Foreword

Medical knowledge is expanding so rapidly that busy pediatricians may find it difficult to keep up in their daily practice. *American Academy of Pediatrics Quick Reference Guide to Pediatric Care* is the go-to reference for pediatricians and their busy schedules, providing them with the information they need while seeing patients or between appointments without having to sift through paragraphs of information.

This trusted resource contains the entire Point-of-Care Quick Reference—over 240 topics—from the American Academy of Pediatrics online resource *Pediatric Care Online* at www.pediatriccareonline.org. Succinctly displayed in a bulleted format, the content covers key aspects of pediatric care: disease prevention, screening, treatment, signs and symptoms, emotional and behavioral problems, specific clinical problems, and critical situations.

In addition, 32 pages of more than 90 color images, algorithms, and graphs further enhance many of the topics, such as cardiac arrhythmias, neurocutaneous syndromes, ocular trauma, dizziness and vertigo, hematuria, preventive cardiology, and shock.

To further aid in decision-making at the point of care, the appendix houses more than 80 tools that pediatricians need most when seeing patients: formulas, reference range values, and growth charts, as well as tables for development, feeding and nutrition, immunization, medications, and obesity to name just a few.

The content in this publication was culled from the following best-selling AAP resources:

Pediatric Care Online

American Academy of Pediatrics Textbook of Pediatric Care

Red Book: 2009 Report of the Committee on Infectious Diseases, 28th Edition

Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents, 3rd Edition

Pediatric Nutrition Handbook

It is our hope that *American Academy of Pediatrics Quick Reference Guide to Pediatric Care* will be the standard point-of-care reference for pediatricians, pediatric residents, and medical students alike as they strive to provide the best care possible for infants, children, adolescents, and young adults.

Section 1

Topics

Abdominal Distention

DEFINITION

- Distention of abdomen may be from either normal causes or pathologic processes.
- Healthy infants may have variable degrees of abdominal distention caused by:
 - Aerophagia during feeding
 - Crying
 - Transient constipation
- Distention in healthy toddlers may result from:
 - Lumbar lordosis
 - Hypotonia of the abdominal rectus muscles
- Nonpathologic distention may exceed the mild distention seen with some intraabdominal cancers.

MECHANISM

- Abdominal distention may occur in:
 - Healthy infants (frequently) and children
 - Newborns and children who have intestinal obstruction
 - Infants and children who have systemic conditions
- Multiple underlying mechanisms can result in abdominal distention.
- Tympanitic distention results from accumulation of air/gas, either intraluminal or extraluminal.
 - Air swallowing (aerophagia)
 - Constipation
 - Gastrointestinal (GI) ileus
 - Gastrointestinal obstruction
 - Malabsorption
 - Peritonitis
 - Pneumoperitoneum
 - Pneumomediastinum (children on respirators)
- Distention from an intraabdominal mass
 - Constipation
 - Renal
 - Adrenal
 - Hepatic
 - Splenic/lymphatic
 - GI
 - Mesenteric/omental
 - Genitourinary (uterine, ovarian, vaginal)
- Distention from ascites
 - Urinary
 - Cardiac
 - Hepatic
 - Biliary/GI

- Chylous
- Idiopathic

- Distention from abdominal wall hypotonia
 - Generalized neuromuscular hypotonia
 - Rickets
 - Hypothyroidism

HISTORY

- Newborns
 - Pregnancy history of mother
 - Oligohydramnios suggests distal urinary obstruction.
 - Polyhydramnios is seen with upper GI obstruction.
- Older infants and children
 - History should establish duration and pattern of the child's distention.
 - Intermittent distention suggests intermittent GI obstruction.
 - Progressive distention suggests:
 - Intraabdominal tumor
 - Progressive hepatosplenomegaly
 - Ascites
 - The primary care physician must be careful to differentiate a parent's question about whether a toddler's potbelly is normal from reports of progressive or marked distention, or palpable abdominal mass.
 - Comprehensive medical and surgical history and review of systems is warranted.
 - Medication use, including herbal and alternative therapies, with particular attention to agents that can cause GI ileus and constipation
 - Family history should include questions about:
 - Cystic fibrosis (meconium ileus)
 - Polycystic kidney disease
 - Metabolic diseases
 - History of fetal death or early neonatal deaths that might indicate unrecognized metabolic disease, which might produce hepatomegaly, splenomegaly, and congenital ascites
 - Although rare, the presence of inherited syndromes that predispose a child to an intraabdominal cancer should be elicited.
 - In Wilms tumor, these include the WAGR syndrome (Wilms tumor, aniridia, genitourinary anomalies, and mental retardation), Denys-Drash syndrome, and Beckwith-Wiedemann syndrome.
 - Incidence of hepatoblastoma and adrenal carcinoma is increased in children with Beckwith-Wiedemann syndrome.
 - Children with DNA fragility syndromes and immunodeficient states are at risk for lymphoma and leukemia.

- In all female adolescents who have abdominal distention
 - A confidential history of sexual activity
 - History of the onset of puberty and menarche
- The symptoms below suggest cancer, but their absence does not exclude it.
 - Fever
 - Weight loss
 - Failure to thrive
 - Anorexia
 - Fatigue
 - Irritability
 - Bone pain
- A systematic review of symptoms referable to the intra-abdominal organs should be done.
 - Gastrointestinal obstruction
 - Vomiting
 - Pain
 - Obstipation
 - Delayed passage of meconium at birth
 - Malabsorption
 - Diarrhea
 - Greasy, bulky, malodorous stools
 - Occult hydronephrosis: possible presentations in older infants and children
 - Recurrent fever from urinary tract infection (often misdiagnosed as viral illness or otitis media)
 - Gross hematuria after minor trauma
 - Voiding difficulty in boys with posterior urethral valves

PHYSICAL EXAM

- Inspect the profile of the abdomen with the child in a supine position.
 - Note whether distention is generalized (maximal at the umbilicus) or localized.
 - Pattern and prominence of the abdominal veins should be noted.
 - Prominent superficial veins may indicate portal hypertension or obstruction to the systemic venous return.
- Imperforate anus or an incarcerated hernia will be apparent.
 - Differentiation of remaining causes of lower intestinal obstruction involves radiographic evaluation.
- Steatorrhea and growth failure with muscle wasting (a thin-limbed child with a bloated abdomen) may be associated with tympanitic distention from:
 - Fat malabsorption syndrome
 - Cystic fibrosis
 - Celiac disease
- Abdomen should be auscultated for:
 - Hyperactive bowel sounds
 - Malabsorption
 - Acute obstruction
 - Rushes
 - Incomplete obstruction
 - Absence of sounds
 - Paralytic ileus
 - Bruits
 - Vascular malformation
 - Percussion can be used to:
 - Differentiate diffuse from more focal epigastric tympani
 - Identify shifting dullness in older children
- Palpate gently for mass and tenderness.
 - Begin from the lower quadrants and progress upward so that the inferior edge of the liver and spleen are appreciated.
 - Abdomen should be assessed for focal or generalized tenderness.
 - Involuntary guarding on gentle palpation is a sensitive sign of peritoneal inflammation.
 - Rebound tenderness in young children is often falsely positive.
 - If an abdominal mass is appreciated, note:
 - Location (see list below)
 - Whether painful
 - If mobile: intraabdominal
 - If nonmobile: retroperitoneal/malignant
 - If moves with respiration: liver and spleen
 - If cystic, solid, malleable: fecal masses
 - If smooth or nodular, and whether crossing the midline: often seen with neuroblastoma
 - Renal ballotement
 - Lifting the kidney anteriorly with a finger in the costo-vertebral angle while palpating with the other hand can help elicit and define features of masses in the flank.
 - Rectal examination properly done can add considerable information to evaluation of:
 - Constipation
 - Anal stenosis
 - Hirschsprung disease
 - Pelvic mass
 - Hydronephrosis may manifest initially as an asymptomatic flank mass in the newborn.

- Signs of ascites
 - Infants: bilateral bulging flanks in the supine position
 - Older children: may detect shifting dullness and a fluid wave
 - Acquired umbilical hernia may indicate massive ascites.

- Genital examination

- In girls, to exclude imperforate hymen with hydrometrocolpos, hematocolpos, and pregnancy
- In both sexes, lower genitourinary tract malformation raises the question of upper genitourinary tract malformation.

DIFFERENTIAL DIAGNOSIS

Tympanitic abdomen in the newborn and infant

- In healthy newborns, aerophagia is common.
- An ill newborn with paralytic intestinal ileus characterized by quiet, nontender abdominal distention may have:
 - Sepsis
 - Birth asphyxia
 - Hypothyroidism
 - Electrolyte imbalance
 - Pneumonia or respiratory distress from aerophagia
- Necrotizing enterocolitis is the most common cause of acquired abdominal distention in premature infants.
- Upper GI obstruction
 - Atresias
 - Annular pancreas
 - Malrotation
- Lower GI obstruction
 - Atresias
 - Meconium ileus
 - Hirschsprung disease
 - Small left colon syndrome
 - Anorectal malformations
 - Incarcerated inguinal hernia

Tympanitic abdomen beyond the newborn period

- Constipation
- GI obstruction
 - Intraluminal
 - Pyloric stenosis
 - Intussusception
 - Bezoar
 - Meconium ileus equivalent
 - Intestinal polyps
 - Parasites (ascariasis)
 - Intrinsic tumors

- Extraluminal
 - Postoperative adhesions
 - Appendiceal abscess
 - Meckel diverticulum
 - Abdominal or pelvic mass causing compression
 - Incarcerated hernia
- Paralytic ileus
 - Abdominal surgery
 - Peritonitis
 - Trauma
 - Shock
 - Sepsis
 - Hypokalemia
 - Medication/anesthesia reaction
- Fat malabsorption syndrome
- Cystic fibrosis
- Celiac disease

Palpable mass in the newborn and infant

- Renal or urinary tract masses account for two-thirds of neonatal abdominal masses.
 - Multicystic kidney
 - Hydronephrosis
 - Polycystic kidney disease
 - Renal vein thrombosis
 - Mesoblastic nephroma
- GI duplications
- Neuroblastoma
- Hydrometrocolpos
- Hematomas from birth trauma
 - Adrenal, hepatic, splenic
- Cysts
 - Choledochal, mesenteric, ovarian, splenic, urachal

Palpable mass beyond the newborn period

- Fecal masses from constipation
- Late presentations of congenital masses
 - Duplications
 - Mesenteric cysts
 - Choledochal cysts
 - Hematocolpos
- Cancer
 - Wilms tumor
 - Neuroblastoma
 - Hepatoblastoma
 - Ovarian tumors
 - Lymphoma (non-Hodgkin)

- Bezoars
- Pancreatic pseudocysts

Ascites in the newborn and infant

- Perforation in an obstructed urinary tract
 - Posterior urethral valves
- Congestive heart failure
- Liver disease
 - Congenital infection
 - Galactosemia
 - Lysosomal storage disease
- Chylous ascites from malformation or perforation of intestinal lymphatics
- Idiopathic

Ascites beyond the newborn period

- Most commonly, a consequence of chronic liver disease with cirrhosis and portal hypertension

Abdominal wall hypotonia

- Generalized hypotonia from neuromuscular disease
- Rickets
- Hypothyroidism

Peritonitis

- GI perforation
- Bacterial peritonitis
- Chemical peritonitis

Causes of distention, by location

- Epigastrium
 - Duodenal atresia
 - Pyloric stenosis
 - Malrotation
 - Gastric duplication
 - Bezoar (mass of eaten hair; usually due to a psychological disorder)
- Flank
 - Wilms tumor
 - Hydronephrosis
 - Multicystic kidney
 - Polycystic kidney
 - Neuroblastoma
 - Renal vein thrombosis
 - Adrenal hemorrhage
- Right upper quadrant
 - Choledochal cyst
 - Hepatomegaly
 - Hepatic tumors
 - Acute hydrops of the gallbladder

- Left upper quadrant
 - Splenomegaly
 - Splenic cyst
- Right lower quadrant
 - Ovarian mass
 - Intussusception
 - Appendiceal abscess
 - Crohn disease
 - Fecal mass
- Left lower quadrant
 - Ovarian mass
 - Fecal mass
- Hypogastrium
 - Hydrometrocolpos
 - Hematocolpos
 - Fecal mass
 - Presacral teratoma
 - Obstructed bladder
 - Urachal cyst

IMAGING

- Although history and physical examination may allow diagnosis, many children require radiographic imaging.
 - Choice of initial imaging technique is dictated by clinical suspicion and locally available resources and expertise.
 - Consulting with radiologist is helpful.
- In questionable cases, plain-film radiographs can confirm fecal mass; reexamination is indicated after laxative therapy to confirm that the masses are no longer present.
- Definitive radiographic evidence of necrotizing enterocolitis includes:
 - Pneumatosis intestinalis
 - Gas visible in the portal venous system of the liver

TREATMENT APPROACH

- Treating the underlying cause is the treatment for abdominal distention.

SPECIFIC TREATMENT

- Transient generalized distention due to aerophagia responds to changes in feeding technique and burping and in consoling techniques for the crying infant.

WHEN TO REFER

- Refer a child with abdominal distention to appropriate consultant if the child has:
 - Refractory vomiting
 - Moderate or severe pain that is undiagnosed

- Mass suspicious for cancer
- Urgent need for surgical or radiologic procedures

WHEN TO ADMIT

- Admit a child with abdominal distention if he or she has:
 - Refractory vomiting or dehydration
 - Peritonitis
 - Toxic or septic appearance
 - Moderate or severe pain that is undiagnosed or not well controlled
 - Mass suspicious for cancer
 - Urgent need for surgical or radiologic procedures

COMPLICATIONS

- Complications depend on the underlying cause of abdominal distention and are usually associated with delay in diagnosis and treatment.

PROGNOSIS

- Prognosis depends on the underlying cause of abdominal distention.

Abdominal Pain

DEFINITION

- Abdominal pain is defined as pain perceived to be in the area of the abdomen (between the thorax and pelvis).
- Recurrent abdominal pain is pain that occurs ≥ 3 times over ≥ 3 months that is severe enough to affect daily activities in children >3 years of age.

EPIDEMIOLOGY

- Abdominal pain is one of the most common symptoms in children and adolescents.
 - Incidence
 - Estimated to account for $\sim 5\%$ of unscheduled office visits
 - Each year, 4 of 1000 children undergo surgery for suspected appendicitis.
 - Prevalence
 - The precise number of children who experience acute abdominal pain is unknown.
 - For recurrent abdominal pain
 - The prevalence is estimated at 0.3–19%, although some large studies suggest 0.3–8%.
 - Higher prevalence in girls, children between 4 and 6 years of age, and in early adolescence

MECHANISM

- The mechanism for abdominal pain depends on its cause.
 - In pancreatitis, injury of the acinar cells and the premature activation of trypsinogen to trypsin in the pancreas caused by obstruction of ductal flow (in most cases) precipitate an aggressive immune response.
 - In marked contrast to adults, the causes of acute pancreatitis in children are:
 - Idiopathic causes
 - Trauma
 - Structural anomalies
 - Multisystem disease
 - Drugs and toxins
 - Viral infections
 - Hereditary causes
 - Metabolic disorders (eg, hyperlipidemia, hypercalcemia)

HISTORY

Description of pain: OLD CAR

- Onset/precipitating event (eg, trauma)
- Location (eg, quadrant, periumbilical)
 - Abdominal pain may be referred (eg, the cause is outside the abdomen).
 - For example, lower-lobe pneumonias may cause inflammatory irritation of the diaphragm, resulting in acute abdominal pain as the presenting symptom.

- Pathology in the abdomen may also refer pain to other locations (eg, irritation of diaphragm may refer pain to shoulder area).

- Duration (eg, continuous, variable, specific time of day only, frequency)
- Character: nature, quality, severity (eg, sharp, tearing, dull, severe enough to awaken from sleep)
- Associated factors that improve or worsen (eg, activities, relationship to meals, relationship to breathing)
- Radiating pattern of pain
- Timing of onset and changes in intensity, location, and quality of pain over time may provide vital clues to diagnosis.
- If pain is recurrent, also consider
 - Timing of the onset of the pain in relation to other events (eg, mealtime, school)
 - Frequency of recurrence and duration of episodes
- Review of systems
 - Alarming symptoms or signs suggest a higher probability or prevalence of organic disease; these include:
 - Involuntary weight loss
 - Deceleration of linear growth
 - Gastrointestinal blood loss
 - Significant vomiting, bloody or bilious vomiting
 - Chronic severe diarrhea
 - Persistent right upper or right lower quadrant pain
 - Unexplained fever
 - Cardiopulmonary review (eg, dyspnea, tachypnea, color changes)
 - Gastrointestinal review (eg, number of bowel movements, frequency, consistency; color; whether blood is present)
 - Genitourinary review (eg, dysuria, hematuria, observed stones)
 - Neuropsychiatric review
 - Children with recurrent abdominal pain are more likely to have headache, joint pain, anorexia, vomiting, nausea, excessive gas, and altered bowel symptoms.

Medical and family history

- Trauma
- Toxin exposures, medications, diet history
- Environmental or behavioral factors (recent changes in family or school, travel, new foods)
- Sick contacts/exposure to illness, exposure to animals
- Previous abdominal surgeries
- Previous weights and growth pattern
- Family or personal history of celiac disease, inflammatory bowel disease, inherited disorders, endocrine disorders, chronic pain disorders

- For girls, obtain menstruation, gynecologic, and sexual histories.
 - Age at onset of menstruation
 - Bleeding frequency, duration, regularity, amount (number of pads/tampons and saturation)
 - Dates of previous menses
 - Concurrent symptoms (bloating, cramping, headaches)
 - Vaginal bleeding or discharge, history of tampon retention
- Perinatal history
 - Was stool passed within the first 24 hours

Personal and lifestyle factors

- Detailed discussions of personal lifestyle factors, especially in adolescents, may be conducted ideally without others present.
 - HEADSSS assessment
 - Home
 - Education
 - Activities
 - Drugs
 - Suicide/depression
 - Sexuality
 - Safety
 - The patient must feel comfortable discussing his or her own symptoms and concerns, even if different from those expressed by parents.
 - Assess parental expectations: The parents may want to relate some of their concerns without the child being present.

PHYSICAL EXAM

- Vital signs and anthropomorphic characteristics
 - Temperature (febrile or not)
 - Respiratory rate, oxygen saturation
 - Pain may elevate the heart rate and blood pressure.
 - Evaluate hydration status and consider orthostatic vital signs as appropriate.
 - Measure height/stature and weight; plot measurements on standardized charts.
 - Growth failure may be consistent with inflammatory bowel disease or cystic fibrosis.
- Physical examination
 - A complete physical examination is indicated.
 - Abdominal examination
 - Assess cooperation of the patient and whether the patient is distractable.
 - Palpate 4 quadrants, flank, and costovertebral angles.
 - Assess for guarding and rebound.
 - Auscultate.

- In infants, examine the umbilicus and periumbilical area for discoloration and signs of infection.
- Consider psoas and obdurator testing if there is clinical suspicion of appendicitis or peritonitis.
- Cardiopulmonary examination
- Genitourinary examination, including urethra
 - In males, examine the scrotum and inguinal canals.
 - In females, perform external examination of the vaginal orifice; consider gynecologic examination as indicated.
- Rectal examination
- Assess for rashes and bruises (eg, palpable purpura on buttocks and lower extremities, abdominal bruising indicative of handlebar injury)
- Pancreatitis
 - Patients usually lie still because movement intensifies pain.
 - Examination of the abdomen may reveal decreased bowel sounds, guarding, and rebound tenderness.
 - The Gray Turner and Cullen signs—discoloration of the flanks and umbilicus, respectively—are typical of hemorrhagic pancreatitis, but are seldom present in children.

DIFFERENTIAL DIAGNOSIS

- Abdominal pain has a very broad differential diagnosis.

Acute abdominal pain

- Main causes of acute abdominal pain, by age
 - Neonate
 - Necrotizing enterocolitis
 - Spontaneous gastric perforation
 - Hirschsprung disease
 - Meconium ileus
 - Intestinal atresia or stenosis
 - Peritonitis owing to gastroschisis or ruptured omphalocele
 - Traumatic perforation of viscus (difficult birth)
 - Infant (<2 years)
 - Colic (<3 months)
 - Acute gastroenteritis or viral syndrome
 - Traumatic perforation of viscus (child abuse)
 - Intussusception
 - Incarcerated hernia
 - Volvulus (malrotation)
 - Sickling syndromes
 - School age
 - Acute gastroenteritis or viral syndrome
 - Urinary tract infection
 - Appendicitis

- Trauma
- Constipation
- Pneumonia
- Sickling syndromes
- Adolescent
 - Acute gastroenteritis or viral syndrome
 - Urinary tract infection
 - Appendicitis
 - Trauma
 - Constipation
 - Pelvic inflammatory disease
 - Pneumonia
 - Mittelschmerz
 - Pregnancy
 - Other gynecologic issues (dysmenorrhea, tubo-ovarian abscess)
- A rare cause of abdominal pain in children and adolescents is pancreatitis.
 - Abdominal pain is present in nearly all patients with pancreatitis and may be of sudden onset or insidious.
 - The most common location of pain is the epigastrium, but it can occur in the right or the left upper quadrant.
 - Often accompanied by vomiting, anorexia, and nausea, with food often aggravating the pain and vomiting.
- Recurrent abdominal pain**
- Normal examination and the absence of alarm signals point toward a functional diagnosis for abdominal pain.
- Studies have shown associations between recurrent abdominal pain and:
 - Family dynamics (eg, children living in a single-parent household are more likely to experience recurrent abdominal pain)
 - Psychological comorbidity (eg, anxiety)
 - Socioeconomic status
 - Children living in low-income, low-educated–worker families were more likely to experience pain.
- Differential diagnosis, by related symptoms/causes
 - Upper gastrointestinal inflammation
 - Gastroesophageal reflux disease
 - Peptic ulcer
 - *Helicobacter pylori* gastritis
 - Nonsteroidal antiinflammatory drug ulcer
 - Crohn disease
 - Eosinophilic gastroenteritis
 - Ménétrier disease
 - Cytomegalovirus gastritis
 - Parasitic infection (*Giardia*, *Blastocystis hominis*)
 - Varioliform gastritis
 - Lymphocytic gastritis or celiac disease
 - Henoch-Schönlein purpura
 - Altered bowel pattern
 - Idiopathic inflammatory bowel disorders
 - Ulcerative colitis
 - Crohn disease
 - Microscopic colitis with crypt distortion
 - Lymphocytic colitis
 - Collagenous colitis
 - Infectious disorders
 - Parasitic (*Giardia*, *Blastocystis hominis*, *Dientamoeba fragilis*)
 - Bacterial (*Clostridium difficile*, *Yersinia*, *Campylobacter*, tuberculosis)
 - Lactose intolerance
 - Complication of constipation—megacolon, encopresis, intermittent sigmoid volvulus
 - Drug-induced diarrhea, constipation
 - Gynecologic disorders
 - Neoplasia (lymphoma, carcinoma)
 - Psychiatric disorder
 - Isolated paroxysmal abdominal pain
 - Obstructive disorders
 - Crohn disease
 - Malrotation with or without volvulus
 - Intussusception with lead point
 - Postsurgical adhesions
 - Small-bowel lymphoma
 - Endometriosis
 - Infection (tuberculosis, *Yersinia*)
 - Vascular disorders
 - Eosinophilic gastroenteritis
 - Angioneurotic edema
 - Appendiceal colic
 - Dysmenorrhea
 - Musculoskeletal disorders
 - Uteropelvic junction obstruction
 - Abdominal migraine
 - Acute intermittent porphyria
 - Mental disorders (factitious disorder, conversion reaction, somatization disorder, school phobia)
 - Functional abdominal pain

- Motility disorders
 - Idiopathic gastroparesis
 - Biliary dyskinesia
 - Intestinal pseudo-obstruction
- Other
 - Obstructive disorders
 - Chronic pancreatitis
 - Chronic hepatitis
 - Chronic cholecystitis
 - Ureteropelvic junction obstruction
 - Abdominal migraine
 - Psychiatric disorder

LABORATORY EVALUATION

- Do not delay consultation for studies if surgical abdomen is suspected.
- Evaluation is guided by clinical suspicion.
- When history and physical examination indicate a dysfunctional or psychogenic cause, urinalysis should suffice as the initial laboratory study.
- Studies may include:
 - Pregnancy test for young women, especially if abdominal imaging is being considered
 - Complete blood cell count with differential
 - Serum chemistries or comprehensive metabolic panel
 - Urinalysis, urine culture
 - Stool hemocult (guaiac)
 - Erythrocyte sedimentation rate
 - Erythrocyte smear and hemoglobin electrophoresis
 - Purified protein derivative testing for tuberculosis
 - Tests for sexually transmitted diseases
 - In patients with diarrhea:
 - Stool ova and parasite
 - Stool culture
 - *Giardia* enzyme-linked immunosorbent assay
 - *Clostridium difficile* toxin
 - Celiac panel
 - Lactose breath test
 - In patients with dyspepsia:
 - *Helicobacter pylori* serologic test
 - When hepatitis is suspected, or if direct hyperbilirubinemia is evident:
 - Liver enzymes, liver function tests
 - When pancreatitis is suspected:
 - Serum amylase and lipase
 - A >3-fold lipase increase is considered consistent with pancreatitis.

IMAGING

- Imaging is guided by clinical suspicion.
 - Early diagnosis of the acute abdomen may often be made solely on clinical grounds, and imaging may not always be indicated.
 - Before abdominal imaging in young women, pregnancy status should be determined.
 - In general, the physician should consider least invasive procedures first, keeping in mind the cost of special studies in terms of pain, discomfort, and time.
- Abdominal radiographs (kidneys, ureter, and bladder)
 - May help to identify distended bowel, bowel obstruction, constipation/fecal impaction, fecaliths (associated with appendicitis), pneumonia
- Abdominal computed tomography
 - May help to identify appendicitis, peritonitis, or other anatomical pathology
- Abdominal and pelvic ultrasonography
 - Safe, noninvasive ways to assess bowel and pelvic organ structures
 - Help clarify the need for urgent surgical intervention (eg, intussusception, ovarian torsion, testicular torsion, kidney abscess)
 - May be operator dependent
 - For pancreatitis:
 - Specificity of approximately 62–67%
 - Most sensitive of available methods to appraise biliary tract for evidence of the cause of acute pancreatitis
 - Indicated when the patient has a history of major blunt trauma to stage severe pancreatitis
 - To assess for substantiation of necrosis, which is often not noted for 48–72 hours after onset
 - To learn whether noteworthy intraabdominal complications are present
- Upper gastrointestinal series
 - Should be considered in patients with recurrent vomiting to define potential anatomic abnormalities, such as gastric outlet disorder or malrotation

DIAGNOSTIC PROCEDURES

- Additional procedures can be performed as guided by clinical suspicion (eg, endoscopy and biopsy).

TREATMENT APPROACH

- In the case of acute abdominal pain, early surgical consultation should be obtained as necessary.
 - Intervention may be indicated even if imaging studies have not been obtained.
 - If a diagnosis is made, treatment is aimed at the underlying disease entity.

SPECIFIC TREATMENT

- The treatment approach for acute and functional abdominal pain are quite different.

Treatment categories for acute abdominal pain

- Acute surgical issue (manage with early surgical consultation and operative correction)
 - Closed loop intestinal obstruction
 - Volvulus (gastric, midgut, sigmoid)
 - Incarcerated hernia (inguinal, internal, external)
 - High-grade bowel obstruction
 - Nonreducible intussusception
 - Malrotation with Ladd bands
 - Ovarian torsion
 - Testicular torsion
 - Acute appendicitis
 - Perforated viscus with diffuse peritonitis or toxicity
 - Ruptured tumor
 - Ectopic pregnancy
 - Trauma, especially if the patient is not hemodynamically stable
- Acute abdominal pain that may require a combined surgical and medical approach
 - Partial small-bowel obstruction
 - Postsurgical adhesions
 - Crohn disease
 - Lymphoma
 - Periappendiceal abscess
 - Abdominal/peritoneal abscess
 - Cholecystitis
 - Gallbladder hydrops
 - Pancreatitis
 - Pancreatic pseudocyst
 - Toxic megacolon or typhlitis
 - Gynecologic issues (such as a stable patient with a tubo-ovarian abscess)
- Acute abdominal pain to be managed medically and/or supportively
 - Pregnancy
 - Upper respiratory tract infection, pharyngitis
 - Pneumonia
 - Viral gastroenteritis, acute gastritis
 - Mesenteric adenitis
 - Partial bowel obstruction
 - Paralytic ileus

- Intestinal gas pain
- Fecal impaction
- Meconium ileus equivalent in cystic fibrosis
- Bacterial enterocolitis
- Peptic ulcer disease
- Acute constipation
- Flare of functional abdominal pain
- Acute hepatitis
- Perihepatitis (Fitz-Hugh–Curtis syndrome)
- Inflammatory bowel disease (eg, Crohn disease, ulcerative colitis)
- Henoch-Schönlein purpura
- Hereditary angioedema
- Hemolytic uremic syndrome
- Pyelonephritis
- Renal calculi
- Dysmenorrhea
- Mittelschmerz
- Pelvic inflammatory disease
- Sickle cell crisis
- Diabetic ketoacidosis
- Poisoning
- Porphyria
- Collagen vascular disease

Treatments for functional abdominal pain

- Treatment of functional gastrointestinal disorders, including functional abdominal pain of childhood, is becoming more common.
- Treatments can be categorized as:
 - Dietary interventions
 - Psychosocial therapies
 - Medical management

Dietary interventions

- Common dietary changes include:
 - High-fiber diet
 - Avoidance of lactose
 - Oligoantigenic diet
 - Low-oxalate diet (for abdominal migraine)
- A high-fiber diet may be suggested, primarily in constipated children, to substitute for nutrient-poor, high-fat, high-calorie diets.
- Dietary manipulation is something that parents and children can understand, and suggesting this intervention may empower the family.

Psychosocial therapies

- Treatment of functional gastrointestinal disorders, including functional abdominal pain of childhood, is becoming more common.
- Specific mind-body techniques include breathing techniques, guided imagery, progressive muscle relaxation, biofeedback, hypnosis, cognitive-behavioral training, and music therapy.
 - Cognitive-behavioral therapy combines operant elements and stress management.
 - Results in short-term improvement, with more than half of patients experiencing freedom from pain
 - The child's coping skills and parent's caregiving strategies predict effectiveness.
 - Disengagement and involuntary engagement are correlated with increased anxiety, depression, and somatic symptoms.
 - Guided imagery, relaxation, biofeedback, and hypnosis show promise.
 - Reported improvement in pain, fewer school absences, better engagement in social activities, and fewer visits to physician's office may result from guided imagery and progressive-relaxation techniques taught over approximately 4 office visits.
 - Such techniques are easy to learn and teach and are office friendly, even for children.

Medical management

- Several drugs have been used to treat recurrent abdominal pain in childhood, including:
 - Famotidine
 - Pizotifen
 - Citalopram, a selective serotonin reuptake inhibitor
 - Children who receive this agent improve in terms of abdominal pain, anxiety, depression, and functional impairment.
 - Peppermint oil
 - The only one that appears to be of specific use for abdominal pain is peppermint oil in the form of a pH-dependent, enteric-coated capsule.
- Other medications (eg, anticholinergics, antiemetics, other antidepressants, simethicone) are commonly used but insufficiently studied.

WHEN TO REFER

- Involuntary weight loss
- Deceleration of linear growth
- Gastrointestinal blood loss
- Significant vomiting

- Chronic severe diarrhea
- Persistent right upper or right lower quadrant pain
- Unexplained fever
- Pregnancy
- Gynecologic issues (including ectopic pregnancy, tubo-ovarian abscess)
- Surgery required
- Family history of inflammatory bowel disease
- Extraintestinal symptoms
- History of psychiatric disorder
- Abnormal test results
- Anemia or low mean corpuscular volume
- Peripheral eosinophilia
- Increased erythrocyte sedimentation rate
- Increased transaminases
- Increased blood urea nitrogen or creatinine
- Hypoalbuminemia
- Low C4 complement level
- Intestinal infection

WHEN TO ADMIT

- Hospitalization is required in the following circumstances.
 - Surgical or medical emergency as determined by diagnostic or therapeutic intervention
 - Inability to tolerate enteral nutrition
 - Inability to maintain hydration status
 - Diagnosis that requires observation to monitor clinical status
- In the case of functional abdominal pain:
 - 50% of patients experience relief of symptoms during hospitalization, but the natural history of the pain does not seem to be affected.
 - As a result, hospitalization is seldom indicated, as it does not help with environmental modification and may reinforce pain behavior.

PROGNOSIS

- Depends on the cause of the acute or recurrent abdominal pain

Acne

DEFINITION

- Acne is a disease of the pilosebaceous unit in which sebaceous glands become enlarged and increase their production of sebum.
- Increased sebaceous gland activity is necessary for acne to develop.

EPIDEMIOLOGY

- Age
 - Prevalent in a large proportion of adolescents and young adults
 - May be seen as late as the 3rd and 4th decades
- Sex
 - Found in up to:
 - 78% of premenarchal girls
 - 100% of adolescent boys

ETIOLOGY

- Hormones
 - Androgenic stimulation of sebaceous glands increases sebum production.
- Follicular obstruction
 - Keratinous impaction develops in the pilosebaceous canal, causing outlet obstruction.
 - Sebaceous and keratinous debris accumulate behind the obstruction.
- Proliferation of the anaerobic bacterium *Propionibacterium acnes*:
 - Contributes to the rupture of the dilated pilosebaceous unit
 - Results in extravasation of pilosebaceous contents into the surrounding dermis and inflammatory acne lesions

RISK FACTORS

- Adolescent age
- Increased level of circulating androgens
- Skin that is rich in sebaceous glands

SIGNS AND SYMPTOMS

- Noninflamed open and closed comedones
 - Obstruction of pilosebaceous canal causes:
 - Open comedones (blackheads)
 - Closed comedones (whiteheads)
 - Closed comedones (whiteheads) appear as dome-shaped, flesh-colored papules that are often overlooked (see Figure 1 on page F1).
 - Acne in prepubertal children is predominantly noninflammatory and easily overlooked.

- Inflammatory papules and pustules
 - Rare in young children and suggests a possible hyperandrogenic condition
 - Possible hyperandrogenic conditions include:
 - Congenital adrenal hyperplasia
 - Rare androgen-secreting tumor
 - Examine for precocious puberty in both sexes and virilization in girls.
- Cystic acne in severe cases
 - Nodules >5 mm in diameter
 - True cysts (compressible nodules under normal-appearing skin)
 - Can result in permanent acne scars
- Lesions appear most frequently on the face.
 - They also often appear on the chest and back.
 - Lower portions of the trunk, buttocks, thighs are involved less frequently.
 - Distal extremities are always spared.

DIFFERENTIAL DIAGNOSIS

Flat warts

- See Figure 2 on page F1.
- Small, flesh-colored
- Sharp, right-angled edge and finely roughened surface
- Variable in size
- Closed comedones are smooth, dome-shaped, and uniformly small.

Milia

- Small epidermal inclusion cysts
- Also confused with inflammatory pustules, especially in infants with neonatal acne

Adenoma sebaceum

- Pink papules that are occasionally confused with acne lesions
- Lesions are actually angiofibromas.
 - They are a dermal manifestation of tuberous sclerosis.
- Adenoma sebaceum lesions should be suspected if they are:
 - Clustered primarily in the center of the face
 - Persistent
 - Resistant to acne therapy

Acne rosacea

- See Figure 3 on page F1.
- An acneiform eruption that can be distinguished from acne by:
 - Background blush of erythema and telangiectasia
 - Absence of comedones
- Most often found in middle-aged adults

Steroid acne

- Can be induced by systemic or topical steroids
- Lacking in comedones
- Involuting slowly and spontaneously after discontinuation of steroids
- Acne from systemic steroids usually is:
 - Made up of numerous small, uniform-sized papules and pustules
 - Found on the upper trunk
 - Lacking in comedones

Gram-negative folliculitis

- Caused by gram-negative organisms in patients being treated for acne with systemic antibiotics
- Should be suspected in patients whose disease flares up during therapy
 - Especially when flare-up produces numerous pustules

Acne conglobata

- Unusually severe acne variant caused by:
 - Sudden deterioration of existing active acne
 - Recurrence of acne that has been quiet for many years
 - Most common in 18- to 30-year-old men
 - Lesions consist of:
 - Comedones
 - Cysts with foul-smelling seropurulent material
 - Burrowing and interconnecting abscesses, leaving irregular and disfiguring scars
 - Has been associated with systemic diseases, such as:
 - Hidradenitis suppurativa
 - Pyoderma gangrenosum
 - Renal amyloidosis
 - Musculoskeletal syndrome
 - The mainstay of treatment is isotretinoin.

Acne fulminans

- A rare and severe form of acne
 - Usually occurs in men
 - Characterized by:
 - Sudden onset of painful acne nodules
 - Rarely by ulcerative lesions
 - Systemic symptoms include fever; leukocytosis; polyarthritis; splenomegaly; erythema nodosum; and lytic bone lesions in long bones, clavicle, and sternum.
- Treatment involves a combination of systemic corticosteroids initially, followed by isotretinoin.
- Prognosis is good, although residual scarring and disfigurement may persist.

DIAGNOSTIC APPROACH

- Diagnosis is rarely difficult.
- Comedonal lesions may require closer inspection to avoid confusion with:
 - Warts
 - Milia
 - Adenoma sebaceum
 - Acne variants

LABORATORY FINDINGS

- In cases of possible hyperandrogenic condition, screening blood studies should include serum levels of:
 - Testosterone
 - Dehydroepiandrosterone sulfate
 - 17-hydroxyprogesterone
- In possible gram-negative folliculitis
 - Bacterial culture with antibiotic sensitivity studies

TREATMENT APPROACH

- Acne is important to the patient seeking help and should be managed seriously.
 - Some young people appear to be more affected psychologically than others, but no one is comfortable with acne.
- Four methods of treatment have proved effective.
 - Topical comedolytic agents
 - Topical and systemic antibiotics
 - Systemic hormonal therapy
 - Systemic retinoids
- The most traditional and effective treatment regimen is a combination of comedolytics and antibiotics.

SPECIFIC TREATMENTS**Comedolytics**

- Retinoids
 - Topical retinoids help disimpact the keratinous plug in the follicular canal.
 - Topical comedolytics are available in a variety of preparations; the preparation strength reflects its irritancy and probably also its efficacy.
 - Tretinoin
 - Preparation strength depends on concentration of the drug and nature of the vehicle in which it is contained.
 - Cream in 0.025% (mildest), 0.05% (mild), 0.1% (moderate)
 - Gel in 0.01% (mild), 0.025% (moderate), 0.05% (strongest)
 - Solution in 0.05% (strongest)

- Adapalene
- Tazarotene
- Benzoyl peroxide
- Salicylic acid
- Azelaic acid
- Sodium sulfacetamide
- Most helpful in treating superficial acne lesions, including comedones and superficial papules and pustules
- Also reduce inflammatory lesions and enhance penetration of other medications
- Consensus is that in most cases, topical retinoids (alone or in combination) should be used as first-line therapy for mild-to-moderate inflammatory acne in addition to comedonal acne.
- Preferred agent for maintenance therapy
- In combination with another topical agent
 - Apply the retinoid at bedtime and the other agent each morning.
 - Adapalene
 - Gel in 0.1% and 0.3% and cream in a concentration of 0.1%.
 - Tazarotene
 - Gel and cream; each is available in concentrations of 0.05% and 0.1%.
 - Benzoyl peroxide
 - Gel in concentrations of 2.5%, 5%, and 10%
 - Salicylic acid
 - Large variety of preparations and concentrations
 - Sodium sulfacetamide
 - Lotion in 10% concentration
 - Patients are initially prescribed in the mildest preparations; potency is increased if necessary.
- Side effects
 - Skin irritation is the most common.
 - ~1% of patients develop true allergic contact dermatitis to benzoyl peroxide.
 - Requires permanent discontinuation of this agent
 - Benzoyl peroxide can bleach clothing and linens.
 - Topical retinoids may make the skin more susceptible to the effects of sunlight.
 - Patients should avoid excessive exposure to the sun and use oil-free sunscreens.

Antibiotics

- Indicated for patients who have inflammatory acne lesions
- Topical agents
 - Erythromycin
 - Clindamycin

- Combinations of benzoyl peroxide and erythromycin or clindamycin are often prescribed before oral antibiotics.
 - Benzamycin® gel (5% benzoyl peroxide and 3% erythromycin) twice daily
 - Benzaclin® gel (5% benzoyl peroxide and 1% clindamycin phosphate) twice daily
- For inflammatory lesions extensive enough to make topical therapy impractical (ie, involving the neck, shoulders, and upper trunk) or unresponsive to a topical regimen, systemic antibiotics are warranted.
 - Tetracycline is the drug of choice.
 - Proven efficacy, relative low cost, and low incidence of side effects, even over a long period
 - Should be taken on an empty stomach (on awakening or on retiring)
 - The initial dose is 500 mg orally twice daily; the dose is decreased to 500 mg once daily after sustained response is achieved.
 - Tetracycline and other drugs in the same class (ie, doxycycline and minocycline) should not be used in patients under 8 years because of dental staining.
 - Erythromycin may be used as an alternative if patient does not respond to tetracycline.
 - Doxycycline and minocycline may also be substituted.
 - Doxycycline is more likely to cause photosensitivity.
 - Minocycline is very expensive.
- Resistance to *P. acnes* may affect as many as 25% of patients taking antibiotics.
 - Preventive measures should be taken.
 - Limit the use of oral antibiotics to shorter periods.
 - Combining topical comedolytics (especially topical retinoids) with topical antibiotics.
 - Avoid the use of oral antibiotics as maintenance therapy.

Systemic retinoids

- Isotretinoin
 - Reduces follicular keratinization, sebum production, and intrafollicular bacterial counts, resulting in a dramatic improvement in acne
 - Therapeutic effect usually takes several months and often persists long after the course of therapy is discontinued.
 - Historically, 6-month courses have been used, but recently some practitioners focus more on total dose given instead of duration.
 - Target is 100 to 150 mg/kg total dose.
 - Side effects are common.
 - Almost all patients experience mucocutaneous reactions (cheilitis, conjunctivitis, and dry mucous membranes of the mouth and nose).

- Extracutaneous complications also occur, including:
 - Elevation of plasma lipid levels
 - Asymptomatic vertebral hyperostoses
 - Depression and pseudotumor cerebri (rarely)
- Female patients must exercise strict birth control while taking this drug.
 - Exposure to isotretinoin in pregnancy has been associated with a 25-fold increased risk of major fetal malformations.
 - The US Food and Drug Administration requires that all patients being prescribed isotretinoin be enrolled in a national registry.
- Isotretinoin is recommended only for:
 - Patients with severe cystic and/or scarring acne (or both)
 - A minority of patients who have severe noncystic acne and have not responded to topical comedolytics and oral antibiotics

Hormonal therapy

- An excellent option for women with moderate to severe acne if:
 - Oral contraception is desired.
 - An alternative to repeated courses of isotretinoin is preferred.
 - Certain endocrine disorders are present.
- All combination contraceptives reduce free testosterone and have a positive effect on acne.
 - No single preparation is demonstrably superior.
- Contraceptives containing only progestins should be avoided because intrinsic androgenic activity may aggravate acne.

Patient compliance

- Patient compliance is the single most important aspect of successful acne treatment.
- To maximize compliance:
 - Take time at the initial visit to explain use, anticipated effects, and side effects of each medication.
 - Printed instructions are good reinforcement.
 - Medications are taken twice daily.
 - Link to an established daily routine, such as brushing the teeth.
 - The concept that the treatment will take time to be effective needs to be emphasized.
 - The most common patient questions, often unasked, pertain to diet, cleanliness, cosmetics, and picking at the lesions.

Diet

- Some evidence indicates that the usual American diet may have adverse effects on acne; however, specific foods have not been implicated.
- For most people, a sensible diet is all that is suggested.

Cleanliness

- A primary question from parents
 - The notion that acne is a function of poor hygiene should be dispelled.
- In general, cleaning agents for acne need not be recommended.
 - Most irritate the skin, unnecessarily compounding irritation caused by topical comedolytics.
- A mild soap-free cleanser is often suggested.

Cosmetics

- Cosmetics have been implicated as possibly contributing to the acne process.
- It is preferable to avoid using them.
- If used, they should be water based and applied sparingly.

Picking

- Much of skin damage in acne patients is self-inflicted.
- Picking, probing, and squeezing cause tissue damage and sometimes produce scars.
- For some patients, picking may become so obsessive that excoriations are the only lesions seen.

WHEN TO REFER

- Patients unresponsive to oral antibiotics and topical comedolytics
- Patients with cystic or scarring acne
- Young girls with acne or girls with acne and irregular menses
- Patients with acne fulminans
 - Abrupt onset of cystic acne, fever, arthralgias

FOLLOW-UP

- The first scheduled return visit should be at 2 to 3 months after the start of therapy.
 - Improvement usually occurs within this period.
 - At this visit, the acne regimen can be adjusted as necessary.
 - For example, comedolytics and antibiotics can be increased (or reduced) depending on the initial response.
- Continued improvement is to be expected with continuation of therapy.
 - For many, the dose of systemic antibiotics can be reduced gradually and eliminated after 6 to 12 months.
 - Most patients require prolonged maintenance therapy (often over years) with topical agents.
 - Some require continued topical antibiotic therapy.

COMPLICATIONS

- The major complications are the psychosocial ramifications of acne.
 - May be compounded and perpetuated by permanent scars

- Scars are easier to prevent than to treat.
 - The emphasis in acne is on early, aggressive medical therapy.
- Established scars are difficult to treat.
 - Acne scars are best treated when inflammatory lesions are quiescent.
 - Many patients have been disappointed with the results of dermabrasion.
 - Patients treated with isotretinoin should wait for at least 1 year before having dermabrasion.
 - Bovine collagen injections have produced short-term improvement.
 - Repeated injections are often necessary.
 - Long-term results are not yet known.
 - Laser resurfacing by experienced operators has produced some promising results.

PROGNOSIS

- With proper treatment, the prognosis for acne is good, if not excellent.
- Patients should understand that most therapy controls rather than cures acne.
- Cystic acne has been the most difficult to treat, but isotretinoin has become a powerful tool for its treatment.
 - Potential exists for prolonged remissions, sometimes lasting for years after a single course of therapy.
 - Because of serious side effects, its use is usually reserved for patients who have severe cystic or scarring acne (or both) that does not respond to standard treatment.

Acute Surgical Abdomen

DEFINITION

- Abdominal pain that may require immediate surgical intervention
- 3 major diagnoses are the most common and the most likely to cause complications if treatment is delayed.
 - Malrotation and midgut volvulus, which usually presents in the newborn period
 - Intussusception, which occurs most often in children between 2 months and 2 years of age
 - Appendicitis, which is most common in children >5 years
- There are also other causes of abdominal pain, some requiring immediate surgical intervention.
 - For a more complete list of potentially emergent diagnoses, see Differential Diagnosis.

ETIOLOGY

- Malrotation and midgut volvulus
 - At 5–6 weeks' gestation, the elongating midgut pushes out into the umbilical coelom.
 - When it returns to the abdominal cavity at 10–12 weeks' gestation, it rotates and fixes to the posterior abdominal wall.
 - The duodenum returns first and is mainly retroperitoneal.
 - It courses behind the mesenteric vessels and enters the peritoneal cavity at the duodenal jejunal junction, just to the left of L2, the ligament of Treitz.
 - The colon enters the abdomen last and rotates so that the ileocecal region is in the right lower quadrant.
 - The right and left colon are fixed to the posterior abdominal wall by avascular attachments.
 - Thus, the small-bowel mesentery is normally fixed along a line from the ligament of Treitz in the left upper quadrant just to the left of L2 to the right lower quadrant at the right sacroiliac joint.
 - This long fixation prevents the lengthy mass of small bowel from rotating with the superior mesenteric artery and vein as a center.
 - This rotation, twisting, or volvulus would obstruct blood flow to the intestine and cause gangrene.
 - If an anomaly of rotation is present, or if this long fixation does not occur, then volvulus can occur.
 - In such anomalies of rotation and fixation (usually termed *malrotation* or *nonrotation*), the avascular adhesion of the cecum still appears to occur, but:
 - The cecum is usually in the midabdomen.
 - The adhesive bands (now called *Ladd bands*) cross the duodenum to the right upper quadrant.
 - This obstruction of the duodenum in malrotation causes bilious emesis.
 - The possibility of volvulus in malrotation requires urgent intervention.

- Intussusception occurs when the terminal ileum telescopes into the right colon.
 - This causes bowel obstruction and ischemia because the mesenteric vessels are dragged along with the ileum.
 - Intussusception is most likely due to hypertrophic ileal lymphatic tissue, which acts as a food bolus that can be swallowed by the more distal bowel.
- Appendicitis is probably caused by obstruction of the lumen by feces or hypertrophic lymphatic tissue.
 - Blockage allows stasis and bacterial multiplication to occur in the closed space.

SIGNS AND SYMPTOMS

- In brief, indicators of an acute surgical abdomen include:
 - Pain lasting >1 hour that is severe enough to require analgesics
 - Bilious emesis
 - Abdominal pain of any sort lasting >6 hours
 - Obstipation
 - Localized abdominal tenderness
 - Guarding
 - Rebound
 - Guaiac-positive stools, melena, or hematochezia
- Indicators of nonsurgical problems include:
 - Diarrhea
 - Symptoms of systemic illness: headache, sore throat, and myalgia
 - Emesis precedes pain
 - High fever very early in the illness
 - No abdominal tenderness
- Physical examination
 - Inspection of the abdomen can reveal distention or a mass.
 - Palpation should begin by gently stroking all abdominal quadrants while looking at the patient's face.
 - With peritonitis, cutaneous hyperesthesia is often present, which can be determined by narrowing of the outer canthus of the eye (wincing).
 - The clinician should gently percuss the entire abdomen.
 - Pain on percussion is termed *rebound* and indicates peritonitis, which can be localized or general.
 - Other tests for rebound, such as pushing in on the abdomen and then suddenly letting go, are very painful and unnecessary.
 - Percussion can also indicate gaseous distention of the intestine by the resonant note of tympany.
 - Palpate the abdomen quadrant by quadrant while looking at the patient's face.
 - The clinician should make several passes of each quadrant, with each being deeper.

- Look for a mass, tenderness, and guarding.
 - When the examiner pushes on a quadrant of the abdomen over the rectus muscle and it pushes back, this is known as *guarding*.
 - Guarding cannot occur voluntarily; it indicates localized peritonitis and, most often, the need for surgery.
 - If both the right and the left rectus push back, this is known as *rigidity*, which indicates generalized peritonitis.
 - Rigidity can be performed voluntarily.
- Auscultation of the abdomen offers no useful information.
 - No data support lack of bowel sounds with an ileus or high-pitched hyperactive bowel sounds with obstruction.
- Rectal examination is useful in:
 - Pelvic abscess
 - Obtaining stool for guaic testing for intussusception
- The clinician should assess structures or organs superior and inferior to the abdomen.
 - Pneumonia, inguinal hernia, and testicular torsion can cause abdominal pain.
- Malrotation and midgut volvulus
 - Usually develops in the newborn period but can occur at any age.
 - The characteristic symptom is bilious emesis.
 - This symptom should provoke urgent gastrointestinal (GI) contrast studies.
 - Approximately one-third of all children with bilious emesis require operative intervention (although not always for malrotation and midgut volvulus).
 - Any child with bilious emesis who has abdominal pain or tenderness should have either surgery or a contrast examination.
- Intussusception
 - Most children have intermittent colicky abdominal pain.
 - Some will be lethargic.
 - The child appears well between bouts of pain (approximately 20 minutes).
 - Physical examination reveals a mass in the epigastrium and a feeling of emptiness in the right lower quadrant (signe de Dance).
 - Tenderness and guarding are present as ischemia progresses.
 - Stool is usually guaiac positive, and a currant-jelly bloody stool may be passed.
- Appendicitis
 - Early symptoms are diffuse or periumbilical abdominal pain.
 - Anorexia, nausea, vomiting, and localization of the pain to the right lower quadrant follow.
 - Physical examination reveals:
 - Fever (temperature to 38.6°C)
 - Right lower quadrant tenderness
 - Guarding

Most Common Diagnoses in Boys With a Chief Complaint of Abdominal Pain by Age^a

<2 yr (n = 56)		2–5 yr (n = 128)		5–12 yr (n = 230)		>12 yr (n = 86)	
Diagnosis	Frequency (%)	Diagnosis	Frequency (%)	Diagnosis	Frequency (%)	Diagnosis	Frequency (%)
Abdominal pain	30 (60)	Abdominal pain	59 (46)	Abdominal pain	117 (51)	Abdominal pain	33 (38)

- Symptoms usually progress over 36 hours until perforation occurs.
 - Usually, diffuse peritonitis follows.
 - After perforation, the tenderness is no longer localized and the guarding becomes rigidity.
 - Temperature increases above 38.6°C.
- Colitis—ulcerative, bacterial, amebic (C)
- Typhlitis

DIFFERENTIAL DIAGNOSIS

Common causes of abdominal pain

- Diagnoses are listed for boys and girls with abdominal pain [(C) indicates most common causes].
- Peritoneum—inflammatory
 - Bacterial
 - Primary
 - Secondary
 - Perforated viscus
 - Stomach, duodenum
 - Appendix
 - Foreign body
- Hollow intestinal organs—inflammatory
 - Appendicitis (C)
 - Cholecystitis
 - Gastroenteritis (C)
 - Regional enteritis (C)
 - Meckel diverticulitis
- Hollow-intestinal organs—noninflammatory
 - Intussusception
 - Malrotation and midgut volvulus
 - Intestinal obstruction (C)
 - Inguinal hernia
 - Biliary colic
 - Peptic ulcer
 - Constipation (C)
 - Cystic fibrosis
- Enteric infections (gastroenteritis)
 - *Shigella*
 - *Salmonella*
 - *Campylobacter*
 - *Clostridium difficile*
 - Viral gastroenteritis (C)
- Unusual infections
 - Malaria
 - Tuberculosis of the spine
 - Osteomyelitis
 - Psoas abscess
 - Helminthic infestation

Most Common Diagnoses in Girls With a Chief Complaint of Abdominal Pain by Age^a

< 2 yr (n = 25)		2–5 yr (n = 94)		5–12 yr (n = 248)		>12 yr (n = 150)	
Diagnosis	Frequency (%)	Diagnosis	Frequency (%)	Diagnosis	Frequency (%)	Diagnosis	Frequency (%)

■ Solid viscera

- Acute hepatosplenomegaly
- Abscess of spleen or liver
- Pancreatitis
- Hepatitis
- Fitz-Hugh–Curtis syndrome
- Mesenteric lymphadenitis
- Torsion of:
 - Testicle
 - Scrotal appendages
 - Omentum
 - Spleen
- Appendix epiploica

■ Gynecologic (C)

- Salpingitis
- Mittelschmerz
- Ovarian cyst (usually ruptured)
- Menstrual pain
- Threatened abortion
- Ectopic gestation
- Ovarian torsion
- Pelvic inflammatory disease
- Endometritis
- Endometriosis

■ Urinary tract (C)

- Pyelonephritis
- Hydronephrosis
- Calculi
- Cystitis

■ Trauma (C)

- Rectus muscle tear
- Hematoma
- Solid-organ injury
- Hollow-organ injury

■ Trauma to a previously unsuspected mass

- Hydronephrosis
- Wilms tumor

■ Medical diseases

- Pneumonia
- Sickle cell anemia (C)
- Henoch-Schönlein purpura
- Streptococcal pharyngitis
- Lead poisoning
- Green-apple bellyache
- Hemolytic-uremic syndrome

- Diabetic ketoacidosis (C)
- Porphyria
- Hyperlipidemia
- Rheumatic fever
- Epilepsy
- Migraine
- Hemophilia
- Herpes zoster
- Systemic lupus erythematosus

■ Immunosuppressed patients

- Ischemic colitis
- Typhlitis
- Primary peritonitis

■ Nonorganic—chronic

- Recurrent
- Psychogenic
- Functional
- Psychophysiologic

Specific considerations

■ Secondary bacterial peritonitis

- Usually caused by appendicitis
- Can result from any hollow-organ perforation, eg, spleen, kidney
- Peritonitis and pain from these ruptured organs are probably caused by irritation from blood and urine in the peritoneal cavity.

■ Perforation of jejunum by blunt abdominal trauma

- Radiograph of the patient's upright abdomen may not show free air, and computed tomography (CT) may show only a small amount of fluid.
- Persistent abdominal tenderness after blunt trauma may be the only sign of perforated jejunum.
- In children, a history of trauma may not be obvious (a fall or wrestling match) and may be difficult to elicit, particularly if the child is reluctant to admit unsafe activity to parents.

