CT may be required to make this important differentiation; the treatment for congenital lobar emphysema is lobectomy.
 - Aspiration or chest tube placement in a patient with congenital lobar emphysema is associated with substantial risk of death.
- Portable ultrasonography devices may play a role in the future.
 - An application for thoracic ultrasonography for pneumothorax in children has yet to be established.
- Tension pneumothorax
 - Intervention should not be delayed for radiologic imaging to confirm the diagnosis.

Pneumomediastinum

- Recognized by air outlining mediastinal structures, such as:
 - Thymus (sail sign)
 - Superior surface of the diaphragm (continuous-diaphragm sign)
- Usually bilateral
- Does not move with decubitus positioning
 - Helps differentiate from anteromedial pneumothorax (see Figure 61 on page F21)
 - Pneumothorax may also be present.

DIAGNOSTIC PROCEDURES

- Pneumothorax
 - Fiberoptic bronchoscopy
 - Assesses the possibility of a bronchial tear
 - Used in trauma patients with a large pneumothorax and persistent air leak into the pleural space despite tube thoracostomy
 - Clinicians must rule out traumatic rupture of the esophagus; mortality approaches 100% if surgical treatment is not prompt.

CLASSIFICATION

- Pneumothoraces are typically classified as:
 - Spontaneous
 - Traumatic
 - Iatrogenic
- Spontaneous pneumothorax
 - Occur in the absence of antecedent thoracic trauma
 - Primary spontaneous pneumothorax
 - Secondary spontaneous pneumothorax
- Primary spontaneous pneumothorax affects patients who do not have:
 - Clinically apparent lung abnormality
 - Underlying condition known to promote pneumothorax
- Secondary spontaneous pneumothorax occurs in the setting of underlying pulmonary disease, such as:
 - Pneumonia
 - Asthma
 - Cystic fibrosis
- Traumatic pneumothorax
 - Trauma to the chest is classified as:
 - Blunt
 - Penetrating
- Pneumomediastinum
 - No apparent consensus exists regarding classification of pneumomediastinum.

TREATMENT APPROACH

- Failure to recognize and properly manage pneumothorax or pneumomediastinum can have serious consequences.
- Primary spontaneous pneumothorax
 - Guidelines for the management of spontaneous pneumothorax in adult patients have been published by the British Thoracic Society and American College of Chest Physicians.
 - No similar guidelines exist for treatment of infants and small children.
 - In the recommended treatment pathways, adult guidelines distinguish between:
 - Small primary spontaneous pneumothorax, defined as <15–20% of the chest volume
 - Large primary spontaneous pneumothorax
 - Guidelines estimate loss of lung volume by:
 - Distance from the lung apex to ipsilateral thoracic cupola at the parietal surface on a standard upright radiograph
 - Usually underestimates volume loss
 - Another way to estimate the size of a pneumothorax: The volume of the lung approximates the ratio of lung diameter to hemithorax cubed.
 - Using this system, a pneumothorax smaller than 15% would be considered small.

SPECIFIC TREATMENTS**Pneumothorax****Primary spontaneous pneumothorax**

- Supplemental oxygen and observation in the emergency department for 3–6 hours, followed by repeat chest radiography to exclude progression of pneumothorax, is recommended for adolescents and young adults if:
 - Pneumothorax is small.
 - Severity of acute symptoms is mild with unlabored breathing.
 - Room air saturations are >90%.
- Patients must have careful instructions to:
 - Return for worsening shortness of breath
 - Have follow-up in 12 hours to 2 days with planned chest radiography to document improvement
- Breathless patients should undergo intervention, regardless of pneumothorax size.
- Supplemental oxygen is administered to all patients with pneumothorax.
 - Increases pleural air reabsorption rate 3- to 4-fold above the baseline of 1.25% per day
 - Recommended to hasten resolution
- A 15% pneumothorax is expected to resolve in ~12 days without oxygen therapy.

- Management of small primary spontaneous pneumothorax
 - Children with small primary spontaneous pneumothorax are typically admitted for observation.
 - Based on adult guidelines, older children and adolescents with asymptomatic small primary spontaneous pneumothorax who have been observed in the emergency department for 3–6 hours can be discharged home.
 - Closely follow up, as recommended for adult patients.
 - Any patient with breathlessness should:
 - Be admitted
 - Undergo intervention to remove the air
- Management of moderate to large primary spontaneous pneumothorax in adolescents and young adults
 - British guidelines recommend simple aspiration as first-line treatment for:
 - All symptomatic primary spontaneous pneumothoraces
 - All pneumothoraces with >2 cm rim of air on chest radiograph (large)
 - US guidelines do not generally endorse attempts at simple aspiration over placement of a chest drain.
 - Recent publications regarding primary spontaneous pneumothorax in adults show that aspiration is successful in >50% of cases.
 - Failure is more likely if pneumothorax is >40%.
 - In British guidelines, patients with successful aspiration of a primary pneumothorax may be observed in the emergency department for similar follow-up.
 - The American College of Chest Physicians recommends placement of a chest drain for symptomatic or any large (>3 cm rim) primary spontaneous pneumothorax.
 - Patients are then managed with either a:
 - Heimlich valve (one-way valve)
 - Chest tube to water seal or suction
- Management of large primary spontaneous pneumothorax in children
 - Simple aspiration versus chest tube placement for children with large pneumothorax is based on experience of the treating physician.
 - Published pediatric series suggest that hospital admission with placement of a pleural catheter or chest tube is usual practice.

Spontaneous secondary pneumothorax in young adults and children

- Guidelines recommend hospital admission for:
 - Treatment of the underlying condition
 - Symptomatic treatment, if needed
- Small pneumothoraces can be treated with oxygen therapy and observed.
- Large pneumothoraces are drained either by aspiration or by chest tube placement.

Traumatic pneumothorax

- If tension pneumothorax is suspected, emergency needle aspiration of the second intercostal space in the midclavicular line is required.
- If the patient improves with needle aspiration, a chest drain should immediately be placed on that side.
- A substantial number of pneumothoraces not seen on initial chest radiographs are found on subsequent CT or ultrasonography of the chest.
- Placement of a larger-caliber chest drain for symptomatic or large pneumothorax among trauma victims is customary treatment.
 - Many patients require positive pressure ventilation.
 - May have an accompanying hemothorax
 - Small asymptomatic pneumothorax may be observed if:
 - The patient is not receiving positive pressure.
 - Radiographic evaluation does not reveal chest multitrauma.

Iatrogenic pneumothorax

- Should be tailored to the patient's clinical circumstance
- Patients receiving positive pressure ventilation are at risk of extension of pneumothorax.
 - Generally require chest tube placement
- Provide supportive care with close observation for patients not on mechanical support who have a small pneumothorax and limited symptoms.

Chest tube insertion and management

- Planning
 - Before inserting the chest tube, predrainage risk assessment is appropriate.
 - Risk of hemorrhage should be corrected when possible.
 - Routine platelet count and bleeding times are recommended only for patients with known risk factors.
 - When possible, the clinician should obtain informed consent and provide sedation with standard monitoring.
 - Risks include:
 - Bleeding
 - Infection
 - Failure of pneumothorax resolution
 - Laceration of the lung
 - Extrathoracic placement with potential injury of abdominal organs
- Positioning
 - The preferred position for chest drain insertion is supine with the ipsilateral arm above the patient's head to expose the axilla.

- Alternative positions are:
 - Patient sitting upright leaning over an adjacent table with a pillow
 - Lateral decubitus position
- The safe area is bordered by:
 - Lateral margin of pectoralis major muscle
 - Anterior margin of the latissimus dorsi muscle
 - Line superior to the horizontal level of the nipple
 - Apex below the axilla
- Supine position minimizes risk to underlying structures, such as:
 - Internal mammary arteries
 - Breast tissue
 - Solid organs
- A more posterior position is chosen if pneumothorax is loculated and posterior.
 - Loculated collections are most safely approached under fluoroscopic guidance.
 - A more posterior position is safe.
- The second intercostal space in the midclavicular line may be chosen for apical pneumothorax.
 - The position is uncomfortable.
 - May leave a visible scar
- Thoracostomy tube size selection
 - Smaller tubes are recommended for aspirating air.
 - More comfortable compared with larger tubes, which are recommended for draining blood or a large air leak
 - Age-based sizes for thoracostomy tubes recommended for trauma victims by the American Heart Association are:
 - Newborns (2–5 kg): 8–12 French
 - <1 yr (5–11 kg): 14–20 French
 - Children 1–8 yr (12–30 kg): 20–28 French
 - Children >8 yr (>30 kg): 29–36 French
- Adult guidelines for pneumothorax management recommend relatively smaller tubes for draining air.
 - British guidelines recommend a 10–14 French tube for management of pneumothorax in adults.
 - The American College of Chest Physicians recommends initial management with a 16–22 French tube in patients not at risk for large air leaks.
- Insertion techniques
 - Small-bore chest tubes are usually inserted with aid of a needle and guidewire using a modified Seldinger technique.
 - Blunt dissection is not needed because a dilator is used.
 - Blunt dissection of subcutaneous tissue and muscle into pleural cavity is performed for insertion of medium and large chest drains.
- A finger-sized opening allows exploration to ensure that no underlying organs will be damaged.
- Once the tube is past the chest wall, it is directed:
 - Apically to drain air
 - Basally to drain fluid
- The chest tube is sutured in place.
- If an incision has been made:
 - 1 stitch is placed to assist with wound closure after tube removal.
 - 1 stitch is placed to secure drain.
- Chest radiography is done to check placement and resolution of pneumothorax.
- Management of chest drain
 - The chest tube is connected to a closed system with a water seal device.
 - If the lung fails to expand quickly:
 - Continuous suction is delivered through a measured column of water until the lung has completely reexpanded.
 - The closed system allows detection of air bubbles through water chamber, suggesting continued visceral pleural air leak.
 - Air leak may be caused by a leak in the system.
 - Chest tube air holes are outside the chest.
 - Chest tubing connections are not airtight.
 - The chest tube should remain in place as long as persistent air leak is present.
 - Surgical referral is recommended if:
 - Air leak persists for >4–7 days in patients without preexisting lung disease.
 - Earlier referral is recommended if:
 - The lung fails to expand.
 - A large air leak and underlying lung disease are present.
 - Chest tubes are removed in a staged manner after pneumothorax is resolved.
 - Suction is discontinued.
 - The chest tube is placed on a water seal.
 - Opinions differ regarding the appropriate length of time for a water seal trial, ranging from 3–24 hours.
 - Chest radiography is done to rule out recurrence, and the chest tube may be removed.
 - The chest tube should never be clamped unless:
 - The clinician is expert in chest tube management.
 - The patient has constant nursing supervision.
- Management of pneumomediastinum
 - Initial therapy for pneumomediastinum is directed at the underlying disease process.

- Observation is standard management because:
 - Mediastinal air decompresses into the cervical fascia.
 - Rarely causes tamponade
- Continued air leakage among patients receiving mechanical ventilation may be decreased by:
 - Efforts to decrease intrathoracic pressures
 - Efforts to decrease tidal volume
- If signs of tamponade occur:
 - A mediastinal tube should be placed via echocardiographic guidance by a skilled specialist.
- High prevalence of asthma-related pneumomediastinum
 - Children for whom the underlying cause of pneumomediastinum is unknown should undergo diagnostic pulmonary function tests after an acute episode.

WHEN TO ADMIT

- Children with symptomatic pneumothorax of any size should be admitted to a hospital for observation or management.
- All infants with pneumomediastinum or pneumothorax should be admitted to a hospital.
- Any trauma victim with pneumothorax or pneumomediastinum should be admitted to a trauma center for evaluation and management.

WHEN TO REFER

- Infants and children with primary or secondary spontaneous pneumothorax or spontaneous pneumomediastinum
 - Refer to either a hospital or an emergency department for evaluation and management.
- All children with spontaneous pneumothorax
 - Refer to a lung specialist for follow-up because of the risk of recurrent pneumothorax.
- Infants and children with traumatic pneumothorax
 - Refer to a trauma center for evaluation and management.
- Infants and children with iatrogenic pneumothorax
 - Should be cared for by physicians with expertise in chest drain insertion and management
- Infants and children with pneumomediastinum and signs of cardiac tamponade
 - Should be evaluated by a cardiologist or surgeon able to place a mediastinal drain

FOLLOW-UP

- Children can be discharged from emergency department with follow-up within 24 hours in emergency department if they have:
 - Asymptomatic small primary spontaneous pneumothorax
 - Been observed for 6 hours in the emergency department
 - Reliable transportation and social circumstances

- All patients should be referred to a lung specialist for follow-up care.

COMPLICATIONS

- Risk of recurrence
 - Children with primary spontaneous pneumothorax have a 17–54% risk of recurrence.
 - The greatest risk of recurrence is within 1 year.
 - Some experts recommend CT to detect pleural blebs after initial pneumothorax to help determine risk of recurrence.
 - At this point, surgical treatment is generally limited to children with recurrent pneumothorax.
 - Surgery usually involves:
 - Repair of the air leak
 - Adhering the visceral pleura to the parietal pleura (pleurodesis)
 - Surgical approach via mini-thoracotomy or video-assisted thoracoscopic surgery (VATS) is based on the surgeon's preference.
 - VATS is associated with:
 - Less postoperative pain
 - Shorter hospital length of stay
- Spontaneous pneumothorax
 - Known complication of asthma
 - Tension pneumothorax is present in almost 30% of patients who die suddenly of asthma.
 - Nearly 3.5% of all patients with cystic fibrosis will experience pneumothorax.
 - Subsequent pneumothoraces are common.
 - Some familial cases without evidence of connective tissue disease occur.
 - Spontaneous pneumothorax is a well-recognized complication of AIDS associated with *Pneumocystis (carinii) jiroveci* pneumonia.
 - Catamenial pneumothorax
 - Condition related to endometriosis with diaphragmatic hernia
 - Should be considered in female patients with spontaneous pneumothorax temporally related to menstruation

PREVENTION

- Primary spontaneous pneumothorax recurrence
 - Smoking cessation should be encouraged.

Poisoning

DEFINITION

- Injuries are a leading cause of pediatric morbidity and mortality.
- Poisoning is one important mechanism of injury.

EPIDEMIOLOGY

■ Incidence

- >2 million exposures are reported annually to the American Association of Poison Control Centers (AAPCC).
 - 65% are exposures that involve children and adolescents ≤19 years old.
- 2.5% of annual childhood and adolescent deaths from unintentional injury are poison related.
- For children <6 years of age, an average of 24 deaths per year from poisoning (1983–2004), 4% of all poisoning fatalities and a 94% decrease from 1959.

■ Prevalence

- Repeat exposures may occur in 10–40% of childhood poisoning victims.

■ Age

- Of children exposed to poisoning, 80% are <6 years old.
- 55% of childhood exposures are in boys.
- 45% of adolescent exposures are in boys.
- Childhood exposures peak between 1 and 3 years of age.
 - Unusual in children <6 months
 - Unintentional ingestion is unusual after age 5 years.

ETIOLOGY

■ Top poison exposure categories

- <6 years old
 - Cosmetics and personal care products: 13%
 - Cleaning substances: 10%
 - Analgesics: 7%
 - Topical agents: 6%
 - Plants: 6%
 - Cough and cold preparations: 5%
 - Insecticides, pesticides, rodenticides: 4%
 - Vitamins: 3%
 - Gastrointestinal (GI) preparations: 3%
 - Antimicrobial drugs: 3%
 - Other: 40%
- 6–19 years old
 - Analgesics: 14%
 - Cough and cold preparations: 6%
 - Antidepressants: 5%
 - Cleaning substances: 5%
 - Cosmetics and personal care products: 5%

- Stimulants and street drugs: 4%
- Sedative-hypnotic drugs: 4%
- Antihistamines: 3%
- Art and craft supplies: 3%
- Other: 44%

■ Top fatal poisoning categories

- <6 years old
 - Analgesics: 24%
 - Carbon monoxide (CO): 14%
 - Hydrocarbons: 11%
 - Cough, cold, antihistamine preparations: 10%
 - Insecticides, pesticides, rodenticides: 5%
 - Envenomations : 4%
 - Cardiovascular agents: 4%
 - Anticonvulsants: 3%
 - Drugs of abuse: 3%
- 6–19 years old
 - Analgesics: 26%
 - Drugs of abuse: 26%
 - Antidepressants, antipsychotics: 12%
 - Hydrocarbons: 10%
 - Cough, cold, antihistamine preparations: 4%
 - Alcohols: 3%
 - CO: 3%
 - Cleaning agents and chemicals: 3%
 - Cardiovascular agents: 2%
 - Sedative-hypnotic drugs: 2%

RISK FACTORS

■ Behavioral characteristics that increase the risk of ingestion

- Hyperactivity
- Impulsive risk-taking behavior
- Rebelliousness
- Negativistic attitude
- Social isolation
- Poor parenting skills
- Maternal depression

■ Unintentional or intentional (in older children and adolescents) exposures occur at times of:

- Family disorganization
- Deviations from normal routines
- Family stress

■ Most exposures occur in the child's own home.

- Kitchen
 - Cleaning products are often stored in easily accessible locations.
 - Improper storage containers

- Bedroom
 - Medications are left out.
- Bathroom
 - Medications and cosmetics
- Grandparents' home
 - Lower level of vigilance
 - Lack of child-resistant containers
- Children <6 months old are at risk from:
 - Second hand exposure to psychoactive substances
 - Medication error
 - Child abuse and neglect

SIGNS AND SYMPTOMS

- When no specific history of toxic exposure can be found, the diagnosis of poisoning can be challenging.
- Signs and symptoms of poisoning can mimic those of many acute illnesses.
- Physicians should ask about possible exposure to medications, gases or fumes, or other potentially harmful substances around the home in the face of rapid onset of symptoms in:
 - Central nervous system (CNS)
 - GI system
 - Respiratory system
- Physicians should always consider poisoning when faced with a puzzling situation in which the diagnosis is unclear.
- Some toxins, such as opioids or anticholinergic agents, produce a typical constellation of signs and symptoms known as a *toxidrome*, or toxic syndrome.
 - Sympathomimetic
 - Agitation
 - Diaphoresis
 - Fever
 - Mydriasis
 - Tachycardia
 - Opioid
 - Respiratory depression
 - Miosis
 - Coma
 - Bradycardia
 - Anticholinergic
 - Blind as a bat—mydriasis
 - Dry as a bone—dry skin
 - Hot as Hades—fever
 - Red as a beet—red skin
 - Mad as a hatter—central nervous system stimulation
 - Decreased GI motility—decreased bowel sounds
 - Urinary retention—full bladder

- Cholinergic
 - Defecation
 - Urination
 - Miosis, muscle fasciculations, muscle weakness
 - Bronchorrhea, bradycardia, bronchospasm
 - Emesis
 - Lacrimation
 - Salivation

DIFFERENTIAL DIAGNOSIS

Analgesics

Acetaminophen

- Available in many formulations and dosages
- Often formulated in combination with other medicines, such as opioids, diphenhydramine, dextromethorphan, and pseudoephedrine
- Acetaminophen-containing products lead to:
 - 7% of all childhood exposures
 - 4% of all adolescent exposures
 - 12% of all childhood and adolescent poisoning fatalities
- Toxicity occurs after overdose or therapeutic error.
 - After an overdose, patients are usually asymptomatic for the first 24 hours, although they may have mild GI distress.
 - Clinical hepatitis develops over the next 2 days and may progress to fulminant hepatic failure.
 - Patients may recover spontaneously.
 - Liver transplantation may be necessary in severe cases.
 - Poison control centers will refer children for evaluation after ingestion of 150 mg/kg.
 - Toxicity in an adult is expected after an ingestion of 15 g.
- The only test necessary in an otherwise healthy patient is an acetaminophen level drawn 4 hours after the exposure.
 - Levels drawn before this time will not reliably predict the need for antidotal therapy.
- Additional laboratory testing may be appropriate in the following scenarios.
 - Overdose of extended-release preparation
 - Mixed overdose
 - Patient seeking care late
 - Underlying chronic disease
 - When otherwise medically indicated

Salicylates

- Available in many formulations, including standard, enteric-coated, extended-release, and chewable tablets
- Salicylates are formulated together with opioids and over-the-counter cold remedies, antidiarrheal agents, herbal medications, and analgesic ointments.
- Patients ingesting >150 mg/kg are at risk of toxicity.

- Methylsalicylate is a liquid formulation used as a topical analgesic (oil of wintergreen).
 - 100% solution contains 1.5 g/mL.
 - Even a single teaspoon of this formulation presents a significant risk for toxicity in a toddler.
- Patients may have respiratory alkalosis, a metabolic acidosis, or a mixed acid-base disturbance; children usually exhibit acidosis.
- Patients demonstrate:
 - Altered mental status
 - Hypovolemic shock
 - Seizures
 - Coma
 - Hyperthermia
 - Hypoglycemia
 - Hypokalemia
 - Noncardiogenic pulmonary edema (sometimes)
- Laboratory evaluation requires assessment of electrolytes, blood gas, and salicylate level.
- Symptoms of acute intoxication are typically seen with salicylate levels >30 mg/dL.
- Severe toxicity is typically found with levels of 80–100 mg/dL.
- Ferric chloride can be used as a quick bedside test to confirm exposure.
 - Urine that contains salicylate turns purple or brown when 1 or 2 drops of 1% ferric chloride are added to 1 mL of urine.
 - This test is positive after taking even 1 aspirin tablet; thus, proof of overdose still requires a salicylate level.
- Salicylate toxicity is likely with elevated salicylate levels, but toxicity does not specifically correlate with salicylate levels.

Antidepressants

Tricyclic antidepressants

- Classic tricyclic antidepressants, such as imipramine or amitriptyline, have largely been replaced by selective serotonin reuptake inhibitors (SSRIs) as first-line agents in the treatment of depression.
- Tricyclic antidepressants are still used to augment SSRIs and to treat such conditions as insomnia or neuropathic pain.
- Ingestion of 1 or 2 pills may be toxic in a toddler.
- Symptoms of toxicity appear within 6 hours of ingestion.
 - Patients who remain asymptomatic throughout this observation period are unlikely to develop toxicity.
- Symptoms include:
 - Hypotension
 - Prolonged QRS and QT intervals on electrocardiography (ECG); right bundle branch block; and wide, complex dysrhythmias
 - Brief generalized seizures occur 1 to 2 hours after ingestion.

- Anticholinergic effects contribute to delirium, coma, and seizures.

SSRIs

- SSRIs, such as fluoxetine, sertraline, and paroxetine, are first-line agents for treatment of depression and anxiety.
- SSRIs have decreased toxicity compared with the classic tricyclic antidepressants.
- The primary adverse effects of SSRIs result from excessive serotonergic stimulation.
- Serotonin syndrome, a rare but potentially lethal condition, includes:
 - Altered mental status
 - Agitation
 - Myoclonus
 - Hyperreflexia
 - Diaphoresis
 - Tremor
 - Diarrhea
 - Incoordination
- If untreated, patients may develop:
 - Lactic acidosis
 - Rhabdomyolysis with renal failure
 - Hepatic dysfunction
 - Disseminated intravascular coagulation
 - Acute respiratory distress syndrome
- Serotonin syndrome most commonly results from therapy with a combination of serotonergic agents or combination of an SSRI with amonoamine oxidase inhibitor.

Antihistamines

- Antihistamines are commonly available in prescription and over-the-counter allergy medications, antinausea medications, and sleep aids.
- Available in both short- and long-acting formulations and found in combination with other medications, such as acetaminophen
- First-generation H1 antagonists (eg, diphenhydramine) typically cause sedation and CNS depression.
- Second-generation H1 antagonists (eg, loratadine) generally have less sedation than the first-generation agents.
 - However, several agents in this class (eg, terfenadine) were withdrawn from the US market because of the high risk of torsades de pointes.
- H2-receptor antagonists, such as ranitidine and cimetidine, primarily act in the GI tract.
- Antihistamine toxicity is marked by either:
 - CNS depression with somnolence or coma
 - CNS excitation with tremor, hyperactivity, hallucinations, or seizures

- Peripherally, antihistamines cause an anticholinergic toxidrome.
- Association of fever and altered mental status may be confused with meningitis or encephalitis.

CO

- CO, an odorless, colorless, tasteless, and nonirritating gas, is a by-product of hydrocarbon combustion and is the leading cause of poisoning deaths in the US.
- Toxic effects of mild CO poisoning can be nonspecific.
 - Headache is the most common.
 - A nonspecific viral syndrome is mimicked with:
 - Malaise
 - Nausea
 - Dizziness
- Severe disease produces CNS and cardiac toxicity.
 - Altered mental status
 - Seizure
 - Syncope
 - Coma
 - Dysrhythmias
 - Myocardial ischemia
- Significant toxicity is often associated with:
 - Metabolic acidosis
 - Increased lactate levels
- Cherry-red skin, although frequently mentioned, is rarely seen.
- Higher carboxyhemoglobin (CO-Hb) levels are associated with more severe disease; no correlation exists between specific symptoms and a particular level.
 - Children develop symptoms at lower CO-Hb levels than adults.
- CO causes lesions in the deep white matter and damage to the thalamus, basal ganglia, hippocampus, and globus pallidus.
- After 2 weeks, delayed effects include:
 - Neurocognitive deficits
 - Personality changes
 - Focal neurologic symptoms
 - Movement disorders
 - Although children can experience delayed effects, adults have a higher risk, particularly if loss of consciousness occurs during the early phase of the exposure.
- When a pregnant woman is exposed to CO, the fetus is at particular risk.
 - Brain damage and fetal death have been reported, generally after severe maternal exposures.

- The best measure of CO exposure is the CO-Hb level.
 - Normal CO-Hb levels are 1–2%; smokers may have levels of 5–10%.
 - Fetal hemoglobin may be assayed as CO-Hb.
 - Infants may have a CO-Hb level of approximately 3%.
 - Standard pulse oximeters cannot differentiate CO-Hb from oxyhemoglobin.
 - Blood gas CO oximetry is necessary to obtain accurate measurements of CO-Hb and methemoglobin.
 - High levels indicate significant exposure.

Cardiovascular medications

- Although childhood poisoning with cardiovascular agents is unusual, small doses may cause serious toxicity.
- Cardiovascular agents may be divided into 4 important classes.
 - Cardiac glycosides
 - β -Adrenergic blockers (BBs)
 - Calcium-channel blockers (CCBs)
 - α_2 -Adrenergic agonists

Cardiac glycosides

- Cardiac glycosides include:
 - Digoxin
 - Digitalis, and related compounds found in such plants as oleander and foxglove
 - Some toad venoms (bufotoxin) (popular as hallucinogens and aphrodisiacs)
- Symptoms associated with acute overdose are typically:
 - Nausea
 - Vomiting
 - Headache
 - Weakness
 - Confusion
 - Changes in vision
 - Palpitations
 - Dizziness
- Severe acute overdose will lead to:
 - Hyperkalemia
 - Bradycardia
 - Hypotension
 - Dysrhythmia
 - Hypercalcemia, hypokalemia, hyperkalemia, or hypomagnesemia can exacerbate cardiac toxicity.
- Chronic overdose is often characterized by:
 - Nausea and vomiting
 - Psychiatric disturbances
 - Drowsiness

- Headache
- Hallucinations

BBs and CCBs

- BBs, such as propranolol, atenolol, and metoprolol, are commonly prescribed for treatment of hypertension, angina, dysrhythmias, and headache.
 - β_1 -Receptor blockade results in decreased myocardial contractility and conduction.
 - β_2 -Receptor blockade increases smooth muscle tone (bronchospasm) and peripheral vascular tone (hypertension).
- After an oral overdose of BBs, symptoms begin within 2 hours; sustained-release formulations may result in delayed onset.
- Manifestations include:
 - Hypotension
 - Bradycardia
 - Wide QRS and PR intervals on ECG
 - Bundle branch block
 - Ventricular dysrhythmias such as ventricular tachycardia and torsades de pointes
 - CNS depression ranging from drowsiness to coma and seizures
 - Bronchospasm in patients with a history of asthma
 - Hyperkalemia
 - Hypoglycemia

α_2 -Adrenergic agonists (clonidine)

- Used to treat hypertension and other disorders, such as attention-deficit/hyperactivity disorder and nicotine withdrawal
- Oral and patch formulations are both available.
- Even 1 or 2 clonidine pills may cause toxicity in a toddler.
- Patches contain high doses of clonidine to ensure transdermal delivery, and they are a particular problem when ingested by children.
- Toxic symptoms begin within an hour of ingestion and can last up to 24 hours.
- Clonidine toxicity mimics opioid toxicity, with:
 - Altered mental status
 - Coma
 - Respiratory depression
 - Miosis
- Other symptoms include:
 - Hypotension
 - Bradycardia
 - Dysrhythmias, such as first- and second-degree atrioventricular block

Caustic ingestions

- Caustic agents are broadly categorized as *acids* and *alkalis*.
- Serious caustic exposures are unusual in childhood, but these agents can cause significant injury.
- Acids injure tissue by coagulation necrosis.
 - Even though the resulting eschar may limit the initial depth of injury, esophageal, gastric, or intestinal injuries frequently occur.
 - Significant exposures may cause metabolic acidosis or acute renal failure.
- Alkali ingestions injure tissue rapidly by liquefactive necrosis.
 - Within minutes, tissue edema develops in the oropharynx and esophagus, potentially leading to airway obstruction.
 - Scar tissue from full-thickness burns in the esophagus may progress to strictures over several weeks.
- Caustic ingestions produce:
 - Dysphagia
 - Odynophagia
 - Drooling
 - Stridor
 - Hoarseness
 - Abdominal pain
 - Nausea
 - Vomiting
 - GI hemorrhage and perforation
 - Tissue eschar may sometimes mask findings despite a significant acid ingestion.

Hydrocarbons

- Categorized into 3 classes:
 - Aliphatics (kerosene, gasoline, mineral seal oil, solvent, paint thinners)
 - Aromatics (industrial solvents, such as benzene and toluene)
 - Terpenes (turpentine and pine oils)
- Hydrocarbon aspiration after unintentional exposure to such household products is a leading cause of poison-related death in young children.
- Pulmonary toxicity results from chemical pneumonitis after aspiration.
- Local or diffuse infiltrates, pleural effusions, and pneumatoceles may develop.
- Lipoid pneumonitis may result from ingesting hydrocarbons with high viscosity, such as petroleum jelly.
- Most patients experience coughing after hydrocarbon exposure, but cough does not by itself indicate pulmonary toxicity.
- Within 30 minutes, significant exposures cause:
 - Gaspings
 - Choking

- Gagging
- Vomiting
- Patients may develop:
 - Cough
 - Tachypnea
 - Rales
 - Rhonchi
 - Wheeze
 - Diminished breath sounds
- In the most severe cases
 - Acute lung injury
 - Hemorrhagic pulmonary edema
 - Respiratory failure
 - Long-term respiratory dysfunction
- Respiratory effects may progress over the first 24 hours and resolve over the next 2–5 days.
 - Associated acute symptoms may include CNS depression and fever.

Insect repellents

Diethyltoluamide

- *N,N*-diethyl-3-methylbenzamide (DEET) provides broad protection against many insects and is available in a variety of formulations.
- Toxicity may occur after acute ingestion or with dermal exposures.
- Systemic toxicity causes:
 - Confusion
 - Ataxia
 - Generalized seizures
 - Encephalopathy
- Severe exposures may result in:
 - Hypotension
 - Bradycardia
- Encephalopathy may result from oral ingestions or chronic cutaneous exposures at high doses.
- Chronic exposures can lead to:
 - Insomnia
 - Muscle cramps
 - Mood changes
 - Rash

Lindane

- Lindane (γ -hexachlorocyclohexane) is an organochlorine insecticide used topically to treat scabies and pediculosis.
- Organochlorines are absorbed from the skin and are distributed into fat.
- Elimination half-life is between 20 hours and 10–20 days.

- Prodrome of headache, dizziness, ataxia, and tremors may be followed within 1–2 hours by self-limited seizures.
- Other complications include:
 - Disseminated intravascular coagulation
 - Anemia
 - Myoglobinuria
- Repeat and chronic exposures may be associated with:
 - Elevated aminotransferase levels
 - Leukopenia
 - Leukocytosis
 - Thrombocytopenia
 - Pancytopenia
 - Aplastic anemia

Iron

- Iron poisoning remains a problem for toddlers.
- Most significant toxicity is related to ingestion of adult iron tablets, not children's liquid or chewable vitamin preparations.
- Iron is a GI irritant that causes:
 - Abdominal pain
 - Nausea
 - Vomiting
 - Diarrhea
- Severe poisoning causes mucosal ulceration and hemorrhagic necrosis, leading to hematemesis, melena, or hematochezia.
- GI fluid losses lead to hypovolemic shock and contribute to positive anion gap metabolic acidosis.
- Absorbed iron leads to the production of free radicals, with adverse effects on cellular metabolism, which exacerbate the acidosis.
- A shock state in combination with iron's direct toxic effects contributes to progressive myocardial dysfunction and acute hepatic injury.
- As hepatocellular damage progresses, coagulation is disrupted, further exacerbating the GI hemorrhage.
- In rare cases, corrosive injury to the GI tract leads to gastric outlet obstruction weeks after the ingestion.
- In general, the higher the dose of iron ingested, the greater the likelihood of toxicity.
- Iron toxicity based on the ingested dose of elemental iron:
 - <20 mg/kg: none or minor
 - 20–40 mg/kg: mild to moderate
 - 40–60 mg/kg: moderate to severe
 - >60 mg/kg: severe
- Iron toxicity based on serum iron level (mg/dL)
 - Serum iron <300: expected toxicity, none or minor
 - Serum iron 300–500: expected toxicity, mild to moderate
 - Serum iron >500: expected toxicity, severe

- Peak serum iron level is best measured 4–6 hours after ingestion.
- GI symptoms alone do not predict severe toxicity but do confirm exposure.

Isoniazid

- Isoniazid (isonicotinyl hydrazine [INH]) is primarily used for prophylaxis and treatment of tuberculosis.
- It can cause hepatic toxicity, peripheral neuropathy, and optic neuritis even at therapeutic doses.
- INH doses of >30 mg/kg are likely to cause acute toxicity.
- Effects occur within 2 hours of ingestion.
- Patients initially experience:
 - Nausea
 - Vomiting
 - Slurred speech
 - Dizziness
 - Tachycardia
 - Urinary retention
 - Hyper- or hyporeflexia
- Significant toxicity causes:
 - Anion gap metabolic acidosis
 - Coma
 - Refractory seizures
 - Seizures

Lead poisoning

- The principal childhood source of lead is from deteriorating paint in pre-1970s-era houses.
- Other sources include:
 - Pica
 - Lead-based plumbing
 - Ceramics
 - Imported goods in lead-soldered cans
 - Folk remedies for colic advocated by some Chinese, South Asian, and Hispanic cultures
- GI absorption is facilitated by deficiencies in essential trace elements, such as iron, calcium, and zinc, which compete for the same absorption sites.
- Most children with a long history of lead exposure and absorption are asymptomatic.
 - A threshold no-effect level for lead has not been defined, and decreased IQ has been observed among children with whole-blood lead (BPb) levels <10 mcg/dL.
 - BPb levels as low as 15–20 mcg/dL have been associated with learning disabilities and mild decreases in IQ.
- Manifestations include:
 - Pallor
 - Hearing impairment
 - Constipation

- Behavioral disturbances
- Loss of developmental milestones
- Declines in school performance
- Encephalopathy is the most significant clinical manifestation of lead toxicity.
 - Subacute encephalopathy may cause:
 - Anorexia
 - Intermittent abdominal pain
 - Nausea
 - Vomiting
 - Constipation
- Children with BPb levels >70 mcg/dL may experience:
 - Coma
 - Intractable seizures
 - Death
- Patients with BPb <70 mcg/dL may exhibit:
 - Ataxia
 - Incoordination
 - Lethargy
 - Irritability
- Peripheral neuropathy is uncommon in children, but wrist and foot drops may occasionally occur with sickle cell disease.

Organophosphates

Pesticides

- Ingestion of the agent directly or through contaminated fruit is the most common route of exposure in children, although these agents are highly lipophilic and are well absorbed through the skin, eyes, and lungs.
- Assistance in identifying individual agents can be obtained from the US National Pesticide Telecommunications Network, 800/858-7378.
- Acute organophosphate poisoning causes cholinergic symptoms.
- CNS symptoms are often the presenting symptoms in younger children.
- The diagnosis is made when patient has a confirmed exposure or history of a suspected exposure and consistent physical findings.
- Hydrocarbon carrier may produce an odor of garlic.
- Symptoms occur within several hours but may be delayed for several days with more fat-soluble compounds.
- The poisoned patient has:
 - Pinpoint pupils
 - Vomiting
 - Changes in mental status
 - Copious secretions

- If untreated, combination of bronchial hypersecretion, bronchial constriction, and failure of respiratory musculature leads to respiratory failure, which may be complicated by coma and convulsions.
- Atypical presentations can occur in children.
- Clinical sequelae that have been reported in children include:
 - Mydriasis
 - Tachycardia
 - Hyperglycemia
 - Metabolic acidosis
 - Prolongation of the QT interval with subsequent torsades de pointes
- Intermediate syndrome, uncommon in children, is delayed toxicity that occurs after the resolution of initial cholinergic symptoms.
 - Symptoms (below) present 1–3 days after the cholinergic crisis, are not responsive to atropine, and require supportive care for several weeks.
 - Proximal muscle weakness
 - Cranial nerve deficits
 - Hyporeflexia
 - Increased risk of the intermediate syndrome appears to exist with the more lipophilic agents.
 - These may not have been accessible to antidote.
 - They are released from fat-storage sites into the circulation.
- Delayed symptoms reported up to 3 weeks after exposure
 - Polyneuropathy
 - Ataxia
 - Neuropsychiatric symptoms
 - Peripheral neuropathy
 - Spasticity
 - Most improve with time and do not cause permanent disability.
- Serum levels of both butyrylcholinesterase (pseudocholinesterase) and red blood cell cholinesterase (true cholinesterase) can be measured, but red blood cell cholinesterase is a more sensitive measure of toxicity.
 - Red blood cell cholinesterase testing is not available in most hospital laboratories.
 - Treating a patient for suspected poisoning should not wait for laboratory confirmation.

Nerve agents

- Sarin, soma, tabun, and VX are all agents with very rapid rates of permanent cholinesterase inactivation, leading to the rapid onset of severe cholinergic symptoms.
 - Agents can be dispersed through a blast or aerosolized.
 - Overall, these agents are more dense than air and are concentrated near the ground; thus, children may have an increased exposure risk.
- Sarin, soma, and tabun are volatile liquids with easily inhaled fumes.
 - The volatile fumes of sarin, soma, and tabun are quickly dispersed in the air and degrade within several hours.
- VX is less volatile and more likely to be absorbed through the skin.
- Patients exposed to these agents are not at further risk once they are removed from the site of exposure.
 - VX is more persistent in the environment and may present risk for ongoing exposure.
- More information on organophosphates and other chemical agents with potential for use as chemical weapons can be found at www.bt.cdc.gov/chemical.

Plants

- >750 toxins have been identified in >100 plant species.
- Plants do not require labeling for potential toxins, as is done for pharmaceuticals and household products, and no federal regulations exist on sales of plants or herbs.
- Exposure occurs by contact with the skin or eyes or by ingestion.
- Only a very few patients seek medical attention; even fewer require intervention (see table Toxic Plants).
- The most common plants that result in clinical sequelae are peace lily, holly, philodendron, poinsettia, pokeweed, poison ivy, rubber tree, and nightshade.

Substance abuse

Marijuana

- Made from dried leaves of the plant *Cannabis septima*
- Extracts of the *Cannabis* plant are available as hashish (dried resin) and hash oil (liquid extract).
- Medical marijuana is available in pill form (Dronabinol).
- The active component is tetrahydrocannabinol, a psychoactive compound.
- When inhaled, the onset of action is 10–30 seconds, and the effects last from 1–4 hours.
- Ingestion results in slower onset of action (30–60 minutes) and more prolonged effects.
- Clinical effects include euphoria, impaired motor coordination and speech, impaired short-term memory, paranoia, and agitation.
- Other effects include dry mouth, conjunctival injection, tachycardia, and urinary retention.
- In rare circumstances, patients may experience hallucinations, delusions, and psychosis.

Lysergic acid diethylamide (LSD)

- LSD is available in several forms, including liquid-impregnated blotter paper, microdots, tiny tablets, windowpane gelatin squares, liquid, powder, and tablets.
- LSD is usually ingested and has rapid GI absorption.

Toxic Plants^a

	Plant	Toxin or Toxic Part	Toxicity and Treatment
Houseplants and Cultivated Flowers	Aloe	Latex contains anthraquinones	Oral irritation, nausea, vomiting, diarrhea
	Anemone	Protoanemonin aglycone	Irritation of mucous membranes and GI system
	Autumn crocus, glory lily	Colchicine	GI, respiratory, renal, CNS toxicity
	Christmas pepper	Capsicum	Strong irritant, stinging or burning of mucous membranes
	Chrysanthemum	Sesquiterpene, lactones, pyrethrins	Skin reactions
	Iris	Resin-like podophyllotoxin	Gastroenteritis
	Jerusalem cherry	Solanine alkaloids	GI, CNS depression
	Lily-of-the-valley, foxglove, oleander	Cardiac glycosides	Irritation of mucous membranes, CV toxicity
	Monkshood, larkspur	Alkaloid aconitine	• Restlessness, salivation, irregular heartbeat • Rx: gastric decontamination
	Narcissus, amaryllis, daffodil	Alkaloid lycorine	Vomiting and diarrhea
	Philodendron, caladium, dumb cane, elephant ear, peace lily, pothos	Oxalates	• Irritation of buccal mucosa, edema, gastroenteritis, hypocalcemia • Rx: rinse mouth with milk; administer calcium
Snow-on-the-mountain	Unknown acrid principle in milky sap	Irritation of mucous membranes and GI system	
Wildflowers and Weeds	Buttercup, morning glory	Protoanemonin; seeds contain lysergic acid monoethylamide	GI irritation, CNS stimulation, hallucinations
	Deadly or black or climbing nightshade, jimson weed, henbane	Atropine, solanine, and related glycoalkaloids	• Anticholinergic • Rx: physostigmine
	Death camus	Veratrum alkaloids	• Nausea, vomiting, hypotension, bradycardia, syncope, paresthesia, weakness • Rx: atropine
	Green or false hellebore	Veratrum alkaloids	• GI irritation, respiratory, CV depression • Rx: atropine
	Horse nettle	Solanine alkaloid	GI, CNS depression
	Jack-in-the-pulpit, wild calla, skunk cabbage	Calcium oxalate crystals	• Irritation and burning of mouth • Rx: rinse with milk and magnesium hydroxide
	May apple	Podophylloresin	May produce peripheral neuropathy, vomiting, colic, diarrhea, drowsiness, impaired vision
	Poison hemlock	Alkaloid coniine	Salivation, nausea, vomiting, diarrhea, sensory disturbances, seizure, coma; death from respiratory paralysis
	Poison ivy, oak, sumac, wood	Urushiol	• Rhus dermatitis—red, itchy and clear blisters that exude serum; if ingested, causes severe mucosal irritation • Rx: topical or oral corticosteroids

Toxic Plants^a, continued

	Plant	Toxin or Toxic Part	Toxicity and Treatment
Wildflowers and Weeds, continued	Pokeweed	Podophyllotoxins	Vomiting, sweating, colic, diarrhea, CNS depression
	Rosary pea	Abrin	Burning sensation of mouth and throat, delayed GI, depression of vasomotor center, CV collapse
	Spurges	Unknown acid principle	Severe mucosal irritation
	Water hemlock	Cicutoxin	<ul style="list-style-type: none"> • Generalized seizures • Rx: symptomatic to prevent/control seizures
	White snakeroot	Tremetol, may be in milk of poisoned cow	Weakness, vomiting, tremor, and death
Cultivated Flowers and Crops	Castor bean	Ricin, must be chewed to release	Burning sensation of mouth and throat, delayed GI, depression of vasomotor center, hepatic, hemolysis, convulsions, and death
	Potato, tomato	Foliage and sprouts contain solanine alkaloids	GI irritation, headache, CNS depression, dermatitis
	Rhubarb	Leaves contain oxalate crystals and soluble oxalates	<ul style="list-style-type: none"> • Irritation of mucosa, hypocalcemia with seizures • Rx: rinse mouth with milk, replace calcium
	Tobacco	Nicotine	Salivation, gastroenteritis, seizures
Trees and Woody Shrubs	Black locust	Toxalbumin	Anorexia, weakness, GI, dilated pupils, irregular and weak pulse
	Cherry, apple, peach, apricot, choke cherry	Leaves, pits, or seeds contain glycosides hydrolyzed to hydrocyanic acid upon chewing	<ul style="list-style-type: none"> • Dyspnea, paralysis, convulsions, coma, and death • Rx: cyanide antidote kit
	Daphne	Glycoside in which the aglycone is dihydroxycoumarin	Burning and irritation to the skin and GI tract, bloody diarrhea, stupor, weakness, and convulsions
	English holly	Ilexanthin and ilex acid	Vomiting and diarrhea
	Mistletoe	Berries contain lectins, phoratoxin, viscotoxin, polysaccharides	Gastroenteritis and CV collapse
	Mountain laurel, rhododendrons	Grayanotoxin	<ul style="list-style-type: none"> • Local and GI irritation, respiratory and CV depression • Rx: atropine
	Yew	Alkaloid taxine	Vomiting, colic, hypotension, respiratory depression

Abbreviations: CNS, central nervous system; CV, cardiovascular; GI, gastrointestinal; Rx, treatment.

^a Adapted from: Rodgers GC, Matyunas NJ. *Handbook of Common Poisonings in Children*. 3rd ed. Elk Grove, IL: American Academy of Pediatrics; 1994.

- Psychedelic effects include existential experiences, intensified perceptions, hallucinations, and paranoia.
 - Clinical signs of LSD intoxication are most intense in the early part of the intoxication and include:
 - Tachycardia
 - Palpitations
 - Blurred vision
 - Tremors
 - Incoordination
 - Mydriasis
 - Users may experience flashbacks during which an individual re-experiences aspects of the acute intoxication.
 - These episodes are short-lived and self-limited but may provoke anxiety.
- Phencyclidine (PCP) and ketamine**
- PCP can be used orally or intravenously, smoked, or inhaled.

- Ketamine is a derivative of PCP and is used medically as a dissociative anesthetic.
 - Also a popular recreational agent because of its short duration, low cost, and hallucinatory effects
 - Recreational ketamine is diverted from medical, dental, and veterinary sources and is administered orally, intramuscularly, and intravenously.
- Clinical effects of PCP can last up to 48 hours after a large dose is ingested.
- Ketamine intoxication will typically last for ~8 hours after oral exposure and 90–120 minutes after intramuscular or nasal exposure.
- PCP and ketamine cause a dissociative psychotic reaction demonstrating as changes in body image and feelings of spiritual separation from the body.
 - Users may have difficulty seeing themselves as separate from their environment.
 - PCP users may experience dangerous or violent behavior.
 - The emotional state created by PCP is frequently unpleasant.
- Physical signs of PCP and ketamine intoxication include:
 - Nystagmus
 - Ataxia
 - Sensory impairment
 - Catatonia
 - Tachycardia
 - Hypertension
 - Increased secretions
- Ketamine intoxication is usually less severe and more short-lived than PCP intoxication.
- Both ketamine and PCP also have sympathomimetic effects.
- Supportive care in a quiet environment with minimal loud or noxious stimuli is usually all that is needed.
- Verbal and physical contact with friends or family members may be helpful.
- When agitated, patients should be sedated with appropriate doses of benzodiazepines.
- Prolonged or severe psychosis will require psychiatric evaluation.

Stimulants

- Cocaine, amphetamines, and related compounds are the most commonly used stimulants.
 - All have sympathomimetic effects.
 - Cocaine is a short-acting stimulant with local anesthetic properties.
 - Cocaine can be insufflated (snorted), smoked, or injected.
 - When smoked or used intravenously, cocaine effects begin almost immediately and peak within several minutes.
 - With nasal use, effects begin in a few minutes and peak after 30 minutes.

- Crack is a purified alkaloid form of cocaine that vaporizes instead of burning, allowing it to be smoked.
 - *Freebasing* describes heating a cocaine solution until it vaporizes and then inhaling the fumes.
- Amphetamines are α -methylphenylethylamine and its derivatives.
 - Amphetamines have been used to treat narcolepsy, asthma, and obesity, but their primary current medical indication is for treatment of attention-deficit/hyperactivity disorder (eg, methylphenidate).
 - Amphetamines cause altered perception, stereotypical and psychotic behaviors, and locomotor stimulation.
- Methylenedioxymethamphetamine (MDMA) is an amphetamine derivative commonly known as *ecstasy*, a popular club drug used at raves and rock concerts.
 - MDMA stimulates feelings of enhanced emotion and arousal, and hallucinations can occur at high doses.
 - Acute ingestion causes a functional increase in the serotonin concentration; with chronic use, however, serotonin stores are depleted.
- The clinical effects associated with these agents are related to stimulation of the CNS and cardiovascular system.
 - Severe effects include seizures and intracranial hemorrhage.
 - Cardiac toxicity of stimulants can cause tachycardia, hypertension, myocardial ischemia, and dysrhythmias.
 - Specific sequelae of cocaine use include:
 - Endocarditis
 - Pneumothorax
 - Tactile hallucinations
 - Amphetamines have been reported to cause:
 - Choreoathetoid movements
 - Compulsive behaviors
 - MDMA can cause hyponatremia resulting from the intake of large volumes of water combined with the release of alcohol dehydrogenase.

Inhalants

- Inhalation of volatile hydrocarbons, such as glue, spray paint, or gasoline, is a common form of adolescent substance abuse.
- Typically, patients sniff (inhale directly), huff (soak a rag and inhale from it), or bag (squirt or spray hydrocarbon in a bag and inhale from the bag or place the bag over the head).
- Acute presentation and management of inhalant intoxication differs from the hydrocarbon aspiration syndrome.
- The primary acute effect of hydrocarbon inhalation is altered mental status.
- At high doses, inhalation may cause:
 - Significant CNS depression
 - Coma
 - Respiratory depression

- Halogenated hydrocarbons, such as typewriter correction fluid (trichloromethane) or Freon, are cardiotoxic.
 - Sensitize the heart to catecholamines
 - Can cause malignant dysrhythmias
 - Sudden sniffing death occurs when a patient has been using these agents, experiences a catecholamine surge (eg, when running away from police), and develops sudden ventricular fibrillation.

Sedative-hypnotic agents

- Sedative-hypnotic agents encompass a diverse group of agents, including benzodiazepines, barbiturates, ethanol, and γ -hydroxybutyrate (GHB).
- Benzodiazepines, such as diazepam or alprazolam, are commonly prescribed anxiolytic agents.
 - Flunitrazepam (Rohypnol, or “roofies”) is an illicit benzodiazepine common in drug-facilitated sexual assault (date rape); its anxiolytic effects are also used to soften the coming-down phase after cocaine or heroin use.
- Barbiturates, such as phenobarbital, thiopental, or pentobarbital, are commonly used sedative, anesthetic, or anticonvulsant agents.
- Ethanol (ethyl alcohol) is commonly used by teens and preteens and is a contributing factor to injuries related to motor-vehicle collisions, homicide, fire, drowning, and suicide attempts.
 - At high doses, ethanol intoxication progresses to CNS depression, with coma and death resulting from respiratory suppression.
 - Ethanol is frequently ingested with other drugs.
- GHB was introduced as an anesthetic agent and gained popularity with bodybuilders as a reputed facilitator of growth hormone release.
 - It is currently a schedule-3 drug prescribed for narcolepsy and other sleep disorders.
 - Available in either pill or powder form
 - May cause agitation or sedation, vomiting, bradycardia, hypotension, coma, and seizures
- Sedative-hypnotic agents are usually identified on urine drug screens.
 - Benzodiazepines can be detected from 1–30 days after ingestion, depending on the individual agent.
 - Barbiturates may be detected up to 4 days after ingestion, although phenobarbital may be detected in urine up to 4 weeks later.
 - Blood alcohol concentrations are routinely available.
 - Standard urine drug assays do not screen for GHB.
- The hallmark of sedative-hypnotic intoxication is CNS depression with or without respiratory depression.
 - Respiratory depression can be seen with barbiturate intoxication but is unusual after benzodiazepine intoxication alone.

- Any combination of agents, including ethanol, increases the risk of respiratory depression.