■ Injury to spleen or kidney

- May be related to previously undiagnosed enlarged kidney (hydronephrosis, Wilms tumor) or spleen (mononucleosis)

■ Perforated ulcer

- Rare in children
- Characterized by free air on abdominal and chest radiographs

■ Meckel diverticulitis is less common than bleeding from a Meckel diverticulum.

- Signs, symptoms, and other findings are not especially different from those of appendicitis.

- Foreign bodies
 - Most, including open safety pins, will pass through a child's gastrointestinal tract without event, but perforation can occur.
 - Bowel obstruction
 - Usually causes bilious emesis, abdominal pain, and distended abdomen (unless it is a high small-bowel obstruction)
 - Radiography of the upright abdomen shows distended loops of bowel with air-fluid levels and no gas in the colon or rectum.
 - Causes of bowel obstruction include adhesions from previous operation, incarcerated hernia, and congenital bands.
 - Ectopic gestation
 - Can be diagnosed with a pregnancy test or ultrasonography
 - Other gynecologic conditions: ovarian torsion, pelvic inflammatory disease
 - Ultrasonography is important in diagnosis.
 - Pelvic examination may reveal discharge from the cervical os or cervical motion tenderness, indicating pelvic inflammatory disease.
 - Testicular disease
 - Pain is often referred to the abdomen.
 - The diagnosis can usually be made on physical examination (see Scrotal Swelling and Pain).
 - Gallbladder disease
 - Right upper quadrant symptoms and signs
 - Can be confirmed by ultrasonography
 - Pancreatitis
 - Usually has an underlying cause in children
 - Ultrasonography and pancreatic enzyme measurement often confirm pancreatitis.
 - Torsion of spleen or omentum
 - Uncommon cause of abdominal pain
 - Can be diagnosed by ultrasonography
 - Torsion of an epiploic appendage (the fat hanging off the colon)
 - Only diagnosed at laparotomy or laparoscopy
 - Constipation
 - Abdominal pain caused by sensitivity of GI mucosa to distention
 - Cystic fibrosis
 - Caused by meconium ileus equivalent even in older child (constipation), although intussusception occurs more frequently in patients with cystic fibrosis
 - Typhlitis
 - In immunocompromised patients, indicated by right lower quadrant pain and tenderness
 - Inflammatory mass can be seen on CT and can be monitored with ultrasonography.
 - Most medical diagnoses of abdominal pain can be ruled out by lack of tenderness or guarding on physical examination.
 - Sickle cell crisis
 - Sickle cell anemia frequently causes abdominal pain and typical leukocyte counts of 14,000–16,000 cells/mm³.
 - If the clinician is not sure of the diagnosis, treatment for sickle cell crisis, even including transfusion, is best.
 - If the pain resolves, the diagnosis was not appendicitis.
 - If the pain does not resolve, the patient needs to go to surgery.
- ### DIAGNOSTIC APPROACH
- Ordering a complete blood count with differential and urinalysis is reasonable when abdominal pain is the chief symptom.
 - Examination by a pediatric surgeon should be done before any other tests, including imaging studies, are ordered in the patient's best interest.
 - Complete history is important in evaluating all patients with abdominal pain.
 - Emphasis should be placed on eliciting:
 - Nature, location, radiation, and timing of the pain
 - Whether pain is associated with physical activity or eating
 - Most patients with an acute surgical problem have anorexia and usually have nausea and vomiting.
 - Generally, bowel habits are unchanged, or patients have constipation.
 - Diarrhea is unusual in diseases requiring urgent operation.
 - Pain usually precedes vomiting.
 - Systemic symptoms, such as headache and myalgia, are seldom present.
 - Pharyngitis does not rule out a surgical problem.
 - Clinicians must certainly ask specifically about genitourinary tract symptoms, other illnesses, and prior operations.
 - The physical examination of the abdomen is crucial.
 - Appendicitis
 - When considering appendicitis, observation is a useful diagnostic aid.
 - If appendicitis cannot be diagnosed with history, physical examination, complete blood count, urinalysis, and plain films, then 6–12 hours of observation with serial examination and a repeat leukocyte count may be diagnostic.
 - Patients with appendicitis generally worsen; those without appendicitis usually improve.
 - If observation does not clarify the diagnosis, CT is indicated.
 - Patient should have enteric preparation with contrast, or contrast should be instilled rectally so that it can reach the cecum.

- Intravenous contrast is also important because it makes the presence of inflammation much clearer.
- If a patient reports symptoms lasting >72 hours, consider perforated appendicitis with abscess or phlegmon.

LABORATORY FINDINGS

- Complete blood count with differential and urinalysis is reasonable when abdominal pain is the chief symptom, although tests may not be decisive.
- Leukocyte count
 - In acute appendicitis without perforation, the count is elevated from 9000 to 14,000 cells/mm³.
 - After perforation, the leukocyte count exceeds 14,000 cells/mm³.
 - If the bowel is perforated or gangrenous, or if an intraabdominal abscess exists, the leukocyte count will exceed 12,000 cells/mm³.
- Patients with anemia can have one of many medical conditions, such as sickle cell anemia, Henoch-Schönlein purpura, and lead toxicity.
- Urinalysis
 - High specific gravity indicates hypovolemia.
 - Ketones in urine indicate significant anorexia and emesis.
 - Leukocytes and bacteria indicate a urinary tract infection.
 - Erythrocytes indicate trauma or stone.
 - Casts may indicate glomerulonephritis that can be associated with primary peritonitis.
- Stool guaiac test
 - Most patients with intussusception will have a positive result.

IMAGING

- When appendicitis is suspected, diagnosis can often be made without resorting to imaging studies.
- When malrotation is in question, an upper GI series is the best test.
- If the patient already has signs of peritonitis and abnormal signs on plain-film radiography, then prompt operation may be appropriate.
- When intussusception is considered, contrast enema is indicated.
 - Signs of obstruction or necrotic bowel should prompt immediate surgery.
- When appendicitis is a possibility, the first imaging studies should be radiography of the chest and abdomen.
 - If the diagnosis is not clear, ultrasonography is the next step in girls, CT in boys.
 - Involving the surgeon early will allow a more prompt and accurate diagnosis.
- Plain-film radiographs of the abdomen can show:
 - Bowel obstruction

- Distended loops of bowel, air-fluid levels, absence of colonic gas
- Localized ileus, free air in the abdomen, scoliosis, or the impression of a mass
- Appendicitis
 - Scoliosis to the right, an ileus pattern, and a fecalith early in process
 - In perforated appendicitis, impression of a right lower quadrant soft-tissue mass may be present, as well as a gas pattern of bowel obstruction, with multiple loops of bowel with air-fluid levels.
- The chest radiograph may show free air under diaphragm or pneumonia.
- Ultrasonography is useful in:
 - Ovarian disease
 - Appendicitis
 - In female patients, ultrasonography can help evaluate possibility of ovarian or tubal disease.
 - Intussusception
 - Can also be diagnosed with contrast enema
 - Malrotation with midgut volvulus (reversal of the normal superior mesenteric artery and superior mesenteric vein relationship)
- CT is useful in diagnosing:
 - Appendicitis in patients with sickle cell anemia or immunocompromise (patients receiving a transplant and those being treated for cancer)
 - Appendicitis by visualization of abscess or phlegmon
 - When the diagnosis cannot be made clinically, most surgeons prefer abdominal CT with intravenous contrast and with contrast of the GI tract in which the contrast has reached the colon.
- An upper GI series is the surest way to determine malrotation.
 - Assess for the position of the ligament of Treitz.
 - Normally, the ligament of Treitz should be at the level of the pylorus and just to the left of the midline, with the second portion of the duodenum coursing posteriorly on a lateral view.
 - If the imager is inexperienced, barium enema can help find the position of the cecum, which is normally below the iliac crest and to the right of the midline (although it can occasionally be in this position in malrotation).

TREATMENT APPROACH

- Hydration
 - All patients with an acute surgical abdomen have volume depletion.
 - Administering intravenous hydration at 1.5 times the

maintenance requirement with appropriate solutions is reasonable.

- Broad-spectrum antibiotics (ampicillin, gentamicin, and metronidazole) and analgesics (morphine) are of benefit.
 - Should probably be started only after consultation with the surgeon
- Nasogastric tube
 - If a patient is vomiting or has marked abdominal distention
- No food or drink should be given until the diagnosis and disposition are decided for any patient with abdominal pain as any part of the chief symptom.

SPECIFIC TREATMENTS

Malrotation and midgut volvulus

- Once the diagnosis has been made in a patient with symptoms, surgery is urgently required to:
 - Untwist the bowel
 - Perform a Ladd procedure
- If the diagnosis of malrotation is serendipitous and symptoms are not present, a Ladd procedure should be performed to decrease the likelihood of volvulus.
 - Ladd bands are lysed, and the duodenum and colon are separated in an attempt to create a broad mesentery.
 - Appendix is removed because it will not usually be in the right lower quadrant and thus complicate any future diagnosis of appendicitis.
 - It is hoped that adhesions will be created to help decrease the chance of volvulus.

Intussusception

- Reduction can be made by contrast enema using barium, nonionic contrast, or air.
- When contrast enema reduction fails, surgery is necessary.
- The intussusception can usually be reduced surgically, or resection and anastomosis can be performed.
 - The appendix is also removed.

Appendicitis

- Once the diagnosis of appendicitis has been made:

- Surgery is indicated.
- Administering analgesics and antibiotics is reasonable.
- Surgery is performed either laparoscopically or by laparotomy, regardless of whether perforation has occurred.
- Laparoscopy is especially useful when the diagnosis remains in doubt.
 - The entire abdomen and pelvis usually can be well visualized.
 - It can reduce morbidity associated with the large incision needed in obese patients.
- Patients with symptoms of appendicitis lasting >72 hours can be treated with broad-spectrum intravenous antibiotics.
 - If their symptoms resolve in 2–3 days, they can be discharged home on antibiotics.
 - Some clinicians ask patients to return in 6–8 weeks for interval appendectomy, which can be done laparoscopically.
 - Elective laparoscopic appendectomy results in little morbidity, even after perforation.
 - Most patients will eat the evening of the operation and be discharged the next day.
 - Immediate surgery for delayed presentation of perforated appendicitis can result in a very large incision and a long, complicated hospital course.

WHEN TO ADMIT

- All patients with acute surgical abdomen need to be admitted.

WHEN TO REFER

- All patients with acute surgical abdomen need to be referred to pediatric surgeons.

COMPLICATIONS

- Intussusception
 - Recurs in 15% of cases, usually within 72 hours of the original disease
 - Treatment is the same as that in the initial occurrence.

Adrenal Dysfunction

DEFINITION

- Adrenal insufficiency
 - Syndrome characterized by wasting, hyperpigmentation, and adrenal gland atrophy
 - May be primary or secondary
 - Primary may be:
 - Congenital (congenital adrenal hyperplasia [CAH])
 - Acquired
- Adrenal hyperfunction
 - Premature adrenarche
 - Early onset of adrenal androgen secretion accompanied by pubarche
 - Cushing syndrome
 - Any form of glucocorticoid excess
 - Cushing disease
 - Glucocorticoid excess caused by adrenocorticotropic hormone (ACTH) hypersecretion
 - Adrenal medullary diseases
 - Neuroblastoma, pheochromocytoma

EPIDEMIOLOGY

- Adrenal insufficiency
 - Primary
 - Prevalence: 10 in 100,000 persons
 - Age: most prevalent in women age 25–45 years
 - Sex: The female-to-male ratio is approximately 3:1.
 - Secondary
 - Prevalence: 15–28 to 100,000 persons
 - Adrenal hyperfunction
 - Premature adrenarche
 - Most common in children with early onset of pubic and body hair growth
 - Traditional age limit has been 8 years for the onset of pubic hair in girls and 9 years in boys.
 - Lowest age limit for girls has been contested after a large cross-sectional study revealed the relatively common occurrence of either early pubic hair or breast enlargement in healthy black girls after age 6 years and in white girls after age 7 years.
 - Cushing syndrome
 - Incidence: 0.05 in 100,000 persons per year
 - Neuroblastoma
 - Most common tumor encountered in young children
 - Incidence: approximately 1 in 100,000 per year among children <15 years
 - Average age is 2 years at diagnosis in North America.
 - Mass screening of infants is done in Japan to allow earlier diagnosis.

ETIOLOGY

- Primary adrenal insufficiency
 - CAH (72%), most often caused by deficiency of enzyme 21-hydroxylase
 - Autoimmune adrenal insufficiency (13%)
 - Rare syndromes (15%)
- Secondary adrenal insufficiency
 - Abrupt discontinuation of glucocorticoid therapy is the most common cause.
 - Other pituitary hormone deficiencies cause the remainder of cases.
- Adrenal hyperfunction
 - Cushing syndrome is the most frequent noniatrogenic cause for glucocorticoid excess in adolescents.
 - Medullary disease in adolescents is most often caused by a pheochromocytoma; transmission is autosomal dominant.

SIGNS AND SYMPTOMS

Adrenal insufficiency

- Acute adrenal insufficiency
 - Hypotension and lethargy are common signs at presentation.
 - Patients and family members should be taught to recognize a change in energy level or demeanor as a potential warning sign.
 - May occur during febrile illness, especially when accompanied by dehydration, vomiting, diarrhea, or any combination of these reactions
- Primary adrenal insufficiency
 - Abdominal pain, headache, anorexia, weight loss, lethargy, postural hypotension or shock, proneness to dehydration, salt craving, hyperpigmentation, loss of axillary or pubic hair
 - Findings are nonspecific and gradual in onset.
 - Hyperpigmentation may be difficult to appreciate in dark-skinned patients; creases of the palms and of the oral mucosal surfaces are clues.
 - Hypoglycemia
 - May be present in patients who have adrenal insufficiency with or without growth hormone (GH) deficiency
 - Seldom severe enough to cause seizures
 - Gastrointestinal symptoms
 - Abdominal cramps, nausea, vomiting, and diarrhea are prominent in some patients.
 - Sexual and/or reproductive dysfunction
 - Decreased libido, potency, or amenorrhea may accompany either primary or secondary adrenal insufficiency in adolescents and adults.

- Orthostatic hypotension
 - More marked in primary than secondary adrenal insufficiency
 - CAH: classic form
 - One-quarter of patients produce enough aldosterone to avoid salt-wasting crises; these patients are termed *simple virilizers*.
 - CAH: nonclassic (milder) form
 - Less marked adrenal androgen excess
 - Early pubic hair and rapid advances in height in both sexes
 - Hirsutism, oligomenorrhea, or acne in adolescent girls
 - Not all persons with increased 17-hydroxyprogesterone typical of nonclassic 21-hydroxylase deficiency are symptomatic; boys are much less likely have symptoms.
 - Secondary adrenal insufficiency
 - Patients tend to be pale, in contrast to the hyperpigmentation seen in primary insufficiency.
 - Children may have delayed growth and puberty, manifestations of GH, and gonadotropin deficiencies in addition to ACTH deficiency.
 - Headaches, visual disturbances, polyuria, and polydipsia may also be seen in pituitary disorders.
 - Chronic unexplained signs or symptoms such as these should prompt consultation with a pediatric endocrinologist.
- Adrenal hyperfunction**
- Prominent clinical features of adrenocortical hyperfunction in adolescents are excess central body weight gain with stunted statural growth.
 - Premature adrenarche
 - Most overweight and obese children who are growing in height at a normal pace do not have a causal underlying endocrine disease.
 - Overweight children secrete more adrenal sex hormones than lean children.
 - They may develop secondary sexual characteristics at an earlier-than-average age.
 - Obese children often show advanced bone ages, but are not usually short.
 - In most cases, children with premature adrenarche do not exhibit rapid growth in stature or advanced bone age.
 - Presence of isolated pubic hair or axillary hair with or without apocrine body odor does not necessarily presage early breast development and menstruation.
 - Endocrine evaluation should be reserved for children with:
 - Unusually early pubarche
 - Multiple signs of early puberty
 - Rapidly progressive pubertal development or statural growth (or both)
 - Nonisosexual puberty (eg, a girl with hirsutism or other signs of virilization, a prepubertal boy with gynecomastia)
 - Cushing syndrome
 - Typical appearance
 - Excess central body weight with stunted statural growth
 - Annual school photographs can often help reveal subtle changes in physiognomy and habitus over time.
 - Other characteristic findings are:
 - Easy bruisability
 - Broad and purplish striae
 - Hyperglycemia
 - Hypertension
 - Most obese adolescents do not have Cushing syndrome and do not require screening unless growth arrest or other suspicious signs are observed.
 - Neuroblastoma
 - Common presenting signs include:
 - Abdominal mass
 - Fever of unknown origin
 - Hematuria
 - Spinal cord compression
 - Pathological fracture
 - Hypertension
 - Metastases to liver and bone occur in approximately 50% of cases by the time of tumor detection.
 - Pheochromocytoma
 - May cause either episodic or chronic hypertension, usually accompanied by:
 - Tachycardia
 - Headaches
 - Anxiety
 - Sweating
 - Flushing
 - Weight loss may also be observed.
 - Thorough family history should be obtained for endocrine tumors, especially medullary thyroid carcinoma and hyperparathyroidism.
- DIFFERENTIAL DIAGNOSIS**
- Adrenal insufficiency
 - Often goes unrecognized for extended periods
 - Findings may be mistaken for:
 - Infection
 - Malnutrition
 - Gastrointestinal disease
 - Inborn errors of metabolism

- Anorexia
- Chronic fatigue syndrome
- Depression
- The mild nonclassic form of CAH may be mistaken in girls for polycystic ovarian syndrome.
- Adrenal hyperfunction
 - Premature adrenarche
 - Differential diagnosis includes
 - Nonclassic forms of CAH
 - Adrenal virilizing tumors
 - Pheochromocytoma
 - Differential diagnosis includes
 - Panic attacks
 - Thyrotoxicosis
 - Renovascular disease
 - Drug abuse (especially cocaine or amphetamines)

DIAGNOSTIC APPROACH

- Diagnosis of adrenal insufficiency is frequently delayed or missed.
- Perform laboratory studies for adrenal dysfunction in cases of unexplained, nonspecific symptoms of:
 - Pain
 - Salt craving
 - Weight loss

LABORATORY FINDINGS

Adrenal insufficiency

- The most commonly recognized findings by laboratory screening are:
 - Hypoglycemia
 - Low plasma cortisol
- The gold standard test is a corticotropin-stimulated serum 17-hydroxyprogesterone.
 - Strict quality control is important to avoid false-positive high levels generated by nonspecific measurement of cross-reacting hormones.
 - Classic simple virilizing or salt-wasting CAH
 - Basal and stimulated 17-hydroxyprogesterone levels are markedly increased, generally >10,000 ng/dL (~300 nmol/L).
 - In classic CAH, cortisol levels are invariably low and fail to respond robustly to stress or exogenous stimulation.
- Early-morning basal serum 17-hydroxyprogesterone measurements below 200 ng/dL (~6 nmol/L) usually rule out even mild forms of 21-hydroxylase deficiency.
 - Nonclassic 21-hydroxylase deficiency
 - Stimulated serum 17-hydroxyprogesterone levels are moderately increased, usually >1500 ng/dL (approximately 45 nmol/L).

- Newborn screening test results from filter papers are not comparable to serum hormone levels.
 - Filter paper samples are measured differently.
 - Each state's laboratory has its own reference range for screening tests.
- Early-morning (8:00 am) serum or salivary cortisol levels accompanied by increased ACTH may also be diagnostic.
 - If zona glomerulosa function is affected, hyponatremia and hyperkalemia will be accompanied by high plasma renin activity and low serum aldosterone.
 - If adrenal insufficiency results from pituitary or hypothalamic dysfunction, ACTH levels will be low.
 - Diagnosis can be confirmed by absence of at least a 2-fold increment in serum cortisol 60 minutes after stimulation with a standard dose of intravenous ACTH 1-24.
 - A low dose of cosyntropin can be used to test ACTH reserve in cases of suspected secondary adrenal insufficiency.
- Patients with a known history of high-dose, long-term glucocorticoid treatment should undergo documentation of plasma cortisol level during intercurrent illness and before undergoing any surgery.
 - 8:00-am level >10 mcg/dL or cosyntropin ACTH 1-24 challenge test with cortisol levels >15 to 18 mcg/dL after 30 to 60 minutes
 - These levels have been derived mainly from adult studies and may not be relevant to infants and small children.
 - Insulin-induced hypoglycemia may be used to test ACTH.
 - Many clinicians are reluctant to use this test because of the danger of potential hypoglycemic seizures.
 - If documentation cannot be obtained in time, treating patients with supplemental stress corticosteroid coverage in the perioperative period within 1 year of withdrawal of therapy is safest.

Adrenal hyperfunction

- Premature adrenarche
 - Mildly increased levels of dehydroepiandrosterone (DHEA) and DHEA sulfate
 - Tend to be consistent with the child's Tanner stage of pubic hair
 - DHEA sulfate has a longer half-life in the circulation and thus is not subject to circadian variability, making it a better screening tool.
- Cushing syndrome
 - Measurement of increased midnight salivary cortisol or high 24-hour urine-free cortisol, or both
 - Diagnosis may be confirmed by a nonsuppressed morning cortisol level after dexamethasone administration.

- Adrenal carcinomas (but not typically adenomas) will secrete cortisol, mineralocorticoids and androgens.
 - If adrenal carcinoma is suspected on the basis of ACTH-independent (ie, nonsuppressible) cortisol excess, request additional studies.
- Aldosterone and plasma renin activity
- DHEA sulfate
- Androgens
- Ectopic ACTH production by carcinomas is almost never seen in children.
- Pheochromocytoma
 - Diagnosis is made either by:
 - Increased 24-hour urine-free metanephrines (collected in an acid container)
 - High-performance liquid chromatography measurement of plasma-free metanephrines
 - Blood should be obtained from an indwelling venous catheter in a patient who has been fasted overnight and at rest for at least 20–30 minutes; the sample tube must be iced and processed immediately.
 - If possible, psychoactive drugs, especially tricyclic antidepressants, should be discontinued at least 2 weeks before testing.
 - Chemistry profile may demonstrate hyperglycemia.
 - Genotyping for the *RET* oncogene should be performed; if positive, other family members should be tested.
 - Screening tests for pheochromocytoma may include 24-hour ambulatory blood pressure.
- Neuroblastoma
 - Biochemical markers include:
 - Plasma and urinary dopamine
 - Vanillylmandelic acid
 - Homovanillic acid

IMAGING

- Imaging studies are required to verify clinical suspicion of adrenal tumor.
- Magnetic resonance imaging (MRI)
 - Suspected Cushing syndrome
 - Thin-slice abdominal images, including the adrenal glands
 - Carcinoma
 - Will often show a necrotic center or calcification and irregular borders, or both
 - Benign nonfunctioning adenomas
 - Typically homogeneous and more similar in density to normal adrenal tissue

- Metaiodobenzylguanidine scan
 - Norepinephrine analogue labeled with radioiodine taken up specifically by catechol-producing tumor tissue, but not normal adrenal medulla
 - Helpful in cases in which thin-slice, contrast-enhanced computed tomography (CT) or MRI fails to show a mass, yet biochemical tests and clinical findings are suggestive for pheochromocytoma
- Positron emission tomography and somatostatin analogues
 - May demonstrate masses not visible on CT or MRI
- Ultrasonography or CT
 - Used if adrenal hemorrhage is suspected
- Bone scan
 - Usually informative in neuroblastoma, revealing bone metastases, soft-tissue calcifications, or both
- Radiographs or dual x-ray absorptiometry
 - Demonstrates low bone density secondary to pituitary tumor

DIAGNOSTIC PROCEDURES

- Selective catheterization of the inferior petrosal sinuses with measurement of ACTH level on either side
 - In pituitary tumors that cannot be localized by imaging
 - Should be done at a specialized center

TREATMENT APPROACH

- Primary adrenal insufficiency
 - Prompt treatment with glucocorticoids and mineralocorticoids is life saving.
 - CAH usually requires lifelong treatment with corticosteroids titrated to maintain levels of adrenal androgen precursors in the normal to mildly increased range.
 - Adolescents should undergo gynecologic or testicular evaluation.
 - Children who do not exhibit precocious pubarche and adolescents who are not troubled with symptoms of androgen excess may not require treatment.
- Secondary adrenal insufficiency
 - The patient's growth, weight gain, vital signs, and sense of well-being should guide therapy.
- Adrenal hyperfunction
 - Provide dietary counseling and advise a rigorous exercise program to determine whether weight gain can be controlled.
 - Glucocorticoids should be tapered as soon as is practical.
 - Obtain a telephone consultation with a pediatric endocrinologist if in doubt.

SPECIFIC TREATMENTS

Acute adrenal insufficiency

- Children in hypotensive crisis or shock should be treated urgently.
- Individuals who cannot tolerate oral maintenance or stress doses during an illness require parenteral glucocorticoid administration.
 - Hydrocortisone suppositories are an option if parenteral administration is not feasible and if the patient does not have diarrhea.
- After emergency department evaluation, a large-bore intravenous catheter should be inserted for repletion of intravascular volume with saline solutions containing 5% dextrose.
 - More concentrated dextrose (eg, 25% dextrose in water) should be administered to treat refractory hypoglycemia.
- If acute and severe adrenal insufficiency is suspected, treatment should not be delayed for diagnostic testing.
- Stress doses of glucocorticoids should be given simultaneously with fluids.
 - Hydrocortisone is the treatment of choice because of its quick onset of action and mineralocorticoid activity.
 - Prednisone and dexamethasone are long-acting, with a slower onset of biological action.
 - Prednisone is not an ideal choice for treating acute adrenal crisis because it must be converted to prednisolone to be effective.
 - Dexamethasone does not cross-react in cortisol assays; thus, a diagnostic ACTH stimulation test may be performed immediately after administration.
- Liberal quantities of intravenous sodium chloride plus large doses of hydrocortisone will usually:
 - Restore normotension
 - Correct electrolyte abnormalities
 - Obviate need for mineralocorticoid treatment or pressor agents in the acute situation
- As vital signs stabilize, glucocorticoids and fluid infusions are tapered over several days.
- Once the patient can eat and take oral medications, oral glucocorticoids may be substituted.
- Supplemental sodium chloride may be provided if dietary salt intake is inadequate.

Primary adrenal insufficiency/CAH

- The classic form requires lifelong medical management with oral corticosteroids.
- Patients with salt wasting require both glucocorticoids and mineralocorticoids.
 - Advanced age and increasing dietary salt consumption may allow tapering or discontinuation of mineralocorticoids.

- Supplemental sodium chloride may be required for:
 - Infants who consume very little dietary sodium
 - Patients in tropical climates
 - Patients who engage in intense exercise with excessive sweat sodium losses
- Simple virilizing patients with poorly controlled disease benefit from mineralocorticoid therapy.
 - May obviate need for high-dose glucocorticoids in some
- The nonclassic form requires low-dose glucocorticoid therapy only.
- Dosing
 - Should be titrated to maintain levels of adrenal androgen precursors in the normal to mildly increased range
 - Some clinicians prefer to treat CAH with a higher dose of cortisol or a longer-acting glucocorticoid at night to suppress the early-morning ACTH-mediated adrenal androgen production.
- Maintenance glucocorticoid replacement therapy
 - Once growth is near complete, if satisfactory control of adrenal androgens is not achieved, more potent and long-acting glucocorticoids, eg, prednisone or dexamethasone, may be used.
 - In general, lower doses of glucocorticoids are required to treat Addison disease than CAH.
 - Patients with low serum sodium, high potassium, or increased plasma renin activity should receive daily oral fludrocortisone and sodium chloride supplements, adjusted to normalize these analytes.
 - DHEA is an optional hormone supplement for older women with adrenal insufficiency and low energy or libido, but no data exist on its use in adolescents.
- Adolescent girls with severe forms of CAH should undergo gynecologic examination before sexual activity.
 - Vaginoplasty may be necessary, depending on previous genital surgical procedures.
 - Psychological counseling should be provided by a professional experienced in treating this type of disorder.
- Adolescent boys should undergo careful testicular palpation and sonography to rule out testicular adrenal rests that can compromise fertility.
- Strict control of adrenal hormone levels can shrink benign tumors in many cases.

Secondary adrenal insufficiency

- Management is similar to that of primary adrenal insufficiency.
- Children who do not have precocious pubarche and adolescents who are not troubled with symptoms of androgen excess may not require treatment, or they may discontinue treatment when symptoms have abated and growth is complete.

- The patient's growth, weight gain, vital signs, and sense of well-being should guide therapy.
- Stress dosing
 - All patients with adrenal insufficiency must be informed about the need to increase their glucocorticoid dose during stress to prevent a potentially fatal adrenal crisis.
 - All such patients should wear a medical alert tag and carry an emergency medical information card to ensure that medical providers know about the underlying disorder.
 - Severe stresses, such as illness accompanied by higher fever (temperature $\geq 38.5^{\circ}\text{C}$), surgery, and major trauma, should be accompanied by tripling of oral hydrocortisone maintenance doses to prevent hypoglycemia, hypotension, and even cardiovascular collapse.
 - Supplemental parenteral hydrocortisone is suggested before general anesthesia and surgery.
 - Doses are empiric and are not determined by evidence-based guidelines. Intravenous or oral stress doses may be gradually tapered as the patient recovers until the maintenance dose is attained.
 - Mild physical stresses, such as immunizations, uncomplicated viral illnesses, low-grade fever (temperature $< 38.5^{\circ}\text{C}$), athletic activity, and emotional stress, do not usually require stress doses of glucocorticoids.

Adrenal hyperfunction

- Premature adrenarche
 - Institute dietary counseling.
 - Advise a rigorous exercise program to determine whether weight gain can be controlled.
- Telephone consultation with a pediatric endocrinologist is advised if in doubt.
- Cushing syndrome
 - If possible, glucocorticoids should be tapered as soon as practical, while substituting other therapeutic agents.
 - Patients with adrenal tumor or nodular hyperplasia as the source for cortisol excess will most often undergo adrenalectomy.
 - In some patients, attenuation of cushingoid features and improvement of statural growth may take months to years.
- Cushing disease
 - Cushing disease has traditionally been treated primarily with transsphenoidal tumor resection.
 - Once ACTH levels have decreased, the patient needs long-term glucocorticoid replacement therapy.
 - Directed radiotherapy, such as gamma knife and linear accelerator techniques, can also induce gradual remission of ACTH hypersecretion.

- Medical therapy with such drugs as ketoconazole are an alternative for Cushing syndrome or Cushing disease either in the short term (eg, while waiting for radiotherapy to take effect) or long term to reduce cortisol secretion.
 - This type of treatment will not induce a permanent cure.
- Neuroblastoma
 - Medical and surgical management depends on staging risk.
 - Low-grade tumors may spontaneously regress.
- Pheochromocytoma
 - In preparation for surgery, treat for ≥ 1 week with a drug with both α -adrenergic blocking (eg, phenoxybenzamine) and β -adrenergic blocking (eg, labetalol) properties.
 - α -Methyl-L-tyrosine (Demser) is also used to inhibit the rate-limiting step of catechol synthesis.
 - $\sim 10\%$ of pheochromocytomas are bilateral; thus, both adrenals should be explored at surgery.
 - If both adrenals are removed, substitution therapy will be required as for primary adrenal insufficiency.

WHEN TO ADMIT

- Children in hypotensive crisis or shock
 - Treat urgently in the office.
 - Transfer immediately by ambulance to the nearest emergency center.
- Extreme hypertension should prompt immediate emergency hospitalization.

WHEN TO REFER

- Referral to a pediatric endocrinologist or other appropriate specialist
 - Children with hyperglycemia (immediate referral)
 - Obese child with statural growth arrest (for more complete evaluation)
 - Children with a family history of familial tumor syndromes
 - Early detection of affected genetic status may dictate intervention before tumors develop.
- Because premature adrenarche is most often benign, telephone consultation with a pediatric endocrinologist should be considered before referral.

FOLLOW-UP

- Adrenal insufficiency
 - Monitor during therapy:
 - 17-hydroxyprogesterone, androstenedione, and testosterone
 - Attempts to suppress 17-hydroxyprogesterone to normal range usually require excessively high glucocorticoid doses and have the undesirable consequence of growth suppression and iatrogenic Cushing syndrome.

- Plasma renin activity in patients requiring mineralocorticoid replacement
- Frequent headaches, lethargy, nausea, or abdominal pain may indicate inadequate treatment; signs include orthostatic pulse or blood pressure changes.
- Measurement of ACTH is not helpful.
 - ACTH is seldom completely suppressible in patients treated for CAH.
- Testosterone is helpful in managing prepubertal children of both sexes, and adolescent girls and women.
 - Not as useful a marker of adequate therapy in adolescent boys and men
- Continuing reminders to patients, families, and medical personnel regarding the need for higher doses of glucocorticoid replacement therapy during intercurrent illness and surgery
 - Failure to increase glucocorticoid supplementation during physical stress remains a significant cause of morbidity and mortality.
 - Patients should be given letters explaining their condition and appropriate emergency management.
 - Among critically ill children, a low incremental cortisol response to ACTH does not predict mortality, although the effect of glucocorticoid treatment is not known.
- Pheochromocytoma
 - Careful long-term follow-up of patients, with regular checks of blood pressure and catechol measurements, is crucial.
- Preventable deaths were attributed to hypoglycemia or secondary adrenal insufficiency in patients of all ages and were associated with a variety of causes of hypopituitarism.
- The death rate remained fairly constant throughout middle childhood and with advancing age (1 per 113 to 173 person-years).

■ Adrenocortical hyperfunction

- Premature adrenarche
 - A subset of girls with premature adrenarche may develop polycystic ovarian syndrome, insulin resistance, or metabolic syndrome.
- Cushing disease
 - Surgical success largely depends on the skill of the surgeon and the nature of the lesion.
 - The cure rate ranges from 60–80%.
- Pheochromocytoma
 - Cancer and recurrence may occur in approximately 10–15% of cases.

PREVENTION

■ Adrenal insufficiency

- To prevent mortality from adrenal crisis, among other reasons, the US and many other countries perform newborn screening.

■ Adrenocortical hyperfunction

- No strong evidence has been found to warrant preventive drug treatment in anticipation of possible polycystic ovarian syndrome in young girls with premature adrenarche.

PROGNOSIS

■ Adrenal insufficiency

- If unrecognized, adrenal insufficiency may produce a life-threatening crisis, with acute cardiovascular collapse.
- Information concerning mortality in secondary adrenal insufficiency mostly comes from recent reports regarding follow-up of individuals treated with pituitary GH.
 - Up to 4-fold increase in mortality compared with the general population in children treated with pituitary GH has been reported, probably due to development of other hormone deficiencies.

Airways Obstruction

DEFINITION

- Airways obstruction is blockage of the airway.
- Airways obstruction may result from:
 - Aspiration of a foreign object
 - Reduction in the inner diameter of the airway
- Acute airways obstruction can occur throughout the respiratory tract.

MECHANISM

- Infants have a greater incidence of respiratory compromise compared with older children.
 - They have smaller airways diameter and increased airways resistance.
 - Connective tissue and cartilaginous structures in infants are not completely hardened.
 - Cartilaginous structures include:
 - Larynx (epiglottis, aryepiglottic folds, arytenoid cartilage, tracheal cartilage)
 - Trachea
 - Bronchi
 - Bronchioles
 - Chest wall
- In the infant and young child, the narrowest portion of the airways is the cricoid ring.
- In the older child and adolescent, the narrowest portion of the airways is the vocal cord aperture.

HISTORY

- Obtain a pulmonary history.
 - Onset of respiratory distress
 - Acute
 - Gradual
 - Duration
 - Factors that worsen or improve signs and symptoms
- Obtain a prenatal and birth history.
 - Problems during pregnancy
 - Decreased fetal movement
 - Oligohydramnios
 - Gestational age at birth
 - Type of delivery
 - Vaginal
 - Need for forceps or vacuum extraction
 - Caesarean
 - Abnormalities in presentation
 - Breech
 - Shoulder dystocia

- Resuscitation efforts required during birth
 - Intubation
 - Mechanical ventilation
 - Supplemental oxygen

- If foreign body aspiration is suspected:
 - Determine whether the event was witnessed.
 - Determine the type of object aspirated.
 - Determine what time the event occurred and how much time has elapsed.

PHYSICAL EXAM

- Determine whether the child requires emergent intervention.
 - Assess upper airways patency.
 - Assess the degree of respiratory effort.
 - Note the child's level of consciousness.
 - Observe the child's facial expression.
 - A child with incipient respiratory collapse may:
 - Have furrowed eyebrows
 - Be unable to regard and focus on the examiner
 - Appear fatigued and anxious
 - Observe for nasal flaring.
 - Note whether the child is diaphoretic.
 - Determine the effectiveness of respiratory function.
- Simple observation, without an examination, is valuable.
 - Determine the respiratory rate.
 - Note whether tachypnea is present.
 - Note whether respirations are regular or irregular.
 - Observe whether the child is using accessory muscles or has retractions.
 - Note the movement of the head and neck with respiration.
 - Note the relative ratio of inspiration to expiration.
 - Normal inspiratory:expiratory ratio is 1:2.
 - Does the child recognize his/her parents?
 - Can the child speak?
 - Can the child suck on a bottle or pacifier?
 - Listen to the quality of the child's cry.
- Perform a chest examination.
 - Observe for symmetry, pectus deformity, and size of the thorax.
 - Observe chest wall movement.
 - It may be diminished because of weak or inefficient breaths.
 - Percuss the thorax and note the presence of:
 - Localized air trapping
 - Hyperresonance

- Lobar consolidation
- Dullness
- Auscultate breath sounds.
 - Listen for crackles, wheezing, or stridor.
 - Note whether sounds occur on inspiration, expiration, or throughout the respiratory cycle.
 - Note distribution, pitch, and quality of breath sounds.
- Abnormal breath sounds are more prominent on the inspiratory or expiratory phase of breathing, depending on the site of the disease.
- For any rate of airflow, the degree of respiratory effort is directly proportional to the degree of obstruction.
- Complete upper airways obstruction is a medical emergency in which no effective air movement is present and child cannot:
 - Cough audibly
 - Speak
 - Produce any sound
- Children with respiratory failure have inadequate oxygenation, ventilation, or both and appear:
 - Ashen
 - Obtunded
 - Lethargic or extremely anxious
- In respiratory failure:
 - Central cyanosis may be present.
 - Chest wall movement may be diminished.
- Partial obstruction
 - Audible phonation and presence of breath sounds indicates airways patency.

DIFFERENTIAL DIAGNOSIS

Early infancy

- Laryngomalacia
 - Most common cause of stridor in an infant
 - Stridor is positional: severity is greater when the infant is supine, less when the infant is prone.
 - Onset typically within the first 2 weeks of life
 - Worsens in the first several months and resolves by 1 year of age
 - Respiratory characteristics
 - Stridor predominates on inspiration.
- Vocal cord paralysis
 - May be unilateral or bilateral
 - Often associated with birth trauma
 - Trauma associated with delivery: shoulder dystocia, forceps delivery, vacuum extraction
 - Airway instrumentation: intubation in the delivery room, mechanical ventilation

- May also result from:
 - Elevated intracranial pressure
 - Congenital Arnold-Chiari malformation
 - Intracranial mass
- When caused by birth trauma, the condition improves over time.
- Extrinsic compression of the trachea, which may be caused by:
 - Thyroglossal duct cyst
 - Ectopic thyroid tissue
 - Esophageal duplication cyst
 - Lymphoma
 - Cardiac or vascular anomaly
- Craniofacial anomalies
 - These put children at risk for chronic and severe obstruction of the upper airway.
 - Mechanical ventilation might be required in the interim.
- Tracheomalacia
 - Congenital disorder of the trachea
 - Symptoms usually appear before 2 months of age.
 - Has both inspiratory and expiratory sounds
 - Chronic wheezing is present.
 - May be misdiagnosed as asthma

Children beyond the newborn period

Acquired infectious causes of airways obstruction

- Epiglottitis (See table on following page)
 - The infectious organism is *Haemophilus influenzae* type b. Routine vaccination of children with Hib vaccine has decreased the incidence of infections with *Haemophilus influenzae* type b.
 - Age range: 2–6 years
 - Onset is rapid, over a period of hours.
 - Clinical presentation
 - Fever
 - Drooling
 - Dysphagia
 - Muffled voice
 - While epiglottitis is rare, it can result in a medical emergency.
- Laryngotracheobronchitis (croup)
 - Most common upper respiratory obstruction in childhood
 - Age range: 6 months to 3 years
 - Peak incidence in second year of life
 - Occurs most commonly in late fall and early winter
 - Worse at night

- Symptoms
 - Barky cough
 - Hoarse voice
 - High-pitched inspiratory stridor
 - Fever
- Retropharyngeal abscess
 - Most common in children between the ages of 2 and 4 years
 - Presenting symptoms:
 - Neck pain
 - Fever
 - Sore throat
 - Children may be unwilling to move the neck because of discomfort.
- Peritonsillar abscess
 - Most common deep neck infection in children and adolescents
 - Clinical presentation:
 - Severe sore throat
 - Fever
 - Muffled voice
 - Swelling of the neck accompanied by neck pain
- Bacterial tracheitis
 - Incidence is low, but illness is serious.
 - Affects children between 4 and 8 years of age
 - Distinguish from croup by patient age, severity of illness, and symptoms that worsen over time.
 - Clinical presentation
 - Fever
 - Barky cough
 - Stridor
- Laryngeal papillomatosis
 - Infection of the airways by human papillomavirus
 - Most commonly acquired as the neonate passes through the birth canal
 - Diagnosed in children between 2 and 4 years of age
 - Clinical presentation:
 - Hoarseness
 - Stridor
 - Respiratory distress in advanced cases
- Vascular anomalies, such as vascular ring
 - Structural anomalies can produce extrinsic compression of the airway, resulting in obstruction and respiratory distress.
 - With severe obstruction, infants may exhibit failure to thrive.

Comparison of Epiglottitis, Laryngotracheobronchitis, Spasmodic Croup, and Bacterial Tracheitis

Factor	Epiglottitis	Viral Croup	Spasmodic Croup	Bacterial Tracheitis
Age (yr)	2–6	0.6–2	0.5–3	4–8
Organism	<i>Haemophilus influenzae</i> type b	Parainfluenza 1,2,3	Gastroesophageal reflux	<i>Staphylococcus aureus</i> , <i>Haemophilus influenzae</i> type b
Season	All year	Late spring, late fall	All year	All year
Clinical Presentation	Child sitting Toxic Drooling Dysphagia Muffled voice	Child lying down Nontoxic Barking cough Hoarseness	Nontoxic Barking cough Hoarseness	Toxic Barking cough
Onset Prodrome	Rapid over a few hours	Variable; few hours to 4 days	Sudden	Variable; few hours to 5 days
Stridor	Less common	Common	Very common	Common
Fever	High	Low-grade	Afebrile	High
Chest Retractions	Less common	Common	Common	Common
Lateral Neck Film	Swollen epiglottis	Subglottic narrowing	None	Pseudomembrane in trachea
Progression	Rapid	Usually slow	Rapid	Usually slow, occasionally rapid
Recurrence	Rare	Common	Very common	Rare

Acquired noninfectious causes of airways obstruction

- Vocal cord dysfunction
 - Sudden onset of labored breathing with inspiratory stridor
 - Often self-limiting
- Anaphylaxis
 - If edema involves the retropharynx or larynx, the clinical presentation may be severe and life-threatening.
 - Onset of symptoms is usually sudden.
 - The patient may have urticaria and facial edema.
- Foreign body aspiration
 - Usually seen in children <3 years, with peak incidence between 1 and 2 years of age.
 - Most commonly aspirated objects include:
 - Peanuts, nuts, and seeds
 - Food particles
 - Hardware
 - Pieces of toys, eg, balloons, small marbles
 - Respiratory characteristics depend on where the foreign body is lodged.
 - Wheeze predominates on expiration.
 - Stridor predominates on inspiration.

LABORATORY EVALUATION

- C1 esterase measurement may be necessary in children with suspected angioneurotic edema.

IMAGING

- Anteroposterior or lateral neck radiograph may be required to diagnose:
 - Laryngotracheobronchitis
 - Epiglottitis
 - Retropharyngeal abscess
 - Peritonsillar abscess
- Inspiratory and expiratory radiographs may be required in the case of foreign body aspiration.

DIAGNOSTIC PROCEDURES

- Flexible bronchoscopy may be required to diagnose:
 - Laryngomalacia
 - Subglottic stenosis
 - Laryngeal cysts, webs, and hemangiomas
 - Vocal cord dysfunction
 - Epiglottic cysts
 - Laryngeal papilloma
- Rigid bronchoscopy may be required to diagnose:
 - Foreign body aspiration
 - Retained foreign body

- Suspension laryngoscopy may be required if laryngotracheoesophageal clefts are suspected.
- Fluoroscopy may be required to diagnose:
 - Foreign body aspiration
 - Laryngomalacia
- Pulmonary function testing may be necessary in children with suspected subglottic stenosis.

TREATMENT APPROACH

- Acute airways obstruction resulting in severe respiratory distress is a medical emergency and should be treated accordingly.
- In less emergent situations, the child can be treated appropriately as per the diagnosis.

SPECIFIC TREATMENTS**Anaphylaxis**

- Treatment must be immediate.
- Initial therapy is intramuscular injection of epinephrine.
- After initial treatment, systemic corticosteroids should be provided.

Foreign body aspiration

- In children with severe respiratory distress, treat immediately with rigid bronchoscopic removal of the foreign body.
- Rigid bronchoscopy is preferred, as it provides control of the airway throughout the removal process.

Laryngomalacia

- The disorder improves over time.
- Infants rarely require an artificial airway.

Vocal cord paralysis

- Unilateral cord paralysis requires no specific therapy and resolves over time.
- Tracheotomy may be necessary in infants with bilateral vocal cord paralysis.

Tracheomalacia

- Use of β -agonists may worsen the airflow obstruction.
- Medications that increase the smooth-muscle cell tone of the trachea can improve airflow.

Laryngotracheobronchitis (croup)

- Most children have an uncomplicated course and are managed without formal medical care.

Peritonsillar abscess

- See Pharyngitis and Tonsillitis.

Bacterial tracheitis

- Antibiotics and supportive care are essential.
- Some otolaryngologists recommend placing tracheotomy tubes in children with bacterial tracheitis.

Laryngeal papillomatosis

- Remove the obstructing lesions with laser ablation to prevent regrowth.
 - Recurrent ablations may be required.

Vocal cord dysfunction

- Patient education, speech therapy, and biofeedback to teach patients to control vocal cord movement have produced favorable results.
- The goal is to train the extrinsic laryngeal muscles.

WHEN TO REFER

- An otorhinolaryngologist or general surgeon should be consulted if there is a high index of suspicion for foreign body aspiration.

WHEN TO ADMIT

- Patients with severe respiratory distress requiring supplemental oxygen.
- Infants with upper airways obstruction who have difficulty drinking and maintaining hydration.
- Patients with epiglottitis, retropharyngeal abscess, or bacterial tracheitis.

FOLLOW-UP

- Patients with laryngomalacia and tracheomalacia need to be followed carefully for weight gain and improvement in symptoms.

COMPLICATIONS

- In bacterial tracheitis, complications include:
 - Toxic shock syndrome
 - Septic shock
 - Postintubation pulmonary edema
 - Acute respiratory distress syndrome
 - Subglottic stenosis

PROGNOSIS

- Prognosis depends on the cause of airways obstruction.

Allergic Rhinitis

DEFINITION

- Atopic disease caused by exposure to allergens and characterized by nasal congestion, sneezing, rhinorrhea, and pruritus
 - Seasonal variation (hay fever)
 - Year-round (perennial) form
- May exist alone or in combination with asthma or atopic dermatitis

EPIDEMIOLOGY

- Prevalence
 - Allergic rhinitis is the most common of the atopic diseases, occurring in approximately 15% of the general population.
 - The perennial form is more common than the seasonal variation
- Age
 - In children, relatively uncommon before the age of 3 years
 - Increases in frequency thereafter, reaching peak prevalence in adolescence
- Seasonality
 - Symptoms peak in spring and fall in colder climates.
 - Symptoms can occur year-round in warmer climates, with the highest levels occurring in warmer, more humid months.

ETIOLOGY

- Allergic rhinitis is caused by exposure to an allergen and subsequent sensitization in a child who has a genetic predisposition to atopy.
- Reexposure to the same allergen causes an immediate type I hypersensitivity reaction.

RISK FACTORS

- As with all atopic disease, the tendency to develop allergic rhinitis is inherited.
- Exposures: seasonal allergic rhinitis
 - Pollens
 - Wind-borne from trees and grasses in the spring
 - From weeds (especially ragweed) in the fall
 - Flower pollens rarely cause allergic problems.
 - Great variation according to location
 - Molds
 - Indoors and outdoors
- Exposures: perennial allergic rhinitis
 - Animal dander
 - Skin (dander) and saliva of household pets, such as dogs and cats
 - Rodent allergens, found predominantly in urine of vermin and pets, such as hamsters and guinea pigs

- Dust mites
 - Major allergen in house dust and major cause of perennial allergic rhinitis
 - Prosper in warm, moist, indoor environments, colonizing pillows, mattresses, and carpets
- Cockroaches
 - Common in urban areas

SIGNS AND SYMPTOMS

- Severity of symptoms varies depending on individual level of sensitivity and the intensity of antigen exposure.
- Younger children usually have perennial symptoms, whereas pollen sensitivity becomes more common after the age of 4 years.
- Acute seasonal variety
 - Physical examination may be striking, especially during periods of seasonal rhinitis, or unremarkable when symptoms are quiescent.
 - Pale, bluish, and boggy nasal mucosa with a clear serous discharge
 - Nasal turbinates are enlarged, sometimes enough to obstruct the airway almost completely.
 - Children who have perennial problems often have typical allergic facies.
 - Allergic shiners (dark discoloration beneath both eyes)
 - Dennie lines (extra folds below the lower eyelids)
 - Allergic crease (horizontal line across the bridge of the nose)
 - Elongated facies caused by chronic mouth breathing
 - Tonsils and adenoids often are enlarged.
 - Evidence of middle-ear effusion may be found.
 - Nasal polyps can occur but are uncommon in childhood allergic rhinitis.
- Perennial variety
 - Sufferers typically have less dramatic or fewer specific symptoms.
 - Although nasal congestion is still the most prominent symptom, children often display such symptoms as:
 - Frequent colds
 - Recurrent otitis media
 - Nasal speech
 - Mouth breathing
 - Snoring
 - Fatigue
 - Epistaxis
 - Nasal discharge is usually clear unless the child has a superimposed infection.

- Many children perform the “allergic salute,” a maneuver in which they sniff and sweep the palm of their hand upward across the tip of the nose in attempt to open their nasal passages, remove secretions, or relieve nasal itching.
- Facial grimacing is used to relieve nasal itching.

DIFFERENTIAL DIAGNOSIS

■ Conditions that are often confused with allergic rhinitis:

- Recurrent upper respiratory tract infections
 - Differentiated from allergies by their intermittent course; history of contagion; and the presence of fever, purulent nasal discharge, or erythematous, inflamed nasal mucosa
 - Eosinophils will not be prominent on a nasal smear.
 - Family history for allergy is more likely to be negative.
- Vasomotor rhinitis
 - Poorly defined condition that may begin at any age
 - Characterized by hyperreactivity of the nasal mucous membranes to a wide variety of irritant stimuli
 - The prominent symptom is usually perennial nasal obstruction that responds poorly to environmental controls or medications.
 - Usually, no family history of allergy, although other family members may report chronic nasal congestion
 - Nasal smear and skin test results are negative, serum IgE is normal, and no eye signs or other atopic manifestations are present.
- Nonallergic rhinitis with eosinophilia
 - Affects adolescents and adults
 - Nasal smear results are positive for eosinophils, but serum IgE is normal and skin test results are negative.
- Adenoid hypertrophy
 - Typically presents as nasal obstruction with little or no rhinorrhea
 - Commonly associated with recurrent middle ear, nasal, or sinus infections
 - In severe cases, obstruction leads to obvious changes in the structure of the face and palate caused by chronic mouth breathing.
 - Snoring is common, as is a nasal quality to the voice.
- Nasal foreign body
- Choanal atresia
- Rhinitis medicamentosa
- Cystic fibrosis
- Nasopharyngeal tumor

DIAGNOSTIC APPROACH

- Allergic rhinitis is characterized clinically by a combination of nasal congestion, sneezing, rhinorrhea, and pruritus.
- Diagnosis of seasonal variety typically is based on the clinical presentation, physical examination, and knowledge of local pollens.
 - For local pollen counts, see American Academy of Allergy, Asthma & Immunology web site, www.aaaai.org
- Nonspecific perennial symptoms pose a more difficult diagnostic challenge.

LABORATORY FINDINGS

■ Nasal smear for eosinophils

- Simple office procedure that can help confirm the clinical diagnosis of allergic rhinitis
- The patient blows his or her nose into plastic wrap or wax paper.
 - A cotton swab may be used to obtain secretions if the patient cannot blow.
- Secretions are spread onto a glass slide, left to dry, and then prepared with Hansel or Wright stain.
 - If >10% of cells seen on the smear are eosinophils, an ongoing allergic process is probable.
 - Strongly positive results are most likely during heavy exposure to the allergen.
 - Concurrent nasal infection may obscure the results, and eosinophils may be absent during the off season.
 - Not recommended as a screening test for allergic rhinitis

■ Leukocyte count

- Blood eosinophilia is occasionally found.
 - >5% eosinophils on the differential leukocyte count *or*
 - >250/ μ L eosinophils in total

■ Serum IgE

- Elevated total serum IgE level suggests atopy, but many patients who have allergic rhinitis have a normal serum IgE level.
- Not recommended as a screening test for allergic rhinitis

■ Skin tests

- Can detect antigen-specific IgE and identify specific allergic sensitivities in patients in whom the diagnosis is in question or who need more aggressive management
- Should be performed by a physician who is trained in their use
- Should be interpreted in the context of the clinical history

■ Radioallergosorbent tests

- Can detect antigen-specific IgE and identify specific allergic sensitivities in:
 - Patients in whom the diagnosis is in question
 - Patients who are in need of more aggressive management

- Higher cost and slightly lower sensitivity than skin test
- Accurate overall and can be used efficiently in the primary care physician's office as a limited screening test for allergy
 - Also will identify specific allergens to be targeted for environmental control
- When extensive laboratory testing is needed, referring the patient to an allergist will usually be more cost effective.

TREATMENT APPROACH

- Management of allergic rhinitis incorporates information from a thorough history and physical examination.
- Stepwise program of treatment typically consists of allergen avoidance measures and pharmacotherapy.
- Each child's treatment must be individualized for:
 - Age
 - Severity of symptoms
 - Specific environmental issues
 - Presence or absence of complications
 - Coexisting medical conditions

SPECIFIC TREATMENTS

Environmental control

- First line of therapy at all ages
- Particular attention should be directed to the child's bedroom and other settings where substantial amounts of time are spent.
- Dust mite allergy
 - Reduce exposure via dust mite–proof encasements for mattresses, box springs, and pillows.
 - Remove stuffed animals and similar items.
 - Hot wash bed linens every 1–2 weeks.
- Household pets
 - Ideally, pets should be removed.
- There is some benefit from keeping the pet out of the child's bedroom, using mattress and pillow encasements, removing carpets, and using an air cleaner in the bedroom.
- Pollens
 - Close windows and use an air conditioner.
 - Forced-air heating and cooling systems can be improved by adding humidifiers and air filters.
 - Keep relative humidity below 50% to discourage dust mite and mold growth.

Oral antihistamines

- First-line pharmacologic treatment
- Most effective in controlling rhinorrhea, sneezing, and pruritus
 - Less effective in relieving nasal congestion

- First-generation antihistamines: diphenhydramine, chlorpheniramine, hydroxyzine
 - Very effective, but use may be limited by their sedative side effects
 - Can impair school performance significantly
 - Many children can be treated effectively with a single bedtime dose, especially if symptoms are worse at night.
- Second- and third-generation antihistamines: loratadine, desloratadine, cetirizine, fexofenadine
 - Now approved for use in children
 - Not necessarily more potent, but lack of sedation is an important advantage

Oral decongestants

- Pseudoephedrine may have value in some children, especially when nasal congestion is a major symptom.
- Can be used either alone or in combination with an antihistamine
- Should be used with caution because some children experience significant stimulatory effects, which may produce:
 - Hyperactivity
 - Irritability
 - Sleep disturbance

Leukotriene antagonist

- Montelukast
 - Approved for treatment of both seasonal and perennial allergic rhinitis
 - Similar in efficacy to oral antihistamines
 - Generally well tolerated
 - May be particularly useful in children with coexistent asthma and allergic rhinitis

Oral corticosteroids

- Prednisone
 - Rarely, short courses may be needed for severe cases that do not respond to other therapies.
 - Topical sprays
 - Nasal corticosteroids are the most effective pharmacologic agents for allergic rhinitis.
 - Available preparations include:
 - Beclomethasone
 - Budesonide
 - Fluticasone
 - Mometasone
 - Triamcinolone
 - Mometasone and fluticasone are approved for use in patients ≥ 3 years of age.

- Oral corticosteroids carry the slight potential to adversely affect growth in children; therefore, they should always be used at the lowest possible dose.

Decongestant nasal sprays and other topical preparations

- Decongestant nasal sprays
 - May provide transient relief, often followed after several days of use by rebound congestion
 - Prolonged use of nasal sprays often leads to worsening of symptoms (rhinitis medicamentosa) and should be discouraged.
- Other topical preparations
 - Antihistamine: azelastine
 - Of similar potency to oral antihistamines; can also have sedative side effects
 - Nasalcromolyn sodium
 - A safe drug that is reasonably effective, although its usefulness is significantly limited by the need to use it 4–6 times a day
 - Ipratropium nasal spray
 - Approved for children ≥ 6 years of age and may be helpful in the control of rhinorrhea
 - May have a particular advantage in cases of nonallergic rhinitis in which excessive rhinorrhea is a major symptom

Immunotherapy

- Use if clinical history and skin test results correlate.
 - Must be used selectively
 - Typically reserved only for patients in whom standard medications and avoidance measures have failed
- 3- to 5-year course of regular injections achieves maximal benefit and minimizes the chance of relapse after discontinuing treatment.
 - Most effective in treating seasonal allergic rhinitis, with $>80\%$ of patients achieving significant relief
 - Beneficial for most cases of perennial disease
- As treatment progresses, patients can expect a gradual decline in symptoms and reduced reliance on medication.
- Disadvantages
 - Possible local and generalized reactions
 - Inconvenience and expense associated with regular injections

WHEN TO REFER

- Perennial symptoms
- Poorly controlled disease
- Suspected complications (eg, chronic sinusitis)
- Need for immunotherapy
- Parental needs

COMPLICATIONS

- Children who have allergic rhinitis may suffer early from an increased incidence of respiratory infections, acute otitis media, and eustachian tube dysfunction, leading to serous otitis media.
 - Several studies have suggested an association between allergy and chronic serous otitis media.
 - Only 1 of many risk factors
- Acute and chronic sinusitis are common, probably the result of reduced ciliary clearance and obstruction of sinus ostia.
- Asthma is often seen in combination with allergic rhinitis but is not viewed typically as a complication of untreated allergic rhinitis.
- Occasional abnormal facial development, a high arched palate, and orthodontic problems from chronic mouth breathing
 - Especially in cases with associated adenoid hypertrophy

PROGNOSIS

- Allergic rhinitis waxes and wanes over time.
- Most children tend to improve with time, although very few ($<10\%$) lose their symptoms completely.
- Remission of symptoms may result from changes in environment, avoidance programs, and immunotherapy.
- The care provider should counsel patients that allergic symptoms can be controlled but not eliminated entirely.
 - Success of any treatment depends on the patient's understanding of the causes of symptoms and compliance with the prescribed regimen.

PREVENTION

- Prevention of recurrence involves:
 - Control of environmental factors
 - Avoidance of allergens
 - Compliance with treatment

Alopecia and Hair Shaft Anomalies

DEFINITION

- Alopecia
 - Loss of hair
- Hair shaft anomalies
 - Stubby growth of broken hair rather than true alopecia

EPIDEMIOLOGY

- Sex:
 - In general, may occur in either sex
- Androgenetic alopecia
 - Age
 - 15% of adolescents >14 years of age
 - Fullest expression is most common in the mature adult.
 - Sex
 - Occurs most often in males
- Loose anagen syndrome
 - Age
 - Preschoolers between 2 and 5 years of age
 - Sex
 - Females are more often affected.

MECHANISM

- Hair loss can result from:
 - Congenital disorders
 - Hereditary disorders
 - Head trauma
 - Physical or emotional stress
 - Stress on the hair from:
 - Braiding
 - Teasing
 - Other tightly pulled hairstyles
 - Antimetabolites for treatment of cancer
- Loss can be:
 - Total
 - Thinning
 - 50% loss is necessary before the casual observer will notice hair loss.
- Phases of hair growth/loss
 - Anagen phase
 - Active hair growth over 2–6 years
 - Lanugo, the first hair made by hair follicles in utero
 - Lanugo is lost a few months after birth and is a normal process that results in a temporary near-baldness.
 - In many instances, parents are concerned with the thinning or with a localized area of loss, usually over the occiput, the result of the pressure of the head as the infant lies in the crib.

- Telogen phase
 - Resting period of ~3 months
 - As many as 15% of scalp hairs may be in the telogen phase at any time.
 - Up to 100 hairs are lost from the scalp daily and 200 with shampooing (not apparent to casual observer).

HISTORY

- A precise, pointed history is necessary.
- When a child loses scalp hair suddenly, a toxic event should be suspected.
 - Accidental poisoning, eg, rat poison containing thallium or coumarin
 - In most instances, over several months, new hairs will replace lost hairs, unless the exposure to the toxic element is chronic.
- True congenital alopecia is rare.
 - May be inherited as an autosomal-recessive trait
 - If the loss is not due to this genetic circumstance but is congenital, it is most often evidence of a significant hereditary disorder.
- Hairs may be thin or poorly anchored to the scalp or have a variety of shaft abnormalities.

PHYSICAL EXAM

- The entire body and all its hair-bearing parts must be observed.
 - The pediatrician must not limit the examination simply to the site of hair loss.
- It is important to determine if alopecia is scarring or nonscarring.
- The texture of hair may be helpful in finding the source of difficulty.
- Appropriate diagnosis requires microscopic differentiation of the hair and its root.

DIFFERENTIAL DIAGNOSIS

Congenital alopecia

- Ectodermal dysplasia
- Skeletal defects
 - Cartilage-hair hypoplasia
 - Congenital ectodermal dysplasia
 - Orofaciodigital syndrome
- Inherited metabolic or endocrine disorders
 - Phenylketonuria
 - Homocystinuria
 - Congenital hypothyroidism

■ Serious chromosomal defects

- de Lange syndrome
- Trisomy 13 syndrome
- Surfeit of signs and symptoms beyond simple loss of hair

■ Nonscarring alopecia with hair shaft abnormalities

■ Trichorrhhexis nodosa

- Common abnormality of the hair shaft characterized by:
 - Fragile, short hair with grayish-white nodules
 - Breakage of hair and short stubble over the scalp
 - White specks marking the nodes may appear after some physical and chemical injuries.
- Usually accompanied by a history of hair straightening or repeated vigorous brushing and combing

■ Monilethrix (beaded hair syndrome)

- Scalp hairs have regularly spaced differences in their circumference, suggesting a chain of beads.
- Fragile, short, stubble-like growth
- Associated problems suggestive of a more widespread ectodermal defect:
 - Cataracts
 - Brittle nails
 - Faulty teeth

■ Pili torti (twisted hair)

- Fragile, short, light/“off”-colored hair appears spangled as a result of light reflection.
- Texture is coarse and lusterless.
 - As though straight and curly hair were competing for a place in the same strand
- Associated with Menkes kinky hair syndrome, an X-linked disease characterized by:
 - Low serum copper level
 - Progressive cerebral degeneration
 - Arterial degeneration
 - Suggestion of scurvy in the bones

■ Nonscarring alopecia without hair shaft abnormalities

■ Alopecia areata

- Most often seen as an acute problem
 - Sharply demarcated, round, nearly bald patches
 - Inflammatory signs are not present.
- Patches tend to be several centimeters in diameter, usually on the scalp.
 - Possible anywhere on the body where hair is found (see Figure 4 on page F1)
 - Loss may comprise only a few patches or a total absence of body hair (alopecia universalis), including eyebrows and eyelashes.

- Sometimes salmon-colored, as a manifestation of the presumed inflammation seen histologically around the hair follicle
- Exclamation point hairs may appear throughout the patch.
- Hairs at the periphery of an area are plucked easily and may be particularly colorless and thin.

• Fingernails may be pitted.

- Possible indication of a more extensive ectodermal problem
- Cause
 - Unknown, but may be related to a T cell-mediated autoimmune process
 - Associated with acute autoimmune thyroid disease and vitiligo
 - Possible genetic predisposition

■ Androgenetic alopecia

- Male baldness pattern
 - Begins most often with a receding hairline and some thinning over the vertex
- Diffuse thinning with retained frontal hair in the female
- Hairs from affected follicles do not epilate easily on pulling, but they are shorter and finer because of normal pubertal androgen increase in susceptible individuals.
- Cause
 - Genetically determined

■ Trichotillomania

- Irregularly shaped areas of thinned stubble of varying lengths
 - Large, patchy, ill-defined patterns
 - Area of hair loss is most accessible to the probing hand.
 - May simulate alopecia areata (see Figure 5 on page F1)
- Patient may eat hair, which can accumulate in the stomach and form a trichobezoar (hairball).
 - Abdominal pain
 - Possible acute intestinal obstruction
 - Palpable as an abdominal mass
- Cause
 - Some children have a compulsive need to pull out their hair or even eyebrows or eyelashes.
 - May sometimes (but not always) provide a major clue to an underlying psychosocial problem

■ Traumatic alopecia

- Bizarre patterns conforming to site and method of injury
 - May be accompanied by redness and inflammation
 - Pustular involvement of the follicles is possible.

- Causes
 - Head trauma
 - Braiding
 - Constant teasing or straightening with heat or chemicals
 - Hairstyles (eg, barrettes, ponytails, braids, or cornrows) that cause constant and prolonged traction, especially along the hairline
 - Telogen effluvium
 - Diffuse thinning with easy epilation from all areas of scalp
 - Nonpatterned
 - Nonscarring
 - Hair loss may increase to as much as 60%.
 - During such a period, the situation is similar to that of animals, which shed seasonally.
 - Causes
 - May be related to a history of stress
 - Prolonged fever
 - Pregnancy
 - Severe illness
 - Anagen effluvium
 - Significant thinning
 - Loose anagen syndrome
 - Hair appears sparse.
 - Hairs are quite easily and painlessly pulled from the scalp.
 - Individual hairs are not fragile.
 - Hair over the occiput often is matted and sticky.
 - Typically, the child's hair is said to be slow growing, seldom requiring cutting.
 - Causes
 - Hereditary factor may be involved.
 - Most cases are sporadic.
- Potentially scarring alopecia without hair shaft abnormalities**
- Tinea capitis and kerion
 - Presentation varies.
 - Round, minimally inflamed alopecic area with slight seborrheic scale
 - Boggy, tender often pustular, severely inflamed kerion
 - Lesions tend to be more elevated than in other forms of tinea and may be characterized by black dots.
 - Tinea capitis (see Figure 6 on page F2) should be considered:
 - When a child has patches of alopecia or stubbly hair growth
 - When alopecia is accompanied by local adenopathy
 - Even in the absence of crusting, scaling, redness, or other inflammatory signs
 - Differential diagnosis includes:
 - Seborrheic dermatitis
 - Atopic dermatitis
 - Psoriasis
 - Causes
 - *Trichophyton tonsurans*
 - *Microsporum canis*
 - *Microsporum audouinii*
 - Kerion
 - Delayed hypersensitivity reaction to fungus
 - If unchecked, resultant scarring interferes with the regrowth of hair (see Figure 7 on page F2).
 - Early diagnosis and treatment are therefore helpful.
 - Lupus erythematosus
 - Discoid variant
 - Discoid, well-demarcated erythematous plaques
 - Scale
 - Plugged follicles
 - Atrophy and/or thinning as a result of broken, fragile hair with acute flares (lupus hair)
 - Can be disfiguring to the scalp
 - With scarring, can cause permanent hair loss (see Figure 8 on page F2)
 - Systemic variant
 - Scalp may be erythematous.
 - Scarring is not characteristic.
 - Acrodermatitis enteropathica
 - Abnormal zinc absorption
 - Cutaneous manifestations simulating:
 - Psoriasis
 - Epidermolysis bullosa
 - Pyoderma
 - Candidiasis
 - Zinc deficiency can result in:
 - Abdominal pain and diarrhea
 - Wispy alopecia
 - Dystrophic development of the fingernails, suggesting widespread ectodermal involvement
 - Cause
 - Autosomal-recessive
- LABORATORY EVALUATION**
- Light microscopy
 - Anagen hairs
 - Fat, healthy follicle bulbs
 - Attached emerging long terminal hair

- Telogen hairs
 - Small bulb
 - Attached hair with a club-shaped appearance
- Light microscopic characteristics of various alopecias:
 - Trichorrhexis nodosa
 - Nodes along hair shaft similar to interlocking broom or brush ends
 - Monilethrix
 - Variable shaft thickness gives a beaded appearance with internodal breakage.
 - Pili torti
 - Irregularly spaced twists along the shaft appear flattened
 - In cross-section, a straight hair appears round, and a curly hair appears oval.
 - Both configurations may be seen in a single strand; this can be an important clue to Menkes kinky hair syndrome.
 - Alopecia areata
 - Exclamation point hairs from periphery of patches with poorly pigmented shaft and tapered attenuated bulb
 - Androgenetic alopecia
 - Increased telogen:anagen ratio, frontal scalp
 - Trichotillomania
 - Normal cuticle, shaft, and anagen bulb of varying lengths
 - Traumatic alopecia
 - Normal cuticle, shaft, and anagen bulb of varied lengths
 - Telogen effluvium
 - >25% of pulled hairs are telogen club hairs with no pigment
 - Anagen effluvium
 - Tapered anagen bulbs
 - Loose anagen syndrome
 - Anagen hairs have misshapen pigmented anagen bulbs with ruffled cuticle and no external root sheath.
 - Tinea capitis and kerion
 - Potassium hydroxide preparation of broken hairs (black dot hairs) reveals clusters of chains of arthrospores around or in the hair shaft and bulb.
 - Lupus erythematosus
 - Not applicable if there is scarring
 - Short, broken (frayed) anagen hairs
- Mycologic analysis
 - *T tonsurans* indicates tinea capitis.
 - In rare cases, the endothrix fungi *M canis* and *M audouinii* invade the hair shaft and cause breakage and stubbiness.
 - *M canis* tends to cause much more inflammation than does *M audouinii*.

- Endothrix fungal infections, but not *T tonsurans*, can produce a greenish fluorescence under Wood light in a darkened room.

IMAGING

- Radiography
 - Congenital alopecia
 - Skeletal defects
 - Trichotillomania
 - Presence of a trichobezoar

DIAGNOSTIC PROCEDURES

- Biopsy
 - Miniaturized anagen bulbs in androgenetic alopecia
 - Fungus *T tonsurans*

TREATMENT APPROACH

- Treatment depends on the underlying cause of alopecia.
 - There may be helpful treatments.
 - The pediatrician's role may be only diagnostic and supportive.

SPECIFIC TREATMENT

Trichorrhexis nodosa

- A gentle approach results in gradual improvement.
- Eliminate any noxious exposure.

Monilethrix

- No treatment is known.
- Some degree of recovery may occur spontaneously, particularly after puberty or during pregnancy.

Alopecia areata

- Spontaneous regrowth
 - About one-third of patients will regrow hair spontaneously in 6 months.
 - About one-third will regrow hair spontaneously within 5 years.
 - About one-third must be treated to stimulate hair growth.
- Cortisone cream
 - Topical applications have been used with some success.
- Cortisone injection
 - Direct injection into the scalp or eyebrow hair follicles can be effective.
 - The process is painful.
 - Large areas (>50% scalp hair loss) that require infiltration present difficulty.
 - Use with caution in the older, more cooperative child.

- The pediatrician must carefully assess the impact of the disease and the treatment on the child before selecting this procedure.
- The patient should be referred to a dermatologist for consideration of this intervention.
- Oral corticosteroid therapy
 - Risks serious complications, but is occasionally used
- Minoxidil
 - 5% minoxidil solution twice daily
 - Can be effective for small, stubborn alopecic areas
- Irritants
 - Used for extensive alopecia
 - Dinitrochlorobenzene immunotherapy
 - Tars, such as short-contact anthralin
 - Psoralen with ultraviolet A light (PUVA therapy)
 - Use only in children >12 years.
 - Should be performed only by a knowledgeable dermatologist in controlled circumstances
- Efficacy of treatment
 - Difficult to assess because of the waxing and waning nature of alopecia areata
 - Pediatricians should remind patients and families that this process is nonscarring, which always has the potential for full regrowth.

Androgenetic alopecia

- No therapy is reliably effective.
- Some patients may be helped by:
 - Topical minoxidil twice daily
 - Hair transplant micrografts
- Finasteride
 - Can be given after 18 years of age in male patients
 - Contraindicated in female patients because of the possibility of genital defects in exposed male fetuses if a pregnancy occurs

Trichotillomania

- Petroleum jelly
 - The primary care pediatrician can paint the attacked areas in an attempt to frustrate the habit.
- Imipramine
- Fluoxetine
- Psychiatric intervention
 - Without attention to the possibility of an underlying emotional issue, other treatments are temporary.
 - Family structure and interaction with siblings and parents and with friends at home and at school should be explored in an effort to find stressors.
 - Consulting a psychiatrist should also be considered.

- Surgery or endoscopy
 - Referral for removal of a trichobezoar

Traumatic alopecia

- Simply discontinuing the stress will help.
- Injured hair follicles will often require ≥ 3 months to return to an anagen phase.

Loose anagen syndrome

- Management is limited to reassurance and the passage of time.
- The hair eventually grows thicker and longer, and its pigmentation increases.

Tinea capitis

- Griseofulvin is the standard of care.
 - Topical antifungal agents do not provide adequate treatment.
 - Several other systemic fungistatic agents are effective.
 - The long course of oral therapy with griseofulvin (~2 months) may present difficulties with compliance in a young child.
- Terbinafine
 - This fungicidal drug appears effective when given for 2–4 weeks but is currently not approved for this use by the US Food and Drug Administration (FDA).
- Itraconazole and fluconazole
 - May be safe for short courses in children but are not FDA approved for this use
 - Liquid itraconazole has been associated with diarrhea in children and with pancreatic adenocarcinoma in laboratory animals and should be avoided.
- Prednisone
 - Oral, tapered over 10 days
 - Rapidly decreases tenderness and inflammation of a kerion
 - Prevents widespread id reaction
- Secondary infection
 - With *M canis* or after treatment with an irritant
 - Inflammation may require treatment with an antibiotic.

Lupus erythematosus

- Discoid variant
 - Early treatment with topical or intralesional steroids may prevent scarring.
- Systemic variant
 - Loss of hair is generally temporary.

Acrodermatitis enteropathica

- Oral zinc sulfate is the treatment of choice.
- Strategies for the patient to hide noticeable loss of hair
 - Suggest that the child wear a baseball cap or other concealing adornment if appropriate.

- A hairpiece can be designed for a child.
- These steps serve in the interim while practitioners:
 - Attempt potentially helpful treatments
 - Wait expectantly if their role is diagnostic and supportive
- Management if recovery of hair is questionable
 - Work with and listen to the patient and family to:
 - Achieve an emotional balance consistent with reality
 - Adopt suitable coping mechanisms
 - Plastic surgery
 - Expertise should be sought for consideration of hair transplants and scalp reduction (for scarred areas) when possible.

WHEN TO REFER

- Rapid, diffuse hair loss
- Chronic, progressive, localized, or diffuse hair loss without regrowth
- Scarring alopecia
- Inability to grow hair as a result of breakage, loss, or abnormal texture of hair
- Appearance of scalp mass or plaque affecting localized hair loss

FOLLOW-UP

- Liver function testing
 - If antifungal medications are used for >12 weeks
 - At the start of therapy if any suggestion of preexisting liver disease exists

PROGNOSIS

- The possibility that hair will not regrow must be considered when loss:
 - Follows high fever or chronic toxicity
 - Is accompanied by scarring
 - Occurs in the areas of:
 - Nevi
 - Aplasia cutis
 - Persistent hemangioma

- Prognosis for the return of hair depends on:
 - Elimination of the toxic stimulus
 - Whether the loss is accompanied by scarring
 - Loss associated with nonscarring conditions is recoverable.
 - Loss with scarring (eg, from iatrogenic scalp injury during delivery or from a burn) is permanent.
- Alopecia areata
 - The more extensive the loss and the younger the child, the less likelihood is of a full recovery.
 - Prognosis is best when:
 - Loss is less widespread.
 - Only 1 or 2 patches are present.
 - When hair does regrow, it may initially be white.
 - Eventually, color returns, and casual observers cannot identify the formerly affected area.
- Traumatic alopecia
 - In childhood, the hair will usually return, although regrowth can be slow.
- Loose anagen syndrome
 - After recovery and even into adulthood, the hair may still pull out easily and painlessly.
- Lupus erythematosus
 - Discoid variant
 - Hair loss can be permanent.
 - Systemic variant
 - Loss of hair is generally temporary.
 - There is no scarring, unlike in discoid disease.

PREVENTION

- Hair is fragile.
 - It should be handled gently and without physical or chemical assault.
 - In children, hair is probably best left alone, except for:
 - Simple washing
 - Simple cutting to suit the fashion

Altered Mental Status

DEFINITION

- Consciousness
 - Awareness of self and the environment
- Coma
 - Unresponsiveness to all stimuli, including pain, with the eyes remaining closed
- Alteration of consciousness
 - Begins with becoming unaware of self
 - Followed by reduced awareness of the environment
 - Finally, an inability to be aroused
- Stages between consciousness and coma
 - A progression of symptoms is not an all-or-nothing phenomenon; rather, a continuum of levels of consciousness may exist.
 - Confusion: responses are slowed and cognitive abilities are impaired, usually accompanied by some disorientation
 - Delirium: a succession of confused and unconnected ideas, often with aggression, agitation, and combativeness, with episodes of somnolence and withdrawal
 - Lethargy: a state of profound slumber with limited movement and speech; can be awakened with moderate stimuli
 - Stupor: unresponsive except to repeated, vigorous stimuli
 - Vegetative state: loss of all cognitive neurologic function, communication, and awareness; may retain some non-cognitive functions

EPIDEMIOLOGY

- Nontraumatic coma
 - Bimodal distribution
 - Most common in infants and toddlers
 - Smaller peak in adolescence
 - Infection of the brain/meninges is the most common cause of altered mental status: more than one-third of nontraumatic cases.
 - Exposure to or ingestion of toxic substances is the next most common cause.
 - Accidental ingestion, especially in toddlers
 - Intentional ingestion in adolescents
- The overall incidence of traumatic and nontraumatic coma is similar.
 - However, the rate of traumatic injury tends to increase throughout childhood.

ETIOLOGY

AEIOU TIPS

- AEIOU TIPS is a helpful mnemonic in categorizing the etiology of altered mental status.

- A
 - Alcohol
 - Abuse
- E
 - Epilepsy
 - Encephalopathy
 - Electrolyte abnormalities
 - Endocrine
- I
 - Insulin
 - Intussusception
 - Inadequate fluid
- O
 - Overdose
 - Oxygen deficiency
 - Occult trauma
 - Obstructed ventriculoperitoneal shunt
- U
 - Uremia
- T
 - Trauma
 - Temperature abnormality
 - Tumor
- I
 - Infection
- P
 - Poisoning
 - Psychiatric
 - Postictal
- S
 - Shock
 - Stroke
 - Space-occupying lesion (intracranial)

Commonly ingested agents that cause altered mental status

- Amphetamines
- Anticholinergics
- Anticonvulsants
- Barbiturates

- Benzodiazepines
- Clonidine
- Cocaine
- Dextromethorphan
- Ethanol
- Haloperidol
- Narcotics
- Phenothiazines
- Salicylates
- Selective serotonin reuptake inhibitors
- Tricyclic antidepressants

Infants

- Infection of the brain, meninges, or both
- Complication of congenital malformation (cardiac or central nervous system)
- Metabolic
 - Urea cycle defects
 - Organic acidemias
 - Disorders of amino acid metabolism
- Seizure
- Abuse

Children

- Infection of the brain, meninges, or both
- Seizure
- Toxin
- Trauma
- Metabolic
- Abuse
- Intussusception
- Complications from surgical correction of congenital malformations

Adolescents

- Toxin
- Trauma
- Infection
- Psychiatric
- Seizure
- Complications of surgical correction of congenital malformations
- Metabolic disorder
- Diabetic ketoacidosis is the most common metabolic disorder that occurs with alteration of consciousness.
- Can occur at any age, but is more common in adolescence

SIGNS AND SYMPTOMS

History

- Circumstances of the onset of the neurologic symptoms
 - Events and actions directly preceding the change in mental status
 - Especially for young children and children with chronic conditions, ascertain baseline state of functioning and responsiveness.
- If the alteration in consciousness occurred abruptly, consider:
 - Seizure
 - Sudden cardiac arrhythmia
 - Trauma
 - Structural lesion (epidural hematoma, cerebral contusion)
 - Nonaccidental trauma, especially if the caregiver's history is inconsistent with the clinical findings
 - Ingestion of a toxic substance
 - Ingestion in a young child may not have been witnessed.
 - A detailed list of potential poisons to which the child may have access, including prescription and nonprescription medications, should be obtained.
 - The adolescent may admit to an intentional overdose, but the history is often obscure or unobtainable.
 - In these cases, interviews with accompanying friends and family members are essential.
 - Intracranial hemorrhage
- More gradual change in mental status may suggest:
 - Infection
 - Metabolic abnormality
 - A child with diabetes may have ketoacidosis or hypoglycemia.
 - Children with a metabolic disorder or with hepatic or renal failure may develop encephalopathy.
 - Slowly growing intracranial mass
- Associated symptoms may include:
 - Weakness
 - Headache
 - Vomiting
 - Dizziness
 - Diplopia
 - Seizure-like activity
- Altered mental status preceded by headache (especially on awakening), double vision, and vomiting suggests increased intracranial pressure.

Physical examination

- Establish a baseline with which future examinations can be compared for improvement or deterioration of the child's clinical status.
- Regardless of the underlying cause, patients with an acute change in mental status may exhibit:
 - Reduced awareness of self
 - Reduced awareness of the environment
 - Agitation with periods of heightened mental activity
 - Inability to be aroused
- Although the child appears unresponsive in severe cases, initial changes in mental status are often subtle.
 - Changes are recognized by assessing the child's actions and responses to external and internal stimuli (behavior).
 - Appearance
 - Level of alertness
 - Speech
 - Cry
 - Gaze
 - Mood, consolability
 - Thought
 - Judgment
- Vital signs are particularly important.
 - Hyperthermia
 - Infection
 - Heatstroke
 - Some toxins (eg, cocaine, anticholinergics, phencyclidine)
 - Hypothermia
 - Exposure to cold
 - Alcohol overdose
 - Hypertension, bradycardia, irregular respirations (Cushing triad)
 - Impending cerebral herniation
 - Appear late in the course of increasing intracranial pressure
 - Abnormalities in heart rate and blood pressure
 - Fever
 - Pain
 - Arrhythmias
 - Hypovolemia
 - Myocardial injury
 - Status epilepticus
 - Abnormal respirations
 - Pain
 - Hypoxia
 - Acidosis

- Intoxication
- Brainstem lesions
 - In some cases, the respiratory pattern may be a clue to the level of neurologic dysfunction.
 - Posthyperventilation apnea (short apnea after deep breathing) occurs with lesions in the cerebral hemispheres.
 - As dysfunction moves rostrally from the midbrain to the medulla, the respiratory pattern progresses from Cheyne-Stokes breathing (crescendo-decrescendo hyperpnea followed by apnea) to central neurogenic hyperventilation (sustained, rapid, deep breathing).
 - Irregular, sporadic, apneustic respiration occurs with low brainstem dysfunction.

■ Mouth and throat

- Examine for signs of airway obstruction causing hypoxia.

■ Head and neck

- Bulging fontanelle and nuchal rigidity are signs of meningitis or meningeal irritation from an intracranial mass.
- Head trauma can cause:
 - Intracerebral, epidural, or subdural bleeding
 - Contusions
 - Diffuse axonal injury
 - These conditions can lead to cerebral dysfunction, either by primary neuronal damage or the effects of cerebral herniation with brainstem compression.

■ Skin examination to help identify:

- Hypoxia
- Anemia
- Jaundice
- Carbon monoxide and other poisonings
- Trauma
- Some infections

■ Feigned coma

- Adolescents who are pretending to be unresponsive usually:
 - Avoid hitting themselves when their hand is raised and then allowed to drop to their face
 - Resist opening their eyes
 - Close their eyes quickly and deliberately after being held open by the examiner, as opposed to true coma, during which the eyes close slowly

Neurologic examination

- Directed at determining whether the underlying cause is structural or medical
- Pupillary reflex
 - Pupils may function normally if the insult is confined to the cerebral hemispheres.
 - With thalamic/hypothalamic insult, pupils are miotic but reactive.

- With midbrain involvement, pupils may be midposition, irregular, or dilated; reflexes may be absent if oculomotor nerves are involved.
- Bilateral fixed and dilated pupils indicate massive central nervous system (CNS) dysfunction.
- A unilateral dilated pupil is a sign of uncal herniation.
- Not all abnormal pupillary response is from increased intracranial pressure.
 - Mydriasis
 - Horner syndrome
 - Exposure to anticholinergics, amphetamines, cocaine, tricyclic antidepressants
 - Miosis
 - Cold exposure
 - Exposure to opiates, ethanol, barbiturates, cholinergic agents (eg, organophosphates), clonidine
- Extraocular movements
 - Should be noted at rest
 - Deviation may mean seizure activity or a structural lesion.
 - Asymmetry suggests midbrain/upper pons involvement.
 - Absence suggests lower pons/medullary involvement.
 - Negative doll's eyes (eyes appear painted on the face because they remain stationary with respect to head movement) suggest low brainstem injury.
- Motor function
 - Spontaneous movements should be evaluated for signs of hemiparesis.
 - Structural lesion or uncal herniation
 - Tone should be assessed for flaccidity and responses to painful stimuli.
 - Patients who are unresponsive may have depressed brainstem function.
 - Those with increased tone may have diffuse cortical injury.
- Posturing
 - Poor prognostic sign
 - Decorticate posturing
 - The patient flexes the arms, wrists, and hands and adducts the upper extremities while internally rotating and plantar flexing the lower extremities.
 - Occurs as a result of diffuse damage to the cerebral cortex, white matter, and basal ganglia
 - Decerebrate posturing
 - The patient exhibits marked opisthotonus with extended arms and hands.
 - Usually the result of extensive damage involving the midbrain

DIFFERENTIAL DIAGNOSIS

- A normal level of consciousness requires functioning cerebral hemispheres and a functioning ascending reticular activating system (ARAS).
- Altered mental status can result from depression of the cerebral hemispheres, a localized abnormality of the ARAS, or global CNS dysfunction affecting both.
- Structural lesions in general produce dysfunction of the ARAS.
- Medical causes usually affect cerebral function.
- Differentiation of structural and medical causes rests on the ability to assess the function of the ARAS.
 - The ARAS is located in the vicinity of the pupillary light reflex and of the cranial nerves that control eye movements and conjugate gaze.
 - The pupillary light reflex is relatively resistant to metabolic insult.
 - Its preservation, even if sluggish, is an important way to differentiate structural from medical causes of altered mental status.
 - Asymmetric eye movements or a fixed gaze suggests a structural lesion in the region of the ARAS.
- Structural (anatomic) causes
 - Cerebrovascular accident
 - Cerebral vein thrombosis
 - Hydrocephalus
 - Intracerebral tumor
 - Subdural empyema
 - Trauma
 - Intracranial bleeding
 - Diffuse cerebral swelling
 - Shaken baby syndrome
- Structural lesions are often characterized by:
 - Unequal or unreactive pupils or inability to abduct an eye
 - Focal neurologic findings
 - Structural causes may occur without focality, such as acute bilateral cerebrovascular disease or early acute hydrocephalus.
- Medical (toxic-infectious-metabolic) causes
 - Anoxia
 - Diabetic ketoacidosis
 - Electrolyte abnormality
 - Encephalopathy
 - Hypoglycemia
 - Hypothermia or hyperthermia
 - Infection (sepsis)
 - Inborn errors of metabolism

- Intussusception
- Meningitis and encephalitis
- Psychogenic
- Postictal state
- Toxin
- Uremia (hemolytic-uremic syndrome)
- Medical causes usually produce:
 - Dysfunction in both cerebral hemispheres
 - Preserved pupillary reflexes
 - Nonfocal neurologic findings
 - Some medical causes may be accompanied by focal neurologic findings: eg, hypoglycemia, hypercalcemia, uremia, and a postictal state with Todd paralysis.

DIAGNOSTIC APPROACH

- In the continuum of mental status changes, initial alterations in mental status are often subtle.
 - Child- and age-specific responses to external and internal stimuli should be assessed.
- The underlying cause of altered mental status must be sought.
 - Neuroimaging of the brain
 - Fastest, most reliable test to differentiate structural from medical causes of altered mental status
 - The mnemonic AEIOU TIPS (see Etiology) is helpful when considering the major categories of illness or injury.
- Child abuse should always be considered in an infant with an altered level of consciousness and/or unexplained bruising.

LABORATORY FINDINGS

- First, determine whether the patient has life-threatening metabolic derangements.
 - Then look for the underlying cause.
- Rapid bedside glucose determination
 - Identifies hypoglycemia within minutes of clinical evaluation
 - In addition to being a common cause of altered mental status, hypoglycemia also accompanies many other underlying causes, such as diabetes, metabolic disorders, and sepsis.
- Serum chemistry panel
 - Calcium and sodium abnormalities
 - Serum bicarbonate and arterial blood gas levels
 - May show acidemia, either as a direct result of an underlying metabolic disorder or as a result of abnormal respiratory effort
 - Serum ammonia measurement
 - Important screening test for many inborn errors of metabolism
 - Mild hyperammonemia can be a nonspecific finding in children.

- Serum osmolarity
 - May be helpful if poisoning with methanol, ethylene glycol, or isopropanol is suspected
- Serum cooximetry
 - Measures carbon monoxide level
- Blood culture
 - Obtain if the child is febrile.
 - Hemoglobin levels
 - To determine whether anemia is present
 - Leukocyte count
 - May be high if the altered mental status is from an infection
- Directed drug levels
 - If ingestion of a toxic substance is considered
 - Qualitative urine toxicology screening can identify a variety of commonly ingested agents, but its usefulness is limited by the delay until results are available.

IMAGING

- The decision whether to use computed tomography (CT) or magnetic resonance imaging (MRI) depends on a variety of factors.
 - Clinical situation
 - Stability of the patient
 - Availability of the test
- CT
 - Readily available in the setting of an acute change in mental status
 - Rapidly identifies acute intracranial bleeding, masses, or contusions in emergency situations
- MRI
 - Uses no ionizing radiation and thus poses reduced risk to the developing brain
 - Provides more detail of the soft tissues and better imaging of the brain parenchyma, cerebellum, and brainstem than CT
- Plain radiography, ultrasonography
 - Diagnostic for intussusception

DIAGNOSTIC PROCEDURES

- Electrocardiography
 - Abnormalities may be seen in cardiac causes.
 - Myocarditis
 - Dysrhythmias
 - A normal electrocardiogram finding does not rule out these disorders.
 - Many serious drug overdoses have electrocardiographic findings.
 - Prolongation of the QRS interval with tricyclic antidepressants

- Ischemic changes with cocaine overdose
- QT prolongation with neuroleptic overdose (phenothiazines, thioridazine, haloperidol, chlorpromazine)

■ Stool guaiac test

- A positive result raises concern about intussusception.

TREATMENT APPROACH

■ Management is similar to that of any emergency condition.

■ Primary objectives

- Stabilize the child's clinical status.
- Correct any acute life-threatening conditions.

■ Once stabilized, the child should be transported to an acute care facility for additional evaluation and management.

SPECIFIC TREATMENTS

Initial management

■ ABCs—airway, breathing, circulation

- Obstructed airway is usually identified by:
 - Stridor
 - Abnormal breathing pattern
- Immediate maneuvers to open the airway by either:
 - Manual positioning
 - Oral airway
 - Endotracheal intubation
- Oxygen
 - Should be routinely administered

■ Peripheral intravenous (IV) catheter

- Should be placed, as many of the causes of altered mental status require IV fluid or medication
- Bedside blood glucose levels should be obtained immediately.
 - Hypoglycemia is readily identified and easily corrected with administration of IV dextrose.
- Additional blood tests to help determine the underlying cause should be performed.

■ Naloxone

- Empiric administration should be considered if the underlying cause is unknown.
- Naloxone can reverse the depressive cardiorespiratory effects of narcotic ingestion.
- It may also be helpful in ingestions of:
 - Clonidine
 - Dextromethorphan
 - Valproic acid
 - Captopril

- A fluid bolus with normal saline should be administered if the patient has signs of poor perfusion or hypotension.
- Acid-base and electrolyte abnormalities, if present, should be corrected.

Intracranial pressure

■ May be high if:

- The patient has a history of trauma
- The suspected cause is structural
- Infection is present

■ Head position

- Should be elevated to 30 degrees and placed in a midline position

■ Hyperventilation

- Can be a temporizing measure to reduce intracranial pressure

■ Every effort should be made to:

- Stabilize the child as soon as possible
- Obtain emergent CT
- Consult with a neurosurgeon

■ Obstructive hydrocephalus

- Results from an intracranial mass lesion or obstructed ventriculoperitoneal shunt
- May need to be relieved emergently with:
 - Ventriculoperitoneal shunt tap
 - Ventriculostomy

Medical causes

■ Fever

- May indicate an infectious origin
- Intravenous antibiotics should be given after a blood culture is obtained.

■ If meningitis is suspected:

- Lumbar puncture can be performed to help confirm this diagnosis.
- It should be performed if the patient is stable and does not have focal neurologic signs.
 - If the child is clinically unstable, lumbar puncture should be deferred.
- Empiric IV antibiotics should be administered without delay.

■ If herpes encephalitis is suspected:

- Empiric acyclovir should be provided.

■ Intussusception

- Can be reduced by an air-contrast enema

When a clear cause cannot be identified

- Ingestion of a toxic substance should be suspected.
 - Family members should be questioned about the availability of any medication.
 - If possible, the bottle of the medication should be checked and the remaining pills counted to estimate the maximal amount ingested.
 - For some ingestions, antidotes are available.
 - Specialists at the local poison control center can assist in the management of a suspected overdose.
 - Many children will require a dose of activated charcoal.
 - Binds the toxin and limits intestinal absorption

WHEN TO ADMIT

- Any child with altered mental status

PROGNOSIS

- Prognosis depends on the cause of the coma, early diagnosis, and early institution of therapy.

PREVENTION

- Childproofing the house, obtaining appropriate vaccinations, and educating teenagers about risk-taking behaviors can prevent a significant number of cases of coma in young children and adolescents.
-

Amblyopia

DEFINITION

■ Amblyopia

- Poor vision resulting from blurred retinal image that disrupts normal visual development

■ Strabismus

- Ocular misalignment
 - Esotropia (eye turned in)
 - Exotropia (eye turned out)
 - Vertical (eye turned up or down)
 - Alternating
 - The child cortically turns off or suppresses images from deviated eye to prevent double vision.
 - Associated with alternating suppression and allows equal monocular visual development with no amblyopia

EPIDEMIOLOGY

■ Amblyopia

- Occurs in about 2% of the general population
- Most common cause of decreased vision in childhood
- Greatest susceptibility during first 3–4 months of life (critical period of visual development)
- Can occur in older children
- Acquired strabismus can cause less severe amblyopia up to 7 or 8 years of age.

■ Visual development and amblyopia

- Critical period: 1 week to 4 months (most susceptible to amblyopia)
- Visual plasticity: 5 months to 8 years (susceptible to amblyopia)
- Visually mature: 9 years to adulthood (persons do not develop amblyopia but may retain limited plasticity)

MECHANISM

■ Amblyopia

- Caused by disruption of neurodevelopment in visual areas of brain because of abnormal visual stimulation during the early developmental period
- Structural damage in visual centers in the brain, including the lateral geniculate nucleus and visual cortex, can occur if abnormal stimulation is severe and persists during early period of visual development.
- 2 basic forms of abnormal visual stimulation
 - Blurred retinal image (unilateral or bilateral)
 - Strabismus, with strong preference for one eye and constant suppression of deviated eye
- Other causes of blurred images leading to amblyopia
 - Anisometric amblyopia: Unilateral refractive error causing blurred image is a common cause of amblyopia.

- Opacity in visual axis

- Large cataract or corneal opacity

- Severity of amblyopia depends on:

- When the abnormal stimulus begins

- Length of exposure to abnormal stimulation

- Severity of image blur

- The more severe the image blur, the earlier the onset.

- The longer the duration of a malapropos stimulus, the more severe the effects on neurodevelopment and visual acuity.

PHYSICAL EXAM

■ Inspection

- Check symmetry: Compare fellow eyes; look at pupils, eyelids, and lid fissures.
- Check for face turn or head tilt (compensatory mechanisms to reduce strabismus or damp nystagmus).
- Check for ocular irritation (red eye, squinting).
- If the timing of the onset of ocular abnormality is in question, seek family photographs for documentation.

■ Ocular motility

- Assess by having the patient follow a target right, left, up, and down, observing for full ocular rotation.
- Patients with muscle weakness show limited eye movement.
- Consult with an ophthalmologist if limitation of eye movement is identified.

■ Preverbal children

- Document the infant's ability to fix and follow a moving target.
 - From birth to approximately 2 months of age, ability is sporadic.
- Test and record pupillary response, even in premature infants.
- For infants 2–6 months old, test the ability to fix and follow on small toy or human face
 - Cover 1 of the patient's eyes and move a compelling target (eg, the examiner's face or a toy) right, left, up, and down to observe if patient's eyes accurately follow.
 - Test each eye individually (with both eyes open the eyes will track together, even if 1 eye is blind).
 - Observe for central fixation with the presence of accurate smooth pursuit (the child looks directly at the target and follows the target).
 - If the child has trouble locking on the target and appears to be looking off center, poor fixation and poor vision are indicated.

■ Verbal children

- By age 2.5–3 years, most children should be able to cooperate with optotype visual acuity testing using picture cards.
 - Allen cards
 - E-game
 - Wright figures
 - Snellen letters
- Test each eye separately, ensuring that the occluded eye is covered.
- To prevent the child from peeking, use an adhesive patch rather than a paddle occluder.
- Examine patients with their customary eyeglasses or contact lenses.
 - If patients forget their corrective lenses, first test vision without correction and then retest using a pinhole (see under Diagnostic Procedures).
- In children with very poor vision, measure visual acuity by the ability to:
 - Count fingers at a distance of 1–2 feet
 - See hand motions at a distance of 1 foot
 - Perceive any light

DIAGNOSTIC PROCEDURES

■ Pinhole test

- Pinholes are commercially available.
- The pinhole test can also be done by placing several small pinholes close together in a 3- × 5-inch card.
- If the patient's visual acuity improves after viewing through the pinhole, refractive error is probably the cause of the decreased vision.
- The pinhole test can estimate corrected visual acuity when a patient is without customary lenses.
- Pinholes will improve vision to approximately 20/30, even with large refractive errors.

■ Cover test

- Probably unnecessary for vision screening
 - The Bruckner test (bilateral red reflex test) and corneal light reflex test are more specific for detecting a true strabismus with a demonstrated deviation (ie, tropia).
- Many healthy children show eye movement shift with alternate cover testing, thus making the test difficult to interpret.
- Cover 1 eye for 3–4 seconds, then remove the cover.
- If eye tends to drift, eye under the cover will drift.
- If the patient has a history of intermittent strabismus (especially intermittent exotropia) but the eyes appear well aligned, the cover test may be helpful.
- Referral to an ophthalmologist is indicated by history alone.

■ Red reflex test

- Single best vision-screening examination for infants and young children
- Performed using direct ophthalmoscope to view the reflex off the retina
- Bruckner test (simultaneous bilateral red reflex)
 - Hold the ophthalmoscope about 2 feet in front of the child.
 - Use the broad beam to illuminate both eyes at the same time.
 - Ask the child to look directly into the ophthalmoscope light, and dim the room lights.
 - Start with ophthalmoscope on low illumination, then slowly increase illumination until the red reflex is seen.
 - The red reflex fills the pupil, and a small white light reflex appears to reflect off the cornea.
 - The light reflex is actually a reflection from just behind the pupil, but it is commonly called the *corneal light reflex* or the *Hirschberg reflex*.
 - The Bruckner test gives both red reflex and corneal light reflex simultaneously.
- Findings
 - The key sign of a normal red reflex test is symmetry.
 - Opacity in the optical media or large area of retinal disease will result in an abnormal red reflex.
 - Cataract can block red reflex or reflect light to give white reflex.
 - Retinoblastoma has a yellowish-white color and produces yellow reflex.
 - Anisometropia (difference in refractive error) results in unequal red reflex.
 - Strabismus causes brighter red reflex in deviated eye, and corneal light reflex will be off center.

■ Corneal light reflex test (Hirschberg test)

- Best way to assess ocular alignment
- Hold a muscle light or flashlight at the examiner's nose and point it toward the patient's nose.
- Have the child look directly at the light (otherwise the light will appear off center).
- The light reflex should be symmetrically centered or slightly nasally deviated.
- Displacement of the light reflex indicates strabismus.

SPECIFIC TREATMENT

■ Amblyopia

- Treatment strategy
 - Provide clear retinal image
 - In cases of unilateral amblyopia, force use of the amblyopic eye by occluding the good eye.

- Correct refractive errors with spectacles or contact lenses.
- Visually significant opacities, such as cataracts, must be surgically removed.
- Patients with strabismic amblyopia may or may not require optical correction, but almost all require occlusion therapy to correct ocular dominance.

WHEN TO REFER

- Poor fixation at 5–6 months of age
- Esotropia after 2 months of age
- Abnormal red reflex
- Visual acuity of 20/50 or worse in a 3- to 5-year-old
- >2-line difference between fellow eyes
- Visual acuity $\leq 20/40$ in children ≥ 6 years
- Lack of full ocular rotation (eye movement in a circle)
- Strabismus, including intermittent strabismus

COMPLICATIONS

- If not treated early, amblyopia can result in permanent vision loss.
- Delay in diagnosis of disease, such as congenital cataracts, retinoblastoma, and congenital glaucoma, may result in irreversible amblyopia; vision loss; and, in the case of retinoblastoma, death.

PROGNOSIS

- The earlier the intervention, the better the prognosis for amblyopia.
- Children with visually significant congenital cataracts are best treated during the first week of life because delaying surgery until after 3–4 months carries a poor visual prognosis.

- Patients with less severe amblyopia, such as anisometropic amblyopia (difference in refractive error), have a better prognosis even when treated between 3 and 8 years of age.
 - After 8–9 years of age, prognosis is poor.
- Patients with amblyopia who are treated late can show significant improvement.
- Patients with presumed congenital cataracts who are identified after the critical period may show some visual improvement with aggressive amblyopia management.
- Suppression disrupts binocular fusion; if not corrected early, strabismus will cause loss of binocular fusion and stereopsis.

PREVENTION

- Vision screening examinations
 - Start at birth.
 - Continue as part of routine checkups.
 - Essential parts of screening: I-ARM
 - **I** = Inspection
 - **A** = Acuity
 - **R** = Red reflex
 - **M** = Motility
 - Infant screening examinations take <1 minute but can detect most eye diseases.

Amenorrhea

DEFINITION

- Amenorrhea is the absence of menses.
 - Primary amenorrhea: failure to start menstruation
 - Secondary amenorrhea: cessation of menses in an adolescent who has previously menstruated
 - Many diseases and clinical states may cause either primary or secondary amenorrhea.

EPIDEMIOLOGY

- The mean age at menarche onset in the US has decreased slightly, per national health surveys.
 - In 1973, the average age at menarche was 12.76 years.
 - Currently, the average age is 12.54 years, with some racial/ethnic variation.
 - 90% of girls will have menstruated by 13.75 years.
 - <10% menstruate before 11 years of age.
 - Menstruation usually begins approximately 2 years after breast budding.
 - The interval between the 2 events can be as short as 6 months or as long as 4 years.
 - After the onset of menarche, many teenagers will menstruate sporadically.
 - Regular monthly cycles often are not established until 1–2 years after menarche.
- Gynecologic age is important when evaluating an adolescent who seems to have secondary amenorrhea.
 - Gynecologic age is the time since onset of menarche.
 - When amenorrhea is defined as missing 3 consecutive menstrual periods in a given year, researchers found its frequency to be:
 - 12.5% of girls with a gynecologic age <1 year
 - 5.4% of girls with a gynecologic age ≥7 years
- Abrupt cessation of menstruation in a teenager who has established regular cycles is of greater concern than the absence of menses for 3–4 months in a teenager who has a gynecologic age of 6 months to 1 year.
- In adolescents, stress-related conditions are the most common cause of secondary amenorrhea, followed by pregnancy.

MECHANISM

- The ovarian cycle
 - The ovarian cycle is controlled by pulsatile gonadotropin-releasing hormone (GnRH) secretion by the hypothalamus acting on the anterior pituitary gland, stimulating the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH).
 - These gonadotropins bind to ovarian cells.
 - During the follicular phase, these gonadotropins stimulate follicular growth.

- Secretion of estradiol from growing follicles results in a positive feedback loop, leading to increased GnRH secretion and a surge in LH and FSH.
- This surge leads to ovulation and a surge in progesterone secretion.
- As the luteal phase is entered, progesterone and estradiol provide a negative feedback effect, resulting in decreased pulsatile secretion of LH.
- In the absence of human chorionic gonadotropin from the embryo, the progesterone level decreases and the endometrial lining is shed, resulting in menses.

■ Causes of amenorrhea

- Pregnancy
- Disorders in the hypothalamic-pituitary-ovarian axis
- Central nervous system (CNS) or ovarian dysfunction
- A natural sequelae of underlying genetic processes
- Secondary to anatomic outlet obstruction.

HISTORY

- Given the broad differential diagnosis for amenorrhea, many factors must be assessed.
- Menstrual history
 - Age at onset of menstruation
 - Bleeding frequency, duration, regularity, amount (number of pads/tampons and saturation)
 - Dates of previous menses
 - Concurrent symptoms (bloating, cramping, headaches)
- Menstrual history of mother and first-degree female relatives
- Medical and family history, including:
 - Trauma
 - Endocrine disorders
 - History of meningitis or tumor
 - Irradiation
 - Surgery
 - Weight changes and growth patterns
- Detailed discussions of personal lifestyle factors are ideally conducted without others present.
 - HEADSSS assessment
 - Home
 - Education
 - Activities
 - Drugs
 - Sexuality
 - Suicide/Depression
 - Safety
 - Exercise patterns
 - Body image; subtle development of physical features, such as weight gain, acne, or hirsutism

PHYSICAL EXAM

■ Vital signs

- Evaluate blood pressure.
 - High blood pressure may indicate renal disease or Cushing syndrome.
 - Low blood pressure may indicate Addison disease.
- Plot previous growth data (especially height, weight, and body mass index).
 - Leveling of linear growth may be consistent with hypothyroidism.
 - Growth failure may be consistent with inflammatory bowel disease.
 - Short stature may be consistent with Turner syndrome.
 - Extremes of body mass index may suggest the diagnosis (eg, anorexia, female athlete triad, Cushing syndrome, Prader-Willi syndrome)

■ Physical examination

- A complete examination is indicated.
- Examine sexual development.
 - Assess the sexual maturity of breast and genitalia.
 - Atrophied breast tissue may suggest weight loss.
 - Pelvic examination is essential to evaluate female genitalia.
 - An imperforate hymen or a transverse vaginal septum may prevent menstrual blood from escaping.
 - If the hymenal opening is patent, the examination should proceed to determine the presence of a normal vagina, cervix, and uterus.
 - If the hymenal opening is very small, the cervix and uterus can be palpated by means of a bimanual rectoabdominal examination.
 - The size of the clitoris should be noted.
 - Clitoromegaly indicates the presence of excess androgens.
 - Lack of or scant pubic hair in a girl with Tanner stage 3 to 4 breast development suggests androgen insensitivity syndrome.
- Examine for features of genetic conditions.
 - A webbed neck, short stature, and widely spaced nipples suggest Turner syndrome.
- Examine for features of endocrine disorders.
 - Hirsutism, receding hairline, excessive acne, moon facies, striae, thyroid abnormalities, buffalo hump
 - Acanthosis nigricans suggests insulin resistance.
 - Nipple discharge may indicate elevated prolactin levels.
- Examine for neurological abnormalities indicative of potential CNS malformation or tumor.
 - Pupils, extraocular muscles, visual fields, smell, and cranial nerve functions

- Funduscopy to look for papilledema
- Reflexes
- Examine for evidence of self-inflicted injury.
 - Cuts, burns, scars

DIFFERENTIAL DIAGNOSIS

Advice to patients

- Adolescent girls can be reassured that they should anticipate menarche 2–3 years after the initiation of puberty when:
 - Puberty starts late, but progression through puberty appears normal
 - Physical examination is also normal
 - This is especially likely with family history of late menarche in first-degree female relatives.

When to evaluate

- The point at which the clinician elects to pursue an evaluation depends on:
 - Anxiety of the patient and her family
 - Possibility of pregnancy
 - Likelihood that a potentially serious disease is responsible for the amenorrhea
- Evaluation is warranted when:
 - No signs of secondary sexual development are present by 13 years of age
 - Evaluation should include an assessment for delayed puberty.
 - Menarche has not occurred by 16 years of age, even if growth is normal and secondary sexual characteristics have developed
 - 3 consecutive menstrual cycles are absent
 - A patient who has previously menstruated has had amenorrhea for >6 months
 - Development has halted

Differential diagnosis

- The differential diagnosis for amenorrhea is broad and includes:
 - Pregnancy
 - Immature hypothalamic-pituitary-ovarian axis
 - Familial-physiologic delay
 - Suppressed hypothalamic-pituitary-ovarian axis
 - Eating disorders (including anorexia nervosa)
 - Drugs (eg, hormonal contraception, cocaine, phenothiazines)
 - Systemic factors
 - Acute illness (includes viral illness)
 - Chronic illness (includes inflammatory bowel disease, renal failure)
 - Depression

- Psychosocial stress
- Environmental change (eg, transitioning to college)
- High-level athletic training (eg, female athlete triad)
- Endocrine-related cause
 - Thyroid
 - Hyperthyroidism
 - Hypothyroidism
 - Adrenal
 - Addison disease
 - Cushing syndrome
 - Late-onset congenital adrenal hyperplasia (21-hydroxylase deficiency)
 - Tumor
- CNS-related (hypothalamic, pituitary) issues
 - Developmental defects (eg, Kallmann syndrome)
 - Infiltrative disease
 - Head trauma
 - Sheehan syndrome (postpartum hypopituitarism)
 - Primary empty sella syndrome
 - Changes from prior meningitis
 - Irradiation
 - Surgery
 - Tumor (eg, prolactinoma)
- Ovarian malfunction
 - Gonadal dysgenesis
 - Ovarian failure
 - Radiation or chemotherapy
 - Ovarian removal or destruction
 - Polycystic ovary syndrome (PCOS)
 - Tumor
- Genetic conditions
 - Laurence-Moon-Bardet-Biedl syndrome
 - Prader-Willi syndrome
 - Turner syndrome
- Outlet obstruction (primary amenorrhea)
 - Uterus
 - Uterine synechiae
 - Congenital abnormalities (müllerian agenesis, androgen insensitivity)
 - Vagina, cervix, hymen
 - Agenesis
 - Imperforate hymen
 - Transverse septum

LABORATORY EVALUATION

- For primary amenorrhea
 - Consider imaging as indicated before laboratory workup.
 - Consider karyotyping and serum testosterone measurement.
- If a uterus is present, or when considering secondary amenorrhea:
 - Obtain urine pregnancy test, and consider toxicology studies.
 - If negative, obtain FSH, prolactin, and thyroid studies.
- If the FSH level is elevated, consider ovarian failure and consider karyotyping and screening for endocrinopathies.
- If the FSH level is low or normal, consider a physiologic, hypothalamic, or pituitary cause and chronic illness.
- If amenorrhea is in context of androgen excess, consider PCOS and late-onset congenital adrenal hyperplasia.
 - Serum testosterone (total and free)
 - Dehydroepiandrosterone (DHEA) and its sulfate (DHEA-S)
 - If the DHEA-S level is elevated, obtain a first morning 17-hydroxyprogesterone level.
 - Isolated elevated testosterone suggests an ovarian origin, whereas elevated DHEA-S suggests an adrenal origin.
- Assess the patient's estrogen status.
 - Measure serum estradiol levels, **or**
 - Assess by progesterone challenge or by vaginal maturation index (see Diagnostic Procedures)
- In the case of eating disorders, consider a more thorough metabolic and functional evaluation.