Opioids

- Morphine, meperidine, codeine, hydrocodone, oxycodone, and propoxyphene are commonly used analgesic agents.
- Heroin is primarily used for its psychoactive effects; methadone is prescribed to treat heroin addiction.
- Different formulations of these agents are available for oral, intravenous, intramuscular, and subcutaneous administration.
 - These agents can also be insufflated or smoked.
 - Intravenous administration (morphine, meperidine, and heroin) leads to rapid onset of effect and carries the highest risk for adverse effects.
- Management of intoxication is based on history of exposure and the presence of clinical symptoms.
- Classic opioid toxidrome includes:
 - Respiratory depression
 - CNS depression
 - Miosis

Toxic alcohols

Methanol and ethylene glycol

- Found in many commercial products, including antifreeze, windshield washing fluid or de-icer, and picnic stove fuel
- Ethylene glycol has a sweet taste and is found in antifreeze, inks, pesticides, adhesives, cosmetics, and paints.
- Metabolites of methanol and ethylene glycol are toxic.
- Methanol intoxication causes:
 - Nausea
 - Headache
 - Decreased vision with mydriasis
 - Weakness
- Symptoms, if untreated, may progress to:
 - Blindness
 - Coma
 - Death
- Ethylene glycol intoxication produces neurologic symptoms.
 - Drunkenness
 - Coma
 - Tachypnea
 - Pulmonary edema
- Ethylene glycol toxicity may cause acute renal failure with precipitated oxalate crystals.
- Antifreeze often contains fluorescein as an additive to help mechanics locate radiator leaks; thus, a Wood lamp examination of the urine for fluorescence is sometimes suggested to help identify ethylene glycol.
 - This test lacks sensitivity.

Isopropyl alcohol (isopropanol)

- Found in common household products, such as rubbing alcohol.
- May be ingested intentionally as a substitute for ethanol
- Unmetabolized isopropanol causes clinical toxicity; as little as 20 mL can cause symptoms.
- GI toxicity causes nausea and vomiting and can progress to hemorrhagic gastritis.
- CNS findings include ataxia, muscle weakness, areflexia, lethargy, and coma.
- Isopropanol ingestion can cause myocardial depression with tachycardia and hypotension, renal tubular acidosis, and tracheobronchitis.
- Patients have increased serum osmolality and ketonuria but do not have metabolic acidosis.
- The clinical presentation is not usually severe and is rarely fatal.

Warfarin-like rodenticides

- The most common rodenticides (rat poisons) are coumarin anticoagulants that cause the rodent to bleed to death.
- Signs of coagulopathy become apparent when active factor levels fall below 30% and may not occur until days after ingestion.
- Superwarfarins are more lipophilic and occupy hepatic binding sites with a higher affinity.
- Warfarin ingestion may produce symptoms for approximately 1 week; superwarfarins may cause effects that persist for months.
- Single toddler exposures to standard warfarin or superwarfarin rodenticides do not typically lead to toxicity.
- Toxicity has been reported in children who repeatedly ingest superwarfarins or in large suicidal ingestions by adolescents or adults.
- Prothrombin time will remain normal for 1–2 days until factor levels have decreased; therefore, testing immediately after exposure is not very helpful.

DIAGNOSTIC APPROACH

- Telephone triage is an important first step in managing potentially toxic exposures.
 - Many exposures can be managed over the telephone, although home therapy of serious poisonings is limited.
- Determine:
 - Name and type of agent
 - Quantity involved
 - Weight of the child
 - Presence or absence of symptoms
- Symptoms alone may indicate toxicity even though, by history, neither the agent nor the dose would have predicted it.
- In the case of nontoxic exposures, reassurance is appropriate.

- Prompt decontamination may reduce subsequent symptoms and need for further treatment.
 - Skin and eyes may be washed in the home or office, if appropriate.
 - Activated charcoal is available in some areas for home administration, but its use has not gained widespread acceptance.
- All calls regarding potentially toxic exposures should be referred to trained poison information specialists at local and regional poison control centers.
 - A list of regional poison centers can be found at the Web site of the AAPCC.
 - The AAPCC toll-free telephone number is 800/222-1222.
- All patients with altered mental status should be evaluated for hypoglycemia.
- Intoxication or poisoning is only one cause of altered mental status.
 - Other important causes are trauma and CNS infection.
 - Trauma is especially important to consider because intoxication is common before trauma.
 - When the cause of altered mental status is unclear, cranial computed tomography should be considered.
 - Lumbar puncture may be performed in cases of altered mental status, especially in the presence of fever.
- Screening tests that are generally appropriate, especially for adolescent patients include:
 - ECG for agents, such as tricyclic antidepressants, that have characteristic ECG findings
 - Pregnancy testing in adolescent girls, because suicidal adolescents often have an acute stressor (such as pregnancy)
 - Acetaminophen levels should be assessed after a suicidal ingestion
 - Acetaminophen is widely available
 - Most patients are asymptomatic after acetaminophen ingestion.
 - A limited window exists for antidotal therapy.

TREATMENT APPROACH**Resuscitation**

- Some poisons cause toxicity that requires immediate attention.
 - Airway obstruction
 - Difficulty breathing
 - Dysrhythmias
 - Hypotension
 - Seizures
- Resuscitation generally proceeds according to the recommendations of pediatric advanced life support and advanced cardiac life support.

- Patients with airway obstruction or respiratory failure require urgent airway management and may require assisted ventilation or endotracheal intubation.
 - Antidotes are described in detail in the Antidote Table.
 - Patients with respiratory depression should receive an empirical trial of naloxone.
 - Both diagnostic and therapeutic for opioid (or clonidine) intoxication
 - May preclude the need for intubation
 - Escalating the dosing scheme allows administration of sufficient naloxone to reverse respiratory depression without precipitating withdrawal in a long-term user.
 - For patients with a prolonged opioid effect that outlasts the effect of a single dose of naloxone, it can be administered as a continuous infusion.
 - Naloxone administration may precipitate seizures as part of withdrawal in newborns born to opioid-dependent mothers.
 - Seizures are not a typical part of the withdrawal syndrome in long-term users.
 - Hypotension
 - Should be treated with a saline bolus and infusion
 - If unresponsive to fluid alone, may require use of a vasopressor
 - Use of dopamine is common, but it acts indirectly by releasing epinephrine and norepinephrine, which are stored in the nerve terminal.
 - When these stores are depleted, a direct-acting agent, such as norepinephrine, may be useful.
 - Empirical use of the benzodiazepine antagonist flumazenil to treat CNS depression after an overdose of an unknown agent is controversial.
 - Flumazenil administration is appropriate in a known acute benzodiazepine exposure associated with significant CNS or respiratory depression.
 - Flumazenil may precipitate withdrawal seizures in the patient with benzodiazepine dependence.
 - It may induce dysrhythmias or seizures in patients exposed to tricyclic antidepressants.
 - If the duration of flumazenil effect is shorter than that of the toxin, then repeat doses or a continuous intravenous infusion of flumazenil may be required.
 - Seizures require urgent intervention.
 - Benzodiazepines, specifically lorazepam or diazepam, are the preferred agents for the initial treatment of most toxin-induced seizures.
 - Seizures related to INH or the *Gyromitra* species of mushrooms (false morel) should be treated with pyridoxine (vitamin B₆).
 - Seizures related to hypoglycemia should be treated with dextrose.
 - Agitation is a common manifestation of altered mental status and places the patient at risk of injury, hyperthermia, and rhabdomyolysis.
 - Benzodiazepines are the preferred sedative agents, and dose should be titrated to effect.
 - Extremely agitated patients may require high doses.
- Decontamination**
- Considered in 2 large categories:
 - Surface decontamination of the skin and eyes
 - GI decontamination
- Surface decontamination**
- Skin exposures require thorough washing with soap followed by copious rinsing.
 - Eye exposures require copious irrigation with water or saline.
 - Decontamination must occur before other interventions, even resuscitation, with agents in which significant dermal absorption occurs.
 - Remove and secure clothing.
 - Health care workers must be appropriately protected.
 - Prehospital approach to managing chemical incidents includes decontamination at the site, although decontamination facilities are being built at many health care facilities.
 - Information can be found at the Web site of the Centers for Disease Control and Prevention.
- GI decontamination**
- *GI decontamination* refers to any procedure that removes toxin or reduces absorption from the GI tract and includes:
 - Emetic agents
 - Lavage
 - Activated charcoal
 - Cathartic agents
 - Emetic agents
 - Both the AAP and American Academy of Clinical Toxicology currently recommend against the use of syrup of ipecac for poison management, even at home.
 - *Gastric lavage* describes the procedure of irrigating the stomach with a large volume of fluid through a large-bore tube passed through the mouth into the stomach.
 - Should be performed when:
 - Risk of toxicity is great.
 - Likelihood of recovering the toxin is high.
 - Other treatment modalities are unavailable.
 - Certain agents, such as anticholinergic agents or opioids, may delay gastric emptying and slow GI transit time.
 - May remain in the stomach for >1 hour
 - May be available for removal by lavage
 - Contraindicated after the ingestion of hydrocarbons, acids, or alkaline agents

Antidote Table^a

Substance	Antidote	Dose	Comments
Acetaminophen	N-acetylcysteine	<ul style="list-style-type: none"> • IV: 150 mg/kg over 15 min, then 50 mg/kg over 4 hr, then 100 mg/kg over 16 hr • PO: 140 mg/kg load, then 70 mg/kg/dose every 4 hr for 17 doses 	<ul style="list-style-type: none"> • AE: vomiting (PO); anaphylactoid reaction (IV). • IV protocol requires large volumes of free water, which may cause hyponatremia and seizures in children.
Anticholinergic agents (eg, atropine)	Physostigmine	<ul style="list-style-type: none"> • P: 0.5 mg IV slowly • A: 2 mg IV slowly 	<ul style="list-style-type: none"> • May repeat dose after 15 min. • AE: cholinergic symptoms occur with excessive dosing.
Benzodiazepines	Flumazenil	<ul style="list-style-type: none"> • P: 0.01 mg/kg IV slowly every min (max 1 mg) • A: 0.1–0.2 mg IV slowly every min (max 1 mg) 	<ul style="list-style-type: none"> • Titrate to effect or maximal dose. May not reverse respiratory depression. If positive response is of short duration, may be administered as a continuous infusion. • AE: withdrawal symptoms in dependent or chronic use; seizures or dysrhythmias in cyclic antidepressant overdose.
β-Adrenergic antagonists	Glucagon	<ul style="list-style-type: none"> • P: 0.1 mg/kg IV slowly • A: 3–5 mg IV slowly 	<ul style="list-style-type: none"> • If positive response is of short duration, may be administered as a continuous infusion. • AE: vomiting, hyperglycemia, hypocalcemia.
	Insulin and dextrose	<ul style="list-style-type: none"> • Insulin 0.5 U/kg/hr IV, with • Dextrose 1 g/kg/hr 	AE: hypo- or hyperglycemia, hypokalemia.
	Amrinone	750 mcg/kg over 3–5 min slowly (max 3 mg/kg)	<ul style="list-style-type: none"> • May use other phosphodiesterase inhibitors with equal efficacy (eg, milrinone). • AE: hypotension.
Carbon monoxide	Oxygen (100%)	100% oxygen by nonrebreather	Treat until normal CO level or until hyperbaric oxygen initiated.
	Oxygen (hyperbaric)	100% oxygen at 2–3 atmosphere for 20 min	AE: pneumothorax, perforated tympanic membrane.
Calcium-channel blockers	Calcium chloride (10%)	<ul style="list-style-type: none"> • P: 20 mg/kg (0.2 mL/kg) IV slowly, via central line • A: 1–2 g (10–20 mL) IV slowly 	May use glucagon, insulin, and dextrose as adjunctive treatment in CCB as in BB toxicity.
	Calcium gluconate (10%)	<ul style="list-style-type: none"> • P: 60 mg/kg (0.6 mL/kg) • A: 3–6 g (30–60 mL) IV 	AE: hypercalcemia, phlebitis, nausea, vomiting, flushing, confusion, angina.
Cyanide	Amyl nitrate	One ampule by inhalation for 30 seconds every 3 min until IV access	AE: methemoglobinemia (see caution for sodium nitrite below).
	Sodium nitrite (3%)	<ul style="list-style-type: none"> • P: 0.33 mL (10 mg) IV (for Hb at 12) • A: 10 mL IV over 10 min 	<ul style="list-style-type: none"> • Dose varies according to weight and Hb level. See package insert. • AE: methemoglobinemia. • Use with caution in unconfirmed or unlikely cyanide poisoning (eg, in the setting of smoke inhalation), because induced methemoglobinemia may exacerbate hypoxemia from other causes.
	Sodium thiosulfate (25%)	<ul style="list-style-type: none"> • P: 1.6 mL/kg IV (for Hb at 12) • A: 50 mL IV over 3 min 	<ul style="list-style-type: none"> • Dose varies according to weight and Hb count. See package insert. • AE: hypotension, CNS toxicity.

Antidote Table^a, continued

Digoxin	Digoxin-specific antibody fragments (Digibind)	<ul style="list-style-type: none"> For known ingested dose: number of vials = mg ingested × 1.5 For known serum digoxin concentration (SDC, ng/mL): number of vials = SDC × weight (kg)/100 For unknown SDC or dose acute overdose: 10–20 vials For chronic overdose: P: 2 vials; A: 5 vials 	<ul style="list-style-type: none"> Each 40-mg vial binds 0.6 mg digoxin. AE: hypokalemia, worsening CHF.
Ethylene glycol and methanol	Ethanol (10%)	800 mg/kg (8 mL/kg) IV over 20–60 min, then 80–130 mg/kg/hr (0.8–1.3 mL/kg/hr) IV	Titrate to serum ethanol 100 mg/dL. Increase dose during dialysis and in chronic alcoholics. Oral dosing may be used in select cases.
	Fomepizole (4-methylpyrazole)	15 mg/kg over 30 min IV, then 10 mg/kg/dose every 12 hr × 4 doses, then 15 mg/kg/dose every 12 hr	<ul style="list-style-type: none"> Continue therapy until serum methanol or ethylene glycol level <20 mg/dL. Increase dose during dialysis. AE: headache, nausea, dizziness, bradycardia, eosinophilia, transient increase of liver enzyme levels
Heparin	Protamine sulfate	Use 1 mg protamine for every 100 units of heparin to be neutralized.	AE: hypotension, bradycardia, hemorrhage. Use with caution with known fish allergy.
Iron	Deferoxamine	5–15 mg/kg/hr IV (max 6 g/24 hr)	<ul style="list-style-type: none"> Titrate dose slowly to avoid hypotension. Continue therapy until <i>vin rose</i> urine color clears, symptoms clinically resolve, or maximal dose attained. Deferoxamine challenge no longer suggested. AE: flushing, hypotension, acute respiratory distress syndrome.
Isoniazid	Pyridoxine (vitamin B ₆)	<ul style="list-style-type: none"> Known INH dose: 1 g per g of INH ingested IV slowly Unknown INH dose: 5 g IV over 10 min 	<ul style="list-style-type: none"> Administer 1 g every 23 min. AE: CNS toxicity—headache, seizure, peripheral neurotoxicity.
Lead	Succimer (DMSA)	10 mg/kg/dose PO every 8 hr × 5 days, then 10 mg/kg/dose twice daily × 14 days	AE: rash, neutropenia, increased LFTs, GI upset.
	Dimercaprol (BAL)	<ul style="list-style-type: none"> 75 mg/m²/dose IM every 4 hr Max: 450 mg/m²/dose/24 hr 	<ul style="list-style-type: none"> Pretreatment with diphenhydramine suggested. Contraindicated with peanut allergy, hepatic insufficiency. AE: G6PD hemolytic crisis, nausea, vomiting, histamine release.
	CaNa ₂ EDTA	1–1.5 g/m ² /day continuous IV infusion × 5 days	<ul style="list-style-type: none"> In cases of encephalopathy, administer after dimercaprol to prevent increased CNS lead levels. AE: phlebitis.
Methanol	See Ethylene glycol		
Methemoglobinemia	Methylene blue (1%)	1–2 mg/kg IV over 5 min	<ul style="list-style-type: none"> Repeat doses as needed. AE: dyspnea, chest pain, and hemolysis.

continued

Antidote Table^a, continued

Opioids	Naloxone	0.5–2 mg IV/IM/SC/ET (max 10 mg)	<ul style="list-style-type: none"> Higher dose may be required for certain agents. Can repeat dose every 2–3 min until response or max dose. If no response to total 10-mg dose, unlikely opioid intoxication. If positive response is of short duration, may be administered as a continuous infusion. In setting of possible opioid dependence, consider initial dose of 0.05 mg to avoid withdrawal. AE: opioid withdrawal (piloerection, agitation, vomiting).
Cholinergic agents (eg, malathion)	Atropine	<ul style="list-style-type: none"> P: 0.02 mg/kg IV initial dose (minimum 0.1 mg) A: 0.5–1 mg IV initial dose 	<ul style="list-style-type: none"> Double dose every 3–5 min. Titrate to reduced bronchorrhea or improved oxygen saturation. May require total doses 5 or 10 times the initial dose or higher. AE: anticholinergic toxicity.
	Pralidoxime	<ul style="list-style-type: none"> P: 25–50 mg/kg over 30–60 min, then 20 mg/kg/hr A: 1–2 g IV over 15–30 min, then 0.5 g/hr 	Pralidoxime should be administered in addition to atropine. Continue therapy for 24–72 hr.
Oral antidiabetic agents	Octreotide	<ul style="list-style-type: none"> P: 1–2 mcg/kg SC/IV every 6–12 hr A: 50–100 mcg SC/IV, then 50 mcg every 12 hr 	<ul style="list-style-type: none"> Continue therapy until euglycemic. May require several days of therapy. AE: bradycardia, dysrhythmias, GI upset, hyperglycemia.
	Dextrose	<ul style="list-style-type: none"> Neonate: 0.2 g/kg IV (use D₁₀W, 2 mL/kg) P: 0.5–1 g/kg IV (use D₂₅W, 2–4 mL/kg) A: 25–50 g IV (use D₅₀W) 	AE: hyperglycemia, extravasation may cause local tissue reaction.
Tricyclic antidepressants	Sodium bicarbonate	1–2 mEq/kg IV bolus, then titrate to pH ~7.5 with additional doses or with continuous infusion	AE: volume overload, hypernatremia, metabolic alkalosis.
Warfarin	Vitamin K	<ul style="list-style-type: none"> P: 1–5 mg SC/IM/IV/PO, every 6–8 hr PRN A: 10 mg SC/IM/IV/PO, every 6–8 hr PRN 	Much larger doses may be required. Continue therapy until INR within normal limits.

Abbreviations: AE, Adverse effects; BB, β -adrenergic blocker; CCB, calcium-channel blocker; CHF, congestive heart failure; CNS, central nervous system; CO, carbon monoxide; D₁₀W, 10% dextrose and water; ET, endotracheally; G6PD, glucose-6-phosphate dehydrogenase; GI, gastrointestinal; Hb, hemoglobin; INH, isoniazid; IM, intramuscular; INR, international normalized ratio of prothrombin time; IV, intravenous; LFT, liver function tests; max, maximum; PO, oral; PRN, as needed; SC, subcutaneous; SDC, serum digoxin concentration.

^a Pediatric (P) and adult (A) doses are the same unless specifically noted.

- The most likely complication is vomiting, with aspiration of stomach contents.
 - Risk is highest in patients with a depressed level of consciousness and a diminished gag reflex.
 - Risk can be reduced by intubating the patient with a cuffed endotracheal tube.
- Unusual complications include esophageal or gastric perforation, dysrhythmias, hypothermia, and fluid and electrolyte abnormalities.
- Activated charcoal is a mainstay in poison management.
 - Adsorbs toxins in the GI tract to prevent absorption into the bloodstream
 - Effectively binds most large molecules, such as acetaminophen, aspirin, and phenobarbital
 - Does not adsorb small molecules, such as lithium or iron
 - Can be administered in single or multiple doses
 - The most common side effect is vomiting.
 - If the patient has a depressed level of consciousness, then the airway must be protected.

- Only contraindication is GI tract obstruction or perforation
- Should not be provided after acid or alkali exposures, because the charcoal will obscure endoscopic view of the esophagus and stomach
- Cathartic agents are used to enhance elimination from the GI tract.
 - Evidence supporting this therapy is not strong.
 - Such agents as magnesium citrate and magnesium sulfate are rarely used because of associated fluid and electrolyte abnormalities.
 - Sorbitol is the most frequently used and is typically administered with activated charcoal.
 - Fluid and electrolyte abnormalities are uncommon unless multiple doses are administered.
 - Only 1 combination dose of sorbitol and charcoal is suggested, even for cases in which multiple doses of activated charcoal are planned.
- *Whole-bowel irrigation (WBI)* is flushing the entire GI tract with an isoosmotic electrolyte solution, polyethylene glycol.
 - Frequently used to prepare the bowel for surgery
 - Large volumes (liters) of polyethylene glycol are infused until the effluent turns clear.
 - Not associated with fluid and electrolyte abnormalities, but patients sometimes experience GI discomfort and bloating
 - May be particularly helpful for agents that cannot be adsorbed with activated charcoal, such as iron or lithium, and for extended-release medications

Enhanced elimination

- Ion trapping, particularly urinary alkalinization, enhances drug clearance.
 - Most often used for salicylate poisoning
 - May enhance elimination of phenobarbital, chlorpropamide, and myoglobin
 - In theory, elimination of weak bases, such as phencyclidine and amphetamines, should be enhanced in acidic urine; however, urinary acidification has greater risk than benefit and is not used therapeutically.
- Hemodialysis provides definitive therapy for a limited number of agents, including:
 - Ethylene glycol
 - Lithium
 - Methanol
 - Salicylate
- Charcoal hemoperfusion is generally suggested for theophylline and sometimes for carbamazepine poisonings.
 - However, specialized charcoal cartridges have been difficult to obtain recently, and these poisonings are being treated with new high-efficiency, high-flux hemodialysis techniques.

Supportive care

- Continuation of care given in resuscitation, with ongoing attention paid to cardiorespiratory and neurologic status

SPECIFIC TREATMENTS

Analgesics

Acetaminophen

- N-acetylcysteine (NAC) is the specific antidote.
 - The decision to initiate NAC therapy requires using the Rumack-Matthew nomogram (see Figure 62 on page F21).
 - If a level on samples drawn 4 hours or later is above the possible toxicity line, then the patient should receive NAC.
 - This treatment approach is also applicable to patients who overdose with an extended-release preparation of acetaminophen.
- The oral formulation of NAC may still be available for use in some locations.
 - The sulfurous smell and foul taste of oral NAC frequently lead to nausea and vomiting.
- Intravenous NAC is reconstituted in 5% dextrose in water and administered according to a complex regimen that delivers a large volume of free water to the patient.
 - Intravenous NAC should be administered in consultation with a toxicologist familiar with its use.
 - The incidence of adverse reactions to intravenous NAC administration, primarily anaphylactoid reactions, may be as high as 20%.
 - These side effects are not completely mitigated by lowering the infusion rate but are usually amenable to therapy, after which treatment can be restarted.
 - Sick patients show altered mental status and hypovolemic shock.
 - Hepatotoxicity is unlikely if NAC is administered within 8–10 hours of the time of ingestion.
 - After this time, efficacy may be reduced, especially when patients wait before seeking care.
 - If a patient arrives ≥ 4 hours after ingestion and a level will not be available within the 8-hour window, then NAC should be administered pending results.
 - Although efficacy is reduced after 8 hours, NAC should still be administered, even to patients who seek care very late after the time of ingestion.
 - Reports have been issued of children developing hyponatremia and seizures secondary to intravenous NAC.
- If patients progress to fulminant hepatic failure, they may require liver transplantation.
 - Spontaneous recovery is not associated with long-term clinical or pathological sequelae.
- If a patient's acetaminophen levels are assessed on samples

drawn ≥ 4 hours after ingestion and the level is below the possible toxicity line of the nomogram, then the patient is medically clear.

- If the level is above the line and the patient begins NAC therapy within 8–10 hours, then the patient is medically clear at the end of treatment.

Salicylates

- Decisions regarding therapy are based on clinical evidence of toxicity.
- Need for intubation is unusual; hypoventilation after intubation may worsen acidosis.
- Fluid resuscitation is critical.
- Patients may require treatment for hypoglycemia.
- Several doses of activated charcoal are useful to prevent the absorption of ingested salicylate and may interrupt enterohepatic circulation.
- Rarely, salicylate tablets form a conglomeration in the stomach that requires surgical removal.
- In the case of methylsalicylate, patients may require skin decontamination to prevent ongoing dermal absorption.
- The first intervention to enhance salicylate elimination is to alkalinize the urine.
 - Optimal elimination occurs at a urine pH > 8 .
- Any patient with clinical evidence of salicylate toxicity is a candidate for alkalinization unless administering large volumes of fluid is contraindicated.
- Hemodialysis is used to eliminate salicylate and correct acidosis.
 - Indications for hemodialysis include:
 - Persistent CNS toxicity
 - Severe, worsening, or intractable acidosis
 - Extremely high salicylate levels (usually > 100 mg/dL)
 - Any condition that precludes the administration of a high-volume bicarbonate infusion, such as pulmonary edema, renal insufficiency, or congestive heart failure
- Any patient with evidence of significant toxicity requires hospital admission for further evaluation and management.
 - If no evidence of toxicity is found after 4–6 hours of observation, then the patient is medically clear.

Antidepressants

Tricyclic antidepressants

- Gastric lavage should only be performed when adequate airway protection is ensured because of the high risk of coma, seizures, and dysrhythmias in tricyclic antidepressant overdose.
- Reversal agents, such as flumazenil and physostigmine, are contraindicated in the setting of known or possible tricyclic antidepressant overdose.

- Initial management of patients with significant cardiovascular or CNS toxicity follows the principles in Treatment Approach (Resuscitation).
- Specific therapy for tricyclic antidepressant–related wide complex ventricular dysrhythmias and hypotension is hypertonic sodium bicarbonate administration.
 - Increase the serum pH to approximately 7.5.
 - A more alkaline pH lowers the concentration of free drug by stimulating protein binding; increased serum sodium overcomes sodium-channel blockade.
 - Adverse effects include volume overload, hypernatremia, and severe metabolic alkalosis.
- For persistent wide-complex tachycardias or torsades de pointes, limited evidence supports the use of magnesium.
- Benzodiazepines are suggested for seizures.
 - Barbiturates and propofol may be considered as adjuncts for seizures refractory to benzodiazepines.
 - Phenytoin should not be used because it blocks sodium channels and exacerbates tricyclic antidepressant cardiotoxicity.
- Medical admission will be required for patients with signs of cardiovascular or neurologic toxicity.

SSRIs

- The main focus of therapy is to decrease muscle rigidity and its sequelae, myoglobinuria and renal failure.
- Initial therapy to achieve muscle relaxation is benzodiazepines.
- Adjunctive therapy may be provided with cyproheptadine, a histamine and serotonin antagonist.
- Severe hyperthermia should be treated with aggressive cooling.
- If muscle rigidity is severe and unresponsive to conventional measures, then neuromuscular blockade can be used after the patient is intubated.
- Asymptomatic patients do not require medical admission.
- Patients with symptoms of serotonin syndrome should be admitted to the hospital for further evaluation and management.

Antihistamines

- Most patients with antihistamine toxicity do well with supportive care alone.
- For large ingestions or ingestions of sustained-release formulations:
 - Gastric lavage *or*
 - WBI
- Administration of activated charcoal is appropriate.
- Significant agitation or seizures should be treated with benzodiazepines.

- Physostigmine, a carbamate with cholinergic properties, is an antidote for patients with anticholinergic toxicity and is appropriate for use in a pure antihistamine overdose with moderate to severe symptoms.
 - Adverse effects of physostigmine include seizures and ventricular dysrhythmias.
 - Physostigmine is contraindicated for patients with evidence of cardiotoxicity or for treatment of overdoses of cardiotoxic agents, such as tricyclic antidepressants.
 - Physostigmine therapy should not be administered as nonspecific therapy for unknown coma or agitation.
- Patients who remain asymptomatic after 4–6 hours may be medically cleared.
- Symptoms may sometimes be delayed after a large ingestion, and patients may require a longer period of observation.

Carbon monoxide

- All exposed patients should initially receive 100% oxygen until an accurate estimate of exposure can be determined or a CO-Hb level can be measured, or both.
- A pH and blood lactate should be obtained concurrently; lactate seems to correlate to some extent with severity.
- Hyperbaric oxygen therapy is the preferred treatment for serious CO poisoning.
 - Increases concentration of dissolved oxygen to displace CO from binding sites on hemoglobin, myoglobin, and cytochrome oxidase
 - Improves the delivery of oxygen to tissues
 - Reduces lipid peroxidation
 - Limited data suggest it reduces the incidence of delayed neurologic and neuropsychiatric effects, particularly if administered within 6 hours, although data are conflicting.
 - Seems to be safe for pregnant women and may benefit the fetus
 - Hyperbaric chambers can be located through the Undersea and Hyperbaric Medical Society Web site (www.uhms.org/).
- Potential candidates for hyperbaric oxygen therapy include patients with:
 - Significant CNS, cardiovascular, or neuropsychiatric symptoms
 - Persistent metabolic acidosis or other symptoms that do not respond to standard 100% oxygen therapy
 - CO-Hb levels >25%
 - Pregnant women or children with CO-Hb levels >15%
- In general, symptomatic patients require hospitalization for further evaluation and management.
- Patients with relatively low CO-Hb levels and mild symptoms, especially when symptoms resolve after a short course of oxygen therapy, do not require hospitalization.
- Identifying and ameliorating the source of CO is imperative.

- Contact other potentially exposed persons who may require evaluation.

Cardiovascular medications

Cardiac glycosides

- Activated charcoal and steroid binding resins, such as cholestyramine, will adsorb cardiac glycosides in the GI tract and may interrupt their enterohepatic circulation.
- Hyperkalemia should be aggressively treated with bicarbonate, insulin, and glucose.
 - Calcium administration is contraindicated for the treatment of hyperkalemia, as it can exacerbate glycoside toxicity.
- Magnesium sulfate should be used in patients with hypomagnesemia.
- Kayexalate can also be administered.
- Significant toxicity is treated with digoxin-specific antibody antigen-binding fragments.
 - In the acute setting, Digibind therapy is used to treat:
 - Significant dysrhythmia
 - Serum digoxin levels >15 ng/mL at any time or >10 ng/mL 6 hours after ingestion
 - Serum potassium level >5 mEq/L
 - Hypotension
 - Second- or third-degree heart block
 - Digoxin dose >10 mg in a teenager or adult or >4 mg in a child
 - Digibind causes a marked increase in the measured serum digoxin level; thus, posttreatment levels do not reliably indicate a response to therapy.
- Adjunctive therapy includes:
 - Atropine for bradycardia
 - Phenytoin and lidocaine for ventricular dysrhythmias
- Cardioversion should be avoided because the ensuing sympathetic discharge can be fatal.
- Classes Ia, Ic, II, and IV antidysrhythmics are contraindicated because they decrease atrioventricular conduction and worsen bradycardia and other dysrhythmias.

BBs and CCBs

- For both BB and CCB ingestions (see also Antidote Table):
 - Activated charcoal can be administered.
 - WBI should be considered for ingestions of sustained-release preparations.
 - Glucagon is considered the specific antidote for significant cardiovascular symptoms related to BB overdose.
 - It may also be useful for CCB ingestions.
 - High-dose insulin and glucose is another therapeutic option.
 - Insulin may increase myocardial glucose utilization or alter myocardial calcium handling.
 - Calcium chloride may be useful.

- Amrinone, a phosphodiesterase inhibitor, may be useful for refractory hypotension.
 - By inhibiting the breakdown of cyclic adenosine monophosphate, amrinone, as does glucagon, increases inotropy.
- In both CCB and BB overdose, adjunctive therapy for severe refractory bradycardia includes:
 - Atropine
 - Epinephrine
 - Isoproterenol
 - Cardiac pacing
- Patients may require therapy for hyperglycemia, hyperkalemia, or seizures.
- All symptomatic patients with a history of a BB or CCB overdose should be admitted to an intensive care unit.
- Patients who are asymptomatic 6 hours after ingestion may be discharged unless they ingested a sustained-release formulation.

α_2 -adrenergic agonists (clonidine)

- Naloxone should be administered in cases of respiratory depression; high doses may be required (see Antidote Table).
 - May also be useful in cases of CNS depression or hypotension
- When naloxone is effective but clonidine toxicity outlasts naloxone's effect, continuous infusion of naloxone is indicated.
- Decontamination with activated charcoal is appropriate.
- WBI may be indicated for children who have ingested clonidine patches.
- Atropine may have modest effects on bradycardia, and fluids and pressors are indicated for hypotension.
- All symptomatic patients should be admitted to the hospital.
- Patients may be discharged if they are asymptomatic 4 hours after ingestion.

Caustic ingestions

- Gastric lavage is contraindicated because of the risk of esophageal or gastric perforation.
- Activated charcoal absorbs caustic chemicals poorly and may interfere with endoscopy.
- Plain-film radiography of the chest and abdomen is helpful to rule out pneumomediastinum, pneumoperitoneum, and aspiration pneumonitis.
- Esophagoscopy defines the extent of injury and should be performed in symptomatic patients.
- If any suspicion of perforation exists:
 - Surgical consultation should be obtained.
 - Broad-spectrum antibiotics should be administered.
- In large-volume acid ingestions, nasogastric suction performed within 30 minutes of exposure may prevent the passage of acid into the small intestine.

- Neutralization of acids and bases should be avoided because of the excessive heat and the risk of emesis.
- Repeat esophagography will be required 3–4 weeks after caustic ingestion to check for strictures.

Hydrocarbons

- Contaminated clothing should be disposed of properly.
- Skin should be washed with soap and water to limit continuing exposure.
- GI decontamination plays only a limited role; toxicity is related more to pulmonary exposure than to GI absorption.
- Most patients experience nausea and vomiting after hydrocarbon exposure and do not require further gastric emptying.
 - Gastric emptying is contraindicated after most hydrocarbon ingestions; risk of aspiration increases with any gastric-emptying procedure.
 - Gastric emptying (although controversial) may be considered in 2 cases.
 - When the patient has swallowed a large volume of hydrocarbon but has not already vomited
 - When the swallowed hydrocarbon can have systemic toxicity or is the carrier for another toxin, characterized by the mnemonic CHAMP (camphor, halogenated hydrocarbons, aromatic hydrocarbons, heavy metals, and pesticides)
- Symptomatic patients have radiographic evidence of aspiration as early as 30 minutes after exposure.
 - Asymptomatic patients occasionally develop radiographic changes, but importance of these changes is unclear.
- Management of pulmonary toxicity includes:
 - Supplemental oxygen
 - Humidified air
 - Intravenous fluids
 - Nebulized β_2 -agonists may be useful.
- Severely ill patients may require:
 - Continuous positive airway pressure
 - Mechanical ventilation with positive end-expiratory pressure
 - Extracorporeal membrane oxygenation
- Corticosteroids are not beneficial.
- Leukocytosis and fever are associated with hydrocarbon aspiration, and at least early in the course, do not signify infection.
- Patients with persistent respiratory symptoms should be hospitalized.
- Patients should be observed for 6 hours if:
 - They are symptomatic.
 - Symptoms have resolved and radiographic findings are normal.

- If they are asymptomatic at the end of the observation period, then they may be medically cleared.

Insect repellents

- Treatment entails avoidance and decontamination with soap and water.

Iron

- Asymptomatic patients do not require gastric emptying.
- Patients experiencing toxicity vomit spontaneously, and no additional benefit exists to gastric emptying.
- Gastric lavage has a limited role after significant ingestion or when pills are radiologically evident in the stomach.
 - Gastric lavage is often unsuccessful at removing pills from the stomach and cannot remove pills that have passed into the lower GI tract.
 - WBI may be more effective than other treatments at removing these residual pills.
 - In rare cases, surgery may be necessary to remove iron pills.
- Radiographs detect residual iron pills in <3% of all ingestions, but their does not exclude a toxic overdose.
 - Chewable and liquid iron formulations do not appear on abdominal radiographs.
- Significant iron poisoning is associated with both increased serum glucose level and an increased leukocyte count; however, normal values do not rule out significant exposure.
- Total iron-binding capacity greater than the serum iron level was once thought to be protective in poisoning.
 - However, total iron-binding capacity is factitiously increased in the setting of iron poisoning.
 - Deferoxamine also interferes with the accurate measurement of total iron-binding capacity.
- Patients with significant poisoning are often in shock, with positive anion gap metabolic acidosis.
 - These patients need immediate and vigorous resuscitation.
 - Decisions regarding treatment will usually have to be made on clinical grounds alone.
- Chelation therapy with deferoxamine should be considered for any symptomatic child who:
 - Is in shock *or*
 - Has an altered mental status *or*
 - Is experiencing protracted vomiting or GI bleeding
- Serum iron levels >500 mcg/dL or abdominal radiographs suggesting a serious ingestion may also be an indication for chelation.
- Desferrioxamine, the deferoxamine-iron chelate, is excreted in the urine and imparts a dark brown or *vin rose* color to the urine.
 - This color change is only a qualitative measure of desferrioxamine and is an unreliable marker of iron elimination.

- Chelation therapy should continue until the child is clinically improved and the metabolic acidosis is resolved, but duration of therapy >24 hours may present an increased risk of toxicity.
- Patients who remain asymptomatic without treatment for 6 hours after ingestion are medically clear.

INH

- If an asymptomatic patient seeks care soon after a significant exposure, then gastric lavage is appropriate.
- Activated charcoal may be provided.
- To prevent seizures, prophylactic pyridoxine should be administered to patients who seek care within 2 hours of ingestion.
- Seizure therapy
 - Can begin with typical anticonvulsants, such as benzodiazepines or phenobarbital
 - Phenytoin is not useful in treating INH-related seizures.
- Definitive therapy requires administration of pyridoxine, the specific antidote for INH toxicity.
- If intravenous pyridoxine is unavailable, crushed tablets can be given by nasogastric tube.
- Hemodialysis may be considered for patients with massive toxic ingestions.
- Patients who remain asymptomatic for 6 hours can be medically cleared.

Lead poisoning

- In all cases of suspected lead poisoning:
 - Any sources of lead exposure should be identified and abated.
 - Parents should be counseled regarding optimal nutrition.
- Symptomatic children are typically hospitalized to remove them from the source of lead and to administer chelation therapy.
 - Oral intake should be restricted.
 - Intravenous fluid resuscitation should be started if the use of ethylenediaminetetraacetic acid (EDTA) is anticipated.
 - If abdominal radiography finds radiopaque material, then WBI with polyethylene glycol should be initiated.
- BPb levels <45 mcg/dL
 - Patients do not require chelation therapy.
- Asymptomatic children with BPb between 45 and 70 mcg/dL
 - Chelate with oral succimer *or*
 - Intravenous CaNa₂ EDTA
- Children with BPb >70 mcg/dL
 - Chelate in the hospital with intramuscular dimercaprol (also known as *British anti-lewisite*) and
 - Intravenous CaNa₂ EDTA
- After initial chelation therapy, decision to repeat treatment depends on symptoms and follow-up BPb levels.

- Encephalopathy
 - Treated with the same 2-drug regimen but for a longer course
- 3 lead chelating agents are available in the US:
 - Dimercaprol
 - CaNa₂ EDTA
 - Succimer (dimercaptosuccinic acid [DMSA])
- A fourth agent, D-penicillamine, is not approved by the US Food and Drug Administration, but its use may be necessary in the unusual event of adverse reactions to both DMSA and CaNa₂ EDTA.

Organophosphates

Pesticides

- For a suspected or confirmed organophosphate exposure, decontamination should follow the principles above.
 - Rescuers and health care workers are at risk of exposure if the patient has not been appropriately decontaminated.
 - Contaminated clothing must be safely discarded.
 - For ocular exposures, the eyes should be copiously irrigated.
- After ingestions, gastric lavage may be appropriate.
 - Activated charcoal can be administered.
 - Lavage fluid is contaminated and must be safely discarded.
- The immediate life-threatening problem is bronchorrhea (copious airway secretions).
 - A patient in severe respiratory distress should be intubated.
 - The goal of therapy is to dry the airway secretions with atropine.
 - High-dose, continuous infusions of atropine may be required.
 - Succinylcholine should not be used for rapid-sequence intubation because it requires the inactivated cholinesterase for its metabolism.
 - Tachycardia, which may be related to either atropine administration or hypoxia, is not a contraindication to use of higher doses.
- The organophosphate-acetylcholinesterase enzyme complex ages over time, leading to irreversible inactivation of the enzyme.
 - 2-Pralidoxime, also known as 2-PAM, can hydrolyze the bond and reactivate the cholinesterase when administered before complete aging.
 - Because this agent does not cross the blood-brain barrier, reversal of neurologic symptoms requires atropine.
 - The efficacy of pralidoxime varies with the different organophosphate compounds, but it should be administered in all cases of severe toxicity.

- All patients with organophosphate toxicity require admission.
- Time to full recovery depends on the agent and can range from a few hours to several weeks.

Nerve agents

- Treatment for these agents is the same as that outlined for organophosphate pesticides above.
- The US Food and Drug Administration has approved an atropine autoinjector for children that is available for prehospital use.

Plants

- Only a very few patients seek medical attention; even fewer require intervention (see table Toxic Plants).
- Prevent plant exposures through education.
 - Parents must learn the names of plants they purchase, be familiar with plants that are toxic, and keep them safely away from children.

Substance abuse

Marijuana

- Compared with other hallucinogens, the effects of marijuana are usually mild and self-limited and require minimal medical intervention.

PCP and ketamine

- Supportive care in a quiet environment with minimal loud or noxious stimuli is usually all that is needed.
- Verbal and physical contact with friends or family members may be helpful.
- When agitated, patients should be sedated with appropriate doses of benzodiazepines.
- Prolonged or severe psychosis will require psychiatric evaluation.

Stimulants

- Treatment of stimulant intoxication requires good supportive care.
 - Benzodiazepine sedation is the most effective treatment for agitation, chest pain, hypertension, hyperthermia, and seizures.
 - Rhabdomyolysis is a common complication of stimulant use and may require:
 - Aggressive intravenous hydration
 - Urinary alkalization
 - Hemodialysis (rarely)
 - Hyperthermia requires aggressive cooling.
- Patients who respond appropriately to sedation and remain asymptomatic for a 4- to 6-hour period of observation are medically clear.
- Cocaine-associated chest pain is usually short-lived and benign; approximately 6% of patients will have acute myocardial infarction.

- Most cases occur in the absence of underlying heart disease and can occur in adolescence.
- Management of myocardial ischemia and dysrhythmias may require the use of benzodiazepines, nitroglycerin, phentolamine, aspirin, morphine, and CCBs.
- Wide-complex tachycardias associated with cocaine may respond to bicarbonate.
- If patients display persistent signs of cardiac involvement (eg, chest pain, ECG changes, abnormal cardiac enzymes), admit to a chest pain observation unit.
- Patients are medically clear if they have normal levels of troponin I, no new ischemic ECG changes, and no cardiovascular complications during a 12-hour observation period.

Sedative-hypnotic agents

- Medical interventions should be focused on drug-specific side effects.
- Flumazenil, a specific benzodiazepine antagonist, is appropriate in the setting of a known benzodiazepine exposure associated with significant CNS depression, respiratory depression, or both.
 - Empiric use of flumazenil to treat respiratory or CNS depression after overdose of an unknown agent is not suggested.
 - Flumazenil should not be administered to patients with possible long-term benzodiazepine use because of the high risk of inducing withdrawal.
- Patients with suspected sedative-hypnotic intoxication should be admitted for monitoring of respiratory and neurologic status.
 - Barbiturate and benzodiazepine use may require prolonged hospitalization as a result of prolonged duration of effect.
 - Patients with uncomplicated ethanol ingestion can usually be observed and discharged after observation in an emergency department setting.
 - GHB and Rohypnol usually have short durations of action and can typically be managed in the emergency department.

Opioids

- Patients with respiratory or CNS depression related to known or presumed opioid intoxication should receive naloxone (see Antidote Table).
- Opioid metabolites are excreted in the urine and can be detected on a urine drug screen up to 4 days after acute use and longer after long-term use.
- Patients who are awake and alert after opioid use do not require further medical evaluation.
- Patients whose status is reversed by a single dose of naloxone should be observed for at least several hours in case of recurrence of symptoms.

- Patients with significant opioid symptoms who have received high doses or a continuous infusion of naloxone require hospitalization.

Toxic alcohols

Methanol and ethylene glycol

- These agents have rapid absorption from the GI tract, so gastric lavage and activated charcoal have limited utility.
 - May be useful for patients who seek care soon after large-volume ingestions
 - Maintaining the pH near normal with sodium bicarbonate will reduce availability and enhance the elimination of some toxic metabolites.
- Fomepizole is available for the treatment of methanol and ethylene glycol intoxication.
 - If the patient ingested ethanol along with methanol or ethylene glycol, onset of toxicity may be delayed.
 - Folate enhances the metabolism of formic acid and is adjunctive therapy for methanol poisoning.
 - Thiamine and pyridoxine shunt ethylene glycol metabolism toward less toxic metabolites and are adjunctive therapy for ethylene glycol poisoning.
- Definitive therapy requires hemodialysis to remove both the toxic alcohols and their metabolites.
 - Indications are severe acidosis, visual or mental status changes, or high serum concentrations (methanol or ethylene glycol >25 mg/dL).

Isopropyl alcohol (isopropanol)

- These patients require supportive care and symptomatic therapy.
- In severe cases, hemodialysis may be necessary for:
 - Persistent hypotension
 - Plasma levels >400 mg/dL
 - Prolonged coma
 - Underlying renal or hepatic disease that limits the metabolism and excretion
- Any patient with suspected or confirmed significant toxic alcohol ingestion and any symptomatic patient should be hospitalized.
- Patients with no symptoms who are treated early have an excellent prognosis.
- Patients with seizures, coma, or pH <7.20 have a poor prognosis.
- Asymptomatic patients who ingested small volumes of isopropanol can be medically cleared after several hours of observation.

Warfarin-like rodenticides

- Ingestions >0.0125 mg/kg of brodifacoum should be treated with charcoal and decontamination.

- Blood products (fresh-frozen plasma, packed red blood cells, whole blood) should be administered for significant bleeding, such as intracranial hemorrhage.
- Symptomatic patients should receive vitamin K (see Antidote Table).
 - Oral administration of vitamin K is preferred to intravenous administration, which has been associated with anaphylactoid reactions.
- An asymptomatic patient whose samples have abnormal laboratory values should be monitored and provided oral vitamin K.
- Asymptomatic patients with an international normalized ratio of prothrombin time <3.0 should not receive vitamin K and may be monitored as outpatients.

WHEN TO ADMIT

- Altered mental status, dehydration, electrolyte abnormalities, respiratory distress, and acid-base abnormalities after exposure to poisons
- After exposure to delayed onset toxins/drugs, when the amount of toxin/drug exposed to is not known
- Exposure to cardiotoxic drugs for monitoring

WHEN TO REFER

- A poison center should be consulted when one is not familiar with the management of patient exposed to particular drugs/toxins.

FOLLOW-UP

- Poisoning and injury prevention should be discussed with parents within a few days of a poison exposure call.
 - Experience suggests that addressing prevention at the time of the initial call is less effective than doing so later.
 - Recent exposure focuses the mind of the parents, providing a valuable opportunity to impart advice on poison prevention.

PREVENTION

- Effective prevention strategies are directed toward the environment of all children and require parental cooperation.
- Primary care physicians must educate parents and caregivers in the importance of:
 - Safe storage practices for household products and prescription drugs
 - Use of child-resistant closures

- The AAP recommends anticipatory guidance about poisoning prevention, beginning with the 6-month well-child visit.
- All parents should be given the telephone number of the local or regional poison control center and should be advised to keep the number posted by the telephone for immediate use.
- Toxic substances (medications, psychoactive substances, alcohol, household chemicals and products) must be:
 - Inaccessible to children
 - Stored in locked cabinets or boxes
 - Kept in their original containers
 - Discarded in a manner that prevents access by the child
- Parents should be advised to exercise particular care with agents that can be fatal to a toddler in small doses.
 - Antihistamines
 - Benzocaine
 - BBs (sustained release)
 - CCBs (sustained release)
 - Camphor
 - Clonidine
 - Diphenoxylate-atropine (Lomotil)
 - Ethylene glycol
 - Methanol
 - Methylsalicylate (oil of wintergreen)
 - Opioids (methadone, codeine, OxyContin)
 - Phenothiazine
 - Quinine, chloroquine
 - Sulfonylurea antidiabetic agents
 - Theophylline
 - Tricyclic antidepressants
- Other highly toxic substances
 - Acetonitrile (artificial fingernail remover)
 - Ammonium fluoride (wheel cleaner, rust-removal agent)
 - Selenious acid (gun bluing compound)
 - Brodifacoum (superwarfarin rat poison)

Polyuria

DEFINITION

- Clinical definition: urine production $>2 \text{ L/m}^2$ per 24 hr
- Functional definition: inappropriately high urine output relative to circulating volume and osmolarity

MECHANISM

- Polyuria can be a manifestation of:
 - Excessive persistent fluid intake (primary polydipsia)
 - Osmotic (solute) diuresis, as in uncontrolled diabetes mellitus
- Polyuria in diabetes insipidus
 - Central diabetes insipidus results from a deficiency in vasopressin secretion.
 - Secretion of vasopressin by the posterior lobe of the pituitary gland is inadequate to maintain normal serum osmolality, resulting in diuresis of varying degrees of severity.
 - Vasopressin deficiency is associated with certain congenital malformations
 - Septo-optic dysplasia
 - Holoprosencephaly
 - Can result from central nervous system (CNS) injury or tumor resection
 - Familial vasopressin deficiency is rare, accounting for approximately 5% of all cases.
 - Nearly one-half of cases result from a primary brain tumor.
 - Approximately 18% of cases result from histiocytosis or other infiltrative processes.
 - Approximately 25% of cases are idiopathic.
 - Nephrogenic diabetes insipidus is the result of reduced renal sensitivity to circulating vasopressin.
 - Renal disorders, both congenital and acquired, may be associated with polyuria because of complete or partial inability of the renal tubule to concentrate urine despite normal or elevated circulating levels of vasopressin.

HISTORY

- A detailed history often reveals the cause of polyuria.
 - Age at onset
 - Pattern of fluid intake
 - Rate of onset
 - Feeding history
 - To identify infants who have water intoxication
- Urine output $>5 \text{ mL/kg}$ per hr in a child should raise concerns.
- Polyuria often is associated with:
 - Polydipsia
 - Frequent urination

- Nocturia
 - New onset of nocturia often is the first manifestation of loss of concentrating ability.
- Differentiating polyuria from other conditions depends on total urine output.
 - If the exact daily urinary volume is unknown, a detailed history of fluid intake and urinary habits is helpful.
- With an older child, parents may notice increased fluid intake rather than polyuria.

PHYSICAL EXAM

- Infants with polyuria do not have independent access to fluids and may fall into negative water balance, resulting in:
 - Weight loss
 - Dehydration
 - Electrolyte disturbances

DIFFERENTIAL DIAGNOSIS

Systems involved in maintenance of serum osmolality and water balance

- In reaching a diagnosis in a patient who has polyuria, the clinician must consider systems involved in maintaining normal serum osmolality and water balance.

Neurogenic vasopressin deficiency

- Familial
- Idiopathic
- Congenital malformations
 - Septo-optic dysplasia
 - Holoprosencephaly
 - Encephalocele
- Acquired
 - Head trauma
 - Vascular event
 - Thrombosis
 - Hemorrhage
 - Postinfection
 - Meningitis
 - Encephalitis
 - Congenital cytomegalovirus
 - Toxoplasmosis
 - Tumor
 - Craniopharyngioma
 - Germinoma
 - Optic glioma
 - Systemic infiltrative diseases
 - Histiocytosis
 - Syphilis

- Tuberculosis
- Sarcoidosis
- Guillain-Barré syndrome
- Autoimmune disorders

Renal vasopressin insensitivity

- Familial nephrogenic diabetes insipidus
 - V2-receptor gene defect (X-linked)
 - Aquaporin-2 gene defect (autosomal recessive)
- Renal tubular defects
 - Cystinosis
 - Distal renal tubular acidosis
 - Bartter syndrome
 - Renal Fanconi syndrome
 - Arthrogyroposis-renal tubular dysfunction-cholestasis (ARC) syndrome
- Renal structural defect
 - Renal dysplasia
 - Familial juvenile nephronophthisis–medullary cystic disease
 - Oligomeganephronia
- Acquired
 - Postobstructive
 - Chronic pyelonephritis
 - Obstructive uropathy
 - Drug-induced
 - Lithium
 - Amphotericin B
 - Associated with systemic disease
 - Sickle cell disease
 - Sarcoidosis
 - Amyloidosis
 - Metabolic
 - Hypercalcemia
 - Hypokalemia

Excessive fluid intake

- Primary polydipsia
- Water intoxication

Osmotic diuresis

- Diet-induced
- Drug-induced
- Diabetes mellitus (type 1 or 2)

Diabetes insipidus

- Characterized by:
 - Polyuria
 - Polydipsia

- Dilute urine
- Dehydration
- Hypernatremia

- Hypernatremia and dehydration may cause irritability in young children.
- Familial forms of both central and nephrogenic diabetes insipidus exist.
 - In most familial nephrogenic diabetes insipidus, severe polyuria occurs within the first weeks of life.
 - Growth failure is common with both nephrogenic and central diabetes insipidus.