IMAGING

- Imaging studies may be considered as clinically indicated.
 - Consider adrenal/ovarian imaging when the patient has:
 - Evidence of virilization (eg, clitoromegaly)
 - Serum androgen levels elevated in the tumor range
 - Consider pelvic ultrasonography if:
 - Pelvic or rectoabdominal examination cannot confirm the presence of uterus
 - Bimanual examination is abnormal
 - Consider magnetic resonance imaging if:
 - Congenital abnormalities are suspected
 - Consider dual-energy x-ray absorptiometry to evaluate bone density:
 - When estrogen levels are low

DIAGNOSTIC PROCEDURES

- Assess the patient's estrogen status:
 - By progesterone challenge
 - A positive result indicates an estrogen-primed uterus.
 - Administer 10 mg of medroxyprogesterone acetate for 5–10 days.
 - Any spotting or bleeding in the week afterward is considered a positive result.
 - Some experts recommend measuring FSH before performing a progesterone challenge.
 - Women with hypergonadotropic amenorrhea will have withdrawal bleeding.
 - By vaginal maturation index
 - A vaginal maturation index is performed by:
 - Collecting cells from the upper lateral sidewall of the vaginal wall using a moistened cotton-tipped applicator
 - Rolling on a glass slide
 - Fixing by using the same technique as for Papanicolaou smear preparation
 - Samples can be interpreted on the basis of estrogen and pubertal status.

TREATMENT APPROACH

- Treatment of amenorrhea depends on the underlying cause.

SPECIFIC TREATMENT

Pharmacologic treatments

- Secondary amenorrhea and normal estrogen levels
 - Medroxyprogesterone, 5–10 mg for 12–14 days
 - Can be used every 1–3 months to stimulate withdrawal bleeding

- Sexually active patients with PCOS
 - Treat with combined contraceptives.
- Patients with PCOS may benefit from additional medications for:
 - Underlying metabolic abnormalities
 - Hirsutism, acne, or other findings associated with androgen excess

Other

- In some patients with low estrogen levels (restrictive eating disorders, female athlete triad):
 - Normalizing weight for height is important.
 - Address disordered eating and intensity of athletic training.

WHEN TO REFER

- If the amenorrhea seems to be secondary to a chronic illness that the pediatrician cannot manage
- If the pediatrician cannot offer or feels uncomfortable performing a thorough gynecologic assessment
- If long-term hormonal therapy is required
- If the patient has an eating disorder
- If evidence exists of anatomic or chromosomal abnormality
- If evidence exists of a complicated endocrine or developmental disorder
- If evidence exists of a CNS, adrenal, or ovarian tumor

WHEN TO ADMIT

- If the patient has metabolic derangements requiring close monitoring

FOLLOW-UP

- Regularly scheduled follow-up visits until menarche occurs are warranted.

Anaphylaxis

DEFINITION

- Severe allergic reaction mediated by IgE and involving ≥ 2 organ systems
- Anaphylactoid reactions are clinically similar but not attributable to IgE.
 - Clinical syndrome and treatment are the same as for anaphylaxis.
- Anaphylaxis may be uniphasic, biphasic, or protracted.

EPIDEMIOLOGY

- Incidence
 - 0.04% to 0.4%
 - May be higher because of underreporting and underrecognition
- Sex
 - In childhood, more likely in boys than in girls
 - In adults, more likely in women than in men
- 0.5% to 3.0% of the population experiences systemic reaction after *Hymenoptera* stings.
- Biphasic reactions occur in 4–20% of patients.
- Food-induced anaphylaxis
 - More common in children than in adults

ETIOLOGY

- Mediated through antigen-induced, IgE-mediated mast cell and basophil degranulation and histamine release
- May be induced by foods, some medications, insect stings (*Hymenoptera*), exercise

RISK FACTORS

- Atopy is a predisposing factor for food-induced anaphylaxis.
- Risk factors associated with death from anaphylaxis include:
 - Extremes of age
 - Concomitant cardiac disease
 - Asthma
 - Delay of epinephrine administration
 - Use of β -blockers

SIGNS AND SYMPTOMS

- Respiratory
 - Bronchospasm with wheezing
 - Possibly, stridor or hoarseness
 - Cyanosis
- Upper respiratory findings
 - Nasal congestion
 - Rhinorrhea
 - Sneezing
 - Lingual and pharyngeal edema

- Cardiovascular
 - Tachycardia followed by hypotension
- Skin
 - Urticaria
 - Angioedema or flushing
 - Pruritus
 - May see only cardiovascular and no cutaneous signs or symptoms
- Lightheadedness
- Weakness and palpitations
- Sense of impending doom
- Ocular
 - Tearing
 - Conjunctival erythema
 - Edema (chemosis)
- Gastrointestinal
 - Diarrhea
 - Vomiting
- Headache

DIFFERENTIAL DIAGNOSIS

- Vasodepressor reactions, especially after an emotional stressor
 - Hypotension
 - Pallor
 - Weakness
 - Nausea
 - Bradycardia (only occurs in 5% of patients with anaphylaxis)
 - Loss of consciousness
 - Lack of skin and airway manifestations that are usually seen in anaphylactic reactions
 - Prompt recovery after assuming recumbent position
- Panic attacks
 - Palpitations
 - Flushing
 - Shortness of breath
 - Gastrointestinal symptoms
 - If accompanied by vocal cord dysfunction and stridor, panic attacks may mimic anaphylaxis.
- Systemic mastocytosis
 - Anaphylaxis may occur because mast cell lesions bind IgE and release histamine and other mast cell mediators.
 - Urticaria pigmentosa may suggest this diagnosis.

- If lesions are primarily internal
 - Total serum tryptase
 - Serum concentrations are acutely elevated in patients with anaphylaxis.
 - Concentrations are increased in mastocytosis even when patients are not acutely ill.
 - Urinary histamine metabolites
 - Genetic testing for mastocytosis
 - These tests are not useful for managing acute episodes, which are indistinguishable from anaphylaxis.
- Hypoglycemia
 - Flushing mimicking an early allergic skin reaction
 - Flushing may be associated with:
 - Tachycardia
 - Anxiety
 - Diaphoresis
 - Lightheadedness

DIAGNOSTIC APPROACH

- History and clinical assessment are far more important than laboratory testing in the initial evaluation of anaphylaxis.
- Seek history of recent food ingestion, insect sting, medication intake, and exercise.
- Food ingestion
 - Reaction can occur in first 2 hours after eating, usually within the first 30 minutes.
 - Reactions beginning up to several hours later have been reported.
 - Common allergens
 - Peanuts (62% of cases)
 - Nuts
 - Fish
 - Shellfish
 - Milk, soy, and eggs in infants and toddlers
 - In some, inhalation of offending antigen is sufficient to lead to a reaction.
- Insect sting
 - *Hymenoptera* insect sting (ie, bees, yellow jackets, hornets, wasps, fire ants)
 - History of exposure to particular insects may be important later if immunotherapy is to be considered.
 - Removing the stinger early is important to avoid further venom injection.
 - Identification of the wound or stinger helps identify the species.
 - Bees (and very rarely yellow jackets) leave a stinger; other *Hymenoptera* do not.
- Medication-induced
 - Antibiotics, most commonly penicillin
 - Aspirin and other nonsteroidal antiinflammatory agents
 - Drugs that are administered intravenously or intramuscularly are absorbed more rapidly and are associated with more frequent/severe reactions.
 - Radiocontrast media
 - Latex (becoming less common)
- Exercise-induced anaphylaxis
 - Usually occurs in teenagers and young adults
 - Prodrome of flushing and abdominal pain may occur followed by collapse during exercise.
 - Some cases occur only after ingesting foods that cross-react with pollens (eg, melons that cross-react with ragweed, apples that cross-react with birch)
 - Some have exercised-induced anaphylaxis after nonspecific food ingestion combined with exercise.
 - May follow episodes of exercise-induced urticaria

LABORATORY FINDINGS

- Histamine plasma concentration are not usually a reliable or useful marker.
- Histamine metabolites in the urine may be useful in diagnosis of systemic mastocytosis.
- Specific IgE may be useful to determine the cause.
 - Skin prick tests for specific allergens
 - Serum antigen specific IgE tests
 - Radioallergosorbent assay
 - Enzyme-linked immunosorbent assay
 - At time of presentation, these tests will not be valid because specific IgE may no longer be present.
- Serum tryptase
 - May remain elevated in blood for up to 6 hours after the event
 - Measurable for several days later in serum samples that have been refrigerated
- If cyanosis or respiratory compromise
 - Pulse oximetry
 - Arterial blood gas determinations

TREATMENT APPROACH

- Airway should be secured.
- Obtain respiratory rate, blood pressure, and pulse.
 - Place the patient in supine position with feet elevated if blood pressure is decreased.
 - If wheezing is present, balance the recumbent position with need to allow adequate air exchange.
 - Administer oxygen.

- For *Hymenoptera* sting, to slow systemic absorption of antigen and anaphylactic mediators:
 - Tourniquet applied on an extremity proximal to sting
 - Medication injection

SPECIFIC TREATMENTS

Pharmacologic therapy

- Epinephrine
 - Most important initial treatment
 - Give intramuscularly, preferably in the outer thigh, while assessment is being made.
 - The dose may be repeated as needed every 10–15 minutes.
 - Administered as a 1:10,000 solution intravenous if severe hypotension with peripheral vasoconstriction
- Fluid replacement
 - Needed for hypotension from increased vascular permeability
 - Children require up to 30 mL/kg of crystalloid solution in the first hour.
 - Adults require 1–2 L over the first hour.
- Intravenous vasopressors
 - In severe refractory hypotension, continuous infusions of either:
 - Dopamine
 - Norepinephrine
 - Epinephrine
- Inhaled albuterol
 - May be used for wheezing that is not responsive to parenteral epinephrine
- H₁ antihistamines
 - Relieve symptoms; highly effective for relieving skin manifestations and oropharyngeal angioedema
 - Not effective for treating life-threatening symptoms that do not involve the upper airway
 - Do not replace the need for epinephrine
 - First-generation H₁ antihistamines commonly cause drowsiness and may impair patient's ability to relate progress or resolution of symptoms.
 - Intravenous H₁ antihistamine (eg, diphenhydramine) combined with cimetidine (piggyback infusion) blocks both the cardiac and peripheral vascular effects of histamine.
- Adrenal corticosteroids
 - Decrease vascular permeability
 - Do not prevent biphasic reactions
- Glucagon (1 mg)
 - For patients on a β -blocker (more frequent in adults than children)
 - For refractory hypotension

- Methylene blue
 - For severe anaphylactic hypotension
- Venom immunotherapy
 - Indicated for treatment of insect sting reactions

WHEN TO ADMIT

- Admit for:
 - Hypotension
 - Airway compromise
- Observation for up to 24 hours is recommended for biphasic reactions.
 - Cannot reliably be prevented with corticosteroids
 - Cannot be predicted

WHEN TO REFER

- Refer to an allergist for:
 - Identification of responsible agent
 - Patient education and management

FOLLOW-UP

- After an anaphylactic episode, discharge patient with epinephrine in an autoinjection device for self-administration.
 - The patient must be able to use the device.
 - The patient must understand that it should be available anywhere he/she goes.
 - The patient must understand that the devices have expiration dates and should be renewed periodically.
- Workup to identify the cause of the reaction
- Provide education on avoidance; this is particularly important for foods, insect stings, and medications.
 - In cases of exercise-induced anaphylaxis, patients should be advised to avoid exercising alone.
- Medic alert bracelet should be advised.

COMPLICATIONS

- Anaphylactic shock

PROGNOSIS

- Patients with biphasic reactions often experience recurrence of initial signs and symptoms several hours after their apparent resolution.
- Foods causing anaphylaxis in childhood are usually responsible for lifelong allergies.
 - Children are not likely to outgrow these reactions.
 - Unlike allergies to peanuts, nuts, fish, and shellfish, most children become tolerant to milk and soy with time, and some will become tolerant to eggs.

Anemia and Pallor

DEFINITION

- Anemia is a laboratory finding reflecting a decrease in red blood cell (RBC) mass below an age-appropriate normative value; this can be either:
 - Reduction in RBC number
 - Reduction in RBC mass (hematocrit)
 - Reduced hemoglobin concentration
- Anemia may be associated with pallor but is more likely to be a silent symptom.
- Pallor and anemia are clinical manifestations of an underlying disease process requiring a thorough evaluation.
- Types of anemia
 - Microcytic anemias: mean corpuscular volume (MCV) less than appropriate for age
 - Normocytic anemias: MCV within normal range for age
 - Macrocytic anemias: MCV greater than appropriate for age
- MCV changes with age; see Laboratory Evaluation for normal values.

EPIDEMIOLOGY

- Age
 - Toddlers (12–24 months) and adolescent girls account for most cases of iron-deficiency anemia.
- Race/ethnicity
 - Black persons are at greatest risk for sickle cell anemia.
 - Thalassemias occur primarily in patients of Mediterranean and Southeast Asian descent.

MECHANISM

- Sideroblastic anemia is inherited and occurs in childhood.
- Iron-deficiency anemia results from:
 - Poor iron intake
 - Poor iron absorption
 - Blood loss
 - Common causes of gastrointestinal bleeding
 - Cow milk protein allergy
 - Gastric and duodenal ulcers
 - Meckel diverticulum
 - Polyps
 - Hemorrhoids
 - Gastritis
- Thalassemias are disorders of hemoglobin production.
 - α -Thalassemia is caused by deficient production of the α chain.
 - β -Thalassemia is caused by deficient production of the β chain.

- Causes of microcytic anemia
 - Iron-deficiency anemia
 - Lead poisoning
 - Copper deficiency
 - Malnutrition
 - Chronic disease
 - Thalassemia
 - Hemoglobin E trait
 - Sideroblastic anemia
 - Atransferrinemia
 - Inborn errors of metabolism
- Causes of normocytic anemia
 - Infection
 - Acute blood loss
 - Renal disease
 - Connective tissue disorder
 - Hepatic disease
 - Hemolysis
 - Hypersplenism
 - Cancer
 - Aplastic anemia
 - Dyserythropoietic anemia
 - Drugs
- Causes of macrocytic anemia
 - Megaloblastic anemias from vitamin B₁₂ or folate deficiency
 - Reticulocytosis
 - Postsplenectomy
 - Myelodysplastic syndrome
 - Aplastic anemia
 - Fanconi anemia
 - Diamond-Blackfan anemia
 - Persons syndrome
 - Dyskeratosis congenita
 - Paroxysmal nocturnal hemoglobinuria
 - Down syndrome
 - Hypothyroidism
 - Hepatic disease, jaundice
 - Drugs (eg, phenytoin, methotrexate)

HISTORY

- Thorough history may help identify risk as well as cause.
- Diet can identify children most likely to develop iron-deficiency anemia.

- Signs of systemic illness (fever, weight loss) with anemia may indicate underlying systemic disease, such as an autoimmune disorder.
- Historical factors important for diagnosis of anemia
 - Age
 - Nutritional anemias are rare in term infants but more common in infants born preterm, school-age children, and adolescents.
 - Significant anemia diagnosed in the first 6 months of life in a term infant is most likely due to a congenital anemia.
 - Sex
 - Glucose-6-phosphate dehydrogenase (G6PD) deficiency and pyruvate kinase deficiency are X-linked disorders.
 - Race/ethnicity
 - Thalassemias are more common in patients of African or Asian descent, whereas thalassemia syndromes are more common in patients of Mediterranean descent.
 - Nutrition
 - Sources of iron, folate, vitamin B₁₂, and vitamin E should be documented.
 - A history of pica suggests iron deficiency.
 - Medications
 - Phenytoin and methotrexate can induce a megaloblastic anemia.
 - Oxidants can induce hemolytic anemias
 - Sulfa drugs can produce a hemolytic anemia in patients with G6PD deficiency.
 - Family history
 - Anemia, jaundice, gallstones, cholecystitis, splenomegaly, splenectomy, or hemolytic crisis may suggest an inherited hemolytic anemia.
 - Infections
 - Infections may induce hemolysis or RBC hypoplasia or aplasia (parvovirus B19).
 - Hepatitis may induce aplastic anemia.
 - Common acute bacterial and viral infections may result in mild anemia from decreased RBC production or increased RBC destruction, or both.
 - These anemias are typically short-lived but commonly identified on routine screening.
 - Gastrointestinal
 - The gastrointestinal tract is a common source of blood loss.
 - Nutritional deficiencies may result from malabsorption syndromes.

PHYSICAL EXAM

- Most mild/moderate anemias are asymptomatic.
- Possible symptoms of anemia
 - Infants and toddlers
 - Fatigue
 - Irritability
 - Pallor
 - Increased sleep
 - Poor feeding
 - Failure to thrive
 - Older children and adolescents
 - Fatigue
 - Pallor
 - Exercise intolerance
 - Dizziness
- Headaches
- Shortness of breath
- Palpitations
- Pallor
 - Rare in mild anemias but common in children with moderate to severe anemia
 - Does not necessarily indicate a low hemoglobin level
 - Frequently only seen reliably with hemoglobin concentrations <8 g/dL
 - May be more easily identified in nail beds, mucosa, conjunctiva, and palmar creases
- Signs of hemolytic anemia
 - Splenomegaly
 - Icterus
- Signs of chronic hemolytic anemia (eg, thalassemia)
 - Frontal bossing
 - Maxillary prominence
- Leukemia or lymphoma may present with anemia with focal lymphadenopathy and hepatosplenomegaly.
- Cardiovascular signs
 - Mild to moderate decrease in RBC mass may result in pulmonary flow murmur.
 - More severe anemias may be associated with signs of congestive heart failure.

DIFFERENTIAL DIAGNOSIS

Utility of subclassification

- Subclassification of anemias as microcytic, normocytic, and macrocytic greatly reduces the differential diagnosis and limits the number of laboratory tests needed for diagnosis.

Anemia in newborns

■ Classifying the cause into 1 of 3 broad classifications is helpful.

- Blood loss
 - Twin-to-twin transfusions
 - Chronic blood loss throughout pregnancy
 - Infant may have pallor and microcytic, hypochromic anemia but appear otherwise well and hemodynamically stable.
 - Infants with acute blood loss
 - May have pallor, tachypnea, tachycardia, hypotension, and decreased tone
 - Normocytic, normochromic anemia with a reticulocytosis will be detectable soon after birth.
- Hemolysis
 - Different maternal blood types or antigens, maternal drug use, or neonatal infections
 - Microangiopathic hemolysis may occur in infants with thrombi, disseminated intravascular coagulation, and Kasabach-Merritt syndrome (multiple cavernous hemangiomas).
- Decreased production

Differential diagnosis of specific pathologic RBC features

■ Target cells: surface-to-volume ratio is increased.

- Thalassemia
- Hemoglobinopathies
- Hemoglobin C disease
- Hemoglobin E disease
- Hyposplenism or postsplenectomy
- Hepatic disease
- Severe iron-deficiency anemia
- Abetaproteinemia
- Lecithin or cholesterol acyltransferase deficiency

■ Spherocytes: hyperdense cells with a decreased surface-to-volume ratio and an increased mean corpuscular hemoglobin concentration

- Hereditary spherocytosis
- Hemolytic anemia (autoimmune, ABO incompatibility, water dilution)
- Microangiopathic hemolytic anemia
- Hemoglobin SS disease
- Hypersplenism
- Burns
- After RBC transfusions
- Pyruvate kinase deficiency

■ Acanthocytes (spur cells): cells with 10–15 spicules that are typically irregular in length, spacing, and width; cells usually smaller than normal RBCs

- Disseminated intravascular coagulation
- Microangiopathic hemolytic anemia
- Hyposplenism or postsplenectomy
- Hepatic disease
- Hypothyroidism
- Vitamin E deficiency
- Abetalipoproteinemia
- Malabsorption

■ Echinocytes (burr cells): cells with 10–30 spicules that are typically of similar size and distributed evenly

- Dehydration
- Renal disease
- Hepatic disease
- Pyruvate kinase deficiency
- Peptic ulcer disease
- After RBC transfusion

■ Pyknocytes: hyperchromic RBCs with decreased volume and distorted shape

- Similar to acanthocytes and echinocytes

■ Blister cells: contain a clear area in RBCs that contains no hemoglobin

- Hemoglobin SS disease
- G6PD deficiency
- Pulmonary emboli

■ Basophilic stippling: retention of RNA, resulting in fine blue inclusions in the cytoplasm

- Iron-deficiency anemia
- Lead poisoning
- Hemolytic anemias
- Pyrimidine 5'-nucleotidase deficiency

■ Elliptocytes: elliptical-shaped cells

- Hereditary elliptocytosis
- Iron-deficiency anemia
- Thalassemia
- Hemoglobin SS disease
- Sepsis
- Megaloblastic anemia
- Malaria
- Leukoerythroblastic reaction

■ Teardrop cells: microcytic and hypochromic cells that are teardrop-shaped

- Normal finding in newborns

- Thalassemia
- Myeloproliferative diseases
- Leukoerythroblastic reaction
- Schistocytes: RBC fragments that result from trauma
 - Disseminated intravascular coagulation
 - Hemolytic anemia and microangiopathic hemolytic anemia
 - Kasabach-Merritt syndrome
 - Purpura fulminans
 - Hemolytic-uremic syndrome
 - Uremia, glomerulonephritis, acute tubular necrosis
 - Cirrhosis
 - Malignant hypertension
 - Thrombosis
 - Thrombotic thrombocytopenic purpura
 - Amylosis
 - Chronic relapsing schistocytic hemolytic anemia
 - Burns
 - Connective tissue disorders
- Stomatocyte: area of central pallor is more slitlike than round
 - Stomatocytosis (hereditary)
 - Thalassemia
- Nucleated RBCs: normal on peripheral blood smear in the first week of life only
 - Significant bone marrow stimulation
 - Congenital infections
 - Hyposplenism or postsplenectomy
 - Leukoerythroblastic reaction, particularly with severe infections and leukemias or metastatic tumors in the bone marrow
 - Megaloblastic anemia
 - Dyserythropoietic anemia
- The following tests are not necessary in initial diagnosis but help identify cause.
 - Iron studies
 - Erythrocyte sedimentation rate
 - Serum bilirubin
 - Serum lactate dehydrogenase
- Normal values for hemoglobin (g/dL)/hematocrit (%)/MCV (fL), by age
 - Cord blood: 15.3/49/112
 - 1 day: 19.0/61/119
 - 1 week: 17.9/56/119
 - 1 month: 17.3/54/112
 - 2 months: 10.7/33/100
 - 3 months: 11.3/33/88
 - 6 months–2 years: 12.5/37/77
 - 2–4 years: 12.5/38/79
 - 5–7 years: 13/39/81
 - 8–11 years: 13.5/40/83
 - 12–14 years
 - Girls: 13.5/41/85
 - Boys: 14/43/84
 - 15–17 years
 - Girls: 14/41/87
 - Boys: 15/46/86
- Black children on average have normal hemoglobin values that are approximately 0.5 g/dL lower than those in white and Asian children.

LABORATORY EVALUATION

- Tests to perform
 - Hemoglobin level and hematocrit
 - RBC morphology (see Differential Diagnosis)
 - MCV
 - Reticulocyte count
 - Elevated count implies bone marrow compensation for chronic blood loss or hemolysis.
 - Low count may suggest impaired RBC production or acute blood loss.
 - Stool guaiac tests for occult blood should be performed at several different times to capture intermittent bleeding.

IMAGING

- Chest radiograph may be required if pulmonary hemosiderosis needs to be ruled out.

DIAGNOSTIC PROCEDURES

- Bone marrow aspiration and biopsy may be required in patients with anemia suspected of having bone marrow involvement or abnormalities.

TREATMENT APPROACH

- Treatment of compensated anemia is dictated by the cause of the anemia.
- Patients with uncompensated anemia should be admitted to the hospital for observation and possible transfusion.
- Many patients with microcytic anemia or normocytic anemia have early iron-deficiency anemia, and a course of supplemental iron is appropriate.

SPECIFIC TREATMENT

- Specific treatment depends on the underlying hematologic disorder.
- For a child with hypochromic, microcytic anemia found on routine blood cell count with history of poor iron intake or excessive milk intake:
 - Give a trial of supplemental iron (3–6 mg/kg of elemental iron per day, divided into ≥ 2 doses) rather than drawing additional blood for analysis.
 - Reticulocyte count should increase within 5–7 days.
 - Assuming that the dietary deficiency is corrected, supplemental iron should continue for 2–3 months after the hemoglobin concentration has normalized.
- Thalassemia major requires long-term transfusion therapy.

WHEN TO REFER

- Referral to hematologist
 - Hemoglobin level < 8 g/dL or hematocrit $< 25\%$
 - Anemia of unknown origin
 - When anemia is associated with disorder in leukocytes or platelets
 - If hemoglobinopathy or RBC membrane defect is suspected or confirmed
 - If no clear vitamin B₁₂ or folate deficiency, for assessment of macrocytosis to rule out myelodysplasia or cancer
- Referral to a pediatric oncologist is warranted for management of most macrocytic anemias that are not related to nutritional deficiencies.

WHEN TO ADMIT

- Profound anemia (hemoglobin level < 5 – 6 g/dL or hematocrit < 15 – 20%)
- Uncompensated anemia or anemia associated with a rapidly decreasing hemoglobin level
- Anemia in an ill child
- Tachycardia followed by orthostasis, headache, dizziness, and hypotension

FOLLOW-UP

- Patients receiving a therapeutic trial of iron for suspected iron-deficiency anemia should be followed up at 1 week for repeated measurement of the reticulocyte count or at 1 month for hemoglobin measurement.
 - If there is no change in reticulocyte count or hemoglobin level, consider noncompliance with therapy, a problem with iron assimilation, or another diagnosis for microcytic anemia.

COMPLICATIONS

- If iron deficiency is not diagnosed and treated early, it may adversely affect the cognitive function of brain.

PREVENTION

- All infants are provided with iron-fortified food after 6 months of age.
- All infants are checked for hemoglobin and lead levels between 9 and 12 months of age.
- All children and adolescents, especially menstruating girls, need to be checked for hemoglobin and hematocrit yearly.

Animal Bites

DEFINITION

- Bites occur from dogs (most common), cats (second most common), humans, and wild animals.

EPIDEMIOLOGY

- Incidence
 - An estimated >2 million people across the US are bitten by animals annually.
 - Dog bites account for >90%; cat bites account for most of the remainder.
- Severity
 - 50% are trivial and require no medical treatment.
 - 10% are severe enough to require suturing.
 - 2% result in hospitalization.
- Age
 - Children have the greatest number of animal bites (peak age group, 5–14 years)
 - 50% of all school-age children report being bitten by an animal at some point in their life.
 - Adults are typically bitten on an extremity; children are more likely to be bitten on the head or neck.
- Sex
 - Boys are twice as likely as girls to be bitten by a dog.
 - Girls receive twice as many cat bites.
- Environment
 - Most animals live in the victim's neighborhood (75%) or home (15%).
 - Bites are usually provoked by humans.

ETIOLOGY

- Most bacteria associated with bite wounds are common organisms that reside in the animal's oral cavity or on the victim's skin and involve several pathogens.
- *Pasteurella multocida*, a gram-negative, facultative anaerobe, is found in the mouths of most dogs and cats.
 - Highly associated with cat bite infections (up to 80%) and to a lesser extent with dog bite infections (12–50%)
- Gram-negative aerobes (eg, *Pseudomonas*, *Klebsiella*, and *Enterobacter* spp) are found more often than gram-positive aerobes (eg, staphylococci, streptococci) or anaerobes (eg, *Bacteroides*, *Fusobacterium*, and *Peptococcus* spp).
- Human bites are rarely infected by *P multocida* but are often associated with gram-positive organisms, gram-negative anaerobes, or *Eikenella corrodens*.
 - Human bites can transmit HIV and hepatitis B.

RISK FACTORS

- The following factors increase the risk for infection.
 - Cat and human bites, in part because these bites more often cause puncture wounds
 - Bites to the hand
 - Waiting >24 hours to seek medical attention

SIGNS AND SYMPTOMS

- Important points to elicit while taking history
 - Length of time since injury
 - Type of animal (including domestic or wild)
 - Whether the attack was provoked or unprovoked
 - Animal's present location
 - Immunization status and health
 - Prior wound management
- Animal bites from nondomestic animals require special attention.
 - Evaluate children who may have been exposed to rabies.
 - Know when to treat.
- Human bites can transmit HIV and hepatitis B virus.
 - Test for these in situations of high risk.
- Physical examination entails a thorough musculoskeletal and neurologic examination.
 - Determine whether underlying structures were damaged.
 - Inspect wound for signs of infection.
 - Pay special attention to the hand because superficial signs of infection (redness, swelling, purulent drainage) may be absent.
 - Cellulitis
 - Due to *P multocida*
 - Generally develops rapidly, within hours of the animal bite
 - Systemic signs (fever, lymphangitis) are usually absent.
 - Development over days makes it more likely the result of gram-positive cocci or other pathogenic bacteria.
 - Cat-scratch disease is a common complication of cat bites and (less common) bites by other animals.
 - Begins with a red, painless papule at the site of recent scratch or bite
 - Within weeks: tender, enlarged, regional lymph node, usually associated with fever, malaise, and other systemic symptoms

LABORATORY FINDINGS

- Gram stain of a wound specimen is not useful.
- Cultures of infected wounds:
 - Have no growth in one-third of cases
 - Do not predict the likelihood of subsequent infection
 - May help ensure that the causative bacteria are sensitive to the antibiotic used
- Cat-scratch disease
 - Caused by *Bartonella henselae*
 - Can be diagnosed clinically or confirmed by serologic testing

IMAGING

- Radiologic studies
 - May be necessary for deep puncture wounds to determine whether the periosteum has been penetrated
 - Include the calvaria of small children who experience bites to the head.

TREATMENT APPROACH

- The initial step is meticulous wound care.
 - Gently clean the wound with soap and water.
 - Saline irrigation with a syringe and 19-gauge needle generates pressure on the tissues that facilitates cleansing and reduces risk of infection.
 - Devitalized tissue should be debrided.
 - Puncture wounds should be cleaned, but irrigation is ineffective and may result in further damage.
 - Elevation and immobilization are important for significant extremity injuries.
- The child's immunization status should be assessed and tetanus prophylaxis provided if indicated.
- Primary closure of lacerations is controversial.
 - Wounds that are clearly infected should not be closed.
 - Most noninfected lacerations can be sutured for cosmetic purposes or for hemostasis.
 - After meticulous cleansing and irrigation
 - Hand wounds are the exception, owing to great likelihood of infection and risk of serious complications from deep, closed-space infections.
 - Suturing of the hand is suggested only for large wounds.
- Prophylactic antibiotics in noninfected bite wounds is controversial.
 - They are indicated after a human or animal bite of the hand.
 - No evidence indicates that they are effective for other types of bites.

- Infected bite wounds brought to medical attention after 24 hours should be treated with antibiotics.
- For wild animal bites, consult with the local health department to determine the risk of rabies for particular geographic region.
 - Bats, skunks, foxes, raccoons, and other carnivores are considered rabid until proved otherwise by laboratory tests.
 - In the interim, or if the animal cannot be found, treatment with human rabies IgG (HRIG/RIG) and human diploid cell vaccine (HDCV) is suggested.
 - Rabies prophylaxis is now suggested after exposure to bats in a confined setting, even when no bites are visible.
 - The location of a bat bite is rarely known; HRIG/RIG dose may be given in the thigh.
 - If the bat can be captured and submitted for testing, then rabies prophylaxis can be avoided in 60% of the cases.
- Treatment approach for rabies
 - Wild carnivores
 - Begin HRIG/RIG and HDCV.
 - Submit the animal's head for testing.
 - Healthy domestic dogs and cats
 - Quarantine the animal; treat only if the animal develops symptoms.
 - Stray or sick dogs and cats
 - Submit the animal's head for testing.
 - Delay treatment until test results are known unless the clinical likelihood of rabies is high.
 - If the animal is unavailable, then complete a full series of HRIG/RIG and HDCV.
 - Rodents, rabbits
 - Unlikely to be rabid (except woodchucks)
 - Treat only if the animal acted strangely and cannot be tested.
 - Current recommendations call for most, if not all, of the HRIG/RIG dose (20 IU/kg of body weight) to be infiltrated in and around the site of the bite.

SPECIFIC TREATMENTS

- Choice of antibiotics depends on culture results or, if cultures are not available, on the likely pathogens.
- Amoxicillin/clavulanic acid (Augmentin) is an excellent choice for empirical treatment of bites from all animals.
- Intravenous antibiotics
 - Indicated in patients with:
 - Infected hand bites
 - Moderate to severe infections at other bite sites
 - Those who present with systemic symptoms, such as high fever

- For cat bites
 - Penicillin G for *P multocida*, plus antistaphylococcal antibiotic (eg, cefazolin or trimethoprim/sulfamethoxazole [TMP/SMX])
 - Penicillin-allergic children may be treated with azithromycin and an antistaphylococcal antibiotic.
- For dog bites
 - Ampicillin/sulbactam
 - Penicillin-allergic children may be treated with clindamycin and TMP/SMX.
- Cat-scratch disease
 - Generally self-limited and does not benefit from antibiotics
 - Large, tender, fluctuant lymph nodes may require aspiration or incision and drainage.

WHEN TO ADMIT

- Infected wounds requiring intravenous antibiotics
- Extensive facial wounds requiring skilled nursing care

WHEN TO REFER

- Complex wounds that require surgical repair
- Bites to the face or hand that require plastic surgery
- Infected wounds that do not respond to initial treatment
- Children with human bites from an adult
- Cases involving wild animal bites; consult with local health department to determine risk of rabies in a specific animal for a particular geographic region.

FOLLOW-UP

- If the animal that caused the bite is quarantined because its rabies status is unknown, then the animal and the bitten individual need close follow-up.

COMPLICATIONS

- Deep infections of tendons or bones and systemic infections can occur if animal bites go untreated.
- Major morbidity from animal bites results from direct trauma and infection.
- Dog bites can cause lacerations or avulsions if infected.
- Puncture wounds can result in deep-tissue infections.

PREVENTION

- Education about responsible pet care is important.
- Preschool-age children:
 - Should not be left alone with a pet
 - Should be advised never to tease animals, approach strange animals, or play with pets that are eating.
- Families who have children should be advised not to buy wild animals or dogs bred for aggressiveness.
- Vaccinations for pets and routine visits to the veterinarian should be encouraged.
- Families traveling with children should be on the alert for stray animals in foreign countries.
 - If the family is planning to spend an extended period in a country with endemic rabies, then prophylactic rabies vaccination should be strongly considered.

Anorexia Nervosa

DEFINITION

- Purposeful loss of weight beyond a healthy state
 - Intense fear of gaining weight or becoming fat, even though underweight
 - Disturbance in perception of body weight or shape, undue influence of body weight or shape on self-evaluation, or denial of seriousness of the current low body weight
- Restricting type: during current episode, person has not regularly engaged in binge-eating or purging behavior (ie, self-induced vomiting or the misuse of laxatives, diuretics, or enemas)
- Binge-eating or purging type: during the current episode, person has regularly engaged in binge-eating or purging behavior (ie, self-induced vomiting or the misuse of laxatives, diuretics, or enemas)

EPIDEMIOLOGY

- Sex
 - At least 0.5–1% of girls and young women
 - 0.2% of boys and young men
- Age
 - Bimodal peak of onset occurs during the adolescent years at 14.5 and 18 years.
 - Increasingly seen in both prepubertal children and adults

ETIOLOGY

- Several factors develop into an eating disorder.
 - Adolescent girls may be:
 - Culturally primed
 - Biologically at risk
 - Psychologically vulnerable in response to a particular precipitant
 - Insult by family or friends
 - Exposure to someone who has an eating disorder
 - Stressful situation
- Behavior perpetuated by:
 - Initial positive psychological feedback for improved appearance
 - Biochemical changes in response to decreased nutrition

RISK FACTORS

- Serotonergic system genetic defects relate to susceptibility.
- Low self-esteem
- Perfectionism
- Obsessiveness
- Family factors
 - History of eating disorders
 - Family dieting
 - Focus on weight in the family

- Very preterm small-for-gestational-age at infancy
- Psychiatric illnesses
 - Depression
 - Anxiety
 - Obsessive-compulsive disorder

SIGNS AND SYMPTOMS

- Concern about weight loss, vomiting, or abnormal eating attitudes noticed by family, friends, or school authorities
- Common for patients to be brought in against their will, although some may seek help willingly
- Distortion in body image
- History of bingeing or purging
- Overexercising
- Psychosocial changes
 - Fighting with the family
 - Withdrawing from friends
 - Performing less optimally in school
 - Improved school performance due to withdrawal from friends and family
- Symptoms of malnutrition
 - Alopecia
 - Cold hands and feet
 - Dry skin
 - Constipation
 - Fatigue
 - Absence of ≥ 3 consecutive menstrual cycles
 - Scaphoid abdomen
 - Muscle wasting
 - Acrocyanosis
 - Decreased subcutaneous fat
 - Lanugo hair similar to that seen in newborns
 - Ecchymoses
 - Diminished reflexes
- Weight percentage below ideal body weight (IBW)
 - Calculated by comparing current weight with the average weight expected for height, age, and sex (as determined by standard pediatric growth charts)
 - Serves as both diagnostic criterion and as gross estimate of the degree of malnutrition
 - Weight $< 25\%$ below IBW: severe malnutrition
 - Weight 20% below IBW: moderate malnutrition
 - Weight not yet 20% below IBW: mild malnutrition
 - Body mass index is being used increasingly to describe nutritional status.

- Vital signs that show malnutrition
 - Decline in blood pressure
 - Decreased pulse
 - Cardiovascular changes
 - Decline in electrocardiogram (ECG) voltage
 - Sinus bradycardia
 - Prolonged QTc
 - Orthostatic hypotension
 - Increased vagal tone
 - Poor myocardial contractility
 - Mitral valve prolapse
 - Pericardial effusion
 - Decreased left ventricular mass

DIFFERENTIAL DIAGNOSIS

- Differential diagnosis of eating disorders includes possible causes of weight loss or vomiting and other psychiatric causes of poor appetite.
- Medical causes
 - Cancer
 - Central nervous system tumors
 - Gastrointestinal problems
 - Malabsorption
 - Celiac disease
 - Inflammatory bowel disease
 - Endocrinologic problems
 - Diabetes mellitus
 - Hyperthyroidism
 - Hypopituitarism
 - Chronic illnesses/infections
 - Superior mesenteric artery syndrome
- Psychiatric causes
 - Depression
 - Obsessive-compulsive disorder
 - Psychosis (especially schizophrenia)
 - Patients may have concomitant depression or psychosis with anorexia; separate criteria must be used to establish each entity.
 - Sleep disorders
 - Hallucinations, delusions, or obsessions

DIAGNOSTIC APPROACH

- Distortion of body image, a hallmark of anorexia nervosa
 - Evaluate by exploring the patient's views of initial, current, and desired weight.
- Establish patient's eating and exercise patterns.

- A full psychosocial history must be obtained as part of initial evaluation to establish the diagnosis and the psychosocial severity of the disorder.
 - The patient's functioning in the family, in school, and among peers must be evaluated.
- Assess use of vomiting or medications designed to promote weight loss.
 - Diet pills
 - Laxatives
 - Diuretics
 - Ipecac
- Avoid being misled by the patient who is not completely forthcoming; results of physical examination and laboratory tests often suggest the true extent of the disorder.
- Initial evaluation of weight loss includes:
 - Determination of the diagnosis and its severity
 - Evaluation of other possible causes of weight loss and the effects of malnutrition
 - Analysis of the psychological context of the illness
 - Decision about treatment
- For girls, a full menstrual history should be obtained.
 - Age at menarche
 - Last normal menstrual period
 - Usual length of menses
 - Heaviness of flow
 - Presence of dysmenorrhea
 - Regularity of menses

LABORATORY FINDINGS

- Initially, laboratory results may be normal.
- Workup should include:
 - Complete blood count
 - Leukopenia
 - Occasionally thrombocytopenia
 - Rarely, severe anemia (being protected for some time from iron-deficiency anemia by the concomitant amenorrhea)
 - Serum electrolytes
 - Evidence of dehydration
 - Elevated sodium level
 - Elevated blood urea nitrogen level
 - Excessive drinking
 - Signs of hyponatremia
 - Dilute urine
 - Hypokalemia, often severe

- Nutrient values that may be altered
 - Zinc
 - Calcium
 - Magnesium
 - Copper
 - Vitamin B₁₂
 - Folate
- Hormone testing
 - Relative hypothyroidism caused by combination of euthyroid sick syndrome and decreased production on a hypothalamic basis can be an adaptive response to inadequate nutrition.
 - Low-normal levels of triiodothyronine, thyroxine, thyroid-stimulating hormone, or any combination
 - In patients with amenorrhea, low levels of:
 - Luteinizing hormone
 - Follicle-stimulating hormone
 - Estradiol
 - Prolactin
 - Hypercortisolemia with loss of diurnal variation
 - Low levels of insulin-like growth factor 1
- Liver and thyroid function tests
- Urinalysis for specific gravity and ketonuria is often helpful.
- ECG for persons with bradycardia

IMAGING

- Magnetic resonance imaging (MRI) of the brain, gastrointestinal series, or other tests may be considered in some cases for patients who claim to be eating well or not vomiting on purpose.
- Abnormalities may be found on computed tomography and MRI of the brain.
 - These are generally reserved for evaluating other possible causes when diagnosis is in question.
 - MRI changes including gray matter deficits and elevated cerebrospinal fluid volumes; these may not be reversible.
- Gastric emptying studies may show:
 - Delayed gastric emptying
 - Decreased gastrointestinal motility
- Bone densitometry, using dual-energy x-ray absorptiometry
 - Bone density values are correlated with body mass index, age at onset, and duration of illness.
 - Common test in evaluation of patients with eating disorders/amenorrhea of 6–12 months' duration

DIAGNOSTIC PROCEDURES

- To document orthostatic changes:
 - Patient's blood pressure and pulse should be checked in the sitting position, followed by standing for 2 minutes.
 - Significant findings, either:
 - Increase of 20 beats/min in pulse
 - Decrease of 20 mm Hg in systolic blood pressure
 - Decrease of 10 mm Hg in diastolic blood pressure

TREATMENT APPROACH

- Medical and nutritional rehabilitation are crucial.
 - Restoration of body weight to within 10% of IBW, with restoration of menses, are primary goals.
 - If malnutrition is mild to moderate (15–25% below IBW), restoration may be accomplished on outpatient basis.
 - If malnutrition is moderate to severe (>25% below IBW), treatment usually requires hospitalization.
- Medical treatment includes management of:
 - Electrolyte abnormalities
 - Cardiovascular issues
 - Endocrine disorders
 - Other organ system dysfunction
 - These are managed simultaneously with or aided by nutritional rehabilitation.
- Nutritional therapy
 - Daily intake of 3 substantial meals and 3–4 snacks is usually sufficient to bring about required weight gain.
 - At inpatient units, meals are generally provided as part of a strict regimen, and snacks generally consist of high-calorie supplements.
 - Too-rapid weight gain is associated with severe metabolic abnormalities in some patients (refeeding syndrome).
 - Slow refeeding and phosphorus supplementation are required in patients with severe malnutrition to prevent this syndrome (which can involve cardiac failure, hemolysis, coma, and death).
- Behavioral therapy is normally a necessary component of treatment.
 - The goal is to offer external positive and negative reinforcements to replace specific internal sensors that usually control appetite and weight gain but are missing.
 - Not intended to be definitive but to stabilize weight and diet in a more medically healthy patient
 - Inpatient treatment
 - Strict plans on some psychiatric units involve removal of privileges (using the phone, television, and regular clothing) if weight goal is not achieved each day.

- Less strict plan used on some adolescent medicine units
 - Includes phases of treatment, moving from 1 phase to another based on achievement of progressively higher weight goals
 - Each phase incorporates additional daily privileges (eg, mobility on the unit, exercise, meals, snacks, passes), so that improved weight and eating patterns lead to additional privileges/responsibilities.
 - If the patient does not respond to such a phased system, an all-liquid diet, provided by mouth or, more rarely, nasogastric tube, may be substituted.
- Outpatient treatment
 - Use of monetary or similar rewards may not be strong enough to overcome the fear of eating.
 - Fear of hospitalization itself may be the sole motivation.
- A team approach is needed to treat disease; this may consist of:
 - Primary care physician
 - Psychiatrist
 - Psychologist or social worker
 - Nutritionist
 - The exact combination is determined by local expertise, availability, and preference.
 - Team meetings or discussions are held frequently to prevent miscommunication that can sabotage treatment.
- The team may use multimodal therapy, including:
 - Medical management
 - Nutritional rehabilitation
 - Behavior therapy
 - Individual psychotherapy
 - Family and group therapy
 - Psychopharmacology
 - Such multimodal therapy holds the best promise for successful treatment.
 - Degree to which each of these approaches is incorporated varies with both:
 - The preferences of the treatment team
 - The requirements of the individual patient
 - Each of these approaches may be used for inpatients, day-program patients, and outpatients.
- Only physicians familiar with psychopharmacologic agents should prescribe these as part of the treatment, given the potential for SSRIs to increase risk of suicide in a minority of children and adolescents.
- Not effective in promoting weight gain or treating symptoms of depression or obsessive-compulsive disorder when body weight is low
- Atypical antipsychotic agents at low doses can improve weight gain and treat symptoms of depression and obsessional thoughts.
- Menses restoration
 - Generally requires an estradiol level >30 mg/dL
 - Estrogen replacement has not been shown to reverse or prevent bone loss.

Dietary plan

- In outpatients
 - May be developed on the basis of the patient's and the family's prior eating habits or on a specific dietary plan offered by the physician or a nutritionist
 - Should be specific so that ambiguities that can lead to family fighting are avoided
 - Should provide 2000–3000 calories a day
 - Some may be supplied as high-calorie supplements.
 - Should be balanced and include foods from each of the major food groups
 - Weight gain should be 1–2 pounds per week (inpatient gains may be 2–4 pounds per week).
 - Compliance with the dietary regimen may be evaluated by having the patient keep a diet diary; however, many patients do not keep these records accurately and honestly.

Individual psychotherapy

- An essential part of treatment
- Exploration of underlying psychological features and determination of possible mechanisms for change are appropriate for most patients.
- Because anorexia often serves as a defense against other difficult aspects of life, psychological change is acknowledged as the necessary precursor to significant improvement.
- No single type of therapy is better than others.
- Associated with improved weight gain and psychosocial function

Family therapy

- Important, especially for younger patients
- Family sessions, arranged in varying combinations to include parents and siblings, generally focus on disordered communication patterns that often accompany the disorder.
- Resolving specific conflicts arising from the eating disorder itself becomes important.

SPECIFIC TREATMENTS

Pharmacologic therapy

- Selective serotonin reuptake inhibitor (SSRI) antidepressants
 - Helps with concurrent psychiatric disorder
 - Helps treat obsessive-compulsive symptoms

- Course of the disorder is more difficult for adolescents whose families are unable or unwilling to make necessary changes in their customary patterns of communication and parenting.
- Outpatient treatment in which families provide and supervise all meals is increasingly used for younger patients with anorexia nervosa, with positive results.

Group therapy

- For mild anorexia, may be only approach used
- Groups may focus on psychotherapeutic approach or more specifically on behavioral changes.
- The risk of patients learning bad habits from one another is outweighed by benefit derived; this is especially true for patients who have had social difficulties during adolescence.

WHEN TO ADMIT

- Any ≥ 1 of the following should prompt admission.
 - Severe malnutrition (weight $<75\%$ IBW)
 - Dehydration
 - Electrolyte disturbances
 - Cardiac disturbances
 - Physiologic instability
 - Bradycardia
 - Hypotension
 - Hypothermia
 - Orthostatic changes
 - Arrested growth and development
 - Failure of outpatient treatment
 - Acute food refusal
 - Acute medical complication of malnutrition
 - Syncope
 - Seizures
 - Cardiac failure
 - Pancreatitis
 - Acute psychiatric emergencies
 - Suicidal ideation
 - Acute psychosis
 - Comorbid diagnosis that interferes with the treatment of the eating disorder
 - Severe depression
 - Obsessive-compulsive disorder
 - Severe family dysfunction

WHEN TO REFER

- A team approach is most often used.
- Refer to a dietician if the primary care physician or staff does not have the expertise or time to set a nutritional plan with the patient.
- Refer to a psychotherapist if:
 - The patient is open to therapy.
 - The patient cannot attain goals set by the physician, even if the patient is resistant.
- Refer for psychopharmacologic evaluation if:
 - Both the physician and the therapist believe the patient might benefit from medication
 - Patient is bingeing and open to medication
 - Obsessive-compulsive symptoms are interfering with treatment
- Refer to adolescent medicine if:
 - The physician is not comfortable treating the patient.
 - The physician cannot provide sufficient time for patient needs.
 - The patient does not adhere to the physician's treatment plan.

COMPLICATIONS

- Acrocyanosis
- Dry skin
- Lanugo
- Ecchymosis
- Fatigue
- Muscle wasting
- Decreased subcutaneous fat
- Decreased deep-tendon reflexes
- Constipation
- Delayed gastric emptying
- Delayed gastric motility
- Orthostatic hypotension
- Bradycardia
- Mitral valve prolapse
- Pericardial effusion
- Electrocardiographic abnormalities
- Decreased left ventricular mass and contractility
- Psychomotor retardation
- Growth delay
- Pubertal delay
- Amenorrhea
- Osteopenia, osteoporosis
 - 3-fold increase in the long-term risk of fracture development

PROGNOSIS

- Adolescents with severe anorexia nervosa have a protracted disease course; recovery estimates 10–15 years later vary from 76% to 24%.
- Estimated 50% of patients do well in the long term.
- 30% show varying degrees of improvement.
- 20% do poorly despite adequate treatment.
- Patients who are younger or have milder disease fare better.
- Predictors of poorer outcome
 - Older age
 - Vomiting
 - Premorbid personality problems
 - Any particular patient with these may do well with treatment.
- Mortality is higher than in any other psychiatric illness, up to 5% per decade after the onset of the eating disorder.

PREVENTION

- Best preventive strategies are not clear.
- Early case detection is most effective.
 - The earlier an eating disorder is treated, the easier the treatment will be and the less entrenched the disease becomes.
 - Families, friends, school personnel, and health professionals must be vigilant for signs and symptoms of an eating disorder so that early treatment can be initiated.

- Programs are geared toward teenage boys and girls, primarily in school settings.
 - Aimed at maintaining a healthy body image and healthy eating
 - Work to promote self-esteem without relation to weight
 - Seem to succeed in terms of increasing awareness and knowledge about eating disorders
 - Effectiveness is debatable.
 - Programs focused on building self-esteem are being explored.
 - Classroom interventions
 - Staff training throughout the school
 - Informal discussions between staff and students
 - Integration of material about eating issues into the curriculum
 - More intensive work with persons at high risk
 - Changes within the school with respect to cafeteria food and physical education
 - Referrals and outreach (both within the school and the community)
-

Anuria and Oliguria

DEFINITION

- Oliguria is decreased urine output.
 - Infants: <0.5 mL/kg per hour for 24 hours
 - Older children: <500 mL/1.73 m² body surface area per day
- Anuria is absence of any urine output.
 - Normal, healthy newborns may have no urine output for 24 hours after birth.
- Oliguria is much more common than anuria but can lead to anuria, resulting in serious renal damage that requires specialized care.

EPIDEMIOLOGY

- Incidence of oliguria or anuria is unknown in previously healthy children.
- In hospitalized patients
 - Oliguric acute renal failure (ARF) occurs in:
 - 10% of newborns in the intensive care unit
 - 2–3% of older children requiring intensive care
 - 8% of patients undergoing cardiac surgery
- Prevalence of ARF in newborns
 - Prerenal: 85%
 - Renal: 11%
 - Postrenal: 3%
- Prevalence of ARF in older children
 - Prerenal: 66%
 - Renal: 33%
 - Postrenal: <1%

ETIOLOGY

Causes of oliguria, anuria, and ARF

- Common causes of oliguria, anuria, or ARF are best defined in relation to the patient's age.
- Prerenal ARF caused by dehydration is the most common cause of oliguria/anuria (70% of community-acquired cases of ARF and up to 60% of hospital-acquired cases).
- Renal ARF caused by intrinsic renal damage can be categorized into 3 types.
 - *Acute tubular necrosis* (ATN) results from prolonged ischemia or drug- or toxin-mediated renal tubular injury (reversible).
 - *Glomerular lesions* may occur with postinfectious glomerulonephritis.
 - *Vascular lesions* may occur with hemolytic-uremic syndrome or Henoch-Schönlein purpura.

■ Postrenal ARF

- Mechanical or functional obstruction to urine flow
 - May be in lower urinary tract, eg, posterior urethral valves
 - May be bilaterally in the upper tract, eg, bilateral ureteropelvic junction obstruction (rare)
- Unilateral obstruction can cause ARF in patients with only 1 functioning kidney.
- More common in newborns than in older infants

Most common causes of oliguria and anuria in neonates and children

■ Neonates

- Prerenal
 - Perinatal asphyxia
 - Respiratory distress syndrome
 - Hemorrhage
 - Sepsis or shock
 - Congenital heart disease
 - Dehydration
 - Drugs (indomethacin, maternal use of ACE inhibitors or nonsteroidal antiinflammatory drugs)
- Renal
 - Acute tubular necrosis
 - Exogenous toxins (aminoglycosides, amphotericin B)
 - Endogenous toxins (hemoglobin, myoglobin, uric acid)
 - Congenital kidney diseases
 - Vascular (renal vein thrombosis, renal artery thrombosis)
- Postrenal
 - Posterior urethral valves
 - Meatal stenosis
 - Bilateral ureteral obstruction
 - Neurogenic bladder

■ Children

- Prerenal
 - Dehydration
 - Hemorrhage
 - Burns
 - Third-space loss (surgery, trauma, nephrotic syndrome)
 - Renal loss (diabetes mellitus, diabetes insipidus, diuretics)
 - Shock
 - Decreased cardiac output
- Renal
 - Acute tubular necrosis
 - Glomerulonephritis

- Exogenous toxins (aminoglycosides, amphotericin B)
- Endogenous toxins (hemoglobin, myoglobin, uric acid)
- Vascular (hemolytic-uremic syndrome, vasculitis)
- Postrenal
 - Posterior urethral valves
 - Meatal stenosis
 - Bilateral ureteral obstruction
 - Neurogenic bladder

RISK FACTORS

- Common underlying comorbid conditions
 - Neurologic conditions
 - Compromised thirst mechanism
 - Serious disability and total dependence on others for nutrition and hydration, eg, patients with severe cerebral palsy
 - Renal diseases that impair ability to concentrate the urine, eg, salt-losing nephropathy or chronic renal failure
 - Gastrointestinal conditions that cause hypoalbuminemia and decreased intravascular volume, eg, celiac disease or hepatic failure
 - Endocrine disease, such as:
 - Diabetes insipidus, associated with increased hypotonic urine output
 - Diabetes mellitus, associated with osmolar diuresis
 - Hematologic conditions that impair urine concentration mechanism
- Oncologic emergencies, eg, tumor lysis syndrome (causes renal failure, particularly if patient is not well hydrated)
- Therapy that may predispose to renal failure because they impair renal autoregulation in the presence of mild renal insufficiency or dehydration
 - Nonsteroidal antiinflammatory drugs
 - Angiotensin-converting enzyme inhibitors
 - Aminoglycosides
 - Radiologic contrast media

SIGNS AND SYMPTOMS

- Clinicians need to search for specific signs of underlying renal disease.
 - Severe anemia due to hemolytic-uremic syndrome
 - Butterfly rash on face/musculoskeletal involvement in systemic lupus erythematosus
 - Purpuric rash over buttocks and extensor surface of lower extremity in Henoch-Schönlein purpura.
 - Palpable kidney may be due to:
 - Renal vein thrombosis
 - Polycystic kidney disease

- Multicystic dysplastic kidney
- Hydronephrosis
- Palpable bladder with weak urine stream or dribbling suggests obstruction.
- Sacral tuft of hair or myelomeningocele may be seen with neurogenic bladder (can cause obstructive uropathy/postrenal oliguria or anuria).
- Symptoms of prerenal cause
 - Vomiting
 - Diarrhea
 - Hemorrhage
 - Sepsis
 - Decreased oral intake
 - Increased thirst
 - Palpitations
 - Fatigue
 - Clinical signs of dehydration
 - Weight loss
- Symptoms of hypovolemia (ie, prerenal pathology)
 - Tachycardia
 - Dry mucous membranes
 - Sunken eyes
 - Orthostatic blood pressure changes
 - Decreased skin turgor
 - Hypotension
- Symptoms of intrinsic renal disease
 - Gross hematuria
 - Pharyngitis or impetigo a few weeks before the onset of gross hematuria
 - Hypertension
 - Edema
 - Bloody diarrhea
 - Often precedes hemolytic-uremic syndrome
 - Younger children, particularly infants: signs of congestive heart failure
 - Hepatomegaly
 - Gallop rhythm
 - Pulmonary edema
- Symptoms of systemic vasculitis (eg, systemic lupus erythematosus)
 - May see history of fever, joint pains, and skin rash
- Recurrent sinusitis or lower respiratory tract infections may suggest Wegener granulomatosis.
- Hemoptysis may indicate pulmonary-renal syndrome, due to either:
 - Goodpasture syndrome
 - Microscopic polyangiitis

DIAGNOSTIC APPROACH

- Thorough history and physical examination are important in identifying the cause of oliguria or anuria.
 - Comprehensive physical examination is key to assessing severity of the disease process and possible cause.
 - In prerenal and postrenal ARF, early diagnosis and prompt treatment often result in quick recovery.
- Detailed history of recent or ongoing long-term medication use is important for excluding possible interstitial nephritis.
- In neonates, history of umbilical artery catheterization implies renal artery thrombosis.
- Family history is helpful in diagnosing such conditions as diabetes insipidus and polycystic kidney disease.