Central diabetes insipidus

- When a diagnosis of central diabetes insipidus has been made, studies must be undertaken to ascertain the cause.
 - Although many cases are idiopathic, thorough evaluation for an underlying organic lesion must be conducted.
 - Once vasopressin deficiency has been identified, full investigation of other pituitary functions, visual field examination, and magnetic resonance imaging of the brain will likely be the next steps in evaluation.
- Autosomal-dominant form typically does not occur until 5–10 years of age.
- DIDMOAD syndrome typically presents in early childhood.
 - Diabetes insipidus, diabetes mellitus, optic atrophy, and deafness
- After head trauma or surgery, patients may have a period of antidiuresis after transient polyuria, followed by persistent central diabetes insipidus (triple-phase response).
- In recent years, fewer cases of diabetes insipidus have been diagnosed as idiopathic; more have been diagnosed as secondary to CNS infection or intracranial birth defects.
 - Autoantibodies to hypothalamic vasopressin cells have been detected in some children previously thought to have idiopathic diabetes insipidus.
 - Approximately 50% of the patients who have histiocytosis also have vasopressin cell autoantibodies.
- In adolescents with acquired lymphocytic or granulomatous hypophysitis, hyperprolactinemia and other anterior pituitary dysfunction may accompany diabetes insipidus.
- The underlying lesion may not be evident at the initial evaluation.

Nephrogenic diabetes insipidus

- Inherited forms of nephrogenic diabetes insipidus are rare.
- Symptoms of profound polyuria typically occur within the first weeks of life.
 - Vomiting
 - Fever
 - Failure to thrive

- Hypernatremic dehydration
 - Recurrent hypernatremic dehydration may lead to CNS damage or even death.
 - Breastfed infants may show signs later than those who are bottle fed because of the lower osmotic load in human milk.
- Older children and adults may be able to adjust oral fluid intake to maintain serum osmolality.
- A rare form of autosomal-recessive nephrogenic diabetes insipidus has been described in patients with mutations in the gene for the water-channel protein aquaporin-2.
- Other renal tubular defects in which vasopressin resistance has been observed must be considered.
- An association between nephrogenic diabetes insipidus and the ARC syndrome has been recognized.
 - Affected children are prone to severe growth impairment, intellectual disability, and deafness.
- The most commonly reported risk factors for reversible vasopressin insensitivity in 1 study were:
 - Lithium
 - Longer duration of treatment with lithium correlated with increased risk of irreversible diabetes insipidus.
 - Antibiotics
 - Antifungals
 - Antineoplastic agents
 - Antivirals
- Metabolic disturbances can result in reversible vasopressin resistance.
- Hypercalcemia and hypokalemia each may be associated with nephropathy in which tubular ability to conserve water is lost.
- Certain systemic disorders may cause renal tubular dysfunction and result in polyuria.
 - Sickle cell disease
 - Sarcoidosis
 - Amyloidosis

Excess water intake

- Polyuria may be a consequence rather than a cause of excessive fluid intake.
- Primary polydipsia, or compulsive water drinking, is a rare cause in childhood.
 - Most common in older children or adults who have emotional disturbances
 - Approximately 80% of cases are believed to occur in girls and women.
 - Onset is gradual.
 - Some investigators believe the disorder to be caused by a primary psychiatric disturbance.
- One study in adults showed evidence of a defect in water excretion, osmoregulation of water intake, and vasopressin secretion.
- Water intoxication is another cause of polyuria.
 - Incidence has increased over the past 20 years.
 - Particularly common among infants in impoverished circumstances in which caretakers feed diluted formula or water
 - Life-threatening hyponatremia may ensue without prompt treatment.

Osmotic diuresis

- May cause polyuria with renal water loss
- Glycosuria often is found to be the cause of sudden onset of polyuria in children with uncontrolled diabetes mellitus.
 - In both type 1 and type 2 diabetes mellitus, diminished carbohydrate utilization results in hyperglycemia and glycosuria.
 - When present in urine at high concentrations, glucose acts as an osmotic diuretic, resulting in polyuria.
- Chronic hyperglycemia can cause a form of partial nephrogenic diabetes insipidus.
- Treatment with large volumes of dextrose-containing intravenous fluids can result in hyperglycemia and polyuria.
- In contrast, renal glycosuria is characterized by a defect in renal tubular reabsorption of glucose, resulting in glycosuria without hyperglycemia or polyuria.
- Osmotic diuresis also may be provoked by:
 - Mannitol
 - Radiologic contrast agents
 - High-protein feedings (in which urea acts as the osmotic agent)
 - Release of bilateral urinary tract obstruction

LABORATORY EVALUATION

- Baseline values
 - Serum sodium level (mEq/L)
 - Normal: 135–145
 - Central diabetes insipidus: normal or elevated
 - Nephrogenic diabetes insipidus: normal or elevated
 - Psychogenic polydipsia: low normal
 - Serum osmolality (mOsm/kg)
 - Normal: 280–290
 - Central diabetes insipidus: normal or elevated
 - Nephrogenic diabetes insipidus: normal or elevated
 - Psychogenic polydipsia: <280
 - Urine osmolality (mOsm/kg)
 - Normal: 50–1200
 - Central diabetes insipidus: <200

- Nephrogenic diabetes insipidus: <300
- Psychogenic polydipsia: <200
- Plasma vasopressin
 - Central diabetes insipidus: low
 - Nephrogenic diabetes insipidus: normal or elevated
 - Psychogenic polydipsia: low
- Urine osmolality is best interpreted with a concomitant serum sample.
 - A hyperosmolar state suggests vasopressin deficiency or insensitivity, provided that the serum glucose concentration is normal.
 - Low serum osmolality with hyponatremia suggests either primary polydipsia or water intoxication.
 - Serum sodium usually is normal in diabetes insipidus as long as free access to fluids exists and thirst mechanism is intact.
 - Hyponatremia is commonly seen in infants with diabetes insipidus or when a central lesion exists that also impairs thirst.
- Blood chemistries will detect causes of nephrogenic diabetes insipidus, such as hypercalcemia and renal impairment.
- 24-hour measurement of fluid intake and output
 - Useful for confirming polyuria before ordering laboratory tests
- Urinary specific gravity on a first-voided morning specimen can be affected by the presence of glycosuria, proteinuria, or radiocontrast material.
 - Both types of diabetes insipidus and primary polydipsia result in relatively dilute urine.
 - Disorders resulting in renal tubular damage, such as sickle cell disease, are more likely to have isosthenuria with specific gravities of approximately 1.010.
- Urinalysis with microscopy performed on a first-voided morning specimen also provides valuable information.
 - Protein, casts, or formed blood elements in the urine suggest a renal disorder.
 - Glycosuria with ketonuria strongly suggests diabetes mellitus.
- Other baseline studies include:
 - Serum electrolytes
 - Glucose
 - Urea
 - Phosphate
 - Creatinine
 - Calcium
 - Osmolality
 - Liver function tests
 - Complete blood count

IMAGING

- When central diabetes insipidus has been diagnosed, studies must be undertaken to ascertain the cause.
 - Magnetic resonance imaging of the pituitary and hypothalamus to assess for:
 - Pituitary masses
 - Craniopharyngioma
 - Pinealoma
 - Pituitary stalk abnormalities

DIAGNOSTIC PROCEDURES

Water deprivation test

- In children with low urine specific gravity, polyuria, and no glycosuria, the next step in evaluation is referral to a specialist for a formal water deprivation test to determine if a defect exists in vasopressin production or renal responsiveness.
- Should be undertaken with great caution in younger children
- Should not be performed in newborns
- Should follow a 24-hour period of free access to fluids
- Because of the possibility of volume depletion, the study should be carried out during the day, when supervision is optimal.
- At baseline, the clinician should:
 - Record vital signs and weight.
 - Obtain blood and urine for:
 - Osmolality
 - Urine specific gravity
 - Serum sodium concentration
 - Serum urea nitrogen level
 - Hematocrit
- Blood also should be obtained at the beginning and conclusion of fluid restriction to determine plasma antidiuretic hormone (ADH) levels.
 - These may be helpful if the response to the water restriction test is equivocal.
- Fluid intake is restricted for up to 8 hours, during which the patient must be supervised closely to avoid surreptitious drinking.
 - In patients with very low urine osmolality who are strongly suspected of having nephrogenic diabetes insipidus, the response to exogenous ADH can be determined without the need for prior fluid restriction.
- The patient should be weighed and have vital signs recorded every 2 hours for the first 4 hours, then hourly.
- Blood and urine should be collected after 4 hours, then every 2 hours, for measurement of:
 - Osmolality
 - Serum sodium
 - Urine specific gravity

- The test should be terminated when one of the following end points is reached.
 - The patient has lost $\geq 5\%$ of body weight.
 - Urine specific gravity is >1.020 .
 - Urine osmolality exceeds 600 mOsm/kg.
 - Plasma osmolality exceeds 300 mOsm/kg.
 - Serum sodium exceeds 147 mEq/L.
- At the conclusion of the test:
 - Weight and vital signs are recorded.
 - Blood and urine are collected for measurement of:
 - Osmolality
 - Serum sodium
 - Urine specific gravity
- In healthy children, and in most children with primary polydipsia:
 - Weight remains constant.
 - Urine specific gravity increases.
 - Urine volume decreases.
- Concentrating ability
 - Often impaired in primary polydipsia
 - Maximal urine osmolality of 500–600 mOsm/kg, compared with >800 mOsm/kg in healthy individuals
- Diabetes insipidus should be suspected in the setting of:
 - Continued diuresis
 - Dehydration
 - Weight loss
 - Hyperosmolality
- A small increase in urine osmolality may occur in both forms of diabetes insipidus from either partial vasopressin deficiency (central) or partial vasopressin resistance (nephrogenic).
- Administration of exogenous ADH may help differentiate between the 2 disorders.
 - In an older child, the test can be performed after water deprivation test or at a subsequent visit.
 - Extreme caution is required with infants or small children because of the danger of fluid overload and hyponatremia.
 - Patient is given free access to water after administration of desmopressin acetate, a synthetic derivative of vasopressin.
 - Intake, output, and urine specific gravity are recorded every 30–60 minutes.

Interpretation of water deprivation test

- Clinical situation: normal
 - Plasma vasopressin: increased
 - Urine osmolality: >800
 - Urine specific gravity after vasopressin: increased
- Clinical situation: central diabetes insipidus
 - Plasma vasopressin: Low
 - Urine osmolality: <300
 - Urine specific gravity after vasopressin: increased
- Clinical situation: nephrogenic diabetes insipidus
 - Plasma vasopressin: high
 - Urine osmolality: <200
 - Urine specific gravity after vasopressin: unchanged
- Clinical situation: psychogenic polydipsia
 - Plasma vasopressin: unchanged
 - Urine osmolality: 500–600
 - Urine specific gravity after vasopressin: unchanged/increased

TREATMENT APPROACH

- Management of polyuria depends largely on the underlying diagnosis and must be individualized.
- Patients often are found to have a chronic disease that requires close, long-term surveillance.

SPECIFIC TREATMENT

Central diabetes insipidus

- In a severely ill patient, aqueous vasopressin, 0.1–0.2 units/kg, subcutaneously every 4–6 hours
 - Vasopressin may also be given by continuous intravenous infusion.
 - Reported starting doses vary from 0.5–4.6 mU/kg per hour; doses should be increased or decreased as needed.
- Once the child's condition has stabilized, management consists of desmopressin acetate.
 - Desmopressin can be administered orally in tablet form or instilled intranasally.
 - Should be given at the lowest dose that produces anti-diuretic effect
 - Intranasally
 - Total daily dose may range from 5 mcg in infants to 40 mcg in older children, divided into 2 or 3 doses as needed.
 - Children receiving dose multiples of 10 mcg may use nasal spray; those on smaller or intermediate doses must use a rhinal tube.
 - Orally
 - Therapeutic doses of oral desmopressin generally are 15–20 times larger than intranasal doses.
 - Greater variability exists in the effective dose.
 - Response to treatment must be monitored closely if the route of administration is changed.
- Treatment of small children and infants with central diabetes insipidus can be difficult, with rapid changes in serum osmolality potentially leading to complications.

- Parents must carefully monitor fluid intake and output in younger children.
- Because young infants are fed liquids exclusively and have high fluid requirements, vasopressin can greatly increase risk of severe hyponatremia.
 - These children are best managed with fluid therapy alone.
 - Small doses of desmopressin may be required:
 - If adequate fluid intake is difficult to maintain
 - If caloric intake is inadequate because of excessive fluid consumption
 - The risk of hyponatremia can be reduced by allowing escape from the antidiuretic effect for 1 hour before the next dose.
- A child with adipsia or hypodipsia is best managed by fixing the desmopressin dose and fluid intake.
- Daily weights and frequent sodium levels are useful in assessing fluid status at home.

Nephrogenic diabetes insipidus

- Children with nephrogenic diabetes insipidus should be allowed free access to fluids.
- Parents of infants who have this disorder need to offer frequent water feedings to allow infants to maintain osmotic homeostasis.
- A low-salt diet has been helpful in reducing urine output.
- Thiazide diuretics can reduce polyuria further by reducing amount of urine delivered to the distal tubule.
 - Both indomethacin and amiloride, when given concurrently with a thiazide, have been found effective at reducing urine output.

Primary polydipsia

- Once a neurogenic lesion has been ruled out, medical therapy is not indicated.
- Psychotherapy may be useful in addressing the emotional problem causing the polydipsia.

Hyponatremia

- Can result from several factors, including:
 - Excessive ingestion of hypotonic fluids *and/or*
 - Exogenous administration of vasopressin derivatives
- Patients with asymptomatic hyponatremia can be treated safely with:
 - Fluid restriction *or*
 - Isotonic saline, if a fluid deficit is present
- Symptomatic or severe hyponatremia (serum sodium <115 mEq/L) is an emergency.
 - Should be treated with hypertonic saline to increase the serum sodium level at a rate of 1 mEq/L per hour for 3–4 hours, limiting the increase in sodium to no greater than 10 mEq/L over 24 hours.
 - Rapid increases in serum sodium may lead to central pontine myelinosis.

- The primary care physician should take a cautious approach and limit initial therapeutic increase in sodium to 125 mEq/L with subsequent small incremental elevations in serum sodium concentrations.

Osmotic diuresis

- Osmotic diuresis induced by drugs or diet generally is self-limited.
- In diabetes mellitus, polyuria secondary to hyperglycemia and glycosuria resolves with treatment of the underlying condition.

WHEN TO REFER

- Hypotonic polyuria (confirmed by 24-hour urine and urine osmolality <300 mOsm)
- Need to perform water deprivation test
- Polyuria after neurosurgery
- Polyuria and polydipsia secondary to diabetes mellitus
- Structural renal diseases leading to polyuria should be referred to a pediatric nephrologist.
- Children with vasopressin deficiency are best referred to an endocrinologist or neurologist so that the cause of the diabetes insipidus can be determined.

WHEN TO ADMIT

- Polyuria and dehydration
- Diabetic ketoacidosis
- Severe hyponatremia or hypernatremia
- Suspected diabetes insipidus in an infant

FOLLOW-UP

- Patients with diabetes insipidus should be closely observed, after diagnosis, until an appropriate dose of desmopressin acetate is determined.

COMPLICATIONS

- Hypernatremia in patients with diabetes insipidus
- Hyponatremia in patients with psychogenic polydipsia
- Central pontine myelinosis if hyponatremia is corrected rapidly

Postoperative Care

BACKGROUND

Ambulatory surgery

- Routinely performed outpatient surgical procedures include:
 - General surgery
 - Femoral, inguinal, and umbilical herniorrhaphies
 - Lymph node and other diagnostic biopsies
 - Central line insertion
 - Fistulotomy
 - Genitourinary surgery
 - Orchiopexy, hydrocele
 - Circumcision
 - Hypospadias repair
 - Otorhinolaryngeal surgery
 - Myringotomy and tube placement
 - Adenoidectomy
 - Tonsillectomy
 - Bronchoscopy
 - Ophthalmologic surgery
 - Strabismus
 - Examination under anesthesia
 - Orthopedic surgery
 - Tendon lengthening
 - Spica changes
 - Fracture reductions
- Complications
 - Incidence of serious postoperative complications in healthy children undergoing ambulatory surgery is relatively low (<1%).
 - Some minor postoperative problems occur commonly.
 - Can be classified as early or late, depending on time of onset
 - Often, family will call on primary care physician, rather than surgeon or anesthesiologist, to diagnose and treat these problems.
 - Primary care physician must be aware of existence of and recommended treatment for these complications.

Postoperative nausea and vomiting

- Postoperative nausea and vomiting (PONV) are the most frequent complications of general anesthesia.
- Most common cause of:
 - Delayed discharge from postanesthesia care unit (PACU, formerly called the recovery room)
 - Unanticipated hospitalization after outpatient surgery

- Cause is multifactorial, with following factors playing an important role:
 - Predisposition
 - History of postoperative vomiting
 - Susceptibility to motion sickness
 - Anesthetic drugs or techniques used
 - Procedure being performed
 - Skill of the anesthesiologist providing anesthetic
 - Motion
- Certain surgical procedures are associated with a >50% incidence of postoperative vomiting.
 - Strabismus surgery
 - Middle ear surgery
 - Orchiopexy
 - Umbilical hernia repair
- Perioperative use of *any* opioid is associated with a high incidence of PONV.
 - Even when general anesthetic drugs associated with a lower incidence of nausea, such as propofol, are used
- The complex act of vomiting
 - Involves coordination of the respiratory, gastrointestinal, and abdominal musculature controlled by emetic center
 - Stimuli from several areas within the central nervous system can affect the emetic center, including:
 - Afferents from the pharynx, gastrointestinal tract, and mediastinum
 - Afferents from the higher cortical centers (including the visual center and the vestibular portion of the eighth cranial nerve)
 - Chemoreceptor trigger zone in the area postrema of the ventral lateral nucleus
 - Area postrema of the brain is rich in dopamine, opioid, and serotonin receptors
 - Blockade of these receptors is an important mechanism of action of the most commonly used antiemetics.

Emergence phenomena after general anesthesia

- Emergence from general anesthesia in healthy patients is often accompanied by transient symmetrical neurologic changes.
 - Sustained and nonsustained ankle clonus
 - Bilateral hyperreflexia
 - Babinski reflex
 - Decerebrate posturing
 - These reflexes can often be detected within minutes of discontinuing general anesthetic and may persist for hours.
- The discovery of focal neurologic deficits in a postoperative patient is never normal.

- Such neurologic deficits:
 - Should point to a possible central or peripheral nervous system injury
 - Require investigation
- During emergence from general anesthesia, children are prone to:
 - Disorientation
 - Hallucinations
 - Uncontrollable physical activity at times
 - This hyperexcitable, hyperactive state is sometimes referred to as *emergence delirium*.
 - Occurs most commonly if a patient awakens in pain after receiving a potent vapor anesthetic
 - Halothane
 - Sevoflurane
 - Isoflurane
 - Desflurane
 - Other causes include:
 - Sensory deprivation (eye bandages, eye lubricant)
 - Residual anesthetic
 - Awakening in a strange, *unfriendly* environment (the PACU)
 - Perioperative use of ketamine
- Occasionally, some lingering evidence of behavioral perturbations may persist for 12–24 hours.
- Some children who have undergone general anesthesia and surgery may experience:
 - Sleep disturbances
 - Nightmares (terrors)
 - Separation anxiety
 - Aggression toward authority
 - Loss of nighttime bladder control on the night after surgery

Intubation-related complications

- On awakening from general anesthetic, children who have undergone the following will report sore throat:
 - Endotracheal intubation
 - Airway manipulation or instrumentation (laryngeal mask airway)

Postintubation croup

- Also known as *postextubation subglottic edema*
- Children are more prone to develop croup after intubation than are adults because of differences in airway anatomy.
 - Narrower laryngeal and tracheal lumens that are more easily compromised by mucosal edema
 - Narrowest portion of the younger child's airway is at the level of cricoid cartilage, not at the level of the larynx.

- Endotracheal tube can easily pass through the vocal cords and become wedged in the subglottic area.
 - Internal tracheal mucosal injury can occur.
- Other contributing factors to development of croup are:
 - Traumatic or repeated intubations
 - Coughing (bucking) on the tube
 - Changing the patient's position after intubation
 - Providing general anesthesia to children who have a current or recent upper respiratory tract infection
 - Children who have Down syndrome may be at increased risk because of increased incidence of occult subglottic narrowing.
- The incidence of postintubation croup has been reduced to 1% (from 6%) of all endotracheally intubated children through:
 - Use of sterile, implant-tested endotracheal tubes
 - Routine intraoperative use of humidification of administered gases
 - Use of appropriately sized (air leak pressure of <30 cm of water), uncuffed endotracheal tubes in children <5

Succinylcholine

- Succinylcholine is a short-acting, depolarizing muscle relaxant.
- Used to facilitate intubation of the trachea in children
- Carries risk of fatal hyperkalemia in children with undiagnosed Duchenne muscular dystrophy
- It was commonly used in the past, but now used less frequently in favor of relatively fast-onset, nondepolarizing muscle relaxants such as rocuronium.
 - Use reserved for patients:
 - Who have no known risk of malignant hyperthermia or hyperkalemia
 - Who need true rapid sequence intubation because of:
 - Intestinal obstruction
 - Increased gastric contents from a recent meal

Early postoperative surgical problems

Fever

- Postoperative fever is generally caused by the 4 Ws (see table Common Causes of Postoperative Fever).
 - Wind (lungs): atelectasis
 - Wound (operative site): infection
 - Water (urinary tract): urinary tract infection
 - Walker (legs): deep vein thrombosis
- In most patients, fever in the early postoperative period is so common that it can be regarded as a normal response to:
 - Operative trauma
 - General anesthesia

Common Causes of Postoperative Fever

Site	Etiology	Time	Incidence	Sign or Symptoms	Diagnosis	Therapy
Wind (lungs)	Atelectasis	24–48 hr	Very common	Cough, shortness of breath, retractions	Examination, chest radiography	Cough, deep breathing, incentive spirometer
Wound (operative site)	Infection	<24 hr–7 days	Rare	Pain, erythema, induration	Examination wound cultures	Antibiotics, open wound
Water (urinary tract)	Urinary tract infection	3–5 days	Very rare	Dysuria, hematuria	Examination urinalysis, culture	Remove indwelling catheter, antibiotics
Walker (legs)	Deep-vein thrombosis	>3 days	Extremely rare	Swelling, heaviness of lower extremities, superficial venous congestion, palpable cord	Examination, duplex Doppler, venography	Bed rest, elevation, heparin (Coumadin), thrombolytics

- Pyrexia (rectal temperature greater than 101.2°F [38.5°C]) within 24 hours of operation and general anesthesia is common.
- Fever is usually caused by atelectasis, which has many causes.
 - Ciliary motion within the tracheal-bronchial tree is depressed by:
 - Endotracheal intubation
 - Inhalational general anesthetics
 - Use of nonhumidified gases
 - This interferes with normal pulmonary clearance mechanisms.
 - Atelectasis occurs when these factors are combined with:
 - Small tidal volume breathing
 - Somnolence
 - Splinting caused by pain
 - Cough suppression caused by pain or opioid analgesics
- Other causes of postoperative pyrexia are rare, and include:
 - Urinary tract infections
 - Do not usually produce symptoms in the immediate postoperative period
 - Are a cause of late postoperative fever, usually occurring 3–5 days after operation
 - Children generally are symptomatic and complain of dysuria.
 - Infants may have hematuria.
 - Dehydration
 - Infected intravenous access sites
 - Thyroid storm
 - Pheochromocytoma
 - Malignant hyperthermia
 - Fever associated with malignant hyperthermia usually starts intraoperatively.

Wound infection

- Rarely a cause of fever
 - A retrospective analysis of the postoperative course of 256 febrile children at the Hospital for Sick Children in Toronto, Canada, found:
 - Only 4 had infections that required treatment, and all 4 had significant and obvious associated signs of infection.
 - Local tenderness
 - Crepitation, or erythema at the incision site
 - Tachypnea
 - Cough
 - Dysuria
 - Headache
- The postoperative day on which a wound infection becomes apparent and local signs of sepsis produced by the infection vary according to the organism and the concomitant use of antibiotics (see table Postoperative Wound Infections).
- As a general rule, the earlier the onset of wound sepsis, the more destructive and life-threatening the infection will be.
- Most wound infections do not usually become apparent until the fifth to tenth postoperative day.
 - Rare exceptions are infections caused by beta-streptococcus, *Clostridium difficile*, *Clostridium perfringens (welchii)*.
 - Produce life-threatening wound infections that can become apparent within 24–48 hours of surgery
 - In most instances, children with these infections:
 - Develop high, spiking fevers (temperatures of 102.2°F–105.8°F [39 C–41°C])
 - Become irrational
 - Develop jaundice
 - Have a surgical incision site that is red, warm, and intensely painful on palpation
 - Have vesicle formation, wound crepitation, and an exudate may be present

Postoperative Wound Infections

Onset (Postoperative Day)	Usual Pathogens	Wound Appearance	Other Signs
1–3	<i>Clostridium welchii</i>	Brawny, hemorrhagic, cool	High standard fever (temperature 39–40°C)
		Occasional gaseous crepitance	Irrational behavior
		Putrid <i>dishwasher</i> exudate	Leukocytosis (>15,000 leukocytes/mm ³)
		Intense local pain	Occasional jaundice
2–3	<i>Streptococcus</i>	Erythematous, warm, tender	High, spiking fever (temperature 39–40°C)
		Occasionally, hemorrhagic with blebs	Irrational at times
		Serous exudate	Leukocytosis (white blood cell count >15,000 mm ³)
			Rare jaundice
3–5	<i>Staphylococcus</i>	Erythematous, warm, tender	High, spiking fever (temperatures of 38–40°C)
		Purulent exudate	Irrational behavior at times
			Leukocytosis (12,000–20,000 leukocytes/mm ³)
>5	Gram-negative rods	Erythematous, warm, tender	Sustained low-grade to moderate fever (temperature 38–40°C)
		Purulent exudate	Rational behavior
			Leukocytosis (10,000–16,000 leukocytes/mm ³)
>5	Symbiotic (usually anaerobes plus gram-negative rods)	Erythematous, warm, tender	Moderate to high fever (temperature 38–40°C)
		Focal necrosis	Leukocytosis (>15,000 leukocytes/mm ³)
		Purulent, putrid exudate	Occasional jaundice Mentation variable

Drainage

- A small amount of serosanguineous drainage in the postoperative dressing is normal.
 - Not a cause for alarm
- Superficial hematoma just below incision site
 - May cause serosanguineous discharge from the operative site 2–3 days after the operation
 - Recognized by characteristic ecchymoses and fluctuance
- Serous drainage from a wound may be caused by:
 - Creation of a large dead space during the operative procedure
 - Usually drain 4–7 days after surgery
 - Liquefaction of adipose tissue
 - Characterized by yellow drainage
 - Occurs 2–3 weeks after surgery

Postoperative bleeding

- Persistent bleeding is defined as:
 - Bleeding and bloody ooze that continues for more than 6–8 hours after the operation *or*
 - Need to change a blood-soaked wound dressing more than twice in the first 6–8 hours after surgery
- Almost always indicates inadequate hemostasis
- Is usually due to a superficial skin arterial bleeding site
- Coagulopathy might also be responsible.

Posttonsillectomy hemorrhage

- Incidence is estimated to be 5–10%.
- 1–3% of patients who have tonsillectomy require additional operation.

- Bleeding that occurs after tonsillectomy may occur either early or late.
 - Early: in the first 24 hours, but usually after hospital discharge
 - Due to failure of hemostasis and may be due to coagulopathy
 - Late: 5–14 days after surgery
 - Results from dislodgement of the scab from the operative bed
 - Either form may be severe and life-threatening.
- Hemorrhage is frequently associated with:
 - History of poor postoperative fluid intake *and*
 - Volume contraction resulting from blood loss

Miscellaneous early postoperative problems

Urinary retention

- In contrast to adults, urinary retention is rare in pediatric surgical outpatients.
- Most children who undergo surgery through the inguinal canal void within 8 hours of the operation.
 - Regardless of intraoperative anesthetic technique or postoperative analgesic regimen
 - Parenteral and enteral opioids *and/or*
 - Regional anesthesia (caudal epidural blockade or ilioinguinal-iliohypogastric nerve blocks)
 - This finding is significant.
 - Theoretically, opioids and regional anesthetics, particularly caudal epidural blockade, may interfere with the neural mechanisms responsible for emptying of the bladder.
 - Many investigators who argued against the routine use of caudal anesthesia *and/or* opioids for the treatment of postoperative surgical pain based their opinions on the theoretical risk of urinary retention.

Scrotal swelling

- Scrotal swelling and concomitant discoloration of the scrotum commonly occur after:
 - Inguinal herniorrhaphy *and/or*
 - Hydrocelectomy
- Initially, this process:
 - Can produce swelling alone
 - May progress to bluish discoloration as bleeding and clot lysis occur
- Usually the result of bleeding from the cut edge of the peritoneal sac
 - Derived from either a hernia or hydrocele
- The swelling and color change should resolve in 4–6 weeks.

Late postoperative surgical problems

Pyrexia

- Pyrexia 48 hours or more after outpatient surgery:
 - Is unusual
 - May indicate a serious wound infection (see tables Common Causes of Postoperative Fever and Postoperative Wound Infections)
- In patients who develop fevers more than 5 days after a surgical procedure:
 - Primary care physicians should suspect an anaerobic infection or a mixed (sympiotic) infection of anaerobic and gram-negative rods.

Wound infection

- Gram-positive infections
 - The most common causes of wound infection
 - Wound infections caused by *Staphylococcus aureus* or *Staphylococcus epidermidis*
 - Usually characterized by a milky white, purulent drainage
 - Usually occur 3–5 days after surgery (see table Postoperative Wound Infections)
 - Usually produce high, spiking fevers (temperatures of 102.2°F–104°F [39°C–40°C])
 - Leukocytosis (white blood cell count of >12,000/mm³)
 - After Gram stain and culture, treat patient with a penicillinase-resistant antibiotic such as oxacillin.
- Enteric, encapsulated, gram-negative organisms such as *Escherichia coli*
 - Usually associated with:
 - Erythema
 - Tenderness
 - Possibly, purulent discharge
 - Usually occur >5 days after surgery
 - Enteric organisms such as *E coli* are sensitive to:
 - Penicillin
 - Cephalosporins
 - Aminoglycosides
- Anaerobic infection or a mixed (sympiotic) infection of anaerobic and gram-negative rods caused by:
 - Gram-positive cocci of *Clostridium perfringens*; infection causes:
 - Exquisite pain
 - Brown discoloration
 - A wound that is crepitant to palpation
 - Gas may be seen in the subcutaneous tissues on a plain radiograph.

- Gram-negative rods of the *Bacteroides* species (usually *Bacteroides fragilis*)
 - Wound infections caused by *Bacteroides* are usually purulent and malodorous.
- Both of these anaerobic infections are life threatening.

Venous thromboembolism

- Not as common in children as in adults
- Occurs in children during postoperative period
- Incidence increases in adolescence.
- Primary care physician should be alert to following symptoms, which may indicate deep-vein thrombosis:
 - Extremity pain
 - Swelling
 - Discoloration
 - Patient should be referred for immediate evaluation.
- Patients at highest risk are those who are immobilized after surgery and have at least 1 of the following other risk factors:
 - Major lower extremity orthopedic surgery
 - Spinal cord injury
 - Major trauma or trauma to the lower extremities
 - Previous history of deep-vein thrombosis or venous thromboembolism or pulmonary embolism
 - Pregnancy
 - Oral contraceptive use
 - Inflammatory bowel disease
 - Nephrotic syndrome
 - Burns
 - Obesity
 - Central venous catheter in the lower extremity
 - Known acquired or inherited thrombophilia
 - Acute infection
- Pulmonary embolism
 - Patients who develop venous thromboembolism are at risk.
 - Mortality rate is as high as 20%.
 - Symptoms include:
 - Dyspnea
 - Chest pain
 - Cough
 - Hemoptysis
 - Fever

Practical aspects of the postsurgical wound

- Wound healing represents a highly dynamic, integrated series of cellular physiological and biochemical events.
- Morphological events that make up the healing of closed wounds include:
 - Inflammation

- Epithelialization
- Cellular influx
- Fibroplasia
- The inflammatory phase begins immediately.
 - During its early stages, white blood cells:
 - Migrate into the wound
 - Engulf and remove cellular debris and tissue fragments
 - This phase sets the stage for subsequent events in the healing process.
- After dead material is removed, the epidermis and dermis immediately adjacent to the wound edges begin to thicken within 24 hours after injury.
- Within 48 hours, entire wound surface is reepithelialized.
 - During this critical period, wound should be kept dressed and dry.
- Between days 2 and 3, an influx of fibroblasts into the wound occurs deep in the epithelium.
- By the fourth or fifth day, fibroblasts begin to lay down collagen fibers, which continues for several months.
 - Remodeling of collagen takes place for >1 year.
- From surgeon's point of view, all morphological events of wound healing lead to a single important conclusion: Wounds become stronger with time.
 - Closing the wound with suture material only serves to hasten the process.
 - Normally, a simple wound will attain 50% of the strength of surrounding uninjured tissue by 28 days.

Scar formation

- Hypertrophic scars
 - Predisposition of black people and white people of Mediterranean descent
 - Tend to resolve with time
 - As a rule, not associated with prolonged itchiness
- Keloid formation
 - Tumors characterized by massive formation of scar tissue in and beneath the skin after any trauma, including surgery.
 - Keloids grow well beyond the borders of the incision unlike hypertrophic scar formation.
 - Keloids tend to recur after excision.
 - Children have a greater tendency to form and re-form keloids than adults do.
- All skin wounds and surgical skin incision sites will scar.
 - Regardless of the expertise of the surgeon or use of plastic surgical techniques in closing the skin
 - Notion that plastic surgery is scarless is a myth.
- Scar tissue will permanently pigment when exposed to intense sunlight during the first 6 months of its formation.
 - Will usually become red to dark brown-black

GOALS

- Guidelines to select appropriate procedures and patients for outpatient surgery and anesthesia are continually evolving.
 - In general, procedure itself should not involve:
 - Excessive bleeding
 - Open entry into a major body cavity
 - Patient should not require any special postoperative nursing care.
 - Patient must have a responsible adult at home available to provide care until recovery is complete.
- Postoperative pain management
 - Physician's obligation to manage pain and relieve patient suffering is:
 - Crucial element of the professional commitment to patient care
 - Not merely a lofty ideal
 - Effective pain management produces a myriad of patient benefits, including:
 - Reduced morbidity and mortality
 - Early mobilization
 - More rapid recovery
 - Return to work, school, and play

GENERAL APPROACH

PONV

Contribution of anesthetic technique to PONV

- Certain anesthetic agents and techniques produce more vomiting than others.
- Effects of the following general anesthetic inhalational agents are controversial:
 - Sevoflurane
 - Isoflurane
 - Nitrous oxide
- Some studies report significantly more vomiting when these anesthetics are used, whereas others do not.
- Newer inhalation agents, such as desflurane, claim to be associated with less PONV.
- Gas anesthetics have repeatedly been shown to cause more PONV than intravenous techniques.
- Regional anesthetic techniques that use local anesthetics either centrally (eg, epidural) or peripherally (peripheral nerve block) produce less vomiting than general anesthetic techniques.
 - Rarely feasible without concomitant general anesthesia in children
- Propofol
 - New intravenous general anesthetic agent
 - Produces significantly less vomiting and nausea than others when given alone

- Opioids have been consistently shown to cause nausea and vomiting.
 - Morphine
 - Meperidine
 - Fentanyl
 - Codeine
 - Oxycodone
 - Hydromorphone
- Individual patients may find 1 opioid drug more nauseating than another.
- Changing from 1 drug to another may decrease amount of nausea and vomiting.
- Avoiding opioids perioperatively may solve only part of the puzzle.
 - However, pain control is essential in children who undergo surgery.
 - Opioids are the most common analgesic drugs used for this purpose.
- Use of nonsteroidal antiinflammatory drugs (NSAIDs)
 - Ketorolac is a powerful NSAID.
 - Almost as potent as morphine as an analgesic
 - Does not produce nausea, vomiting, or respiratory depression
 - NSAIDs affect platelet aggregation and adhesiveness.
 - Use limited in many patients who are at risk for postoperative bleeding (especially after tonsillectomy)
 - Have been shown to impair osteoblastic activity
 - Many orthopedic surgeons forbid use of NSAIDs during and after operations in which new bone formation is important (fractures, spine fusions).
 - Extent to which this effect is clinically important is controversial.

Contribution of postoperative oral intake to PONV

- Many anesthesiologists prefer to restrict patients from taking anything by mouth until they are ready and willing to drink and eat.
 - This restriction means that child leaves the hospital while still fasting.
 - Children must say they are thirsty, or better still hungry, and specifically ask for something to drink or eat before any food or liquid is offered.
 - Even in the youngest patients, risk of dehydration is low, particularly if intravenous fluids were appropriately administered perioperatively.
 - In current practice, virtually all children undergoing surgery and anesthesia receive intravenous fluids that contain salt and sugar in the operating room and PACU.
 - If fluids sufficient to supply maintenance and replacement requirements were given during this period, postoperative fast will be readily tolerated.

- As anesthesiologists are abandoning stringent, prolonged preoperative fasts, they are increasingly appreciating benefits postoperatively.
 - Unfortunately, many institutions continue to require that patients drink and ambulate before discharge.
 - This restriction contributes to incidence of unanticipated hospital admission after outpatient surgery because of vomiting.

Emergence phenomena after anesthesia

- Before discharge from the PACU, the following should be completely resolved:
 - Disorientation
 - Hyperactivity
 - Excitability
 - Hallucinatory visual disturbances

Early postoperative surgical problems

Fever

- Most patients with low-grade postoperative fevers require only physical examination to differentiate between a septic and nonseptic process.
- Extensive (and expensive) diagnostic workups are rarely indicated.

Drainage

- Only persistent bleeding requires immediate surgical attention.
- Small hematomas directly below a wound, umbilicus, or scrotum usually spontaneously drain or resorb.
 - A nonexpanding hematoma will usually resolve within 4–6 weeks after surgery.
 - If wound hematoma is associated with pain, child should be examined by the operating surgeon.
- Regardless of size, hematomas and seromas:
 - Are excellent culture media for bacteria
 - Increase the likelihood of wound infection
- Hematomas and seromas should be closely watched for.
 - Usually characterized by the triad of:
 - Pain
 - Wound dehiscence
 - Persistent drainage

Miscellaneous early postoperative problems

Urinary retention

- Many surgeons, anesthesiologists, and ambulatory care administrators have insisted that children void before discharge after outpatient procedures that require anesthesia.
 - Many patients cannot void on command, particularly in the PACU or hospital.
 - The knowledge that all patients void within 24 hours of operation and virtually all spontaneously void within

10 hours of a procedure strongly suggests that voiding before discharge is unnecessary.

Late postoperative surgical problems

Pyrexia

- Pyrexia 48 hours or more after outpatient surgery requires evaluation and examination by the patient's primary care physician or surgeon.
 - The wound is examined for signs of inflammation, such as:
 - Warmth
 - Tenderness
 - Erythema
 - Swelling
 - If any of these signs or symptoms are present, the operating surgeon should be informed.

Wound infection

- Gram-positive infections
 - After Gram stain and culture, patient is treated with a penicillinase-resistant antibiotic such as oxacillin.
- Enteric, encapsulated, gram-negative organisms such as *E coli* are sensitive to:
 - Penicillin
 - Cephalosporins
 - Aminoglycosides

Scar formation

- Overall management of the abnormal scar should be determined by:
 - Anatomic position of the wound
 - Age of the patient
 - Any underlying associated diseases
- Advise patients and their families that when exposing the surgical incision site to the sun, the incision site should be:
 - Completely covered *or*
 - Protected with zinc oxide or a sunblock with a sun-protection factor number >30 for 6 months after surgery

SPECIFIC INTERVENTIONS

PONV

Treatment

- Several techniques are available to treat or prevent PONV, including:
 - Altering the anesthetic technique (eg, avoiding perioperative use of opioids)
 - Using antiemetics perioperatively (either prophylactically or as treatment) (see table Dosage Guidelines for Commonly Used Antiemetics)
 - Droperidol
 - Phenothiazines
 - Ondansetron

Dosage Guidelines for Commonly Used Antiemetics^a

Pharmacological Group (Generic)		Brand Name	Dosage (mg/kg)	Adverse effects
Phenothiazines	Chlorpromazine	Thorazine	IV, PO: 0.5–1.0 every 6–8 hr	Drowsiness, hypotension, arrhythmias, extrapyramidal symptoms; potentiates effects of opioids, sedatives
	Prochlorperazine	Compazine	PO, PR: 0.1 every 6–8 hr (maximum dose 10 mg)	
Butyrophenones	Droperidol	Inapsine	IV: 0.01–0.03 every 6–8 hr	Drowsiness, hypotension, arrhythmias; droperidol has black box warning: prolongs QT interval, extrapyramidal symptoms; lowers seizure threshold; potentiates effects of opioids, sedatives
	Haloperidol	Haldol	IV: 0.01 every 8–12 hr	
Antihistamines	Promethazine	Phenergan	IV: 0.25–0.5 every 6 hr	Drowsiness, hypotension, arrhythmias; contraindicated in patients taking MAO inhibitors; Phenergan contraindicated in children <2 years old because of cases of fatal respiratory depression ^a
	Diphenhydramine	Benadryl	0.5–1.0 every 4–6 hr (maximum dose 50 mg)	
Benzamides	Metoclopramide	Reglan	IV, PO: 0.05–0.1 every 6 hr	Adverse effects include extrapyramidal symptoms
Anticholinergic	Scopolamine	Hyoscine transdermal scopolamine	IV, PO: 0.005 every 4–6 hr apply behind ear 4 hr before needed; lasts 72 hr	Adverse effects include dry mouth, blurred vision, fever, tachycardia, constipation, urinary retention, drowsiness, amnesia
Antiserotonin	Ondansetron	Zofran, Zofran ODT	IV, PO: 0.15 every 8 hr, (maximum dose 4 mg)	Adverse effects include bronchospasm, tachycardia, headaches, lightheadedness, may prolong QT interval

Abbreviations: MAO, monoamine oxidase; IV, intravenous; ODT, oral dissolving tablet; PO, orally.

^a FDA MedWatch (www.fda.gov/Safety/MedWatch/SafetyInformation/SafetyAlertsforHumanMedicalProducts/ucm52554.htm).

- Antihistamines
 - Limiting oral intake postoperatively
- Treatment of PONV is the same as that used for viral gastroenteritis.
 - Cooling-off period of 2–4 hours followed by sips of clear fluids that contain sugar and salt
 - Oral rehydration solution
 - Each sip is separated by several minutes.
 - Giving fluids or solids prematurely only aggravates the problem.
- Antiemetics**
 - Antiemetics can be used either prophylactically or to treat the problem once it develops.
 - The most common antiemetics are those that block receptors within the vomiting center.
 - Four major neurotransmitter systems play a role in mediating the emetic response:
 - Dopaminergic
 - Histaminic
 - Cholinergic
 - Serotonergic
 - Antiemetic drugs may act at more than 1 receptor.
 - Tend to have a more prominent action at 1 or 2 receptors
 - The most commonly used antiemetics, in order of use, include:
 - Benzamides
 - Metoclopramide
 - Trimethobenzamide hydrochloride
 - Serotonin antagonists
 - Ondansetron
 - Dolasetron
 - Phenothiazines
 - Prochlorperazine
 - Promethazine (Phenergan)
 - Butyrophenones
 - Droperidol
 - Haloperidol
 - Antihistamines
 - Hydroxyzine
 - Diphenhydramine

- Anticholinergics
 - Scopolamine
 - Atropine
- Most of these antiemetic classes (except serotonin antagonists) produce sedation.
 - Can interfere with rapid return to baseline function and hospital discharge
- Promethazine
 - Identified as a contributing cause in a significant number of deaths in children <2 years to whom it had been administered for vomiting:
 - Occurring either in the postoperative period after hospital discharge or
 - Because of gastroenteritis
 - In 2004 the US Food and Drug Administration mandated a black box warning.
 - Original warning seemed to apply only to brand name suppository formulations.
 - Warning was clarified in 2006 to make sure that both health care professionals and parents understood that the warning applies to all formulations: *“Medications containing promethazine hydrochloride (HCl) should not be used for children less than 2 years of age because of the potential for fatal respiratory depression. This includes promethazine HCl in any form: syrup, suppository, tablet, or injectable. Cases of respiratory depression including fatalities have been reported with use of promethazine HCl in children less than 2 years of age. Caution should also be exercised when administering promethazine HCl in any form to pediatric patients 2 years of age and older.”*
 - This warning is especially germane in children postoperatively who may be receiving opioids that may cause respiratory depression.
- Ondansetron oral dissolving tablet
 - New dose form
 - Found to be an effective and acceptable formulation in:
 - Children undergoing adenotonsillectomy
 - Infants and children with gastroenteritis treated in an emergency department
 - Like all serotonin antagonists, it is more expensive than older antiemetics.
 - Has advantages of:
 - Oral dosing
 - Lack of side effects, such as sedation or extrapyramidal reactions seen with metoclopramide
- Effective dose and cost of serotonin antagonists
 - Can be reduced by the coadministration of intravenous dexamethasone in the perioperative period
 - Has also been shown to prolong the duration of antiemetic effect

Prolonged nausea and vomiting

- Nausea and vomiting that persists beyond 12–24 hours is unusual.
 - Requires evaluation to determine the state of hydration
 - Intravenous rehydration and consideration of alternative conditions may be necessary.
- In rare instances, excessive postoperative air swallowing may lead to acute gastric dilation in young children.
 - Recognition of the characteristic distended abdomen and gastric splash, if present, should be followed by nasogastric decompression.

Concomitant medications

- Postoperative vomiting may interfere with resumption of long-term oral medication regimens.
- All long-term administered oral medications should be taken on the morning of surgery, except:
 - Monoamine oxidase inhibitors
 - Oral hypoglycemics
 - Diuretics
- Ability of patients to take medications preoperatively has reduced stress associated with deciding when to restart oral medications postoperatively.
- Most drugs administered in the long term have half-lives of elimination >12 hours.
 - Anticonvulsants
 - Bronchodilators
 - Digitalis
- Missing a dose of these drugs for 1 or 2 half-lives (12–24 hours) will have minimal, if any, effect on blood levels.
 - This situation assumes that therapeutic blood levels existed before surgery began.
- If vomiting persists beyond 24 hours, parenteral drug administration may be required.

Emergence phenomena after general anesthesia

- PACU treatment for these phenomena may include:
 - Small doses of analgesics (eg, fentanyl)
 - Flumazenil, if midazolam was administered
- In some instances, atropine may be responsible for this reaction.
 - It will be accompanied by other features of anticholinergic syndrome.
 - Flushed cheeks
 - Mydriasis
 - Low-grade fever
 - This reaction may be treated by administration of physostigmine, an anticholinesterase that:
 - Crosses blood-brain barrier
 - Reverses central nervous system effects of atropine
 - Potentiates action of acetylcholine at nerve terminals

- Prevalence of such anticholinergic reactions has been reduced since the replacement of halothane with sevoflurane as the primary gas for mask anesthetic induction in children.
 - Sevoflurane does not cause the bradycardia seen with halothane.
 - Makes routine use of atropine unnecessary in pediatric anesthetic practice, except to counteract the muscarinic effects of anticholinesterase administration for reversal of nondepolarizing muscle relaxant
- Children who are extremely anxious during induction of anesthesia:
 - Are more at risk of developing postoperative negative behavioral changes compared with children who appear calm during the induction process
 - Benefit from premedication with a benzodiazepine (midazolam) before induction of anesthesia
 - Kain et al have clearly demonstrated that oral premedication with midazolam is more effective at reducing preoperative anxiety and postoperative, delayed alterations in behavior than either:
 - Parental presence
 - Extensive preoperative behavioral program
- Ketamine is associated with sleep disturbances after administration.
 - Incidence of nightmares after ketamine administration is lower in children than in adults.
 - Reported to occur in 5–10% of patients who receive it
 - Incidence is mitigated by concomitant administration of benzodiazepine, usually midazolam.
 - Regardless of cause, sleep disturbance is time limited.
 - Rarely persists beyond 48 hours after surgery and general anesthesia
 - If it becomes overwhelming, can be treated with oral diazepam
 - In most cases, 1 dose given at bedtime cures the problem completely.

Intubation-related complications

- Once cough, gag, and swallowing reflexes have returned to baseline, intubation-related discomfort can be alleviated with:
 - Fruit-flavored ice pops
 - Ice chips
 - Common throat lozenges or sprays
- Analgesics are rarely required.
 - If needed, acetaminophen will usually suffice.

Postintubation croup

- Treatment of postintubation croup is the same as for viral laryngotracheitis.
- Humidification is effective in most cases.

- Nebulized racemic epinephrine therapy is rarely necessary.
 - If needed, patient should not be discharged from PACU to home.
 - Must be admitted for overnight observation because of potential for rebound edema formation.
- Efficacy of corticosteroids in treating postintubation croup has been controversial.
 - Most studies have shown them to be effective.
- Most anesthesiologists will prescribe dexamethasone for this problem.
 - No controlled, prospective trials have validated its use for this purpose.

Succinylcholine-induced myalgia

- Succinylcholine administration normally will result in:
 - Some damage to the muscle cell
 - Leakage of intracellular potassium
 - Increased blood levels of:
 - Creatinine phosphokinase
 - Myoglobin
 - Myalgia
 - As intense and debilitating as myalgia produced by an influenza infection
 - Treatment is supportive.
 - Pain usually resolves over several days.
 - Magnitude can be avoided by pretreating the patient with small doses of:
 - A nondepolarizing muscle relaxant
 - Calcium

Early postoperative surgical problems

Fever

- Early ambulation, deep breathing, and coughing
 - Can be extremely helpful in alleviating or preventing atelectasis and postoperative fever
 - Important medical advantage of ambulatory surgery
 - Patients are more likely to be up and about when they are at home rather than in the hospital.

Wound infection

- Beta-streptococcus, *C difficile*, *C perfringens (welchii)*:
 - Produce life-threatening wound infections that can become apparent within 24–48 hours of surgery
 - Patients require immediate hospitalization and treatment.

Postoperative bleeding

- Direct digital pressure applied to the wound will slow or stop flow of blood until bleeding site can be investigated and controlled by the operating surgeon or designee.

Drainage

- If a hematoma progressively expands, it may require operative exploration to:
 - Evacuate the clot
 - Control any ongoing bleeding

Posttonsillectomy hemorrhage

- Requires immediate emergency evaluation
- Rehydration with isotonic fluid is always required.
- Transfusion, although unlikely, may be required even if:
 - A subsequent operation is performed and
 - Control of bleeding is achieved

Miscellaneous early postoperative problems**Urinary retention**

- To minimize bladder distention, children and adolescents should be encouraged to urinate:
 - Immediately before coming to the operating room
 - As soon as possible postoperatively
- In some practices, primary care physicians do not routinely require patients to void before postoperative discharge from the PACU; exceptions to this rule include patients who report lower abdominal distention and discomfort, who are initially treated with:
 - Ambulation, in the case of the older child or adolescent
 - Gentle pressure on the lower abdomen, in the case of infants
 - If these measures do not lead to voiding and amelioration of symptoms, bladder catheterization should be performed.
 - The need for bladder catheterization is rare.
 - Patients requiring bladder catheterization should then be observed for ability to urinate spontaneously.
 - If bladder function does not return:
 - Patient should be admitted to the hospital.
 - Specimen of urine should be sent for urinalysis and culture.
 - Patient's surgeon should decide whether a bladder catheter should be reinserted.
- In the experience of some practitioners, urination after outpatient surgery requires a *less is more* attitude.
 - The more attention the physician pays to this issue, the more problems are created.

Scrotal swelling

- An urgent consultation with the patient's surgeon is needed if the following occur:
 - Fever
 - Erythema
 - Tenderness
 - Progressive enlargement of the hemiscrotum

- In many instances, such patients require:
 - Additional exploratory surgery
 - Operative evacuation of the hematoma via a suprainguinal or transscrotal approach

Late postoperative surgical problems**Pyrexia**

- Pyrexia 48 hours or more after outpatient surgery
 - If the wound appears to be the source of the fever and infection, the wound:
 - Can be probed with a sterile swab (Q-Tip)
 - A Gram stain and culture obtained
 - If pus is present, the wound should be:
 - Opened
 - Copiously irrigated
 - Debrided
 - Regardless of the presence of pus, a culture swab should always be sent for Gram stain and culture.
- In patients who develop fevers >5 days after a surgical procedure
 - Primary care physicians should suspect an anaerobic infection or a mixed (sympiotic) infection of anaerobic and gram-negative rods.
 - Skin surrounding the wound should be examined closely for the presence of:
 - Crepitus and vesicle formation
 - Purulent and putrid discharge
 - Focal necrosis
 - All of these conditions indicate the development of:
 - Gas gangrene *or*
 - Necrotizing fasciitis
- These anaerobic types of infections can be caused by:
 - Gram-positive cocci of *Clostridium* perfringens
 - Gram-negative rods of the *Bacteroides* species (usually *Bacteroides fragilis*)
 - Both of these anaerobic infections are life threatening and require:
 - Immediate hospitalization
 - Resuscitation
 - Operational evaluation and intervention
- If surgical incision site does not appear to be responsible for development of fever
 - Thorough history and physical examination should be performed.
 - Particular attention should be devoted to the lungs and intravenous administration sites.
 - Atelectasis often follows general anesthesia and surgery.