LABORATORY FINDINGS

- Risk factors, history, and results of physical examination will help in the selection of appropriate laboratory tests.
- Urinalysis is the most important noninvasive diagnostic test.
 - Thorough examination of a freshly voided or bladder-catheterized urine sample helps distinguish prerenal from renal causes.
 - Normal or near-normal urinalysis, with few cells, few or no casts, or little or no proteinuria, is seen in prerenal disease, obstruction, and some cases of acute tubular necrosis.
 - A sample showing muddy-brown granular casts and epithelial cell casts strongly suggests acute tubular necrosis.
 - Erythrocyte casts are diagnostic of glomerulonephritis.
 - Proteinuria indicates glomerular disease.
- Urinary indices important for diagnosis of oliguria
 - Urinary sodium
 - <10 mEq/L in oliguria resulting from intravascular volume depletion
 - Neonates: prerenal disease is associated with urine sodium concentration <20 – 30 mEq/L.
 - Specific gravity
 - >1020 in prerenal oliguria
 - Creatinine
 - Urine/plasma creatinine ratio >40 in prerenal oliguria
 - Urine/plasma creatinine ratio <20 if renal cause
 - Osmolality
 - Urine/plasma osmolality >1.5 in prerenal oliguria
 - Urine/plasma osmolality <1.5 if renal cause
- Fractional excretion of sodium
 - $<1\%$ suggests reabsorption of almost all filtered sodium in response to decreased renal perfusion (prerenal).
 - In acute tubular necrosis: $>2\%$

- Blood urea nitrogen (BUN) and serum creatinine
 - In prerenal oliguria, increased BUN level is marked and the BUN/serum creatinine ratio is >20 .
 - BUN/creatinine ratio of 10 – 15 suggests intrinsic renal damage.

IMAGING

- Renal ultrasonography
 - Generally not indicated in children with prerenal failure from dehydration who respond promptly to fluid resuscitation
 - Provides important information regarding
 - Kidney size and echogenicity
 - Renal blood flow
 - Collecting system
 - Urinary bladder
 - Children with intrinsic causes
 - Echogenic and slightly enlarged kidneys
 - Bilateral hydronephrosis or hydroureteronephrosis and bladder wall thickening indicate obstruction of bladder outlet causing postrenal oliguria/anuria.
 - Ultrasonography can detect congenital disorders, such as polycystic kidney disease and multicystic dysplastic kidney.
- Doppler examination of renal blood flow is helpful in diagnosing renal vascular thrombosis.

CLASSIFICATION

- Prerenal: dehydration is the most common cause of oliguria/anuria in children.
- Renal: intrinsic renal disorders, such as acute tubular necrosis and glomerulonephropathies
- Postrenal: obstruction to urinary flow in posterior urethral valves in boys

TREATMENT APPROACH

- Major goal of treatment of prerenal oliguria/anuria is to restore intravascular volume.
- Oliguria/anuria due to intrinsic renal conditions needs to be managed by a pediatric nephrologist.
- Urology needs to be consulted in patients with postrenal obstructive lesions.

SPECIFIC TREATMENTS

- A dehydrated child with oliguria/anuria should receive a fluid bolus of normal saline or lactated Ringer's solution at 20 mL/kg to restore fluid volume.
 - Depending on response, another bolus may be needed.
- Estimation of volume status is needed to begin and continue fluid therapy.

■ Amount is assessed by history and physical exam that includes assessment of:

- Body weight
- Anterior fontanelle in infants
- Heart rate
- Mucous membranes
- Skin turgor
- Capillary refill
- Peripheral edema
- Blood pressure

■ Children with oliguria and volume overload may:

- Benefit from furosemide
- Require fluid restriction
- Need blood pressure and acid-base monitoring

■ Children with oliguria due to obstruction may require urinary catheterization.

- Relief of obstruction may be followed by postobstructive diuresis and may need fluid/electrolyte replacement.

WHEN TO ADMIT

■ See When to Refer.

WHEN TO REFER

■ Refer to a nephrologist or admit (or both) if child has any of the following:

- Persistent oliguria or anuria despite adequate fluid challenge in a dehydrated child

- Persistent oliguria or anuria that continues after removal of the offending nephrotoxins

- Oliguria or anuria associated with:

- Swelling
- Hypertension
- Gross hematuria
- Abnormal blood chemistry
- Severe systemic signs or symptoms

- Urology referral for oliguria or anuria caused by obstructive uropathy

PREVENTION

■ The key to preventing oliguria or anuria is adequate hydration in at-risk patients.

- Patients who have just undergone surgery
- Patients receiving nephrotoxic medications
 - Amphotericin B
 - Acyclovir
 - Radiocontrast agent
- Patients at risk of tumor lysis syndrome
- Patients at risk of pigment nephropathy caused by hemoglobinuria or myoglobinuria

Apparent Life-Threatening Event

DEFINITION

- An apparent life-threatening event (ALTE) is:
 - Frightening to the observer, who may fear the infant has died
 - Characterized by some combination of:
 - Apnea
 - Color change
 - Marked change in muscle tone
 - Choking
 - Gagging
- ALTE replaced the terms:
 - *Aborted crib death*
 - *Near-miss sudden infant death syndrome (SIDS)*
 - Change corrects erroneous implication of an association between ALTE and SIDS.
- Pathologic apnea
 - Respiratory pause
 - Prolonged, lasting ≥ 20 seconds **or**
 - Associated with cyanosis, pallor, hypotonia, or bradycardia
 - Central apnea
 - No respiratory effort for 20 seconds, or shorter if associated with hypoxemia or bradycardia
 - Obstructive apnea
 - Respiratory effort in thoracic or abdominal impedance tracings, or both
 - No airflow in nasal and end-tidal carbon dioxide tracings
 - Mixed apnea
 - Central and obstructive events at the same time
- Periodic breathing (common in young infants)
 - Breathing pattern:
 - ≥ 3 respiratory pauses > 3 seconds
 - < 20 seconds of respiration between pauses

EPIDEMIOLOGY

- Frequency and prevalence are unknown.
 - Estimates:
 - 0.21% of all children and 0.6% of all patients < 1 year seeking care at an emergency department
 - 9.4 per 1000 live births
- Age
 - Median age at presentation of infants with an ALTE ranges between 7 and 8 weeks of age.
- Sex
 - Relatively equal distribution

ETIOLOGY

- A variety of different disorders can lead to an ALTE.
- Up to 50% of cases of ALTE remain unexplained and are considered idiopathic.

RISK FACTORS

- Premature birth
 - Approximately one-third of patients with an ALTE
- Previous ALTE
 - 19% of patients

SIGNS AND SYMPTOMS

History

- Detailed history and description of the infant at the time of the ALTE are particularly important.
 - Most infants appear normal by the time of evaluation.
 - Perinatal history
 - Full-term or premature birth
 - Pregnancy or perinatal complications
 - Medical and surgical history
 - Previous evaluations and treatments
 - Prior hospitalizations
 - Medications
 - Sleep and feeding habits
 - Breastfeeding versus bottle feeding
 - Usual amount and frequency of feedings
 - Usual behavior and temperament
 - Family history
 - Siblings with ALTE, SIDS, or early death
 - Family history of genetic, metabolic, cardiac, or neurologic problems
 - Parental or caretaker history
 - Smoking or drinking habits
 - Recent medical problems and treatments
 - Usual sleep conditions
 - Sleep position when placed down for sleep and when found
 - Sleeping attire
 - Bedding materials
 - Other conditions
 - Clothing
 - Room temperature
 - Use of pacifiers
- ### Circumstances and characteristics of the ALTE
- Preceding events
 - Recent fever or illness
 - Medications for the infant and others in the home

- Immunizations
- Sleep deprivation
- Change in daily life routine
- Place and time
 - Exact place in which the ALTE occurred, eg:
 - Child's bed
 - Parent's bed
 - Parent's arms
 - Bathroom
 - Sofa
 - Car
 - Time of event
 - Time since last feeding
 - Estimated time to recover from the ALTE
 - Estimated duration of event
- Witnesses and interventions
 - Who discovered or witnessed the ALTE
 - Reason that led to the discovery of the ALTE (noise, unusual cry)
 - Any interventions performed, eg:
 - Gentle stimulation
 - Shaking
 - Cardiopulmonary resuscitation
 - Child's response to the intervention
- Description of infant during ALTE
 - State of infant when event began: asleep or awake
 - If asleep:
 - Child's body position
 - Type of bedding
 - Face covered or free
 - If awake, was the child:
 - Being fed
 - Being handled
 - Crying
 - Being bathed
 - Child's appearance when found
 - Consciousness
 - Muscle tone
 - Color
 - Respiratory effort
 - Choking
 - Gasping
 - Emesis
 - Sweating

- Limb or eye movements
- Pupil size
- Skin or rectal temperature

Physical examination

- Detailed physical examination is essential to uncover any clues to the underlying cause.
- The clinician should:
 - Pay particular attention to abnormalities that may account for the infant's symptoms
 - Neurologic
 - Respiratory
 - Cardiac
 - Note any evidence of physiological compromise, eg:
 - Mental status changes
 - Cyanosis
 - Apnea

DIFFERENTIAL DIAGNOSIS

- Differential diagnosis focuses on determining the underlying condition associated with the ALTE.
- Gastrointestinal
 - Gastroesophageal reflux disease (GERD) (31%)
 - Diagnosis most often associated with an ALTE
 - Its precise role is debated.
 - GERD is common in the general population; the physician should not assume a causal relationship when it is discovered in an infant with a history of an ALTE.
- Neurologic
 - Seizures (11%)
- Respiratory
 - Lower respiratory tract infections (8%)
 - Pertussis
 - Respiratory syncytial virus infection
- Cardiovascular
 - Cardiac arrhythmias
 - Persistent ductus arteriosus
- Endocrine, metabolic
 - Inborn errors of metabolism
- Infectious
 - Urinary tract infections
- Neoplastic
 - Brain tumor
- Drug-related
 - Opioid-related apnea

■ SIDS

- Apnea is not predictive of or a precursor to SIDS.
 - ALTEs are not near-miss SIDS cases.
 - Apnea appears to resolve at an age before most SIDS deaths occur.
- Infants with an ALTE are:
 - 1–3 months younger than infants who die of SIDS
 - More likely to be found during the daytime or while sleeping supine at the time of the event
- <7% of patients with SIDS have a history of an ALTE.
- Although the SIDS mortality rate markedly decreased between 1986 and 1994, the mean annual admission rate for ALTEs did not change significantly.

■ Other

- Child abuse should be considered in children with a history of:
 - Recurrent cyanosis
 - Apnea
 - ALTE witnessed only by a single caretaker or in a family with previous unexplained infant deaths
 - Clinicians must be vigilant to avoid stigmatizing or adding to the distress of families.
- Factitious illness

DIAGNOSTIC APPROACH

■ ALTE:

- Describes a clinical syndrome rather than a specific diagnosis
- Is a common, nonspecific disorder of the young infant
 - Usually self-limited
 - May be potentially serious and life threatening

■ No single accepted standard for evaluation

- Thorough clinical assessment is most likely to lead to a diagnosis of the underlying problem.
 - Detailed history
 - Physical examination
- Diagnostic studies and observation should be based on the findings of the clinical assessment.
 - If enough tests are performed, the increasing likelihood of false-positive results will diminish their diagnostic value.

LABORATORY FINDINGS

■ The yield of most studies is low.

- Even if a positive result is found, the question of a causal relationship still remains.

■ Consider in infants with no identified cause after clinical assessment:

- Complete blood count
- Urinalysis and culture
- Blood culture

■ Additional studies to consider after an initial period of observation:

- Metabolic studies
 - These studies may not be available in all hospitals.
 - A pediatric specialist may need to be consulted to interpret the results.
- Tests for respiratory pathogens as indicated
- Toxicology screen
- Child abuse

IMAGING

■ Consider in infants with no identified cause after clinical assessment.

- Usually after an initial period of observation

■ Chest radiography

■ Skeletal survey

- Child abuse

■ Upper gastrointestinal series

- Not sensitive for diagnosing GERD, but may be useful for identifying intestinal obstruction that contributes to GERD
 - Volvulus
 - Gastric outlet obstruction

■ Brain neuroimaging

- Child abuse

■ Gastroesophageal reflux study

DIAGNOSTIC PROCEDURES

■ Electrocardiography

- Child with a witnessed seizure
- Consider in infants with no identified cause after clinical assessment.

■ Continuous cardiorespiratory (CR) monitoring with pulse oximetry

- Detects:
 - Apnea
 - Bradycardia
 - Hypoxemia

■ Polysomnography (PSG)

- Suspected hypoxemia or hypercarbia associated with an atypical ALTE
- Prolonged clinical course

- Recurrent or severe episodes
- Obstructive apnea
 - Repeat PSG may be necessary to determine when and if intervention is needed.
- If CR monitoring in the inpatient unit fails to provide a clear diagnosis
 - Central apneas (no respiratory effort for 20 seconds, or shorter if associated with hypoxemia or bradycardia)
 - Obstructive apneas (respiratory effort in thoracic or abdominal impedance tracings, or both, with no airflow in nasal and end-tidal carbon dioxide tracings)
 - Mixed apneas (central and obstructive events at the same time)
 - Episodes of periodic breathing
- Pneumography
 - Unattended studies that collect data on respiratory effort with:
 - Thoracic impedance monitor
 - Nasal flow
 - Oxygenation
 - Cardiac rhythm
 - But not:
 - Sleep staging
 - Carbon dioxide signal
 - Abdominal effort
 - Pneumography generates more technical artifacts and is less informative than PSG.
 - Should be limited to medical centers where PSG is unavailable
- 24-hour pH probe or milk scan by ^{99m}technetium
 - If GERD is the suspected cause of an ALTE
 - Up to 89% of infants with an ALTE may have a positive milk scan.
 - Only 41% of these infants have a correlating clinical diagnosis.
- Dilated funduscopic examination
 - Child abuse

TREATMENT APPROACH

- A period of observation with continuous CR monitoring in the hospital when a benign cause of ALTE is not evident:
 - Gathers additional information
 - Directs appropriate diagnostic studies
- Education and guidance should be provided to the guardian.
- Monitoring in the home setting after hospitalization detects recurrence.

SPECIFIC TREATMENTS

Hospital admission

- Hospital admission may not be required if:
 - The ALTE appears to be benign.
 - The patient is normal when evaluated immediately after the event.

Hospitalization with CR monitoring

- Required if:
 - The episode was significant.
 - The child required intense stimulation.
 - Physical examination reveals an abnormality.

Intensive care unit admission

- If the witnessed event or a review of the history suggests severe CR compromise
- Treatment directed at the underlying diagnosis determined by the evaluation should be started.
 - For example:
 - Antibiotics for suspected bacterial infection
 - Anticonvulsants for an infant with seizures
 - Medications for GERD

Stimulants

- Caffeine may correct periodic breathing associated with hypoxemia.

Preparation for discharge home

- Once the infant has been stabilized, consideration should be made for home CR monitoring.
 - Particularly for infants with an ALTE of unknown cause

WHEN TO ADMIT

- History, examination, or diagnostic studies suggest physiologic compromise.

WHEN TO REFER

- Suspected:
 - Seizure disorder
 - Hypoxemia
 - Hypercarbia
 - Cardiac dysrhythmia
- Vascular ring identified
- Congenital facial anomalies with obstructive apnea
- Evidence of child abuse
- Atypical manifestation

FOLLOW-UP

- Home CR monitoring
 - An ALTE is an indication for home monitoring.
 - Episodes of periodic breathing and obstructive apnea events will not be captured on home CR monitoring unless a secondary effect of these events on heart rate occurs.
 - Review of results
 - CR monitor results should be reviewed by a practitioner or specialist who is trained in their review.
 - Physician should establish a specific plan for periodic review.
 - In most cases, results should be reviewed monthly if the guardian has no concerns about the baby, or sooner if guardian reports ≥ 1 significant events.
 - Discontinue when:
 - No further physiologically significant events have occurred
 - No further objective evidence of pathologic events for ≥ 6 weeks
- Parents and caregivers should be counseled on:
 - Cardiopulmonary resuscitation for infants
 - In case further ALTEs occur after discharge
 - Practicing safe sleeping techniques (see Prevention)
 - Avoiding passive smoke exposure

PROGNOSIS

- Morbidity and mortality vary according to underlying diagnosis.
 - Mortality of infants with apnea of infancy
 - 0–6%
 - In healthy term and premature infants, apnea events become rare by 43 weeks' postmenstrual age.

- ALTE recurrence rate
 - 0–24%
- Long-term outcomes for infants with an unexplained ALTE
 - Unpredictable
 - Severe event requiring resuscitation, recurrent ALTE, or seizure disorder:
 - $>25\%$ risk of death
 - However, normal cognitive and behavioral outcomes have been reported up to 10 years after an ALTE.

PREVENTION

- Parents and caregivers should be counseled on:
 - Safe sleeping tips
 - Infants should be placed on their backs to sleep.
 - Redundant soft bedding and soft objects in the infant's sleeping environment should be avoided.
 - Adults and infants sleeping in the same bed is discouraged.
 - Excessive clothing and extreme room temperatures should be avoided.
 - Passive smoke exposure
 - Should be avoided during fetal and postnatal development

Appendicitis

DEFINITION

- Ischemia and inflammation of the vermiform (worm-shaped) appendix, which leads to local peritoneal inflammation
- Without surgical intervention, the appendix will eventually rupture, causing peritonitis.

EPIDEMIOLOGY

- Age
 - Rare in the first 2 years of life, accounting for <2% of childhood cases, but morbidity is high
 - More common after age 10
- Sex
 - Boys and girls are affected equally before puberty.
 - After age 15, twice as many boys are affected as girls.
- Seasonality
 - Increased incidence in spring and autumn

ETIOLOGY

- Appendicitis is always initiated by obstruction of the appendiceal lumen; the cause is:
 - Usually, a fecalith or lymphoid hyperplasia
 - Rarely, a parasite, tumor, or foreign body
 - Rarely, inspissated secretions in cystic fibrosis
- Organisms cultured from the peritoneal cavity after perforation include:
 - Aerobic bacteria; the most common organisms are:
 - *Escherichia coli*
 - *Staphylococcus aureus*
 - *Enterococcus organisms*
 - Anaerobic bacteria; the most common species are:
 - *Bacteroides*
 - *Clostridium*

RISK FACTORS

- Family history of appendicitis
 - Unclear whether related to genetics or diet

SIGNS AND SYMPTOMS

- Pain
 - Dull, steady, periumbilical at onset
 - If sufficient to awaken patient from sleep, may indicate acute appendicitis
 - Patients may be most comfortable lying supine with their legs flexed.
 - After 4–6 hours, it may shift to the right lower quadrant, but location may vary.
- Anorexia
 - Consistent, though not invariable finding

- Vomiting
 - 1 or 2 episodes, but not preceding pain
- Bowel habits
 - Usually unchanged
- Low-grade fever
 - Rarely above 100.3°F (37.9°C) before perforation
- In infants thought to have abdominal pain symptoms:
 - Vomiting and fever
 - Colicky appearance
 - Abdominal distention
 - Diffuse tenderness is likely; infants are rarely seen before perforation.

DIFFERENTIAL DIAGNOSIS

- Most common conditions that must be differentiated
 - Gastroenteritis
 - Abdominal examination is generally benign.
 - Vomiting and diarrhea usually occur before onset of pain.
 - Constipation
 - Pain is usually diffuse.
 - The patient often has a history of constipation.
 - Abdominal flat-plate roentgenogram can help in the diagnosis.
 - A small Fleet enema is often diagnostic and therapeutic.
 - Urinary tract infection
 - Urinalysis will help rule this out.
 - Diabetic ketoacidosis
 - Urinalysis will help rule this out.
 - Sick cell crisis
 - Right lower-lobe pneumonia
 - May generate referred pain to the right lower quadrant of the abdomen
 - Examine the lungs to rule out.
 - Primary peritonitis
 - Inflammatory bowel disease
 - Check for an elevated erythrocyte sedimentation rate (ESR).
 - With appendicitis, ESR is usually normal.
- Gynecologic conditions
 - Pelvic examination is indicated for any adolescent girl who has abdominal pain.
 - A thorough history, pelvic examination, and appropriate diagnostic studies can rule out:
 - Pelvic inflammatory disease
 - Ovarian torsion
 - Ruptured ectopic pregnancy

- Dysmenorrhea
- Mittelschmerz
- Ruptured corpus luteum cyst
- Unusual conditions that are indistinguishable from or mimic appendicitis
 - Henoch-Schönlein purpura
 - Hemolytic-uremic syndrome
 - Rocky Mountain spotted fever
- Surgical emergencies that mimic appendicitis and may be ruled out only in the operating room
 - Meckel diverticulitis
 - Intestinal adhesions
 - Intussusception
 - Necrotizing enterocolitis

DIAGNOSTIC APPROACH

- To differentiate appendicitis from other disorders:
 - A thorough history, especially of pain, is invaluable.
 - A period of observation can safely differentiate surgical and nonsurgical conditions.
 - Appendix rarely perforates within 24 hours of the onset of pain.
 - Perforation of the appendix may be associated with an initial decrease in pain.
 - Symptoms worsen within a few hours.
- In any infant thought to have abdominal pain, consider appendicitis.
 - With a high index of suspicion, surgery must be performed immediately to prevent or manage perforation.
- Physical examination
 - A gentle, nonthreatening approach is most effective.
 - Assess for peritoneal signs, such as pain on walking or coughing.
 - If the patient can jump up on the examining table, he or she does not usually have appendicitis.
 - Abdominal tenderness
 - Always present
 - Often greatest at the McBurney point (two-thirds of the distance on a direct line from the umbilicus to the anterosuperior iliac spine)
 - There may be hyperesthesia of the skin overlying the painful area.
 - Rebound abdominal tenderness (particularly referred to the right lower quadrant) is common.
 - Pain in the right lower quadrant may be accentuated when the inflamed appendix is located retroceally, by:
 - Placing the patient in the left decubitus position and extending the right leg at the hip, placing tension on the

right psoas muscle, the origins of which underlie the appendix (psoas sign)

- Placing the patient supine and internally rotating the flexed right hip, extending the right internal obturator muscle, the origins of which also underlie the appendix (obturator sign)
- When the inflamed appendix is located anteriorly, pain in the right lower quadrant may be accentuated when the patient is asked to sit up from a supine position while pressure is placed against the forehead.
- Bowel sounds may be diminished or hyperactive.
- Rectal examination often reveals right-sided tenderness.
- Pelvic examination should be performed for any adolescent girl with abdominal pain.
- Without surgical intervention, appendicitis eventually will lead to rupture and peritonitis.

LABORATORY FINDINGS

- Blood count and urinalysis
 - The leukocyte count is most often 10,000–20,000 cells/ μ L.
 - Slight increase in the number of neutrophils, particularly young forms

IMAGING

- Clinical decision rules are used to:
 - Aid in the diagnosis of appendicitis
 - Avoid overuse of imaging studies
- Consultation with a pediatric surgeon may:
 - Minimize the need for imaging studies
 - Reduce rates of perforation and negative appendectomy
- Radiography
 - Abdominal roentgenograms are occasionally helpful.
 - Absence of abnormalities on images does not rule out appendicitis.
 - Suggestive features include:
 - Calcified appendicolith
 - Air-filled appendix
 - In neonates, diagnostic signs include:
 - Appendicolith
 - Free peritoneal fluid
 - Bowel wall edema
 - Rarely, free air
- Ultrasonography and computed tomography (CT)
 - Recently have been used to establish the diagnosis in equivocal cases
 - In 1 study, selective use of CT and ultrasonography:
 - Decreased incidence of perforated appendicitis from 35.4% to 15.5%
 - Decreased the rate of removing a normal appendix (a negative appendectomy) from 14.7% to 4.1%

TREATMENT APPROACH

■ Nonsurgical management

- For patients who have symptoms for ≥ 5 days and a palpable mass consistent with an appendiceal abscess, many surgeons prefer initial nonsurgical management.
- This approach lowers the incidence of diffuse peritonitis and associated complications precipitated by surgical manipulation during acute inflammatory stages.

■ Surgical management

- Incidence of rupture increases dramatically 24–36 hours after the onset of abdominal pain.
- Delaying surgery >36 hours results in at least a 65% incidence of perforation.
- Once the diagnosis is made, the patient must be prepared for immediate surgery.
- Laparoscopic appendectomy is being performed at many institutions.

SPECIFIC TREATMENTS

Nonsurgical management

- For patients who have symptoms for ≥ 5 days and a palpable mass consistent with an appendiceal abscess, many surgeons prefer initial nonsurgical management.
 - Treatment with broad-spectrum antibiotics for 14 days
 - Initiated in the hospital and completed at home
 - If the clinical condition allows and barring interim complications, the child returns in 6–8 weeks for elective appendectomy.

Surgical management

- Nothing is given by mouth.
- A nasogastric tube is inserted and placed on low suction if the child is vomiting.
- Intravenous hydration is started (eg, 10 mL/kg/h of lactated Ringer's solution).
- Fever may be controlled with acetaminophen given by rectum.
- Broad-spectrum antibiotics are administered intravenously before surgery.
 - For example, ampicillin, gentamicin, and clindamycin or acephalosporin
 - Antibiotics have been shown to reduce morbidity even in nonperforated cases.
- Appendectomy is performed as soon as the patient's condition has been stabilized.

WHEN TO ADMIT

- Hospitalize for inpatient observation if the diagnosis cannot be excluded.
- Hospitalize for appendectomy if the diagnosis of appendicitis is made.

- Average hospital stay is approximately 2 days.
 - Significantly longer in cases of perforation

WHEN TO REFER

- Refer to surgery immediately whenever appendicitis is suspected.

FOLLOW-UP

- In nonsurgical management
- Antibiotics, initiated in the hospital and completed at home
- Subsequent elective appendectomy in 6–8 weeks

COMPLICATIONS

- Complications that increase morbidity include:
 - Peritonitis
 - Postoperative abscess
 - Prolonged ileus
 - Perforation
 - Significantly increases risk of postoperative adhesive small-bowel obstruction
- Recent studies have shown that female infertility is not a long-term complication of a ruptured appendix.

PROGNOSIS

- For uncomplicated appendicitis treated with prompt surgical intervention:
 - Mortality is much less than 1%.
 - Long-term morbidity is primarily the risk of adhesive small-bowel obstruction.
- The incidence of perforated appendicitis exceeds 30%, despite increasing use of radiographic imaging.
- For infants <2 years of age:
 - Incidence of perforation approaches 100%.
 - Morbidity is high.
- A ruptured appendix increases the risk of mortality in:
 - Infants
 - Older children with delayed diagnosis who develop sepsis
- A higher index of suspicion on the part of families and pediatricians may:
 - Lead to earlier diagnosis of the condition
 - Reduce incidence of appendiceal perforation and its morbid complications

PREVENTION

- The risk of appendicitis may be reduced with a high-fiber diet.

Asthma

DEFINITION

- Asthma is a chronic lung disease characterized by 3 features.
 - Airway obstruction that is at least partially reversible
 - Airway hyperreactivity or hyperresponsiveness to a variety of external stimuli
 - Chronic inflammation of the airway

EPIDEMIOLOGY

- Prevalence
 - 15 million people in the US have asthma.
 - Asthma affects 5 million children or adolescents.
 - This represents between 3% and 7% of the children in the US.
 - Asthma prevalence in children <5 years has increased 160% in the past 2 decades.
- Age
 - In 80% of patients with asthma, onset of symptoms began before 5 years of age.
- Childhood asthma is responsible for:
 - 13 million physician visits
 - 200,000 hospitalizations
 - 10 million lost school days
 - 550,000 emergency department visits
 - 8 million prescriptions
- The number of deaths from childhood asthma has doubled in the past 2 decades.

ETIOLOGY

- Typically, an external trigger initiates the inflammatory cascade.
 - This trigger may be identifiable.
 - Common triggers include:
 - Viral respiratory infections
 - Exercise
 - Irritants, such as tobacco smoke
 - Allergens
 - Animal dander
 - Dust
 - Dust mites
 - Cockroaches
 - Food, eg, nuts, food additives
 - Mold
 - Change in the weather, particularly cold air
 - Emotional expression, such as laughter or anger
 - Gastroesophageal reflux disease
- The immediate response to the trigger exposure is bronchospasm and bronchoconstriction.
 - Airway constriction leads to cough, wheezing, and shortness of breath.

- Immediate decrease in forced expiratory volume (FEV₁)
 - This returns to normal 4–8 hours after exposure.
- A second, more severe decrease in FEV₁ occurs 8–24 hours after trigger exposure.

RISK FACTORS

- The most common cause of wheezing in infants and young children is upper respiratory tract infections.
- The strongest predictor of wheezing continuing into asthma is atopy.
- Allergens and irritant exposures increase the risk for asthma.
 - Cockroach allergy in children living in urban areas
 - Exposure to maternal smoking
- Prematurity increases risk for asthma.
- Risk factors for asthma
 - Major criteria
 - Parent with asthma or atopic dermatitis
 - Minor criteria
 - Allergic rhinitis
 - Wheezing apart from colds
 - Eosinophilia $\geq 4\%$
 - Children at increased risk for asthma between 6 and 13 years of age are those with:
 - 1 of the 2 major criteria **and**
 - 2 of the 3 minor criteria **and**
 - Wheezing
- The number of deaths from childhood asthma has doubled in the past 2 decades.
 - Risk factors associated with asthma deaths include:
 - History of sudden, severe exacerbations
 - Prior admission to the intensive care unit
 - Prior intubation for asthma
 - Within a 12-month period:
 - ≥ 2 hospitalizations or
 - ≥ 3 emergency department visits
 - Use of >1 canister per month of inhaled short-acting β -agonist
 - Long-term use of oral corticosteroids
 - Difficulty perceiving airflow obstruction or its severity

SIGNS AND SYMPTOMS

- A detailed medical history should be obtained from the patient and family.
 - Ask about symptoms, such as cough, wheezing, shortness of breath, or chest tightness.
 - Frequency
 - Severity

- Are the symptoms made worse by triggers?
 - Identify triggers, if possible.
- Are the symptoms worse during the day or night?
- Physical examination should focus on the upper respiratory tract, chest, and skin.
 - Look for signs of allergic disease.
 - Conjunctivitis
 - Allergic shiners
 - Pale boggy turbinates
 - Rhinorrhea
 - Polyps
 - Transnasal crease
 - Physical signs **not** usually associated with asthma include:
 - Failure to thrive
 - Cyanosis
 - Clubbing

DIFFERENTIAL DIAGNOSIS

- Gastroesophageal reflux
- Not all wheezes indicate asthma.
- Other diagnoses to consider:
 - Cystic fibrosis
 - Foreign body aspiration
 - Vocal cord dysfunction
 - Airway lesions
 - Airway stenosis
 - Tracheal webs
 - Tracheobronchomalacia
 - Vascular rings
 - Mediastinal masses
 - Gastroesophageal reflux or recurrent aspiration
 - Heart failure
 - Immunodeficiency
 - Parasitic diseases
 - Bronchiolitis caused by viral pathogens

DIAGNOSTIC APPROACH

- For a diagnosis of asthma, the following must be present.
- Recurrent, episodic symptoms of airflow obstruction
 - Cough
 - Wheezing
 - Shortness of breath
 - Chest tightness
- Airway flow obstruction or limitation that is at least partially reversible
 - In older children, spirometry before and after bronchodilator use can determine this.

- In younger children, assess by a positive response to a β -agonist.

LABORATORY FINDINGS

- In general, laboratory evaluation is peripheral to the diagnosis.
 - Testing for immunoglobulin E level and allergies may be useful so that appropriate treatment can be started.
 - Complete blood count with differential may indicate an allergic or immunologic condition.

IMAGING

- Chest radiography
 - May be useful to rule out other conditions, such as foreign body aspiration

DIAGNOSTIC PROCEDURES

- Spirometry is the gold standard for measuring severity of obstructive airway disease.
 - Should be performed on any child ≥ 5 years of age who can perform the test
 - Spirometry is preferred over peak flow monitoring.
 - Peak flow measurements reflect large airway function.
 - Measurements to assess:
 - FEV₁
 - Forced vital capacity
 - Forced midexpiratory flow rate
 - Examination of flow volume loop
 - Perform at baseline and then annually.
 - Determines airflow obstruction and whether this airflow obstruction is reversible
- Pre- and post-bronchodilator spirometry is recommended.
 - Confirm the diagnosis
 - Classify disease severity
- Objective measures of lung function are useful:
 - To diagnose airflow obstruction
 - To determine the reversibility of airflow obstruction
 - To assess daily variation and monitor changes over time
 - To manage exacerbations in severe airway obstruction
- Peak flow meters are useful as monitoring tools.
 - They lack sensitivity for diagnostic use.
 - Reference values vary, depending on the brand of the peak flow meter.
 - As a monitoring tool, peak flow measurement can assist the clinician to:
 - Determine whether airway narrowing is occurring before the patient becomes symptomatic.
 - Monitor the effect of medication addition or withdrawal
 - Determine when to seek help

- Determine the effect of triggers
- Determine changes in lung function

CLASSIFICATION

■ National Heart, Lung, and Blood Institute Guidelines for Asthma Severity

- Mild intermittent asthma
 - >80% FEV₁ and peak expiratory flow rate (PEFR) before bronchodilator use
 - <12% and 20% change, respectively, after bronchodilator use
- Mild persistent asthma
 - >80% FEV₁ and PEFR before bronchodilator use
 - >12% and 20% change, respectively, after bronchodilator use
- Moderate persistent asthma
 - 60–80% FEV₁ and PEFR before bronchodilator use
- Severe persistent asthma
 - <60% FEV₁ and PEFR before bronchodilator use

■ Symptom class: current clinical features

- Intermittent asthma
 - Intermittent symptoms (wheeze, cough, dyspnea) <2 times/week
- Brief exacerbations (from a few hours to a few days)
- Nighttime asthma symptoms <2 times/month
- Mild persistent asthma
 - Intermittent symptoms (wheeze, cough, dyspnea) >2 times/week but <1 time/day
 - Exacerbations that may affect activity and sleep
 - Nighttime asthma symptoms >2 times/month but <1 time/week
- Moderate persistent asthma
 - Symptoms (wheeze, cough, dyspnea) daily
 - Exacerbations >2 times/week; may last days and affect activity
 - Nighttime asthma symptoms >1 time/week
- Severe persistent asthma
 - Continuous symptoms
 - Frequent exacerbations
 - Frequent nighttime asthma symptoms
 - Physical activities limited by asthma symptoms

■ Patients with intermittent asthma experiencing severe exacerbations requiring hospitalization should be treated as having moderate persistent asthma (category 3 above).

■ Children requiring intensive care should be treated as having severe persistent asthma (category 4 above).

- These children should be referred to an asthma specialist.

■ Classification can change over time.

- Ongoing review of symptoms and treatment plan every 1–6 months is helpful.

TREATMENT APPROACH

■ Therapy has 5 major goals.

- Prevent chronic and troublesome symptoms
- Maintain normal or near-normal pulmonary function
- Maintain normal activity levels, including exercise
- Prevent exacerbations
- Provide optimal medical regimen with minimal or no adverse side effects

■ There are 4 interventions to achieve these goals.

- Objective measurements of lung function
 - Spirometry
 - Peak flow monitoring
- Pharmacologic therapy
 - Relieve obstruction and provide quick relief of symptoms.
 - Short-acting β -agonists
 - Systemic corticosteroids
 - Anticholinergic agents
 - Treat underlying inflammation.
 - Long-acting β -agonists
 - Inhaled corticosteroids
 - Nonsteroidal antiinflammatory agents
 - Leukotriene (LT) modifiers
 - Theophylline
- Environmental control of allergies and irritants
- Patient education

SPECIFIC TREATMENTS

Short-term pharmacologic therapy

■ Quick relief of symptoms

■ Short-acting β -agonists are the most well known in this category.

- Bronchodilate
- Bronchoprotect
- Can prevent exercise-induced bronchospasm
- Most common side effects
 - Tachycardia
 - Tremor
 - Headaches
 - Palpitations
 - Hypokalemia
 - Hyperglycemia

■ Examples

- Albuterol
 - Oral solution: 2 mg/5 mL
 - 0.1–0.2 mg/kg, 3 times/day
 - Do not exceed 12 mg/day.
- Albuterol (Proventil HFA, Proair HFA)
 - Metered-dose inhaler (MDI): 108 mcg/puff
 - 2 puffs, 15 minutes before exercise
 - 2 puffs, 3–4 times/day, as needed
- Albuterol (Ventolin HFA)
 - MDI: 100 mcg/puff
 - 2 puffs, 15 minutes before exercise
 - 2 puffs, 3–4 times/day, as needed
- Albuterol (AccuNeb)
 - Nebulizer solution: 0.63 mg/3 mL; 1.25 mg/3 mL
 - 0.63 to 1.25 mg, 3–4 times/day, for ages 2–12 years
- Albuterol sulfate
 - Nebulizer solution: 2.5 mg/3 mL; 0.083% (unit dose)
 - 0.05 mg/kg (min: 1.25 mg; max: 2.5 mg), 3–4 times/day
- Levalbuterol (Xopenex)
 - Nebulizer solution: 0.31 mg/3 mL; 0.63 mg/3 mL; 1.25 mg/3 mL
 - 0.31–0.63 mg, 3 times/day, for maintenance
 - 1.25 mg, 3 times/day, for acute bronchospasm and patients who are unresponsive to lower dose
- Levalbuterol (Xopenex HFA)
 - MDI: 45 mcg/puff
 - 1–2 puffs up to every 4 hours
- Pirbuterol (Maxair)
 - MDI: 200 mcg/puff
 - 2 puffs 3–4 times/day, as needed
- A short course of oral corticosteroid is a quick-relief medication.
 - Broad antiinflammatory effects
 - Usually given for 3–10 days to:
 - Gain initial control of asthma
 - Speed resolution of moderate to severe persistent exacerbations
 - Methylprednisolone (Medrol)
 - Tablets: 4, 6, 8, 16, 24, 32 mg
 - Short-course (3–10 days)
 - 4 burst: 1–2 mg/kg/day (max: 60 mg/day)
 - Prednisolone
 - Tablet: 5 mg
 - Short-course (3–10 days)
 - 4 burst: 1–2 mg/kg/day (max: 60 mg/day)
 - Prednisolone (Pediapred)
 - Liquid: 5 mg/5 mL
 - Short-course (3–10 days)
 - 4 burst: 1–2 mg/kg/day (max: 60 mg/day)
 - Prednisolone (Prelone syrup)
 - Liquid: 15 mg/5 mL
 - Short-course (3–10 days)
 - 4 burst: 1–2 mg/kg/day (max: 60 mg/day)
 - Prednisolone (Orapred ODT)
 - Chewable tablet 10, 15, 30 mg
 - Short-course (3–10 days)
 - 4 burst: 1–2 mg/kg/day (max: 60 mg/day)
 - Prednisone (Prednisone)
 - Tablet: 1, 2.5, 5, 10, 20, 50 mg
 - Liquid: 5 mg/5 mL
 - Short-course (3–10 days)
 - 4 burst: 1–2 mg/kg/day (max: 60 mg/day)
 - Prednisone (Prednisone Intensol)
 - Liquid: 5 mg/5 mL
 - Short-course (3–10 days)
 - 4 burst: 1–2 mg/kg/day (max: 60 mg/day)
- Anticholinergic agents, in combination with a β -agonist, have a positive effect on acute asthma exacerbations.
 - The most common agent is ipratropium.
 - Decreases vagal tone, leading to bronchodilation
 - Blocks reflex bronchoconstriction to irritants
 - Has no effect on the early- or late-phase response
 - Acts an additive to a β -agonist
 - Ipratropium bromide (Atrovent HFA)
 - MDI: 17 mcg/puff
 - Nebulizer solution: .20 mg/mL; 0.02% (ampule)
 - 1–2 puffs 4 times a day or 1 ampule 4 times a day
 - 0.25–2 mg/kg or every other day in single dose as needed for long-term control up to a maximum of 60 mg/day
 - Ipratropium bromide/albuterol (DuoNeb)
 - Nebulizer solution: 0.20 mg/mL/2.5 mg albuterol (ampule)
 - 1 ampule 4 times a day
 - 0.25–2 mg/kg or every other day in single dose as needed for long-term control up to a maximum of 60 mg/day

Long-term pharmacologic therapy

- Treat the underlying inflammatory disorder.

Inhaled corticosteroids

- Inhaled corticosteroids are the most effective long-term antiinflammatory medications currently available.
 - Available in variety of delivery formats:
 - MDI

- Dry powder inhaler (DPI)
 - Nebulizer
 - Improves long-term symptoms in pulmonary function
 - Reduces the need for quick-relief medications
 - Major issues and concerns
 - Growth delay
 - Ocular problems, such as cataracts and potential glaucoma
 - Thrush
 - Contraindicated during certain infections (herpes simplex)
 - Budesonide inhalation suspension (Pulmicort Flexhaler)
 - Approved for nebulization by the US Food and Drug Administration
 - May be used in infants as young as 12 months.
 - DPI: 90 mcg/inhalation
 - Low dose: 2–4 inhalations/day, once daily or divided twice daily
 - Medium dose: 6–8 inhalations/day, divided twice daily
 - DPI: 180 mcg/inhalation
 - Low dose: 1–2 inhalations/day, once daily or divided twice daily
 - Medium dose: 3–4 inhalations/day, divided twice daily
 - High dose: 8 inhalations/day, divided twice daily
 - Budesonide (Pulmicort respules)
 - Liquid: 0.25 mg/2 mL; 0.5 mg/2 mL
 - Low dose: 0.5 mg, once or twice daily
 - High dose: 1.0 mg, once or twice daily
 - Beclomethasone dipropionate (QVAR HFA)
 - MDI: 40 mcg/puff
 - Low dose: 1–4 puffs/day, divided twice daily
 - Medium dose: 4–8 puffs, divided twice daily
 - MDI: 80 mcg/puff
 - Low dose: 1–2 puffs/day, divided twice daily
 - Medium dose: 2–4 puffs/day, divided twice daily
 - High dose: 8 puffs/day, divided twice daily
 - Flunisolide (AeroBid, AeroBid M)
 - MDI: 250 mcg/puff
 - Low dose: 2–4 puffs/day, divided twice daily
 - Medium dose: 4–6 puffs/day, divided twice daily
 - High dose: 8 puffs/day, divided twice daily
 - Fluticasone propionate (Flovent)
 - MDI: 44 mcg/puff
 - Low dose: 2–4 puffs/day, divided twice daily
 - MDI: 110 mcg/puff
 - Medium dose: 2–4 puffs/day, divided twice daily
 - MDI: 220 mcg/puff
 - Medium dose: 2 puffs/day, divided twice daily
 - High dose: 3–8 puffs/day, divided twice daily
 - DPI: 50 mcg/inhalation
 - Low: 2–4 inhalations/day, divided twice daily
 - DPI: 100 mcg/inhalation
 - Medium: 2–4 inhalations/day, divided twice daily
 - DPI: 250 mcg/inhalation
 - Medium: 2 inhalations/day, divided twice daily
 - High: 3–8 inhalations/day, divided twice daily
 - Mometasone furoate (Asmanex Twisthaler)
 - DPI: 220 mcg/inhalation
 - Low dose: 1 inhalation/day, at night
 - Medium dose: 2–3 inhalations/day, once (at night) or divided twice daily
 - High dose: 4 inhalations/day, divided twice daily
 - Triamcinolone (Azmacort)
 - MDI: 200 mcg/puff
 - Low dose: 4–8 puffs/day, divided 3–4 times/day
 - Medium dose: 8–12 puffs/day, divided 2–4 times/day
 - High dose: 12–16 puffs/day, divided twice daily
- Combination inhaled corticosteroids and long-acting β -agonists**
- Fluticasone propionate and salmeterol (Advair)
 - DPI
 - 100 mcg/50 mcg inhalation
 - Low dose: 1 inhalation, twice daily
 - 250 mcg/50 mcg inhalation
 - Medium dose: 1 inhalation, twice daily
 - 500 mcg/50 mcg inhalation
 - High dose: 1 inhalation twice daily
 - MDI
 - 45 mcg/21 mcg puff
 - 2 puffs, twice daily
 - 115/21 mcg/puff
 - 2 puffs, twice daily
 - 230/21 mcg/puff
 - 2 puffs, twice daily
- Nonsteroidal anti-inflammatory agents**
- Cromolyn sodium (Intal)
 - Mast-cell stabilizer
 - Decreases early- and late-phase response after allergen challenge
 - Has a good safety profile

- Can be dispensed as a nebulizer solution or
 - Nebulizer: 20 mg/2 mL in an ampule
 - 1 ampule, 3–4 times/day
 - MDI: 1 mg/puff
 - 1–2 puffs, 3–4 times/day
 - This dose may be inadequate to affect airway hyperresponsiveness.

■ Nedocromil

- Has a good safety profile
- Poor patient compliance with this medication due to its unpleasant taste.
- MDI: 1.75 mg/puff
 - 1–2 puffs, 2–4 times/day

LT modifiers

- Block synthesis of LTs or block LTD4 receptors
- Can be administered orally
- Improve symptoms and pulmonary function
- Can negatively affect the pharmacokinetics of certain medications
- Montelukast (Singulair)
 - Sprinkles: 4 mg for ages 12–23 months
 - Tablet
 - 4 mg, chewable, for ages 2–4 years
 - 5 mg, chewable, for ages 6–14 years
 - 10 mg, for ages >14 years
 - 1 tablet or packet in the evening for all dose formulations
- Zafirlukast (Accolate)
 - Tablet
 - 10 mg for ages 7–11 years
 - 20 mg for ages ≥12 years
 - 1 tablet, twice a day; take 1 hour before or 2 hours after meals.
- Zileuton (Zyflo Filmtab)
 - 600 mg for ages ≥12 years
 - 1 tablet, 4 times/day

Long-acting β -agonists

- Relax the bronchial smooth muscle
- Only available as DPIs
- Salmeterol (Serevent diskus)
 - DPI: 50 mcg/blister
 - 1 inhalation, twice daily
- Formoterol (Foradil aerolizer)
 - DPI: 12 mcg/capsule
 - 1 capsule inhaled twice daily, or 15 minutes before exercise

■ Sustained-release albuterol (VoSpire ER)

- Tablet: 4 mg, 8 mg
- Maximal dose:
 - 6–12 years: 4 mg, twice daily
 - ≥12 years: 8 mg, twice daily

Theophylline

- Use has diminished in children with asthma owing to need for frequent monitoring and side effects, some of which are life threatening.
- Uniphyll, Theo-24
 - Capsules: 100, 125, 200, 300, 400, 600 mg
 - Starting dose: 10 mg/kg/day
- Elixophyllin
 - Liquid: 80 mg/15 mL
 - Maximal dose (for children <1 year of age): $(0.2 \times \text{age in weeks}) + 5 = \text{mg/kg/day}$
- Theo-Dur
 - 50, 75, 125, 200 mg sprinkles
 - Maximal dose (for children ≥1 year of age): 16 mg/kg/day, not to exceed the adult maximum of 800 mg/day.

Omalizumab

- Anti-immunoglobulin E humanized monoclonal antibody
- Only prescribed by asthma specialists

WHEN TO ADMIT

- Admission may be required when:
 - The child does not respond to β -agonist therapy.
 - The child has peak flows <50% of personal best after β -agonist therapy.
 - The child has difficulty breathing, as evidenced by:
 - Chest and neck pulling in
 - Hunched posture
 - Trouble walking or talking
 - Stopping playing or inability to restart
 - Gray or blue lips or fingernails

WHEN TO REFER

- Refer the child to an asthma specialist when:
 - The child has had a life-threatening exacerbation.
 - The child has been admitted to an intensive care unit.
 - Goals of asthma therapy are not being met after 3–6 months of treatment.
 - Signs and symptoms are atypical.
 - Severe persistent asthma is present.
 - The child requires >2 bursts of oral corticosteroids per year.

FOLLOW-UP

- Factors that influence adherence to asthma therapy
 - Medication characteristics
 - Taste
 - Dosing schedule
 - Side effects
 - Expense
 - Patient variables
 - Apathy
 - Misperception of disease severity
 - Failure to obtain medication
 - Physician factors
 - Poor communication
 - Failure to monitor patients regularly
 - Incorrect medication and dose level
- To assess medication compliance:
 - Determine what factors may have prevented proper use of prescribed medications.
 - Bothered by taste
 - Cost
 - Concern about side effects
 - Denial
 - Difficulty remembering or organizing medications
 - Difficulty tolerating side effects
 - Difficulty using delivery system
 - Difficulty with school
 - Unable to understand how medicine works
 - Inconvenient or inappropriate dosing schedule
 - Embarrassment
 - Fear of addiction
 - Lack of parental supervision
 - Language difficulties
 - Rebellion
 - Unable to refill prescription on time
 - Inadequate transportation to health services
 - Inadequate transportation to the pharmacy
- To promote successful disease management:
 - The clinician should use a friendly manner and be attentive.
 - The patient should be supported and praised for success.
 - Elicit family concerns and allay their fears.
 - Ongoing education should be provided to reinforce the medication regimen and technique of administration.
 - Keep the therapy as simple as possible.
 - Limit number of medications.
 - Limit number of doses.

- Communicate with school personnel.
 - Have a plan for the child with asthma.
 - The child should be allowed to carry and use a short-acting β -agonist for quick relief of symptoms.

COMPLICATIONS

- There are 5 questions to ask when the patient does not respond to reasonable therapy.
 - Is it asthma?
 - Anatomic lesions or other medical conditions should be ruled out.
 - Is the patient adherent to the medication regimen?
 - Is the patient's technique for medication delivery appropriate?
 - Did the patient run out of medication and not realize it or say so?
 - Is there a continual exposure present that is causing problems for the patient?
- A referral or second opinion should be considered if the desired effect is not being achieved.

PREVENTION

- Warning signs and symptoms that a patient may experience before an asthma attack
 - Chest pain
 - Irritable
 - Fatigue
 - Quiet
 - Eczema flare-up
 - Fever
 - Scratchy throat
 - Heartburn, gastroesophageal reflux
 - Heart palpitations
 - Decreased exercise tolerance
 - Mood changes
 - Runny or stuffy nose
 - Headaches
 - Wheezing
 - Cough
 - Loss of appetite
 - Trembling hands
 - Watery eyes
 - Dark circles under eyes

Atopic Dermatitis

DEFINITION

- Atopic dermatitis (AD) is a multifactorial dermatologic condition involving chronic inflammation of the skin.
- Sometimes referred to as *eczema*, a general term to describe skin that is erythematous, scaling, vesicular, and crusting.
- May be the initial condition signaling the progression to further allergic disease, known as the *atopic march*
- Associated immunoglobulin E (IgE)-mediated diseases
 - Allergic rhinitis
 - Asthma
 - Food allergies

EPIDEMIOLOGY

- Prevalence
 - >10% of infants and young children may be affected.
 - ~5% of adolescents are affected.
 - In 2007, 18 million Americans had a self-reported diagnosis, with more than one-third having the diagnosis confirmed by a physician.
- Age
 - Predominantly disease of infancy and childhood
 - Onset occurs in first year of life in the majority of affected individuals.
- Sex
 - Both sexes are affected equally.

ETIOLOGY

- The exact cause is unknown, but genetic and environmental factors play a role.
- Involves:
 - Dysfunction of the epidermal barrier and
 - Dysfunction of the immune system
 - Abnormal IgE-mediated (type I) reaction
 - Abnormal cell-mediated (type IV) reaction
- The hygiene hypothesis states that decreased exposure to microbes stunts immunologic maturation of Th1 cells.
- Other cells implicated in the development of AD
 - Macrophages
 - IgE-bearing Langerhans cells
 - Eosinophils
 - Mast cells
 - Resulting inflammatory reactions lead to disruption of the epidermis.
- Potential antigenic triggers
 - Airborne allergens (dust mites, cat and dog dander, molds, pollen)
 - Foods (especially milk, eggs, peanuts)

- Infectious agents
- Contact allergens
- Psychological stress may exacerbate AD.

SIGNS AND SYMPTOMS

Acute dermatitis

- Associated with:
 - Severe pruritus
 - Redness
 - Vesicles
 - Exudation
 - May have subacute pattern of pruritus, redness, and scaling

Chronic lesions

- Marked by:
 - Excoriations
 - Lichenification (thickened skin and deeper or exaggerated skin lines)
 - Postinflammatory hypopigmentation or hyperpigmentation

Infantile AD

- Eruption of erythematous papules on facial cheeks and extensor surfaces of arms and legs
- Dry hair, scaly scalp (often)

Childhood AD

- Begins at approximately 3 years and lasts through puberty
- The areas most affected include:
 - Antecubital and popliteal folds
 - Neck
 - Flexor surfaces of wrists and ankles
 - More subacute and chronic dermatitis.

Adult AD

- Additional clinical signs include:
 - Diffuse involvement of the body
 - Xerosis
 - Lichenification
 - Central facial pallor

Other clinical manifestations

- Keratosis pilaris
 - Characteristic goose flesh appearance secondary to multiple, small, skin-colored or mildly erythematous keratotic papules located on upper arms, thighs, and facial cheeks
- Lichen spinulosus
 - Tiny hairlike spines top the small papules that occur in crops on various locations
- Pityriasis alba
- Dennie-Morgan folds

- Urticaria
- Hyperlinear palms
- Juvenile plantar dermatosis
 - Mainly affects the feet, rarely the hands
 - Produces shiny, fissured skin on the plantar surfaces
- Nummular eczema
- Cataracts

DIFFERENTIAL DIAGNOSIS

- Seborrheic dermatitis
- Seborrhea is associated with scaling, commonly on the scalp, forehead, and around the eyebrows.
- Can be accompanied by pruritus
- Contact dermatitis (allergic and irritant forms)
 - Diagnosis often requires positive exposure history to the potential offending agent.
 - Limited in distribution on the body to the area of contact
 - More likely to have acute onset and localized appearance
- Psoriasis
- Scabies
- Dermatophyte infection
- Systemic immunologic or metabolic disorders
 - Wiskott-Aldrich syndrome
 - Leiner disease
 - Histiocytosis X
 - Ataxia telangiectasia
 - Ahistidinemia
 - Agammaglobulinemia
 - Hartnup disease
 - Hurler syndrome
 - Eosinophilic gastroenteritis
 - Acrodermatitis enteropathica
 - Phenylketonuria

DIAGNOSTIC APPROACH

- Diagnosis is determined solely by history and clinical examination.
- Criteria for diagnosis (patient characteristics to look for)
 - Major criteria (all must be present)
 - Pruritus
 - Typical morphology and distribution
 - Facial and extensor involvement during infancy and early childhood
 - Flexural lichenification and linearity by adolescence
 - Chronic or recurring dermatitis

- Minor criteria (≥ 2 must be present)
 - Personal or family history of atopy (eg, asthma, allergic rhinoconjunctivitis, atopic dermatitis)
 - Immediate skin test reactivity
 - White dermatographism or delayed blanch to cholinergic agents
 - Anterior subcapsular cataracts
- Associated conditions (≥ 4 must be present)
 - Xerosis, ichthyosis, hyperlinear palms
 - Pityriasis alba
 - Keratosis pilaris
 - Facial pallor, infraorbital darkening (allergic shiner)
 - Dennie-Morgan fold
 - Elevated serum IgE level
 - Keratoconus
 - Nonspecific hand dermatitis
 - Recurring cutaneous infections
- Patients may have AD and not meet these criteria.

LABORATORY FINDINGS

- No routine laboratory studies are needed for diagnosis.
- Specific tests to rule out other disorders, on a case-by-case basis
 - If infections are recurrent, consider an immunodeficiency workup.
- Bacterial cultures of encrusted or exudative skin lesions/nares to detect staphylococcal organisms are warranted when:
 - Secondary infection is suspected
 - Improvement is not noted with standard therapy
- Patch testing may be considered to pinpoint potential antigenic triggers, which may add a component of contact dermatitis.
- Skin biopsy may be necessary when the definitive diagnosis is in question.

TREATMENT APPROACH

- Treatment of uncomplicated cases
 - Treatment to relieve dryness, inflammation, and pruritus and eradicate secondary bacterial infections
 - Daily applications of emollients (cream or ointment), especially after brief warm baths
 - Ointments are better than emollients in more severe cases.
 - If discomfort (stinging sensation) occurs or if ointment feels too occlusive (eg, in humid weather), creams can be substituted.

- Bathing should last no longer than 5 minutes.
 - Mild soaps or nondetergent cleansers are recommended.
 - Pat dry with a towel and apply emollient immediately to all skin.
 - Apply prescription topical medicines to affected areas.
- Inflammation is best treated with corticosteroids.
 - Generally, ointments tend to work better than creams.
 - Ointments remain the choice for chronic dermatitis in which dryness and lichenification predominate.
 - Creams
 - Sometimes preferred for cosmetic appeal
 - Can be used for acute weeping, erythematous lesions
- Treatment of complicated cases
 - If flares continue despite compliance with medication and appropriate skin care, a secondary infection may be responsible that requires treatment.
 - Many patients have significant colonization with *Staphylococcus aureus*.
 - If *S aureus* superinfection occurs, hospitalization for aggressive care and intravenous antibiotics may be required.
 - Skin cultures may help identify appropriate antibiotic sensitivities.
 - Application of nasal mupirocin may be necessary to eradicate bacterial carriage.
 - May also require treatment for herpes simplex virus, human papillomavirus (HPV), and molluscum contagiosum

SPECIFIC TREATMENTS

Steroids

- Low-potency topical agents, such as 1% hydrocortisone or desonide:
 - Can be used for mild disease, even on the diaper area and face
 - Twice-daily dosing should be limited to a 2-week course or less.
- Mid- to high-potency steroids, such as triamcinolone or fluocinonide:
 - Can be used in more severe cases on the trunk and extremities
- Strong, halogenated steroids:
 - Should not be applied to the face, axillae, or groin
 - Oral systemic steroid taper should rarely be prescribed.
- Most worrisome side effects
 - Dermal and epidermal atrophy
 - Suppression of the pituitary-adrenal axis
 - Applying topical steroids to the occluded groin area of a diapered child increases the risk of systemic side effects.

Nonsteroidal immunomodulators and other topical medications

- Topical tacrolimus and pimecrolimus
 - Approved for children ≥ 2 years of age
 - Most efficacious in mild to moderate disease
 - Alternatives to topical steroids
 - Can be applied to the face
 - Theoretical risk of cancer
- Other topical medications, coal tar and doxepin, are not routinely prescribed by pediatricians.

Pharmacologic therapy

- Antihistamines may help relieve pruritus, especially if dermatitis accompanies allergic rhinitis, urticaria, and sleep disturbance.
 - Nonsedating antihistamines, such as loratadine, can be used daily.
 - The sedating antihistamines, hydroxyzine and diphenhydramine, are most useful at bedtime.
- Efficacy of alternative medicine, such as herbal or probiotic supplementation, remains unknown.

Behavior modification

- Teach the child to rub rather than scratch.
- Have the child wear mittens or socks on his or her hands when in bed at night to reduce the itch-scratch cycle.
- Trim the fingernails frequently to avoid trauma and infection.

Diet

- Dietary management is controversial, and changes should be made judiciously.
- Peanuts, milk, and eggs are the most common food culprits.
- If food allergies are highly likely, as determined by a pediatric allergist, then strict avoidance of foods that serve as antigenic triggers should be encouraged; the most common are:
 - Cow milk
 - Hen eggs
 - Soy
 - Peanuts
 - Tree nuts (and seeds)
 - Wheat
 - Fish and shellfish

Secondary infections

- Topical or oral antibiotics
 - Cephalexin
 - Dicloxacilli
 - Amoxicillin-clavulanate
 - Azithromycin
 - Clindamycin
 - Mupirocin (topical)

- HPV treatments
- Vesicants
- Immunomodulators
- Cryotherapy
- Ablation with carbon dioxide laser
- Molluscum contagiosum treatments
 - Manual expression
 - Cryotherapy
 - Topical application of cantharidin or imiquimod
- Widespread herpes infection requires treatment with intravenous acyclovir.

Aggressive interventions for severe cases

- Prescribed at the discretion of the skin experts
 - Systemic immunomodulators
 - Ultraviolet light therapy

WHEN TO ADMIT

- Severe cases requiring systemic immunomodulation
- Extensive secondary bacterial infection requiring intravenous antibiotics
- Widespread herpes infection (eczema herpeticum, Kaposi varicelliform eruption)

WHEN TO REFER

- Recalcitrant cases should be referred to a dermatologist or allergist.
- Secondary HPV or molluscum contagiosum infections should be referred to a dermatologist for aggressive treatment.

COMPLICATIONS

- *S aureus* superinfection
 - Hospitalization for aggressive care and intravenous antibiotics may be required.
 - Skin cultures may help identify antibiotic sensitivities.
 - Application of nasal mupirocin may be necessary to eradicate bacterial carriage.
- Herpes infection, known as eczema herpeticum or Kaposi varicelliform eruption:
 - Requires treatment with intravenous acyclovir.
- HPV infection
- Molluscum contagiosum infection

PREVENTION

- AD cannot be prevented, but meticulous adherence to proper skin care can control symptoms and secondary infection.
- Moisturization of the skin with daily applications of emollients, especially after bathing, is crucial to keep the skin hydrated.
- Prophylactic avoidance of food allergens, both for lactating mothers and infants via exclusive breastfeeding in the first 6 months of life, may be helpful in families with a strong family history of atopy.

Attention-Deficit/Hyperactivity Disorder

DEFINITION

- Attention-deficit/hyperactivity disorder (ADHD) is a common neurodevelopmental disorder in children and adolescents.
- Frequently diagnosed in children with academic underachievement or behavioral problems
- Hallmarks are hyperactivity, impulsivity, and inattention that are beyond normal developmental expectations for a child's age.
- Core symptoms interfere with attainment of many normal developmental milestones (academic, fine-motor, and social and adaptive skills).

EPIDEMIOLOGY

- Prevalence
 - 6.8% of school-age children
- Sex
 - Diagnosed in boys 3 times more than in girls (9.2% vs 3.0%)
- Age
 - Rates of diagnosed ADHD increase with age up to 9 years of age.
 - Rates level off or decline, depending on whether youth are taking medications.
- Race/ethnicity
 - Diagnosed in white children at a greater rate than in black or Hispanic children (8.6% vs 7.7% and 3.7%, respectively).

ETIOLOGY

- Whether the symptoms of ADHD represent a unique disorder or merely one end of the continuum of age-appropriate behavior is unclear.
- Data supporting ADHD as a unique disorder
 - Cohort studies have consistently shown similar long-term outcomes for youth identified with ADHD (predictive validity).
 - Twin studies suggest a genetic predisposition.
 - Genetic studies have shown higher rates of gene alterations involving dopamine neurotransmission in people with ADHD.
 - Brain imaging and physiologic studies suggest a neurodevelopmental process leading to ADHD.
- Psychosocial and environmental factors may contribute.

RISK FACTORS

- Coexisting conditions
 - Oppositional defiant disorder (average prevalence rate, 35.2%)
 - Conduct disorder (25.7%)
 - Mood disorders

- Anxiety disorders (25.8%)
- Depressive disorders (18.2%)
- Learning disabilities (12–50%)

SIGNS AND SYMPTOMS

- *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)* criteria for diagnosis
 - Either 1 or 2 of the following 3 overarching criteria
 - 1. ≥ 6 of the following symptoms of inattention, persistent for ≥ 6 months, to a degree that is maladaptive and inconsistent with developmental level
 - Often fails to give close attention to details or makes careless mistakes in school work, work, or other activities
 - Often has difficulty sustaining attention in tasks or play activities
 - Often does not seem to listen when spoken to directly
 - Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (not caused by oppositional behavior or failure to understand instructions)
 - Often has difficulty organizing tasks and activities
 - Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (eg, schoolwork, homework)
 - Often loses things necessary for tasks or activities (eg, toys, school assignments, pencils, books, tools)
 - Is often easily distracted by extraneous stimuli
 - If often forgetful in daily activities
 - 2. ≥ 6 of the following symptoms of hyperactivity or impulsivity have persisted for ≥ 6 months to a degree that is maladaptive and inconsistent with developmental level
 - Often fidgets with hands or feet or squirms in seat
 - Often leaves seat in classroom or in other situations in which remaining seated is expected
 - Often runs about or climbs excessively in situations in which doing so is inappropriate (in adolescents or adults, may be limited to subjective feelings of restlessness)
 - Often has difficulty playing or engaging in leisure activities quietly
 - Is often on the go or often acts as if driven by a motor
 - Often talks excessively
 - Often blurts out answers before the questions have been completed
 - Often has difficulty awaiting his or her turn
 - Often interrupts or intrudes on others (eg, butts into conversations or games)

- Some hyperactive-impulsive or inattentive symptoms causing impairments were present before 7 years of age.
- Some impairment from the symptoms is present in ≥ 2 settings (eg, at school [or work] or at home).
- Clear evidence exists of clinically significant impairment in social, academic, or occupational functioning.
- Symptoms do not occur exclusively during the course of:
 - A pervasive developmental disorder
 - Schizophrenia
 - Other psychotic disorder
- Symptoms are not better accounted for by another mental disorder, such as:
 - Mood disorder
 - Anxiety disorder
 - Dissociative disorder
 - Personality disorder
- The *DSM-IV* criteria do not account for differences in presentation by age, sex, or race/ethnicity; clinicians must exercise judgment in their use of the criteria.
- Any symptoms suggestive of possible harm to self or others warrant immediate evaluation by a skilled clinician.

DIFFERENTIAL DIAGNOSIS

- Conditions that may mimic or co-occur with ADHD
 - Developmental differences or normal variants
 - Normal variation
 - Giftedness
 - Sociocultural differences in expectations or parenting, or both
 - Medical disorders
 - Medication side effects
 - Substances of abuse
 - Hearing impairment
 - Visual impairment
 - Obstructive sleep apnea
 - Toxins (eg, chronic lead exposure or acute lead intoxication; chronic iron-deficiency anemia)
 - Thyroid disorders
 - Chronic disease complications
 - Neurologic or developmental disorders
 - Learning disabilities
 - Pervasive developmental disorders
 - Tic disorders (Tourette syndrome)
 - Communication disorders
 - Processing disorders
 - Mental retardation

- Neurodevelopmental syndromes (eg, fetal alcohol syndrome, fragile X syndrome)
- Cerebral palsy
- Seizure disorders (petit mal or developmental delays)
- Sequelae of central nervous system trauma or infection
- Neurodegenerative disorders
- Motor coordination disorders
- Psychosocial or environmental problems
 - Stress in family situation (marriage, separation or divorce, birth of sibling, death)
 - Stress in environment (new home, new school)
 - Family dysfunction
 - Parenting dysfunction
 - Neglect, abuse, or both
 - Parental psychopathology
 - Parental substance abuse
 - Inappropriate educational program
- Emotional or behavioral disorders
 - Oppositional defiant disorder
 - Conduct disorder
 - Depressive disorders
 - Anxiety disorders
 - Bipolar disorder
 - Obsessive-compulsive disorder
 - Posttraumatic stress disorder
 - Adjustment reaction
 - Schizophrenia

DIAGNOSTIC APPROACH

- No biological marker or gold standard diagnostic test exists that can reliably identify persons with and without ADHD.
- Ascertain whether any other disorders or factors exist that may better explain a child's symptoms and impairment.
 - Such conditions may:
 - Be the primary cause of the child's behavioral and attention difficulties
 - Increase the child's level of impairment if comorbid with ADHD
 - Evaluation can be streamlined through a complete history and thorough physical examination.
- The AAP recommends that children age 6–12 years should undergo evaluation for ADHD if they exhibit any of the following.
 - Inattention
 - Hyperactivity
 - Impulsivity

- Academic underachievement
- Behavior problems
- Diagnosing ADHD is complicated by the fact that presentations of ADHD can vary substantially.
- Core symptoms result in 3 distinct subtypes of ADHD recognized in the *DSM-IV Text Revision (TR)*:
 - Predominantly inattentive subtype (ADHD-IA)
 - Hyperactive/impulsive subtype (ADHD-HI)
 - Subtype that includes a combination of both inattentive and hyperactive/impulsive features (ADHD-CT)
 - In addition, many conditions can coexist with ADHD, further adding to variation in presentation.
- Essential step: comprehensive history, with particular attention to:
 - Presenting complaint
 - Development
 - School history
 - Family history
 - Social history
- Physical examination (usually normal)
 - Can help identify other problems that may contribute to or represent the cause of behavior problems
 - May allow the opportunity to assess a child's mental status and interaction with caregivers
- Several excellent ADHD rating scales for parent and teacher respondents are commercially available to clinicians.
 - Vanderbilt Rating Scales
 - Available in the public domain at no cost
 - ADHD Rating Scale
 - Conners' Rating Scales
 - Swanson, Nolan, and Pelham (SNAP) Rating Scales
- There are often co-occurring behavioral or developmental conditions; all youth undergoing an evaluation for ADHD should be assessed for these conditions.
 - Take a complete history.
 - Several ADHD ratings scales (ie, Vanderbilt, Conners' Rating Scales and SNAP-IV) include items that query for symptoms of depression or anxiety, oppositional-defiant, and conduct disorders.
 - Rating scales exist that specifically target the assessment of particular conditions including depression, anxiety, and disruptive behaviors.
 - Center for Epidemiological Studies Depression Scale for Children
 - Multidimensional Anxiety Scale for Children
 - Eyberg Child Behavior Inventory
- Questionnaires that review *DSM-IV TR* criteria for most common childhood mental health disorders in 1 instrument
 - Child Symptom Inventory
 - DISC Predictive Scales
- Algorithm to assess ADHD
 - **Step 1:** Patients with behavior problems or academic difficulties undergo a complete physical examination, including hearing and vision assessments, and are given assessment materials.
 - Assessment materials may contain:
 - Pediatric intake history form
 - Request for school records
 - Behavior rating scales
 - Educational materials
 - **Step 2:** Once the results and assessment materials have been reviewed, patients may be scheduled for an evaluation.
 - Number of visits needed to complete an evaluation depends on the complexity of symptoms and amount of time available at each visit.
 - The time reported to complete the overall evaluation, review background records, provide patient and family education, and establish a treatment plan may be 90–240 minutes.
 - Offices have found multiple solutions for obtaining assessment materials and completing an evaluation, including:
 - Use of written assessment or computerized packets
 - Longer appointments scheduled at designated times (eg, evenings, Saturday mornings, one particular clinic session every other week)
 - Partnerships with local schools
 - Use of affiliated health care personnel, including social workers or mental health professionals
 - ADHD toolkit includes:
 - Vanderbilt Rating Scales (both parent and teacher initial assessment and follow-up forms)
 - Sample cover letter to assist physicians in creating an office-based system for efficiently evaluating a child for ADHD.
- Clinicians should obtain data from schools on children's level of functioning and academic achievement.
 - Results of multidisciplinary evaluations
 - Individual educational programs (IEPs)
 - Achievement test results
 - Grades
 - Written or verbal teacher narratives

- Many ADHD rating scales use teacher versions that can be used to facilitate endorsement of diagnostic criteria or to assess for other conditions by school or after-school personnel.
- If the child is home schooled or heavily involved in after-school activities, clinicians may want to obtain information from adults overseeing these programs (coaches, religious educators, after-school caregivers, and tutors).

LABORATORY FINDINGS

- Blood lead levels and thyroid hormone levels are infrequently abnormal in youth with ADHD.
 - There is little evidence that these tests adequately discriminate between youth with and without ADHD.

IMAGING

- Youth with ADHD often have abnormalities on brain imaging or electroencephalography.
 - Abnormalities are not consistent.
 - Do not usually represent clinically significant findings
 - Do not adequately discriminate youth with and without ADHD

CLASSIFICATION

- ADHD can be classified as the following 3 types.
 - Predominantly inattentive subtype (ADHD-IA)
 - Hyperactive/impulsive subtype (ADHD-HI)
 - A combination of both inattentive and hyperactive/impulsive features (ADHD-CT)

TREATMENT APPROACH

- ADHD is a chronic condition that requires ongoing, collaborative care.
 - ADHD affects youth across multiple domains of functioning, and understanding the implications across these domains is important.
 - Parents are important partners in treatment because they ultimately implement any program.
 - Youth with ADHD are often cared for by a spectrum of health and school professionals; the child eventually has to take all of this over.
 - Strategies include educational and support groups, such as:
 - Children and Adults with ADD
 - Learning Disabilities Association
- The AAP recommends that clinicians, parents, and the child, with school personnel, identify specific target outcomes in functioning that they hope to affect with treatment.

- 3 broad treatment modalities have been recommended, most often combined (multimodal treatment).
 - Medications
 - Psychosocial interventions directed at the child in the home and school
 - Classroom assistance
 - Solid evidence exists for the use of stimulant medication, behavioral-modification strategies, and their combination.
- If psychostimulants are used, medication choice, dose, and time interval must be carefully titrated to meet the individual child's needs.
 - Several trials may be necessary before the most effective medication type and dose with the fewest side effects are identified.
 - It is important to document changes in ADHD symptoms and target outcomes, and the development of any side effects.
- Behavioral-management interventions that seek to improve parenting practices, school function, and peer relationships decrease ADHD symptoms and impairment.
 - Parent training programs
 - Youth-focused intensive summer camp programs
 - Behavioral consultation in the classroom
- School-based services are a critical part of a comprehensive management plan.
 - Communication with school personnel is essential for diagnosing ADHD and for optimal titration of medication.
 - Evidence exists for effectiveness of highly structured behavioral-management strategies implemented by school staff, such as:
 - Daily report cards
 - Point or token systems with primary outcomes of:
 - Following classroom rules
 - Complying with teacher requests
 - Improving peer interactions
 - Increasing classwork productivity
 - Comorbid learning disabilities can be identified by school staff.
 - Specific learning interventions require an IEP, as stipulated under the Individuals with Disabilities Education Act (IDEA).
 - Learning disabilities coexistent with ADHD usually fall into the category of language-based disorders of learning or impaired mathematics performance.
- It is important to educate school personnel about ADHD-associated behaviors.
 - Motor challenges, including dysgraphia, with resultant poor handwriting
 - Problems related to poor visual-motor abilities (eg, copying materials off of a board or textbook onto paper)

- Inconsistent performance
- Delayed acquisition of core reading and math skills
- Low productivity
- Delay in rapid retrieval of facts
- Difficulty with higher-level problem solving involving multiple steps
- Impaired reading comprehension
- Poor meta-cognitive abilities (eg, organization, time management, breaking tasks down into smaller components)
- Most alternative treatment approaches lack real evidence for or against their use.
 - Dietary recommendations
 - Ocular training
 - Hypnotic and biofeedback regimens

SPECIFIC TREATMENTS

General

- Psychostimulants (methylphenidate, dextroamphetamine, and mixed salts of amphetamine) with careful medication management:
 - Address core symptoms and improve sustained attention, organization, and motor inhibitor control
 - Decrease disruptive behaviors (eg, fidgetiness, impulsive interrupting, aggression, relational interactions, oppositionality)
 - Increase the accuracy of performance and improve short-term memory, reaction time, and seatwork computation; however, the effect is smaller than that seen for behavioral challenges
 - Are effective for about 70%; increases to >90% if an alternative stimulant is tried after initial failure
 - Children starting on medication should have a complete medical history taken (including a family history of heart disease or arrhythmias, as well as symptoms of shortness of breath, chest pain, dizziness, or palpitations on exertion) and a physical examination.

Stimulant medications, dosing, and duration of effects

■ Dextroamphetamine/levoamphetamine

- Adderall (scored tablet)
 - Start with 5 mg 1–2 times per day and increase by 5 mg each week until good control is achieved.
 - Maximal recommended dose: 40 mg
 - Duration of effect: 4–6 hours
- Adderall RX (capsule; sprinkle-able)
 - Start at 5 mg in the morning and increase by 5 mg each week until good control is achieved.
 - Maximal recommended dose: 30 mg
 - Duration of effect: 10–12 hours

■ Dextroamphetamine

- Dexedrine (tablet) or Dextrostat (scored tablet)
 - Start with 5 mg 1–2 times per day and increase by 5 mg each week until good control is achieved.
 - Maximal recommended dose: 40 mg
 - Duration of effect: 4–6 hours
- Dexedrine Spansules (sustained-release capsule)
 - Start with 5 mg once daily and increase by 5 mg each week until good control is achieved.
 - Duration of effect: 6–10 hours

■ Methylphenidate

- Ritalin or Methylin (scored tablet, chewable, or oral solution)
 - Start with 5 mg 1–2 times per day and increase by 5 mg each week until good control is achieved.
 - May need a third reduced dose in the evening
 - Maximal recommended dose: 60 mg
- Focalin (scored tablet)
 - Start with 2.5 mg 1–2 times per day and increase by 2.5 mg each week until good control is achieved.
 - May need a third reduced dose in the evening
 - Maximal recommended dose: 30 mg
 - Duration of effect: 4–5 hours
- Ritalin-LA (capsule; sprinkle-able), Ritalin-SR (tablet), Metadate-ER (tablet), Metadate-CE (capsule; sprinkle-able)
 - Start with 10–20 mg in the morning and increase each week until good control is achieved.
 - Alternatively, titrate using short-acting methylphenidate and then switch over to a longer-acting form.
 - May need a second dose or regular methylphenidate dose in the evening
 - Maximal recommended dose: 60 mg
 - Duration of effect: 6–10 hours
- Focalin XR (capsule; sprinkle-able)
 - Start with 5 mg in the morning and increase by 5 mg each week until good control is achieved.
 - Maximal recommended dose: 30 mg
 - Duration of effect: 8–10 hours
- Concerta (capsule; noncrushable)
 - Start at 18 mg in the morning and increase by 18 mg each week until good control is achieved.
 - Maximal recommended dose: 72 mg
 - Duration of effect: 8–12 hours
- Daytrana (patch)
 - Worn daily for 9 hours; replace once a day in the morning

- Skin sensitization as compared with contact rash may occur rarely; the US Food and Drug Administration advisory board recommends oral methylphenidate use before the patch.
- 12 hours

■ Lisdexamfetamine

- Vyvanse (sprinkle in water and immediately drink)
 - Start at 30 mg in the morning and increase by 20 mg each week until good control is achieved.
 - Maximal recommended dose: 70 mg
 - Duration of effect: 12 hours

Risks

■ Common side effects

- Headaches
- Stomachaches
- Insomnia
- Anorexia
- Possible growth delay (approximately 1 cm in height lost per year)
- Irritability
- Emotional lability or constriction
- Compulsive picking of the nose or skin
- Possible high abuse potential

■ Other safety concerns

- Cardiovascular
 - Elevations in heart rate and blood pressure
 - Rare events, such as stroke, myocardial infarction, and sudden death, particularly in youth with preexisting cardiac disease
 - Youth should be monitored for the emergence of hypertension
- Psychiatric concerns
 - New onset or acute exacerbation of aggressive symptoms
 - Rare hallucinogenic symptoms, particularly visual hallucinations related to bugs

Management of side effects

■ General

- For mild side effects, allow 7–10 days for tolerance to develop.
- Evaluate time-action, and determine whether timing of administration can be adjusted to minimize side effects.
- Determine whether side effects are related to other disorders or current environmental stressors and adjust accordingly.
- If these strategies fail, consider an alternative stimulant.

■ Weight loss or anorexia

- Administer medication during or after a meal.
- Try calorie enhancement strategies, such as high-protein instant breakfasts or protein bars.
- Get eating started with any highly preferred food before giving regular foods.
- Allow grazing in the evening when appetite suppression wanes.
- Change stimulant medications.
- Consider drug holidays.

■ Dizziness

- Monitor blood pressure and pulse.
- Encourage adequate hydration.
- If dizziness is associated only with peak drug effect, try a longer-acting preparation.

■ Insomnia or nightmares

- Establish bedtime routine.
- Omit or reduce the last dose or change to the standard, short-acting version if the patient is using longer-acting preparation.
- Administer medication earlier in the day.
- Try a different stimulant.
- Give “Sleep Problems” handout (sample available at www.dbpeds.org).
- Consider additional medication as a last resort.

■ Dysphoric mood/emotional constriction

- If the problem occurs during peak drug effect, reduce the dose or switch to a longer-acting preparation.
- Evaluate when it occurs.
- Try a different stimulant.
- Consider comorbid anxiety or depression disorders requiring alternative or adjunctive treatment.
- Consider additional medication as a last resort.

■ Rebound

- Try to decrease precipitous drop in blood levels by:
 - Using a stepped-down dose at the end of the day
 - Increasing morning long-acting dose
 - Adding a smaller dose of short-acting medication toward the end of the day
- Switch to a longer-acting preparation.
- Combine longer-acting and short-acting preparations.
- Overlap stimulant dosing.

- Tics
 - Conduct drug trial at different doses, including no medication, to be sure that tics are drug related.
 - For mild tics that abate after 7–10 days, reconsider risk versus benefit and negotiate a new informed consent with the parent or guardian.
 - Conduct a drug trial to see whether tics abate with another stimulant.
 - Consider a nonstimulant treatment, such as clonidine, alone or in combination with a stimulant.
 - Refer to a mental health specialist or neurologist skilled in the management of tics.
- Psychosis
 - Discontinue stimulant treatment.
 - Assess for presence of coexisting bipolar or thought disorder.
 - Consider alternative treatments, or referral to mental health specialist.

Other medications

- Other medications used as second-line treatment of ADHD:
- Selective norepinephrine reuptake inhibitor (atomoxetine)
 - Common side effects
 - Stomachache
 - Nausea
 - Appetite suppression
 - Weight loss
 - Warnings have surfaced regarding aggression, suicidality, reversible hepatotoxicity, and cardiac effects
- Tricyclic antidepressants (desipramine, nortriptyline)
 - Low toxic-to-therapeutic ratio has limited widespread use
- Atypical antidepressants (bupropion)
 - Suggested as an option in youth with comorbid depression
- α -Agonists (clonidine and guanfacine)
 - Moderate effects on hyperactivity and impulsivity, aggression, and tics
 - Given their effect on the cardiovascular system, care must be taken to avoid stopping these medications abruptly, which might result in rebound hypertension.
 - Sedation, particularly with clonidine, can be a significant problem.

Behavioral techniques

- In combination with medication, may allow reduction of the medication dose.
- Therapeutic benefits of stimulant medication usually occur during the day, whereas behavioral interventions may be used in the late afternoon or evening in place of an additional dose of medication.

- Disruptive disorders that commonly co-occur with ADHD have been shown to respond to behavioral modification.
- Psychosocial treatment may help to enhance parents' positive perception of their children and of their own parenting abilities.
- Results for medication last only as long as a youth continues to take the medication, whereas behavioral interventions may extend over time.
- Medications may be more expensive than behavioral interventions in the long run.
- Specific techniques
 - Positive reinforcement
 - Provide rewards or privileges contingent on the child's performance.
 - Time-out
 - Remove access to positive reinforcement contingent on performance of unwanted or problem behavior.
 - Response cost
 - Withdraw rewards or privileges contingent on the performance of unwanted or problem behavior.
 - Token economy
 - Combining positive reinforcement and response cost.
 - The child earns rewards and privileges contingent on performing desired behaviors and loses rewards and privileges based on undesirable behavior (eg, working toward a prize).

WHEN TO ADMIT

- The core symptoms of ADHD should not necessitate admission to a medical or psychiatric hospital.
- Indications for admission result from:
 - Symptoms related to mental health conditions that may co-occur with ADHD
 - Adverse event secondary to medication used to treat ADHD
 - A medical condition resulting from the core symptoms of inattention, hyperactivity, or impulsivity associated with ADHD (eg, accidental injury)

WHEN TO REFER

- Refer to a mental health or school-based professional if:
 - A comorbid condition is suspected
 - A clinician is not equipped to evaluate sufficiently for these types of disorders in the office setting
 - Results of assessment are discrepant or complicated clinical picture exists and the primary care physician is uncomfortable continuing evaluation
 - Psychological testing is needed
 - Intensive parent training in behavior modification is needed

- Coexisting conditions that are unresponsive to treatment for ADHD are present (oppositonality, depression, and anxiety may improve with treatment of ADHD core symptoms)
 - Psychosocial or pharmacologic interventions for a coexisting mental health disorder
 - Significant familial stress or psychopathology
 - Domestic violence
 - Substance abuse
 - A mental health resource list can help identify local mental health care providers on the family's insurance plan who can evaluate the youth for possible comorbid mental health disorders.
 - Bright Futures provides a template for mental health referrals that can be used to structure referral information.
 - For school referrals, parents should be directed to draft a letter requesting a multidisciplinary evaluation, including psychoeducational testing, if the history suggests a possible learning disability, such as:
 - Reading disorder (dyslexia)
 - Mathematics disorder (dyscalculia)
 - Disorder of written expression
 - Communication disorder
 - Public schools are required to respond to family requests for evaluations within a specified period (determined by school district policies).
 - Children attending private schools or those who are home schooled are eligible to receive an evaluation through their local school district.
 - Families may be referred to independent psychologists for psychoeducational evaluations through their insurance plans.
 - Clinicians should inquire whether the local school district accepts outside evaluations before making any referrals.
- FOLLOW-UP**
- Youth functioning should be systematically monitored over time to evaluate whether target outcomes are achieved or adverse side effects to treatment develop.
 - If targeted outcomes are not met, the clinician, parents, and school personnel should collaboratively determine:
 - Validity of the diagnosis
 - Adherence to all components of the treatment plan
 - Possibility of previously unidentified coexisting conditions
 - The ADHD toolkit includes sample management plans and follow-up assessment forms to assist clinicians in monitoring treatment.
 - Once a child is stable on a medication, AAP treatment guidelines recommend an office visit every 3–6 months to reassess
 - Academic performance
 - Behavior
 - Side effects
 - More intensive visits may be necessary around predictable periods of change.
 - Entry into middle or high school
 - Onset of puberty
 - Trials off medication are important to conduct but should be scheduled so as to not overlap with
 - Beginning of school terms
 - Examinations
 - Family stressors
 - Families, youth, and clinicians should consider carefully using medication in the afternoons and evenings, on weekends, and during the summer.
 - Take into account:
 - Severity of a youth's dysfunction
 - Effect on family and peers
 - Cultural expectations
 - Presence of any decrease in weight or height velocity
 - School-based services
 - Youth can access school-based services through local public school system
 - Individual teachers will often modify curriculum or classroom environment to address a child's needs.
 - Many schools have an interdisciplinary council (eg, student study team, multidisciplinary assessment team) that informally reviews a child's academic performance and behavior and suggests possible remediation.
 - Through Section 504 of the Rehabilitation Act, school systems are mandated to provide accommodations in the mainstream classroom.
 - Under IDEA, school systems provide a continuum of special education services, ranging from accommodations in the mainstream classroom to a special day class in a public or private, nonpublic placement.
 - Youth with ADHD often qualify for special education services because of a coexisting specific learning disability, language disorder, or severe emotional disturbance.
 - Organizational difficulties may require:
 - Supervision of the writing of homework assignments in a planner
 - Extra set of books at home
 - Assistance breaking large projects into small steps

- Approaches to problems with handwriting
 - Access to a computer for written work
 - Copies of teacher lectures
 - Electronically recorded textbooks
- If behavior interferes with the child's academic performance or the ability of other children in the classroom to learn, then a behavioral intervention plan is necessary that delineates:
 - What behaviors a youth displays
 - Factors that escalate or dampen the behavior
 - Appropriate behavioral interventions
- Consideration should be given to the appropriate educational placement of a child.
 - Mainstream classroom with or without assistance from a resource specialist
 - Special day class
 - Private nonpublic placement
- Sample letters requesting a 504 plan or IEP, as well as additional information on these programs, are available in the ADHD toolkit and on the Bright Futures Web site.
- Concerns exist that these accommodations may lead to youth who feel entitled to extra assistance and will not be able to function adequately in college or the workplace setting.
 - Accommodations must be provided within the context of teaching the child to understand his or her own strengths and weaknesses
 - The child needs to develop compensatory strategies for addressing their areas of challenge.

PROGNOSIS

- Youths with ADHD who have been monitored into adolescence demonstrated increased risk for:
 - Poor academic attainment
 - Impaired familial and peer functioning
 - Lower self-esteem
 - Substance abuse
 - Delinquency
 - Driving-related accidents
- Treatment may ameliorate some risks, particularly for substance abuse.
- Age-dependent decline appears to exist in apparent symptoms as children grow older.
 - Hyperactivity and impulsivity tend to remit at a greater rate than inattention.
- As many as 70% of children and adolescents continue to be symptomatic in adulthood, but outcomes are improved with:
 - Familial stability and support
 - Ongoing therapeutic relationships with a health care professional
 - Higher IQ

Autism

DEFINITION

- Autism is a neurobiological developmental disorder characterized by:
 - Developmental delays in language and communication
 - Abnormalities in language
 - Impairments in social behavior
 - Narrow repertoire of interests
 - Ritualized behavior

EPIDEMIOLOGY

- Prevalence
 - 100–200 per 100,000 children
 - More common in boys than in girls

ETIOLOGY

- No known, single cause has been found.
- There is increasing evidence for a genetic link.
 - May affect neurologic development as early as the prenatal period

RISK FACTORS

- Medical and genetic conditions associated with autism
 - Fragile X syndrome
 - Cornelia de Lange syndrome
 - Tuberous sclerosis

SIGNS AND SYMPTOMS

History

- Medical history
 - Birth and neonatal history
 - History of seizures
 - Hyperactivity (extreme)
 - Pica
 - Family history of autism or mental retardation
- Developmental history
 - Milestones may be delayed.
 - Regression in development can occur.
- Psychosocial history
 - Irritability
 - Self-injury possible
 - Feeding or sleeping problems frequent

Physical examination

- Head circumference
 - Sometimes larger than in nonautistic children

- Motor impairments may include:
 - Hand flapping
 - Hypotonia
 - Limb apraxia
- Rule out tuberous sclerosis.
 - Neurocutaneous disorder affecting the brain and other organs
 - Present in 0.4–3% of children with autism
 - Expose to ultraviolet light and observe for ash-leaf-shaped depigmented macules; this is diagnostic.

Screening and evaluation standardized instruments

- Autism Diagnostic Interview: Revised
 - For children 18 months to adulthood
 - Semistructured parent interview provides comprehensive information.
 - Requires specialized training to administer
 - >1 hour required to complete
- Autism Diagnostic Observation Schedule
 - For children 18 months to adulthood
 - A trained examiner observes child-adult interactions and codes behaviors.
 - Requires specialized training to administer
 - 30 minutes to complete
- Modified Checklist for Autism in Toddlers
 - For children 18 months old to 30 months old
 - Parent or teacher questionnaire
 - Widely used in research and clinical settings for screening
 - Lacks specificity as a diagnostic measure
 - 5 minutes to complete
- Pervasive Developmental Disorders Behavior Inventory
 - For children 18 months to 12.5 years
 - Parent or teacher questionnaire
 - Comprehensive; may be sensitive to treatment effects
 - 30–45 minutes to complete
- Social Responsiveness Scale
 - For children 4–18 years
 - Parent or teacher questionnaire
 - Emphasizes social disability
 - 20 minutes to complete

DIFFERENTIAL DIAGNOSIS

- Autism spectrum disorders (ASDs)
 - Autistic disorder
 - Child meets full diagnostic criteria for:
 - Language (delayed or impaired)
 - Social interaction (impaired)
 - Repetitive, restricted behaviors

- Asperger disorder
 - Typical language development is present.
 - Impaired social interactions
 - Repetitive, restricted behaviors
- Pervasive developmental disorder not otherwise specified
 - Child presents with language delays; impaired social interaction; or restricted, repetitive behaviors.
 - However, these symptoms are not present to the degree that would warrant a more specific diagnosis.
- Pervasive developmental disorders that are not ASDs
 - Childhood disintegrative disorder
 - Children experience a period of developmental regression after at least 2 years of normal development.
 - Rett syndrome
 - Deceleration of head growth before 48 months
 - Loss of purposeful hand movements before 30 months
 - Development of stereotyped hand movements
 - Severe language and cognitive delays
 - Associated with mutations of the *MECP2* gene on the X chromosome
 - More common in girls than boys
- Developmental language disorder
 - Delays in receptive or expressive language skills
 - Social interaction skills are not impaired.
 - Children do not demonstrate repetitive, restricted behaviors.

DIAGNOSTIC APPROACH

- Diagnosis is not straightforward.
 - There is no single biological marker, laboratory test, or procedure to identify autism.
- Primarily a behavioral diagnosis, based on:
 - Comprehensive history
 - Direct observation
 - Standardized assessment
- Comorbid conditions with autism
 - Mental retardation
 - Reported in approximately 70% of children with autism
 - Children with autism and mental retardation have the poorest prognosis.
 - Seizures
 - Gastrointestinal problems
 - Sleep difficulties
 - Behavioral problems
 - Pica
 - Self-injury
 - Aggression

LABORATORY FINDINGS

- There is no single test for autism.
- Lead screening
 - Pica is a common comorbidity that is associated with lead toxicity.
- DNA analysis and karyotype testing
 - To rule out fragile X syndrome
- Metabolic and genetic testing should be considered in children with:
 - Unusual and dysmorphic features
 - Seizures
 - Abnormal growth
- Electrophysiologic testing is needed only in patients with:
 - Suspected seizure disorder
 - Severe sleep problems
 - Developmental regression

IMAGING

- No imaging evaluation procedures are needed in routine evaluation for autism.
- Standard assessment should be considered in children with co-occurring neurologic findings, including:
 - Seizures
 - Asymmetric motor functioning
 - Cranial nerve dysfunction
 - Severe headache

TREATMENT APPROACH

- General approach for managing ASDs
 - Screen to identify children at risk.
 - Refer to a specialist for evaluation.
 - Manage medical comorbidities.
 - Prescribe and manage psychopharmacologic medications.
 - Refer for psychosocial interventions.

SPECIFIC TREATMENTS

Psychopharmacologic treatment

- Behavioral problems present in autism can be partially managed with medication.
- Risperidone
 - Atypical antipsychotic
 - Used to treat irritability, aggression, self-injury, and tantrums
 - Approved by the US Food and Drug Administration for use in autism
- Fluoxetine, sertraline
 - Selective serotonin reuptake inhibitors
 - Used with limited success for rigidity and anxiety

- Stimulants, atomoxetine
 - Designed to improve attention and limit distractibility
 - Used with limited success

Psychosocial interventions

- Early intervention is critical.
 - Children age 2–7 years
- Highly intensive, behaviorally oriented programs
 - Known by several names
 - Applied behavior analysis
 - Discrete trial training
 - Intensive behavioral intervention
 - Early intensive behavioral intervention
 - Programs ideally offered for:
 - At least 2 years
 - 40 hours per week
 - One-on-one behavioral instruction
 - The literature is mixed, but targeted outcomes include:
 - Age-level functioning
 - Normal intelligence
 - Average adaptive behavior
 - Regular educational placement

WHEN TO ADMIT

- Severe malnutrition related to restricted food interests
- Evaluation for gastrointestinal problems
- Evaluation for seizure disorder
- Evaluation for sleep disorder
- Life-threatening self-injurious behavior or aggression
- Psychopharmacologic toxicity

WHEN TO REFER

- Refer to a developmental specialist if, at the age of 18–24 months, any of the following are present.
 - The child does not engage in simple pretend play.
 - The child does not point to objects of interest.
 - There is an inability to direct the child’s attention.
 - The child has little interest in other children.
 - The child cannot follow simple instructions.
 - There is little or no expressive language, including:
 - Single words by 18 months
 - Phrases by 24 months

PROGNOSIS

- Prognosis has improved over the past 3 decades.
- For children with developmental disabilities
 - Increased availability of community special education services since the early 1980s
 - Decreased institutionalization
 - Increased access to learning experiences
- Parents, teachers, and health professionals have learned to advocate for children with developmental disabilities.
- Research into autism is a federal research priority.

Back Pain

DEFINITION

- Pain or discomfort in the region from the upper thoracic vertebra (T1) and shoulder girdle to the sacrum and surrounding musculature
- Patients may have a specific sense of localization (eg, to a muscle group or vertebral body), or sense the pain as diffuse or deep and difficult to localize.

EPIDEMIOLOGY

- Prevalence
 - Back pain is uncommon in pediatrics.
- Age
 - Most studies have shown that back pain increases with age.
 - <10% of preteens report back pain.
 - Nearly 50% of 18- to 20-year-olds have ≥ 1 episode of lower back pain.
 - A 6-year study in a tertiary orthopedic setting found:
 - Back pain constituted <2% of referrals in children age 15 years or younger, but roughly half of these children had serious underlying diseases.
 - From early adolescence onward:
 - Back pain becomes more common.
 - Back pain is more likely to be related to injury or repetitive stress.

MECHANISM

- Back pain has many potential mechanisms.
- In the context of febrile illness, strongly consider an infectious, inflammatory, or neoplastic process.
- Back pain may also be secondary (eg, to vasoocclusive changes from sickle cell disease, or a progressive anatomic or structural issue).
- Consider musculoskeletal and trauma-related causes, and that in older children pain may be functional.

History

History should ascertain:

- Description of pain: OLD CAR
 - **O**nset/precipitating event (eg, trauma)
 - **L**ocation (eg, midline, paraspinal)
 - **D**uration
 - **C**haracteristics, nature, or quality (continuous or not, severity, whether present when awakening from sleep)
 - **A**ssociated factors which improve or worsen (eg, activity)
 - **R**adiating pattern of pain
- Related neurologic findings

- Changes in urination or defecation
- Whether fever is present
 - Exposures to infectious agents (eg, tuberculosis)
 - Signs of systemic illness
 - Weight loss
 - Bone pain in other locations
 - Bruising
 - Organomegaly
 - Adenopathy
- Specific activities, especially those that require spinal extension (gymnastics, football); history of training
- Changes in activities, such as walking, play, sports activities
- Growth patterns/recent growth spurt
- Consider an evaluation of family and social factors if functional pain is in the differential diagnosis.
- Special considerations
 - Confirm pain history with others (parents, coaches, school personnel).
 - Children may minimize pain because of fear of procedures.
 - Children and adolescents usually do not use pain symptoms for secondary gain.

PHYSICAL EXAM

Physical examination considerations

- Vital signs
 - Temperature (febrile or not)
 - Pain may elevate the heart rate and blood pressure.
- Spinal examination
 - Palpate for step-offs.
 - See whether there is midline or paraspinal tenderness.
 - Straight leg-raising test
 - A positive result is highly suggestive of nerve root compression.
 - Using cervical flexion to accentuate the patient's symptoms may add to the test's sensitivity.
 - Any reproduction of the patient's usual symptoms during testing before 60 degrees of hip flexion, or marked asymmetry, should be considered a positive result.
 - Pain after 60 degrees or limited to the posterior thigh is more likely caused by hamstring tightness.
 - May evaluate for scoliosis
 - In case of trauma, check ABCs, C-spine, ribs, pelvic

stability and implement C-spine and other precautions as needed

- Neurologic evaluation: Evaluate the following at or below the suspected level of the lesion:
 - Motor function (including symmetry, strength, gait, coordination)
 - Sensation
 - Reflexes
 - Rectal sphincter tone
- Evaluate the skin for evidence of bruising or trauma.
- Check for the presence of organomegaly or lymphadenopathy.

Physical considerations particular to adolescents

- Look for excessive lordotic curvature, especially in children who perform repetitive spinal extension (eg, gymnasts, football linemen).
- Look for evidence of connective tissue disorders.
 - Hyperextensibility
 - Marfanoid body habitus
 - Joint hyperextensibility
 - Pectus excavatum
 - Pes planus
 - Dislocated lenses
 - Hernia
 - Arachnodactyly
 - Scoliosis
- Stork test: can pain be reproduced reliably by hyperextension of back while standing on one leg?
- Waddell test: presence of ≥ 3 of the following 5 criteria may help determine whether significant psychologic stress is associated with chronic low back pain.
 - Inappropriate tenderness that is superficial or widespread
 - Pain on pressing the top of the head or on passive rotation of shoulders and pelvis
 - Distraction signs, such as inconsistent performance between straight-leg raising in the seated and supine positions
 - Strength and sensory loss patterns that do not fit a directional distribution
 - Overreaction during the physical examination

DIFFERENTIAL DIAGNOSIS

All children

- Be aware of the relatively higher risk of serious underlying disease in younger children, even those without specific physical findings.
- Back pain before adolescence is uncommon.
- The combination of fever and back pain strongly suggests
 - an infectious, inflammatory, or neoplastic process in all age groups.
- Fever in the setting of conditions below should prompt aggressive diagnostic evaluation for cancer.
 - Weight loss
 - Bone pain in other locations
 - Bruising
 - Organomegaly
 - Adenopathy
- Neurologic symptoms along with back pain may indicate lumbar disk herniation or other nerve compression.
- Idiopathic scoliosis usually does not cause back pain; thus, scoliosis with pain should raise concern for spinal tumor.

Infants (through 3rd or 4th year of life)

- Infants are not always capable of localizing or complaining about pain in the back.
- Differential diagnosis includes:
 - Diskitis
 - Unexplained fever or toxicity *and*
 - Refusal to walk or stand
 - Leukemia
 - Lymphoma
 - Vasooclusive crisis
 - Vertebral osteomyelitis/epidural abscess, in a child with sickle cell disease
 - Trauma (especially intentional injury)
 - Pyelonephritis

Children

- Pyelonephritis
 - Consider with fever; costovertebral angle tenderness; dysuria; polyuria; urinary urgency; or cloudy, dark, or pink/red-tinged urine.
- Diskitis
 - Unusual, if not rare, condition
 - Most common in children <10 years
 - Typical discomfort in an upright posture
 - Refusal to walk or pain when bending forward
 - Even in the absence of fever, a child (especially preschool age) who refuses to walk should be evaluated for diskitis.
- Tethered cord
 - Back pain when walking may be the only sign at presentation.
 - Sacral dimple of unclear depth, hairy patch, or discoloration
 - Bowel or bladder issues
 - Lower extremity weakness
- Vertebral osteomyelitis

- Usually affects school-age children and teenagers
- Causes severe back pain and systemic symptoms
- Ankylosing spondylitis
 - Consider with a family history of rheumatoid disease.
- Vasooclusive crisis
 - Consider in patients with sickle cell disease.
- Leukemia, lymphoma
- Primary vertebral tumors
 - Ewing sarcoma
 - Aneurysmal bone cyst
 - Benign osteoblastoma
 - Osteoid osteoma
- Spinal tuberculosis (Pott disease)
 - Rare in US children; mainly occurs in children where tuberculosis is endemic
 - Consider if back pain is accompanied by low-grade fever.
- Muscular or ligamentous strain in this age group should be considered only after a thorough diagnostic evaluation.

Adolescents

Acute pain (<3 weeks)

- Lumbar disk disease
- Muscle or ligament strain
- Sciatica/piriformis syndrome
- Vertebral osteomyelitis
- Epidural abscess
- Spinal tuberculosis
- Pyelonephritis
 - Consider with fever; costovertebral angle tenderness; dysuria; polyuria; urinary urgency; or cloudy, dark, or pink/red-tinged urine.

Chronic pain (≥3 weeks)

- Spondylolysis
 - One of the most common identifiable causes of low-back pain in this age group
 - Athletes participating in gymnastics, dance, cheerleading, football, and diving are at highest risk.
- Spondylolisthesis (anterior movement of vertebral body on top of another, usually L5 on S1)
 - A result of bilateral spondylolysis
 - One of the most common identifiable causes of low-back pain in this age group
- Scheuermann kyphosis (thoracolumbar spinal deformity with localized vertebral body changes)
- Facet or vertebral dysfunction
- Sacroiliac dysfunction

- Lumbar disk disease
 - Especially in athletes or others with cumulative trauma
- Spinal stenosis
- Spondyloarthropathy
- Tumor or cancer
 - Osteoid osteoma and osteoblastoma
 - Consider in cases of nocturnal back pain, even if relieved by nonprescription analgesics.
- Muscular or ligamentous strain
 - Typical presentation
 - Lower back pain ≤3 weeks' duration
 - With or without recollection of an acute injury
 - Pain is exacerbated by lifting, stooping, and exercising.
 - May be caused by repetitive strain coupled with genetic predisposition and environmental factors, such as:
 - Studying or reading while sitting at a desk
 - Carrying an excessively heavy backpack (10–20% of body weight)
- Functional (nonorganic) pain
- Ankylosing spondylitis

LABORATORY EVALUATION

- Complete blood count
- Uric acid
- Lactate dehydrogenase level
- Erythrocyte sedimentation rate
- Urinalysis and culture (if considering nephrolithiasis, urine calcium and creatinine)

IMAGING

- Imaging is guided by clinical suspicion; options include:
- Radiographs of the spine (anteroposterior [AP], lateral, oblique views)
- Computed tomography (CT)
- Magnetic resonance imaging (MRI)
- Nuclear medicine imaging (bone scans)
- Single-photon emission computed tomography (SPECT)
- By suspected diagnoses:
 - Muscle or ligament strain
 - Studies not routinely indicated
 - Compression fracture (eg, after trauma such as motor vehicle accident, or athletic injury)
 - Spinal radiography (AP, lateral)
- Diskitis

- Spinal radiography
- MRI as indicated
- Osteoid osteoma or osteoblastoma
 - Spinal radiography
 - Primary vertebral tumors almost always will be visible.
 - CT is the definitive study.
 - If radiography is inadequate, consider bone scan, CT, or MRI.
- Scheuermann disease
 - Spinal radiography (lateral)
 - Diagnosis is confirmed by anterior wedging of ≥ 3 contiguous vertebrae, by ≥ 5 degrees.
 - Consider oblique views, as associated with spondylolysis
- Spondylolysis
 - Spinal radiography (AP, lateral, oblique)
 - “Scotty dog with a collar” can be seen on the oblique view.
 - Normal radiography may not rule out the diagnosis.
 - Consider SPECT if the diagnosis is highly suggested.
 - A positive radiograph and negative SPECT indicates that spondylolysis not metabolically active (may not be the cause of back pain).
 - Back pain on extension with normal radiographs and positive SPECT usually indicates facet or vertebral dysfunction
- Spondylolisthesis
 - Spinal radiography (lateral)
 - Used to diagnose anterior slippage and to stage treatment
 - Rarely, may reveal congenital absence of a lumbosacral articular process

DIAGNOSTIC PROCEDURES

- In the case of vertebral osteomyelitis/epidural abscess, consider aspiration and culture.

TREATMENT APPROACH

- Consider whether pain is acute (<3 weeks) or chronic.
 - Acute pain, especially with a history of musculoskeletal injury, may be managed conservatively.
- Chronic pain demands further investigation.
- Back pain that results from an underlying disorder will probably require treatment of the primary condition, in addition to treatment of pain.
- Psychosocial or nonorganic causes should be considered if:
 - Thorough diagnostic evaluation of chronic back pain is unrevealing *and*

- Usual management involving exercise and stretching is not beneficial.
- As children and adolescents usually do not use pain symptoms for secondary gain, do not assume that pain is feigned; rather, assume that it represents a very real physical symptom rooted in psychologic or emotional distress.
 - This distress can be addressed openly by the clinician.
 - After diagnosis, remember to reconsider organic causes, especially if symptoms continue to evolve.

SPECIFIC TREATMENT

Diskitis

- Treatment depends on cause.
- Most experts recommend:
 - If bacterial cause, parenteral followed by oral antibiotics
 - Rest and pain management

Vertebral osteomyelitis/epidural abscess

- Prompt orthopedic surgery consultation
- Antibiotics (ensure staphylococcal coverage)
- Rest and pain management

Ankylosing spondylitis

- Best coordinated by a pediatric rheumatologist
- Antiinflammatories
- Physical and occupational therapy

Vasocclusive crisis

- Careful evaluation and reassessment for acute chest syndrome and other related complications
- Hydration, red blood cell transfusion as indicated
- Pain management
- Physical therapy as indicated

Cancer, including leukemia, lymphoma, Ewing sarcoma

- Manage with a pediatric oncologist.

Osteoid osteoma

- Nonsteroidal antiinflammatory agents (NSAIDs)
- Refer to pediatric orthopedic surgery for possible excision

Musculoskeletal back pain

- For acute pain, think PRICEMMMS (Protection, Rest, Ice, Compression, Elevation, Medication, Motion, Modalities, Strength)
- For chronic pain, heat may be helpful.
- Discourage bed rest, as this may delay recovery.
- Teach proper posture.
- Pain-free activity may be resumed gradually.

- Backpack weights should not exceed 15–20% of the person's body weight.
- Exercises may be helpful.
 - Stretch after warming the muscles by gentle exercise
 - Improve flexibility of lower back and hamstrings
 - Strengthen core musculature (abdomen, hips, and back)
 - Abdominal muscle strengthening reduces pelvic tilt and decreases the tendency toward lordosis.
 - Strengthening spinal extensor muscles (eg, by raising the torso and head off the floor/exercise ball while lying prone) is recommended, as decreased strength and endurance of these muscles is associated with lower back pain.
 - May use an exercise ball or Pilates instruction
- Full sit-ups with fixed feet and bent knees should be discouraged.
 - Uses hip flexors rather than abdominal muscles
 - Increases intervertebral disk pressure
- Continuous frequency ultrasonography and massage may be helpful.

Spondylolysis

- Treatment is controversial and may be best managed with a pediatric sports medicine specialist or orthopedic surgeon.
- Provide symptomatic relief.
- Thoracolumbar bracing to prevent extension has been shown to be helpful; bracing should be used up to 6 months or until the patient is pain-free with extension.
- Some experts advocate restricting extension activities without a brace.
- Consider the Williams program: physical therapy that promotes abdominal strengthening and hamstring stretching.
- Bone stimulators have been used as adjunctive therapy.

Scheuermann disease

- Treatment is usually conservative.
 - Physical therapy: strengthening and stretching exercises
 - Avoid painful activities.
 - Analgesic medication if needed
- Thoracolumbar bracing and surgery may be indicated if kyphosis exceeds 60 degrees.
- Refer patients in whom conservative management fails, those

with intractable pain, or those in whom kyphosis progresses to orthopedic surgery (pediatric or spinal).

WHEN TO REFER

- Prompt and urgent evaluation and referral are needed when back pain is accompanied by:
 - Radicular pain down the leg
 - Numbness or tingling
 - Bowel or bladder problems
 - Erectile dysfunction
 - Loss of sphincter tone on rectal examination
 - High clinical suspicion of vertebral osteomyelitis/epidural abscess
- Consider referral for:
 - Ankylosing spondylitis
 - Refer to pediatric rheumatology.
 - Leukemia, lymphoma, and Ewing sarcoma
 - Refer to pediatric oncology.
 - Osteoid osteoma
 - Refer to pediatric orthopedic surgery.
 - Spondylolysis
 - Refer to a pediatric sports medicine specialist or orthopedic surgery.
 - Scheuermann disease
 - Refer to orthopedic surgery (pediatric or spinal) if patients in whom conservative management fails, those with intractable pain, or those in whom kyphosis progresses or when diagnosis and evaluation are outside of scope of expertise

WHEN TO ADMIT

- Admit patients with back pain with associated fever or neurologic findings or when prompt and thorough diagnostic assessment cannot be completed as an outpatient.

PROGNOSIS

- Prognosis depends on the underlying etiology of back pain.

PREVENTION

- Muscular low back pain prevention measures
- Proper posture
- Backpack should not exceed 15–20% of body weight.
- Stretch to improve flexibility of lower back and hamstrings
- Exercise to strengthen core musculature (abdomen, hips, and back)

Bacterial Skin Infections

DEFINITION

- Bacterial infections of the skin are common and most often caused by gram-positive bacteria
 - *Staphylococcus aureus*
 - Group A streptococci
- The clinical disease that results depends on the infection's location in the skin.

ETIOLOGY

Impetigo

- *S aureus* is the major cause of impetigo in childhood.
 - Responsible for virtually 100% of bullous impetigo
 - Causes approximately 75% of nonbullous impetigo
- The remainder of cases is caused by group A β -hemolytic *Streptococcus*.

Pyoderma

- Presumably, trauma to the skin results in inoculation, followed by infection.
- Frequently extends through the epidermal layer into the underlying dermis
- The process may start with small erythematous papules and rapidly proceed through vesicular, pustular, and crusted stages.
 - May be clinically confused with impetigo
- Streptococcal pyoderma is more common in warm, humid environments.
 - Higher humidity favors survival of group A streptococci on normal skin.