- Infected intravenous insertion sites, phlebitis, or thrombophlebitis, especially in the female adolescent taking birth control pills, also can occur.
- Additionally, routine causes of pyrexia in children can occur in the postoperative patient and include:
 - Upper respiratory tract infections
 - Gastroenteritis
 - Otitis media

Wound infection

- Treatment of a serious wound infection is straightforward.
 - Inpatient hospitalization
 - Opening the wound along its entire length
 - Drainage
 - Wide debridement of necrotic tissue
 - High-dose intravenous antibiotics
 - Penicillin
 - Clindamycin
 - Metronidazole
 - Cefotetan
 - In selected cases, hyperbaric oxygen therapy
 - These wounds are not closed.
 - Are allowed to close spontaneously by contracture.
 - If only cellulitis is detected, wound should not be opened.
 - Patient should be given intravenous antibiotic therapy.
 - Lymphangitis, characterized by its characteristic red streaks and tender regional adenopathy, should also be treated with intravenous antibiotics in the hospital.

Venous thromboembolism

- Patients at risk for venous thromboembolism should receive prophylactic measures, which may include:
 - Compression stockings
 - Pneumatic sequential compression devices
 - Or both (until ambulatory)
- Patients with 3 or more risk factors may be treated with pharmacologic prophylaxis:
 - Subcutaneous heparin *or*
 - Low-molecular-weight heparin

Practical aspects of the postsurgical wound

- Wound dressings are not required after 48 hours.
- Wound contamination with stool and urine should be cleansed with water or saline.

- Overlying dressing should be replaced.
- Detergent soaps and peroxide should be avoided.
- By postoperative day 4, wound may be washed with:
 - Warm water
 - Bland soap (eg, Ivory, Dove, Neutrogena)
- Most wounds are closed using absorbable suture material, which:
 - Maintains tensile strength for 60–90 days
 - Supplies an appreciable amount of wound strength to allow normal healing process to take place
 - Does not require suture removal
- Closing wounds with absorbable suture material allows child to return to activity at an earlier time.
- Adolescents with uncomplicated inguinal hernia repair may return to:
 - Nonstrenuous activity 7–10 days postoperatively
 - Full activity by 4–6 weeks
- Whenever possible, toddlers are kept off tricycles and bicycles for 7–10 days.
- Infants should be treated as if no operation was performed.
 - Full bath by the fourth postoperative day
 - No restrictions for carrying the infant

Scar formation

- Keloid formation
 - A thorough family history may be a predictor of this pathological process.
 - An abnormal scar should be observed for a minimum of 6 months postoperatively.
 - If it does not resolve
 - Trial excision should be attempted staying within the confines of the lesion to see what response is obtained.
 - If it recurs
 - Should be reexcised and 1% triamcinolone injected beneath the scar, which will produce some keloid resolution
- Hypertrophic scar
 - Should be treated with pressure

Posttraumatic Stress Disorder

DEFINITION

■ Posttraumatic stress disorder (PTSD) is a psychiatric disorder that can develop in response to being the direct victim of or witnessing traumatic events.

- Child abuse
 - Domestic, community, or school violence
 - Vehicular or other accidents
 - Fires
 - Natural disasters
 - Terrorism
 - War
 - Traumatic medical conditions
- To receive a diagnosis of PTSD:
- The child must have experienced a traumatic event that qualifies as a serious traumatic stressor.
 - The American Psychiatric Association *Diagnostic and Statistical Manual (DSM-IV)* requires specific criteria for a PTSD-level stressor: It threatens the child's or significant others' life or physical integrity.
 - For children, more leeway exists in defining PTSD-level traumas.
 - In reaction to the traumatic exposure, the child must have experienced subjective fear, helplessness, or horror.

EPIDEMIOLOGY

- Most children are remarkably resilient in the face of trauma.
- Do not go on to develop PTSD
- Prevalence
- Has been estimated based on studies of various types of stressful events
 - Rates vary considerably by type of event.
 - Other characteristics related to prevalence
 - Demographics
 - Family characteristics
 - Research methods
 - Few nationally representative studies
 - Early studies of adolescents and young adults reported overall lifetime PTSD rates of 9.2%.
 - Some rates reported separately
 - 2.8% of boys
 - 10.3% of girls
 - A more recent study of adolescents (age 12–17 years) reported different rates than previous studies.
 - Slightly higher rates for boys (3.7%)
 - Lower rates for girls (6.3%)
 - Among inner-city children
 - As many as 90% of inner-city adolescents report significant exposure to traumatic events.

- Rates of PTSD vary after different types of traumatic events.

- Exposure to acute physical injury (23%)
- Natural disasters (24–39%)
- Community violence (27%)

■ Many children may not meet the full criteria for PTSD.

- Show heightened posttraumatic stress symptoms after exposure to various events, including:
 - Family violence (15%)
 - Natural disasters (24%)

RISK FACTORS

■ Risk factors for PTSD and other mental health difficulties after traumatic exposure include:

- Female sex
- More frequent or intense exposure to traumatic event
- Preexisting anxiety disorder
- Lack of parental or other support
- Parental psychopathology
- Parental PTSD related to the index trauma
- Past trauma exposure

SIGNS AND SYMPTOMS

Components of PTSD

■ The 3 core symptom clusters of PTSD are reexperiencing, avoidance or numbing, and hyperarousal.

■ To meet full PTSD criteria, the patient must have at least:

- 1 reexperiencing symptom
- 3 avoidance or numbing symptoms
- 2 hyperarousal symptoms
- These symptoms must all:
 - Be present for at least 1 month *and*
 - Cause functional impairment in social, school, family, health, other important area of daily living

■ Children who do not meet these criteria are still considered to have significant PTSD symptoms.

Reexperiencing symptoms

■ Reexperiencing symptoms occur when upsetting feelings are experienced after memories or reminders of traumatic event recur.

- Example: The child saw her father shot to death.
 - Began reliving the shooting whenever a thunderstorm occurred
 - The sound of thunder reminded the child of the sound of the gunshots that killed her father.

- Symptoms may be idiosyncratic and hard for parents and primary care physicians (PCPs) to identify.
 - Example: The child screamed and hit his grandmother whenever she sang what she thought was his favorite lullaby.
 - It gradually emerged that the boy’s mother had sung this song to him before she was hit by a car and killed.
 - The song was not a reminder of comfort and happy times with his mother, but rather a traumatic reminder of the night she died.
- Symptoms include:
 - Recurrent and distressing memories or thoughts of the event
 - Repetitive play
 - Recurrent distressing or frightening dreams
 - Nonspecific scary dreams in younger children
 - Feeling as though traumatic event is occurring again in the present (flashbacks, rare in younger children)
 - Intense psychological distress when reminded of the trauma
 - Physiologic reactions to trauma reminders, including:
 - Upset stomach
 - Headaches
 - School refusal

Avoidance or numbing symptoms

- Children’s trauma reminders are accompanied by strong, upsetting feelings.
- Children may develop avoidance coping strategies to escape upsetting feelings.
 - Will try to avoid talking about the traumatic experience
 - Will avoid thinking about it
 - Will avoid places, people, and situations that serve as trauma reminders
 - For some children, these avoidant strategies become generalized.
 - Avoid place where the traumatic event happened and all similar places.
 - A child who was beaten up on the way to school becomes avoidant of going to school at all.
 - A child who was sexually abused in the bathroom at home is now afraid of all bathrooms.
 - Children who deal with fear through avoidance are:
 - Reinforcing their fears
 - Not extinguishing them
 - As avoidance strategies become ineffective:
 - Some children may become emotionally numb to escape the overwhelming fear they feel.

- Symptoms include:
 - Efforts to avoid thoughts, feelings, or talking about traumatic event
 - Avoiding activities, places, people, or situations that serve as trauma reminders
 - Inability to remember an important aspect of the trauma
 - Loss of interest or participation in significant activities
 - Detachment or estrangement from others
 - Restricted affect
 - In older children and teens, a sense of a foreshortened future

Hyperarousal symptoms

- Includes hyperarousal symptoms not present before the traumatic event
- In children who have experienced chronic trauma, it may be difficult to:
 - Assess the onset of these symptoms
 - Distinguish them from other syndromes such as attention-deficit/hyperactivity disorder
- Symptoms include:
 - Difficulty falling or staying asleep
 - Irritability
 - Temper outbursts
 - Trouble concentrating
 - Hypervigilance
 - Increased startle response
 - In young children, development of new fears not previously present

DIFFERENTIAL DIAGNOSIS

- Subclinical PTSD
 - Children with significant PTSD symptoms without meeting strict psychiatric criteria of the disorder often have comparable functional impairment to those with the full disorder.
 - Many exposed children may experience subclinical PTSD.
 - With or without symptoms that interfere with their functioning or cause impairment in other domains, such as:
 - Behavioral dysfunction
 - Aggression
 - Hypersexuality
 - Social incompetence
 - Anger
 - Explosiveness
 - Relationship conflicts or problems
- PTSD is not the only, or even most common, outcome for children to experience after trauma exposure.

■ PTSD most typically co-occurs with other difficulties, such as:

- Depression
- Anxiety
- Behavioral problems
- The PCP may have to include other assessments or instruments to evaluate these potential comorbidities.

■ In some cases, parents may initially identify other clinical concerns that may relate to child's recent exposure to traumatic events.

- Children may develop problems in the absence of PTSD symptoms.
- Substance abuse, self-injury, and serious behavior problems are common sequelae of traumatic experiences.
 - Particularly in child physical abuse and domestic violence

■ Childhood traumatic grief

- A condition that PCPs should be prepared to recognize and refer for specialized intervention
- Occurs in a minority of children who lose significant others to death under traumatic (frightening, unexpected) circumstances
 - The child gets stuck on traumatic circumstances of the death.
 - The child cannot move through typical stages of grieving.
 - The child may seem less sad than children who are mourning in a more usual fashion because the affected child develops PTSD symptoms of avoidance and numbing, and the child may:
 - Not talk about the deceased
 - Avoid visiting the cemetery
 - Seem detached from parents and friends
 - Become easily angered and irritable when others want to reminisce about the deceased
- Parents may become angry because they interpret this behavior to mean the child:
 - Is not mourning loss of the deceased
 - Does not seem to care about the death
- PCP can help the child and family by:
 - Recognizing the signs and presentation of childhood traumatic grief
 - Educating the family about this condition

DIAGNOSTIC APPROACH

Role of the pediatrician

■ PTSD is often underrecognized in:

- Young children who have difficulty reporting certain PTSD symptoms
- Those who have experienced traumas associated with shame, secrecy, or stigma
 - Sexual abuse

- Domestic violence

- Bullying

■ Reliance on parental reports of the child's symptoms greatly improves diagnosis.

- Parents may not wish to provide accurate reports of the child's trauma exposure or symptoms.
 - Traumatized themselves
 - Perpetrators of the child's traumatic experience

■ Many traumatized children do not spontaneously report traumatic experiences or trauma symptoms.

■ PCPs may be in the best position to:

- Identify these children
- Influence developmental trajectory positively

■ PCPs should be:

- Aware of the high prevalence of child trauma exposure
- Willing and able to assess children for presence of PTSD symptoms in the primary care setting

Assessing trauma exposure

■ PCPs who have a favorable relationship with patients will feel comfortable asking the child about possible exposure to a variety of different types of traumas at well-child care appointments.

■ Children and parents should be asked these questions in private, rather than together.

- Many types of trauma are believed by children or parents to be:
 - Stigmatizing
 - Shameful
 - Things that should be kept secret within the family
- Children may be less likely to disclose such information in the presence of a parent than when alone with the PCP.
 - Reporting requirements in the case of child maltreatment should be followed if the child discloses maltreatment in this context.
- Some general questions designed to elicit information about the child's potential exposure to traumatic events:
 - Has any significant change occurred in the child's life or functioning since the last visit?
 - Since the last time the child was seen, has something really scary or upsetting happened to the child or someone in the child's family?
 - Has any significant change occurred in the child's behavioral or emotional functioning?
 - Has anyone reported or observed any sudden changes in the child's behavior or mood?

- Monitor children's potential exposure to specific traumatic events or experiences.
 - Key domains that should be included in an interview
 - Severe crashes or injury-causing events
 - Vehicular
 - Falls
 - Fires
 - Medical trauma, illness, or related procedures
 - Long hospitalization
 - Painful procedures
 - Natural disasters
 - Storm
 - Hurricane
 - Blizzard
 - Earthquake
 - Flood
 - Hit by lightning
 - Physical violence
 - Toward child or other
 - Threatened or happened
 - Bullying
 - Domestic violence
 - Adults fighting, attacking, shooting, stabbing, beating each other up at home
 - Sexual abuse
 - Unwanted touches in private parts
 - Taking pictures
 - Internet abuse
 - Physical abuse at home
 - Beating, punching, hitting by parent or older sibling
 - Traumatic death
 - Knew of or observed someone die
 - Ask about circumstances: was death sudden, shocking, terrifying, gory?
 - Other scary, frightening events
 - Kidnapping
 - Terrorism
 - Self-report instruments are available for inquiring about trauma exposure.
 - Commonly used exposure instruments include:
 - Trauma Exposure Structured Interview for Children
 - Can be administered as a self-report instrument
 - UCLA PTSD Index for *DSM-IV*

Assessing PTSD symptoms

Physician assessment

- When assessing the child for the presence of PTSD symptoms, symptoms should be anchored to a specific stressor.
 - The child should be asked whether any specific experienced events were upsetting or scary.
 - If the child reports that any of these events were distressing, the clinician should:
 - Determine which was most traumatic from the child's perspective
 - Assess child for presence of PTSD symptoms

Self-report screening methods

- In most PCP practices, time demands will preclude PCPs from conducting personal interviews to assess PTSD symptoms for all children.
 - A child self-report PTSD screening measure can be used in office settings.
- 9-item Abbreviated UCLA PTSD Index (see Figure 63 on page F22)
 - Has been used in school settings after disasters, with good results
 - Score of 20 highly correlates with a diagnosis of PTSD.
 - Children with scores ≥ 20 should be referred for evaluation.
 - Clinical judgment should be used to determine whether children with scores between 10 and 19 should also be referred for evaluation, especially if they have clinically meaningful symptoms of PTSD.
- Trauma Symptom Checklist for Children
 - Alternative self-report method for evaluating severity of posttraumatic symptoms
 - Developed to evaluate children's responses to unspecified traumatic events in an array of symptom domains by using several scales
 - Posttraumatic stress
 - Anger
 - Anxiety
 - Depression
 - Sexual concerns
 - Preoccupation
 - Dissociation
 - Includes several scales relevant to the assessment of post-traumatic stress symptoms and other symptoms related to PTSD.
 - Standardized on a large sample of racially and socioeconomically diverse children from urban and suburban settings.

- Provides norms according to age and sex, as well as clinical cutoff scores
- The child is asked to indicate how often each item happens by using a 4-point scale.
 - 0 = never
 - 1 = sometimes
 - 2 = lots of times
 - 3 = almost all the time
- Posttraumatic stress subscale consists of 10 items reflecting posttraumatic stress symptoms
 - Intrusive recollections of traumatic events
 - Sensory reexperiencing and nightmares
 - Dissociative avoidance
 - Fears
 - This particular subscale has high internal consistency and good criterion validity.

TREATMENT APPROACH

- The PCP is in a unique position to promote an initial response to a child who may have been exposed to traumatic events and who exhibits symptoms of PTSD.
 - Opportunities to observe the child during routine physical examinations provide both observational and physical evidence that may be relevant to identification of traumatic exposure and symptoms.
 - These impressions may be confirmed through parental interview when questions about the child's experiences and timing of any recent or sudden reactions to these events can be ascertained.
- Children exposed to traumatic life events who have several risk factors for PTSD may need:
 - More prompt mental health referrals
 - Closer PCP follow-up
 - Both
- Effective treatment is available for children who have significant PTSD symptoms.
 - With optimal interventions, most children are able to recover in as few as 12 treatment sessions.

SPECIFIC TREATMENTS

- Mental health therapies with evidence of effectiveness for PTSD; may be considered for subclinical problems
 - Parent-Child Interaction Therapy
 - Use with physically abused children
 - Abuse-Focused Cognitive-Behavioral Therapy
 - Use with children exposed to domestic violence by using parent-child psychotherapy

- Cognitive Behavioral Intervention for Trauma in Schools project tools
 - Use with adolescents exposed to community violence

WHEN TO REFER

- Children who do not meet full PTSD criteria (ie, do not have ≥ 3 PTSD symptoms and ≥ 1 in each cluster)
 - Still considered to have significant PTSD symptoms and should still be referred for mental health evaluation and treatment
 - Even if the child has only a few PTSD symptoms, if they are of sufficient severity to cause functional impairment, they may warrant a referral for further evaluation.
- Abbreviated UCLA PTSD Index scores
 - Score ≥ 20 : The child should be referred for evaluation.
 - Scores between 10 and 19: Clinical judgment should be used to determine need for referral for evaluation; child should be referred if:
 - Child has clinically meaningful symptoms of PTSD *and*
 - Symptoms are accompanied by functional impairment
 - The child or parent reports that the child is having difficulty getting along with people at school or at home, or child has trouble sleeping, eating, or concentrating.
 - Score < 10 : The child should be referred for further mental health if:
 - The parent or PCP has concerns based on child's clinical symptoms or history after exposure to a traumatic event, because avoidant children are likely to underreport PTSD symptoms.

FOLLOW-UP

- PCPs may be well placed to:
 - Follow up on high-risk children
 - Monitor them for later emergence of mental health difficulties

COMPLICATIONS

- Left untreated, childhood trauma and PTSD are associated with serious and long-lasting negative outcomes.
 - Impairments in:
 - Learning
 - Memory
 - Academic performance
 - Increased risk for:
 - Depression
 - Suicide attempts
 - Completed suicide in adolescence and adulthood

- Substance abuse
- Self-injury
- Risky sexual behaviors
- Impaired physical health and immunity
- Increased health care use in adulthood

PROGNOSIS

- If children are identified and treated with optimal interventions, PTSD symptoms generally:
 - Remit relatively quickly
 - Remit cost effectively
 - Do not return
- Most tested treatment for PTSD leads to reduction of:
 - Depression
 - Anxiety
 - Shame
 - Behavioral difficulties

PREVENTION

- Work toward preventing PTSD by noting when children appear to be at risk for traumatic exposure or experiences.
 - Potential high-risk scenarios that may be reported by the family include:
 - Sudden and frequent moves
 - Major disruptions in caregiving environment or caregiver functioning or status
 - Reports of increased frustration or physical force during child management or disciplinary interactions
 - Exposure to or knowledge of age-inappropriate sexual activities
 - Child reactions to a caregiver that have changed suddenly
 - Exposure to drugs and alcohol
 - Spending a lot of time with nonbiologically related men
 - Offer advice regarding steps that may minimize a child's exposure to high-risk situations.
 - Encourage parents to monitor and promote child safety, both in and out of the home.

Preoperative Assessment

BACKGROUND

- Ambulatory or same-day surgery provides significant medical, psychological, and economic benefits to children and their families.
- Much of the preoperative and postoperative patient care that in the past was provided in the hospital by the surgeon and anesthesiologist is now being performed by the child's primary care physician (PCP).
 - Preoperative evaluation and decisions about medical interventions to minimize perioperative risks often are performed by the PCP because most anesthetics are given on an outpatient basis.
 - The PCP's knowledge of the child's medical history and established relationship with the family means he or she is in the best position to:
 - Determine the state of the child's health
 - Help the family prepare psychologically for surgery
- The child is reevaluated by the anesthesia and surgical teams on the morning of the procedure to determine whether an acute illness has developed.
- Compliance with preoperative medication administration and *nil per os* (NPO) status is determined at that time.

GOALS

- Goal of preanesthetic evaluation is to determine risk of anesthetizing a particular child in his or her current medical condition for a specific procedure
- Factors to consider include:
 - Probability of an adverse event and its associated estimated risk
 - Benefits of the procedure
 - Consequences associated with either proceeding with or delaying the procedure
- All 3 variables—risk, benefit, and consequence—must be considered in the decision to administer an anesthetic:
 - Optimal improvement in underlying disease
 - Effect of any intercurrent processes on overall physiology
 - The risk of adverse perianesthetic events common in children

GENERAL APPROACH

American Society of Anesthesiologists Physical Status Classification

- Summarizes patient's physical condition and may provide means of assessing relative risk of anesthesia
- Class 1: extremely suitable for anesthesia
 - Normal healthy person
 - No underlying medical condition

- Class 2: generally good
 - Mild systemic disease without functional limitations
 - Mild asthma
 - Anemia
 - Controlled seizures
 - Controlled diabetes mellitus
- Class 3: intermediate
 - Severe systemic disease
 - Moderate to severe asthma
 - Poorly controlled seizures
 - Pneumonia
 - Tracheostomy without ventilatory support
 - Poorly controlled diabetes
 - Moderate obesity
 - History of prematurity
 - Cancer
 - Stable organ dysfunction (moderate renal or liver insufficiency)
- Class 4: poor risk
 - Severe systemic disease that is a constant threat to life
 - Severe bronchopulmonary dysplasia (BPD)
 - Sepsis
 - Morbid obesity
 - Advanced organ insufficiency: cardiac, pulmonary (eg, tracheostomy with ventilatory support), hepatic, renal, adrenal disease
- Class 5: extremely poor risk
 - Moribund patient, not expected to survive without procedure
 - Septic shock
 - Severe organ failure
 - Severe trauma

Trends and statistical information in adverse events

- Pediatric Perioperative Cardiac Arrest (POCA) Registry identifies trends in adverse events that occur in children receiving anesthetics and provides data on perioperative risk.
 - Infants and those children with severe systemic disease are at highest risk for perianesthetic mortality.
 - Most common cardiovascular causes of arrest
 - Hemorrhagic hypovolemia
 - Metabolic consequences of massive blood transfusions
- Closed pediatric anesthesia malpractice claims registry allows evaluation of risk of adverse perioperative events.
 - Procedures most commonly cited
 - Dental, ear, nose, throat, maxillofacial procedures (36%)
 - Abdominal procedures (17%)

- Suggests procedures related to the airways are associated with increased risk
- Incidence of adverse events is 75 per 1000 anesthetics
 - Most common events result from:
 - Respiratory causes during the procedure
 - For younger children, respiratory adverse events in the recovery period as well
 - Vomiting during the recovery period

Child's preprocedure anxiety

- Preprocedural sedation, usually by an oral or rectal route, often is effective in modulating anxiety.
- Omitting premedication in an anxious child will result in a traumatic induction, leading to
 - Postoperative maladaptive behaviors
 - Enuresis
 - Night terrors
 - Violent behavior
- Children requiring repeated invasive procedures can develop a posttraumatic stress–like syndrome.

Preoperative fasting guidelines

- Guidelines for type of ingested material (in hours)
 - Clear liquids: 2
 - Breast milk: 4
 - Infant formula: 6
 - Nonhuman milk: 6
 - Light meal: 6
- Many pediatric anesthesiologists require a fast of 8 hours after solid food for elective surgery.
- Children are encouraged to drink clear liquids to minimize:
 - Anxiety
 - Hypovolemia
 - Possible hypoglycemia that may result from a prolonged preoperative fast
- Institution's pediatric anesthesiology division should be consulted to determine specific practice protocols for fasting.

Preoperative laboratory tests

- Routine laboratory tests are rarely indicated in an otherwise healthy child scheduled for outpatient surgery.
- Hemoglobin (Hgb)
 - Routine determination of hematocrit and Hgb are not necessary if previous results during well-child care have been normal.
 - Selective determination should be used in children:
 - With chronic medical illnesses
 - About to undergo procedures with potential for significant blood loss

- Infants <6 months should have preoperative Hgb level measured because the physiological nadir of red blood cell production may cause level to decrease as low as 7 g/dL.
- In ex-premature infants, Hgb levels <10 g/dL have been associated with an increased incidence of postoperative apnea.
- Children of African or African-American ethnicity who have not had Hgb and hematocrit determination after 6 months of age should have these measurements and a sickle cell screening test.

■ Coagulation status

- Required by most surgeons in children undergoing procedures with an increased risk of intra- or postoperative bleeding, even when no history of bleeding disorder in patient or family
 - Tonsillectomy or adenoidectomy
 - Intracranial procedures
- Studies typically include:
 - Prothrombin time
 - Partial thromboplastin time
 - Platelet count

■ Electrolytes

- Routine preoperative testing is not indicated, even for hospitalized patients.
- Child with cardiovascular disease and undergoing digoxin therapy should have
 - Serum sodium
 - Potassium
 - Digoxin
- Serum electrolytes should be evaluated if patient:
 - Has renal insufficiency
 - Is taking diuretics
 - Is taking angiotensin-converting enzyme inhibitors
 - Is taking other medications that increase likelihood of abnormal result
 - Is limited to enteral (nasogastric or gastrostomy tube) feedings or parenteral nutrition

■ Pregnancy testing

- Routine pregnancy screening of all menarcheal girls is performed in many institutions.
 - Many question cost-effectiveness of this practice.
- Pregnancy testing on the day of surgery using point-of-care urine testing is recommended.
 - If positive, the procedure is canceled, the patient is notified, and a pediatric social worker is consulted to help the young woman.

■ Other tests

- Chest radiograph in patients with history of chronic aspiration or lower airway disease

- Electrocardiogram (ECG) is warranted in a child with:
 - Obstructive sleep apnea syndrome
 - BPD
 - Congenital heart disease
 - Severe scoliosis
- Children being treated with anticonvulsants should have serum levels checked to ensure that anticonvulsants are in the therapeutic range.
- Pulmonary function tests
 - May be useful in predicting whether children with pulmonary or thoracic cage abnormalities (eg, scoliosis) are at increased risk for anesthetic complications and postoperative respiratory insufficiency.
 - Most common tests
 - Pulse oximetry
 - Forced vital capacity (FVC)
 - Forced expiratory volume in 1 second (FEV₁)
 - Ratios of the 2 measurements (absolute values of FEV₁/FVC), as predictor of need for postoperative mechanical ventilation
 - Reliable results usually cannot be obtained in children <6 years of age.

SPECIFIC INTERVENTIONS

Preanesthetic history and exam

- Focus on fundamental systems that may have physiological consequences during anesthetic use
- Most departments of anesthesiology provide a standardized form.
- When this form is not provided, the PCP should provide a history and physical exam with all abnormalities identified:
 - Pulmonary (including airways anatomy)
 - Cardiovascular
 - Endocrine
 - Hematologic
 - Neuromuscular
 - When applicable:
 - Premature birth and neonatal course
 - Oncologic disease
 - Exposure to chemotherapeutic agents
 - History of corticosteroid use
 - History of congenital anomalies and corrective procedures
 - Autism and other behavioral-communicative disorders
 - Weight
 - Blood pressure
 - Room-air oxygen saturation or saturation with baseline oxygen supplementation

- Allergies (drugs and latex)
- Cardiac murmur history
- Previous subspecialty encounters: findings, recommendations, and interventions
- Medications
- Extent of neuromuscular disease (eg, hypotonia)
- Airways exam is essential to allow appropriate advanced preparation for special techniques to secure the airways.
 - Adequacy of mouth opening
 - Neck mobility
 - Loose teeth
- Parents should be questioned about any neurologic symptoms, such as:
 - Long-tract signs
 - Hyperreflexia
 - Positive Babinski response
 - Clonus
 - Hand weakness
 - Bladder and bowel dysfunction
 - History of torticollis or neck pain
- Under no circumstances should the words “cleared for surgery” be written on a prescription form after completion of a preoperative history and physical exam.

Respiratory tract risk assessment

- Risk factors for perianesthetic respiratory events
 - Age <5 years
 - Copious secretions
 - Plan for endotracheal intubation required for procedure
 - History of reactive airway disease
 - History of prematurity
 - Parental smoking history
 - Upper respiratory infection within the previous 4 weeks
 - Wet cough
 - Wheezing

Assessment of infections

- Upper respiratory infection (URI) mandates careful risk, benefit, and consequence analysis.
 - If URI is active or recent, patient is more likely to experience laryngospasm, oxygen desaturation, bronchospasm, severe coughing, and breath holding during anesthetic induction and emergence.
 - Incidence of perioperative respiratory events is increased 7 times in children with URI and 11 times if intubated.
 - Risk of airways complications remains high for up to 6 weeks after URI, probably as a result of altered airways reactivity.

- Children with URIs undergoing elective cardiac surgery
 - 4-fold increased incidence of airways complications at induction of anesthesia
 - 2-fold increased incidence of postoperative respiratory complications
 - 5-fold increase in postoperative bacterial infections, as well as extended stay in intensive care unit (ICU)
- Respiratory events associated with a mild to moderate URI commonly are managed with:
 - Additional oxygen supplementation
 - Prolonged postanesthesia care unit stay
 - Inhaled beta-agonists
 - Corticosteroids
- Small percentage of patients require unplanned hospitalization for stridor, pneumonia, or other complications.
- Usually, no significant increase in respiratory complications among children anesthetized *during* an acute URI, which has led some researchers to advocate *not* canceling surgery for these children.
- Delay surgery 4–6 weeks after resolution of symptoms if:
 - Temperature >101.3°F (38.5°C)
 - Purulent nasal discharge
 - Lower respiratory symptoms (eg, productive cough, crackles, wheezes, or positive chest radiograph findings)
- An additional screening tool is the child's room-air oxygen saturation.
 - If child with a URI (and no chronic lung disease) has room-air oxygen saturation of less than 96% at sea level, then the case will be rescheduled.
- Parents should be told that increased adverse perioperative respiratory events occur in children exposed to cigarette smoke at home.

Asthma

- Many anesthetic procedures can produce bronchospasm, which is frightening, challenging to treat, and sometimes catastrophic.
 - Ventilation is difficult, if not impossible, and may result in:
 - Hypercapnia
 - Acidosis
 - Hypoxia
 - Cardiovascular collapse
 - Death
- To prevent, asthma medical therapy should be escalated preoperatively, even in asymptomatic patients or patients with well-controlled asthma.
 - Short courses of corticosteroids are extremely effective in preventing perioperative wheezing, even in patients who have severe asthma.
 - Children who take asthma medications only as needed should begin use of their inhaled beta-agonists or oral medications 3–5 days preoperatively.
 - Children taking medications on a long-term basis (oral or inhaled) should have corticosteroids added in doses normally used for an acute exacerbation.
- The child with severe asthma who takes bronchodilators and corticosteroids regularly requires:
 - Intensification in frequency of nebulizer treatments
 - Added bronchodilators
 - Increased corticosteroids
 - On occasion, all of these measures
- Asthma therapy should never be deescalated or stopped before surgery.
- Optimization of child's condition should be documented by achieving maximal peak flow rate for that child.
- Children taking theophylline (uncommon) should have serum levels measured preoperatively to optimize drug administration and avoid possible toxic effects.
- Despite fasting, all oral medications may be taken with small amounts of water on the morning of surgery.
- Children with asthma are not candidates for procedures performed at freestanding facilities if they:
 - Have been hospitalized for asthma within previous 3 months
 - Had an exacerbation in the previous month
 - Have a room-air oxygen saturation of $\leq 96\%$
- *Elective* surgery should never be performed in a child who is wheezing actively or who has had a recent asthma attack.

Premature infants and risk of postoperative apnea

- Nonanemic premature infants who have postconceptual age (gestational age added to age after birth) >56 weeks have less than a 1% risk of developing postoperative apnea.
- Hemoglobin concentration <10 g/dL increases the risk.
- Postoperative apnea may resolve spontaneously.
 - Considered serious because cerebral arterial desaturation can occur after only 5 seconds of apnea
- All at-risk patients (those with a postconceptual age <60 weeks), regardless of anesthetic technique, should be admitted to monitored, high-surveillance inpatient units for 24 hours after anesthesia and surgery.
- Infants born prematurely who were intubated and received ventilatory assistance as neonates are at increased risk for subglottic stenosis.
 - Negative history does not exclude the diagnosis.
 - History of croup or stridor is an important warning sign.

BPD

- Evaluate pulmonary status and optimize conditions before anesthesia and surgery to minimize perioperative risks of:
 - Bronchospasm
 - Atelectasis
 - Pneumonia
 - Respiratory/cardiac failure
- These children may benefit from:
 - Bronchodilators
 - Antibiotics
 - Diuretics
 - Nutritional support
 - Corticosteroid therapy
- Respiratory infections or bronchospasm in children who have BPD must be treated thoroughly before elective surgery.
- If severe BPD and bronchospasm are present, preoperative treatment with increased inspired oxygen tension may decrease pulmonary vasoreactivity and improve cardiovascular function.
- Possibility of associated right-ventricular dysfunction should always be considered and, when indicated, evaluated with ECG and echocardiography.
- Children taking diuretics (eg, furosemide and spironolactone) on a long-term basis require a preoperative measurement of serum electrolytes.
- Many infants with BPD receive frequent courses of corticosteroids, and perioperative corticosteroid coverage may be required.
- Children with BPD may require continuous postoperative monitoring and ventilatory assistance for an extended period (24–48 hours).
 - Risks of general anesthesia and intubation can sometimes be avoided with judicious use of either a laryngeal mask airway or a regional anesthetic.
 - Parents must be cautioned that either approach might be unsuccessful and intubation still required.

Obstructive sleep apnea syndrome (OSAS)

- OSAS can be consequence of abnormal upper airways anatomy, upper airways dysfunction, or both
- With adenotonsillectomy, 10–30% incidence of perioperative complications that can include:
 - Laryngospasm
 - Pulmonary edema
 - Postoperative airways obstruction
 - Respiratory arrest
- Risk factors for these complications include:
 - Age <3 years
 - Severe OSAS on polysomnography
 - Infants born prematurely

- Right-ventricle hypertrophy
- Pulmonary hypertension
- Recent URI
- Signs of respiratory distress
- Trisomy 21
- Craniofacial anomalies
- Neuromuscular disease
- Failure to thrive
- Obesity
- Oxygen saturation nadir <80% during sleep study has been noted to increase a child's probability of postoperative complications to 50%.
- Children undergoing urgent, as opposed to elective, tonsillectomy have a 2-fold increased risk of postoperative complications.
- Children <3 years have high rate of postadenotonsillectomy airways obstruction and respiratory complications
 - Should be admitted overnight for observation and cardiorespiratory monitor and continuous pulse oximetry
- Details of the sleep study, if performed, should be reviewed, but due to study expense and the unavailability of pediatric sleep centers, many children undergoing adenotonsillectomy have the diagnosis of OSAS made on clinical grounds.
- Postoperatively, children with OSAS, especially those <3 years, should be admitted to the pediatric ICU or other highly monitored location
 - Incidence of obstructive events and pulmonary complications may increase in first 24 hours after surgery.

Cystic fibrosis

- In patients with cystic fibrosis, anesthesia usually is required for:
 - Otolaryngology procedures (eg, sinus surgery)
 - Central line placement
 - Bronchoscopy
 - Esophagoscopy
 - Laparotomy for intestinal obstruction
 - Placement of enteral feeding devices
- Incidence of postoperative complications is 10–22%.
- Incidence of perioperative mortality is 1–5%.
- Adolescents with severe pulmonary dysfunction are at risk for massive hemoptysis (25% will experience recurrent massive hemoptysis).
- Most complications are pulmonary; general anesthesia may have at least short-term deleterious effects on pulmonary function.
- Primary focus
 - Determine severity of pulmonary disease.
 - Use all methods possible to optimize it in consultation with pediatric pulmonologist.

- Pulmonary function tests will demonstrate:
 - Hyperinflation
 - Lower airways obstruction
 - Responsiveness to bronchodilators
- Chest radiographs/computed tomography studies document degree of disease heterogeneity.
 - Useful in determining risk of pneumothorax during positive pressure ventilation
- Preoperative room air pulse oximetry further helps to quantify the degree of underlying pulmonary dysfunction.
 - Patients with cystic fibrosis who are chronically hypoxemic are at risk for pulmonary hypertension and cor pulmonale.
 - An echocardiographic evaluation should be performed in this subset of patients.
- Recent sputum culture to detect any acute pulmonary infections that need preoperative antibiotics or contact precautions
- Chest physiotherapy and mucolytics are useful in improving sputum clearance.
- Preoperative nutritional support and optimization of pancreatic enzyme supplementation mitigates effects of growth failure and hypoalbuminemia.
- Correction of electrolyte and coagulation abnormalities with oral agents is useful in decreasing need for acute interventions.

Preexisting cardiovascular disease, risk assessment

- Disqualification for procedures performed at freestanding ambulatory surgical facilities:
 - Current use of cardiac medications
 - Prolonged QT syndrome
 - Residual cardiac disease

Heart murmurs

- Innocent murmurs, frequently episodic and associated with a normally split second heart sound, normal exercise tolerance, and a normal ECG, include:
 - Still's murmur
 - Most common in late preschool
 - Exacerbated by fever, exercise, and anemia
 - Low pitch vibratory
 - Increased by exercise
 - Decreased by standing
 - Pulmonary murmur
 - Most common during middle to late childhood
 - Can appear during febrile illnesses, anemia, and pregnancy
 - Blowing midsystolic
 - Increased by expiration
 - Decreased by standing

- Supraclavicular bruit
 - Harsh systolic ejection
 - Increased by pressure
 - Decreased by shoulder extension
- All murmurs of questionable status should be evaluated by a pediatric cardiologist.
- All pathologic findings should be communicated directly to the pediatric anesthesiologist.
- Children with congenital heart disease (whether repaired or not) should have a cardiac evaluation within 1 year before surgery, even if asymptomatic.

Williams syndrome

- High risk for perioperative complications
- Thorough history noting change in exercise tolerance, dyspnea, angina, and syncope
- Complete cardiologic evaluation, including an ECG, should be performed before the administration of each anesthetic, looking for:
 - Evidence of outflow tract obstruction
 - Coronary artery anomalies
 - Segmental wall motion abnormalities suggestive of myocardial ischemia
 - Anesthetic induction must be performed with great care, avoiding extremes in heart rate and blood pressure.

Prolonged QT syndrome

- Patients at increased risk for torsade de pointes
- Perform preoperative ECG (looking for a $QT_c > 470$ ms in male patients and > 480 ms in female patients) if there is history of any of the following manifestations:
 - Syncope
 - Seizures
 - Sudden cardiac death after an increase in sympathetic activity (in the form of exercise, auditory stimulus, or emotional stress)
 - Family history of sudden death
 - Long-term administration of one of the drugs listed in the table *Drugs That Prolong the QT Interval or Induce Torsades de Pointes*
 - Children with long QT syndrome should have electrolytes measured to ensure that serum levels of potassium, calcium, and magnesium are normal.

Subacute bacterial endocarditis prophylaxis

- Antibiotic prophylaxis to prevent bacterial endocarditis is recommended if undergoing any procedure with a risk of bacteremia (eg, dental, sinus, airways) or when the surgical site is contaminated.
 - Unrepaired cyanotic congenital heart defect (CHD), including palliative shunts and conduits

Drugs That Prolong the QT Interval or Induce Torsades de Pointes

Generic Name	Brand Name	Category ^a
Albuterol ^{b,c}	Ventolin, Proventil	3
Amantadine	Symmetrel	2
Amiodarone	Pacerone, Cordarone	1
Amphetamine/ dextroamphetamine	Adderall	3
Atomoxetine ^c	Strattera ^c	3
Azithromycin	Zithromax	2
Chloral hydrate	Noctec	2
Chloroquine	Arelan	1
Chlorpromazine	Thorazine	1
Clarithromycin	Biaxin	1
Clozapine	Clozaril	2
Dextroamphetamine	Dexedrine	3
Disopyramide	Norpace	1
Dobutamine ^b	Dobutrex ^b	3
Dolasetron ^b	Anzemet ^b	2
Dopamine ^b	Intropin ^b	3
Droperidol	Inapsine	1
Ephedrine	Rumatuss	3
Epinephrine	Primatene, Bronkaid	3
Erythromycin ^c	Erythrocin ^c , EES ^c	1
Felbamate ^c	Felbatol ^c	2
Flecainide	Tambocor	2
Foscarnet	Foscavir	2
Fosphenytoin ^c	Cerebyx ^c	2
Gemifloxacin	Factive	2
Granisetron ^{b,c}	Kytril ^{b,c}	2
Halofantrine	Halfan	1
Haloperidol	Haldol	1
Isoproterenol	Isupres, Medihaler-Iso	3
Isradipine	Dynacirc	2
Levalbuterol ^c	Xopenex ^c	3
Levofloxacin	Levaquin	2
Lithium	Lithobid, Eskalith	2
Metaproterenol	Alupent, Metaprel	3

Generic Name	Brand Name	Category ^a
Methadone	Dolophine, Methadose	1
Methylphenidate ^c	Ritalin ^c , Concerta ^c	3
Milodrine	ProAmatine	3
Moxifloxacin	Avelox	2
Nicardipine	Cardene	2
Norepinephrine	Levophed	3
Octreotide	Sandostatin	2
Ofloxacin	Floxin	2
Ondansetron ^{b,c}	Zofran ^{b,c}	2
Pentamidine	Pentam, NebuPent	1
Phenylephrine	Neosynephrine	3
Pimozide	Orap	1
Procainamide	Pronestyl	1
Pseudoephedrine	PediaCare, Sudafed	3
Quetiapine	Seroquel	2
Quinidine	Quinaglute, Cardioquin	1
Risperidone ^c	Risperdal ^c	2
Salmeterol	Serevent	3
Sotalol	Betapace	1
Tacrolimus	Prograf	2
Telithromycin	Ketek	2
Terbutaline	Brethine	3
Thioridazine	Mellaril	1
Tizanidine	Zanaflex	2
Venlafaxine	Effexor	2
Ziprasidone	Geodon	2

^a Category 1: Drugs that are generally accepted by authorities to have a risk of prolonging the QT interval and causing torsades de pointes. Category 2: Drugs that may prolong the QT interval but at this time lack substantial evidence for causing torsades de pointes.

Category 3: Drugs to be avoided for use in patients with diagnosed or suspected congenital long QT syndrome (in addition to drugs in categories 1 and 2).

^b Drugs that are commonly used in the perioperative period.

^c Drugs that are commonly used in children.

A continuously updated and complete list of drugs that prolong QT may be found at www.azcert.org/medical-pros/drug-lists/drug-lists.cfm.

- Completely repaired CHD with prosthetic material or device (placed by surgery or by catheter intervention) within 6 months of procedure
- Repaired CHD with residual defects or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
- Cardiac transplantation recipients who develop cardiac valvopathy
- Prosthetic cardiac valves
- Previous infective endocarditis
- Oral endotracheal intubation by itself is not an indication for subacute bacterial endocarditis (SBE) prophylaxis, but nasotracheal intubation requires it.
- Hemodynamically insignificant lesions (eg, bicuspid aortic valve, mitral valve prolapse) no longer require prophylaxis for any procedure.
- CHD repaired with prosthetic material require prophylaxis only for the first 6 months after repair.
- Patients with prosthetic valves or those palliated with shunts or conduits require prophylaxis.
- In most circumstances, prophylactic antibiotics can be administered orally 1 hour before the procedure, with a minimal amount of water.
 - When necessary, give antibiotic intravenously, when started after induction of anesthesia.
 - Starting an IV catheter in an awake child is unnecessary solely to administer antibiotics for SBE prophylaxis.
- Delayed gastric emptying
- Limited joint mobility
- Involvement of the cervical spine and temporomandibular joints can result in difficulties with laryngoscopy and intubation of patients with diabetes.
- Most diabetic patients can undergo minor surgical procedures with insulin administered subcutaneously, as outlined below for procedures less than 2 hours, by type of insulin:
 - Mixed insulin
 - Day before procedure: usual intermediate or long-acting
 - Day of procedure: 50% intermediate or long
 - Short-acting insulin
 - Day before: usual short-acting
 - Day of: no short-acting
 - Glargine (lantus)
 - Day before: usual short-acting or take none
 - Day of: Take none
 - Insulin pump
 - Day before: normal rate
 - Day of: normal rate
- Diabetic patients should be the first case of the day.
- Blood glucose levels should be measured on arrival to preoperative preparation area.
 - If blood glucose level is >250 mg/dL, then subcutaneous regular insulin or an insulin pump bolus should be administered according to a sliding scale to decrease to 150 mg/dL.
- For major procedures, or if brittle diabetes, give continuous infusion of insulin, along with infusion of glucose to maintain a blood glucose level of 150–200 mg/dL.
- Many institutions prohibit use of the patient's insulin pump intraoperatively with conversion to a continuous intravenous infusion.
- Hourly blood glucose measurements are performed throughout the procedure, and additional glucose or insulin is titrated as appropriate.

Endocrine disorders

Diabetes mellitus

- Avoid hyperglycemia complications
 - Increases in perioperative morbidity and mortality
 - Delayed wound healing
 - White blood cell dysfunction
 - Increased infectious complications
- Perioperative evaluation includes evaluation of insulin regimen, adequacy of metabolic control, and any end-organ dysfunction.
 - Normal electrolyte levels
 - No evidence of ketonuria
 - HbA_{1C} level should be within endocrinologist's acceptable range.
 - HbA_{1C} level is a dynamic reflection of mean blood glucose level during the previous 8–12 weeks.
- Unfavorable systemic manifestations include:
 - Renal microangiopathy
 - Coronary artery disease
 - Hypertension
 - Retinopathy
 - Peripheral neuropathies
- **Congenital adrenal hyperplasia**
 - Focus of preoperative evaluation for patients with congenital adrenal hyperplasias is to:
 - Characterize exact nature of enzymatic deficiency
 - Understand whether both glucocorticoid and mineralocorticoid arms of steroidogenesis are involved
 - State of hydration, blood pressure, and electrolytes are evaluated to determine adequacy of baseline supplementation.
 - Usual maintenance hydrocortisone dose is inadequate to cover physiological stresses.
 - Patients scheduled for major surgery are given 100 mg/m² hydrocortisone in 4 divided IV doses for the first 24 hours, then tapered slowly.

- Some endocrinologists prefer a continuous infusion of hydrocortisone during surgery.

Secondary adrenal insufficiency

- Due to exposure to exogenous corticosteroids
- Asthmatic children who received a single 5-day course of high-dose systemic corticosteroids have normal adrenal function by 10 days after treatment.
- Children who have received at least 3 courses of high-dose burst (5 days) systemic corticosteroids within the previous year in addition to their maintenance inhaled corticosteroids have no evidence of adrenal dysfunction 30 days after the last burst.
- Patients receiving prolonged therapy for >3 weeks, evening doses, and continuous dosing (versus alternate-day dosing) are more likely to have adrenal insufficiency, which may take more up to a year to resolve.
- Fluticasone at doses >500 µg/day causes adrenal suppression in 20% of children.
 - Children receiving high doses of fluticasone may undergo a cosyntropin stimulation test to determine risk for adrenal suppression.
 - If they do not have this test, the best course is to administer *stress-dose* corticosteroids perioperatively.
 - Intranasal corticosteroids can cause adrenal suppression in children.
- Situations requiring stress-dose corticosteroid coverage:
 - <10 days after a burst (5 days) of corticosteroids
 - <30 days after completion of the last of multiple short courses of corticosteroids
 - <1 year after completing a prolonged course of steroids (>3 mo)
 - Previously treated with fluticasone >500 µg/dL
 - Daily parenteral or enteral corticosteroids for >3 weeks
 - Evening doses of corticosteroids
 - Impaired response to cosyntropin stimulation test
- Stress-dose corticosteroid recommendations by degree of surgical stress
 - Minor: <1 hr (eg, hernia)
 - Hydrocortisone 25 mg/m² IV
 - Methylprednisolone 5 mg/m² IV
 - Moderate (extremity surgery)
 - Hydrocortisone 50 mg/m² IV
 - Methylprednisolone 10 mg/m² IV or usual oral dose and reduced parenteral dose
 - Major (laparotomy)
 - Hydrocortisone 25 mg/m² IV every 6 hr
 - Methylprednisolone 5 mg/m² IV 6 hr
 - At start of surgery through the operative day

- May return to maintenance corticosteroid administration on the first postoperative day if the patient is stable

– Wean over 1–3 days.

Thyroid disease

- Hypothyroidism
 - Patients with undertreated hypothyroidism have multisystem disease that can have profound anesthetic implications.
 - Cardiac dysfunction
 - Myocardial depression
 - Bradycardia
 - Torsade de pointes
 - Hypotension
 - 2nd-degree baroreceptor dysfunction
 - Decreased intravascular volume
 - Respiratory
 - Blunted ventilatory response to hypoxia and hypercapnia
 - Pharmacologic
 - Increased sensitivity to depressant effects of anesthetic agents
 - Hypothermia
 - Reduced metabolic rate
 - Adrenal insufficiency
 - Delayed gastric emptying
 - Primary objective in preoperative evaluation is to confirm that the patient is euthyroid.
 - If thyroxine (T₄) level is low and thyroid-stimulating hormone level is elevated, *elective* surgical procedures should be postponed for at least 2 weeks to allow for adequate thyroxine supplementation.
 - Children recently diagnosed with hypothyroidism and those with unexpected bradycardia should undergo a cardiologic evaluation to determine extent of myocardial involvement.
 - T₄ supplementation in the perioperative period should be managed in collaboration with a pediatric endocrinologist.
 - 8 AM cortisol level is useful in establishing whether the child has occult adrenal dysfunction.
 - Children should take their levothyroxine on the morning of surgery.
- Hyperthyroidism
 - During perioperative period, undertreated patients with hyperthyroidism can have thyroid storm with malignant hyperthermia-like symptoms.

- Corticosteroids improve outcomes in patients with thyroid storm; antithyroid medications, potassium iodide, β -blockers are useful in the management of these children.
 - β -Blockers should be titrated to restore heart rate to age-appropriate norms.
- Children with hyperthyroidism should have clinical and chemical evidence of euthyroid state before elective procedures.
 - Elective procedures may need to be delayed until euthyroid state is established.
- Children with goiters should undergo sufficient imaging to delineate extent of airways compromise.

Hematologic conditions

- Previously undiagnosed anemia could indicate serious underlying disorder that requires additional evaluation before surgery:
 - Sickle cell anemia
 - Blood dyscrasia
- Any significant anemia (hemoglobin <9 g/dL) should be determined preoperatively.
- Presence of a mild anemia should not delay urgent surgery.
- Anemia from nutritional causes (eg, iron deficiency) often requires relatively brief period of therapy for improvement.
- For elective surgery, consultation with anesthesia and surgical teams may be required.

Inherited coagulopathies

- Von Willebrand disease (vWD)
 - Patients with type 1 vWD can undergo minor surgical procedures with preoperative DDAVP administered IV 30 minutes before the procedure.
 - 10% of patients with type 1 vWD do not respond to DDAVP.
 - Advance determination of quality of response is fundamental to the preoperative evaluation.
 - Type 1 nonresponders, and patients with type 2 and type 3 vWD, require preoperative administration of plasma-derived human factor VIII concentrate (Humate-P)
 - All patients with vWD undergoing major surgical procedures require factor replacement preoperatively.
- Hemophilia A, B, and C
 - Perioperative management depends on the planned procedures.
 - Patients undergoing major surgical procedures require factor VIII and factor IX levels approximating 100% of normal from 30 minutes before procedure, through the first postoperative week.
 - Patients undergoing minor procedures can be covered with factor levels that are 50% of normal after second postoperative day.

- Some patients with mild hemophilia A have a sufficient response to DDAVP to provide adequate protection for minor procedures.
- Need for fresh-frozen plasma transfusion in hemophilia type C patients should be determined by a pediatric hematologist.

■ Platelet abnormalities that usually require perioperative platelet transfusions include:

- Wiskott-Aldrich syndrome
- Diamond-Blackfan syndrome
- Thrombocytopenia absent radii
- Glanzmann thrombasthenia
- Bernard-Soulier syndrome

Oncologic disease

- Treatments often have the potential to cause profound peri-anesthetic complications.
- Most recent ECG report should be included in preoperative evaluation.

Cerebral palsy

- Preoperative evaluation for patients with cerebral palsy should include:
 - Assessment of room-air oxygen saturation
 - Degree of underlying reactive airway disease
 - Presence of snoring and other obstructive symptoms suggestive of inadequate airways tone
- Preoperative evaluation and preparative regimen is often directed toward ensuring pulmonary status is optimal.
- Chest radiographs may be helpful in the child who has had previous episodes of significant pulmonary consolidation.

Genetic disease

- Airways obstruction and hypoxemia are preeminent concerns resulting from:
 - Abnormalities of upper airways and trachea
 - Altered chest wall mechanics and respiratory drive
 - Reduction in the pulmonary bed from hypoplasia or destruction as the result of gastroesophageal reflux.
- Hypertension and dysrhythmias, cardiomyopathies, and structural heart disease are common.
- ~60% of the 10,000 genetic diseases have central or peripheral nervous system abnormalities.
- Presence of neuromuscular diseases will often dictate specific drug use and technique for airways management.

Down syndrome

- Perioperative evaluation focuses on numerous anomalies associated with Down syndrome that have perianesthetic implications.
- With craniofacial and upper airways anomalies, airways obstruction often persists after adenotonsillectomy because of mid-face hypoplasia.