Folliculitis

- Infection of the hair follicles, caused almost exclusively by *S aureus*
 - In rare cases, the infection is caused by gram-negative organisms.
 - Occurs occasionally in patients whose acne is being treated with antibiotics
 - Moderately common, primarily affecting older children and young adults
- *Pseudomonas aeruginosa* is the usual cause of hot tub folliculitis.
 - Pruritic papules and pustules on the trunk and proximal extremities
 - Usually clears without treatment, although antipruritics can be used

Furuncles and abscesses

- Pus-filled nodule or boil resulting from unchecked folliculitis
- Almost always caused by *S aureus*
- Many clinicians use the terms *furuncle* and *abscess* interchangeably.

- Abscesses are collections of pus in the dermis and deeper skin tissues.
 - They do not originate from a primary folliculitis.
 - Bacteria may be inoculated into the skin and underlying soft tissue by traumatic injury, including surgery.
 - Most skin abscesses are caused by *S aureus*, but gram-negative and anaerobic organisms also can be causes.

Cellulitis

- Deep, locally diffuse infection of the skin with systemic manifestations and life-threatening potential
- *S aureus* and group A streptococci more commonly are responsible for cellulitis of the extremities.
 - On an extremity, the bacteria presumably have been externally inoculated into the deep dermal tissue.
 - The portal of entry is often undetectable clinically.
 - A hematogenous or lymphangitic source is also possible and may explain the development of cellulitis in cases in which overlying skin is unbroken.
- *S aureus* and group A streptococci are the most common cause of perianal dermatitis.
 - Two-thirds of these patients have positive pharyngeal cultures.
- Preseptal (periorbital) cellulitis is likely to be caused by:
 - *Streptococcus pneumoniae* in younger children
 - Group A streptococci in older children
- In rare cases, other aerobic and anaerobic bacterial organisms, as well as deep fungal agents, such as *Cryptococcus neoformans*, can cause cellulitis.
 - These infections usually occur in immunosuppressed individuals.
- Before the introduction of protein-conjugated *Haemophilus influenzae* type b (Hib) vaccines in 1988, Hib was a frequent cause of facial cellulitis (buccal cellulitis).
- The incidence of invasive infections from this organism in the US has decreased by 95%.
- Now occurs primarily in:
 - Undervaccinated populations
 - Infants who have not completed the primary Hib vaccine series
- Almost 90% of cases of facial cellulitis in the post-Hib vaccine era are related to:
 - Trauma
 - Dental infection
 - Sinus infection

Community-associated methicillin-resistant *S aureus* (MRSA) infections

- The prevalence of community-associated MRSA is increasing.
- The most frequently reported presentation is furunculosis, followed by skin abscesses and cellulitis.
- Less frequent are bullous and nonbullous impetigo, nodules, pustules, and scalded skin syndrome.

RISK FACTORS

- Uncontrolled diabetes
- Immunodeficiency involving reduced neutrophil number and function

SIGNS AND SYMPTOMS

Impetigo

- History
 - The patient usually has no history of preceding trauma to the skin.
 - Mild to moderate itching may be associated with lesions.
 - Other family members also may be affected.
- Physical findings
 - Most commonly found on the face
 - Lesions may be single or multiple and scattered elsewhere on the body as well.
 - Usually yellow- or honey-colored crusts that when removed reveal a pink, superficially eroded, glistening base
 - A culture sample should be obtained from this base.
 - Intact bullae, if present, contain deceptively clear fluid.
 - Blisters break easily, leaving behind a superficially denuded skin surface covered with a thin, brown, varnish-like crust surrounded by a thin rim of loose, ragged epidermis that represents the remnants of the blister roof.
 - Surrounding erythema is minimal.
 - Regional lymphadenopathy is rare.

Pyoderma

- History
 - May occur in epidemics among children of lower socioeconomic status who live in crowded conditions in a warm, humid environment
 - In contrast to impetigo, lesions occur most commonly on the lower extremities.
 - Usually preceded by trauma such as a scratch or insect bite
 - Family members may be affected.
- Physical findings
 - Early lesion is a pustule with surrounding erythema.
 - Typically, the more advanced lesion of ecthyma is seen.

- Lesion appears as a thick, usually brown crust surrounded by erythema.
 - When the crust is removed, an actual ulcer is revealed.
- Regional adenopathy is often present.

Folliculitis

- History
 - Appears most commonly as a chronic eruption unaccompanied by symptoms
 - Occasionally, a patient has mild discomfort or pruritus.
- Physical findings
 - Lesions are usually located on the buttocks and upper portion of the thighs.
 - Scattered individual small papules and pustules
 - On close inspection, hairs can be seen growing out of the very center of many of the lesions.

Furuncles and abscesses

- History
 - A history of trauma may be elicited but often is not, especially with furuncles.
 - Immunodeficiency states and diabetes may predispose certain patients to bacterial skin infections.
 - The typical patient with a furuncle or abscess has no underlying medical disease.
- Physical findings
 - Furuncles and abscesses are fluctuant masses filled with pus.
 - Often begin as hard, tender, red nodules that become more fluctuant and painful with time
 - Abscesses tend to be larger and deeper than furuncles.
 - The 2 lesions may be difficult to differentiate clinically.

Cellulitis

- History
 - Children often feel and appear ill.
 - Fever may precede clinical skin signs.
 - May complain of pain in the affected area; patients who have perianal cellulitis often have pain on defecation
 - Symptoms of accompanying otitis media may be present in buccal cellulitis.
- Physical findings
 - Fever at the time of presentation is common.
 - The area of involved skin shows the classic signs of inflammation.
 - Redness
 - Swelling
 - Heat
 - Tenderness

DIFFERENTIAL DIAGNOSIS

Impetigo

- Herpes simplex virus (HSV) infection is the condition most often confused with impetigo.
- Clinical clues that suggest herpes rather than impetigo
 - Intact vesicles are more likely in HSV infection.
 - As vesicles age, they become cloudy and ultimately result in crusts that also may be honey colored.
 - The crusted phase most often causes the diagnostic confusion.
- HSV infection tends to be a recurrent condition.
 - Recurrence is not the case with impetigo.
- When an impetiginous pustule is unroofed, it is noticeably filled with pus.
 - A herpetic lesion may appear to be pus filled, but when it is unroofed, only a scant amount of clear fluid is found.
- In impetigo, Gram staining shows numerous gram-positive cocci.
 - In HSV infection, Wright staining of a scraping from the base of a crust or a vesicle reveals multinucleated giant cells.

Pyoderma

- Ecthyma gangrenosum is an uncommon but serious manifestation of sepsis in immune-compromised hosts.
 - Most frequently associated with *P aeruginosa* infection
 - Can be seen with other gram-negative organisms or even with fungi
- Clinical features that help differentiate this lesion from ecthyma
 - Location: ecthyma gangrenosum is often on the upper extremities or in the inguinal or axillary folds.
 - Lesion's appearance: a deeper ulcer is covered with a tightly adherent, black (gangrenous) crust.
 - Host: seriously ill, usually immunocompromised patient with other signs of sepsis

Folliculitis

- Clinically, folliculitis is caused by gram-negative organisms and differs from staphylococcal folliculitis in its distribution.
 - Lesions occur primarily on the face and shoulders, often concentrated in the perioral and perinasal areas.
 - Hot tub folliculitis usually appears on the lower trunk on areas most exposed to the contaminated water in the tub.
- Keratosis pilaris is another common follicular disorder.
 - Exhibits as tiny, rough, scaling papules on back of the upper parts of the arms, buttocks, and thighs
 - Although its distribution may be similar to that of staphylococcal folliculitis, the appearance of the lesions is not.
 - In keratosis pilaris the lesions are smaller, more numerous, and scaling, but not pustular.

Cellulitis

- Erysipelas
 - A form of cellulitis caused most commonly by group A streptococci
 - Infection is limited to the upper dermis.
 - Erysipelas has raised and sharply demarcated borders.
 - Bedside differentiation of erysipelas from cellulitis is sometimes difficult.
 - Not particularly useful clinically since therapeutic considerations are the same for both conditions
- Severe, local, confluent contact dermatitis may sometimes be confused with cellulitis.
 - Both may show marked erythema of the skin.
 - Important differences from contact dermatitis
 - The complaint is of itch rather than pain.
 - The skin usually is not tender.
 - The patient is not febrile.
 - The presence of vesicles also favors contact dermatitis.
 - Vesicles and bullae may sometimes occur in erysipelas or cellulitis as the condition evolves.

Perianal dermatitis

- Originally thought to be cellulitis, but now known to be a more superficial infection
- May be misdiagnosed as candidiasis or diaper dermatitis
- Bright-pink erythema and pain or tenderness of the involved skin suggest bacterial infection.
 - A swab culture usually shows *S aureus* or group A streptococci.
 - Laboratory personnel must be aware that they are to look for these organisms; otherwise, they will look for enteric flora with a culture from this site.

Necrotizing fasciitis

- A fulminant skin infection most often caused by group A streptococci.
 - Flesh-eating bacteria
 - Warm, violaceous, exquisitely tender, and markedly edematous (orange peel-like) skin with indistinct edges.
 - Systemic toxicity is often seen.
 - Fever
 - Leukocytosis
 - Thrombocytopenia
 - Hypocalcemia
 - Hyponatremia
 - Systemic antibiotics are an adjunct to prompt surgical debridement.

Erythema infectiosum

- Fifth disease, caused by parvovirus B19
- Erythema of the cheeks, with a slapped-cheek appearance
- Important diagnostic differences between erythema infectiosum and cellulitis
 - Involvement is bilateral.
 - The site is not usually very tender.
 - The patient does not appear toxic.
 - The patient may be mildly febrile.

LABORATORY FINDINGS

- Impetigo
 - Gram stain of either the clear blister fluid or serum underlying the crusts shows gram-positive cocci.
 - Cultures grow *S aureus* or *Streptococcus pyogenes*.
- Pyoderma
 - Culture sample taken from the base of the denuded ulcer usually grows group A β -hemolytic streptococci.
 - *S aureus* is occasionally recovered concomitantly, thought to be a secondary invader.
- Folliculitis
 - Culturing is not usually necessary in the typical case.
 - If presentation is atypical and laboratory confirmation is desired, then the contents of a fresh pustule should be cultured.
- Furuncles and abscesses
 - Gram stain of the pustular material may identify the bacterial cause.
 - For precise identification, cultures are required.
 - For anaerobic cultures: aspirate the pus, seal the syringe, and deliver to the laboratory.
 - If insufficient material is available to aspirate, a swab culture can be used for anaerobic and aerobic cultures.
 - Blood culture results rarely are positive in patients with furuncles or abscesses.
 - Not indicated unless the patient shows signs of sepsis
- Cellulitis
 - Leukocytosis is a common finding.
 - Causative pathogen is usually assumed from history and physical examination.
 - Identifying it by culture is difficult.
 - Blood cultures are positive in <5% of cases.
 - Many advocate culturing the skin directly.
 - Prepare the skin with an antiseptic.
 - Introduce an 18- or 21-gauge needle into the deep dermis and aspirate.

- If no material is obtained, inject 0.5 to 1 mL of non-bacteriostatic saline and re-aspirate.
- All aspirates should be Gram stained and cultured.
- Causative organism is identified in approximately 25% of cases.
- Skin aspiration is best in special cases.
 - Immunocompromised host
 - Cellulitis that is not responsive to empiric therapy
 - Cellulitis secondary to an unusual exposure, such as an animal bite
- In neonates or undervaccinated hosts with facial cellulitis, lumbar puncture with culture of cerebrospinal fluid may disclose unsuspected meningitis.

SPECIFIC TREATMENTS**Impetigo**

- Topical and systemic antibiotics can be used to treat impetigo.
- Mupirocin topical antibiotic ointment has been reported to equal or exceed the efficacy of oral erythromycin in the treatment of bacterial impetigo.
 - A cream form is also available.
 - Topical mupirocin should be considered whenever feasible because it can be effective in treating impetigo caused by MRSA.
 - Infected area should be washed carefully and crusts gently removed, if possible, 3 times daily before antibiotic cream or ointment is applied.
- Traditional topical preparations that contain bacitracin or neomycin, either alone or in combination
 - Poorly absorbed, thus not particularly effective
- Systemic antibiotics should be used for more extensive lesions.
 - Clindamycin might be an appropriate choice in the era of MRSA.
 - Studies of this approach have not been published.
 - Traditional choices in the pre-MRSA era
 - Erythromycin
 - Penicillinase-resistant penicillin (eg, dicloxacillin)
 - Amoxicillin-clavulanic acid
 - Cephalexin
 - These agents would still be appropriate for treatment of disease caused by methicillin-sensitive *S aureus* or *S pyogenes*.
 - Treatment course should be 7–10 days.
 - Patients with more extensive disease who fail traditional empiric antibiotic therapy should have cultures and susceptibility studies performed.

Pyoderma

- Antibiotics are the treatment of choice, but route of administration is debated.
- Prophylactic topical agents, such as mupirocin, may be applied to scratches or insect bites to prevent the development of pyoderma.
- Systemic antibiotics are recommended for streptococcal infections, particularly if the infection is extensive.
 - Injectable benzathine penicillin G
 - A 7- to 10-day course of oral penicillin or erythromycin is preferred if the patient is likely to be adherent to the prescribed regimen.
 - Penicillin treatment occasionally fails.
 - Most likely because of the persistence of coexisting penicillinase-producing *S aureus* organisms

Folliculitis

- Mild staphylococcal folliculitis can be managed by having the patient use an antiseptic cleanser (eg, chlorhexidine) or antibacterial soap containing triclosan or triclocarban.
 - Use daily or every other day for at least several weeks.
 - For more extensive involvement a 7- to 10-day course of systemic antibiotics (eg, erythromycin or dicloxacillin) is suggested in addition to the topical regimen.

Furuncles and abscesses

- Very small furuncles can be treated with moist heat, which promotes drainage.
- For larger furuncles, incision and drainage is the appropriate therapy.
- For furuncles <5 cm in diameter, incision and drainage alone results in complete healing in most cases.
- For abscesses >5 cm or patients with surrounding cellulitis or signs of systemic illness, systemic antibiotics should be used.
- If lesions are seen early in their development, then systemic antibiotics may result in involution, obviating the need for incision and drainage.
 - Dicloxacillin, cephalexin, and erythromycin were considered the antibiotics of choice.
 - They need to be reevaluated in light of MRSA in furunculosis.
 - Most community-associated MRSA isolates are susceptible to trimethoprim-sulfamethoxazole.
 - Many are sensitive to clindamycin.
 - Clindamycin has excellent penetration into the infected tissues.
 - Some erythromycin-resistant strains of MRSA have inducible resistance to clindamycin.
 - It is important to know local susceptibility patterns.
- Culture results from abscesses may help in the ultimate selection of the appropriate antibiotic.

Cellulitis

- Systemic antibiotics are the mainstay of therapy.
- Mild cases of cellulitis on an extremity may be treated with:
 - Oral antibiotic
 - Warm soaks
 - Outpatient follow-up in several days
- Cellulitis of the extremity most often is caused by gram-positive organisms; thus, the following are appropriate.
 - Erythromycin
 - Dicloxacillin
 - Cephalexin
- More seriously ill patients should be hospitalized for parenteral antibiotic therapy.
 - Infants and young children, patients with predisposing medical conditions, such as diabetes mellitus
 - Patients with immunodeficiencies or on immunosuppressive therapies
 - Patients in whom sepsis is suspected
- Community-associated MRSA strains are generally more susceptible to non- β -lactam antibiotics than are nosocomial MRSA strains.
 - Clindamycin
 - Trimethoprim-sulfamethoxazole
- Some erythromycin-resistant strains develop resistance to clindamycin during treatment.
 - The microbiology laboratory should provide results of a D-test for strains resistant to erythromycin.
 - If the D-test is negative, then clindamycin can be used.

WHEN TO ADMIT

- Cellulitis with suspected sepsis or suspected underlying serious infection
- Invasive infections (necrotizing fasciitis)
- Staphylococcal scalded skin syndrome
- Toxic shock syndrome

WHEN TO REFER

- Preseptal cellulitis
- Treatment failure
- Recurrent bacterial skin infections

FOLLOW-UP

- Impetigo
 - Exclusion from school
 - A child may be asked to leave school until the infection is treated.
 - The period of infectiousness of impetigo is unknown.

- Most child-care centers and schools recommend exclusion as long as open lesions persist.
- 24 hours after appropriate therapy has been initiated, the child can probably return to school without posing a significant risk to other children.

COMPLICATIONS

Impetigo

- If the infection does not respond rapidly to therapy, it may be caused by an antibiotic-resistant strain.
 - In such cases, initial culture and susceptibility results serve as a guide in selecting an alternate antibiotic.
- Historically, differentiating between staphylococcal and streptococcal impetigo was considered to be important.
 - There was a belief that glomerulonephritis was a sequela of streptococcal impetigo.
 - Evidence now shows that treatment of streptococcal skin infections does not alter the risk of glomerulonephritis.

Pyoderma

- Cellulitis may develop if the infection extends into larger and deeper areas of skin and subcutaneous tissue.
- Some strains of group A streptococci produce the toxin responsible for scarlet fever.
- Acute glomerulonephritis may follow streptococcal infection of the skin.
 - Caused by only a few nephritogenic serotypes (49, 55, and 57) of pyoderma-inducing streptococci
 - The usual period from onset of infection to development of glomerulonephritis is 18–21 days.
- Skin infection with streptococci never leads to acute rheumatic fever.

Furuncles and abscesses

- Recurrent furunculosis
 - Consider an underlying immunodeficiency (rare).
 - Many patients harbor *S aureus* in a sequestered mucocutaneous site, most commonly in the anterior nares.
 - Apply mupirocin to the external nares twice daily for 5 days.
 - Repeat the process monthly or every 2 months.
 - This decreases recurrences by approximately one-half.
 - Some recommend an every-other-day total-body scrub with an antiseptic cleansing agent, such as chlorhexidine, or antibacterial soap containing triclosan or triclocarban
 - Overuse may dry the skin, harming skin integrity.
 - Some advocate the addition of a small amount of bleach to the bath water.
 - Anecdotally, this approach shows some promise.
 - No studies evaluating its efficacy have been conducted.

- Most oral antibiotics do not eradicate nasal carriage of *S aureus*, but clindamycin is an exception.
- In cases that are refractory to all previously described methods, a single oral dose of clindamycin, given daily for 3 months, may be effective at eliminating recurrences.

- In rare cases, a staphylococcal abscess may be the focus of toxin production.
 - Can result in:
 - Staphylococcal scalded skin syndrome, most commonly seen in infants and neonates
 - Toxic shock syndrome
 - Staphylococcal scarlet fever

Cellulitis

- In some instances, findings that are clinically diagnosed as cellulitis may actually be a clue to underlying, deeper-seated infection.
 - Cellulitis of the periorbital tissues may be secondary to sinusitis.
 - Abdominal wall cellulitis may hide an underlying peritonitis.
 - Redness, warmth, and swelling of tissues overlying bones or joints may indicate septic arthritis or osteomyelitis.
 - Facial cellulitis may be caused by an undiagnosed dental abscess.
 - Redness of the neck is sometimes a clue to underlying deep neck space infections.
 - Inflammation of the skin of the sacrum might be from an infected pilonidal cyst.
 - Redness of the pinna or postauricular area may point to malignant otitis externa or mastoiditis.
- Uncomplicated cellulitis was once a serious, life-threatening disease, but antibiotics have now reduced the fatality rate to nearly zero in otherwise healthy patients.

PROGNOSIS

- Impetigo
 - With appropriate antibiotic therapy, prompt healing is expected.
 - Bacteriologic cures occur within 7–10 days.
- Pyoderma
 - In most patients, the lesions heal uneventfully.
 - Because they are deeper, streptococcal lesions often take longer than staphylococcal lesions to heal.
 - Bacteriologic cures are usually accomplished within 1 week.
 - If prompt response is not achieved, then secondary infection from a penicillinase-producing staphylococcal strain should be considered, particularly if penicillin was used for treatment.
 - Erythromycin-resistant strains of group A streptococci may be encountered.

■ Folliculitis

- Most patients respond to treatment.
- If not, bacterial culture should be performed to rule out infection by gram-negative organisms or MRSA.
- Some patients are plagued with recurrences, for which a more prolonged course of antibiotic therapy is recommended.
- In rare cases, the follicular infection extends deeply, producing a furuncle.

■ Furuncles and abscesses

- Untreated lesions often rupture and drain spontaneously.
- After either surgical or spontaneous drainage, uneventful healing is the rule.
- Larger lesions may leave scars.

■ Cellulitis

- With appropriate antibiotic therapy, fever usually resolves within 24 hours.
- If it does not, then a change in antibiotic therapy should be considered, optimally guided by early culture and bacterial sensitivity results.
- The skin reaction resolves more slowly than does fever, sometimes taking ≥ 1 week to subside completely.

Brain Tumors

DEFINITION

- Brain tumors include tumors of the brain parenchyma, cranial nerves, meninges, and the pituitary gland and immediate surrounding structures.
- Although they are rare, they are the second most common cancer and most common solid tumor in childhood.

EPIDEMIOLOGY

- Incidence
 - Primary brain and central nervous system (CNS) tumors in the US
 - 4.3 cases per 100,000 person-years
 - 3410 new cases diagnosed in 2005
 - Incidence appears to be increasing.
- Age
 - Incidence is inversely proportional to age.
 - Highest in children 0–4 years of age (5.0 cases/100,000 person-years)
 - Lowest in patients 10–19 years of age (3.9 cases/100,000 person-years)
- Sex
 - Incidence slightly higher in boys than in girls
 - Higher proportion of medulloblastoma and germ cell tumors in boys

ETIOLOGY

- Brain tumors arise from persistence of:
 - Embryologic precursors of neurons (primitive neuroectodermal tumors)
 - Glial elements that provide structural and nutritional support to the neurons (astrocytomas and oligodendrogliomas)
 - Lining cells, such as:
 - Arachnoid (meningioma)
 - Nerve sheath (schwannoma)
 - Pituitary gland (pituitary adenomas)
 - Intracranial rests (craniopharyngiomas)

RISK FACTORS

- Proven risk factors include:
 - Previous therapeutic radiotherapy
 - Therapy for acute lymphoblastic leukemia, including radiotherapy, increases risk for second malignant neoplasms, including CNS tumors.
 - Predisposing genetic syndromes
 - Neurofibromatosis types 1 and 2
 - Tuberous sclerosis types 1 and 2
 - von Hippel-Landau syndrome
 - Li-Fraumeni syndrome

- Nevoid basal cell carcinoma syndrome
- Turcot syndrome
- Ataxia-telangiectasia syndrome
- Gardner syndrome
- Down syndrome
- Maternal diet
 - Strong protective dose-response relations observed for maternal consumption of:
 - Fruit
 - Vegetables
 - Vitamin C
 - Nitrate
 - Folate
- Children with primary CNS neoplasms without a documented genetic syndrome have increased risk of a second CNS neoplasm.

SIGNS AND SYMPTOMS

General information

- Symptoms often appear weeks to months before diagnosis is made.
 - Interval between onset of symptoms and diagnosis is approximately 9 weeks.
 - Correlate with patient's age and location/histologic type of the tumor
 - In infants, increased intracranial pressure (ICP) may exhibit with nonspecific signs.
 - Drowsiness or lethargy
 - Irritability
 - Vomiting
 - Abnormal tilting of the head
 - Developmental stagnation or regression
 - In older children, the following may occur before overt symptoms (eg, headache, vomiting) develop.
 - Declining academic performance
 - Fatigue
 - Emotional, appetite, or personality changes

Characteristics of symptoms

- Children will typically have a progression of symptoms and physical findings that may not correlate with grade of underlying disease.
 - Manifestations depend on:
 - Site of tumor origin
 - Child's age and developmental level
 - Existence of accompanying hydrocephalus

Specific symptoms

- The most typical symptom is headache, which may be:
 - Frontal
 - Occipital
 - Unilateral
 - Diffuse in location
 - Exacerbated by Valsalva maneuvers
- Vomiting
 - May be the result of increased ICP or, less commonly, direct irritation of the vagal nuclei or the floor of the 4th ventricle
 - May be associated with morning or waking headaches
 - May relieve the headaches
 - Some infants will appear to be failing to thrive as a result of vomiting caused by the increased ICP.
- Seizures are not frequently observed in children with brain tumors.
- More specific symptoms may help localize the tumor.
 - Infratentorial tumors
 - Clumsiness
 - Worsening handwriting
 - Scanning speech
 - Ataxia
 - Infiltrating brainstem glioma
 - Ataxia
 - Diplopia (due to 6th-nerve palsy)
 - Headache
 - Vomiting
 - Supratentorial tumors, cerebral hemispheres
 - Hemiparesis (muscle weakness)
 - Personality changes
 - Focal weakness
 - Language dysfunction
 - Visual field defects
 - Sensory changes
 - Disease along optic nerve
 - Visual loss or visual field defects
 - Tumors near the optic chiasm or hypothalamus
 - Hormonal changes such as growth failure or precocious puberty
 - Tumors of the hypothalamus, diencephalic syndrome in infants, characterized by:
 - Failure to thrive
 - Emaciation
 - Euphoric mood
- Pineal tumors and tumors involving midbrain tectum, Parinaud syndrome
 - Paralysis of upward gaze
 - Convergence-retraction nystagmus
 - Lid retraction
 - Light-near dissociation of the pupils
- Tumors involving suprasellar and hypothalamic region
 - Precocious or delayed puberty
 - Growth failure
 - Hypothyroidism
- Macrocephaly in infants
 - Head circumference measurements that cross percentile lines on standard chart
 - Bulging of the fontanel
 - Split cranial sutures
 - Lack of upgaze
 - Alteration in tone
- Symptoms warranting evaluation for brain tumor in patients with headache
 - Presence or onset of neuralgic abnormality
 - Ocular findings, such as:
 - Papilledema
 - Decreased visual acuity
 - Loss of vision
 - Vomiting that is either:
 - Persistent
 - Increasing in frequency
 - Preceded by recurrent headaches
 - Changes in character of headache
 - Increased severity or frequency
 - Begins awakening child from sleep
 - Recurrent morning headaches or headaches that repeatedly awaken the child from sleep
 - Child with short stature or deceleration of linear growth
 - Diabetes insipidus
 - Neurofibromatosis

DIFFERENTIAL DIAGNOSIS

- Space-occupying lesions and causes of increased ICP
 - Arteriovenous malformations
 - Subdural hematoma, effusion, or empyema
 - Abscess
 - Infarction
 - Hemorrhage
 - Demyelination

- Pseudotumor cerebri
- Hemiplegic migraine
- Todd paralysis
- Venous sinus thrombosis

DIAGNOSTIC APPROACH

- In addition to a thorough history, complete neurologic examination, including the fundus, is required to reveal both localizing and nonlocalizing findings.
- Neurologic findings, with or without complementary history, are required for further investigation and for referring the child to a specialist.
- Repeated neurologic examinations are ideal because signs are frequently progressive in situations in which the diagnosis remains in question.

LABORATORY FINDINGS

- In tumors of pituitary gland the involving the pituitary stalk and hypothalamus, endocrine function should be evaluated before surgery.
- If the pituitary stalk or posterior portion of gland is involved, electrolytes and osmolality measurements can help diagnose diabetes insipidus.
- Patients with nongerminomatous germ cell tumors (choriocarcinoma, yolk-sac tumors, embryonal cell tumors, and the mixed variety) can excrete:
 - α -Fetoprotein
 - β -Human chorionic gonadotropin
 - Alkaline phosphatase
 - These markers are most easily found in cerebrospinal fluid, but they may also be detected in serum.
- HIV serologic testing may be useful if primary CNS lymphoma is suspected (although this is rare in children).

IMAGING

- Computed tomography (CT) is widely available and has short imaging times, requiring less sedation in young children.
 - First modality to be used
 - Initial scan can provide important immediate information about:
 - Presence of hydrocephalus
 - Cerebral edema
 - Midline shifts
 - Risk of uncal herniation
 - Tumors of the brainstem, posterior fossa, and mesial temporal lobe structures may not be clearly visible.

■ Magnetic resonance imaging (MRI)

- Modality of choice for definitive diagnosis of CNS neoplasms
- More sensitive than CT for most brain tumors
- Best for tumors of the brainstem, posterior fossa, mesial temporal lobe, and spinal column
- If seizures with a focal onset are present, either simple partial (focal) seizures or partial seizures with secondary generalization, contrast-enhanced MRI should be used to evaluate the patient for a tumor.

DIAGNOSTIC PROCEDURES

- Diagnosis using histologic evaluation of biopsy material
 - Best way to diagnose some tumors, when a biopsy sample can be obtained without substantial morbidity
 - Biopsy samples of tumors situated in the deep gray masses (eg, the thalamus and basal ganglia) are often obtained by means of a stereotactic navigation system.
 - Diffuse pontine gliomas and tectal plate gliomas are never sampled for biopsy because of:
 - Risk of damaging essential structures
 - Predictable histologic appearance and clinical course
 - Visual pathway glioma and intrinsic pontine gliomas seldom need pathologic corroboration of a diagnosis.

CLASSIFICATION

- World Health Organization classification (published in 2000) has >120 entries.
 - Integrates histopathologic criteria with factors that are:
 - Clinical
 - Epidemiologic
 - Radiologic
 - Biological
 - Molecular genetic
 - Predictive
 - Continues to evolve, with new diagnoses continually being added
 - 4 malignancy grades or estimates of malignant potential
 - Distinction between malignant and nonmalignant tumors may not always reflect the clinical course of the disease.
 - Terms such as *benign* or *malignant* have been replaced by *low-grade* or *high-grade* because the former terms can be misleading.
 - Prognosis for some high-grade tumors is better than for some low-grade tumors.

TREATMENT APPROACH

- Treatment usually requires a multidisciplinary team approach with physicians from:
 - Neurosurgery
 - Neurology
 - Oncology
 - Pathology
 - Radiology
 - Radiation oncology
 - Endocrinology
 - Ophthalmology
- Treatment outcomes are better when care is provided at a specialized tertiary-care cancer center.
 - The AAP released a statement outlining the guidelines for facilities, capabilities, and available personnel.
 - Patients benefit from an experienced team of:
 - Pharmacologists
 - Nurses
 - Neuropsychologists
 - Audiologists
 - Nutritional experts
 - Child life specialists
 - Physical, occupational, and speech therapists
 - Social workers
- Children should be considered for enrollment into a clinical trial whenever one is available.

SPECIFIC TREATMENTS

Surgery

- Presurgical corticosteroid therapy is essential if the patient has brain edema and increased ICP.
 - Methylprednisolone reduces capillary permeability in tumor and adjacent brain tissue.
 - Methylprednisolone often results in rapid or marked resolution of edema, with corresponding improvement of symptoms, and a more relaxed brain during the operative procedure.
- Excision removes the tumor and resolves the surrounding edema.
 - Use of stereoscopic microscopes coupled with real-time surgical navigation systems is the most striking advance.
 - Navigation system permits an operative burr hole to be placed with high precision and allows tumor resection through small openings.
 - Modern microscopes allow the surgeon to distinguish between healthy brain and tumor, yielding a greater likelihood of total resection.

- Electrophysiologic monitoring during surgery contributes to safer and bolder approaches.
- Intraoperative MRI shows promise in selected cases, but its use is limited by high cost and often considerably longer operating times.

- For pilocytic astrocytoma, the strategy of choice is gross total resection.
- For other tumors, debulking of the primary tumor allows more effective chemotherapy and radiotherapy.
 - Chemotherapy improves survival from CNS tumors.

Radiotherapy

- Radiotherapy is an important treatment for all but the youngest patients.
 - In very young patients, new treatment protocols with intensive chemotherapy with stem cell rescue should replace radiotherapy (since the latter has long-term consequences).
- Radiotherapy
 - Best therapy for many tumors, but may result in growth/intellectual development failure, and increased risk of another cancer
 - Treatment planning requires balancing cure rates with profound morbidity and late effects.
 - Current radiotherapies allow small-volume or local irradiation while sparing surrounding tissues and essential structures.
 - External-beam
 - 3-dimensional
 - Intensity-modulated radiotherapy
 - Stereotactic radiosurgery and gamma-knife surgery

WHEN TO ADMIT

- Patients with signs of increasing ICP
 - Admit urgently for evaluation and imaging.
 - CT scanning can provide immediate information about:
 - Ventricular size
 - Volume of the normal cisternal spaces
 - Shifting of normal brain structures
 - Degree of ICP
- Progressive life-threatening symptoms that require urgent consult with neurosurgeon
 - Increasing blood pressure and decreasing heart rate
 - 6th-nerve palsy
 - Occipital headaches caused by irritation of posterior roots of the cervical cord
 - Symptoms may quickly progress to neck stiffness and opisthotonus (body spasm in which the head and heels are bent backward and the body is bowed forward).

- Patients with supratentorial mass lesions may exhibit pupillary dilatation, often unilateral initially, from uncal herniation.
- May culminate in tonsillar herniation, which is a potential sequela of an untreated posterior fossa mass lesion, obstructive hydrocephalus, or both

WHEN TO REFER

- Children require further evaluation because of:
 - History that suggests brain tumor
 - Focal findings at physical examination
- Oncologists, neurologists, and neurosurgeons prefer early referrals if neoplasm is suspected.
 - Tumor will be smaller and easier to resect, causing less damage to adjacent brain tissue.

COMPLICATIONS

- An untreated posterior fossa mass lesion, or obstructive hydrocephalus, or both may lead to tonsillar herniation.
- Radiation therapy may result in failure of growth or intellectual development and increased risk of another cancer.

PROGNOSIS

- Except for medulloblastoma and nongerminomatous germ cell tumors, recent advances have only modestly affected outcomes.
- Survival depends on many factors.
 - Histology
 - Tumor behavior, size, and location
 - Patient age
- Children who survive may experience substantial morbidity.

Bronchiolitis

DEFINITION

- Bronchiolitis is a common, acute viral lower respiratory tract illness of children, occurring during the first 2 years of life.
- In bronchiolitis, acute inflammation of the airways results in:
 - Wheezing
 - Hyperinflation
 - Tachypnea

EPIDEMIOLOGY

Prevalence

- An increasing cause of hospitalization among infants in the US
- An appreciable and escalating economic burden to the health care system
- In 1 review of a private group practice, bronchiolitis caused 4% of hospitalizations among pediatric patients of all ages.

Incidence

- Annual reported rate of hospitalizations attributable to respiratory syncytial virus (RSV) among infants varies from 500 to 4100 per 100,000 infants.
- Recent population-based studies in the US estimate annual RSV-associated hospitalization rates of approximately 1300 per 100,000 children <12 months.
 - >3 times that associated with parainfluenza virus
 - >6 times that attributable to influenza
- Annual rates of hospitalization for bronchiolitis and RSV in other countries reported at 1900 to 2200 per 100,000 children <12 months.
- Rate of outpatient visits attributable to bronchiolitis or RSV is less well studied.
 - May be many times higher than that for hospitalized patients
- Mortality estimates due to bronchiolitis by Centers for Disease Control and Prevention
 - In children <5 years from 1979 to 1997
 - Average of 95 cases annually
 - Range of 66 to 127 cases each year
 - Highest in those <1 year
- Deaths in infants associated with RSV have more recently been estimated to be <500 per year.

Seasonal pattern

- Well-defined in temperate climates
- Reflects the activities of its viral agents, particularly RSV
- Yearly outbreaks of bronchiolitis occur during the winter to spring, when RSV is epidemic in the community (see Figure 9 on page F2).

- In Monroe County, New York, the greatest number of cases is reported during the yearly January-to-February peak of RSV activity.
 - Lesser peaks are observed:
 - During the fall, when parainfluenza virus type 1 is present in the community
 - During the spring, concurrent with the major activity of parainfluenza virus type 3

Age

- Occurs primarily in children within the first 2 years of life.
- >80% of bronchiolitis cases occur during the first year of life.
- Peak attack rate generally occurs:
 - Between 1 and 10 months of age
 - Between 2 and 6 months of age in hospitalized children
- In ambulatory children, the peak attack rate occurs in the second 6 months of life.

Sex

- Boys are approximately 1.5 times more likely than girls to develop bronchiolitis.
- Anatomic and physiologic differences, such as airway tone, may partly explain the male preponderance.

Genetic factors

- May predispose an infant to more severe bronchiolitis
- The following may predispose a patient to more severe disease.
 - Polymorphisms in genes coding interleukins
 - Tumor necrosis factor
 - Other immune mediators
 - An atopic family history
 - Predisposition to hyperreactivity of the airways
 - Native American ancestry

ETIOLOGY

- Bacteria were once thought to be the cause of bronchiolitis.
- Respiratory viruses are now recognized as the major agents of bronchiolitis.
- RSV
 - The most frequently identified cause of bronchiolitis
 - Accounts for approximately 50–85% of cases.
- Parainfluenza viruses (predominantly parainfluenza virus type 3)
 - The next most common agents
- In Monroe County, New York, RSV was isolated from 55% and parainfluenza virus type 3 from 11% of the cases of bronchiolitis examined in pediatric practices.

- Less common causes of bronchiolitis:
 - Rhinoviruses
 - Enteroviruses
 - Influenza viruses
 - Adenoviruses
 - Human metapneumovirus (hMPV)
 - Responsible for 4–10% of lower respiratory tract illnesses in hospitalized children
 - Approximately 3% of the outpatient respiratory illnesses
 - Epidemiologic characteristics and clinical manifestations of bronchiolitis caused by hMPV appear to be very similar to bronchiolitis from RSV.
- Children with bronchiolitis may be infected by >1 virus type simultaneously, usually by viruses that tend to have concurrent or overlapping seasons of circulation.
- Most frequently, the dual infections are caused by:
 - RSV with parainfluenza viruses type 3
 - hMPV 3
 - Influenza
- Respiratory distress arises from:
 - Inflammation of the epithelium
 - Obstruction of the medium and small bronchi and bronchioles
- The viral infection causes:
 - Increased mucus production
 - Edema
 - Necrosis of the bronchiolar epithelium, which is sloughed into the lumen of the small airways
- Because resistance to the flow of air is related inversely to the radius of the lumen, the small diameter of the bronchioles makes the infant particularly vulnerable to obstruction caused by the edema and inflammatory exudate.
- Peripheral to the sites of partial obstruction, air becomes trapped by a process similar to that of a ball valve mechanism.
- During inspiration, the negative intrapleural pressure allows air to flow past the site of partial obstruction.
- On expiration, the positive intrathoracic pressure decreases the diameter of the bronchiolar lumen.
- This causes:
 - An increase in the degree of obstruction
 - Hyperinflation of the lung
- If the inflammation progresses, complete obstruction can occur, and when the trapped air is absorbed, multiple areas of focal atelectasis result.

RISK FACTORS

- Genetic factors may predispose an infant to more severe bronchiolitis.
 - Polymorphisms in genes coding interleukins
 - Tumor necrosis factor
 - Other immune mediators
 - An atopic family history
 - Predisposition to hyperreactivity of the airways
 - Native American ancestry
- Low socioeconomic status
- Exposure to tobacco smoke
- Not being breastfed
- Contact with other young children
 - ≥1 siblings
 - Day care attendance
- Increased risk of bronchiolitis that is severe or requires hospitalization has been associated with:
 - Young age, particularly within the first several months of life
 - Prematurity
 - Low birth weight
 - Cardiopulmonary disease
 - Immunodeficiency

SIGNS AND SYMPTOMS

- Fluctuation of physical findings on examination is characteristic.
- Acute onset of wheezing
 - Auscultation usually reveals wheezing with or without crackles, but findings may vary from hour to hour.
 - Decrease in the auscultatory findings accompanied by increasing respiratory distress may indicate progressive obstruction to the flow of air in the small airways and impending respiratory failure.
- Increased respiratory rate is almost always evident.
 - Tachypnea must be judged on the basis of age.
 - Overall respiratory rate:
 - 50 breaths per minute in full-term newborns
 - 40 breaths per minute at 6 months
 - 30 breaths per minute at 1 year of age
 - Tachycardia commonly accompanies tachypnea.
- Acute inflammation of the airways
- Infants with bronchiolitis typically have a recent history of signs compatible with a common cold:
 - Rhinorrhea
 - Nasal congestion

- A low-grade fever
- Cough
 - More common as infection spreads to the lower respiratory tract
 - Followed by tachypnea
- Fever (in about 50% of infants at diagnosis)
- Clinical appearance
 - Infant may appear irritable, lethargic, or anxious.
 - Signs of increased work of breathing and airway obstruction
 - Flaring of the nasal alae and expiratory grunting
 - Retractions of the chest wall in the subcostal, intercostal, and suprasternal areas
 - Use of the accessory muscles of respiration
 - Prolonged expiration that may be difficult to detect in a young infant who has a rapid respiratory rate
 - Impeded flow of air on inspiration (to a lesser extent)
 - Hyperinflation
 - Increased diameter of the chest
 - Hyperresonance on percussion
 - Liver and spleen may become easily palpable from the downward placement of overinflated lungs.
- Clinical findings may develop from acute complications during the infant's course.
 - Apnea
 - First manifestation of illness in 10–20%
 - Risk of apnea greatest in:
 - Infants of premature gestation
 - Postconceptional age <44 weeks
 - Otitis media
 - Present in 3–30% of infants
 - May be caused by the infecting virus, bacteria, or both
 - Risk of dehydration from:
 - Paroxysms of coughing that trigger vomiting
 - Decreased fluid intake resulting from congested nasal passages
 - Respiratory distress
 - Tachypnea
 - Fever
 - Aspiration
 - Seen frequently in infants hospitalized with RSV bronchiolitis
 - Correlated with an increased risk of subsequent hyperactive airway disease
 - Abrogated by the prophylactic administration of therapy for aspiration

DIFFERENTIAL DIAGNOSIS

- Asthma
 - Wheezing and respiratory distress are associated with both bronchiolitis and asthma in young children.
 - In a single episode, differentiating these 2 entities is often not possible.
 - Both asthma and bronchiolitis may be engendered by viral infection.
 - Differentiation is confounded by the possibility of a link between them.
 - RSV infection in infancy may lead to subsequent wheezing associated with asthma.
 - Previous wheezing episodes and family history of atopy are more suggestive of asthma.
- Gastroesophageal reflux
 - The infant may exhibit episodes of wheezing clinically identical to bronchiolitis.
 - History of the timing of feeding and frequency of wheezing, and lack of upper respiratory tract signs typical of a viral infection, are helpful in differentiating.
- Other entities that may result in wheezing and respiratory distress in the bronchiolitic age group include:
 - Obstruction from an aspirated foreign body
 - A vascular ring
 - Retropharyngeal abscess
 - Significantly enlarged adenoids (rarely)
- Wheezing may also occur in:
 - Congestive heart failure
 - Chronic lung disease (eg, with prematurity or cystic fibrosis)

DIAGNOSTIC APPROACH

- Diagnosis of bronchiolitis is usually based on clinical history and physical findings.
 - Features that strongly support the diagnosis include:
 - Illness occurring during a community outbreak of a major viral agent, mainly RSV
 - Young age (especially <12 months)
 - No prior episode of wheezing
 - Assess risk factors for the development of more severe disease, especially:
 - Presence of prematurity
 - Cardiopulmonary disease
 - Immunodeficiency
 - Other underlying diseases
 - Recent history of signs compatible with a common cold

- Fever
 - Commonly present during the prodromal period and usually not high
 - By the time the child exhibits bronchiolitis associated with RSV, only ~50% are febrile.

LABORATORY FINDINGS

■ Laboratory diagnostic tests

- Not routinely recommended for normal infants at first episode of wheezing
- Except in atypical cases or with abrupt clinical changes, such tests as leukocyte count, arterial oxygen saturation, serum chemistries, and cultures to rule out bacterial infection are generally not helpful or necessary.

■ Pulse oximetry

- Not shown to improve outcomes for infants with bronchiolitis
- Use in hospitalized patients has been associated with:
 - Lower threshold for hospitalization
 - Higher rates of admission to intensive care units and mechanical ventilation

■ Viral identification

- Not routinely recommended
- Assays to identify the specific virus may be warranted:
 - In more severely ill children in whom specific antiviral therapy for RSV or influenza is considered
 - In determining feasible infection control procedures, such as cohorting
- Laboratory assays most commonly used to determine the viral causes are:
 - Isolation in tissue culture
 - Rapid antigen detection assays
- Most of respiratory viruses causing bronchiolitis are identifiable in cell culture within 3–7 days.
- Sensitivity of viral isolation techniques are variable among laboratories and highly dependent on expertise.

■ Rapid viral diagnostic techniques

- Have variable sensitivities
- Should be used only when the virus is prevalent in the community, preferably during peak period of activity
 - Positive predictive value is low when little circulation of the virus occurs in the area.
 - False-positive rate increases as the incidence of the disease in the community falls.
- Detect within hours some types of viruses in respiratory secretions that commonly cause bronchiolitis

- Rapid antigen detection kits are generally not available for the parainfluenza viruses.
- Recent increased use of reverse transcriptase polymerase chain reaction has demonstrated high sensitivity and improvement over viral isolation.

■ Antibody determinations on acute and convalescent sera in young infants are rarely helpful because of:

- Time required to obtain a convalescent serum
- Presence of passive maternal antibody
- Diminished antibody response of young infants to the viral respiratory agents causing bronchiolitis

IMAGING

■ Imaging may be helpful when:

- Diagnosis is not clear
- Course is not as expected

■ It should not be used routinely when:

- The child was previously normal
- Diagnosis can be made based on clinical and historical findings
- Monitoring the course of an infant with bronchiolitis
- Making admission or discharge decisions

■ Findings on chest radiography:

- Are commonly relatively benign
- Do not correlate with severity of illness

■ Classical findings

- Increased bronchovascular markings radiating out from the hila
- Scattered small areas of atelectasis
 - May be mistakenly interpreted as pneumonic infiltration and bacterial infection

■ In prospective studies of children with suspected lower respiratory tract infection, those evaluated with chest x-rays:

- Were more likely to receive antibiotics
- Did not have improved outcome or reduced duration of illness

TREATMENT APPROACH

■ Little agreement exists as to the value and use of therapeutic modalities.

■ Management consists primarily of:

- Supportive care, including adequate rest
- Comfort
- Hydration
- Antipyretics, if necessary

SPECIFIC TREATMENTS

Congestion of nasal passages and upper airway

- May be alleviated by gentle nasal suctioning and positioning
- Mist therapy has not been shown to be beneficial.

Supplemental oxygen

- For the severely affected child who is hospitalized
 - Supplemental oxygen, as indicated by repetitive readings indicating inadequate oxygen saturation
 - No consensus as to the level of oxygen saturation that indicates the need for supplemental oxygen
- Recent bronchiolitis guidelines from the AAP recommend:
 - Initiating supplemental oxygen when the oxyhemoglobin saturation is persistently <90%
 - Consider discontinuing supplemental oxygen when the level is persistently ≥90%

Common therapies

- Frequently used, especially in first-time wheezers, although evidence showing benefit is lacking
- Corticosteroids
- Antivirals
- Antibiotics
- Bronchodilators
 - Studies evaluating their use in bronchiolitis have given variable and contrasting results.
 - Most controlled trials and reviews of β-adrenergic agents have shown:
 - No consistent clinical benefit in children hospitalized with their first episode of wheezing
 - Transient or short-term clinical benefit in outpatients when evaluated by varying clinical score systems
 - AAP recommends that bronchodilators not be used routinely in the management of bronchiolitis, but a carefully monitored trial of inhaled α- or β-adrenergic agents is an option.
 - Bronchodilators should be continued only if a beneficial clinical response is clearly documented.
- Corticosteroids
 - In some facilities, the majority of infants with bronchiolitis are treated with systemic glucocorticosteroids.
 - Meta-analyses have not shown consistent or statistically significant benefit in clinical scores, rates of hospitalization, or outcome.
 - The largest multicenter double-blind randomized trial was conducted in 20 emergency departments and completed in 2006.

- Children 2–12 months of age with a first episode of wheezing from moderate to severe bronchiolitis received >3 respiratory seasons
 - Single dose of oral dexamethasone (1 mg/kg) *or*
 - Placebo
- No significant difference was observed in the requirement for hospitalization.
- The same lack of benefit was observed in subgroups of children with asthma or with family history of asthma.
- AAP recommends that corticosteroid medications not be used routinely for care of infants with a first episode of bronchiolitis.

■ Antivirals

- Few antivirals are potentially useful against the viral agents that cause bronchiolitis.
- Antivirals for influenza have not been approved as therapy for young infants nor evaluated in bronchiolitis.
- Inhaled ribavirin (a synthetic nucleoside)
 - Only agent currently approved for the treatment of RSV lower respiratory tract disease in infants
 - Not recommended routinely to treat children with bronchiolitis
 - Generally should only be considered for use in infants at high risk for severe disease
 - Expensive, difficult to administer to ventilated patients
 - Benefits in clinical outcome are controversial.
 - Use should be decided on an individual basis after consideration of relative benefit to cost.

■ Antibiotics

- Should not be used unless:
 - Bacterial infection is documented *or*
 - Evidence strongly indicates concurrent presence of a bacterial infection.
- Bacterial infection is uncommon in bronchiolitis and RSV lower respiratory tract disease.

■ Chest physiotherapy, including percussion and vibratory techniques:

- Have shown no clinical value
- Are not recommended

WHEN TO ADMIT

- Oral intake is inadequate.
- Child appears toxic or has marked tachypnea or lethargy.
- Respiratory distress is rapidly progressive.
- History suggests apneic episodes.

WHEN TO REFER

- Episodes of bronchiolitis or wheezing are recurrent or started at birth.
- Wheezing continues despite clinical improvement.

COMPLICATIONS

- Apnea
 - Initial manifestation of illness in 10–20% of infants
 - Most at risk of apnea
 - Infants of premature gestation
 - Infants whose postconceptional age is <44 weeks
 - Subsequent prognosis for children with apnea associated with RSV infection is generally good.
 - Does not appear to be associated with increased risk of subsequent apnea, even during subsequent viral infections
- Otitis media
 - Present in 3–30% of infants
 - May be caused by infecting virus, bacteria, or both
- Risk of dehydration from:
 - Paroxysms of coughing that trigger vomiting
 - Decreased fluid intake resulting from congested nasal passages
 - Respiratory distress
 - Tachypnea
 - Fever
- Aspiration
 - Frequent among infants hospitalized with RSV bronchiolitis
 - Correlated with increased risk of subsequent hyperactive airway disease
 - Shown to be abrogated by prophylactic administration of therapy for aspiration

PROGNOSIS

- Most infants improve appreciably within several days.
- Cough and other signs resolve gradually over 1–2 weeks.
- Most hospitalized children are discharged after 3–7 days.
- Radiographic resolution of atelectasis may require several weeks.

- In ambulatory children
 - Median duration has been reported to be 12 days for children <24 months.
 - 18% are symptomatic after 3 weeks.
 - 9% are symptomatic after 4 weeks
- Clinical course tends to be more prolonged in:
 - Young infants
 - Those with underlying conditions
 - Those who acquired the infection nosocomially
- Some studies suggest increase in severity of infection when 2 viruses are present; others do not.
- Despite the increase in hospitalizations, mortality associated with bronchiolitis and RSV has declined.
- Recurrent wheezing
 - The most frequent sequelae of bronchiolitis, especially that caused by RSV
 - Reported in 30–50% of the children hospitalized for bronchiolitis
 - Episodes tend to occur most frequently during the first 2 years after the initial bronchiolitis.
 - Most of these children subsequently improve and become asymptomatic.
- Lung function abnormalities may persist beyond 10 years, despite clinical improvement.
 - Significantly reduced mean expiratory flow rates and increased risk of bronchial hyperreactivity during adolescence have been demonstrated.
 - One episode of bronchiolitis and less severe bronchiolitis not requiring hospitalization have not been associated with later pulmonary abnormalities.
- Relationship between bronchiolitis in early infancy and subsequent hyperreactive airway disease is unclear and confounded by the increasing recognition that asthma or reactive airway disease is a heterogeneous group of disorders with variable pathogenesis.
 - Some follow-up studies have shown that, by school age, risk of hyperreactive airway disease is not greater than in children with no history of bronchiolitis.
- Prognosis for children with apnea associated with RSV infection is generally good.
 - Does not appear to be associated with increased risk of apnea later, even during subsequent viral infections

Bulimia Nervosa

DEFINITION

- Eating disorder involving recurrent episodes of binge eating, along with purging behaviors

EPIDEMIOLOGY

- Prevalence
 - Up to 15% of adolescents report binge eating, purging, or both.
- Sex
 - 2% of female adolescents meet the full diagnostic criteria for bulimia nervosa.
 - 0.3% of male adolescents meet the full criteria.
- Age
 - Symptoms peak at 2–4% among white Western girls and women aged 17–25 years.
 - Modal age of onset is 18–19 years.
 - Occurs rarely in patients <14 years

ETIOLOGY

- Behavior may begin in response to a particular precipitant.
 - Insult by family or friends
 - Exposure to another individual with an eating disorder
 - Stressful situation
- Behavior perpetuated by:
 - Positive psychological feedback that initially accompanies perceived improved appearance
 - Biochemical changes that occur in response to decreased nutrition

RISK FACTORS

- Extreme or frequent dieting
- Early menarche
- Early sexual experiences
- Very early or late puberty and early sexual experiences in boys
- Personal and parental obesity
- Urbanization: occurs at a rate 5 times higher in large cities than in rural areas
- Childhood sexual abuse, especially when psychiatric comorbidity is present
- Premorbid negative self-evaluation
- Stressful life events
- Parental/family factors
 - Parental alcoholism
 - Low parental contact
 - High parental expectations
 - High levels of family conflict
 - Inadequate expression of emotions

- Lack of parental warmth and care
- Inappropriate parental control
- Family history of affective disorders or eating disorders
- Likely genetic factors

SIGNS AND SYMPTOMS

- Recurrent episodes of binge eating, characterized by both of the following:
 - Eating, in a discrete period (eg, within any 2-hour period), more food than most people would eat during a similar period/under similar circumstances
 - Sense of lack of control over eating during the episode (eg, the person feels that she or he cannot stop eating or control what/how much she or he is eating)
- Compensatory behavior to prevent weight gain (at least twice a week for 3 months)
 - Self-induced vomiting
 - Hands should be examined for the Russell sign (ie, irritation on the dorsum of the joints of the fingers used to induce vomiting).
 - Erosion of tooth enamel as a result of vomiting
 - Parotid enlargement
 - Misuse of laxatives, diuretics, enemas, or other medications
 - Fasting
 - Excessive exercise
- Symptoms of malnutrition
 - Cold hands and feet
 - Hair loss
 - Irregular menses
- Symptoms related to purging
 - Heartburn
 - Hematemesis
 - Constipation
 - Diarrhea
- Vital signs: begin initial physical examination with measurements of weight, height, blood pressure, and pulse.
 - Indicators of diet pill use
 - Tachycardia
 - Hypertension
 - Indicators of stimulant laxative or diuretic use
 - Tachycardia
 - Hypotension
 - Excessive exercise may result in significant bradycardia with resting heart.
 - If dehydration needs to be ruled out, measure blood pressure for orthostatic changes (see Diagnostic Procedures).

DIFFERENTIAL DIAGNOSIS

- Other medical causes of weight loss or vomiting
 - Cancer
 - Central nervous system tumors
 - Gastrointestinal problems
 - Malabsorption
 - Celiac disease
 - Inflammatory bowel disease
 - Endocrinologic problems
 - Diabetes mellitus
 - Hyperthyroidism
 - Hypopituitarism
 - Chronic illnesses and chronic infections
 - Superior mesenteric artery syndrome
- Psychiatric causes of weight loss
 - Depression
 - Obsessive-compulsive disorder
 - Psychosis (especially schizophrenia)
 - Sleep disorders
 - Hallucinations, delusions, or obsessions

DIAGNOSTIC APPROACH

- History should include:
 - Frequency of bingeing and purging
 - Maximum, minimum, and usual weight
 - Establish the patient's eating and exercise patterns.
 - Establish vomiting habits.
- Evaluate any medications designed to promote weight loss.
 - Diet pills
 - Laxatives
 - Diuretics
 - Ipecac
- Avoid being misled by the patient; physical examination and laboratory tests suggest the true extent of the disorder.
- The patient may be underweight, overweight, or normal weight.
- Specific abnormalities on physical examination are rarely found; more subtle changes in vital signs, physical examination, and laboratory tests should be sought.
- Full psychosocial history must be obtained to establish diagnosis and the psychosocial severity of the disorder.
 - Patient's functioning in the family, in school, and among peers
 - Possible psychiatric symptoms
 - Sleep disorders
 - Hallucinations, delusions, or obsessions

- Psychosocial changes
 - Fighting with the family
 - Withdrawing from friends
 - Performing less optimally in school, or improved school performance as withdrawal from friends and family intensifies
 - If additional psychiatric symptoms are found, the possibility of an additional diagnosis should be pursued.