- Smaller tracheal diameter usually require endotracheal tube that is 1–2 sizes smaller.
- 40–50% have congenital heart disease
 - Often requires surgical correction
 - Postoperative conduction defects or valvular dysfunction (or both)
 - Need for SBE prophylaxis
 - Pulmonary hypertension and pulmonary vascular disease result.
- See Upper airways obstruction and endothelial cell dysfunction.
- Much higher risk for developing pulmonary hypertension in setting of chronic upper airways obstruction
- Perioperative complications occur in 8–10% of patients with Down syndrome undergoing noncardiac surgery:
 - Severe bradycardia
 - Airways obstruction
 - Difficult intubation
 - Postintubation croup
 - Bronchospasm
 - Incidence of OSAS as high as 57%
 - Some recommend screening with polysomnography for OSAS age 3–4 years.
- Cervical spine instability
 - Can lead to catastrophic neurologic injuries in perianesthetic period
 - Atlantoaxial instability (in approximately 15%)
 - Screened with lateral flexion and extension views of the cervical spine, odontoid views, and measurements of the neural canal width
 - Atlantoaxial distance interval >4–5 mm in any lateral view is abnormal.
- Parents should be asked about recent changes in neuromuscular functions indicative of cord impingement:
 - Loss of bowel or bladder control
 - Sensory deficits
 - Motor changes
- Even in the absence of symptoms, children who have Down syndrome and are ≥ 2 –3 years should have lateral flexion and extension radiographs of the cervical spine before anesthesia to identify patients at risk for subluxation.
 - If radiographs reveal an atlantodens interval of greater than 5 mm (usually maximal in the flexion view), refer for orthopedic or neurosurgical consultation before elective surgery.
- Children <3 years may be at risk
 - Neck radiographs not helpful in diagnosis because of the lack of ossification
 - Anesthesiologist should use neck-protection strategies.

Connective tissue disorders

- Often treated with aspirin or other NSAIDs
 - Should be stopped 1 week preoperatively
 - If agents cannot be stopped, evaluate the extent of platelet impairment by measuring bleeding time.
- Associated dysphagia and esophageal dysmotility can predispose patients to pulmonary aspiration of gastric and esophageal contents.
- Extensive fibrosis of temporomandibular or cricoarytenoid joint can complicate airways management and endotracheal intubation.
- Pulmonary infiltration and fibrosis may complicate intra-operative care by causing hypoxemia.
- Hematologic abnormalities, including anemia of chronic disease, may complicate management.
- History should focus on the extent of disease, the type of treatment, and the child's response to therapy.
- Laboratory assessment may include:
 - ECG
 - Chest radiograph
 - Electrolytes
 - Blood urea nitrogen
 - Creatinine
 - Hemoglobin, hematocrit, and platelet levels
 - Peripheral blood smear
- Patient who has quiescent disease and who has regular follow-up may need nothing other than hematocrit determination.

Skin diseases

- Skin diseases associated with skin fragility
 - Epidermolysis bullosa (EB)
 - Ectodermal dysplasia
- Use of all tape and dressings such as Tegaderm may be forbidden, because removal may cause denuding of the skin, pain, and infection.
- In EB, conventional methods of intubation such as direct laryngoscopy or use of airways adjuncts, such as laryngeal mask airways or oral airways, may be associated with blister formation in the pharynx, tongue, or supraglottic area.
- Scarring on skin of hands and feet may restricts options for venous access.
- Involvement of face, neck, and mouth may result in decreased mouth opening, neck mobility, supraglottic airway narrowing, or any combination.
- Anesthesia team needs advanced notice for face-to-face preoperative evaluation and consultation with patient's dermatologist and PCP, followed by discussion with the family of risks and methods for skin protection and airways management.

Medications

- Dosage should be adjusted to ensure adequate therapeutic levels perioperatively.
- Administration ordinarily is continued at usual doses up to and including day of surgery, except monoamine oxidase (MAO) inhibitors and tricyclic antidepressants.
 - Discontinue use of these agents 2–3 weeks before the scheduled operation.
 - If discontinuation cannot be done without risk, preoperative consultation with anesthesiologist is necessary.
- Selective serotonin reuptake inhibitors
 - Should not be stopped to prepare for surgery
 - Withdrawal can precipitate anxiety, agitation, and diaphoresis.
- Anesthesiologist must be informed because interactions with drugs administered perioperatively can lead to unexpected adverse effects.
- Discontinue psychotropic drugs in perioperative period:
 - Lithium
 - MAO inhibitors
 - Tricyclic antidepressants (eg, amitriptyline)
 - Clozapine
 - Cessation of medications requires involvement of the patient's mental health professional.
- Drugs for attention-deficit/hyperactivity disorder (eg, Strattera, Concerta, and Adderall) may continue preoperatively, but reports of tachycardia and arrhythmias mandate vigilance.
- Herbal or homeopathic medications may lead to unexpected anesthetic reactions; many anesthesiologists advise stopping 2 weeks before surgical procedure
 - Echinacea: purple coneflower root
 - Allergic reactions; decreased effectiveness of immunosuppressants; potential for immunosuppression with long-term use
 - No data on whether to discontinue
 - Ephedra: ma huang
 - Risk of myocardial ischemia and stroke; ventricular arrhythmias with halothane
 - Life-threatening interaction with MAO inhibitors
 - Discontinue ≥ 24 hours before surgery
 - Garlic
 - Potential to increase risk of bleeding, especially when combined with other medications that inhibit platelet aggregation
 - Discontinue ≥ 7 days before surgery
 - Ginkgo: duck foot tree, maidenhair tree, silver apricot
 - Potential to increase risk of bleeding, especially when combined with other medications that inhibit platelet aggregation
 - Discontinue ≥ 36 hours before surgery
 - Ginseng
 - Hypoglycemia
 - Potential to increase risk of bleeding
 - Potential to decrease anticoagulation effect of warfarin
 - Discontinue ≥ 7 days before surgery
 - Kava: awa, intoxicating pepper, kawa
 - Potential to increase sedative effect of anesthetics
 - Potential for addiction, tolerance, and withdrawal after abstinence unstudied
 - Discontinue ≥ 24 hours before surgery
 - St John's wort: amber, goat weed, hardhay, Hypericum, klamathe weed
 - Induction of cytochrome P450 enzymes, affecting cyclosporine, warfarin, corticosteroids, protease inhibitors, and possible benzodiazepines, calcium channel blockers, and many other drugs; decreased serum digoxin levels
 - Discontinue ≥ 5 days before surgery
 - Valerian: all-heal, garden heliotrope, vandal toot
 - Potential to increase sedative effect of anesthetics
 - Benzodiazepine-like acute withdrawal
 - Potential to increase anesthetic requirements with long-term use

Syndromes that may cause difficult intubation

- Beckwith-Wiedemann
 - Macroglossia
- Down syndrome
 - Macroglossia
 - Midface hypoplasia
 - Tracheal narrowing
 - May have atlantoaxial instability that may exhibit only under general anesthesia/neuromuscular blockade
 - Can result in damage to the cervical spinal cord
- Pierre Robin sequence
 - Micrognathia
 - Cleft palate
 - Glossoptosis
- Treacher Collins
 - Hypoplasia of the maxilla and mandible

- Hemifacial microsomia (Goldenhar)
 - Unilateral or bilateral mandibular hypoplasia
 - Macrostomia
- Apert
 - Craniosynostosis
 - Midface hypoplasia
- Freeman-Sheldon (“whistling face”)
 - Microstomia
 - Facial anomalies
- Mucopolysaccharidoses
 - Redundant facial, pharyngeal, and supraglottic soft tissue
 - Neck immobility
- Klippel-Feil
 - Cervical vertebral fusion
 - Neck immobility
- Crouzon
 - Craniosynostosis
 - Midface hypoplasia
- Stickler
 - Mandibular hypoplasia
 - Joint stiffness
- Pfeiffer
 - Craniosynostosis
 - Mid-face hypoplasia
- Some dwarfing syndromes

Prevention of malignant hyperthermia crisis

- Malignant hyperthermia (MH) is an inherited disorder of muscle calcium channels, triggered in affected individuals by exposure to inhalational anesthetic agents or succinylcholine.
- Most patients who are MH susceptible have normal history and physical examinations.
- MH crisis is a cascade of hypermetabolism, electrolyte derangements, arrhythmias, skeletal muscle damage, and hyperthermia, which progresses to death if untreated.
 - Prevalence is 1 in 15,000 general anesthetics in children.
 - Incidence increases if succinylcholine is given in addition to volatile anesthetics.
 - Appropriately treated, mortality is estimated at less than 10%.
- Standard test to screen for MH susceptibility is in vitro caffeine-halothane contracture test; uses a muscle biopsy specimen.
 - Indications for performing:
 - Documented episode of hyperthermia
 - Acidosis
 - Rhabdomyolysis induced by a triggering agent
 - Episode of masseter muscle spasm after exposure to a triggering agent
 - Availability of testable relatives of an MH-susceptible patient
 - Patient at least 5 years of age and 20 kg
- Dantrolene, a muscle relaxant that reduces the release of calcium from muscle sarcoplasmic reticulum, significantly improves outcomes.

Preparticipation Physical Evaluation

BACKGROUND

- >6 million high school students participate in sports each year.
- Preparticipation Examination Task Force
 - Formed in the early 1990s by the American Academy of Family Physicians, AAP, American Medical Society for Sports Medicine, American Orthopaedic Society for Sports Medicine, and American Osteopathic Academy of Sports Medicine
 - Preparticipation physical evaluation (PPE) guidelines were updated in 1997, 2002, and 2004.
 - Are the basis for current PPE
 - Are one of the most commonly performed examinations
- PPE has evolved to allow physicians to provide consistent, high-quality examinations nationwide.

GOALS

- Primary goals of PPE are to:
 - Detect conditions that might predispose athlete to injury
 - Musculoskeletal history and physical examination are the best ways to discover orthopedic problems.
 - Detect conditions that might be life-threatening or disabling
 - Sudden cardiac death in young athletes is rare, but a history of syncope or chest pain with exercise or family history of sudden death under age 50 should be evaluated.
 - Topics that must be discussed and emphasized include:
 - Concussion
 - Heat injury
 - Use of nutritional supplements
 - Meet legal or insurance requirements
- Secondary goals are to:
 - Determine general health
 - Counsel athletes on health-related issues
 - Assess fitness level
- The purpose of PPE is not to disqualify athletes.
 - <2% are actually disqualified based on an evaluation's results.
- Identifying athletes who may need further diagnostic testing, counseling, or rehabilitation is primary goal of PPE, but many other expectations exist.
 - Parental expectations
 - May sometimes expect PPE to be a comprehensive evaluation of athlete's health, including areas that may be considered unrelated to sports participation (eg, teenage sexuality, substance abuse, immunizations)
 - Often think of PPE as comprehensive and the only medical evaluation a child or adolescent needs
 - Physicians often view PPE as a cursory examination intended only to detect conditions that might limit or impair athletic endeavors.

- Because parents and physicians may view PPE differently:
 - Parents must be advised about the intent of PPE.
 - The scope and purpose of PPE must be made clear to parents.
- Ideally, all steps in PPE should be performed by a single physician, even if mass screening is taking place.

GENERAL APPROACH

- PPE typically is conducted by 1 of 3 methods.
 - Locker-room method
 - Athletes traditionally line up single file; the physician examines each athlete individually.
 - Requires few personnel and can be performed with little preparation
 - Affords little privacy for athletes, is usually so noisy that the physician has a hard time auscultating the heart and lungs, and is often too brief
 - Station method
 - Divides examination into several components
 - Physicians, nurses, athletic trainers, and coaches each assigned to a single task
 - Ideally suited for screening large numbers of athletes
 - The benefits are relative efficiency and good ability to identify abnormalities.
 - Affords less rapport with athletes and offers no privacy
 - Athletes have little opportunity to ask questions regarding their health or other medical or personal issues.
 - Office-based method
 - Has the advantage of an established physician-patient relationship
 - The athlete's medical history is known, and continuity of care is fostered.
 - Disadvantages include lack of consistency among physicians, potential for physician unfamiliarity with the sport and its disqualifying conditions, and lack of cost effectiveness.
 - Routine laboratory studies and radiographs are not generally performed.
 - Based on information obtained during history and physical examination, the physician may think that further studies are indicated.
- Timing
 - PPE should be performed:
 - Early enough before the sport's season begins to ensure that athletes with medical problems can be thoroughly evaluated and treated
 - Not so early that intervening injuries are likely to occur

- The best time for evaluation is 4–6 weeks before the first scheduled practice.
 - Allows enough time for thorough evaluations, consultations, and rehabilitation of any identified musculoskeletal injuries
- Current AAP guidelines suggest that PPE should be performed every year.
 - Other sources suggest that PPE be conducted before the beginning of each new level of competition (ie, junior high, high school), with annual updates of history and targeted physical examinations of areas of concern.
- Most state high school athletic associations require annual evaluations.
 - A recent survey found that 65% of states require annual examination for all athletes competing in high school sports.
- History
 - History identifies most potential problems for young athletes.
 - Despite best screening of athletes with intent of preventing sudden death, only a few who die would have been detected through history and physical examination.
 - The key to identifying such problems is the questionnaire that systematically screens for conditions that might cause problems or lead to sudden death during athletic activity.
 - The table Medical History Questions lists some of the most important questions to ask during the examination.
 - PPE forms provided by state high school athletic associations often do not incorporate all the screening questions recommended by the Preparticipation Examination Task Force.
 - Athletes typically complete history forms without input from parents.
 - A study showed that only 40% of PPE forms matched when filled out independently by parent and child.
 - The athlete and his or her parents should complete the form together to obtain a thorough and accurate history.
 - Some issues may arise (particularly when the practice is the medical home) in which adolescent privacy on certain topics should be respected.
- Sports are classified based on the likelihood of collision injury and strenuousness of the exercise.
 - These classifications are used to guide physicians on risk of injury and degree of cardiopulmonary fitness required to engage in the sport successfully.
 - The AAP has established classification guidelines by intensity (see table Sports Classification by Intensity) and level of contact.
 - Contact or collision
 - Basketball
 - Boxing
 - Diving
 - Field hockey
 - Football (flag, tackle)
 - Ice hockey
 - Lacrosse
 - Martial arts
 - Rodeo
 - Rugby
 - Ski jumping
 - Soccer
 - Team handball
 - Water polo
 - Wrestling
 - Limited contact
 - Baseball
 - Bicycling
 - Cheerleading
 - Canoeing and kayaking (white water)
 - Fencing
 - Field events (high jump, pole vault)
 - Floor hockey
 - Gymnastics
 - Handball
 - Horseback riding
 - Racquetball
 - Skating (ice, in-line, roller)
 - Skiing (downhill, water)
 - Softball
 - Squash
 - Ultimate frisbee
 - Volleyball
 - Windsurfing and surfing
 - Noncontact
 - Archery
 - Badminton
 - Bodybuilding
 - Canoeing and kayaking (flat water)
 - Crew rowing
 - Curling
 - Dancing
 - Field events (discus, javelin, shot put)
 - Golf
 - Orienteering
 - Power lifting
 - Race walking
 - Riflery
 - Rope jumping

Medical History Questions

	Question	Reason
1.	Injury or illness since last checkup?	Targets potential physical examination concerns
2.	Chronic illnesses, hospitalizations, or surgeries?	Identifies potential counseling or rehabilitation issues
3.	Any medications or supplements of any type?	Identifies drugs that may inhibit or interfere with sports participation
4.	Allergies to medications, insects, or food?	Alerts physicians and trainers for potential allergic reactions
5.	Dizziness, passed out, chest pain with exercise; history of sudden death in a close relative <50 years of age?	Identifies potential causes of sudden death caused by cardiovascular problems
6.	Have you ever passed out or nearly passed out during exercise? Have you ever passed out or nearly passed out after exercise? Have you ever had discomfort, pain, or pressure in your chest during exercise? Does your heart race or skip beats during exercise? Does anyone in your family have Marfan syndrome?	Targets cardiovascular concerns
7.	Ever been restricted from sports by physician?	Identifies potential disqualifying problems
8.	Any skin problems?	Identifies potential transmittable disease during contact
9.	Concussion, knocked out, unconsciousness, memory loss, seizure, or severe or frequent headache?	Targets neurologic concerns
10.	Stinger, burner, pinched nerve, numbness or tingling in extremities?	Targets neurologic concerns
11.	Problems while exercising in the heat?	Targets heat illness concerns
12.	Asthma, allergies, wheezing, difficulty breathing, or chest pain?	Identifies potential for exercise-induced asthma
13.	Special equipment or devices not usually used in your sport?	Identifies potential concerns for physician follow-up
14.	Glasses, contacts, or vision or eye problems?	Identifies ophthalmologic concerns
15.	Strain, sprain, fracture, joint pain, or swelling?	Identifies potential musculoskeletal problems
16.	Concerns about weight: Do you lose weight regularly for your sport?	Identifies potential disordered eating
17.	Feel stressed out?	Clue to ask follow-up questions regarding drug use, eating problems, sexuality, and home and school problems
18.	Recent immunizations (tetanus, measles, hepatitis B, chickenpox)?	Health maintenance issues
19.	Girls only: menstrual history?	Identifies oligomenorrhea and amenorrhea and potential risk for poor nutrition, stress fractures
20.	Do you wear protective braces, splints?	Identifies injuries that have not been fully rehabilitated

- Running
- Sailing
- Scuba diving
- Strength training
- Swimming
- Table tennis
- Tennis
- Track
- Weight lifting

- Clearance to play
 - Few athletes are disqualified from activity on the basis of conditions identified during PPE.
 - The table Medical Conditions and Sports Participation lists the most current recommendations regarding medical conditions and contraindications to participation.
 - Working with athletes to find safe, enjoyable sports in which they can participate is important.
 - If possible, and depending on the condition detected, sports participation should not be eliminated altogether.

Sports Classification by Intensity^a

High-to-Moderate Intensity High-to-Moderate Dynamic High-to-Moderate Static Demands	High-to-Moderate Intensity High-to-Moderate Dynamic Low Static Demands	High-to-Moderate Intensity High-to-Moderate Static Low Dynamic Demands	Low Intensity Low Dynamic Low Static Demands
<ul style="list-style-type: none"> • Boxing • Crew rowing • Cross-country skiing • Cycling • Downhill skiing • Fencing • Football • Ice hockey • Rugby • Running (sprint) • Speed skating • Water polo • Wrestling 	<ul style="list-style-type: none"> • Badminton • Baseball • Basketball • Field hockey • Lacrosse • Orienteering • Table tennis • Race walking • Racquetball • Soccer • Squash • Swimming • Tennis • Volleyball 	<ul style="list-style-type: none"> • Archery • Auto racing • Diving • Equestrian • Field events (jumping, throwing) • Gymnastics • Karate or judo • Motorcycling • Rodeo • Sailing • Ski jumping • Water skiing • Weight lifting 	<ul style="list-style-type: none"> • Bowling • Cricket • Curling • Golf • Rifle shooting

Adapted from: Rice SG, American Academy of Pediatrics Council on Sports Medicine and Fitness. Medical conditions affecting sports participation. *Pediatrics*. 2008;121(4):841–848.

PHYSICAL EXAMINATION

General

- 2 key components of physical examination (cardiovascular and musculoskeletal) identify most athletes who warrant further evaluation or disqualification.

Cardiovascular examination

- See table Cardiovascular Screening in Athletes.
- Should include evaluation of peripheral pulses, murmurs, and blood pressure
 - All diastolic murmurs and grade 3/6 systolic murmurs warrant further evaluation.
 - Hypertrophic cardiomyopathy
 - One of the most important conditions to detect
 - May produce a systolic murmur that cannot be distinguished from an innocent murmur; the murmur of hypertrophic cardiomyopathy:
 - Increases in intensity with a Valsalva maneuver (decreased ventricular filling, increased obstruction)
 - Decreases with squatting (increased ventricular filling, decreased obstruction)
 - Increases in intensity when the athlete moves from squatting to standing position
 - Blood pressures obtained during PPE often are high.
 - This may be the result of using a blood pressure cuff that is too small, particularly in large adolescents.
 - Sometimes the athlete's blood pressure truly is high when an age-based table of norms is consulted.

- Hypertension rarely is severe enough to disqualify an athlete from participation, but it must be identified and monitored by the athlete's regular physician.
- Weight-training activities should be restricted in patients who have severe hypertension.
- Sudden cardiac death
 - Rare in young athletes; however, history of syncope, chest pain with exercise, or family history of sudden death <50 should be evaluated.
 - Recent research showed that screening for sudden cardiac death that included standardized history, physical examination, and electrocardiography may have helped prevent sudden death caused by cardiomyopathy.

Musculoskeletal examination

- Musculoskeletal examination typically accounts for 50% of abnormal physical findings on PPE.
- Should focus on previously injured or symptomatic areas
- 92% of orthopedic injuries are detected by history alone.
- Some authorities suggest a sport-specific approach to the physical examination.
 - Emphasizes the areas that are most commonly affected or injured in each specific sport
- Special considerations for examination of injured or symptomatic joints include:
 - Inspection for visual deformity, muscle mass, asymmetry, and swelling

Medical Conditions and Sports Participation^a

Condition	Participate?	Explanation
Atlantoaxial instability (instability of the joint between cervical vertebrae 1 and 2)	Qualified yes	Athlete needs evaluation ^b to assess risk of spinal cord injury during sports participation.
Bleeding disorder	Qualified yes	Athlete needs evaluation.
Carditis (inflammation of the heart)	No	Carditis may result in sudden death with exertion.
Hypertension (high blood pressure)	Qualified yes	Persons with significant essential (unexplained) hypertension should avoid weight and power lifting, bodybuilding, and strength training. Those with secondary hypertension (hypertension caused by a previously identified disease) or severe essential hypertension need evaluation.
Congenital heart disease (structural heart defects present at birth)	Qualified yes	Persons with mild forms may participate fully; those with moderate or severe forms or who have undergone surgery need evaluation.
Dysrhythmia (irregular heart rhythm)	Qualified yes	Athlete needs evaluation because some types require therapy or make certain sports dangerous, or both.
Mitral valve prolapse (abnormal heart valve)	Qualified yes	Persons with symptoms (chest pain, symptoms of possible dysrhythmia) or evidence of mitral regurgitation (leaking) on physical examination need evaluation. All others may participate fully.
Heart murmur	Qualified yes	If the murmur is innocent (does not indicate heart disease), then full participation is permitted; otherwise the athlete needs evaluation (see Congenital heart disease and Mitral valve prolapse above).
Cerebral palsy	Qualified yes	Athlete needs evaluation.
Diabetes mellitus	Yes	All sports can be played with proper attention to diet, hydration, and insulin therapy. Particular attention is needed for activities that last 30 minutes or more.
Diarrhea	Qualified no	Unless disease is mild, no participation is permitted, because diarrhea may increase the risk of dehydration and heat illness. See Fever below.
Eating disorders, anorexia nervosa, bulimia nervosa	Qualified yes	These patients need both medical and psychiatric assessment before participation.
Eyes: functionally one-eyed athlete, loss of an eye, detached retina, previous eye surgery or serious eye injury	Qualified yes	A functionally one-eyed athlete has a best-corrected visual acuity of <20/40 in the worse eye. These athletes would experience significant disability if the better eye were seriously injured, as would those with loss of an eye. Some athletes who have previously undergone eye surgery or had a serious eye injury may have an increased risk of injury because of weakened eye tissue. Availability of eye guards approved by the American Society of Testing Materials and other protective equipment may allow participation in most sports, but this determination must be judged on an individual basis.
Fever	No	Fever can increase cardiopulmonary effort, reduce maximal exercise capacity, make heat illness more likely, and increase orthostatic hypotension during exercise. Fever may rarely accompany myocarditis or other infections that may make exercise dangerous.
History of heat illness	Qualified yes	Because of the increased likelihood of recurrence, the athlete needs individual assessment to determine the presence of predisposing conditions and to arrange a prevention strategy.

Medical Conditions and Sports Participation^a, *continued*

Condition	Participate?	Explanation
HIV infection	Yes	Because of the apparent minimal risk to others, all sports may be played that the state of health allows. In all athletes, skin lesions should be properly covered, and athletic personnel should use universal precautions when handling blood or body fluids with visible blood.
Kidney: absence of one	Qualified yes	Athlete needs individual assessment for contact or collision and limited contact sports.
Liver: enlarged	Qualified yes	If the liver is acutely enlarged, then participation should be avoided because of risk of rupture. If the liver is chronically enlarged, then individual assessment is needed before collision or contact or limited contact sports are played.
Malignancy	Qualified yes	Athlete needs individual assessment.
Musculoskeletal disorders	Qualified yes	Athlete needs individual assessment.
History of serious head or spine trauma, severe or repeated, concussions, or craniotomy	Qualified yes	Athlete needs individual assessment for collision or contact or limited contact sports and for noncontact sports if deficits exist in judgment or cognition. Recent research supports a conservative approach to management of concussions.
Convulsive disorder (well controlled)	Yes	Risk of convulsion during participation is minimal.
Convulsive disorder (poorly controlled)	Qualified yes	Athlete needs individual assessment for collision or contact or limited-contact sports. Avoid the following noncontact sports: archery, rifle shooting, swimming, weight or power lifting, strength training, or sports involving heights. In these sports, occurrence of a convulsion may be a risk to self or others.
Obesity	Qualified yes	Because of the risk of heat illness, obese persons need careful acclimatization and hydration.
Organ transplant recipient	Qualified yes	Athlete needs individual assessment.
Ovary: absence	Yes	Risk of severe injury to the remaining ovary is minimal.
Respiratory, pulmonary compromise (including cystic fibrosis)	Qualified yes	Athlete needs individual assessment, but generally, all sports may be played if oxygenation remains satisfactory during a graded exercise test. Patients with cystic fibrosis need acclimatization and good hydration to reduce the risk of heat illness.
Asthma	Yes	With proper medication and education, only athletes with the most severe asthma will have to modify their participation.
Acute upper respiratory infection	Qualified yes	Upper respiratory obstruction may affect pulmonary function. Athlete needs individual assessment for all but mild diseases. See Fever previously listed.
Sickle cell disease	Qualified yes	Athlete needs individual assessment. In general, if status of the illness permits, then all but high-exertion, collision or contact sports may be played. Overheating, dehydration, and chilling must be prevented.
Sickle cell trait	Yes	Individuals with sickle cell trait do not likely have an increased risk of sudden death or other medical problems during athletic participation except under the most extreme condition of heat and humidity and possibly high altitude. These individuals, as with all athletes, should be carefully conditioned, acclimatized, and hydrated to reduce any possible risk.

Medical Conditions and Sports Participation^a, continued

Condition	Participate?	Explanation
Skin: boils, herpes simplex, impetigo, scabies, molluscum contagiosum	Qualified yes	Because the patient is contagious, participation in gymnastics with mats, martial arts, wrestling, or other collision or contact or limited-contact sports is not allowed. Herpes simplex virus is probably not transmitted via mats.
Spleen: enlarged	Qualified yes	Persons with acutely enlarged spleens should avoid all sports because of risk of rupture. Those with chronically enlarged spleens need individual assessment before playing collision or contact or limited contact sports.
Testicle: absent or undescended	Yes	Certain sports may require a protective cup.

^a Adapted from: Rice SG, American Academy of Pediatrics Council on Sports Medicine and Fitness. Medical conditions affecting sports participation. *Pediatrics*. 2008;121(4):841–848.

^b *Needs evaluation* means that a physician with appropriate knowledge and experience should assess the safety of a given sport for an athlete with the listed medical condition. Unless otherwise noted, this term is used because of the variability of the severity of the disease, the risk of injury among the specific sport, or both.

- Palpation for localized areas of tenderness, warmth, and effusion
- Assessment of range of motion (eg, an athlete with hip pain should be tested for loss of internal rotation and abduction, which can be seen in slipped capital femoral epiphysis and Legg-Calvé-Perthes disease)
- Evaluation of neurovascular status by evaluating muscle strength, sensation, reflexes, and pulses of involved limb (eg, an athlete with history of burners should undergo complete neurovascular testing of the neck and upper extremities)
- Evaluation of joint stability (eg, an athlete with knee pain should undergo tests for valgus and varus stress, Lachman test, and posterior drawer test)

Laboratory studies

- Have not been shown to be cost effective or warranted in young asymptomatic athletes
- Routine urinalysis and hematocrit for all athletes have been largely abandoned.
 - Do not identify athletes who require disqualification
 - Have a high rate of false-positive results
- Electrocardiography, echocardiography, and stress testing are not suggested as screening tests in asymptomatic individuals because of the high rate of false-positive findings and high cost.

Special considerations

- Nutritional supplements
 - Sports supplements have become a billion-dollar industry.
 - Athletes as young as age 11 are taking performance-enhancing supplements.

- PPE is the ideal time to question athletes briefly about supplement use.
- Sports supplements contain impurities; when taken inappropriately, they may result in adverse side effects.
 - Muscle cramps
 - Dehydration
 - Abdominal bloating
 - Tachycardia
 - Arrhythmia
 - Death
- Supplement use should be discouraged; young athletes should be told about their possible ill effects.

■ **Obesity**

- Up to 30% of children are obese.
 - Many are seeking to participate in sports.
- Obesity is not a contraindication to sports participation unless a comorbid finding, such as severe hypertension, is present.
- Obese children are at increased risk of heat injury and should be counseled accordingly.
- Sports participation with emphasis on activities that improve fitness should be encouraged for the obese child.

■ **Concussion**

- History of concussion should be addressed during PPE.
- 2 grades of severity: simple and complicated
 - Complicated concussion may include:
 - Amnesia
 - Seizure
 - Prolonged symptoms
 - Loss of consciousness

Cardiovascular Screening in Athletes^a

Condition	Cardiovascular Examination	Abnormality
Hypertension	Blood pressure	Varies with age—general guideline is >135/85 mm Hg in adolescents
Coarctation of aorta	Femoral pulses	Decreased intensity of pulse
Hypertrophic cardiomyopathy	Auscultation with provocative maneuvers (standing, supine, Valsalva maneuver)	Systolic ejection murmur that intensifies with standing or Valsalva maneuver
Marfan syndrome	Auscultation	Aortic (decrecendo diastolic murmur) or mitral insufficiency (holosystolic murmur)

^a Adapted from: Maron BJ, Thompson PO, Puffer JC. Cardiovascular preparticipation screening of competitive athletes: a statement for health professionals from the Sudden Death Committee (clinical cardiology) and Congenital Cardiac Defects Committee (cardiovascular disease in the young), American Heart Association. *Circulation*. 1996;94:850–856.

- Neuropsychological testing is suggested with repeat or complicated concussion.
- Patients must meet 3 criteria to return to play after concussion.
 - Asymptomatic at rest
 - Asymptomatic with exercise
 - No neurocognitive deficits (eg, memory loss, concentration problems, fatigue, foggy, confusion)
- Medical home
 - Adolescents are the most underserved population in health care today.
 - In many instances, their only contact with medical system is PPE.
 - All young athletes should be referred to their pediatric primary care physician for routine care and for follow-up of any ongoing medical conditions.

Preseptal and Orbital Cellulitis

DEFINITION

- Infection of tissues anterior to the orbital septum is described as a *preseptal* or *periorbital* infection.
 - The terms *preseptal* and *periorbital* may be used interchangeably.
- Preseptal cellulitis, or periorbital cellulitis, is often considered as a diagnosis.
 - However, the term is an inadequate diagnostic label unless accompanied by a modifier that indicates the probable pathogenesis.
- Orbital cellulitis is infection of the soft tissues of the orbit posterior to the orbital septum.

ETIOLOGY

- Preseptal cellulitis infections after trauma
 - Result from secondary bacterial infection of local skin trauma, including
 - Insect bites
 - Spread of infection from a focus of impetigo
 - The traumatic injury may be modest or inapparent.
 - Can be caused by any of the following organisms:
 - *Staphylococcus aureus*
 - *Streptococcus pyogenes*
 - *Mycobacterium tuberculosis*
 - In countries where *M tuberculosis* is endemic, this etiology should be considered in patients who present with a swollen lid.
 - *Bacillus anthracis*
 - *Nocardia brasiliensis*
 - *Pasteurella multocida*
 - Ringworm (caused by *Trichophyton* species)
- Bacteremic periorbital cellulitis
 - *Haemophilus influenzae*
 - *Streptococcus pneumoniae*
- Preseptal (periorbital) cellulitis caused by inflammatory edema of sinusitis
 - Complication of paranasal sinusitis
 - Results in swelling around the eye
 - Infecting organisms are the same as those that cause uncomplicated acute sinusitis.
 - *S pneumoniae*
 - Nontypeable *H influenzae*
 - *Moraxella catarrhalis*
- Orbital infections
 - Least common cause of swollen eye
 - Most orbital infections involve formation of a subperiosteal abscess that, in young children, results from ethmoiditis and ethmoid osteitis.

- In the adolescent, subperiosteal abscess can be a complication of frontal sinusitis and osteitis.
- Rarely, orbital cellulitis evolves without formation of subperiosteal abscess.
 - Direct spread from ethmoid sinus to the orbit via natural bony dehiscences in the bones that form the medial wall of the orbit

RISK FACTORS

- Infections can spread to the eye from contiguous structures.
- Venous system provides opportunities for spread of infection from 1 anatomic site to another.
 - Predisposes patient to involvement of:
 - Cavernous sinus
 - Meninges
 - Brain
- Infection originating in the mucosa of the paranasal sinuses can spread to involve the bone (osteitis with or without subperiosteal abscess) and the intraorbital contents.
- Preseptal cellulitis infections after trauma
 - Localized infection of the eyelid or adjacent structure
 - Conjunctivitis
 - Hordeolum
 - Dacryoadenitis
 - Dacryocystitis
 - Trauma
 - Acute sinusitis
- Bacteremic periorbital cellulitis
 - Viral upper respiratory infection (URI)
- Preseptal (periorbital) cellulitis caused by inflammatory edema of sinusitis
 - Sinusitis
- Orbital infections
 - Subperiosteal abscess
 - Orbital abscess
 - Orbital cellulitis
 - Cavernous sinus thrombosis
 - Traumatic inoculation
 - Endophthalmitis
 - In young children, ethmoiditis and ethmoid osteitis
 - In adolescents, frontal sinusitis and osteitis
 - Patients with diabetes and immunocompromised children are at higher risk of fungal orbital cellulitis (especially *Mucor* species).

SIGNS AND SYMPTOMS

Preseptal cellulitis infections after trauma

- Loosely bound periorbital soft tissues permit impressive swelling to accompany minor infection.

- Overlying skin can be bright red with subtle textural changes.
- Intense swelling can lead to shininess (see Figure 64 on page F22).
- Ulceration and vesicle formation in the presence of ringworm
- Some patients have fever.
- Many are afebrile despite dramatic local findings.
- Peripheral leukocyte count is variable.

Bacteremic periorbital cellulitis

- Age <18 months
- History of viral URI for several days
- Sudden increase in temperature (to >39°C)
- Acute onset and rapid progression of eyelid swelling
 - Swelling usually begins in the inner canthus of the upper and lower eyelid.
 - Can obscure the eyeball within 12 hours
- Markedly discolored and erythematous periorbital tissues
- If swelling has been rapidly progressive, the area may have violaceous discoloration.
- The child's resistance to examination commonly leads to an erroneous impression of tenderness.
- Retraction or separation of the eyelids reveals that:
 - The globe is normally placed.
 - Extraocular eye movements are intact.
- The young age of patients, high fever, and rapid progression of findings differentiate bacteremic preseptal cellulitis from other causes of swelling around the eye (see Figure 65 on page F23).
- Bacteremic cellulitis rarely arises from the paranasal sinus cavities.
 - Typeable *H influenzae* organisms are rarely recovered from maxillary sinus aspirates.
 - Typeable *H influenzae* organisms are rarely recovered from abscess material in patients who have serious local complications of paranasal sinus disease (eg, subperiosteal abscess)
 - *S pneumoniae* can cause subperiosteal abscess in patients with acute sinusitis.
 - Such patients are not usually bacteremic.

Preseptal (periorbital) cellulitis caused by inflammatory edema of sinusitis

- Several complications of paranasal sinusitis can result in swelling around the eye.
- The most common and least serious complication is often called *inflammatory edema* or *sympathetic effusion*.
- Typical patient is:
 - ≥2 years old
 - Has had viral URI for several days when swelling is noted
- History of intermittent early-morning periorbital swelling that resolves after a few hours often is present.

- On the day of presentation, eyelid swelling does not typically resolve, but progresses gradually.
- Striking degrees of erythema can also be present.
- Eye pain and tenderness are variable.
- Eyelids can be very swollen and difficult to evert, requiring the assistance of an ophthalmologist.
- When the ethmoid sinuses are completely congested, venous drainage is physically impeded (see Figure 66 on page F23).
 - Resulting in soft-tissue swelling of the eyelids, maximal at the medial aspect of the lids
 - Infection is confined within the paranasal sinuses.
- No displacement of the globe or impairment of extraocular eye movements
- Fever, if present, is usually low grade.
- Peripheral leukocyte count is unremarkable.
- Blood culture results are always negative.
- If a tissue aspiration is performed, culture of specimen has negative result.
- Sinus radiographs show ipsilateral ethmoiditis or pansinusitis.
- The following differentiate inflammatory edema from bacteremic periorbital cellulitis:
 - Age of the child
 - Gradual evolution of lid swelling
 - Modest temperature elevation

True orbital disease secondary to sinusitis

- Orbital infection is the least common cause of a swollen eye.
- Sudden onset of erythema and swelling around the eye (see Figure 67 on page F23)
- Preceded by several days of a viral URI
- Eye pain can precede swelling.
 - Is often dramatic
- Presence of fever, systemic signs, and toxicity is variable.
- Orbital infection is suggested by:
 - Proptosis (with the globe displaced usually anteriorly and downward)
 - Impairment of extraocular eye movements (most often upward gaze)
 - Chemosis (edema of the bulbar conjunctiva) or
 - Loss of visual acuity or decreased pupillary reaction (late in the evolution of the infection)

DIFFERENTIAL DIAGNOSIS

- Young age, high fever, and rapid progression of findings differentiate bacteremic preseptal cellulitis from other causes of swelling around the eye.
- Blunt trauma (resulting in a “black eye”)
 - History provides the key to diagnosis.
 - Eyelid swelling continues to increase for 48 hours and then resolves over several days.

- Tumors that characteristically involve the eye include:
 - Hemangioma of the lid
 - Ocular tumors, such as:
 - Retinoblastoma
 - Choroidal melanoma
 - Orbital neoplasms, such as:
 - Neuroblastoma
 - Rhabdomyosarcoma
 - Langerhans cell histiocytosis
 - Tumors usually cause gradual onset of proptosis in the absence of inflammation.
- Orbital pseudotumor
 - Autoimmune inflammation of orbital tissues, which exhibits:
 - Eyelid swelling
 - Red eye
 - Pain
 - Decreased ocular motility
- Hypoproteinemia and congestive heart failure cause eyelid swelling as a result of local edema.
 - Characteristic findings are bilateral, boggy, nontender, nondiscolored soft-tissue swelling.
- Allergic inflammation
 - Includes angioneurotic edema or contact hypersensitivity
 - Superficially, these problems can resemble findings in acute infection.
 - However, presence of pruritus and absence of tenderness are helpful distinguishing characteristics of allergic inflammation.

DIAGNOSTIC APPROACH

- The child with a swollen eye is commonly seen in primary care.
- Approach to diagnosis (see Figure 68 on page F24) depends on physical examination.
- By far, preseptal infections are most common.
- Infections behind the septum that cause eyelid swelling include:
 - Subperiosteal abscess
 - Orbital abscess
 - Orbital cellulitis
 - Cavernous sinus thrombosis
 - Panophthalmitis
 - Endophthalmitis
 - Although all of these entities can be labeled as orbital cellulitis, a systematic approach allows a more specific diagnosis, thereby directing management.

LABORATORY FINDINGS

- Preseptal cellulitis infections after trauma
 - Peripheral leukocyte count is variable.
- Bacteremic periorbital cellulitis
 - A precise bacteriologic diagnosis is made by recovery of the organism from blood culture.
- Preseptal (periorbital) cellulitis caused by inflammatory edema of sinusitis
 - Peripheral leukocyte count is unremarkable.
 - Blood culture results are always negative.

IMAGING

- Bacteremic periorbital cellulitis
 - Radiographs of the paranasal sinuses are often abnormal.
 - Abnormalities almost certainly reflect the viral respiratory syndrome that precedes and probably predisposes the patient to the bacteremic event rather than a clinically significant sinusitis.
- If retraction of the lids is not possible, orbital computed tomography (CT) may be necessary.
- Orbital infections
- Imaging studies:
 - Are usually performed if orbital disease is suspected.
 - Help determine cause of the clinical findings (see Figure 69 on page F24)
 - Subperiosteal abscess
 - Orbital abscess
 - Orbital cellulitis
- On occasion, CT results can be misleading.
 - They may suggest abscess when inflammatory edema is present.

DIAGNOSTIC PROCEDURES

- Preseptal cellulitis infections after trauma
 - Patients with bacterial cellulitis of traumatized areas rarely have bacteremia.
 - The precise bacteriologic diagnosis is made through culture of exudate from the wound.
 - If there is no drainage, tissue aspiration is carefully attempted.
 - Perform only if it can be done safely (ie, at a distance far enough from the orbit that no potential damage to the eye can occur).
 - Tuberculin syringe with a 25-gauge needle can be used for aspiration.
 - Usually, only a minuscule amount of infected material can be aspirated.

- Small volume of nonbacteriostatic saline (0.2 mL) is drawn into the syringe before the procedure.
 - Not injected into skin
 - Used to expel small volume of tissue fluid onto chocolate agar for culture
- Bacteremic periorbital cellulitis
 - If tissue aspiration is performed, culture of specimen may have a positive result.
 - Lumbar puncture should be performed unless the clinical picture precludes meningitis.
- Preseptal (periorbital) cellulitis caused by inflammatory edema of sinusitis
 - If tissue aspiration is performed, specimen culture is negative.

CLASSIFICATION

- Preseptal
 - Infections: due to local trauma or spread from local infectious site
- Bacteremic
 - Inflammatory: due to inflammatory swelling secondary to sinusitis
- Orbital

TREATMENT APPROACH

- Practitioners frequently need to manage the child whose chief symptom is a swollen eye.
 - Some are trivial or self-limited disorders.
 - Others are sight- or life-threatening problems.
- If orbital disease is suspected, the clinical course is the ultimate guide to management.

SPECIFIC TREATMENTS

Preseptal cellulitis infections after trauma

- Oral antibiotic therapy may be initiated in children who:
 - Are >5 years
 - Are afebrile
 - Have mild cellulitis
 - Have reliable caregivers

Bacteremic periorbital cellulitis

- Requires parenteral therapy
- *S pneumoniae* is the most likely cause in a child who has received both the *H influenzae* type B and pneumococcal conjugate vaccine series.
- Infection is usually bacteremic in the age group in which the meninges are susceptible to inoculation.
 - Use an advanced-generation cephalosporin, such as:
 - Cefotaxime (150 mg/kg per day, divided into 8-hour doses) or ceftriaxone (100 mg/kg per day, divided into 12-hour doses)

- Lumbar puncture should be performed unless the clinical picture precludes meningitis.
 - If cerebrospinal fluid pleocytosis is present, add:
 - Vancomycin (60 mg/kg/day divided into doses every 6 hours) *or*
 - Rifampin (20 mg/kg once daily, not to exceed 600 mg/day)
- If evidence of local infection has resolved and meningitis is not present:
 - A 10-day course of oral antimicrobial therapy is prescribed.

Preseptal (periorbital) cellulitis caused by inflammatory edema of sinusitis

- Antibiotic therapy can be given orally if at the time of the first examination:
 - Eyelid swelling is modest *and*
 - The child does not appear toxic *and*
 - The parents will adhere to management
 - Otherwise, admission to the hospital and parenteral treatment should be undertaken.
- The only source of bacteriologic information is that obtainable by maxillary sinus aspiration.
 - Usually not performed
- Appropriate agents for outpatient therapy have activity against β -lactamase-producing organisms.
 - Amoxicillin-potassium clavulanate
 - Cefuroxime axetil
 - Cefpodoxime proxetil
- Parenteral agents include:
 - Cefuroxime
 - Ampicillin-sulbactam
 - This combination is an attractive choice.
 - Not approved for children <12 years
 - After several days, once the affected eye has returned to near normal, a 14-day course of an oral antimicrobial agent is substituted.
- The use of topically applied intranasal decongestants (eg, oxymetazoline) has not been systematically evaluated.
 - Such agents may be helpful during the first 48 hours.

Orbital infections

Antimicrobial therapy

- Usually, patients with these symptoms are managed successfully with antimicrobial therapy alone.
- Empirical antimicrobial therapy should be chosen to provide activity against:
 - *S aureus* *and*
 - *S pyogenes* *and*

- Anaerobic bacteria of the upper respiratory tract
 - Anaerobic cocci
 - *Bacteroides* species
 - *Prevotella* species
 - *Fusobacterium* species
 - *Veillonella* species
- In addition to the usual pathogens associated with acute sinusitis
 - *S pneumoniae*
 - *H influenzae*
 - *M catarrhalis*
- Appropriate selections include:
 - Cefuroxime (150 mg/kg per day divided into doses every 8 hours) *or*
 - Ampicillin-sulbactam (200 mg/kg per day divided into doses every 6 hours).
 - Clindamycin (40 mg/kg per day divided into doses every 6 hours) *or* metronidazole (30–35 mg/kg per day divided into doses every 8–12 hours) can be added if cefuroxime is used and anaerobic infection is likely
- If surgery is performed
 - Gram stain of material drained from the sinuses or the abscess guides consideration of additional drugs or a change to the regimen.
 - When final results of culture are available, antibiotic therapy may be changed, if appropriate.
 - Intravenous therapy is maintained until the infected eye appears nearly normal.
 - At that time, 3 weeks of oral antibiotic therapy can be substituted.

Surgical drainage

- Presence of a large, well-defined abscess with complete ophthalmoplegia or impairment of vision prompts operative drainage of the paranasal sinuses and the abscess.
- Several studies have reported successful drainage of subperiosteal abscess via endoscopy.
 - Performed through an intranasal approach
 - Avoids external incision
 - In many cases, a well-defined abscess is not seen.
 - Instead, inflammatory tissue is interposed between the:
 - Lateral border of ethmoid sinus *and*
 - Swollen medial rectus muscle
 - On occasion, CT results can be misleading, suggesting abscess when inflammatory edema is present.

WHEN TO ADMIT

- Hospitalize a child with a swollen eye:
 - For parenteral therapy when bacteremic periorbital cellulitis is diagnosed
 - For parenteral therapy when diagnosis of likely bacterial cellulitis is made and
 - Oral therapy has failed *or*
 - The child is febrile *or*
 - The child is <5 years
 - For parenteral therapy and consultation with an ophthalmologist when diagnosis is dacryocystitis
 - When oral therapy has failed
 - If eye is swollen shut and parenteral antibiotics and close observation are required for the management of inflammatory edema (sympathetic effusion)
 - If proptosis, impairment of extraocular movements, diminished pupil reaction, or loss of visual acuity occurs:
 - These signs herald subperiosteal abscess, orbital abscess, orbital cellulitis, and cavernous sinus thrombosis.
 - Presence indicates the need for parenteral antibiotics and the likely need for surgical intervention.

WHEN TO REFER

- Refer a child with a swollen eye to an ophthalmologist in the following instances:
 - When visual acuity is lost
 - When any eyelid swelling occurs in an immunocompromised child or child with diabetes, referral should be immediate.
 - The situation may require urgent treatment.
 - If conjunctivitis is diagnosed, referral is appropriate if clinical findings do not begin to improve after 5 days.
 - Circumstance suggests a diagnosis of either adenovirus or herpes simplex infection.
 - When a chalazion is large and causes local irritation, incision and drainage of the chalazion may be required.
 - When dacryoadenitis has not begun to resolve after 5 days
 - All patients with suspected or proven orbital cellulitis

COMPLICATIONS

- Preseptal (periorbital) cellulitis caused by inflammatory edema of sinusitis
 - Inflammatory edema is part of a continuum.
 - More serious complications result from spread of infection outside the paranasal sinuses into the orbit.
 - Rarely, infection progresses despite initial optimal management of sympathetic effusions.

Prevention of Dental Caries

BACKGROUND

- Dental caries is characterized by progressive destruction of tooth structure by localized bacterial activity.
 - One of the most common bacterial infections afflicting children and adolescents
 - Related to critical interrelationships among:
 - Teeth
 - Dietary carbohydrate
 - Saliva
 - Specific oral bacteria
 - The decay process is initiated by demineralization of the outer tooth surface.
 - Result of organic acids formed during bacterial fermentation of dietary carbohydrates
 - Saliva functions as a remineralizing and buffering solution to counter the effect of demineralization.
 - Carious lesions form if bacterial-derived demineralization exceeds saliva's remineralization and buffering capacity.
 - Incipient lesions first appear as opaque white spots.
 - With progressive loss of tooth mineral, cavitation occurs.

Mechanism

Microbial factors

- *Mutans streptococci*
 - Primary etiologic agent in human dental caries

Salivary factors

- Saliva is the primary host defense against dental caries.
 - Severe caries observed in desalivated experimental animals and xerostomic humans
 - Salivary hypofunction may be a consequence (in part) of diverse factors.
 - Radiotherapy when the salivary glands are within the radiation ports
 - Long-term administration of anticholinergic or parasympatholytic drugs
 - Salivary gland disease (eg, Sjögren syndrome)
- The relationship between salivary gland hypofunction and dental caries involves several factors.
 - Physical flow of saliva augmented by activity of the oral musculature removes a large number of bacteria from teeth.
 - Salivary proteins and enzymes (lysozyme, lactoferrin, and lactoperoxidase) work with other salivary components to:
 - Kill bacteria
 - Interfere with bacterial replication
 - Interfere with the acidogenic potential of cariogenic bacteria

- Other features of saliva
 - Interferes with bacterial attachment through molecular interactions
 - Protects the tooth surface from demineralization
 - Buffers acid through salivary bicarbonate, phosphate, and histidine-rich peptides
 - Remineralizes teeth

Dietary factors

- Most dietary sugars, carbohydrates, and starches are:
 - Readily metabolized to organic acids by *M streptococci*
 - Termed *cariogenic substrates*
- Frequent and prolonged oral exposure to sugars, carbohydrates, and starches facilitates dental caries activity.
- Cariogenic potential
 - Determined not by how much sugar a person eats, but how the sugar is eaten
 - The cariogenic potential of apple juice consumed over a long period (eg, from a bottle all night) differs greatly from that of the same volume of apple juice consumed at a single meal.
 - Sugar from foods retained orally for a long time (eg, a raisin or caramel) is more cariogenic than sugar in foods retained orally for a short time (eg, a liquid that is immediately swallowed).

GOALS

- Promote practice of proper oral hygiene
- Prevent development of dental caries
- Reduce intraoral levels of *M streptococci*
- Refer patients with salivary hypofunction to a pediatric dentist
- Decrease the frequency of cariogenic substrate ingestion
- Refer patients chronically exposed to sweetened medication elixirs to a pediatric dentist

GENERAL APPROACH

- Pediatricians play an important role in the prevention and early diagnosis of dental caries.
 - Routinely question parents about feeding behaviors.
 - Make recommendations that promote dental health.
- Examine the child's dentition as part of routine physical examination.
 - Required equipment
 - An intraoral light
 - Pediatric tongue blade
 - Begin with the distal maxillary molar.
 - Continue with the inspection of each tooth from right to left.
 - Repeat the procedure from the patient's left to right in the mandibular arch.

- Dental caries
 - Frequently appears as a darker-stained area
 - Usually begins in the pits and fissures on the biting surfaces of the molar teeth
 - Contact surfaces between the molar teeth are the second most common area.
 - These areas are difficult to examine.
 - Dentists usually depend on intraoral radiographs.
- Carious lesions
 - Often detected on the front surface of the primary incisor teeth near the gingiva
 - Routinely found in children with severe early childhood dental caries
 - Retracting the lips is necessary to inspect adequately the entire surface of primary incisor teeth.
- Refer to a dentist any child with:
 - Evidence of cavitation
 - Stained fissures
 - Areas of enamel decalcification
- Every child should be evaluated by a dentist by 12 months of age.

SPECIFIC INTERVENTIONS

Fluoride

Water fluoridation

- The recommended optimal level of water fluoridation is 0.7–1.2 ppm fluoride, depending on the amount of water intake.
- Fluoridation of public water supplies has proven to be the most effective, convenient, and economical measure available to prevent dental caries.

Fluoride supplements

- Dramatic reduction in dental caries was demonstrated in populations drinking fluoridated water.
 - Led to recommendations to administer fluoride as dietary supplement for people who did not receive it in drinking water
 - However, fluoride acts topically to prevent dental caries through salivary remineralization of demineralized enamel.
 - This action works best by frequent exposure to relatively low levels of fluoride, as occurs with drinking fluoridated water.
- New fluoride supplementation recommendations have been developed because of:
 - Realization that systemic fluoride ingestion is not the major mechanism of action of fluoride in dental caries prevention
 - Reports of increased dental fluorosis (hypomineralization of enamel)

- Before prescribing fluoride supplements, assess child's exposure to other fluoride sources (eg, toothpaste, fluoridated commercial beverages).
 - Risk of fluorosis increases with increased exposure to fluoride.
- Supplements should be sucked or chewed to enhance the topical action of the fluoride in the supplements.
- Recommended fluoride dose by age and concentration of fluoride in drinking water (ppmF)
 - Birth–6 months
 - <0.3 ppmF: 0
 - 0.3–0.6 ppmF: 0
 - >0.6 ppmF: 0
 - 6 mo–3 years
 - <0.3 ppmF: 0.25 mg
 - 0.3–0.6 ppmF: 0
 - >0.6 ppmF: 0
 - 3–6 years
 - <0.3 ppmF: 0.5 mg
 - 0.3–0.6 ppmF: 0.25
 - >0.6 ppmF: 0
 - 6–16 years
 - <0.3 ppmF: 1.0 mg
 - 0.3–0.6 ppmF: 0.5
 - >0.6 ppmF: 0

Fluoride dentifrice (toothpaste)

- Highly effective in preventing dental decay
- Toothbrushing with a pea-size amount of dentifrice on a toothbrush should be encouraged as soon as teeth begin to emerge.
- Before 6 years of age, children tend to swallow rather than expectorate dentifrice.
 - Nearly all ingested fluoride is absorbed, primarily from the small intestine.

Fluoride rinses

- Those containing 0.05% fluoride are highly effective in reducing dental decay.
- Available without a prescription
- Should be recommended for children ≥6 years of age who are at risk for dental decay because of such conditions as:
 - Compromised salivary flow rates
 - Orthodontic therapy
 - Extensive dental caries
- Not recommended for children <6 years because they cannot expectorate properly
 - Results in excessive fluoride ingestion

Fluoride varnish

- Can be painted on teeth
- Now available in the US
- Contains high concentrations of fluoride (up to 22,600 ppm) suspended in a viscous delivery medium
- Can be applied to teeth of high-risk children by trained personnel in various settings, including the medical office
- Does not require trays or oral suction equipment
 - Unlike foams, rinses, and gels

Dental fluorosis

- Hypomineralization of enamel that occurs when higher than optimal levels of fluoride are ingested during period of enamel formation
 - May vary from very mild to severe
 - Very mild to mild cases appear as chalky whitening of the enamel.
 - Severe fluorosis exhibits as mottled enamel that is pitted and brown.
 - Recent reports have shown a trend toward a higher prevalence of dental fluorosis relative to historical data from earlier studies.
 - Increase was found to correlate with ingestion of fluoride from sources other than drinking water, including:
 - Fluoride supplements
 - Fluoridated toothpaste
 - Commercial beverages containing fluoridated water
- New fluoride supplementation schedule (see above, endorsed by Council on Dental Therapeutics of the American Dental Association)
 - Not recommended prenatally or during the first 6 months of life
 - Not recommended for breastfed infants residing in optimally fluoridated communities
 - Dose level based on the patient's age and fluoride content of the water supply
 - Recommended supplement dose should be considered a maximum.
 - Other sources of ingested fluoride (eg, toothpastes, commercial beverages) should also be taken into account.
- Fluoride level of a water supply can usually be obtained by calling the local water board.
 - Fluoride analysis is indicated when a private water supply is used.
 - The patient's parent should use a plastic container for the water specimen (a glass container may impair the accuracy of the fluoride assay).
 - Send the sample to an appropriate laboratory.

- No fluoride prescription should be written for >120 mg of fluoride, to prevent poisoning from ingestion.
 - Even if a child ingested the entire supply, probably only mild gastric upset would ensue.
 - However, in such an event, a poison control center should be contacted immediately.
- Toothpaste can also provide a topical form of fluoride supplement for children who swallow the toothpaste after brushing.
 - For children who cannot spit, maximal recommended fluoride dose may be ingested simply by brushing a child's teeth once or twice a day.
 - To reduce the risk of dental fluorosis from toothpaste ingestion, a small amount of toothpaste (pea size) should be used in brushing a young child's teeth.
 - Parents should dispense the toothpaste.
 - Young children should not have access to toothpaste.

Oral hygiene

- Thorough daily brushing and flossing of the teeth helps prevent dental caries.
 - Mechanical cleaning disturbs the attachment of dental plaque biofilm to the tooth surface.
- Parents should verify that the child's teeth are clean before bedtime.
 - Buffering capacity and antimicrobial action of saliva decrease during sleep with diminished secretion of saliva.
- Parents should receive professional instruction regarding oral hygiene techniques for children.
 - Information can be obtained from the American Dental Association (see Resources).
- Clinical studies demonstrate that most children ≤ 8 years do not have the hand-eye coordination required for adequate oral hygiene.
 - Parents must assume responsibility for oral hygiene.
 - Degree of parental involvement should reflect the child's level of competency.

Sealants

- Sealants are plastic coatings that are applied professionally to the occlusal (biting) surfaces of the posterior teeth.
- The use of sealants has been shown to be effective in preventing pit and fissure caries.
 - Excellent oral hygiene and optimal fluoride exposure have minimal effect in preventing dental caries in the pits and fissures on the occlusal surfaces of the posterior teeth.
- A survey conducted by the National Institute of Dental Research indicated that relatively few school children in the US have sealants on their teeth.
 - Although efficacious, use of sealants is not routine in prevention of dental caries.

Diet

- Decreasing the frequency of cariogenic substrate ingestion prevents dental caries.
 - Encourage avoidance of between-meal snacks that contain cariogenic substrates.
 - Use of gum, candy, and soft drinks containing sugar substitutes (mannitol, sorbitol, xylitol, and aspartame [with precautions]) is an effective approach for the child with a sweet tooth.
- Chewing sugarless gum has been proven clinically to enhance salivary flow rate and, in turn, neutralize plaque biofilm pH.
- Infants should be weaned from the bottle by 1 year of age to eliminate risk for early childhood dental caries (also known as *nursing bottle dental caries*) (see Figure 70 on page F24).
 - Bedtime and naptime nursing bottles should contain only water.

Prevention of Obesity

BACKGROUND

Obesity and its comorbidities

- Childhood obesity has emerged as a major health problem that increases the risk for chronic illness.
- Obesity is rapidly overtaking smoking as the largest preventable cause of disease in the US.
 - It has the potential to make the current generation of US children the first to have a shorter life expectancy than their parents.
- Obesity prevention, intervention, and treatment must be part of primary care.
- Obesity comorbidities include:
 - Dyslipidemia
 - Type 2 diabetes
 - Nonalcoholic steatohepatitis
 - Polycystic ovarian syndrome
 - Sleep apnea
 - Uniquely pediatric comorbidities occur as a result of injury to open growth plates in the hip and knee.
 - Slipped capital femoral epiphysis
 - Blount disease
 - Comorbidities of obesity add to the burden of chronic disease in children and the health care system.
- Secondary depression and self-esteem issues are becoming increasingly common.
- The number of children who are overweight has increased from 4% in 1962 to 16% in 2002.

Body mass index (BMI)

- A measure that correlates with body fat
 - Calculated as wt/ht^2
 - Used to screen populations for obesity and to categorize individuals to target obesity prevention, intervention, or treatment
 - In adults
 - BMI of 25–29 is overweight.
 - BMI of ≥ 30 is obese.
 - Increased BMI in adults is correlated with increases in obesity-related comorbidities.
 - In children
 - Percentage of body fat changes throughout development.
 - BMI *percentile* must be used as a measure.
 - BMI in 85th–94th percentile is overweight; BMI >95th percentile is obese.
 - BMI >99th percentile has been associated with cardiovascular risk factors:
 - High blood pressure
 - Elevated insulin

- Lipid abnormalities
- Severe adult obesity

Causes of obesity

- The causes of the obesity epidemic are multifactorial and complex.
- These factors play out at the individual, family, community, and population level and account for the global shift in obesity demographics.
- Genetic predisposition
 - The contribution of genetic effects to obesity suggests a strong genetic predisposition toward weight gain.
 - Parental obesity increases the risk that a child will become an obese adult.
 - Infants of mothers who are obese or have diabetes during pregnancy have an increased risk for childhood and adult obesity.
 - The explanation of gene–environment interaction involves *epigenetic mechanisms*, “a set of reversible heritable changes that occur without a change in DNA sequence.”
- A shifting nutrition and activity environment plays a role in both population risk and individual risk of obesity.
- Nutrition- and activity-related behaviors act at the interface between the individual and family and the environment.
 - The concept of the *thrifty genotype*: the transition of a population that evolved under conditions of periodic food scarcity to a state of abundant food and increased inactivity
 - This concept may partially explain the differential susceptibility of ethnic populations.
 - Populations in developing countries who are transitioning to a Western lifestyle also are experiencing a rapid rise of childhood obesity.
 - Minority and disadvantaged children are disproportionately affected by obesity.
 - Lower physical activity levels have been associated with factors that differentially affect disadvantaged populations.
 - Changes in the secular environment have increased calories available to children and families.
 - Portion sizes of commercially available foods began to increase above recommended dietary guidelines in the 1970s.
 - The availability and consumption of snack foods can lead to excess calorie consumption.
 - Consumption of >1 soda per day by children as young as 2 years was correlated with obesity.
 - Eating out has been cited as one of the factors important in the development of the obesity epidemic.
 - The proportion of foods that children consumed from restaurants and fast-food outlets increased by nearly 300% between 1977 and 1996.
 - Fast-food consumption is a significant risk factor for obesity.

- Obesity correlates with the number of hours of television viewing.
 - After-school time is a particularly vulnerable time for children in terms of television exposure.
 - Food advertising may play a role in increases in high-energy food consumption.
- Inactivity has been associated with obesity.
 - In a review of obesity prevention trials moderate to vigorous physical activity was significantly correlated with obesity prevention in children.

GOALS

- Calculation of BMI and classification of weight status at least once a year is an essential component of well child care.
- Pediatricians must be prepared to:
 - Prevent, identify, and treat obesity
 - Treat obesity-related comorbidities
 - Deal with obesity-related emergencies that occur in obese children
 - Hyperosmolar hyperglycemia
 - Pseudotumor cerebri
 - Pulmonary emboli
 - Cardiomyopathy

GENERAL APPROACH

- Early infant weight gain is independently associated with being overweight in childhood.
 - Infants who gain excess weight in the first 4 months of life are likely to be overweight at the age of 7 years.
 - Weight increase between birth and 12 months of age as a ratio of birth weight is independently associated with becoming overweight at 6 years of age.
 - This early weight gain combined with protein intake at 9–12 months of age was able to explain 50% of the variance in boys' BMIs at 6 years.
- Prolonged breastfeeding has been associated with a reduced risk of becoming overweight.
 - In an evidence-based review of breastfeeding studies, breastfeeding was associated with reduction in:
 - Risk of obesity and type 2 diabetes in the children
 - Risk of type 2 diabetes in mothers

Age-appropriate obesity prevention guide

- Age: newborn or infant
 - Nutrition information
 - Promote breastfeeding
 - Teach parents to recognize hunger and satiety cues.
 - Assess family's eating habits and nutrition environment.
 - Limit juice.

- Appropriate activities
 - Encourage face-to-face play time to lay groundwork for shared activity.
 - Take daily walk in stroller to establish outdoor time.
 - Use safe toys.
 - Limit television viewing.

■ Age: toddler

- Nutrition information
 - Remind parents of appropriate portion sizes.
 - “Parents provide (correct portions), child decides (what to eat)”
 - Encourage structured meals and snack time with family.
 - Model desired eating behavior.
 - Address picky eating, food refusal, and grazing if problematic.
 - Discuss safe eating to prevent choking.
 - No sugar-sweetened beverages.
- Appropriate activities
 - Encourage free play in safe indoor and outdoor environment.
 - Spare use of strollers.
 - Limit television and computer time.
 - No television or computer in the bedroom.
 - Review age-appropriate motor skill development.

■ Age: preschool

- Nutrition information
 - Parents, not children, should be deciding on food choices.
 - Limit eating out.
 - Review growth charts, with goal of keeping on the chart.
 - Help parents identify and assess all the different nutritional environments in their child's day (ie, child care, school, extended family, friends).
 - No sugar-sweetened beverages.
 - Be aware of food marketing that targets children.
 - Help parents maintain structured meals and snacks.
 - Help parents address child's behavior around demands for food if a problem.
- Appropriate activities
 - Encourage free play.
 - Encourage outdoor play.
 - Encourage participation, not competition.
 - No more than 2 hr/day television or computer time.
 - Encourage family time that is physically active.

- Age: school age

- Nutrition information
 - Check nutritional choices at school, after-school care, extra-curricular activities; may need to pack food from home.
 - Advocate for change if necessary.
 - Address weekend, vacation, and summer nutritional challenges.
 - Minimize junk food.
 - No sugared beverages.
 - Nutrition decisions are health decisions.
 - Do not bring food into the house that you do not want your child to eat.
 - Monitor after-school eating.
- Appropriate activities
 - Balance free play and entry-level sport participation (fundamental skill development with minimal competition and flexible rules).
 - Focus on fun activities.
 - Limit television and computer time.
 - No television or computer in bedroom.
 - Do not mix television watching and eating.
 - Help child find other indoor activity options.

- Age: early adolescent

- Nutrition information
 - Encourage family meals.
 - Discuss the importance of breakfast (breakfast skipping is common at this age).
 - Help child and family with healthy after-school snack.
 - Help child make decisions around social eating.
 - No sugar-sweetened beverages.
- Appropriate activities
 - Help schedule physical activity around homework and social demands.
 - Encourage extracurricular activities to avoid sedentary time after school.
 - Limit television and computer time.
 - Social-skill building, if needed, can help encourage participation in peer activities.

- Age: middle adolescent

- Nutrition information
 - Review growth chart with adolescent.
 - Help teen self-assessment eating and nutritional choices.
 - Encourage breakfast.
 - Discourage meal skipping.
 - Discuss social eating, healthy choices.
 - Limit fast food.
 - No sugared beverages.

- Appropriate activities
 - Find ways to help teen keep participating in physical activity.
 - Encourage lifestyle activities.
 - Limit television and computer time; find alternatives such as volunteering, hobbies, clubs.

- Age: late adolescent and young adult

- Nutrition information
 - Encourage self-monitoring.
 - Discuss structure and time management of meals, activity, and sleep.
 - Go over health priorities.
 - Provide nutrition information on fast food.
 - Screen for binge eating.
- Appropriate activities
 - Maintain activity of daily living.
 - Limit television and computer time.
 - Encourage lifestyle sports and activities.
 - Take advantage of community and school recreation facilities.

Relying on families

- Obesity prevention and treatment are family based.

- Children's eating habits and preferences can be predicted by their mothers' behaviors.
- Maternal preferences predict child preferences for milk type and amount, which predicts the intake of calcium and cholesterol in the child's diet.
- Early parental behavior influences a child's eating behavior through at least 5 mechanisms:
 - Availability and accessibility of foods
 - Meal structure
 - Adult food modeling
 - Food socialization practices
 - Food-related parenting styles

- Parental modeling appears to be consistently correlated with child eating behaviors and attitudes.

- Attempts by parents to control what children eat or to use food to control other behaviors often is not effective and may have the opposite effect from that which is desired.
- The authoritative parenting style that sets limits in a supportive rather than punitive way has been linked with improved health outcomes and preventing obesity.

- Engaging parents and families to partner in obesity prevention and treatment is a core skill for pediatricians.

- Techniques such as motivational interviewing show promise as feasible office-based interventions.

SPECIFIC INTERVENTIONS

Assessment

- The most current methods for preventing childhood obesity, recommended by an expert panel and endorsed by the AAP, are as follows:
- All children should have BMI measured and weight status classified at least yearly.
 - Children with a BMI in the 99th percentile should be identified for additional study.
- At each well-child visit for all children:
 - Measure height and weight.
 - Calculate and classify BMI.
 - Assess self-efficacy readiness to change lifestyle behaviors.
 - Assess diet, including attention to the following behaviors that may be targets for change:
 - Frequency of eating outside the home
 - Excessive consumption of sweetened beverages, including juice
 - Consumption of excess portion sizes
 - Frequency of breakfast
 - Excessive snack-food consumption
 - Low fruit and vegetable consumption
 - Meal frequency and snack patterns and portions
 - Assess activity, including the following:
 - Environmental support and barriers to physical activity
 - Whether child is meeting a recommendation of 60 minutes of moderate exercise every day
 - Level of sedentary behavior, including whether television and computer time is <2 hours a day in children older than 2 years as recommended
 - Take a focused family history for obesity, type 2 diabetes, and cardiovascular disease, including hypertension and early deaths from cardiovascular disease or stroke.
 - Assess risk for current or future obesity-related comorbidities.
 - Perform a complete physical examination that includes pulse and blood pressure, as well as signs of obesity-related comorbidities.
 - Order the following laboratory tests:
 - BMI in 85th–94th percentile with no risk factors
 - Lipid profile
 - BMI in 85th–94th percentile with risk factors for obesity-related conditions
 - Aspartate aminotransferase
 - Alanine aminotransferase
 - Fasting glucose

- BMI >95th percentile
 - Fasting lipid profile
 - Aspartate aminotransferase
 - Alanine aminotransferase
 - Fasting glucose
 - Blood urea and nitrogen with creatinine

Prevention of obesity

- For children ages 2–18 years with a BMI >5th percentile and <84th percentile, counsel as follows:
 - Diet
 - Limit sugar-sweetened beverages.
 - Encourage recommended fruits and vegetables.
 - Activity
 - Limit television and computer time to 1–2 hours per day.
 - Allow no television or computer in bedroom.
 - Engage in moderate physical activity daily.
 - Behavior
 - Eat breakfast daily.
 - Limit eating out.
 - Encourage family meals.
 - Limit portion sizes.
- Actively engage families with parental obesity or maternal diabetes
 - Child is at increased risk of developing obesity.
- Encourage authoritative parenting style.
 - Discourage *restrictive* parenting style.
- Encourage parents to model:
 - Healthy diets and portion sizes
 - Physical activity
 - Limited television time
- Encourage a diet rich in calcium, high in fiber, and balanced macronutrients.
- Limit consumption of energy-dense foods.
- Ask parents and children about physical activity at school and child care.

Treatment of obesity

- For children who have a BMI >85th percentile, treatment consists of 4 stages, depending on the status of the child.
- Stage 1: Prevention Plus
 - Goal: weight maintenance
 - Monthly follow-up appointments
 - Nutrition
 - ≥5 servings of fruits and vegetables per day
 - Maximum of 2 hours of television or computer time per day; no television in the bedroom

- 1 hour or more of physical activity daily
- No sugar-sweetened beverages
- Behavior
 - Eat breakfast daily.
 - Limit eating out.
 - Eat family meals 5–6 days a week.
 - Allow children to self-regulate eating at meals, and avoid overly restrictive behavior.
- If no improvement is seen after 3–6 months, then the physician should move to Stage 2.
- Stage 2: Structured Weight Management Protocol
 - Goal: weight maintenance that results in decreasing BMI as height increases
 - Stress the following:
 - Develop a plan for use of a low-energy, dense, balanced macronutrient diet.
 - Increase structured daily meals and snacks.
 - Supervised active play at least 60 minutes a day
 - Television and computer time <1 hour per day
 - Increased monitoring of these behaviors, encouraging parents to do so as well.
 - Weight loss is not to exceed 1 pound per month in children aged 2–11 years; 2 pounds per week in children older than 11 years.
 - If no improvement in BMI or weight after 3–6 months, move to Stage 3.
- Stage 3
 - Multidisciplinary intervention by an obesity care team
- Stage 4
 - Tertiary care intervention
- Screening and treatment of comorbidities**
- Type 2 diabetes
 - History
 - Maternal diabetes during pregnancy
 - Small for gestational age
 - Intrauterine growth restriction
 - Family history of diabetes
 - Review of systems
 - Polyuria
 - Polydipsia
 - Nocturia
 - Recurrent vaginal, bladder, or other infections
 - Recent weight loss
 - Physical examination
 - Acanthosis nigricans
- Laboratory assessment
 - Elevated fasting glucose
 - Glycosuria
 - Positive glucose tolerance test
 - Hyperinsulinemia
- Nonalcoholic steatohepatitis
 - History
 - No specific history; some cases have other family members affected
 - Review of systems
 - Possible nausea and right upper quadrant discomfort
 - Physical examination
 - Hepatomegaly
 - Laboratory and imaging assessments
 - Elevated serum aminotransferases
 - Echogenicity of liver on ultrasound
 - Treatment
 - Referral to pediatric gastroenterologist for evaluation and definitive diagnosis
 - Weight loss
- Hypertension
 - History
 - Family history of hypertension or other obesity-related comorbidity
 - Review of systems
 - Usually asymptomatic
 - Physical examination
 - Elevated systolic or diastolic blood pressure
 - Laboratory assessments
 - Evaluation for other causes of hypertension as indicated
 - Treatment
 - Referral to pediatric hypertension specialist
 - Dietary treatment
 - Pharmacologic treatment
- Dyslipidemia
 - History
 - Family history of lipid disorders
 - Cardiovascular disease
 - Review of systems
 - Asymptomatic
 - Other obesity comorbidities, particularly signs of metabolic syndrome
 - Physical examination
 - No specific signs
 - Acanthosis nigricans may indicate metabolic syndrome

- Laboratory assessment
 - Lipid panel
- Treatment
 - Referral to lipid specialist
 - Dietary management
- Sleep apnea
 - History
 - Family history of sleep apnea
 - Review of systems
 - Snoring
 - Snoring with apnea
 - Daytime tiredness
 - Napping
 - Poor concentration in school
 - Enuresis
 - Physical examination
 - Large tonsils or adenoids
 - Imaging assessment
 - Nighttime polysomnography
 - Treatment
 - Referral to pediatric pulmonologist
 - Weight loss
- Slipped capital femoral epiphysis
 - History
 - Knee or hip pain
 - Review of systems
 - Knee or hip pain
 - Limp
 - Physical examination
 - Limp
 - Knee or hip pain
 - Imaging
 - Hip and knee films
 - Treatment
 - Immediate referral to pediatric orthopedist
- Blount disease
 - History
 - Bowing of legs
 - Review of systems
 - Bowing (tibia vera)
 - Knee pain
 - Limp
 - Physical examination
 - Bowed legs
 - Knee pain
 - Limp
 - Imaging
 - Knee films
 - Treatment
 - Referral to pediatric orthopedist
- Depression
 - History
 - Family history of depression
 - History of abuse
 - Psychological trauma
 - Teasing
 - Low self-esteem
 - Review of systems
 - Loss of interest
 - Anger
 - Irritability
 - Sadness
 - Suicidal ideation
 - Physical examination
 - No signs
 - May have sad, irritable appearance with lack of self-care
 - Laboratory or imaging assessments
 - None
 - Treatment
 - Mental health referral for counseling or pharmacologic treatment

Prevention of Smoking

BACKGROUND

- Cigarette smoking is the leading cause of premature death in the US.
- It is categorized as a pediatric disease because it generally starts before adulthood.
- Passive smoking may be the major preventable cause of death in infants and young children.
- The evidence that passive smoking is a cause of death, disease, and disability is extensive.
 - Absorption of tobacco smoke by children is a function of the number of cigarettes smoked around the child and the proximity of the smokers.
 - A dose–response relationship has been noted between exposure and health effects.
 - Passive smoking increases the risk in children for:
 - Respiratory disease, ranging from the common cold to pneumonia and cystic fibrosis exacerbations
 - Acute and chronic otitis media
 - Difficulty with breastfeeding
 - Atopic eczema and skin infections
 - Meningitis
 - Birth defects
 - Decrease in linear growth of 1–2 cm
 - Cataracts
 - Colic
 - Febrile seizures
 - Dental caries
 - Parental smoking increases the risk that a child will become an adult active smoker.

GOALS

- National health priorities include reducing:
 - Smoking prevalence
 - Youth smoking
 - Childhood exposure to passive smoke
- Because of their regular contact with young children and "their families, pediatricians and family physicians have a unique opportunity to intervene against both active and passive smoking.
 - Pediatricians must energetically support public health efforts to promote a tobacco-free environment for all children.
 - Pediatricians and family physicians are the only health care professionals who routinely come into contact with nonsmokers who are at high risk of becoming smokers (ie, preadolescents).
 - They may also be the only medical professionals in routine contact with parents of young children, given that young men and women may have few physician visits for check-ups.

GENERAL APPROACH

- Despite considerable effort, attempts to promote smoking cessation in the pediatric office setting have not been shown to be effective or practical.
- Although bupropion and nicotine-replacement therapy (gum, patch, lozenge, spray) increase quit rates with motivated adult quitters, pharmacotherapy for adolescent smokers has not demonstrated effectiveness overall.
- Reasons for unsuccessful interventions include:
 - Incomplete interventions, lacking either sufficient pharmacotherapy or the right type of counseling
 - Pediatricians' lack of formal training in cessation counseling and discomfort with the process
 - Lack of reimbursement for cessation in the pediatric setting
 - Complexities that arise when the pediatrician recommends over-the-counter pharmaceuticals for a parent rather than the patient (even though the patient is suffering from passive smoking)
- Future clinical efforts should involve:
 - Focus on motivated quitters
 - Availability of cessation experts
 - Reimbursement from medical insurance for comprehensive nicotine addiction treatment
 - Brief motivational counseling that addresses individual psychosocial barriers to successful abstinence
 - Pharmacotherapy (eg, nicotine replacement therapy for the physiological effects of nicotine withdrawal)

SPECIFIC INTERVENTIONS

Clinical interventions

- Ask about smoking.
 - Use a nonaccusatory manner.
 - Communicate that smoking is addictive and harms both the smoker and those around the smoker.
 - Indicate that help is being offered to stop the habit.
- Make informational brochures and smoking cessation programs available.
- Consider nicotine replacement therapy.
- Congratulate nonsmokers (including quitters).
- Record smoking status routinely.
- Notice red flags.
 - Visits for recurrent otitis or hospitalizations for asthma (effects of passive smoking)
 - Preteens who are poor
 - White girls with relatives or friends who smoke
 - Focusing on preadolescent girls for prevention may be the best place to break the cycle of active and passive smoking.

- Suggest steps for smoking parents who are unwilling or unable to quit:
 - Reduce exposure to passive smoking.
 - Forbid smoking inside the home.
 - If these options are not possible, smoke as far away from the child as possible.
- Refer interested parents or teens to a qualified cessation expert or a quit line.

Population-level interventions

- Interventions to increase the unit price for tobacco products
 - Reduce the number of people who start using tobacco
 - Increase the number who quit

- Mass media campaigns
 - Reduce initiation of tobacco use when combined with other actions (eg, increasing the excise tax)
 - May decrease consumption of tobacco products and increase tobacco use cessation
- Providing counseling and support to patients by telephone (as part of a multicomponent cessation strategy)
 - Increases the number of adult smokers who succeed
- Pediatricians can help with community-level efforts by connecting with their local tobacco-control coalitions.

Preventive Cardiology

BACKGROUND

Risk factors for heart disease and atherosclerosis

- Multiple factors should be considered when assessing a child's global risk for premature cardiovascular disease.
 - For more on general aspects of screening, see Hypertension, Heart Failure, and Congenital and Acquired Heart Disease.
- This topic addresses 3 items that should be a part of routine pediatric preventive cardiology assessment for all children and adolescents.
 - Atherosclerosis
 - Obesity
 - Smoking
- Epidemiologic evidence indicates that atherosclerosis is not an inevitable consequence of aging.
 - Rather, it is an acquired disease with well-described risk factors.
 - Evidence of emerging risk factors in children
- Atherosclerosis continues to be a leading cause of death and disability in the US.
- The known risk factors for atherosclerosis include:
 - Hypertension
 - Smoking
 - Elevated low-density lipoprotein cholesterol (LDL-C) level
 - Decreased high-density lipoprotein cholesterol (HDL-C) level
 - Diabetes mellitus
 - Advancing age
 - Male sex
 - A family history of premature heart disease
 - Hypertriglyceridemia
 - Sedentary lifestyle
 - Obesity

Hypercholesterolemia

- Hypercholesterolemia is a primary target in the prevention of atherosclerosis.
- Total cholesterol measures the cholesterol contained in several lipid particles, including:
 - LDL-C, one of the atherogenic lipoproteins; the focus of screening algorithms
 - HDL-C, considered protective against the development of coronary heart disease
 - VLDL-C, very-low-density lipoprotein cholesterol
- Both genetic and environmental factors play a role in the development of hypercholesterolemia.
 - Plasma cholesterol levels are influenced by the quantity and quality of dietary fat intake and the individual's ability to synthesize and degrade cholesterol.

- Severe or familial hypercholesterolemia secondary to a defect in the LDL receptor occurs in approximately 1 in 500 individuals.
- Children with this defect commonly have LDL-C values between 200 and 300 mg/dL.
 - This is 2–3 times higher than the acceptable limits of normal.
 - These children inherit the receptor defect and have a strong predilection for atherosclerotic heart disease as young adults.
- >600 different mutations of the LDL receptor have been described.
 - Approximately 50% of men with 1 of these mutations will have myocardial infarction by age 50 years.
 - Between 75% and 85% will have myocardial infarction by age 60 years.
- Causes of secondary hypercholesterolemia
 - Exogenous
 - Drugs
 - Corticosteroids
 - Isotretinoin (Accutane)
 - Thiazides
 - Anticonvulsants
 - β -Blockers
 - Anabolic steroids
 - Certain oral contraceptives
 - Alcohol
 - Obesity
 - Endocrine and metabolic
 - Hypothyroidism
 - Diabetes mellitus
 - Lipodystrophy
 - Pregnancy
 - Idiopathic hypercalcemia
 - Storage diseases
 - Glycogen storage diseases
 - Sphingolipidoses
 - Obstructive liver diseases
 - Biliary atresia
 - Biliary cirrhosis
 - Alagille syndrome
 - Chronic renal diseases
 - Nephrotic syndrome
 - Others
 - Anorexia nervosa
 - Progeria
 - Collagen disease
 - Klinefelter syndrome

Obesity and physical activity

- Obesity increases the risk for heart disease through its association with abnormalities, such as:
 - Dyslipidemia
 - Hypertension
 - Insulin resistance
 - Glucose intolerance
 - There may be other undefined mechanisms.
- The magnitude of the effect of childhood obesity on cardiac risk is not precisely known.
 - The US Preventive Services Task Force concluded that evidence was insufficient to recommend for or against screening of overweight children and adolescents.
 - Body mass index (BMI) and the thickness of the subcutaneous fat as measured by a skin-fold test are correlated with the degree of coronary atherosclerosis in young adults.
- Adiposity in childhood is strongly associated with adiposity in adulthood.
- BMI is considered an appropriate measure of obesity.

Smoking

- The evidence that cigarette smoking is a risk factor for cardiovascular disease is overwhelming.
- Studies as early as 1940 documented a relationship between tobacco use and coronary artery disease.
- Tobacco use adversely affects lipid levels and is associated with:
 - Decreased exercise capacity
 - Increased platelet aggregation
 - Increased incidence of respiratory illness
 - Increased incidence of low-birth-weight deliveries
 - Increased infant mortality
- Passive smoking is linked with changes in risk factors for coronary artery disease in children.
 - Associated with reduced HDL-C in nonsmoking children, as well as those with high-risk lipid profiles
 - In 2006 the US Surgeon General issued an update on findings and recommendations to eliminate secondhand or passive smoke exposure for children.
- Adolescents are more likely than any other age group to smoke or use tobacco.
 - In 2002 the National Youth Tobacco Survey estimated that:
 - 13% of middle school students were current users of tobacco products.
 - 28% of high school students used tobacco.
 - In 2003 the National Youth Risk Behavior Survey showed a decline in reported current tobacco use among high school students.
 - The estimate was still 22%.
- The risk of smoking initiation increases from ages 12–16 years.
 - Most initiate and become addicted during this critical period.
 - Addiction can occur after smoking as few as 100 cigarettes.
 - Most youth do not become nicotine dependent until after 2–3 years of smoking.
- Children whose parents or siblings smoke are at an increased risk of beginning to smoke.
- Other factors that may predict smoking include:
 - Peer influence
 - Less-educated parents
 - Independence and rebelliousness
 - Decreased concerns about the health risks associated with smoking
- Identifying these factors and addressing them openly is helpful in counseling.

GOALS

- Identify and treat potential atherosclerotic cardiac risk factors in children.
- Providers can educate children and families on preventive strategies.
- A goal of primary care is to prevent disease and to prevent the development of risk factors in children.
 - The long-term hope is that early interventions will ultimately decrease the burden of atherosclerotic heart disease in adult life.
- The relatively new concept of primordial prevention challenges health care providers to work to prevent risk factors.
 - Address the social and environmental factors that maintain them.
 - It is particularly important to address:
 - Obesity
 - Smoking
 - Sedentary lifestyle

GENERAL APPROACH

Guidelines

- Optimal methods of heart disease prevention have generated controversy on such fundamental issues as:
 - What age to begin screening
 - Who should be screened
 - How to treat individuals with elevated cholesterol levels
- The most recent report by the US Preventive Services Task Force found good evidence that children with dyslipidemia become adults with dyslipidemia.

- The study concluded that the evidence was insufficient to recommend for or against screening of lipid disorders in children and adolescents.
- The pediatric National Cholesterol Education Program (NCEP) guidelines will undoubtedly be revised, as have the adult guidelines.
- A revision by the AAP in 2008 has suggested lowering the treatment age to 8 years and adding 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase inhibitors, specifically pravastatin, to the arsenal of medications.
 - This change has not been endorsed by the NCEP or American Heart Association (AHA).
 - Controversy surrounds the lack of long-term data and potential impact of 40–50 years of exposure.
- For now, pediatricians should use the basic strategy proposed by the NCEP and endorsed by the AAP and AHA.

Risk factors and screening

- Although many risk factors for heart disease remain beyond the control of the individual, some can be modified.
 - Hyperlipidemia
 - Level of physical activity
- At least 1 factor—smoking—is completely avoidable.
- Several risk factors for coronary heart disease are now easily identified during childhood.
- The process of atherosclerosis and the habits that influence the risk of heart disease begin early in life.
- Scientifically based recommendations to begin prevention in childhood have been developed.
- Schedule for integrated cardiovascular health promotion in children
 - Age 0–2 years
 - Family history
 - Early heart disease (age ≤ 55 years)
 - Cholesterol
 - Parent's total cholesterol ≥ 240 mg/dL
 - Obesity
 - Plot height and weight on growth charts.
 - Parental obesity present
 - Blood pressure (BP)
 - Family history of hypertension
 - Diet
 - Diet history
 - Early foods influence future food preferences.
 - Physical activity
 - Parent physical activity
 - Discourage television and video viewing.

- Smoking
 - Parental or household smoking?
 - If yes, counsel to quit and refer to smoking cessation.
- Age 2–6 years
 - Family history
 - Update family history
 - Early heart disease (age ≤ 55 years)
 - Parent's total cholesterol ≥ 240 mg/dL
 - Cholesterol
 - Fasting lipids screening
 - Total cholesterol screening
 - Obesity
 - Plot height, weight, and BMI (kg/m^2) on growth charts
 - BMI percentiles
 - BP
 - Start routine BP measurement at 3 years of age (determine if >90 th or 95th percentile for sex, age, and height).
 - Diet
 - Diet history
 - Low-saturated-fat diet including 1% or nonfat milk
 - Moderate salt intake
 - Physical activity
 - Encourage active child-parent play.
 - Limit sedentary behaviors, such as television and video viewing.
 - Smoking
 - Parental or household smoking?
 - If yes, counsel to quit and refer to smoking cessation.
 - Antismoking counseling
 - Includes immediate physical, social, and physiological effects of smoking, risk of addiction, counter-arguing techniques, and resisting social and environmental pressures to smoke.
- Age 6–10 years
 - Family history
 - Update family history
 - Early heart disease (age ≤ 55 years)
 - Parent's total cholesterol ≥ 240 mg/dL
 - Cholesterol
 - Fasting lipids screening
 - Total cholesterol screening
 - Obesity
 - Plot height, weight and BMI (kg/m^2) on growth charts
 - BMI percentiles

- BP
 - BP measurement
 - BP percentiles
- Diet
 - Diet history
 - Low-saturated-fat diet including 1% or nonfat milk
 - Moderate salt intake
- Physical activity
 - Physical activity history
 - Lifestyle and family activities
 - Limit sedentary behaviors, such as television and video viewing.
- Smoking
 - Parental/household smoking?
 - If yes, counsel to quit; referral to smoking cessation.
 - Antismoking counseling
 - Includes immediate physical, social, and physiological effects of smoking, risk of addiction, counter-arguing techniques, and resisting social and environmental pressures to smoke.
- Age >10 years
 - Family history
 - Update family history
 - Early heart disease (age ≤55 years)
 - Parent's total cholesterol ≥240 mg/dL
 - Cholesterol
 - Fasting lipids screening
 - Total cholesterol screening
 - Obesity
 - Plot height, weight and BMI (kg/m²) on growth charts
 - BMI percentiles
 - BP
 - BP measurement
 - BP percentiles
 - Diet
 - Diet history
 - Low-saturated-fat diet including 1% or nonfat milk
 - Moderate salt intake
 - Physical activity
 - Physical activity history
 - Lifestyle and family activities
 - Daily moderate to vigorous activity
 - Limit sedentary behaviors
 - Smoking
 - Parental or household smoking?
 - Assess child smoking.
 - If yes for either, counsel to quit and refer to smoking cessation
 - Antismoking counseling
 - Includes immediate physical, social, and physiological effects of smoking, risk of addiction, counter-arguing techniques, and resisting social and environmental pressures to smoke.
 - The risks of smoking should be a part of routine preventive care discussions.

SPECIFIC INTERVENTIONS

NCEP recommendations

- The NCEP suggests 2 separate approaches to managing hypercholesterolemia in children.
 - A broad, population-based approach
 - An individualized patient approach
- Universal screening of all children is not recommended.

Population-based approach

- The panel suggests that all children >2 years follow the Step 1 diet.
 - No more than 30% of total calories should come from fat.
 - <10% of total calories should come from saturated fat.
 - Total cholesterol consumption should be <300 mg per day.
 - The diet should contain a variety of foods.
 - Diet should be adequate to support growth and maintain an ideal body weight for height and age.
- Characteristics of the AHA Step 1 and Step 2 diets
 - Calories: Step 1 + 2: Adequate for normal growth
 - Total fat: Step 1 + 2: ≤30% of calories
 - Saturated fat
 - Step 1: <10% of calories
 - Step 2: ≤7%
 - Polyunsaturated fat: Step 1 + 2: Up to 10% of calories
 - Monounsaturated fat: Step 1 + 2: Remainder of fat calories
 - Carbohydrates: Step 1 + 2: Approximately 55% of calories
 - Protein: Step 1 + 2: Approximately 15–20% of calories
 - Cholesterol
 - Step 1: <300 mg/dL
 - Step 2: <200 mg/dL

Individualized screening

- In addition to the population-wide diet recommendations, the NCEP guidelines suggest:
 - Assessing risk and performing cholesterol testing in children:
 - >2 years of age with a positive family history
 - Who have a parent with hypercholesterolemia (total cholesterol ≥240 mg/dL)

- Whose parent or grandparent has or had premature coronary heart disease, ie, onset of disease at <56 years
- Conditions that suggest heart disease include:
 - A history of documented myocardial infarction
 - Angina pectoris
 - Peripheral vascular disease
 - Cerebrovascular disease
 - Sudden cardiac death
 - Coronary atherosclerosis as determined by angiography
 - A history of balloon angioplasty or coronary artery bypass graft surgery
- Children whose parental history is unknown or unobtainable may be screened to identify those in need of nutritional advice, especially if they have other risk factors.
- Parents with unknown cholesterol levels should be encouraged to obtain a full lipoprotein analysis.
- Cholesterol levels may need to be determined for children at higher risk for coronary heart disease independent of family history.
 - Those who smoke
 - Those who are obese
 - Those with diets rich in saturated fats and cholesterol
 - Those with diabetes mellitus
- For children with a family history of premature heart disease, guidelines suggest obtaining a fasting lipid profile that includes:
 - Total cholesterol
 - LDL-C
 - HDL-C
 - Triglycerides
- Initial screening for children with a family history of hypercholesterolemia and no history of early heart disease should be done by measuring total cholesterol only.

Risk stratification and treatment

- The AHA and AAP recently proposed a risk stratification and treatment algorithm for children at increased risk for premature coronary heart disease.
- Children identified as needing special consideration for more careful attention to cardiovascular risk factors:
 - Homozygous or heterozygous familial hypercholesterolemia
 - Diabetes mellitus (type 1 or 2)
 - Chronic kidney disease or end-stage renal disease
 - Kawasaki disease
 - Congenital heart disease
 - Chronic inflammatory disease
 - Post-cardiac transplantation
 - Cancer treatment survivors

High-risk stratification

- Tier I: High risk
 - Rationale: Exhibit coronary artery disease at <30 years of age: clinical or pathologic evidence
 - Disease process or condition
 - Homozygous familial hypercholesterolemia
 - Diabetes mellitus, type 1
 - Chronic kidney disease or end-stage renal disease
 - Postorthotopic heart transplantation
 - Kawasaki disease with current coronary aneurysms
- Tier II: Moderate risk
 - Rationale: Accelerated atherosclerosis: pathophysiologic evidence
 - Disease process or condition
 - Heterozygous familial hypercholesterolemia
 - Kawasaki disease with regressed coronary aneurysms
 - Diabetes mellitus, type 2
 - Chronic inflammatory disease
- Tier III: At risk
 - Rationale: High-risk setting for accelerated atherosclerosis: epidemiologic evidence
 - Disease process or condition
 - Cancer treatment survivors
 - Congenital heart disease
 - Kawasaki disease without detected coronary aneurysms

Algorithm for screening, with tier-specific test value cutoffs

- High-risk pediatric populations
 - Step 1: Risk stratification by disease process
 - Step 2: Assess all cardiovascular risk factors.
 - If ≥ 2 comorbidities exist, assign the patient to the next higher risk tier for subsequent management.
 - Step 3: Define tier-specific intervention cut points or treatment goals.
 - Step 4: Initial therapy
 - Tier I: Initial management is therapeutic lifestyle change plus disease-specific management.
 - Tiers II and III: Initial management is therapeutic lifestyle change.
 - Step 5
 - Tiers II and III: If goals are not met after initial management, consider medication.

Tiers I, II, and III treatment recommendations

- Growth and diet
 - Nutritionist evaluation and diet education for all; see Step 1 diet recommendations

- Calculate BMI percentile for sex and height.
 - Step 1, if initial BMI >95th percentile
 - Age-appropriate reduced-calorie training for child and family
 - Specific diet and weight follow-up every 2–4 weeks for 6 months; repeat BMI calculation at 6 months
 - Activity counseling
 - Step 2, if follow-up BMI is:
 - >85th percentile for tier I *or*
 - >90th percentile for tier II *or*
 - >95th percentile for tier III
 - Weight-loss program referral plus exercise training program appropriate for cardiac status
- BP (tiers I, II, and III)
 - BP measurement or interpretation for age, sex, and height
 - Step 1, if systolic BP or diastolic BP is:
 - Equal to the 90th to 95th percentile *or*
 - >120/80 mmHg on 3 separate occasions within 1 month
 - Recommend decreased calorie intake, increased activity for 6 months
 - Step 2, if initial systolic BP or diastolic BP is:
 - >95th percentile (confirmed within 1 week) *or*
 - 6-month follow-up systolic BP or diastolic BP is >the 95th percentile
 - Initiate pharmacologic therapy per Fourth Task Force recommendations.
- Lipids
 - Step 1, if initial LDL-C level \geq 130 mg/dL (tier II) or >160 mg/dL (tier III)
 - Nutritionist training for Step 2 diet along with avoidance of trans fats for 6 months
 - Step 2, if repeat LDL-C level \geq 130 mg/dL in tier II or >160 mg/dL in tier III and the child is 10 years of age
 - Initiate statin therapy with LDL-C goal of 130 mg/dL.
- Triglycerides
 - Step 1, if initial triglyceride level >150 to 400 mg/dL
 - Nutritionist training for low simple carbohydrate, low-fat diet
 - If elevated triglycerides are associated with excess weight, refer to a nutritionist for weight loss management: energy balance training plus activity recommendations.
 - Step 2, if triglyceride level >700 to 1000 mg/dL, initial or follow-up
 - Consider fibrate or niacin if the child is >10 years of age.
 - Weight loss is recommended when triglyceride elevation is associated with overweight or obesity.
- Glucose (tiers I, II, and III, except for patients with diabetes mellitus)
 - Step 1, if fasting glucose level is 100–126 mg/dL
 - Recommend a reduced-calorie diet and increased activity aimed at 5–10% decrease in weight over 6 months.
 - Step 2, if repeat fasting glucose level is 100–126 mg/dL
 - Recommend insulin-sensitizing medication as per an endocrinologist.
 - If the casual glucose is >200 mg/dL or fasting glucose level is >126 mg/dL, diabetes mellitus can be diagnosed.
 - Endocrine referral for evaluation and management
 - Maintain hemoglobin A_{1C} at <7%.
- Smoking (tiers I, II, and III)
 - Step 1: Obtain parental smoking history at every visit and child smoking history beginning at age 10 years. Provide active antismoking counseling for all; a smoke-free home is strongly recommended at each encounter.
 - Step 2: Provide smoking cessation referral for any history of cigarette smoking.
- Activity (tiers I, II, and III)
 - For children in all tiers, participation in activity is at the discretion of the physician.
 - For specific cardiac diagnoses, such as Kawasaki disease and congenital heart disease, activity guidelines are referenced.
 - Step 1: Obtain specific activity history for each child, focusing on time spent in active play and screen time (television + computer + video games).
 - \geq 1 hour of active play per day
 - Screen time limited to <2 hours per day
 - Encourage activity at every encounter.
 - Step 2: After 6 months, if goals are not met, consider referral for exercise testing and recommendations from an exercise specialist.

Tier I specific treatment recommendations

- Rigorous age-appropriate education in diet, activity, and smoking cessation for all
 - Specific therapy as needed to achieve BP, LDL-C, glucose, and HbA_{1C} goals as indicated for each tier, as outlined in the algorithm (see Figure 71 on page F25)
 - Timing should be individualized for each patient and diagnosis.
 - Homozygous familial hypercholesterolemia
 - LDL management: scheduled apheresis every 1–2 weeks beginning at diagnosis to maximally lower LDL-C, plus statin and cholesterol absorption inhibitor
 - Treatment per cardiologist or lipid specialist; specific therapeutic goals for LDL-C are not meaningful with this diagnosis.

- Assess BMI, BP, and fasting glucose: Step 1 management for 6 months
- If tier I goals are not achieved, proceed to Step 2.
- Diabetes mellitus, type 1
 - Intensive glucose management per an endocrinologist, with frequent glucose monitoring or insulin titration to maintain plasma glucose level <200 mg/dL and HbA_{1C} <7%
 - Assess BMI and fasting lipids: Step 1 management of weight, lipids for 6 months
 - If goals are not achieved, proceed to Step 2; statin therapy if >10 years of age to achieve tier I treatment goals
 - Initial BP above the 90th percentile: Step 1 management plus no added salt, increased activity for 6 months
 - BP consistently above the 95th percentile for age, sex, and height: Initiate angiotensin-converting enzyme inhibitor therapy with BP goal to be <90th percentile or <130/80 mm Hg, whichever is lower.
- Chronic kidney disease or end-stage renal disease
 - Optimization of renal failure management with dialysis or transplantation as per nephrologist
 - Assess BMI, BP, lipids, fasting glucose: Step 1 management for 6 months
 - If goals are not achieved, proceed to Step 2; statin treatment if >10 years of age to achieve tier I treatment goals.
- After heart transplantation
 - Optimization of antirejection therapy, treatment for cytomegalovirus, routine evaluation by angiography or perfusion imaging per transplant physician
 - Assess BMI, BP, lipids, fasting glucose: initiate Step 2 therapy, including statins, immediately in all patients >1 year of age to achieve tier I treatment goals.
- Kawasaki disease with coronary aneurysms
 - Antithrombotic therapy, activity restriction, ongoing myocardial perfusion evaluation as per cardiologist
 - Assess BMI, BP, lipids, fasting glucose: Step 1 management for 6 months
 - If goals are not achieved, proceed to Step 2; statin treatment if >10 years of age to achieve tier I treatment goals.
- Most of the information regarding the risk of heart disease in adults is based on fasting LDL-C values.
 - Recommendations in children are also based on fasting LDL-C values.
 - Treatment values are based on percentile ranks of children in the US that exceed the upper norms.
 - Values >95th percentile for children and are considered *high*.
 - Total cholesterol level >200 mg/dL and LDL-C >130 mg/dL
 - Values <75th percentile are considered *acceptable*.
 - Total cholesterol level <170 mg/dL and LDL-C <110 mg/dL
 - Values between these limits are considered *borderline*.
 - A lipid profile, including an assessment of LDL-C, should be ordered if:
 - The initial fasting total cholesterol level is high.
 - After an initial borderline value, the average of the first and second test values is >170 mg/dL.
 - The final evaluation should be based on the average of at least 2 LDL-C measurements.
 - Treatment should follow the general strategy described.
 - Individualized approach: algorithm for assessing and managing hyperlipidemia based on LDL cholesterol.
 - Acceptable (LDL-C <110 mg/dL): Repeat cholesterol testing in 5 years, and advise the family to follow the Step 1 diet.
 - Borderline (LDL-C 110–129 mg/dL): Advise the family to follow the Step 1 diet, provide advice regarding other risk factors, and reevaluate the child in 1 year.
 - High (LDL-C ≥130 mg/dL): Before recommending dietary or medical treatment, obtain a history detailing the use of drugs, such as isotretinoin (Accutane), steroids, and alcohol, to identify any secondary cause of hypercholesterolemia. In addition, screen for other secondary causes of elevated cholesterol, such as liver, thyroid, and renal disease.
 - The initial dietary treatment is to follow a Step 1 diet.
 - This diet is safe and efficacious for managing children with borderline to high LDL-C levels.
 - The child must consume adequate calories while decreasing fat intake.
 - Current dietary guidelines suggest that all children should consume enough calories to reach or maintain desirable weight.
 - Weight reduction in overweight and obese children is often helpful in correcting cholesterol profiles.
 - In contrast to adults, some children with hypercholesterolemia are not overweight.
 - In children who are not overweight, caloric restriction is not the primary treatment for hypercholesterolemia.
 - For children whose LDL-C level remains >130 mg/dL after at least 3 months of careful adherence to the Step 1 diet, the Step 2 diet is advised.
 - No more than approximately 30% of calories from total fat (similar to the Step 1 diet)
 - <7% of calories (compared with 10% in the Step 1 diet) from saturated fat

- Adherence to the Step 2 diet is often improved by having the family meet with a registered dietitian trained in managing hyperlipidemia in children.
 - For children >10 years whose LDL-C level remains >190 mg/dL after 6–12 months of dietary therapy:
 - Consider drug treatment with bile acid-binding resins.
 - Cholestyramine
 - Colestipol
 - Drug therapy should also be considered for those who maintain an LDL-C level >160 mg/dL and have a family history of premature cardiovascular disease.
 - Commercially available dietary products are available in supermarkets.
 - Special margarines with plant sterols and stanols to reduce LDL-C absorption
 - The 2005 AHA/AAP Dietary Recommendations caution against using these spreads
 - Given the possible decrease in absorption of fat-soluble vitamins and β -carotene
 - Other medications, such as HMG CoA-reductase inhibitors (or statins), are not recommended routinely for children.
 - Except in consultation with a lipid specialist
 - For children in designated high-risk groups (see above) who are nonresponsive to diet/exercise intervention
 - A revision by the AAP in 2008 suggested lowering the treatment age to 8 years and added statins, specifically pravastatin, to the arsenal of medications. This change has not been endorsed by the NCEP or AHA. Controversy surrounds the lack of long-term data and potential impact of 40–50 years of exposure.
 - The cholesterol screening and dietary treatment guidelines can be initiated safely by a primary care practitioner interested in nutrition and the prevention of heart disease.
 - Initiation includes:
 - A review of family history
 - Evaluation for secondary causes of hyperlipidemia
 - Dietary counseling
 - Identification of children with risk factors for coronary heart disease should lead to screening of other family members.
 - Many risk factors tend to cluster in families.
 - Evaluation by a lipid specialist with continued general support from the primary care pediatrician is recommended.
 - When the child has severe hypercholesterolemia that is:
 - Unresponsive to dietary treatment.
 - From a family with early onset of heart disease
- Obesity and physical activity**
- A common and reasonable approach in defining obesity in children is based on the use of age and sex percentiles of body mass index.
 - BMI = kg/m^2 , where body weight is measured in kilograms and height is measured in meters.
 - Children with a BMI >95th percentile are considered *obese*.
 - Those with a BMI between the 85th and 95th percentile are considered *overweight*.
 - The Centers for Disease Control and Prevention (CDC) in 2000 adopted different terms to avoid negative labeling of children.
 - *Risk of overweight* is used for children between the 85th and 95th percentile.
 - *Overweight* is used for those above the 95th percentile.
 - Current recommendations from the AHA and AAP suggest that:
 - Pediatricians should feel confident in assessing and charting BMI, beginning at 2 years of age.
 - Pediatricians should counsel parents to address the at-risk child's eating and activity patterns.
 - BMI can be easily calculated and charted for all children.
 - Charting materials for BMI by age and sex should be a part of every primary care pediatrician's practice.
 - Free materials from the CDC can be found online.
 - Overweight children (BMI >95th percentile) should be further screened for:
 - Hypertension
 - Orthopedic symptoms
 - Hypoventilation
 - Abnormalities of lipids and glucose metabolism
 - The magnitude of the abnormalities is an important consideration; additional specialty evaluations should be recommended in individual situations.
 - No single treatment program for overweight children has been proven to be uniformly successful.
 - A combination of diet and exercise therapy with behavioral modification and family counseling is often needed and is the first-line approach.
 - AHA pediatric dietary strategies for individuals >2 years of age.
 - Balance dietary calories with physical activity to maintain normal growth.
 - Perform 60 minutes of moderate to vigorous play or physical activity daily.
 - Eat vegetables and fruits daily; limit juice intake.
 - Use vegetable oils and soft margarines low in saturated fat and trans fatty acids instead of butter or most other animal fats in the diet.

- Eat whole-grain breads and cereals rather than refined grain products.
 - Reduce the intake of sugar-sweetened beverages and foods.
 - Use nonfat (skim) or low-fat milk and dairy products daily.
 - Eat more fish, especially oily fish, broiled or baked.
 - Reduce salt intake, including salt from processed foods.
- The importance of physical activity in preventing or ameliorating cardiac risk factors (obesity, hyperlipidemia, hypertension) has been increasingly recognized.
- In adults, higher levels of physical activity have been associated with decreased rates of heart disease, above and beyond changes in known cardiac risk factors.
- Health care professionals should encourage children to make physical activity a part of their daily routine.
- A Cochrane Review found that many diet and exercise interventions improve eating behaviors and physical activity levels, but are not effective in preventing weight gain.
 - Studies also suggest that children are more likely to be physically active if their parents are active.

Proteinuria

DEFINITION

- In adults, *proteinuria* is defined as a urinary protein excretion >150 mg/day.
- In children, *proteinuria* is defined as protein excretion >4 mg/m²/hr.
 - Finding proteinuria in a single urine specimen in children and adolescents is relatively common.
 - Persistent proteinuria is called *fixed proteinuria*.

EPIDEMIOLOGY

- Prevalence
 - Generally 5–15%
- Age
 - Incidence increases with age
 - Peaks in adolescence
 - Subsequently declines, reaching nadir in adulthood
- Sex
 - For boys, peaks at age 16
 - For girls, peaks at age 13
- Postural or orthostatic proteinuria
 - Accounts for 60% of all cases of asymptomatic proteinuria in children
 - Higher incidence in adolescents
- Transient proteinuria
 - Found in as many as 30–50% of children with proteinuria
- Persistent or fixed asymptomatic proteinuria
 - Prevalence may be as high as 6% in school-aged children.

MECHANISM

- The glomerular filtration barrier, composed of podocytes and vascular endothelium separated by the glomerular basement membrane, prevents passage of macromolecules from blood into urine:
 - Based on both molecular size and electrical charge
 - Size barrier for filtration consists of pores with diameter ~40 Å in the slit diaphragm located between foot processes
 - Approximately the size of albumin (69 kDa)
 - Glomerular capillary wall contains heparan sulfate and proteoglycans:
 - Negatively charged
 - Repel macromolecules with the same electrical charge, such as albumin
- Most inflammatory glomerular diseases lead to proteinuria by:
 - Morphologic alteration of the size barrier
 - Loss of negative charges
- Glomerular hemodynamics affect protein movement across glomerular capillary walls:
 - Glomerular plasma flow rate

- Hydrostatic forces
- Oncotic forces
- Reduction in the number of functioning nephrons leads to proteinuria:
 - Hyperfiltration in the remaining nephrons
- Low-molecular-weight proteins (<40 kDa), such as β₂-microglobulin, retinol-binding protein, and α₁-microglobulin
 - Freely filter through the glomerulus
 - Subsequently reabsorbed by the proximal tubule
 - Tubular injury results in:
 - Inability to reabsorb these proteins
 - Their loss in the urine
- Tamm-Horsfall mucoprotein (uromodulin)
 - Major constituent of urinary casts
 - Formed by the cells of the thick ascending loop of Henle

HISTORY

- First steps in evaluating a child with proteinuria
 - Thorough history
 - Physical examination, looking for indicators of renal disease
- Basic evaluation of proteinuria
 - Presence or absence of symptoms
 - Amount of protein loss
 - Presence or absence of associated findings such as
 - Hematuria
 - Hypertension
 - Azotemia
 - Other urinary or systemic abnormalities
- Warning signs of proteinuria
 - Persistent, fixed, nonorthostatic proteinuria
 - Proteinuria associated with other urinary abnormalities, such as hematuria
 - Proteinuria associated with renal insufficiency, anemia, or hypertension
 - Family history of renal disease, deafness, or autoimmune conditions
 - Proteinuria associated with comorbidities such as:
 - Prematurity
 - Congenital anomalies of other organ systems
 - Hypertension
 - Diabetes
 - Obesity
- Postural or orthostatic proteinuria
 - Children with this type usually are asymptomatic.
 - Proteinuria usually is found on a routine urinalysis.

- When upright, they may spill abnormal amounts of protein in the urine.
- When supine, they have normal urinary protein excretion.
 - After they are recumbent for a few hours (asleep overnight), proteinuria decreases to normal range or disappears.
- **Transient proteinuria**
 - Can accompany:
 - Fever
 - Exercise
 - Stress
 - Dehydration
 - Congestive heart failure
 - Seizures
 - Usually does not exceed 2+ on the dipstick test
- **Symptomatic proteinuria**
 - Patients with a combination of nephritis and nephrotic syndrome pose a clinical challenge even to the most experienced nephrologist.
 - History should include questions about:
 - Recent illnesses
 - Fever
 - Rash
 - Arthralgias
 - Change in urine output and color
 - Symptoms of chronic disease
 - Weight loss
 - Fatigue
 - Duration and severity of symptoms
 - Pay attention to
 - History of urinary tract infections
 - Family history of
 - Urinary reflux
 - Hypertension
 - Deafness

PHYSICAL EXAM

- Measurements of growth parameters
- Blood pressure
- Identification of edema, ascites, and pallor

DIFFERENTIAL DIAGNOSIS

Nonpathological proteinuria

- Results from adjustment of the kidney to extraneous physiological conditions
 - Growth
 - Exercise

- Fever
- Systemic illness
- **Level of proteinuria**
 - Generally <1 g/day
 - Not associated with edema
- **Postural or orthostatic proteinuria**
 - Cause is unknown.
 - No edema, hypertension, or hematuria
 - Normal creatinine clearance and complements
- **Transient proteinuria**
 - Proteinuria associated with vigorous exercise rarely exceeds 2+ on dipstick test.
 - Seems related to intensity rather than duration of exercise
 - May be explained by:
 - Increased glomerular filtration barrier permeability
 - Partial inhibition of tubular reabsorption of protein
 - Effect of exercise increases with age.
 - Considered benign if proteinuria resolves after 48 hours of rest

Pathological proteinuria

Persistent or fixed asymptomatic proteinuria

- **Glomerular causes**
 - Nephrotic syndrome
 - Idiopathic
 - Minimal change disease
 - Mesangial proliferation
 - Focal segmented glomerulosclerosis
 - Membranous nephropathy
 - Glomerulonephritis
 - Postinfectious
 - Immunoglobulin A nephropathy
 - Systemic disease
 - Systemic lupus erythematosus
 - Vasculitis
 - Tumor
 - Subacute bacterial endocarditis
 - Infection (HIV, hepatitis)
 - Drugs or toxins
 - Obesity
- **Tubular causes**
 - Genetic
 - Polycystic kidney disease
 - Cystinosis
 - Wilson disease
 - Lowe syndrome
 - Galactosemia

- Renal tubular acidosis
 - Interstitial nephritis
 - Acute tubular necrosis
 - Interstitial nephritis
 - Heavy metal poisoning
 - Glomerular proteinuria
 - More common of the 2 forms
 - Associated with increased permeability of glomerular filtration barrier
 - May be selective (plasma proteins with molecular weights up to and including albumin), as in minimal change disease
 - May be nonselective (albumin and large-molecular-weight proteins, such as immunoglobulin G), as in most forms of glomerulonephritis
 - *Tubular proteinuria* results from decreased tubular protein reabsorption caused by tubular dysfunction.
- Symptomatic proteinuria**
- When defined as a nephrotic syndrome, often associated with:
 - Gravity-dependent edema
 - Hypoalbuminemia
 - Hyperlipidemia
 - Some children with nephrotic-range proteinuria and hypoalbuminemia remain completely asymptomatic.
 - Edema in nephrotic syndrome results from several factors acting in concert, including:
 - Increased distal nephron sodium reabsorption
 - Increased capillary permeability
 - Low plasma oncotic pressure associated with hypoalbuminemic states
 - May be associated with other abnormalities, including:
 - Hematuria
 - Hypertension
 - Azotemia, as seen in glomerulonephritis

LABORATORY EVALUATION

- Diagnosis of proteinuria depends on laboratory assessment of the level of protein in the urine.
 - Presence of persistent proteinuria on repeat testing indicates renal disease until proven otherwise.
 - Presence of proteinuria should be confirmed by a urine protein/creatinine (P/Cr) ratio on a first morning urine sample.
 - Once confirmed, proteinuria should be quantified by a 24-hour urine collection for measurement of protein and creatinine to determine adequacy of the sample.

Dipstick test

- Most commonly performed urine screening method for protein

- Tetrabromophenol on the reagent strip reacts with the amino group of the protein and changes the color of the strip.
- Test reports findings as:
 - Negative
 - Trace
 - 1+ (30 mg/dL)
 - 2+ (100 mg/dL)
 - 3+ (300 mg/dL)
 - 4+ (2000 mg/dL)
- Primarily detects albumin
- Less sensitive to low-molecular-weight proteins and γ -globulins
- Result of $\geq 1+$ in a specimen with a specific gravity of <1.015 indicates abnormal protein loss.
- False-negative results may be caused by highly dilute urine.
- False-positive results may be caused by:
 - Concentrated urine
 - Extremely alkaline urine
 - Prolonged immersion of the strip
 - Hematuria, pyuria, or bacteriuria
 - Presence of detergents and contaminating antiseptics
 - Chlorhexidine
 - Benzalkonium chloride
 - Presence of antibiotics
 - Penicillins
 - Cephalosporins
 - Sulfonamides
 - Tolbutamide
 - Presence of radiographic contrast materials
- An alternative office procedure is precipitation with sulfosalicylic acid.
 - Provides a more accurate estimate of the total urinary proteins
 - Includes those of low molecular weight
 - To prevent false-positives, should be performed on the first urine voided in the morning.
 - Results should be confirmed by urinalysis.

Timed urine sample

- Traditional and most accurate method
- Measures protein in a timed sample collected over a 24-hr period
- Patient is instructed to void right after waking in the morning and discard this first urine.
- All subsequent urines are collected.
- Last sample added to the collection should be 24 hr after the first sample.

- In adults, a protein excretion of <150 mg in 24 hr is considered normal.
- In children, excretion rates are categorized as:
 - Normal: <4 mg/m²/hr
 - Abnormal: 4–40 mg/m²/hr
 - Nephrotic-range proteinuria: >40 mg/m²/hr
- Sample adequacy can be determined by measuring the creatinine excretion in the sample.
- Steady-state daily creatinine excretion is:
 - 20 mg/kg/day in children 1–12 years of age
 - 22–25 mg/kg in older children
- Weaknesses of this method
 - Cumbersome
 - Can be impractical in children
 - Frequent errors from under- and over-collection

Urine protein-creatinine ratio

- Measurement of the P/Cr ratio in an untimed (spot) urine sample
- Reliable for classification of proteinuria
- Easier than 24-hr urine collection
- Studies in adults and children have shown strong correlation between untimed urine P/Cr ratio and 24-hr urine collection.
 - Nephrotic-range proteinuria: ratio >3.5:1
 - Normal
 - Ratio <0.2:1 in patients ages ≥2 yr
 - Ratio <0.5:1 in children aged 6–24 months

Postural or orthostatic proteinuria

- Children with low-grade asymptomatic proteinuria should be assessed.
- Orthostatic test for postural proteinuria includes 2 separate collections:
 - Supine position
 - Upright position
- At bedtime, the child goes to bed without voiding.
- 30 minutes later the child is asked to void.
- Urine is discarded and time is noted as the start of the collection in supine position.
- Child is then given a large glass of water or another fluid and allowed to sleep.
- All urine passed during the night, including the first specimen voided the next morning, is collected in a jar (specimen 1)
 - Time of the first morning voiding is recorded.
- Child goes about daily activities.
- All urine is collected in a second jar (specimen 2) for approximately the next 12 hr.
- This collection is the upright collection and ends at bedtime when time is again recorded.

- In patients with orthostatic proteinuria
 - Sample obtained in the supine position will be free of protein or will contain a normal amount of protein.
 - Sample obtained in upright position will contain an abnormal amount of protein.
- Children with orthostatic proteinuria generally excrete <1 g of protein in 24 hr.
- Diagnosis of postural proteinuria can be made by assessing first morning urine.
 - Presumptive diagnosis of orthostatic proteinuria can be made if sample has:
 - No protein
 - P/Cr ratio <0.2:1

Persistent or fixed asymptomatic proteinuria

- Patients with a positive dipstick test (≥1+) should undergo a more accurate test.
 - P/Cr ratio
 - Quantitative measurement of protein excretion
- Orthostatic proteinuria should be excluded by repeat measurements on a first morning void.
- In the absence of other abnormalities, patients are diagnosed as having *fixed proteinuria* with
 - ≥2 positive semiquantitative or quantitative tests, 1–2 weeks apart

Other tests

- Level of kidney function can be determined by
 - Serum electrolytes
 - Blood urea nitrogen
 - Creatinine
- Determination of the severity of metabolic changes that occur as a result of urine protein loss guided by
 - Serum albumin
 - Cholesterol
 - Triglycerides
- Based on the child's history, the following testing may be indicated:
 - Complement levels
 - Anti-streptolysin O titers
 - Hepatitis serologic testing
 - HIV testing
- Children should be routinely screened by a standard dipstick test on 2 occasions:
 - Before starting school
 - In early adolescence
- Subsequent testing should be performed as needed.

- Assessment of total protein is appropriate in children to identify both albuminuria and low-molecular-weight proteinuria.
 - Under most circumstances, spot urine samples should be used to detect and monitor proteinuria in children.
 - Obtaining 24-hr timed urine collections usually is unnecessary.
 - First morning specimens are preferred.
 - Random specimens are acceptable if a first morning sample is unavailable.
 - Patients with a positive dipstick test of $\geq 1+$ should undergo confirmation by assessment of the P/Cr ratio within 3 months.

IMAGING

- Renal ultrasound
 - Normal in postural or orthostatic proteinuria, but not usually performed in the evaluation process
 - Should be performed when structural abnormalities are a possibility

DIAGNOSTIC PROCEDURES

- Indications for renal biopsy
 - Fixed, asymptomatic, isolated proteinuria >1 g/day
 - Persistent proteinuria <1 g/day *plus*:
 - Hematuria and casts
 - Renal insufficiency
 - Low complement levels
 - Hypertension
 - Systemic symptoms such as recurrent rashes, joint pains, or fever
 - Family history of kidney disease or autoimmune disease
 - Corticosteroid-resistant nephrotic syndrome

TREATMENT APPROACH

- Medications that reduce proteinuria may provide important long-term benefits for patients with chronic kidney disease.

SPECIFIC TREATMENT

- Orthostatic proteinuria
 - Child should be monitored with annual office visits and check of urine P/Cr ratio.
- Isolated fixed proteinuria <1 g/day detected (urine P/Cr ratio $<1:1$)
 - Twice-yearly visits with determination of urine P/Cr ratio are sufficient.
 - Patient should be assessed for hematuria and hypertension.
 - Restrictions on lifestyle and physical activity are not necessary.
 - Children should receive the recommended daily allowance of protein for their age.

- If proteinuria persists for >1 yr, renal biopsy should be considered.

WHEN TO REFER

- Patient should be referred to a pediatric nephrologist if any abnormalities are found during the initial workup.
- Other indicators
 - Persistent, fixed, nonorthostatic proteinuria
 - Proteinuria associated with other urinary abnormalities, such as hematuria
 - Proteinuria associated with renal insufficiency, anemia, or hypertension
 - Family history of renal disease, deafness, or autoimmune condition
 - Proteinuria associated with comorbidities such as:
 - Prematurity
 - Congenital anomalies of other organ systems
 - Hypertension
 - Diabetes
 - Obesity

WHEN TO ADMIT

- Anasarca
- Proteinuria associated with significant renal insufficiency
- Proteinuria associated with significant hypertension

FOLLOW-UP

- Postural or orthostatic proteinuria
 - Long-term follow-up studies in adults have documented the benign nature of orthostatic proteinuria.
 - Rare cases of glomerulosclerosis have been identified later in life in patients who initially were found to have proteinuria with an orthostatic component.
 - Long-term follow-up of children is necessary if the proteinuria does not resolve.
 - Signs to anticipate include:
 - Appearance of hematuria
 - Hypertension
 - Increase in serum creatinine concentration
 - Proteinuria >1 g/day

COMPLICATIONS

- Proteinuria may indicate:
 - Renal injury
 - Progressive renal disease
- Proteinuria is an established independent risk factor for cardiovascular disease.
 - Large losses of protein through the urine lead to hypercholesterolemia and hypertriglyceridemia.

Pruritus

DEFINITION

- Pruritus, or itch, is the subjective perception of a cutaneous disturbance that is relieved by scratching or rubbing.
- Usually not brought to the primary care physician's attention unless it is generalized, chronic, or associated with an eruption.
 - In such instances, pruritus must be treated with great respect.
 - Severe itching can be physically incapacitating.

MECHANISM

- Because itch is a subjective sensation, objective evaluation to delineate its pathophysiologic characteristics has been difficult.
- Current thinking implicates nonspecific itch receptors.
 - Thought to be free, fine nerve endings at the dermoepidermal junction
 - The exact mediators and their release triggers are unknown.
- Experimental triggers that have produced itch include:
 - Mast cell histamine
 - Physical pressure
 - Heat
 - Electric shock
- Researchers believe that nerve impulses from the intra-epithelial mechanosensitive C fibers:
 - Ascend to the lamina I in the dorsal horn of the spinal cord
 - Travel along the contralateral spinothalamic tract to the thalamus
 - Are then transferred to multiple areas of the cortex
 - Are interpreted as itch
- Subsequent desire to scratch arises in the motor cortex.
- Area 3a in the sensorimotor cortex and the anterior cingulate cortex have been identified as activated when histamine-induced itch and scratch are traced.
- Itch is not a mild form of pain.
 - The pathways are different.
 - Aspirin alone does not relieve itch.

HISTORY

- Most common cutaneous diseases associated with generalized pruritus can be diagnosed based on history and physical examination.
- The answers to the following questions may help diagnose infestation:
 - Are any individual pruritic papules found with a central punctum?
 - Are they on exposed or nonexposed areas?
 - Does anyone else in the family have similar lesions?

- Atopic dermatitis
 - Family history of allergy, asthma, or eczema in a child
 - Chronic eczematous dermatitis over:
 - Extensor surfaces in infancy
 - Flexural areas in childhood
- Acute urticaria
 - Usually from exposure to a drug or other ingestant
 - Cause of contact allergic dermatitis or contact irritant dermatitis may be revealed through thorough history and environmental sleuthing.
 - The cause of 90% of acute urticaria cases remains unknown.
- Certain circumstances alter interpretation: eg, the itch threshold in and around areas of active dermatitis, can be lowered with:
 - Psychic stress
 - Decreased skin hydration
 - Increased skin temperature
 - Night time

PHYSICAL EXAM

- Contact dermatitis
 - Recognizable because of a linear array of:
 - Papulovesicular erythematous lesions
 - Sharp borders that conform to the shape of the contactant
- Acute urticaria
 - Produces intensely pruritic, erythematous, and edematous plaques and papules

DIFFERENTIAL DIAGNOSIS

- In children, generalized pruritus is more commonly associated with local cutaneous disease than systemic disease.
- The major differential diagnoses of generalized pruritus with skin lesions in children are:
 - Infestation
 - Scabies
 - Pediculosis
 - Insect bites
 - Atopic dermatitis
 - Miliaria
 - Contact dermatitis
 - Acute or chronic urticaria
- Children may itch with cutaneous diseases, such as:
 - Psoriasis
 - Lichen planus
 - Linear IgA bullous disease of childhood

- The child who has pruritus, from whatever cause, is at risk for:
 - Psychological damage
 - Infection secondary to impetiginization
 - Scarification
- Systemic causes of pruritus in the child who has pruritus but no skin lesions are:
 - Hyperthyroidism and hypothyroidism
 - Leukemia or lymphoma
 - Chronic renal failure
 - Obstructive biliary disease
 - Xerosis (generalized dry skin)

LABORATORY EVALUATION

- For the child who has pruritus with no primary skin disorder assess for possible systemic causes
 - Complete blood count with differential
 - Urinalysis
 - Complete chemistry panel
 - Thyroid-stimulating hormone test
- With urticaria, if the patient has not used any new drug or food, and if the hives persist despite regular use of antihistamines for several days, rule out occult streptococcal, mycoplasmal, and viral infections by performing:
 - Throat culture and a complete blood count with differential
 - Screens for mycoplasmal disease and infectious mononucleosis

IMAGING

- Chest radiography for the child with pruritus and no primary skin disorder

DIAGNOSTIC PROCEDURES

- Skin biopsy, in rare instances of undiagnosed but persistent lesions

TREATMENT APPROACH

- To relieve itching and prevent scarring (both mental and physical), the scratch-itch cycle must be broken.
 - Itching provokes scratching.
 - When the scratching stops, the itching returns.
- To control itching, the following steps can be helpful:
 - Keep fingernails short to prevent damage from scratching.
 - Keep the child fully clothed except when applying medications.
 - Apply bland emollient creams frequently, especially after bathing.
 - Apply cool compresses to relieve intense pruritus and to remove crusts and debris.

- Apply topical steroids for short periods (generally <2 weeks) to control inflammation.
- Increase the dose of antihistamine until the scratching stops or marked drowsiness occurs.
 - Then reduce the dose to a level that controls scratching but does not cause drowsiness.
- Advise the family to avoid stress, heat, and irritants.
- See the patient frequently to provide support.
- If the child is old enough to understand, explain why these methods are being used.

SPECIFIC TREATMENT

Atopic dermatitis

- Hydration and emollients are the mainstay of therapy.
- Mid- and low-potency topical steroids for inflammation
- Antibiotics for secondary infection
- Cool compresses to bring the scratch-itch cycle under control
- Topical immunomodulators (tacrolimus and pimecrolimus)
 - Short courses (<8 weeks) may be helpful in relieving atopic itch on:
 - Facial skin
 - Thin areas, such as the axillae
 - These medications should not be prescribed for long-term therapy.
- Antihistamine in a tolerable (nonsoporific) dose may relieve itch.
 - Should be given approximately 1 hour before bedtime
 - The itch threshold is lower at night.
 - Hydroxyzine seems to be the most effective agent.
 - Data about the use of nonsedating antihistamines for controlling itch are not consistent.

Heat rash

- Pinpoint crystalline or erythematous papules in areas of occlusion and sweating (miliaria crystallina and miliaria rubra)
 - Controlled by simple measures, such as:
 - Dusting powders
 - Avoidance of tight clothing
 - Reduced exposure to high ambient temperatures

Contact dermatitis

- For use of antihistamines, topical steroids, and compresses, see Atopic Dermatitis.

Topical capsaicin and pramoxine

- May be indicated for localized use in some cases
- Potential for systemic absorption limits prolonged or widespread use.

Ultraviolet B light therapy

- May be helpful for generalized pruritus, such as occurs in:
 - Biliary cirrhosis
 - Severe chronic atopic dermatitis

WHEN TO REFER

- Pruritus with uncommon disease (eg, psoriasis, bullae)
- Chronic pruritus without cutaneous disease (to evaluate for systemic cause)
- Pruritus uncontrolled by usual topical steroids and antihistamines

COMPLICATIONS

- Scratching or rubbing can:
 - Produce extensive disfigurement
 - Linear excoriations
 - Lichenified plaques
 - Predispose the patient to cutaneous infections
 - Cause social isolation
 - The child may be viewed as being contagious or unclean.

Psoriasis

DEFINITION

- T cell–mediated chronic inflammatory disease, clinically characterized by well-demarcated, erythematous plaques with overlying silvery-white scale
- *Plaque-type psoriasis*
 - Most common type
 - Scalp, elbows, knees, and lumbosacral regions are the most commonly affected areas, often with bilateral symmetry.
 - Scalp is the most frequently involved site in children.
 - Facial psoriatic lesions, especially around the eyes, are more common in affected children and may be the only involved site.

EPIDEMIOLOGY

- Incidence
 - Unknown, but common among children
- Age
 - 10% of affected children experience onset of disease before age 10 years and 2% before the age of 2 years
 - Can occur during infancy
- Gender
 - Female-male ratio approaching 2:1, although this finding is controversial
- Race
 - Childhood-onset psoriasis occurs more frequently in the white population compared with the black, Asian, and Native-American populations.
- Psoriatic arthritis
 - Rare in children
 - Most severe form, arthritis mutilans, very rare in children

ETIOLOGY

- Both genetic and environmental factors play a role.
- Associated with a family history of psoriasis in 1st-degree relatives, as well as with certain human leukocyte antigen (HLA) subtypes such as HLA-Cw6, -A3, -Cw1, -DR-7, and -DR-8
 - Chromosome 6, the site of HLA I and II complexes, is thought to carry a gene important in determining genetic susceptibility to psoriasis.
- Environmental triggers that likely precipitate or exacerbate childhood psoriasis
 - Streptococcal infections
 - Upper respiratory infections
 - Trauma
 - Psychological stress

SIGNS AND SYMPTOMS

- Plaque psoriasis
 - Large erythematous plaques with overlying silvery-white or grayish scale
 - Scalp
 - Face
 - Elbows
 - Knees
 - Lumbosacral area gluteal cleft
 - Umbilicus
- Inverse psoriasis
 - Bright-red glazed erythema with no scale
 - Diaper area
 - Axillae
 - Groin
 - Postauricular area
- Pustular psoriasis
 - Widespread bright red erythema studded with 1- to 2-mm pustules
 - Deep-seated 2- to 4-mm pustules in areas of erythema and scaling
 - Widespread, especially in:
 - Flexural areas
 - Genitals
 - Finger web spaces
 - Palms
 - Soles
- Erythrodermic psoriasis
 - Bright red erythema with massive exfoliation
 - Widespread
- Guttate psoriasis
 - Can be the first manifestation of psoriasis
 - Characteristics of lesions
 - 2–10 mm
 - Widespread
 - Symmetrically distributed
 - Round or oval erythematous papules and plaques with silvery-white scale
 - Often have a predilection for the trunk and proximal extremities
- Nail involvement, common with psoriasis
 - Nail pitting (most characteristic finding)—multiple, small, irregularly spaced depressions in the nail plate
 - Other nail findings
 - Discoloration
 - Onycholysis (separation of the nail from the nail bed)

- Longitudinal striations
- Subungual hyperkeratosis
- Presentation of psoriatic arthritis in children
 - Similar to that seen in rheumatoid arthritis, but with no rheumatoid factor or systemic symptoms
 - Bluish discoloration over affected joints
 - Preferentially affects the distal interphalangeal and proximal interphalangeal joints of the hands and feet but also can affect the knees and ankles

DIFFERENTIAL DIAGNOSIS

- Psoriatic diaper rash and other forms of inverse psoriasis
 - Seborrheic dermatitis
 - Langerhans cell histiocytosis
 - Candidal intertrigo
 - Contact dermatitis
- Plaque psoriasis—must be differentiated from other papulosquamous disorders
 - Atopic dermatitis (AD)
 - Psoriatic plaques tend to be more clearly demarcated from surrounding uninvolved skin and usually are less pruritic than AD lesions.
 - AD lesions lack the characteristic silvery-white scale of psoriasis.
 - Psoriasis tends to localize to the extensors, whereas AD preferentially affects flexural areas.
 - Some children exhibit overlap between psoriasis and AD.
 - Pityriasis rubra pilaris
 - Lesions have a classic salmon color.
 - Focal areas of sparing
 - Follicular accentuation
- Pustular psoriasis
 - May be confused with disseminated candidiasis or staphylococcal scalded-skin syndrome.
 - To differentiate:
 - Skin biopsy
 - Gram stain
 - Culture of the contents of several pustules
 - Noninfectious pustular eruptions, such as pustular drug eruptions, may also mimic pustular psoriasis.
 - The history of a recently started medication and a skin biopsy can sometimes help differentiate between pustular psoriasis and a pustular drug eruption.

- Scalp psoriasis
 - May be mistaken for tinea capitis or seborrheic dermatitis
 - Potassium hydroxide preparation and a fungal culture of the scale is important to rule out tinea capitis because the treatment for scalp psoriasis (topical corticosteroids) can exacerbate tinea capitis.
- Guttate psoriasis
 - Pityriasis rosea
 - Pityriasis lichenoides
- Nail changes of psoriasis can be seen in other conditions:
 - Alopecia areata
 - Onychomycosis

DIAGNOSTIC APPROACH

- Issues to investigate when evaluating a child for suspected psoriasis
 - Family history of psoriasis
 - Recent history of streptococcal throat or perianal infection
 - Frequency and duration of eruptions
 - Koebner phenomenon
 - Tendency for lesions to appear on traumatized skin (eg, sunburned, scratched, tattooed)
 - Nail changes (eg, nail pitting)
 - Evaluation for characteristic nail changes can help lead to the diagnosis when it is otherwise not apparent.
 - Behavior of lesions in response to sunlight or tanning bed
 - Joint pains
 - Previous treatment modalities and their efficacy

LABORATORY FINDINGS

- Bacterial culture of oropharynx and perianal area; antistreptolysin titer
 - Rules out streptococcal infection, especially in guttate psoriasis
- Potassium hydroxide preparation of scale
 - Rules out fungal infection, especially in scalp psoriasis and annular lesions

DIAGNOSTIC PROCEDURES

- Skin biopsy
 - Confirm clinical diagnosis of psoriasis, especially in atypical presentations

TREATMENT APPROACH

- Psychosocial impact of the disease on the child and the child's family is a critical consideration.
 - Adverse effect on quality of life
 - Educate the child, siblings, and parents, as well as teachers and classmates, about the nature of psoriasis.

- Give affected families information about available psoriasis support groups.
- Psychological counseling should be sought to equip patients with effective coping skills.
- Identify and eliminate potential triggers/exacerbating factors:
 - Streptococcal infection
 - Medications
 - Lithium
 - β -Blockers
 - Interferon
 - Systemic corticosteroids
 - Stress
 - Skin trauma (piercings, sunburn)
- Topical corticosteroids are most common treatment.
- Less commonly used topical therapies
 - Salicylic acid
 - Topical retinoids
 - Topical calcineurin inhibitors
- Bland emollients are an essential part of the skin care regimen.
 - Moisturization and application of emollients lessens the dryness and scaling associated with psoriasis.
 - In some cases, emollients alone may be sufficient to improve mild psoriasis.
 - In most patients, emollients should be used as adjunctive therapy to antiinflammatory topical medications.
- Oral retinoids, such as acitretin, should be 1st-line systemic agent for severe, recalcitrant cases of childhood psoriasis.

SPECIFIC TREATMENTS

Topical agents

- Emollients
 - Petroleum jelly
 - Aquaphor
 - Theraplex emollient
- Corticosteroids by class
 - Class 1 (ultrapotent)
 - Clobetasol propionate 0.05%
 - Betamethasone dipropionate 0.05%
 - Reserved for unresponsive, thick psoriatic plaques
 - Continuous treatment should not last >2 weeks.
 - Class 2 and 3 (medium to high potency)
 - Fluocinonide 0.05%
 - Betamethasone valerate 0.1%
 - Triamcinolone ointment 0.1%
 - Class 4/5 (medium potency)
 - Hydrocortisone valerate 0.2%
 - Mometasone cream
 - Class 6/7 (low potency)
 - Hydrocortisone (all concentrations)
 - Hydrocortisone 2.5% can be used for facial psoriasis, but is ineffective in many children.
 - Desonide 0.05%
 - Side effects of corticosteroids
 - Possible cutaneous side effects: atrophy, striae, telangiectasia
 - Possible systemic side effects: hypothalamic-pituitary-adrenal axis suppression, growth impairment, cataracts, glaucoma
 - Avoid use of high-potency preparations on face and intertriginous areas.
 - Ointment is the preferred vehicle when treating psoriasis:
 - Occlusive effect
 - Increased potency
 - Useful for dry, scaly lesions
 - Gels
 - Readily absorbed
 - Useful in hairy areas
 - Can cause dryness and irritation
 - Creams
 - Rub in well
 - Are aesthetically pleasing
 - May be less potent than ointment form of same drug
 - Foams, solutions, and oils can be used in the scalp.
- Calcipotriol (Dovonex)
 - Can be used twice a day
 - As monotherapy in limited disease
 - As an adjunct to topical corticosteroids in more severe disease
 - Ointment form
 - Suitable for use on any affected area
 - More likely to cause burning and irritation on the face or groin
 - Available in liquid form for use on the scalp
 - Causes irritation
- Coal tar preparations
 - Liquor carbonis detergens in combination with emollients or corticosteroids
 - Liquid form in bath

- Side effects
 - Irritation, staining, unpleasant odor, folliculitis
 - Increased risk of irritation on face and intertriginous areas
- Anthralin (for stubborn plaques)
 - Anthralin 1% is applied for 5 minutes, with increasing contact time with subsequent treatments as tolerated.
 - Causes irritation and staining of skin, bathtub/sink
- Calcineurin inhibitors
 - Tacrolimus ointment (Protopic) 0.03% or 0.1%
 - Pimecrolimus cream (Elidel) 1%
 - Side effects
 - Occasional burning or itching with first few applications
 - US Food and Drug Administration black-box warning (theoretical malignancy risk based on oral forms)
- Retinoids
 - Tazarotene cream or gel (Tazorac)
 - Issues
 - No data on efficacy in children
 - Dryness, local irritation
 - Pregnancy category X
- Topical application of oils
 - Nighttime application, such as Derma-Smooth Oil (fluocinolone), or nonsteroid oils, such as olive, mineral, or soybean oil, can be a useful adjunct in treating scalp psoriasis in older children.
 - Can be applied to the scalp at night to loosen adherent scale and then shampooed out in the morning
 - Some black patients prefer oilier scalp preparations, such as lotions, ointments, or oils, rather than the foams or gels, because the former preparations also lubricate the hair and prevent brittleness and breakage.
- For scalp lesions
 - Liquid or foam corticosteroid preparations (may cause stinging)
 - Clobetasol foam
 - Clobetasol solution
 - Fluocinonide solution
 - Corticosteroid, tar, zinc, or salicylic acid shampoos
 - Clobex shampoo (clobetasol)
 - T-Sal shampoo
 - Parents should be warned that these might cause dryness of the hair and scalp.

Phototherapy

- Psoralen plus ultraviolet A
 - Should not be used in preadolescent children
 - Issues
 - Cataracts
 - Skin aging
 - Skin cancer
 - Expensive
 - Inconvenient
- Ultraviolet B (UVB)
 - Narrow-band UVB (311–313 nm) can clear plaques with lower amounts of UV light
 - Issues
 - Temporary erythema
 - Expensive
 - Inconvenient
 - Skin aging
 - Skin cancer
 - Very difficult for younger patients

Systemic agents

- Methotrexate
 - Indications
 - Recalcitrant widespread psoriasis
 - Erythrodermic psoriasis
 - Pustular psoriasis
 - Psoriatic arthritis
 - Side effects
 - Bone marrow toxicity
 - Hepatotoxicity
 - Nausea
 - Vomiting
 - Must monitor patient's complete blood count and liver function tests
 - Liver biopsy often performed after a cumulative dose of 1.5–2 g.
- Cyclosporine
 - Indications
 - Recalcitrant widespread psoriasis
 - Erythrodermic psoriasis
 - Pustular psoriasis
 - Side effects
 - Renal and hepatic toxicity
 - Hypertension
 - Hypertrichosis
 - Immunosuppression

- Oral retinoids
 - Indications
 - Erythrodermic psoriasis
 - Pustular psoriasis
 - Side effects
 - Cheilitis
 - Xerosis
 - Skin fragility
 - Hypertriglyceridemia
 - Skeletal abnormalities
 - Teratogenicity (avoid in adolescent girls)
- Systemic retinoids
 - Children with generalized pustular psoriasis have been successfully treated with etretinate.
 - Side effects
 - Pruritus
 - Cheilitis
 - Skin fragility
 - If chronic use
 - Ossification of interosseous ligaments and tendons
 - Skeletal hyperostosis
 - Premature epiphyseal closure (may affect growth)
- Etanercept
 - Indications
 - Severe generalized, recalcitrant psoriasis in older children
 - Psoriatic arthritis
 - Side effects
 - Injection site reactions
 - Live vaccination should be avoided
 - Caution if congestive heart failure, multiple sclerosis, tuberculosis risk factors

WHEN TO ADMIT

- Widespread pustular psoriasis
- Erythrodermic psoriasis

WHEN TO REFER

- Unresponsive to 1st- or 2nd-line therapy
- Widespread disease
- Pustular psoriasis
- Erythrodermic psoriasis
- Worsening joint pains (refer to rheumatologist)

COMPLICATIONS

- Possible complications of erythrodermic psoriasis include:
 - Electrolyte imbalances
 - Cardiovascular compromise
 - Sepsis
 - Considered a dermatologic emergency

Psychosocial Screening

BACKGROUND

- 5–20% of US children have significant functional impairments and psychiatric disorders.
 - Defined by the 4th edition of *Diagnostic Statistical Manual of Mental Disorders (DSM-IV)* and the text revision edition (*DSM-IV-TR*)
 - The majority of cases are not detected by primary care physicians because of:
 - Time limitations at visit
 - Hesitancy among practitioners to attach labels that may stigmatize
 - Absence of widely available and easily implemented screening procedures
 - Lack of adequate training on psychiatric issues
 - Limited resources for referral and treatment, eg, insurance barriers
- A significant number of children and adolescents consider suicide.
- Psychiatric diagnoses do not always take into account important developmental and functional assessments.
- Psychosocial dysfunction can be grouped into 3 main categories:
 - Normal variation
 - Allows for different temperaments, personalities, and developmental paths among healthy children
 - Problems
 - A range of issues that may not meet formal criteria for a psychiatric disorder (eg, anxious reaction to divorce)
 - Disorders
 - Specific conditions that meet the *DSM-IV* criteria
- Psychosocial issues have multiple secondary consequences.
 - Risk factor for unintentional injuries (common cause of death)
 - Fires, falls from windows, drowning, and car accidents are more common among children with psychosocial stressors.
 - School failure
 - Family conflict
 - Juvenile justice interaction

GOALS

- To provide screening methods in harmony with primary care for early, efficient, and effective recognition of developing psychosocial problems.
 - Problems are recognized:
 - Through parental complaints of overt behavioral problems
 - Through school referral

- In the primary care setting
 - In this setting, less obvious dysfunction is often identified (eg, dysfunction stemming from divorce or depression)

- Built-in screening tests can be initiated according to age and risk factors.
 - For example, family history of attention-deficit/hyperactivity disorder (ADHD) or a cluster of positive answers to school dysfunction questions may elicit an ADHD screening questionnaire.

GENERAL APPROACH

- Psychosocial challenges are heterogeneous.
- The average primary care visit is limited in time but includes increasing psychosocial demands.
- Pediatricians should broadly screen for psychosocial dysfunction rather than focusing on psychiatric diagnoses.
 - They should play an active role in detection and treatment of psychosocial problems through routine screening practices with structured instruments.
 - General psychosocial screening increases the referral rate from 1–2% to 4%.
- Once information from assessments is gathered, the presenting symptom should be categorized as:
 - Needs no further action
 - Requires intervention
- Innovative practices may be able to provide adequate treatment despite current health care insurance limits on intervention.
- Many issues can be addressed by primary care with comanagement by mental health professionals or school personnel.
- Some pediatricians have mental health professionals in their practices to provide follow-up, consultation, and ongoing services.
- An office social worker can provide referral services.
 - Provide family and group treatment in the pediatric office setting
 - Provide:
 - Preventive measures in cases of recent divorce or other risks
 - Support for parents raising children with ADHD
 - Treatment for adolescents using substances or dealing with depression, if trained
- More serious problems require:
 - Outside referral for evaluation by a specialist
 - Possibly, ongoing treatment
- The most severe cases often require emergency referral.

SPECIFIC INTERVENTIONS

Interviewing patients

- Pay careful attention to developmental aspects of the child's environment.
 - Family
 - Friends
 - School
 - Play
 - Mood
- Face-to-face interviewing, in which high-risk issues are discussed with the patient and parents, offers many advantages.
- At intake, ask parents for a family history of psychiatric disorder (eg, depression, substance use).
 - Factors in the family that put a child at risk
 - Depression
 - Anxiety
 - Substance use
 - ADHD
- At annual visits, ask about parental discord and marital stability.
- For newborns, assess:
 - Parental coping
 - Family support
 - Maternal depression
 - Has profound emotional and cognitive impact on infant
 - Treatment can greatly help the entire family.
- For toddlers, ask about autonomy and the ability to separate.
- For early school-age children, ask about social functioning.
- For adolescents
 - Ask parents about the teen's autonomy.
 - Ask the adolescent about mood and substance use.

Screening tools

- Parent questionnaires
 - Achenbach Child Behavior Checklist
 - Most studied and best validated instrument
 - Requires approximately 20 minutes
 - Pediatric Symptom Checklist (PSC)
 - A less cumbersome alternative
 - Takes 3–5 minutes
 - Parents can complete the checklist in the waiting room and have it scored by the receptionist or clinical assistant.
 - Pediatrician can quickly recognize and evaluate significant issues.
 - Hampered by parents' limitations in correctly assessing their child's intrapsychic state

- Strength and Difficulties Questionnaire
 - Assesses specifically for emotional difficulties
 - Completed by parents and teachers of children age 4–16 years
 - Similar to the PSC but is perhaps slightly more complicated to score
- Patient questionnaires
 - Human Figure Drawing Screening Device
 - For young children
 - Detects occult anxiety and depression
 - Teenscreen (paper or computer) for depression and suicidality
 - Beck Depression Inventory
 - ≥20% of teenagers have scores that raise concerns.
- Specific screening for Asperger syndrome or autism (young children only)
 - Modified Checklist for Autism in Toddlers
 - Parents Evaluation of Developmental Status

Assessing severity of dysfunction

- Symptoms
 - Number
 - Frequency
 - Duration
 - Places where experienced
- Functioning
 - Family
 - Friends
 - School
 - Activities
 - Self-esteem
- Burden of suffering
 - Intensity
 - Duration
 - Limitations on family activities
 - Danger to self and others
 - Intrusion into developmental tasks or daily activities

Risk factors

- Risk factors for psychosocial problems include:
 - Poor health or chronic medical conditions of child
 - Impaired parenting
 - Poverty
 - Unsafe or inadequate home environment
- See table Children's Well-being: Risk and Protective Factors.

Children's Well-being: Risk and Protective Factors

	Protective Factors That Decrease the Impact of Stress	Risks Factors That Increase the Impact of Stress
Health	Good health	Chronic disease, ill health
Temperament	Example: pleasant mood	Example: negative mood, irritable
Cognitive status	Normal IQ (particularly verbal)	Learning disability or low IQ
Emotional health	Good mental health function	Preexisting emotional disorder
Sociability	Good peer relations	Poor peer relations
Child reaction to stress	Perceives stress as limited; does not blame self	Perceives continued threat; blames self
Quality of attachment	High quality, high continuity; securely attached	Low quality, discontinuous; ambivalent, insecurely attached
Parent competence	Competent	Incompetent
Family resources	Adequate economic resources	Poverty or discrimination
Quality, stability, safety of environment	Adequate, stable, safe	Inadequate, unstable, unsafe
Family relationships	Good communication; little conflict	Poor communication; excessive conflict
Emotional and physical health of caregivers	Caregivers in good emotional and physical health	Mental illness or physical illness in caregivers
Availability or access to community resources	High access	Low access

Brief evaluation

- Clinicians should be consistent with their screening instruments.
- If the patient has a definite psychosocial complaint, attempt to elaborate the symptoms.
- Consider risk factors and developmental concerns.
- Try to assess the child's daily functioning using the following guidelines.
 - Observe younger children while directing questions to the parents.
 - For school-age children, use confirmatory questions, if possible, without the parents being present.
- For adolescents, perform a separate interview with the patient alone.
 - Assess substance use and depression.
 - Inquire about sexual activity.
 - Consider parental abuse, depression, and substance use.
 - Review relevant risk factors and potentially protective factors.
 - Assess safety, eg, potential accident, suicidal ideation, and risk-taking behaviors.
- Complete the severity estimate using the Achenbach Child Behavior Checklist and PSC, ranking the current issue as mild, moderate, or severe.

Puberty: Normal and Abnormal

DEFINITION

■ Normal puberty

- Series of complex hormonal changes that begins at 8–13 years of age in girls and 9–14 years of age in boys

■ Delayed puberty

- Girls
 - No breast development by age 13 years
 - Delay >4–5 years from onset of puberty to menarche
- Boys
 - No testicular enlargement by age 14 years
 - Maturation arrest

■ Precocious puberty

- Appearance of secondary sexual characteristics before 8 years of age in girls and 9 years in boys
- Trends toward earlier onset of puberty in girls have led the Lawson Wilkins Pediatric Endocrine Society to publish recommendations that the cutoff age for precocious puberty should be decreased to 7 years in white girls and 6 years in black girls unless:
 - The tempo of puberty is abnormal.
 - The bone age is advanced >2 years.
 - The predicted height is <150 cm (59 inches).
 - Focal neurologic deficits are present.
 - Headaches are present.
 - The family's or child's emotional state is adversely affected.
- The recommendations remain controversial.

■ Variations of puberty

- Premature thelarche
 - Isolated premature breast development
- Premature adrenarche
 - Isolated premature development of sexual hair

EPIDEMIOLOGY

Normal puberty

■ Onset of pubertal milestones (years) in girls

- Thelarche
 - Non-Hispanic whites: 11.05
 - Non-Hispanic blacks: 10.25
 - Mexican Americans: 10.70
- Sexual hair development
 - Non-Hispanic whites: 10.96
 - Non-Hispanic blacks: 10.25
 - Mexican Americans: 11.17
- Menarche
 - Non-Hispanic whites: 12.52
 - Non-Hispanic blacks: 12.06
 - Mexican Americans: 12.09

- Association between increasing levels of adiposity and earlier sexual maturation in girls: causal nature is unclear

■ Overall age at menarche has decreased by 2.3 months between National Health and Nutrition Examination Survey (NHANES) III (1988–1994) and NHANES IV (1999–2002).

- NHANES IV had more girls with body mass index >85th or 95th percentile and had different racial and ethnic composition.
- Changes within racial and ethnic groups were much smaller, indicating that overall decrease in age at menarche may result from changes in population distribution of race and ethnicity and relative weight.

■ Onset of pubertal milestones (years) in boys

- Testicular enlargement
 - Non-Hispanic whites: 11.08
 - Non-Hispanic blacks: 10.79
 - Mexican Americans: 11.09
- Sexual hair development
 - Non-Hispanic whites: 11.81
 - Non-Hispanic blacks: 11.48
 - Mexican Americans: 12.2
- Peak height velocity for boys is typically 2 years later than for girls and usually occurs during mid to late puberty.

Abnormal puberty

■ Delayed puberty

- Identified much more frequently in boys

■ Precocious puberty

- Significantly more common in girls than boys
- Girls adopted from developing countries may be at particular risk.
- Internationally adopted girls show a trend toward early and rapidly progressing puberty that may be related to increased metabolic activity exhibited if catch-up growth occurs after adoption.

■ Gynecomastia

- Occurs in about 40% of healthy boys
- Mean age of occurrence: 14–15.5 years

MECHANISM

Normal puberty

- The hypothalamus secretes pulses of gonadotropin-releasing hormone (GnRH), which stimulates pituitary gonadotropin production of luteinizing hormone and follicle-stimulating hormone.
- The previously very sensitive hypothalamic-pituitary-gonadal feedback loop becomes less sensitive to the negative effect of gonadal steroids.
- Thus gonadotropin levels increase and stimulate secretion of more sex steroids (testosterone or estradiol, depending on sex), leading to physical changes of puberty.

- Hypothalamic-pituitary-gonadal axis is active during fetal life and infancy until it enters an inactive state during prepubertal years.
- Factors influencing pubertal timing
 - Genetic factors (50–80% of the variation)
 - Environmental influences, especially nutritional status
 - Leptin
 - Secreted by adipocytes and regulates appetite
 - May play permissive role in regulating timing of puberty
- Adrenarche
 - Increase in secretion of adrenal androgens during puberty
 - Associated with development of:
 - Pubic hair
 - Axillary hair
 - Body odor
 - Acne
 - The mechanism that triggers maturation of adrenal cortex at puberty remains poorly understood.

Abnormal puberty

- Delayed puberty
 - Constitutional delay is a slow maturation with appropriate hormonal levels and delayed bone age.
 - Frequently familial
 - Accounts for the majority of cases of pubertal delay
 - Identified more frequently in boys
 - Delayed puberty secondary to underlying chronic systemic disease
 - Deficiency of gonadotropin-releasing hormone secretion by the hypothalamus
 - Either genetic or acquired
 - Deficiency of gonadotropin secretion by the pituitary
 - Either genetic or acquired
 - Gonadal dysfunction
 - Either genetic or acquired
 - Adrenal and gonadal enzyme deficiencies
 - Malnutrition
 - Excessive exercise
- Precocious puberty
 - Central precocious puberty results from early stimulation of the hypothalamic-pituitary axis, with resultant gonadotropin secretion and sex-steroid secretion.
 - Idiopathic
 - Central nervous system abnormalities
 - Severe hypothyroidism
 - Peripheral precocious puberty results from sex-steroid secretion independent of pituitary gonadotropin secretion.
 - Gonadal tumors or cysts

- Adrenal hyperplasia or tumor
- Ectopic gonadotropin-secreting tumors
- Genetic disorders
- Exogenous sex steroids

- Gynecomastia
 - May result from increase in ratio of estrogen to androgen
- Premature thelarche
 - Occurs in girls between 6 months and 3 years of age
 - Breast development
 - Usually moderate
 - Often regresses
 - Seen without other signs of precocious puberty
 - Estrogen or gonadotropic levels do not increase significantly.
 - Statural and skeletal maturation accelerate only mildly, if at all.
 - Does not progress to complete precocious puberty
- Premature adrenarche
 - Usually occurs between 5 and 7–8 years of age
 - Development of sexual hair frequently accompanied by:
 - Mild growth spurt (with slight bone age advancement)
 - Signs of increased adrenal androgens
 - Increase in levels of plasma dehydroepiandrosterone and its sulfate to early pubertal range
 - In girls, no signs of increased estrogen secretion

HISTORY

- History related to possibly abnormal puberty should include thorough review of:
 - Child's medical history, with emphasis on growth, development, significant illnesses, and signs and symptoms related to the endocrine and central nervous systems
 - Exposure to medications and other exogenous agents that can affect puberty
 - Family history of pubertal onset and progression

PHYSICAL EXAM

- Physical examination related to possibly abnormal puberty should include careful:
 - Measurement of growth parameters, with calculation of growth velocity
 - Determination of Tanner staging
 - Attention to the endocrine and central nervous systems

DIFFERENTIAL DIAGNOSIS

Delayed puberty

- Constitutional delay

■ Deficiency of gonadotropin-releasing hormone secretion by the hypothalamus

- Genetic and molecular causes
 - Isolated deficiency
 - Kallmann syndrome
 - Laurence-Moon-Bardet-Biedl syndrome
 - Prader-Willi syndrome
- Acquired causes
 - Infection
 - Neoplasm
 - Infiltrative disease
 - Trauma

■ Deficiency of gonadotropin secretion by the pituitary

- Genetic
 - Panhypopituitarism (including transcription factor mutations in *PRO1*, *HESX1*, and *LHX3*)
 - Isolated deficiency
 - Fertile eunuch (normal follicle-stimulating hormone level, low luteinizing hormone level)
 - Leptin or leptin-receptor deficiency
- Acquired
 - Infection
 - Tumor
 - Excess prolactin secretion, adenoma
 - Trauma

■ Gonadal disorders

- Genetic and molecular
 - Turner syndrome (45, X or structural X abnormalities or mosaicism)
 - Klinefelter syndrome (47, XXY)
 - Noonan syndrome
 - Syndromes of complete androgen insensitivity (no sexual hair)
 - del Castillo syndrome (Sertoli cells only)
 - Pure gonadal dysgenesis
 - Myotonic dystrophy
 - Receptor mutations
- Acquired
 - Gonorrhea (male)
 - Virus (mumps, coxsackie)
 - Tuberculosis (male)
 - After radiation or chemotherapy
 - Torsion
 - Surgery
 - Congenital anorchia (vanishing testes syndrome)
 - Autoimmune

■ Adrenal and gonadal steroid enzyme deficiencies

■ Malnutrition

■ Excessive exercise

■ Chronic systemic diseases

- Congenital heart disease
- Chronic pulmonary disease
- Inflammatory bowel disease, celiac disease
- Chronic renal failure and renal tubular acidosis
- Hypothyroidism
- Poorly controlled diabetes mellitus
- Sickle cell anemia, thalassemia
- Collagen-vascular disease
- Anorexia nervosa
- HIV infection

Isosexual precocious puberty

■ Central (with pituitary gonadotropin secretion)

- Idiopathic
- Central nervous system abnormalities
- Diagnosis is made only after a search for a pathologic cause is negative.
 - Congenital anomalies (hydrocephalus)
 - Tumors (hypothalamic, pineal, other)
 - Hamartoma
 - Postinflammatory condition
 - Trauma
 - Neurofibromatosis
 - Tuberous sclerosis
 - Hypothyroidism (severe)

■ Peripheral

- Exogenous sex steroids
 - Both testes are small.
- Gonadal tumors or cysts
- Adrenal hyperplasia or tumor
 - Both testes are small.
- Ectopic gonadotropin-secreting tumors (chorioepithelioma, hepatoblastoma, teratoma)
 - Both testes are of pubertal size.
- Familial Leydig cell hyperplasia, receptor mutation
- McCune-Albright syndrome, G-protein mutation

Heterosexual precocious puberty

■ Girls

- Congenital adrenal hyperplasia
- Androgen-secreting tumors
 - Adrenal
 - Ovarian
 - Teratoma
- Exogenous androgens

■ Boys

- Estrogen-producing tumors
 - Adrenal
 - Teratoma
 - Hepatoma
 - Testicular
- Exogenous estrogens
- Increased peripheral conversion of androgens to estrogens

■ Gynecomastia

- Klinefelter syndrome
- Partial androgen insensitivity syndrome
- Hyperprolactinemia
- Liver disorders
- Adrenal carcinoma
- Biosynthetic defects in testosterone production
- Androgen receptor defects
- Increased activity of peripheral aromatase
- Certain drugs
 - Estrogen-like effect
 - Diethylstilbestrol
 - Oral contraceptive pills
 - Digitalis
 - Estrogen-containing cosmetics
 - Increase estrogen formation
 - Gonadotropins
 - Clomiphene
 - Inhibit testosterone action
 - Ketoconazole
 - Spironolactone
 - Cimetidine
 - Isoniazid
 - Methyldopa
 - Captopril
 - Tricyclic antidepressants
 - Diazepam
 - Marijuana
 - Phenothiazine

■ Adrenarche

- An abnormal androgen source (eg, tumor or late-onset congenital adrenal hyperplasia) must be excluded.
- May occur in children with mild neurologic problems

■ LABORATORY EVALUATION

- Evaluation for delayed puberty
 - Initial screening tests
 - Luteinizing hormone, follicle-stimulating hormone

- Testosterone or estrogen, depending on sex
- Thyroid-stimulating hormone, thyroid hormone
- If systemic disease is thought to exist:
 - Complete blood count
 - Erythrocyte sedimentation rate, C-reactive protein
 - Comprehensive panel
 - Insulin-like growth factor 1, insulin-like growth factor binding protein 3
 - Urinalysis
 - Celiac disease panel (anti-endomesial IgA antibody or tissue transglutaminase immunoglobulin A and total immunoglobulin A level)
 - Inflammatory bowel disease panel
 - Prolactin
- Other tests (if indicated)
 - Karyotype
 - GnRH or GnRH analogue stimulation test

■ Evaluation for precocious puberty

- Initial screening tests
 - Luteinizing hormone, follicle-stimulating hormone
 - Estradiol, testosterone
 - Dehydroepiandrosterone sulfate
 - 17-Hydroxyprogesterone
 - Thyroid-stimulating hormone, thyroid hormone
- Secondary tests (if indicated)
 - Serum β -human chorionic gonadotropin
 - GnRH
- Measurement of serum gonadotropin levels before and after injection of GnRH usually distinguishes central and peripheral precocious puberty.

■ Gynecomastia

- Initial screening blood work
 - Testosterone
 - Estradiol
 - Luteinizing hormone
 - Follicle-stimulating hormone
 - Liver function tests
 - Prolactin
 - β -Human chorionic gonadotropin level

■ IMAGING

- Evaluation for delayed puberty and precocious puberty can include, if indicated:
 - Bone age
 - Brain magnetic resonance imaging
 - Pelvic ultrasonography

SPECIFIC TREATMENT

Delayed puberty

- Treatment is directed toward the cause when possible.
- In all cases, provide strong psychological support to the adolescent and sometimes to the family.
- Gonadal failure or gonadotropin deficiency
 - Treatment focuses on replacing the appropriate sex steroid.
- Constitutional delay
 - Waiting may be the best course.
 - Boys
 - A short course of low-dose injectable testosterone (eg, 50–100 mg monthly for 4 doses) if delayed development affects psychological well-being
 - Girls
 - Cosmetic treatment (eg, padded bra)
 - Estrogen therapy necessary only occasionally
- GnRH or gonadotropin deficiency
 - Fertility may be induced with GnRH or gonadotropin therapy.

Isosexual precocity

- Suppression or removal of underlying cause
- Idiopathic central precocious puberty
 - GnRH analogues lead to pituitary desensitization and reduce gonadotropin secretion to prepubertal levels.
 - Available intramuscularly (depot), subcutaneously, and intranasally.
 - Depot leuprolide is used most commonly in US.
 - Usually given every 3–4 weeks
 - Longer-acting forms given every 12 weeks are available.
 - Has been used for years, is effective, and has minimal side effects
- Gonadotropin-independent precocious puberty
 - Testolactone and other aromatase inhibitors (anastrozole, letrozole)
 - Spironolactone (androgen receptor inhibitor)
 - Ketoconazole (steroidogenesis inhibitor)
- McCune-Albright syndrome
 - Tamoxifen (estrogen receptor inhibitor)

Heterosexual precocious puberty

- Removal of sex hormone source (exogenous or tumor)
- Suppression with glucocorticoid replacement therapy (congenital adrenal hyperplasia)

Gynecomastia

- Treatment in most cases is reassurance.
- For unresolved or rapidly developing cases:
 - Medical therapy
 - Clomiphene (antiestrogen)

- Tamoxifen (estrogen antagonist)
- Testolactone (peripheral aromatase inhibitor)
- Danazol (synthetic derivative of testosterone)
- No randomized, controlled trials have assessed these drugs.
- Surgical intervention remains the mainstay of treatment.

Isolated premature thelarche and adrenarche

- No treatment is required.

WHEN TO REFER

- Delayed puberty
 - No breast development in girls by 13 years of age
 - No menarche 4–5 years after onset of breast development in girls
 - No testicular enlargement in boys by 14 years of age
 - Maturational arrest
 - Hormonal abnormalities identified by initial screening tests
 - Parental or physician discomfort
- Precocious puberty
 - Signs of puberty before 6–8 years of age in girls
 - Signs of puberty before age 9 in boys
 - Rapidly progressive puberty (eg, stage 3 breast when first noted)
- Heterosexual precocious puberty
 - Hormonal abnormalities identified by initial screening tests
 - Parental or physician discomfort
- Gynecomastia
 - Does not resolve after 2 years
 - Develops rapidly

FOLLOW-UP

- Premature thelarche and premature adrenarche
 - Careful follow-up physical exams are necessary to ensure they do not represent early stages of complete sexual precocity.

PROGNOSIS

- Precocious puberty
 - Can significantly reduce adult height
 - Sometimes adversely affects the child's and family's emotional state
- Adrenarche
 - May be a marker of future polycystic ovary syndrome
- Gynecomastia
 - Usually resolves within 2 years

Pyloric Stenosis

DEFINITION

- Pyloric stenosis (PS) is a condition characterized by abnormal thickening of the antropyloric muscles.

EPIDEMIOLOGY

- Prevalence
 - One of the most common conditions requiring surgery in infants
 - Seen in 100–300 per 100,000 live births
- Incidence
 - Early population-based studies reported an increase in the incidence of PS.
 - More recent reports indicate that the incidence seems to have leveled.
- Sex
 - Boys are affected 4 times more than girls.
 - The commonly held belief that PS primarily afflicts first-born male infants has not been confirmed.
- Race, ethnicity
 - Incidence in white infants exceeds that in black, Native American, or Asian infants.
- Familial association
 - Develops in 5% of boys and 2.5% of girls whose fathers had PS
 - Develops in 19% of boys and 7% of girls whose mothers were affected
 - Concordance is:
 - 0.25–0.44 in monozygotic twins
 - 0.05–0.1 in dizygotic twins

ETIOLOGY

- Obstruction of the intervening lumen of the pyloric channel causes progressively worsening vomiting, resulting in dehydration.
- The mechanism for hypertrophied pyloric muscle and gastric outlet obstruction is not known.
- Uncoordinated gastric peristalsis and pyloric relaxation have been speculated to lead to gastric contractions against a closed pylorus, resulting in work hypertrophy of the pyloric muscle.
- Theories that have been proposed to explain hypertrophy of the pyloric muscle include:
 - Alterations in gastrin production
 - Changes in breastfeeding practice
 - Variations in infant milk formulas
- Impaired neuronal function has been implicated in the development of PS caused by reduction in:
 - Smooth-muscle vasoactive amines
 - Neurons and nerve fibers
 - Interstitial pacemaker cells of Cajal

- Investigators have proposed that deficiency of nitric oxide, a ubiquitous mediator of smooth-muscle relaxation, may be associated with the development of PS.
 - Nitric oxide synthase is selectively depleted in the pyloric muscle of patients with PS.
 - Studies of neuronal nitric oxide synthase gene polymorphisms suggest that this gene represents a susceptibility locus for PS.
- Whether PS is acquired or congenital disorder is still unclear.
 - Onset of clinical symptoms between 2 and 8 weeks of life supports an acquired condition.
 - A genetic basis is supported by:
 - Male predilection
 - Familial cases
 - PS among twins
 - An increased frequency of coexisting malformations

RISK FACTORS

- Prenatal exposure to macrolides
- Postnatal exposure to systemic erythromycin, particularly within the first 2 weeks of life
- Postnatal prostaglandins
- Most infants with PS are otherwise healthy and genetically normal.
- PS has been reported with a greater frequency in infants with:
 - Hiatal and inguinal hernias
 - Malrotation
 - Junctional epidermolysis bullosa
 - Hirschsprung disease
 - Ovarian cysts
 - Ichthyosis
 - Smith-Lemli-Opitz syndrome
 - Deletions of the long arm of chromosome 11
- PS is believed to be associated with the variable transmission of an inheritable trait.
 - Transmission of the PS trait is more frequent from the mother than the father.

SIGNS AND SYMPTOMS

- Typical presentation is projectile, nonbilious vomiting in a full-term male infant between 3 and 6 weeks of age.
- Common age of symptom manifestation is 3–6 weeks.
 - Has been reported in newborns and older infants
- Vomiting
 - Initially, the infant vomits a small amount of food immediately after feeding and continues to gain weight.
 - After a few weeks, vomiting becomes more frequent and projectile, and occurs after every feeding.
 - Initially, the vomitus is nonbilious; over time, it may become brownish in color.

- The infant continues to be hungry immediately after vomiting.
- The infant may subsequently develop gastritis.
- Infants are usually active and alert.
- Lethargy ensues only after significant dehydration.
- Physical examination reveals weight loss and dehydration.
- The enlarged pylorus may be felt as a firm, mobile, ovoid-shaped mass—the so-called olive.
 - If the infant is relaxed, the mass can be felt in approximately 80–90% of cases.
 - The infant's feet should be elevated.
 - The knees should be placed in the flexed position to relax the abdominal muscles.
 - 2 or 3 fingertips are placed in the right upper quadrant, gently advanced into the deeper tissues below the liver edge, and then slowly swept toward the umbilicus.
 - The mass can be felt to roll under the fingertips during this sweeping motion.
 - The mass is rarely palpable in an agitated, crying infant with a contracted abdominal wall.
 - The mass can be best felt immediately after an episode of projectile emesis.
 - At this time, the pylorus is fully contracted and at its firmest consistency.
 - If the mass is not felt with the infant in the supine position, palpation while the infant is lying prone may be successful.
 - Occasionally, the primary care physician may need to:
 - Pass a nasogastric tube
 - Empty the stomach
 - Feed the infant small quantities of dextrose in water to help relax the abdominal wall
- Gastric contractions, which move across the upper abdomen from left to right, may be seen in some infants.
 - Best observed with a bright light directed across the abdomen from the patient's side
 - The examiner should stand at the foot of the examining table.

DIFFERENTIAL DIAGNOSIS

- Other causes of gastric outlet obstruction should be considered in the differential diagnosis of an infant with nonbilious emesis.
 - Foregut stenosis
 - Gastric duplications
 - Antral webs
 - Pylorospasm
 - Annular pancreas
- Malrotation
- Many of these causes can be excluded by ultrasonography or an upper gastrointestinal (GI) tract series.
- When a diagnosis of PS cannot be established in an infant with persistent emesis and a normal ultrasonogram and upper GI tract series, the following possibilities should be considered.
 - Poor feeding regimen
 - Gastroesophageal reflux
 - Sepsis
 - Intracranial disease
 - Renal disorder
 - Adrenal insufficiency
- Salt-losing congenital hyperplasia
 - Prompt diagnosis and immediate therapy are crucial.
 - This condition should be suspected in an infant with:
 - Abnormal genitalia
 - Hyponatremia
 - Hyperkalemia
- When the workup is inconclusive, reevaluating in 1 week to 10 days is reasonable.

DIAGNOSTIC APPROACH

- Palpation of a mass on physical examination alone should aid in making an accurate diagnosis in most patients.
- Once the mass is felt unequivocally, the diagnosis of PS is established and no further diagnostic maneuvers are necessary.
- A large volume of fluid aspirated from the stomach of a fasting infant who has a history of projectile vomiting strengthens the possibility of PS.

LABORATORY FINDINGS

- Persistent vomiting caused by gastric outlet obstruction results in the continuous loss of gastric hydrochloric acid.
- Dehydration causes an increase in aldosterone production, leading to increased renal excretion of potassium.
- The potassium excretion results in a hypochloremic, hypokalemic metabolic alkalosis.
- Depletion of chloride in the blood leads to an exchange of hydrogen and potassium for sodium in the distal tubule, resulting in a paradoxical aciduria.
- A spectrum of electrolyte abnormalities may be seen:
 - Hypoglycemia may be present and may cause seizures.
 - Unconjugated hyperbilirubinemia is common.
 - Correlates with a decrease in hepatic glucuronosyl transferase activity
 - Resolves after treatment

IMAGING

■ Ultrasonography

- Sensitivity approaches 100%
- The most useful technique to confirm the diagnosis in cases in which:
 - PS is suspected clinically
 - Hypertrophied pylorus cannot be palpated
- Measurement of pyloric wall thickness, diameter, and pyloric channel length accurately establishes the diagnosis of PS.
 - Pyloric muscle wall thickness ≥ 3.7 mm and a channel length ≥ 17 mm have been shown to have $\geq 90\%$ positive predictive value (see Figure 72 on page F26).
 - Diagnostic criteria for wall thickness may be reduced to 3 mm in infants < 30 days.

■ Upper GI tract contrast study

- May be performed in infants in whom ultrasonography is not diagnostic
- Characteristic upper GI tract findings in infants with PS include:
 - An elongated and narrowed pyloric channel (string sign)
 - The shoulders of the hypertrophied pylorus bulging into the intestinal lumen (see Figure 73 on page F26)

■ Palpation of a mass on physical examination alone should aid in making an accurate diagnosis in most patients.

■ Increasing reliance is now placed on noninvasive, highly accurate, and relatively inexpensive radiologic tests, such as ultrasonography.

TREATMENT APPROACH

■ Management of PS consists of hydration and pyloromyotomy.

SPECIFIC TREATMENTS

Preoperative management

- In the past, infants often had overwhelming malnutrition and electrolyte abnormalities.
- In the current era of early diagnosis, infants infrequently progress to this severe state.
- Anatomic correction of PS is not a surgical emergency.
- Although PS is a form of intestinal obstruction, gangrene and intestinal perforation do not occur.
- Infants should not undergo surgery until fluid and electrolyte deficits have been corrected.
- If infants undergo surgery with uncorrected alkalosis, the profound effect that surgical stress has on the urinary excretion of sodium may intensify the electrolyte abnormalities.
- Fluid replacement should include deficit correction and daily maintenance fluids.
 - Continuous maintenance infusion of 5% dextrose in 0.45 normal saline

- Addition of 20 mEq/L potassium chloride once urine output is established
- Repeated boluses of isotonic sodium chloride at 20 mL/kg until a serum chloride level of 100 mEq/L is achieved.
- Nasogastric decompression should be performed during fluid and electrolyte resuscitation.

Surgical management

- Surgical myotomy is a reliable and safe procedure.
- Once the volume and electrolyte status is corrected, the infant is ready for surgery.
- Ramstedt pyloromyotomy through a right upper quadrant transverse incision has been the traditional treatment for hypertrophic PS.
- New alternative methods include:
 - Laparoscopy
 - Shorter mean operative time
 - No increase in complications or costs
 - Circumumbilical approach
 - Earlier data suggested that the circumumbilical approach is associated with greater mean operative time and cost.
 - The only randomized trial shows no difference between the 2 approaches.

Postoperative management

- Postoperative vomiting occurs in most infants.
 - Will usually subside by the 2nd to 5th feeding
- Parental education regarding postoperative vomiting is important before surgery.
- Infants should be fed full-strength formula or breast milk every 3–4 hours starting 6 hours after surgery.
- In case of emesis, infants can be refeed the amount vomited 1 hour later, with resumption of the feeding schedule thereafter.
 - This early refeeding has resulted in a reduction in the postoperative hospital stay.
- Discharge criteria
- Infants are usually discharged 24–48 hours after surgery.
- Feeding tolerance must be reassessed before discharge.

Medical management

- Medical management alone has been largely discarded during the last several decades.
- May be considered as an alternative to pyloromyotomy, particularly in children with major concurrent primary disease
- The anticholinergic agent atropine sulfate has been used with success.
 - Prolongs the duration of hospital stay
 - Studies comparing predominantly oral atropine sulfate with surgical myotomy have reported similar success rates.

WHEN TO ADMIT

- All infants need to be hospitalized to correct electrolyte imbalance and for surgery.

WHEN TO REFER

- All infants with PS should be referred to a surgeon for surgery.

COMPLICATIONS

- Intraoperative and early postoperative complications
 - General
 - Morbidity and mortality from surgical repair
 - Have decreased from 50% to <1%
 - Negligible risk of:
 - Intestinal perforation
 - Hemorrhage
 - Wound dehiscence
 - Postoperative infection
 - Hypoglycemia
 - Reactive hypoglycemia
 - Reported in infants who have a wide variety of medical and surgical conditions
 - May cause respiratory arrest and death
 - Constant infusion of dextrose results in hyperinsulinemia.
 - May result in severe hypoglycemia if suddenly terminated before adequate oral feeding is established.
 - Particularly likely if liver glycogen stores have been depleted, as has been shown in infants with PS
 - Death
 - Mortality is <0.1%.
 - Potential causes of death include:
 - Delayed diagnosis
 - Inadequate preoperative rehydration

- Pulmonary aspiration
- Unrecognized perforation
- Hypoglycemia
- Persistent obstruction
- Hemorrhage
- Presence of other associated congenital anomalies

- Late complications
 - Postoperative obstruction
 - Radiographic evaluation is necessary if vomiting persists beyond 5–7 days.
 - Excessive vomiting may be caused by:
 - Persistent stenosis
 - Gastroesophageal reflux
 - Gastric outlet obstruction
 - Small-bowel obstruction attributable to adhesions
 - Upper GI tract contrast series is difficult to interpret but may be helpful.
 - Narrowing and elongation of the pyloric channel
 - Usually persist for weeks to months after a successful operation, even in infants who have minimal or no postoperative vomiting
 - Subsequent operation may be indicated in the rare event of persistent pyloric obstruction.

PROGNOSIS

- The long-term outcome for patients treated for PS is excellent.
- Rapid gastric emptying and duodenogastric reflux have been identified in some patients who had undergone pyloromyotomy 5–7 years earlier.
 - Other studies have shown no differences between previous patients with PS and controls after long-term follow-up.

Rape

DEFINITION

- *Rape* is a legal term or condition, not a medical diagnosis.
- Every state has statutory definitions of sexual assault and rape.
 - Clinicians should be familiar with the statutes in their local jurisdictions.
- In general, *rape* refers to sexual intercourse:
 - With force or threat of force
 - Without a person's consent
- Sexual intercourse may include:
 - Penile-oral penetration
 - Penile-vaginal penetration
 - Penile-anal penetration
- Threat may be:
 - Overtly physical
 - Verbal
 - Implicit
 - Result of age and power differentials between individuals
- Rape entails an assault acted out sexually, rather than a sexual act per se.
- *Male rape* refers to same-sex rape.
- Statutory rape is defined as sexual activity of an adult with an adolescent under the age of legal consent.

EPIDEMIOLOGY

- Prevalence
 - Estimates of unreported rape range from 40–90%.
 - Many victims never report the crime.
- Age
 - Between 40–60% of all rape victims are <18 years of age.
 - Most are adolescents.
 - Female adolescents aged 16–19 are 4 times more likely to be sexually assaulted than women in all other age groups.
 - Worldwide, estimates indicate that between one-third and two-thirds of rape victims are ≤15 years of age.
 - Exact statistics on adolescent rape are not available.
 - 90% of adolescent rape victims are assaulted by someone they know.
 - >50% of these cases occur on a date.
- Sex
 - Most rape victims are women.
 - 5–10% are men.
- Legal statistics
 - Approximately one-half of all reported rapes in the US eventually lead to arrests.
 - Approximately two-thirds of those arrested are prosecuted.
 - Approximately one-half of those prosecuted are found guilty.

- In other words, for every 100 reported rapes, only 16 perpetrators are convicted.
- Male adolescents constitute a large proportion of convicted rape assailants.
 - 40% of convicted rapists are 16–20 years of age.
 - 25% are 20–24 years of age.
- Stranger rape
 - 15–55% of reported rapes are committed by unknown individuals.
- Date rape
 - Estimates of the incidence of date rape are unclear.
 - One survey of middle and high school students reported a history of unwanted sexual activity on dates in:
 - Nearly 20% of the girls
 - >10% of the boys
 - Surveys of college students report history of date rape by:
 - ~25% of female students
 - 6% of male students
 - None of the college students in these surveys reported the sexual assault to authorities.

ETIOLOGY

Types of rape

Known assailant

- In most reported pediatric rape cases, victim knows the assailant.
 - Parent
 - Stepparent
 - Adult relative
 - Family friend
 - Neighbor
 - Acquaintance
 - Classmate
- Victim–assailant relationship may cause conflicting family or social loyalties.
 - Makes victims less likely to report the rape
- Rape victims who know their assailants are prone to:
 - Self-doubt
 - Self-blame
- When rape is reported, information may be received with skepticism and disbelief.
 - Even by professionals to whom victim turns for help

Stranger rape

- More likely to entail:
 - Threats
 - Use of violence
 - Fear of immediate danger

- Associated with a higher incidence of:
 - Reporting
 - Subsequent conviction of the assailant
- Most likely to occur in areas of:
 - Poverty
 - High crime

Date rape

- In cases of young female adolescents (ages 10–15) and older men, questions arise about:
 - Statutory rape
 - Consent
 - Refusal skills
 - Exploitation
- Least likely type of rape to be reported
- More likely to occur on weekends between 10 PM–1 AM
- Occurs in automobiles or at home of assailant
- May not be reported if the rape was facilitated by the administration of pharmaceuticals (*date rape drugs*) that cause anterograde amnesia
 - γ -Hydroxybutyric acid
 - Flunitrazepam (Rohypnol)
 - Ketamine hydrochloride (Ketamine)
- Important issues for victims include:
 - Long-term issues of trust
 - Self-blame
 - Vulnerability
- Female date rape victim may:
 - Not trust her judgment concerning men
 - Blame herself, erroneously believing that
 - She did not resist clearly.
 - She did not resist convincingly enough.
 - Be ashamed that she ended up in a situation that resulted in rape
- Thoughts of guilt may be reinforced by response and degree of support provided by parents, guardians, friends.
- Secrecy applies to discussing the incident in general, making it difficult to obtain catharsis, verbal support, emotional support.

Gang rape

- Typically involves a group of young men raping a solitary female victim
 - May be associated with:
 - Ritualistic behavior
 - Displaced rage on the part of the assailants
- Issues of sexualized rites of passage apply to:
 - Stereotypical adolescent gangs
 - College fraternities

- Victims of college campus gang rapes are more likely to drop out of college than pursue legal recourse.
 - Avoids confrontation with perpetrators at long-term expense of victims

Male rape

- Remains understudied
- Male rape in institutionalized settings often is attributed to:
 - Displaced heterosexual behavior
 - Undifferentiated sexual orientation
 - Aggressive dominance of a weaker partner
- Male rape outside institutions often occurs through coercion by an individual perceived as an authority figure.
- Relevant issues for the male rape victim
 - Loss of control
 - Depression
 - Anxiety
 - Sleep disturbances
 - Suicidal ideation
- Conflicted sexual identity is common after rape among all male rape victims, whether homosexual or not.
- Male rape victims often are controlled by:
 - Entrapment
 - Intimidation
 - Physical force
 - Combination
- Intimidation is accomplished by:
 - Threats of physical harm
 - Brandishing a weapon
- Male victims often perceive the rape as a life-threatening event.
 - Perception may result in long-term psychological problems.
- Boys and men remain reluctant to report rape.
 - Precludes them from benefits of social support, intervention

Male perpetrators

- Tend to fall into 1 of 3 categories:
 - Anger is the primary dynamic.
 - Power or conquest is the central issue.
 - Sadistic person who finds anger and control erotic.
- Anger-driven rapist
 - Act tends to be impulsive, with the intent of hurting, humiliating, degrading.
 - Physical brutality is common.
 - Rape functions as the outlet for anger, with sex as a weapon.

- Power-oriented rapist
 - Engages in premeditated, obsessive, or stalking behavior
 - Rape compensates for social and sexual incompetence or inadequacy.
 - Aggression is less likely to be violent than a means of domination.
 - Both anger- and power-driven rapists have:
 - Serious deficits in social skills
 - Inability to interpret and respond to social cues
- Sadistic rapist
 - Eroticism and violence are enmeshed.
 - Victims typically subjected to premeditated, deliberate acts of cruelty and dehumanization
 - Sadistic perpetrator finds gratification in victim's pain and powerlessness.
- Some rapists are dysfunctional sexually at time of the rape.
 - Most rapists are sexually active with available, consensual partners outside the rape.
- Perpetrators usually appear ordinary by most standards.
 - Most do not have symptoms of:
 - Major psychiatric illnesses such as psychoses
 - Intellectual disability
 - Characteristics noted more commonly among convicted rapists than in general population:
 - Antisocial
 - Schizoid
 - Paranoid
 - Narcissistic
- Alcohol and drug use have been associated with rape.
 - Alcohol intoxication sometimes seems to have the dual effect of:
 - Diminishing perpetrator's sense of responsibility
 - Increasing victim's culpability
 - Perpetrator's act of rape is excused because he was drinking and not responsible for his actions.
 - Victim intoxication is consistently coupled with the process of *unfounding*, or disproving, rape charges.
 - For date rape victims, having been seen drinking with the perpetrator before the attack has serious implications in relation to public, social, and legal responses to the charges.

RISK FACTORS

- Survivors of prior sexual abuse are at particular risk of revictimization.
- Risk for rape is increased in adolescents who engage in high-risk behaviors, including:
 - Running away
 - Using drugs and alcohol

- Date rape
 - Incidence appears highly correlated with one or both parties drinking or using other drugs.
- Male rape
 - Specific subgroups of young men are at particular risk for sexual abuse:
 - Those in institutionalized settings, such as the criminal justice system
 - Street youth who may engage in prostitution
 - Young male homosexuals who may be runaways
 - Youths who have a parental history of physical or sexual abuse
- Parents who were abused themselves may become abusers as adults.

SIGNS AND SYMPTOMS

History

- History taking necessarily entails asking personal and potentially awkward questions.
 - Patient should be assured of privacy and offered respectful compassion.
 - History should include time, date, and location of both event and examination.
 - Recalling the event may be emotionally traumatic.
 - Beginning with relevant, but relatively neutral, medical history sometimes is useful.
 - Include important information such as:
 - Medical history
 - Physical and behavioral symptoms
 - Menstrual history, including
 - Age of menarche
 - Date of last menstrual period
 - Frequency of menses
 - Sexual activity, if relevant
 - Previous pregnancies, miscarriages, and abortions
 - Use of contraceptives
 - Use of feminine hygiene products
 - Additional history should include:
 - Parental response
 - Fear of parental reaction
 - Risk of running away
 - Past and current suicidal ideation
- Next, focus on event itself.
 - Questions should be asked calmly, with sensitivity and patience.
 - Victim's own words should be recorded whenever possible.

- Medical chart is a legal document.
 - Will be subjected to the same scrutiny as any other form of evidence
 - Only historical facts, without embellishment or interpretation, should be recorded.
 - Patient should be asked about:
 - Use of intoxicating substances before or during event
 - Any loss of consciousness
 - Use of weapons or restraints during the assault
 - Patient should be asked to describe in detail:
 - Location of event
 - Appearance of perpetrator
 - Type of sexual contact
 - Positions used
 - Use of force by perpetrator or by victim
 - Removal of clothing and manner in which it was removed
 - Any measures patient took to cleanse or relieve himself or herself
 - Bathing
 - Douching
 - Changing clothes
 - Urinating
 - Defecating
 - Physician should also ask about:
 - Whether assailant used condom or any other means of contraception
 - Presence of clinical symptoms in:
 - Musculoskeletal system
 - Gastrointestinal system
 - Genitourinary system
- Physical examination**
- Complete physical examination from head to toe is warranted, collecting specimens for forensic and laboratory evaluation.
 - Particular focus should be placed on the evaluation of oral cavity, genitals, anus.
 - 40–60% of sexual assault victims will have no visible physical injuries.
 - Inspection of the entire body may provide corroborative evidence necessary to convict perpetrator.
 - Follow-up examinations may reveal emerging bruising or injuries in areas initially noted to have tenderness or swelling, but no visible bruising.
 - Note patient's:
 - Physical appearance
 - Emotional state
 - If patient is wearing same clothing worn at time of the event:
 - Condition should be noted.
 - Each piece should be saved in a separate, labeled bag.
 - Applying a fluorescent lamp to the clothing and skin may illuminate presence of dried semen.
 - Semen fluoresces best at wavelengths of 420 and 450 nm, when viewed through orange goggles.
 - Specialized alternate light sources that emit wavelengths at 420 and 450 nm, such as a Bluemaxx, should be used.
 - Improves detection of dried semen
 - Many other substances will fluoresce as well.
 - Presence of semen cannot be confirmed with this method.
 - Specimens should be marked for later analysis for presence of seminal vesicle-specific antigen.
 - Topical survey of the body
 - Document any evidence of recent trauma or bruising.
 - Photographs may be useful during subsequent litigation.
 - Use a diagram to indicate locations of visible injuries.
 - Clinician should use fluorescent lamp to:
 - Identify fluorescent areas on the skin
 - Obtain swabs of these areas
 - Give particular attention to the examination of the head and neck.
 - Compression injuries of the neck are common if force is used.
 - This type of injury may lead to obstruction of venous return from the head, causing development of:
 - Neck bruising
 - Petechial hemorrhages in eyelids and conjunctiva
 - Inner surface of lips may have tiny abrasions from forced pressure applied to the mouth to prevent the victim from screaming.
 - Common injuries to mouth include:
 - Torn frenulums
 - Palate petechiae
 - Breasts may show bite marks or bruises.
 - Swab all bite marks to collect genetic markers (ABO group)
 - Photo-document injuries
 - Bite impression may be matched to a potential perpetrator.
 - Perform Tanner staging to determine the victim's level of sexual maturation.
 - Breasts and pubic hair in female patients
 - Genitalia and pubic hair in male patients
- Genital examination: female patient**
- After initial physical examination, patient can be draped and placed in lithotomy position.

- Supine frog-leg position may be a suitable alternative if:
 - Patient seems too anxious.
 - Speculum examination is not required to investigate for source of undiagnosed internal bleeding.
 - Speculum examination is not necessary for younger adolescents or children, unless active vaginal bleeding is present.
 - In rare instances of active vaginal bleeding:
 - It may be necessary to perform the pelvic examination with the patient under sedation or general anesthesia.
 - Pelvic examination should begin with inspection of thighs and perineum for evidence of:
 - Trauma
 - Bruising
 - Semen
 - Blood
 - Take appropriate forensic evidence at this time.
 - Recommended procedures for collecting forensic data
 - Forensic evidence kit
 - Complete forms for authorization and release of evidence, history, and physical examination
 - Individual envelopes to be completed if indicated by history provided
 - Additional tests to strongly consider
 - Pregnancy test
 - Syphilis screening
 - HIV test
 - Cultures for gonorrhea (oral, urethral, vaginal, and anal)
 - Cultures for *Chlamydia* (urethral, vaginal, and anal)
 - Wet mount for detection of *Trichomonas* and spermatozoa
 - General inspection of the external genitalia should be performed, documenting any:
 - Erythema
 - Edema
 - Ecchymosis
 - Abrasions
 - In some cultures, an intact hymen is an important indicator of virginity.
 - Patient and parents will be concerned with its structural integrity.
 - An intact hymen does not rule out the diagnosis of rape.
 - Document any acute injuries to the hymen such as:
 - Bruising
 - Petechiae
 - Acute transactions
 - Describe any active bleeding and the location using clock-face orientation.
 - Entire rim of hymen must be visualized.
 - Proper labial traction along with saline-moistened cotton swab rolled around the edges of the hymen is necessary.
 - Use of light source or application of aqueous toluidine blue (1%) to posterior fourchette may help locate and identify acute tears.
 - Many experts use colposcopy, which provides light source, magnification, photodocumentation of exam.
 - Colposcopy or photodocumentation with a camera is essential.
 - Images can later be evaluated by expert review.
 - Older female adolescents should be able to undergo speculum examination of the internal genitals.
 - Will allow a clear view of:
 - Vaginal walls
 - Fornices
 - Cervix
- Genital examination: male patient**
- Examine thoroughly for the presence of infection or trauma:
 - Testes
 - Epididymis
 - Vas deferens
 - Penile shaft
 - Foreskin
 - Glans penis
- Anal examination**
- History of sodomy in both male and female victims indicates need to conduct thorough anal inspection.
 - Clinician should document any:
 - Erythema
 - Ecchymosis
 - Abrasions
 - Rectal bleeding
 - Aqueous toluidine blue (1%) may be applied to help visualize acute microtrauma to the perianal area.
- DIAGNOSTIC APPROACH**
- Purpose of the initial medical evaluation is 4-fold:
 - Treatment of injury and infection
 - Prevention of pregnancy
 - Collection of evidence
 - Psychological assessment with referral for follow-up counseling

General concepts

- Many metropolitan areas have treatment centers with trained interdisciplinary teams available for adolescent and child victims of rape.
 - These treatment centers are ideal sites for an initial evaluation.
 - An interdisciplinary approach is beneficial for several reasons, including ability to:
 - Provide support to the child and family simultaneously
 - Serve as a resource for future services
- Most pediatric rape victims do not use such specialized facilities.
 - May receive medical evaluations at:
 - Emergency departments
 - Private medical offices
 - To minimize physical and psychological trauma of the evaluation
 - Eliminate need for repeat evaluations
 - Maximize probability of collecting forensic evidence
 - The most skilled professional available should perform the initial evaluation.
 - Gender of examiner is less important than his or her:
 - Comfort with adolescents and children
 - Skill at conducting examination
 - Level of compassion
- Rape evaluation can be long and tedious, but should never be rushed.
 - Young person is coping with:
 - Personal outrage
 - Physical pain
 - Psychological pain
 - Patient is expected to tolerate and cooperate with uncomfortable procedures.
 - May feel similar to acts of intrusion and aggression experienced previously
 - Approach to evaluation should be calm, gentle, private.
- Rape protocols, if available, are helpful.
 - Minimize chance for error or omission in evidence-collection process
 - Most jurisdictions have printed standardized forms for the evidence-procurement process.
 - Available in each state's forensic evidence kit
 - Clinician should become familiar with these forms before examining victim.
- Clinician should avoid making inappropriate assumptions about victim based on her psychological state.
 - Many victims are in a state of shock or denial immediately after event.
 - How a patient responds in emergency department depends on numerous factors, including developmental maturity.
 - Physically mature appearance, but cognitive function at the level of a preadolescent, is not uncommon for a 13-year-old child.
 - Patient's psychological state should not alter the physician's approach to care.
 - Clinician should not attempt to minimize victim's sense of personal guilt, shame, anxiety.
 - Clinician should offer immediate reassurance.
 - Before proceeding with evaluation, take a few minutes to
 - Empathize with patient
 - Acknowledge patient's feelings
 - Establishment of patient safety is crucial.
 - Particularly in cases in which acute trauma may compromise pediatric patient's existing coping skills
 - Clinician should never leave patient alone.
- Take whatever time is necessary at the beginning of the evaluation to explain the process.
 - Allow for questions:
 - Particularly for those who never had previous sexual relationships or prior gynecologic examination
 - More experienced patients may still be anxious and fearful of anticipated pain and discomfort.
 - Whenever possible, clinician should allow patient some control over proceedings.
 - Patient should set pace of examination.
 - Patient should be the one who signals when to begin procedures.
 - If victim becomes visibly agitated, clinician should stop and allow patient to regain composure.
 - At no point, should physician continue to examine a child or adolescent against the patient's will.
- When applicable, make reference to prior experience with similar-aged rape survivors.
 - May establish that the patient is not the only child or adolescent to whom this ordeal has happened
 - Establishes that physician:
 - Is familiar with such circumstances
 - Has some practical knowledge with which to anticipate patient's concerns
- Physician should obtain a detailed and relevant history, followed by a thorough general physical examination (see History).
- Some aspects of evaluation will change depending on temporal proximity of evaluation to event.
 - Modifications are necessary if evaluation is conducted later than 72 hours after the assault.

Summarizing examination

- When the physical examination is complete, give patient time to dress and regain composure.
- It is important to discuss:
 - Physical findings
 - Treatment options
 - Plans for follow-up
- Most patients will benefit from knowing their genital anatomy is normal.
- Several studies have demonstrated that >90% of anogenital examination after rape are normal.

Psychological assessment

- Psychosocial and emotional implications of rape in children and adolescents are complex.
 - Circumstance is tempered further by:
 - Young person's stage of development
 - Family's response
 - Young adolescents just beginning to grapple with their own sexuality may believe they deserved to be raped because they have begun to experience sexual urges.
 - Female child who sees her mother respond with tearful distress may feel guilt because of rape and emotional trauma inflicted on the mother.
- How young person copes with rape is related to how society responds to victims.
 - Unlike most crimes, rape often is blamed on victim rather than on perpetrator, particularly in adolescents.
 - Following no other crime is the victim subject to such scrutiny in regard to:
 - Prior reputation
 - Appearance
 - Behavior
 - Justification for rape may include:
 - Running away
 - Sexual activity
 - Hitchhiking
 - This justification places further blame on an already-troubled young victim.
 - Providers of care must avoid compounding such punitive dynamics.

Response to rape

- Immediate response to rape by the victim
 - May vary considerably, ranging from
 - Distraught histrionics *to*
 - Near-mute withdrawal
 - Most victims have intense levels of fear and anxiety.
 - Post-rape acute phase is characterized by varying levels of:
 - Cognitive disorganization

- Shock
- Disbelief
- As occurs in any crisis, many adolescents regress to previous stages of development.
- An adolescent rape victim who was previously self-assured and appropriately independent may become clinging and dependent on parent or health professional.
- Immediate response by the family
 - Unlike other crime victims, the victim of rape rarely contacts the police immediately.
 - Typically, victim contacts an intermediary (friend or family member) first.
 - Most family and friends need guidance to know how best to support victim.
 - Disclosure of rape usually is traumatic for the family, as well as the victim.
 - Parents may blame themselves inappropriately.
 - Parental activities or neglect may have contributed to the rape.
 - Familial responses to a child's rape range from:
 - Denial and disbelief *to*
 - Shame and outrage
 - No guarantee exists that a family is prepared to respond appropriately to a raped child's needs.
 - In some cases, a victim's mother's financial dependence on a perpetrator may confound reactions.
 - During the initial evaluation session, health care professionals must spend time with the family members and friends of the victim to determine:
 - Their psychological response
 - Their ability to support the victim

LABORATORY FINDINGS

- Recovery of laboratory and forensic data probably is the most controversial aspect of evaluation, especially when recovery of semen and sperm is involved.
 - Finding of male ejaculate is neither predictive nor essential for criminal conviction.
 - In one study, physical evidence of rape was found in only 23% of all of the cases that resulted in felony convictions.
 - Forensic evidence identified in younger victims is more often obtained from
 - Child's clothing
 - Bed linens
- Newest developments in forensic science have occurred in the laboratory analysis of semen, including
 - Demonstration of quantifiable levels of acid phosphatase
 - Positive monoclonal antibody test
 - MH5 enzyme-linked immunosorbent assay (specific for seminal vesicle antigen) in vaginal fluids

TREATMENT APPROACH

Legal issues

- All states have laws that require physicians to report cases involving violent assault, including rape.
 - To report statutory rape, the clinician should be familiar with state's laws regarding:
 - Reporting sexual abuse
 - Legal age of consent
 - Reporting concerns include the possibility that reporting statutory rape can raise barriers preventing adolescents from obtaining appropriate medical care.
 - Clinicians have expressed the desire to use their clinical judgment in reporting cases of sexual activity that fall within the definition of statutory rape.
 - Some states require parental notification of a minor's sexual assault.
 - In those states, this statute overrides issues of confidentiality.
- Most states permit a minor to receive treatment for sexual assault without parental consent.
 - All clinicians must be familiar with local statutes.
 - Health care providers should seek additional guidance from legal counsel, such as:
 - Their state attorney general's office
- Consent for treatment of rape is different from consent for collection of evidence.
 - An adolescent patient above the legal age of consent has the ability to:
 - Consent to a medical evaluation and treatment
 - Refuse collection of forensic evidence
 - Consent to both
 - Many victims are reluctant to give permission because they fear:
 - Social isolation
 - Possible retribution by perpetrator
 - Adolescent victims should be informed that to pursue prosecution in the future, evidence must be collected at this time.
 - Physician must ask adolescent patient for permission to:
 - Complete a full evidentiary examination
 - Release evidence to the police
 - Exceptions are cases identified by state law to be child sexual abuse.
 - Require mandatory reporting to child welfare agency, law enforcement, or both
 - Do not require consent from patient or family to report
- From a medical-legal perspective, physicians must realize that responsibility is limited to the documentation of evidence.
 - Determining whether rape really occurred is a court decision.

- Physician will be of most help to the victim and the authorities by:
 - Presuming victim is telling the truth
 - Thoroughly conducting evaluation
 - Keeping accurate medical records

WHEN TO ADMIT

- Rape victim with significant physical and/or psychological trauma
- If there is concern regarding return of rape victim to unsafe environment

FOLLOW-UP

- After the initial evaluation is complete, arrangements should be made for follow-up care for:
 - Medical issues
 - Assessment of the victim's ability to cope with the rape
 - Counseling concerning the rape
- All rape victims and families should be seen as soon as possible by a mental health professional who is:
 - Trained to work with adolescents
 - Knowledgeable about the emotional sequelae of rape

COMPLICATIONS

Sexually transmitted infection

- Most patients are concerned about risk of acquiring a sexually transmitted infection (STI) as a result of the rape.
 - Risk is related directly to:
 - Health status of the assailant
 - Health status of the victim
 - Site of the assault
 - Infectivity of the disease in question
 - Overall risk of contracting an STI from a single encounter is small.
 - Repeat assaults, or assaults by more than one assailant, increase risk of infection.
 - Many adolescent victims of rape engage in high-risk behaviors that put them at increased risk of having a preexisting STI.
 - As many as 50% of sexual assault survivors do not return for follow-up appointments.
 - Centers for Disease Control and Prevention recommends using prophylactic antibiotics for treating potential sexually acquired infections.
 - Prophylactic hepatitis B vaccination against possible exposure is recommended.
- Regardless of antibiotics given, clinician must emphasize that:
 - Incubation periods for STIs vary.
 - High possibility exists that infection may be present even if not detected.

- STI may be missed or treated inadequately at the time of evaluation examination.
- Baseline studies should be obtained at initial evaluation.
- Medical follow-up is crucial.
- After 2 weeks patient should be reexamined for presence of an STI.
- Serial testing should be performed after the assault in most cases for:
 - Syphilis
 - Human papillomavirus
 - HIV infection

Pregnancy

- Occurrence of pregnancy after rape is strongly influenced by:
 - Whether female patient is in fertile interval of her menstrual cycle
 - Possible sexual dysfunction of the assailant
 - Failure to maintain an erection
 - Failure to ejaculate
 - Many adolescents have irregular menstrual cycles.
 - Occurrence of ovulation for any particular cycle may be in question.
- If assault occurred within 5 days of evaluation:
 - Give pregnancy test to rule out presence of existing pregnancy.
 - Offer emergency contraception.
- Two types of emergency contraceptive are available.
 - Plan B is a progestin-only emergency contraceptive that reduces risk of pregnancy by 89%.
 - Low risk of side effects of nausea or vomiting
 - Second type contains both progestin and estrogen.
 - Most brands of daily oral contraception pill contain both progestin and estrogen.
 - Reduces the risk of pregnancy by 75%
 - Offer antiemetics because of frequent side effects of nausea and vomiting.
- Suspect pregnancy when menses do not occur within 4 weeks of rape.
 - At this point, the patient should return for a repeat evaluation.

Short- and long-term psychological sequelae

- Multiple factors will determine how a child or adolescent responds to the rape, such as:
 - Level of social support
 - Coping styles
 - Strengths
 - Developmental variables
 - Cognitive functions

- Response of any given individual cannot be predicted.
- Psychosocial sequelae of rape often vary according to the type of rape involved.
- Children and adolescents who have been rape victims consistently have:
 - Lower levels of self-esteem after rape than general population
 - Higher levels of precocious sexualization than nontraumatized children
- Confusion may exist about normal adult sexual behavior.
 - Sometimes leads to inappropriate sexual, acting-out behaviors
- Some children experience developmental arrests at the time of trauma.
 - Not necessarily readily apparent
- Child and adolescent studies are too scarce to be considered definitive.
 - Earlier and more traumatic rapes correspond with greater chances of developmental and functional impairment.
- Behavioral concerns frequently associated with adolescent rape sequelae include:
 - School phobias
 - Generalized fearfulness
 - Withdrawal
 - Onset of truancy
 - Suicidal ideations
- Increased lifetime risks of major depression and suicide attempts are associated with women in aftermath of rape.
- For male rape victims existing research is less clear.
 - Male sexual trauma in childhood may be associated with sexually abusive behavior toward other boys during adolescence.
- Not all children and adolescents who have been raped will have psychiatric sequelae.
- All of those who have been raped should be assessed and monitored for serious sequelae.
- In cases in which sexual acting out follows rape, careful clinical attention is required to issues such as:
 - Posttraumatic stress disorder
 - Depression
- Self-medication with various substances is an ongoing clinical hazard after rape.
 - Deserves consideration as a red flag for health care providers working with at-risk patients.

PROGNOSIS

- Date rape
 - Parents' and friends' understanding and support of the victim is a significant prognostic factor for recovery.

Rash

DEFINITION

- Change in the skin due to a variety of possible conditions, which can have a wide variety of appearances

EPIDEMIOLOGY

- 10–20% of visits by children to outpatient facilities are associated with a dermatologic problem.

HISTORY

- Diagnosis of skin lesions relies heavily on physical examination and the recognition of types of lesions, but an appropriate, problem-oriented history is first step in diagnosis.
- Sample questions to ask the patient
 - *When did the rash begin? Has it gotten better or worse? Has it occurred in the past?*
 - Such conditions as atopic dermatitis are chronic and recurrent.
 - Others, such as viral exanthems (eg, erythema infectiosum), are acute and self-limited.
 - *Are there associated symptoms?*
 - Generalized erythematous macular eruption associated with fever, nasal congestion, and cough suggests presence of a viral exanthem.
 - Fever, petechiae, and purpura in an ill-appearing child may indicate serious bacterial infection, such as meningococcemia.
 - Atopic dermatitis, contact dermatitis, and scabies characteristically produce pruritus.
 - *Are any medications being taken?*
 - Wheals in a child receiving an oral antibiotic might represent urticaria due to drug allergy.
 - Lithium can worsen acne.
 - Minocycline may cause hyperpigmentation.
 - Neomycin (used in certain topical antibiotic preparations), diphenhydramine (used to reduce pruritus), and certain anesthetics (used to reduce pain or pruritus), applied topically, may induce contact dermatitis.
 - *Are there factors that worsen or precipitate the rash?*
 - Malar rash of systemic lupus erythematosus is worsened by sun exposure.
 - For many with atopic dermatitis, reduced humidity during colder months is associated with exacerbation of disease.
 - *What treatment has been tried, and what was its effect?*
 - Example: Treatment for head lice may fail if product is applied incorrectly or left on the scalp for an insufficient period.
 - Repeating a therapy is unwise if it was used correctly but proved ineffective.
- *Is there a family history of skin disease or other health problems?*
 - Children with atopic dermatitis often have history of atopic disease, including atopic dermatitis, allergic rhinitis, or asthma.
 - If a child has multiple café-au-lait macules (see Figure 74 on page F26) and a diagnosis of neurofibromatosis type 1 is considered, determination of affected first-degree relatives is vital.
 - Whether other family members are similarly affected is relevant if cutaneous infections or infestations suspected.
 - Impetigo, tinea capitis, scabies, and head lice are frequently transmitted within families.
- For adolescents, in particular, the social history may be relevant.
 - *Do you work after school?*
 - Occupational exposure to greases or oils (eg, in a fast-food restaurant or car repair shop) may worsen acne.
 - *Have you ever been involved in a sexual relationship?*
 - Secondary syphilis and disseminated gonococcal infection, for example, have cutaneous manifestations.
 - Molluscum contagiosum, pubic lice, and scabies may be transmitted through sexual contact.

PHYSICAL EXAM

- Recognizing and describing skin lesions accurately are essential to diagnosis.
- Identify the primary lesion, the earliest and most characteristic of the disease.
- Note the distribution, arrangement, and color of primary lesions, along with any secondary changes.
- Types of primary lesions
 - Flat lesions include macules and patches.
 - Macule: small, circumscribed area of color change without elevation or depression
 - Patch: large macule
 - Elevated lesions may be solid or fluid filled.
 - Solid lesions
 - Papules (<0.5 cm in diameter)
 - Nodules (≥0.5 cm in diameter)
 - Wheals: pink, rounded, or flat-topped elevation caused by edema in the skin
 - Plaques: plateau-shaped structures often formed by the coalescence of papules
 - Elevated fluid-filled lesions
 - Vesicles (<0.5 cm in diameter and filled with serous fluid)
 - Bullae (≥0.5 cm in diameter and filled with serous fluid)

- Pustules (<0.5 cm in diameter and filled with purulent material)
 - Cysts (≥0.5 cm in diameter that represent sacs containing fluid or semisolid material)
- Depressed lesions
 - Erosions: superficial loss of epidermis with a moist base
 - Ulcers: a deeper lesion extending into or below the dermis
- Distribution
 - Certain disorders have unique patterns of distribution; noting the parts of the body involved helps with diagnosis.
 - Seborrheic dermatitis commonly involves the scalp, eyebrows, and nasolabial folds.
 - Psoriasis (see Figure 75 on page F26) affects the scalp and areas that are traumatized (elbows and knees).
 - Acne is limited to the face, back, and chest.
 - Lesions may appear in lines.
 - Vesicles in contact dermatitis from poison ivy (see Figure 76 on page F26)
 - Groups or clusters of lesions
 - Vesicles in herpes simplex virus infection (see Figure 77 on page F26)
 - Lesions that follow a dermatome
 - Vesicles in herpes zoster (see Figure 78 on page F27)
 - Lesions forming an annulus or ring
 - Papules in granuloma annulare
 - Patch in erythema migrans
- Color
 - Skin colored
 - Erythematous (pink or red)
 - If erythrocytes are within vessels (as occurs in urticaria, for example), compression of the skin forces the cells into deeper vessels, and blanching occurs.
 - If cells are outside vessels, as in forms of vasculitis, blanching will not occur.
 - Petechiae
 - Purpura
 - Ecchymoses
 - Hyperpigmented (tan, brown, or black)
 - Hypopigmented (pigment is decreased but not entirely absent)
 - Depigmented (all pigment is absent, as in vitiligo)
 - Violaceous
- Secondary changes
 - Crusting (dried fluid)
 - Commonly seen after the rupture of vesicles or bullae (eg, honey-colored crust of impetigo)

- Scaling
 - Fungal infections (eg, tinea corporis) (see Figure 79 on page F27)
 - Psoriasis
- Atrophy
 - Surface depression from absence of dermis or subcutaneous fat
 - Appears thin and wrinkled
- Lichenification
 - Thickening of the skin from chronic rubbing or scratching (eg, as in atopic dermatitis).

DIFFERENTIAL DIAGNOSIS

- The diagnostic approach is best based on the morphology of the patient's lesions.
 - Appropriate history and accurate description of what is seen usually overcomes obstacles to diagnosis.