LABORATORY FINDINGS

- Blood tests
 - Complete blood cell count with differential
 - Electrolytes and serum chemistries
 - Lipid studies
 - Liver function tests
 - Amylase (levels are elevated)
- Urine tests
 - Urinary pH may be elevated.
 - Urinalysis may reveal:
 - Elevated specific gravity in dehydration
 - Elevated ketones in starvation
 - Increased pH in presence of vomiting
- Hormone tests, if menstrual periods are problematic
 - Thyroid function tests
 - Luteinizing hormone
 - Follicle-stimulating hormone
 - Estradiol
 - Prolactin (if amenorrheic)
- Echocardiography
 - If potassium levels are abnormal
 - If history of ipecac use
- Bone density test for osteopenia
 - If oligomenorrheic or amenorrheic

IMAGING

- Magnetic resonance imaging of the brain, gastrointestinal series, or other tests may be considered in some cases for patients who claim to be eating well or not vomiting on purpose.

DIAGNOSTIC PROCEDURES

- To document orthostatic changes:
 - Check blood pressure and pulse with patient in the sitting position, followed by standing for 2 minutes.
 - Significant changes:
 - Increase of 20 beats per minute in pulse
 - Decrease of 20 mm Hg in systolic blood pressure
 - Decrease of 10 mm Hg in diastolic blood pressure

TREATMENT APPROACH

- Cognitive-behavioral therapy, followed by introduction of medication if necessary, has been suggested as a logical treatment approach.
- Treatment may be difficult for any single professional; a team approach is most often used, consisting of:
 - Primary care physician
 - Psychiatrist
 - Psychologist or social worker
 - Nutritionist
- The exact combination should be determined by local expertise, availability, and preference.
 - Team meetings/discussions should be held frequently to prevent miscommunication that can sabotage the treatment.
- Multimodal therapy
 - Medical management
 - Nutritional rehabilitation
 - Behavior therapy
 - May be difficult when treating in the outpatient setting
 - Classic approaches may not be effective because vomiting cannot be measured readily.
 - Cognitive-behavioral approaches allow patients to understand and participate in their own behavioral therapy.
 - Diaries
 - Modification of daily patterns to effect change
 - Individual psychotherapy
 - Essential part of treatment for most patients
 - Exploration of underlying psychological features and determination of mechanisms for change
 - Psychological change is generally acknowledged to be a necessary precursor to significant improvement.
 - Family therapy
 - Important component of treatment, especially for younger patients
 - Family conflicts and problems play a major role in symptom continuation.
 - Sessions arranged in varying combinations to include parents and siblings
 - General focus on disordered communication patterns
 - Resolution of specific conflicts arising from the eating disorder itself is important.
 - The course of the disorder is much more difficult for adolescents whose families are unable or unwilling to make needed changes in their customary patterns of communication and parenting.

- Group therapy
 - For college-aged patients, may be the only approach used
 - Groups may focus on either:
 - Psychotherapeutic approach
 - Behavioral changes
 - Benefits outweigh the risks of learning bad habits from others in the group.
- Psychopharmacology
- The degree to which each of these is used varies by preferences of the treatment team and requirements of the individual patient.
- Each of these approaches may be used for inpatients, day-program patients, and outpatients.
- If hospitalization is necessary for uncontrolled binge or purge cycles, abnormal electrolytes, or unstable vital signs, then supervision after meals, locked bathrooms, and restricted access to food are often needed.

SPECIFIC TREATMENTS

Dietary plan

- An appropriate meal pattern may be developed on the basis of the patient's and family's prior eating habits or a specific dietary plan offered by the physician or nutritionist.
- The plan should be specific so as to avoid ambiguities that can lead to family fighting.
- The plan should provide 2000–3000 calories daily.
 - Some may be supplied as high-calorie supplements.
 - A similar dietary plan without high-calorie supplements may be offered to healthy-weight bulimic patients, who require nutritional adjustment rather than nutritional rehabilitation.
 - Caloric requirements depend on need for weight gain, loss, or maintenance.
- Because caloric restriction may spark binge eating, a nonrestrictive well-balanced diet should be implemented.
- The diet should be balanced and include foods from each major food group.
- Outpatient gains should be 1–2 pounds per week.
- Inpatient gains may be 2–4 pounds per week.
- Compliance may be evaluated with a diet diary, but many patients do not keep records accurately and honestly.

Psychopharmacologic treatments

- Selective serotonin reuptake inhibitor (SSRI) antidepressants
 - Can treat concurrent psychiatric disorder
 - May diminish the urge to binge and purge and help treat obsessive-compulsive symptoms

- Only physicians familiar with the use of these should prescribe them, given concerns about associated increased risk of suicide in a minority of children and adolescents.
- Not effective in treating symptoms of depression or obsessive-compulsive disorder when body weight is low
- Atypical antipsychotic agents at low doses can improve weight gain and treat symptoms of depression and obsessional thoughts.
 - Other antidepressant medications, roughly equivalent to SSRIs
 - Tricyclics
 - Monoamine oxidase inhibitors
 - Fluoxetine at 60 mg per day
 - Anticonvulsants— see modest changes in symptoms
- To restore menses:
 - Generally requires estradiol level >30 mg/dL

WHEN TO ADMIT

- ≥1 of the following:
 - Severe malnutrition (body weight < 75% ideal)
 - Dehydration
 - Electrolyte disturbances
 - Cardiac disturbances
 - Physiologic instability
 - Bradycardia
 - Hypotension
 - Hypothermia
 - Orthostatic changes
 - Arrested growth and development
 - Failure of outpatient treatment
 - Acute food refusal
 - Uncontrollable bingeing and purging
 - Acute medical complication of malnutrition
 - Syncope
 - Seizures
 - Cardiac failure
 - Pancreatitis
 - Acute psychiatric emergencies
 - Suicidal ideation
 - Acute psychosis
 - Comorbid diagnosis that interferes with treatment
 - Severe depression
 - Obsessive-compulsive disorder
 - Severe family dysfunction

WHEN TO REFER

- Refer to a dietician if the primary care physician or staff does not have the expertise or time to set a nutritional plan.
- Refer to a psychotherapist if:
 - The patient is open to therapy.
 - The patient cannot attain goals set by the physician, even if the patient is resistant to psychotherapy.
 - Refer for psychopharmacologic evaluation if both the physician and the therapist believe that patient might benefit from medication if:
 - The patient is bingeing and open to medication.
 - Obsessive-compulsive symptoms are interfering with treatment.
- Refer to adolescent medicine if:
 - The physician is not comfortable treating the patient.
 - The physician does not have the time to treat.
 - The patient does not adhere to the physician's treatment plan.

COMPLICATIONS

- Hypertension or hypotension
- Electrolyte abnormalities
- Dehydration
- Erosion of dental enamel
- Calluses on the dorsum of the hand
- Parotid enlargement
- Acute pancreatitis
- Acute gastric dilatation or rupture
- Mallory-Weiss tears
- Gastric and esophageal irritation
- Gastric and esophageal bleeding
- Gastroesophageal reflux disease
- Barrett esophagus
- Aspiration pneumonia
- Diarrhea, constipation, steatorrhea
- Emetine cardiomyopathy
- Menstrual irregularity
- Polycystic ovarian syndrome
- Osteopenia, osteoporosis

PROGNOSIS

- Approximately 50% of patients recover.
- 30% experience relapse.
- 20% continue to meet the full criteria for bulimia nervosa 5 years after diagnosis.

PREVENTION

- Programs geared toward both teenage boys and girls, primarily in school settings
 - Aimed at maintaining healthy body image, healthy eating
 - Try to promote self-esteem without relation to weight
 - Succeed in terms of increasing awareness and knowledge about eating disorders
 - Effectiveness is debatable.
- Programs focused on building self-esteem/comprehensive school-based approach
 - Classroom interventions
 - Staff training throughout the school
 - Informal discussions between staff and students
 - Integration of material about eating issues into the curriculum
- More intensive work with persons at high risk
- Changes in the school with respect to cafeteria food and physical education
- Referrals and outreach, both within the school and to the community
- Early case detection and treatment are the most effective preventive measures.
 - Treatment will be easier.
 - Disease will be less entrenched.
 - Families, friends, school personnel, and health professionals must be vigilant for signs of an eating disorder so that early treatment can be initiated.

Cancers in Childhood

DEFINITION

- Solid tumors seen in children include:
 - Wilms tumor: malignant renal tumor
 - Neuroblastoma: arises from fetal neural cells that normally develop into the sympathetic nervous system
 - Retinoblastoma: congenital malignant tumor of the retina
 - Rhabdomyosarcoma: tumor that can occur almost anywhere, including sites not normally containing skeletal muscle; can be aggressive and disseminate early
 - Germ cell tumors and teratomas: growths arising from primordial germ cells
 - Ewing family of tumors: Ewing sarcoma of bone, extraosseous Ewing tumor, and peripheral primitive neuroectodermal tumors (PNETs)
 - Malignant tumors that usually arise in bone but may also occur in soft tissues
 - PNET of the chest wall is referred to as *Askin tumor*.
 - Osteosarcoma: bone tumor
 - Non-Hodgkin lymphoma (NHL): heterogeneous group of cancers arising from lymphocytes and lymphoid precursors
 - Migratory; occur at variable sites
 - Lymphoblastic lymphoma (30% of cases)
 - Anaplastic large-cell (10%)
 - Burkitt (40%)
 - Diffuse large B-cell (20%)
 - Hodgkin disease: cancer of the lymphoreticular system characterized by multinucleated giant cells, known as *Reed-Sternberg cells*

EPIDEMIOLOGY

Wilms tumor

- Prevalence
 - Most common abdominal tumor of childhood (5–6% of pediatric cancers)
- Incidence
 - 600–700 new cases diagnosed each year in the US
- Age/sex/race
 - Patients usually 2–5 years of age
 - Rare in teenagers
 - Bilateral disease more common in younger patients and in girls
 - Occurs more often in black patients than in white patients

Neuroblastoma

- Prevalence
 - Second most common abdominal tumor of childhood; most common extracranial solid tumor
 - Most common cancer of infants, accounting for more than one half of cancer cases in infants

- Accounts for 7% of all children with a cancer diagnosis
- Accounts for 15% of childhood cancer mortality

Age/race

- 90% of patients are <5 years.
- 97% of patients receive a diagnosis before 10 years of age.
- Approximately 9.7 white children and 7.4 black children per million in the US diagnosed yearly (800–900 new cases/year)

Retinoblastoma

■ Prevalence

- Unilateral disease is a sporadic form of the tumor in 90% of patients with this presentation; the other 10% have familial retinoblastoma.
- Bilateral disease present in 30–40% of patients.

■ Incidence

- 350 children in the US annually

■ Age

- Diagnosed in 95% before age 4 years; median age of diagnosis is 2 years
- Bilateral disease occurs at an earlier age.

Rhabdomyosarcoma

■ Prevalence

- Accounts for 2–4% of childhood cancers and 5–15% of childhood solid tumors

■ Incidence

- Annual incidence among children (≤18 years of age) in the US is 4.5 per million.
- 400 new cases diagnosed each year

■ Age/sex/race

- 40% are <5 years.
- 47% are 5–14 years.
- The remainder are >15 years.
- Incidence is greater in boys than in girls.
- More common in white patients than in black patients

Germ cell tumors/teratomas

■ Prevalence

- 3% of tumors in children
- Sacrococcygeal teratoma: benign in 80% of patients; occurs in 1/35,000 live births

■ Incidence

- Annual incidence of 4 cases per million children <15 years

■ Age/sex

- Incidence of sacrococcygeal teratoma is greatest in adolescents and very young children.
- Sacrococcygeal teratoma is more common in girls than in boys (2:1 to 4:1).

Ewing family of tumors

- Prevalence
 - 3% of childhood cancers
- Age/race
 - Most common bone tumor in children <10 years
 - Peak incidence between 11 and 17 years (7 per million per year)
 - Ewing sarcoma is extremely rare in patients <5 years, as well as in black and Asian persons.

Osteosarcoma

- Prevalence
 - Most common bone tumor in children: 8.7 per million
 - Comprises 60% of malignant bone tumors
- Incidence
 - Approximately 400 patients diagnosed per year in the US
- Age/sex
 - Peak incidence is at age 14.5 for boys and 13.5 for girls, corresponding to growth spurts, although disease can occur before puberty and after the adolescent growth spurt.
 - Male-to-female ratio of approximately 1.5:1

NHL

- Prevalence
 - Accounts for approximately 10% of childhood cancer cases
 - 60% of lymphomas are NHLs.
- Age/sex
 - Incidence low in children <5 years and then increases
 - More common in boys than in girls (2:1 to 3:1)
 - Greatest sex difference in Burkitt lymphoma; male-to-female ratio is approximately 4.5:1

Hodgkin disease

- Prevalence
 - 6% of cancers in children
- Incidence
 - 600 cases diagnosed in the US each year
- Age/sex/race
 - Two age peaks: 15–30 years of age and late adulthood
 - Extremely rare before 5 years
 - Male predominance throughout preadolescent age range; thereafter, incidence approximately equal in both sexes
 - In older teenagers and young adults, disease is most common among white persons.

ETIOLOGY

- Wilms tumor
 - Anomalies are reported in 13–28% of affected patients.
 - Most involve the genitourinary (GU) tract.
 - Hemihypertrophy is second in frequency, sometimes noted as a component of the Beckwith-Wiedemann syndrome (excessive growth of many body organs).
 - 33% of children with the sporadic form of congenital aniridia have Wilms tumor.
 - Syndromes are associated with germ-line mutations of the *WT1* gene, located at 11p13.
 - WAGR syndrome: association of Wilms tumor, aniridia, GU abnormalities, and mental retardation
 - Denys-Drash syndrome: association of Wilms tumor with ambiguous genitalia and diffuse glomerular disease
 - A second Wilms tumor suppressor locus may be at 11p15; this is also the locus for the familial form of Beckwith-Wiedemann syndrome.
 - Loss of heterozygosity at 1p and 16q has been identified.
- Neuroblastoma
 - May be related to abnormal maturation of fetal neural crest cells
 - Possible prezygotic germinal mutation
- Retinoblastoma
 - Two independent mutations occur in a single retinal cell.
 - Possibly due to abnormalities of chromosome 13q14
 - Possible role of human papillomavirus in sporadic retinoblastoma
- Rhabdomyosarcoma
 - The cause is unknown.
 - Possibly due to mutations in at 11p15 and to chromosomal translocation, t(2:13)
- Germ cell tumors/teratomas
 - Aberrant path of migration: extragonadal germ cell tumors along the dorsal wall of the embryo in midline sites (sacro-coccygeal, retroperitoneal, mediastinal, and pineal regions)
 - Association with a family history of twinning resulted in early theories suggesting that teratomas were abortive attempts at the development of twins.
- Ewing family of tumors
 - Chromosomal translocation, t(11:22) and gene fusion rearrangements
- Osteosarcoma
 - Abnormality at the *Rb* gene; mutation or loss of *RB1* gene
 - Inactivation of *p53* tumor suppressor gene
 - Other chromosomal abnormalities

■ NHL

- Epstein-Barr virus (EBV) or other viral infection may be a contributing factor.
- Immunodeficiency
 - Defect of T-cell regulation
- Genetic
 - Chromosomal aberrations in Burkitt lymphoma
 - Several specific, nonrandom chromosomal abnormalities have been reported in lymphoblastic lymphoma and large-cell lymphomas.

■ Hodgkin disease

- Possible genetic role
- Possible environmental role
- EBV may play a role.
- Underlying immunodeficiency may be involved.

RISK FACTORS

■ Wilms tumor

- May occur in siblings, cousins, and parent-child pairs, particularly in association with specific congenital anomalies and bilateral disease
- Genetic predisposition (15–20% of cases)

■ Neuroblastoma

- Reported to occur with increased incidence in patients with Hirschsprung disease

■ Lymphomas

- Immunosuppressive therapy for renal, cardiac, or bone marrow allografts

■ Osteosarcoma

- Irradiation to the bone, usually for treatment of cancer
- Presence of 1 tumor already
- Hereditary retinoblastoma

SIGNS AND SYMPTOMS

Wilms tumor

- Painless mass that is usually firm, occasionally lobulated, and confined to one side of the abdomen
- Occasionally:
 - Rapid abdominal enlargement
 - Anemia
 - Hypertension (perhaps because of a sudden subcapsular hemorrhage)
- Malaise
- Abdominal pain
- Hematuria
- Fever

Neuroblastoma

- Presenting features largely depend on the location of the tumor.
 - Large, firm, irregular abdominal mass that may cross the midline is often the first sign of disease.
 - Disturbances of bowel or bladder function, possibly from compression by a pelvic mass
 - Cough or respiratory distress, thoracic mass
 - Horner syndrome or heterochromia iridis
 - Dumbbell-shaped mass along backbone, neuroblastomas that arise in the paravertebral ganglia and grow into the intervertebral foramina
- Spinal cord compression may cause pain, extremity weakness, paralysis, or incontinence (difficult to assess if the patient is still in diapers).
 - Cord compression is an emergency requiring surgical decompression, radiation, or chemotherapy to prevent paraplegia.
- If there is hepatic involvement in infants, marked abdominal distention may be followed by respiratory compromise.
- Bluish skin nodules are sometimes noted in infants who have neuroblastoma.
 - Palpation causes erythematous cutaneous flush, lasting for 2–3 minutes, followed by vasoconstriction and blanching.
- Pain, if bone involvement in skull, orbit, or proximal long bones
- Raccoon-like appearance if there is orbital involvement
- In infants with intracranial disease, separation of cranial sutures
- Fever
- Malaise
- Failure to thrive
- Opsoclonus-myoclonus (rapid, dancing-eye movements) is an unusual symptom.

Retinoblastoma

- Abnormal red reflex (leukocoria)
 - *Leukocoria* (cat's-eye reflex) describes a whiteness detected in the pupillary area caused by a large retrolental mass.
- Strabismus
- In rare cases, pain in the eye

Rhabdomyosarcoma

- Disturbance of a normal body function (due to tumor)
- Pain at site of tumor
- Orbital tumor
 - Swelling
 - Proptosis
 - Discoloration
 - Limitation of extraocular motion

■ Head and neck tumor

- Hoarseness
- Difficulty swallowing
- Nasopharyngeal polyps
- Nasopharyngeal obstruction
- Decreased hearing acuity
- Persistent otitis
- Sinusitis, bloody nasal discharge
- Parotitis
- Cranial nerve palsies
- Headache
- Vomiting
- Diplopia

■ Retroperitoneal tumor

- Mass or partial or complete bowel obstruction

■ GU tumor

- Vaginal bleeding
- Pelvic or perineal masses
- Hematuria
- Urinary frequency
- Urinary retention
- May be extruded from the bladder or female genital tract

■ Paratesticular

- Hydrocele
- Incarcerated hernia
- Testicular torsion or testicular mass

■ Pain, difficulty, or refusal to ambulate resulting from bone metastases

■ Fever

■ Fatigue

■ Weight loss

Germ cell tumors/teratomas

■ Sacrococcygeal tumors

- Mass between the anus and the coccyx
- Abnormality of the overlying skin may be noted.
- Intrapelvic tumor may be associated with an external tumor or may be noted by urinary or rectal obstruction.

■ Ovarian tumors

- In infants, present as abdominal mass
- Older girls
 - Abdominal pain
 - Nausea
 - Vomiting
 - Constipation

– Urinary tract obstruction

– Palpable mass noted in 50%

– Acute abdominal pain

– Vaginal tumors in girls <3 years may cause bloody vaginal discharge.

■ Testicular tumors

- Symptom-free scrotal masses
- Torsion in an undescended testis may result in acute abdominal pain.

■ Retroperitoneal teratomas

- In children >2 years
 - Anorexia
 - Vomiting
 - Abdominal pain

■ Tumors of the anterior mediastinum

- Coughing
- Wheezing
- Dyspnea
- Chest pain

■ Intrapericardial tumors

- Heart failure and cardiac tamponade

■ Cranial tumors

- In infants
 - Hydrocephalus
 - Intracranial pressure
- Teenagers
 - Headaches
 - Lethargy
 - Vomiting
 - Diabetes insipidus
 - Seizures
 - Visual disturbance, especially loss of upward gaze

Ewing tumors

■ Pain

■ Swelling

■ Symptoms may initially be attributed to trauma.

■ Palpable mass (in 60% of patients)

Osteosarcoma

■ Bone pain is ubiquitous.

■ Palpable masses

■ Swelling

■ Limited motion

■ Fractures (rare)

NHL

- Localized lymphadenopathy
- Patients with mediastinal masses: history of cough and, occasionally, acute respiratory distress
 - Obstruction can occur during evaluation, even in patients who have few symptoms, particularly with administration of sedation.
 - Obstruction may involve the lower airway, beyond the reach of an endotracheal tube, resulting in an inability to effectively ventilate the lungs.
- Abdominal mass that may involve the ileocecal region, mesentery, ovaries, or retroperitoneum is seen in 30–40% of patients
- Large-cell lymphomas may produce peripheral adenopathy.

Hodgkin lymphoma

- Bone pain is ubiquitous and commonly associated with trauma.
- Palpable masses
- Swelling
- Limited motion
- Weight loss/other systemic effects are rarely seen; if present, overt metastasis is likely.
- Fractures (uncommon)
- Cough, chest pain, and dyspnea may occur with extensive pulmonary metastases.

DIFFERENTIAL DIAGNOSIS**Differential diagnosis of abdominal and pelvic tumors**

- Wilms tumor
 - Age: preschool
 - Clinical signs: unilateral flank mass, aniridia, hemihypertrophy
 - Lab findings: hematuria
- Neuroblastoma
 - Age: preschool
 - Clinical signs: gastrointestinal (GI) or GU obstruction, raccoon eyes, opsoclonus-myoclonus, diarrhea, skin nodules (infants)
 - Lab findings: increased vanillylmandelic acid, increased homovanillic acid, increased ferritin, stippled calcification in mass
- NHL
 - Age: >1 year
 - Clinical signs: intussusception in those >2 years
 - Lab findings: increased urate
- Rhabdomyosarcoma
 - Age: Any

- Clinical signs: GI or GU obstruction, sarcoma botryoides, vaginal bleeding, paratesticular mass
- Lab findings: none

Germ cell or teratoma

- Age: preschool, teens
- Clinical signs
 - Girls: abdominal pain, vaginal bleeding
 - Boys: new-onset testicular mass, hydrocele, sacrococcygeal mass or dimple
- Lab findings: increased human chorionic gonadotropin (hCG), increased a-fetoprotein (AFP)

Hepatoblastoma

- Age: birth to 3 years
- Clinical signs: large, firm liver
- Lab findings: increased AFP

Hepatoma

- Age: school age, teens
- Clinical signs: large, firm liver; hepatitis B, cirrhosis
- Lab findings: increased AFP

Differential diagnosis of head and neck tumors**NHL**

- Age: >1 year
- Clinical signs: lymphadenopathy not responsive to antibiotics, immunodeficiency, EBV (in Africa)
- Lab findings: increased urate

Hodgkin disease

- Age: >10 years
- Clinical signs: lymphadenopathy not responsive to antibiotics; weight loss, night sweats, fever, pruritus
- Lab findings: increased erythrocyte sedimentation rate (ESR)

Rhabdomyosarcoma

- Age: all
- Clinical signs: orbital mass, hoarseness, persistent otitis, sinusitis
- Lab findings: none

Neuroblastoma

- Age: preschool
- Clinical signs: heterochromia iridis, Horner syndrome, opsoclonus-myoclonus, raccoon eyes, skin nodules (infants)
- Lab findings: increased homovanillic acid, vanillylmandelic acid, or both in urine; calcification

Retinoblastoma

- Age: preschool

- Clinical signs: cat's-eye reflex, strabismus, family history
- Lab findings: calcification

Differential diagnosis of tumors of the extremities

■ Ewing sarcoma

- Age: ≥ 5 years
- Clinical signs: pain, swelling; genitourinary or skeletal anomaly; weight loss, fever; malaise (metabolic)
- Imaging: onionskin appearance on roentgenography

■ Osteogenic sarcoma

- Age: teens
- Clinical signs: pain, swelling; familial retinoblastoma; prior radiation to bone; Paget disease
- Imaging and lab findings: Codman triangle (cortical elevation, new bone formation); sunburst ossification of soft tissue; soft-tissue mass; increased alkaline phosphatase level

■ Lymphoma

- Age: all
- Clinical signs: pain

■ Fibrosarcoma

- Age: infants, teens
- Clinical signs: painless mass; prior radiation; plastic implant

■ Rhabdomyosarcoma

- Age: all
- Clinical signs: mass

■ Synovial sarcoma

- Age: teens
- Clinical signs: mass
- Laboratory findings: calcification (40%)

Differential possibilities

■ Retinoblastoma

- Coats disease
- Retrolental fibroplasia
- Persistent hyperplastic primary vitreous
- Toxoplasmosis
- *Toxocara canis* infection
- Other causes of severe uveitis

■ Germ cell tumors/teratomas

- Sacrococcygeal masses: meningocele
- Abdominal or pelvic masses
 - Neuroblastoma
 - Wilms tumor
 - Rhabdomyosarcoma

- Lymphomas
- Hydronephrosis
- Benign ovarian cysts
- Constipation
- Splenomegaly

• Anterior mediastinal tumors

- T-cell lymphoma
 - Leukemia
 - Thymoma
- ##### • Intrascrotal mass
- Testicular torsion
 - Epididymitis
 - Testicular infarction

■ Ewing sarcoma

- Osteosarcoma
- Osteomyelitis
- Benign bone tumors
- Bone cysts
- Lymphoma
- Leukemia
- Neuroblastoma
- Rhabdomyosarcoma

■ NHL

- Other causes of cervical adenopathy
 - Hodgkin disease
 - Neuroblastoma
 - Leukemia
 - Nasopharyngeal carcinoma
 - Rhabdomyosarcoma
 - Thyroid carcinoma
- Anterior mediastinal masses
 - T-cell leukemia
 - Thymoma
- Abdominal masses
 - Constipation
 - Splenomegaly
 - Wilms tumor
 - Rhabdomyosarcoma
 - Neuroblastoma
 - Lymphoma (rare bone tumor)

DIAGNOSTIC APPROACH

■ Wilms tumor

- Begin with history and physical examination.
- Pay particular attention to the associated congenital anomalies and the family history.

■ Neuroblastoma

- Initial physical examination followed by imaging and biopsy

■ Retinoblastoma

- Examination under anesthesia after dilating the pupils is necessary to evaluate the retina.
- Enucleation may be necessary for diagnosis and treatment when disease is unilateral.
- The extent of local disease (extension beyond the globe or optic nerve infiltration) is assessed at the time of enucleation.
- For high-risk patients, bone marrow and cerebrospinal fluid specimens are obtained for evidence of dissemination.

■ Rhabdomyosarcoma

- Initial evaluation should include complete history and physical examination.
- Follow with roentgenography, computed tomography (CT) or magnetic resonance imaging (MRI), and in some instances (eg, GU tract) ultrasonography of involved and adjacent areas.
- Biopsy of the lesion establishes the diagnosis and should be performed before extensive resection.

■ Germ cell tumors/teratomas

- Identified through physical examination
 - In cases of sacrococcygeal mass or abdominal pain, particular attention should be paid to the abdominal and rectal examination.
- Pelvic examination (under anesthesia in young girls) is necessary if ovarian or vaginal tumor is suspected.

■ Ewing sarcoma

- Radiograph should be obtained if:
 - Mass is overlying bone *or*
 - In the presence of bone pain not characteristic of trauma (by lack of history or duration of symptoms)
- Possibility of bone marrow involvement should be evaluated by bilateral bone marrow aspirates and biopsies.
- Identification of micrometastases in the bone marrow by polymerase chain reaction may identify high-risk patients without other evidence of metastases.
- Cerebrospinal fluid should be examined in patients who have parameningeal tumors.
- Biopsy of the lesion is necessary to establish the diagnosis.
 - If possible, tissue should be obtained from soft tissue rather than from cortical bone to reduce potential for pathologic fracture.

■ Osteosarcoma

- Biopsy should be performed by an orthopedic surgeon.
- CT or MRI is used to define extent of primary lesion.

■ NHL

- Complete resection of diseased area is not necessary.
- Lumbar puncture should be performed with cytocentrifugation of cerebrospinal fluid to detect meningeal involvement.

■ Hodgkin disease

- Begin assessment with complete history and thorough physical examination.
 - Particular attention should be paid to B disease symptoms.
- Lymphatic areas to be evaluated include Waldeyer ring and the cervical, supraclavicular, axillary, and inguinal lymph nodes.
 - Node size and presence of tenderness should be noted and recorded carefully.
- A thorough abdominal examination should be performed, particularly to evaluate liver and spleen size; retroperitoneal lymph nodes are not palpable.
- Bone marrow biopsies should be performed in all but those with stage IA or IIA disease.
- Define subdiaphragmatic involvement when radiotherapy is the primary therapeutic modality.

LABORATORY FINDINGS

■ Wilms tumor

- Laboratory studies should include a complete blood count, urinalysis, and renal and liver function tests.
- In some cases, polycythemia or hypocalcemia is present.

■ Neuroblastoma

- Evaluate amplification of the *N-myc* oncogene (poor prognosis); a DNA index >1 indicates disease that is sensitive to chemotherapy (good prognosis).
- The following are confirmatory in patients who have a small round blue cell infiltrate in bone marrow:
 - Increased levels of vanillylmandelic acid and homovanillic acid in 24-hour urine samples
 - Increased vanillylmandelic acid–creatinine or homovanillic acid–creatinine ratios in spot urine samples
 - Ferritin and lactic dehydrogenase levels predict a poor prognosis if increased.

■ Germ cell tumors/teratomas

- Serum AFP and β -hCG should be assayed before surgery.
- Detection of AFP or β -hCG improves ability to monitor the disease status.
 - Rate of disappearance after resection reflects adequacy of the tumor removal.
 - With response to chemotherapy, levels decrease.
 - A significant increase suggests disease recurrence.

■ Osteosarcoma

- Baseline lactic dehydrogenase and alkaline phosphatase levels should be obtained.
- Osteoid found within a sarcomatous tumor is a characteristic histologic pattern.
- Osteosarcoma in the child or adolescent is usually a high-grade tumor characterized by osteoblasts that demonstrate pleomorphism and bizarre mitoses.

■ NHL

- Enzyme studies (terminal deoxynucleotidyl transferase) or gene rearrangement studies may be helpful as are cytogenetic studies, if possible.

■ Hodgkin disease

- Blood cell counts may show:
 - Anemia (caused by hemolysis or chronic disease)
 - Abnormal neutrophil count
 - Thrombocytopenia
- Increased ESR, serum copper level, and ferritin level (in some patients)
- Serum hepatic alkaline phosphatase isoenzyme may be increased.

IMAGING

Wilms tumor

■ Plain-film radiography of the abdomen may show:

- Coarse calcifications, unlike the fine, stippled pattern commonly seen in neuroblastoma
- A mass effect may be noted.

■ Chest radiograph should be obtained; it may demonstrate pulmonary nodules.

■ Ultrasonography is often performed first.

- Particularly helpful in evaluating the renal vein, vena cava, and the right side of the heart for tumor spread.

■ Abdominal CT with contrast

- Studies may reveal an intrarenal mass displacing and distorting the collecting system of the involved kidney.
- Tumors may be very large.
- Minimal kidney parenchyma may be identified.

■ Chest CT

- Should be performed before surgery to detect small pulmonary metastases
- Postoperative atelectasis can obscure metastatic nodules.

■ Liver metastases may be diagnosed either by ultrasonography or by CT.

■ Intravenous pyelography generally is not indicated.

■ MRI may occasionally be indicated to define the extent of the tumor.

■ Bone scans indicated if there is clear cell sarcoma of the kidney (which often spreads to bone).

Germ cell tumors/teratomas

- CT of benign germ cell tumors often reveals calcifications.
- Chest CT and bone scan should be performed to detect pulmonary and bony metastases.
- Teratoma frequently shows cystic and solid, including fat, components on radiologic examination.
- Malignant germ cell tumors often have areas of hemorrhage and necrosis.

Neuroblastoma

- Radiologic examination of the area of primary disease, as well as of areas to which neuroblastoma metastasizes
- CT of the abdomen, pelvis, and chest
 - In cases with cervical masses, CT should include this area.
- MRI should be performed on any patient with intervertebral lesions, because paravertebral lesions may extend into the intervertebral foramina.
- Skeletal survey and a bone scan should be performed to detect bony lesions.
 - Radiography is useful for detecting small lytic lesions at the end of bones.
 - Bone scan helps identify lesions of the skull and tubular bones.
- Positron emission tomography (PET) may also be helpful.

Retinoblastoma

- Ultrasonography is useful to evaluate the mass, particularly if the fundal examination is obscured by hemorrhage or retinal detachment.
- Calcification may be apparent on radiography, ultrasonography, or CT.
- CT helps demonstrate the extent of intraocular disease and may detect possible extraocular extension.
- MRI can help to evaluate the tumor involvement with the optic nerve, the subarachnoid, and the brain.

Rhabdomyosarcoma

- In GU disease, cystourethrography and barium enema may be needed.
- Dental films may be helpful.
- Bone surveys, bone scans, and chest and abdominal CT are necessary to assess for metastatic disease.
- Basal skull erosion may be seen on CT.
- If spinal cord symptoms present, spinal MRI is necessary.

Ewing sarcoma

- CT and MRI are necessary to determine the extent of the primary lesion.
 - Radiography often shows a destructive lesion in the diaphysis.
 - An onionskin appearance arises from periosteal elevation and subperiosteal new bone formation associated with tumor extension through the cortex.

- A mottled pattern may be seen as a result of bone destruction, sclerosis, and cystic formation.
- Associated soft-tissue mass occurs in >50% of patients who have primary tumors of long bones.
- Radionuclide bone scanning can detect primary/metastatic lesions.
- CT of the chest is necessary to determine whether pulmonary lesions are present.

Osteosarcoma

- Radiographs of involved bone may show:
 - Bony destruction with periosteal new bone formation
 - Characteristic sunburst appearance
 - Soft-tissue swelling
 - Necrosis, fibrosis, and calcification
- The extent of the primary lesion is defined further by CT or, preferentially, by MRI.
- Metastatic disease in the lung should be sought by CT (present in 80% of patients with metastases).
- Bone scans can be helpful for outlining primary tumor and detecting multiple primary lesions and metastasis.
- PET may be helpful.

NHL

- Imaging studies should include chest radiograph and CT of the chest and abdomen in all patients.
- Bone scans and gallium scans can be helpful in selected patients, although positron emission tomography (PET) is also being used.

Hodgkin disease

- Chest radiograph and CT of the chest and abdomen
- Gallium scanning
- PET is becoming routine, although it may be most applicable for monitoring response and recurrence as opposed to staging.
- Bone scan should be considered in advanced disease, particularly in the presence of bone pain or increased serum alkaline phosphatase level.

DIAGNOSTIC PROCEDURES

- Wilms tumor
 - Tumor staging upon surgery: favorable histology (FH) or unfavorable histology (UH)
 - FH indicates absence of unfavorable features.
 - UH indicates presence of focal or diffuse anaplasia, defined by the presence of gigantic polyploid nuclei in the tumor sample.
- Neuroblastoma: biopsy and histology
 - In localized disease, a biopsy specimen must be obtained from primary tumor.

- In metastatic disease, neuroblastoma cells can be identified in the primary tumor or in areas of metastases, including the bone, bone marrow, or liver.
- Neuroblastoma produces small round cells with scant cytoplasm that must be differentiated from lymphoma, leukemia, Ewing sarcoma, and retinoblastoma.
- Osteosarcoma: biopsy and histology
 - The biopsy site is of critical importance and should be performed by an orthopedic surgeon with experience in oncology.
 - Osteoid found in a sarcomatous tumor is the characteristic histologic pattern.
 - Osteosarcoma in the child or adolescent is usually a high-grade tumor characterized by osteoblasts that demonstrate pleomorphism and bizarre mitoses.
 - Necrosis, fibrosis, and calcification may be noted.
- NHL
 - Surgical biopsy
 - If adenopathy is present, removal of the most suspicious node is suggested.
 - Biopsy may be contraindicated if large mediastinal masses pose an imminent possibility of airway obstruction, unless endotracheal intubation will ensure airway patency.
 - If distal end of endotracheal tube lies proximal to the mass, localized radiation to the mediastinum may be necessary before specimen is obtained.
 - Alternative sites for obtaining specimens must then be considered.
- Hodgkin disease biopsy
 - Histology defines the 4 subtypes:
 - Nodular sclerosing subtype
 - Has collagenous bands that divide the lymphoid tissues into nodules and the presence of a lacunar variant of the Reed-Sternberg cell
 - Lymphocyte-predominant subtype
 - Characterized by destruction of the lymph node architecture, with cellular proliferation of benign-appearing lymphocytes
 - Reed-Sternberg cells are rarely found in the absence of fibrosis.
 - Disease is usually localized.
 - Mixed-cellularity subtype
 - Lymph node architecture is not preserved.
 - Approximately 10 Reed-Sternberg cells are seen per high-power field, often with interstitial fibrosis.
 - Necrosis is not pronounced.

- Lymphocyte-depleted subtype
 - Characterized by presence of fibrosis, necrosis, and abnormal cells (but only a rare lymphocyte)
 - Rare in children

CLASSIFICATION

Staging of Wilms tumor

- Stage I: Tumor is limited to the kidney and completely resected.
- Stage II: Tumor extends beyond the kidney but is completely resected. Isolated tumor spill may exist confined to the flank.
- Stage III
 - Residual, nonhematogenously spread tumor is confined to the abdomen.
 - Unresectable tumors
- Stage IV: Hematogenous metastases are present.
 - Lung (only site in 80% of patients who have metastases)
 - Liver
 - Lymph node
 - Less commonly, bone, brain, and other sites
- Stage V: Bilateral renal involvement is present; for treatment purposes, each side is staged.

Neuroblastoma: International Neuroblastoma Staging System

- Stage 1: tumors with complete gross resection and microscopically negative ipsilateral and contralateral lymph nodes
- Stage 2: tumors are unilateral tumors with complete or incomplete gross resections but, at the most, only ipsilateral microscopically positive lymph nodes.
- Stage 3: includes tumors that cross the midline or unilateral tumors that have contralateral lymph node involvement
- Stage 4: metastatic disease
- Stage 4S (for special): tumors in infants <1 year who have stage 1 or 2 primary tumors with dissemination limited to liver, skin, or bone marrow

Germ cell tumors

- Low risk: stage I testicular and ovarian tumors
- Intermediate risk: stage II–IV testicular, stage II–III ovarian, stage I–II extragonadal malignant germ cell tumors
- High risk: stage III–IV extragonadal tumors

NHL: Murphy staging system

- Stage I: single tumor, nodal or extranodal
- Stage II
 - ≥ 2 nodal or extranodal sites, both on the same side of the diaphragm
 - GI tumors with only mesenteric nodes involved

- Stage III
 - Involve both sides of the diaphragm
 - Extensive abdominal disease
 - Paraspinal or epidural tumors
 - Any primary intrathoracic tumors
- Stage IV
 - CNS or bone marrow involvement

Hodgkin disease: Ann Arbor staging system

- Stage I
 - Involvement of 1 lymphatic region only
- Stage II
 - Involvement of ≥ 2 lymphatic regions on the same side of the diaphragm
- Stage III
 - Involvement on both sides of the diaphragm, including nodal regions, the spleen, or both
 - The Cotswold modification further divides stage III on the basis of specific subdiaphragmatic nodal sites involved.
 - Stage III_X for bulky mediastinal disease
 - Stage III_E for involvement of a single nodal site that is contiguous with a known nodal site of disease
- Stage IV
 - Involvement of extranodal organs, such as lungs, liver, bone marrow, kidneys, bone, or skin, in addition to lymph nodes

TREATMENT APPROACH

Wilms tumor

- Initial approach is complete resection by nephrectomy.
 - Requires meticulous and gentle surgical techniques to prevent tumor from spilling
 - Large transabdominal incision facilitates full exploration and excision.
 - Entire ureter is removed, and lymph nodes are sampled.
- For bilateral disease, chemotherapy is suggested after bilateral biopsy rather than immediate resection of the most involved site.
- Second-look excision of residual disease may be accomplished by partial nephrectomies, when possible.
- Tumors deemed unresectable by clinical and radiologic evaluation are sampled initially, with second-look resection performed after adequate chemotherapy-induced shrinkage.
- Patients with underlying syndromes, such as WAGR, should be considered for partial nephrectomies because of high risk of renal failure.
- Risk of renal failure is <0.6% in patients with sporadic disease; routine use of partial nephrectomies in this population not usually called for.

Neuroblastoma

- Sensitive to both chemotherapy and radiotherapy
- Surgery
 - Surgery alone may suffice for localized disease; minimal residual disease may regress spontaneously.
 - Complete removal of the tumor offers best chance of cure in higher-risk patients, but often only a diagnostic biopsy is feasible.
 - Surgical reduction after initial cytoreductive therapy may increase the likelihood of cure.
- Chemotherapy
 - Main therapeutic technique
 - Combination therapy is used most intensively in more advanced stages of disease.
 - Intensive regimens are at the limits of bone marrow tolerance.
- Myeloablative therapy
 - Followed by purged autologous stem cell transplantation to restore hematopoiesis improves event-free survival
 - Cis-retinoic acid improves survival for high-risk patients, regardless of whether stem cell transplantation was used.
- Radiation
 - May facilitate surgical resection of residual disease or may reduce risk of recurrence in surgically unresectable disease
 - Emergent situations may be treated with radiation, for example:
 - Large mediastinal mass resulting in respiratory compromise
 - Dumbbell lesion protruding into the intervertebral foramen that causes cord compression
 - Total-body irradiation may be a component of the preparative regimen used before hematopoietic stem cell transplantation.

Retinoblastoma

- Treatment is individualized on the basis of extent of disease and the possibility of preserving vision.
- Enucleation is used for unilateral sporadic disease where large lesions and compromised vision, with removal of the longest segment of the optic nerve possible.
- External-beam radiotherapy
- Plaque brachytherapy
- Cryotherapy
 - For small lesions, most commonly in patients who have hereditary bilateral disease
- Photocoagulation
 - For small lesions, most commonly in patients who have hereditary bilateral disease

- Chemotherapy
 - To allow local therapy to preserve vision
 - Significant tumor shrinkage can be achieved, but local therapy is required for cure.
 - May prevent pineoblastoma, a usually fatal second cancer in patients with hereditary retinoblastoma

Rhabdomyosarcoma

- Requires multitherapeutic approach: chemotherapy, surgery, radiation
- The initial surgical procedure should be diagnostic biopsy.
- Wide resection of the primary tumor, including surrounding normal tissue, is preferable if excessive functional or cosmetic morbidity can be prevented.
- Complete resection is correlated with a better outcome but is possible in only approximately 20% of patients.
- Biopsy should be performed on large regional nodes.
- Second-look surgery after chemotherapy
 - May allow resection with reduction of surgical morbidity
 - Provides assessment of therapeutic response by determining the presence of viable tumor
 - Potentially reduces the dose of radiotherapy
- Chemotherapy
 - Required in all cases
 - Regimens are determined by risk group (based on stage, group, histology, and age).
- Radiation
 - Portals should include the entire extent of tumor volume.
 - Required for patients with embryonal histology and residual disease after surgery and for all patients with alveolar histologic features
 - High doses (60–65 Gy) control local residual disease but have greater morbidity; lower doses result in an increased recurrence rate.

Germ cell tumors/teratomas

- Chemotherapy is effective in most cases.

Ewing sarcoma

- Local therapy alone with either surgery or radiotherapy is unlikely to be curative.
- Chemotherapy cures most localized sarcoma and improves outcome for metastatic disease.
- Choice of radiation or surgery for local control is based on likelihood of preserving function.
- Surgery
 - Functionally expendable bones should be removed.
 - Aggressive surgical procedures, including limb-sparing excisions, are frequently performed.
 - Surgical resection may improve prognosis.

■ Radiotherapy

- Required for local control and will improve prognosis when resection with appropriate margins is not achieved or when the tumor is unresectable
- Preoperative radiotherapy may provide benefit.
- Local failure rate is 22.5%, with higher failure rates for central versus noncentral tumor sites.
- Patients receiving radiotherapy are a negatively selected group with unfavorable tumor sites or size.
- Radiotherapy may also be helpful for treatment of pulmonary or osseous metastases.

■ Chemotherapy

- Effective for extraosseous Ewing sarcoma and peripheral PNETs

Osteosarcoma

■ Surgery

- Amputation has the same survival rate as limb salvage.
- A portion of bone with tumor is removed and replaced by a prosthesis, bone graft, or composite.
 - Performed only if the vascular and neurologic integrity of the limb is not compromised
- Preoperative chemotherapy may reduce the mass enough to make such surgery possible.
- For lesions of the humerus, any preservation of hand function greatly improves quality of life.
- In cases of pulmonary metastasis, surgical resection of nodules may result in long-term survival, even if multiple surgeries are required.

NHL

■ Chemotherapy for all cases

- Treatment regimens differ for lymphoblastic lymphoma versus nonlymphoblastic lymphoma; histologic class predicts efficacy.
- Localized nonlymphoblastic lymphoma can be treated with short-course, low-intensity chemotherapy.
- Localized lymphoblastic lymphoma requires maintenance therapy.
- High-risk patients with lymphoblastic lymphoma are treated with protocols like those used for acute lymphoblastic leukemia.
- Leukemia-like therapy may also be beneficial for patients with anaplastic large-cell lymphoma.

■ Radiotherapy

- Helpful in treating emergent situations, such as:
 - Airway compromise
 - Spinal cord compression
 - Overt meningeal involvement

- Patients with stage III or IV lymphoblastic lymphoma may benefit from prophylactic cranial radiation.
- Plays a role in treating patients:
 - Who do not achieve complete remission after standard chemotherapy
 - Who require bone marrow transplantation or palliative therapy

Hodgkin disease

■ Responds to radiation and/or chemotherapy

- Choosing the appropriate therapeutic plan necessitates assessing risk of recurrence and potential risk for long-term ill effects.

■ Chemotherapy

- ABVE-PC (adriamycin [doxorubicin], bleomycin, vincristine, etoposide, prednisone, and cyclophosphamide)
- Add appropriate additional chemotherapy regimens for patients who do not have a good initial response.
- Cures with chemotherapy alone, even in higher-stage disease, have been described; should define patients who can avoid any radiation
- Chemotherapy with radiotherapy: considerations
 - Age and skeletal maturity of the patient (likely effects on the developing child)
 - Extent of disease present (how much therapy is necessary)
 - Symptoms that might predict a poor prognosis
 - Response to initial therapy

SPECIFIC TREATMENTS

Wilms tumor

- Actinomycin D and vincristine are the mainstays of chemotherapy.
 - Shorter-duration therapy (6 months) with single high doses of actinomycin D results in the same outcome as multiple smaller doses, with less toxicity and cost.
- Addition of doxorubicin and 10 Gy of radiation to vincristine and actinomycin D improves prognosis for stage III–V FH tumors and for stage II–IV tumors with focal anaplasia.
- Cyclophosphamide as a fourth agent can benefit stage II–IV tumors with diffuse anaplasia.

Retinoblastoma

- Vincristine, carboplatin, and etoposide
- Periocular carboplatin has been used in specific clinical situations.
- Emerging therapy includes transpupillary thermotherapy with or without adjuvant chemotherapy.
- Cyclosporin with chemotherapy overcomes multidrug resistance and may improve long-term response to chemotherapy.

Rhabdomyosarcoma

- Vincristine
- Actinomycin D
- Cyclophosphamide

Germ cell tumors/teratomas

- Methotrexate for gestational choriocarcinomas and testicular germ cell tumors
- Ovarian tumors responded to vincristine, actinomycin D, and cyclophosphamide.
- Vinblastine and cisplatin in testicular germ cell tumors of young men
- Standard therapy with cisplatin, etoposide, and bleomycin for intermediate-risk patients
- Higher doses of cyclophosphamide with surgery and standard 3-drug regimen are being studied for high-risk patients.

Ewing sarcoma

- Standard chemotherapy: vincristine, doxorubicin, and cyclophosphamide alternating with etoposide and ifosfamide

Osteosarcoma

- High-dose methotrexate, doxorubicin, and cisplatin are standard therapy for osteosarcoma.

Neuroblastoma

- Cyclophosphamide, doxorubicin, cisplatin, epipodophylotoxin, and vincristine

NHL

- Cyclophosphamide, vincristine, prednisone, methotrexate, doxorubicin, cytosine arabinoside, etoposide, and ifosfamide

Hodgkin disease

- ABVE-PC (adriamycin [doxorubicin], bleomycin, vincristine, etoposide, prednisone, and cyclophosphamide)
- Full-dose radiotherapy (35–45 Gy) is standard therapy for adults with low-stage (I, II, and III) disease.
 - Involved fields and 1 field beyond the area of proven disease are treated.
 - Skeletal and soft-tissue growth, especially in the neck and clavicular areas, are severely compromised when used in children.
 - Low-dose radiotherapy (20–25 Gy) to involved fields only, and not extended fields, in conjunction with chemotherapy results in fewer and less severe late effects from the radiation.

WHEN TO ADMIT

- Patients whose bone marrow has been infiltrated may have pancytopenia and thus be at risk of infection, bleeding, and congestive heart failure as a result of anemia.

- In cases of increased uric acid (risk of urate nephropathy), hyperkalemia, hypocalcemia, or hyperphosphatemia:
 - Medical management includes allopurinol or urate oxidase, urinary alkalization, and binders of potassium and phosphate.
 - Dialysis may be necessary.
 - If delayed arrival to the medical center is anticipated, allopurinol should be started by the referring physician when tumor with a large cell burden is suspected.
 - Leukemia, Burkitt lymphoma, bone marrow involvement
 - Neuroblastoma, Ewing sarcoma, or rhabdomyosarcoma

WHEN TO REFER

- Begin with referral to a pediatric oncologist, even if the initial procedure indicated is surgical.
 - Recognition of potential cancer is essential to ensure that inappropriate therapy will not be administered.
 - The oncologist will advise on radiation and chemotherapy.
- Services at pediatric referral hospitals often ease the pain of being diagnosed with a life-threatening disease.
 - Pediatric social workers, child life workers, and nurses experienced in dealing with children/adolescents with cancer are available.
 - For patients far from a center, initiating therapy at referral medical center and administering a portion of the subsequent treatments/evaluations closer to home, is often possible.
- A local oncologist can assist in giving chemotherapy to children far from a center, but pediatric oncologists at the referral medical center should be involved in:
 - Choosing therapeutic regimen
 - Evaluating major problems
- Emergencies that require immediate referral to a pediatric oncologist include:
 - Cord compression
 - Incontinence
 - Loss of reflexes in the lower extremities
 - Decreased ability to use the lower extremities
 - Decreased rectal sphincter tone
- Refer if there is potential for mediastinal mass or symptoms of superior vena cava syndrome.
 - Swelling, plethora, and cyanosis of the face, neck, and upper extremities
 - Engorged vessels
 - Cough and wheezing
 - Chest pain
 - Headache
 - Diaphoresis
 - Changes in vision

FOLLOW-UP

General

- Maintenance of a relationship with the patient and family is essential.
 - Children receiving treatment for cancer should continue to see their primary pediatrician for well-child visits.
 - Immunizations are delayed until 1 year after therapy is terminated because live vaccines may cause disease, and inactivated vaccines rarely result in a normal immune response.
 - Exception: inactivated influenza vaccine; patient's family should also be immunized
 - The pediatrician should remain involved in continuing developmental issues that are at times exacerbated by the cancer treatment.

Wilms tumor

- During therapy, monitor for disease recurrence at the primary site (usually, with abdominal ultrasonography).
- Medical care should be sought promptly for unexplained masses, pain, or other symptoms.
 - CT may be indicated.
 - Lungs are usually evaluated with chest radiograph.
- Some patients may be followed up with CT of the chest and abdomen at increasing intervals until approximately 5 years after diagnosis.
- Contact sports are often discouraged, although evidence for significant risk of renal injury is lacking.
 - Some experts suggest a kidney guard for particularly active children, if only to serve as a reminder of the need for caution.
- Renal function should be monitored.

Retinoblastoma

- After treatment, follow closely for evidence of recurrence and for second cancers.
 - Examine under anesthesia:
 - Every 2–3 months during the first year
 - Every 3–4 months during the second year
 - Every 6 months thereafter until age 6
- After enucleation, a prosthesis is necessary.
- After radiation, monitor hypothalamic-pituitary axis function.

Neuroblastoma

- Most tumors recur while patients are receiving therapy or shortly afterward.
- Close follow-up with physical examination and radiologic studies should continue after completing therapy.
- Urinary catecholamine levels may be useful in the surveillance of patients who had increased values at diagnosis.
- Patients should be monitored for late toxicities of chemotherapy and radiotherapy.

- High-dose therapy associated with autologous hematopoietic stem cell procedures may result in significant late effects, for example:
 - Hearing loss
 - Renal insufficiency
 - Growth impairment
 - Gonadal failure

Rhabdomyosarcoma

- Follow closely for evidence of recurrent disease for at least 3–5 years after diagnosis.
- CT or MRI of the primary site, chest CT, and bone scans are used for surveillance.
- Radiotherapy often results in unacceptable cosmetic effects in patients who have orbital tumors.
 - For patients with orbital or other tumors of head or face who received radiation to the sinuses, hypothalamus, and pituitary gland
 - Sinusitis is a common symptom.
 - Hormone levels (eg, growth hormone, gonadotrophins) may need monitoring.
- Patients should be monitored for any potential late effects of chemotherapeutic agents.

Teratoma

- Malignant evolution may occur years after removal of an apparently benign tumor, particularly in the sacrococcygeal area.
 - Complete excision of the coccyx is often suggested, with close follow-up.
- Relapse may occur as many as 10 years after diagnosis.
- Late-brain metastases are possible.
- Close follow-up care is essential.
 - Frequent physical examinations and radiologic evaluations
 - Monitoring of AFP and β -hCG levels, if levels are high at diagnosis
 - Salvage therapy may prolong survival or even provide a cure.
- Late effects of chemotherapy should be monitored (see Complications).

Ewing sarcoma

- Follow closely for evidence of recurrent disease for at least 5 years after diagnosis.
- Bone films should be obtained periodically.
- Patients with lower-extremity lesions whose growth is incomplete should be monitored for evidence of leg-length discrepancies; they may require arresting growth in the opposite limb.
- Monitor for potential late effects of specific chemotherapeutic agents (see Complications).

Osteosarcoma

- Imaging of the primary tumor site, bone scans, and chest CTs semiannually for 5 years and then at least chest radiographs annually until 10 years after diagnosis to monitor for recurrent disease.
- Orthopedic evaluation and monitoring for late effects of the chemotherapeutic agents

Hodgkin disease

- Monitor for evidence of recurrent disease for as long as 10–15 years after original diagnosis.
 - Thorough physical examination
 - Complete blood cell count
 - Sedimentation rate
 - Chest radiograph
- Patients should undergo annual mammographic examinations beginning 8 years after therapy or at age 25 years.
- Thyroid function should be assessed for at least 15 years.
 - Thyroid replacement therapy is suggested when the level is increased.
- Menstrual history should be elicited at each visit to check effects of radiation infertility, if relevant.
- Patients who have had a splenectomy are at risk for overwhelming infection.
 - Empirical treatment with intravenous antibiotics is recommended for fever (>101°F).

Other care of survivors

- Neurocognitive function and school performance will be affected in many who are going through or who have undergone treatment.
 - Education specialists, pediatric oncological nurse practitioners, or both can be extremely helpful to child and child's teachers by:
 - Explaining diagnosis and treatment to school administrators and teachers and, when appropriate, to classmates
 - Defining the problems/limitations child will have in keeping up with schoolwork during periods of intensive treatment
 - Providing or arranging (through the school system) for lessons and special tutoring during prolonged hospitalizations and recovery periods at home
 - Legal protection in case of discrimination in the work place is available to survivors through the Americans with Disabilities Act, and advocacy resources exist at both the community and national levels.
 - Pediatricians must be advocates.

COMPLICATIONS**All cancers**

- Recurrence from second cancer is possible for all tumors.

Wilms tumor

- Scoliosis
 - Major problem following treatment with moderate-dose radiation (30–40 Gy), particularly if all vertebrae were not included in the field
 - Less severe with lower-dose radiation (10 Gy) and irradiation of the entire width of the vertebrae adjacent to the renal bed
 - Alterations of vertebral growth and tethering caused by hypoplasia of soft tissues may still result in some degree of curvature.
- Close observation of patients who received irradiation, particularly during growth spurt in puberty, is necessary. Hypoplasia with a decrease in adipose tissue occurs in the radiation field and is accentuated by obesity.

Long-term side effects of chemotherapy

- Chemotherapeutic agents, their possible side effects, and techniques used for follow-up are listed.
- Anthracyclines (eg, doxorubicin)
 - Cardiac: myocardial damage, congestive failure, arrhythmias
 - History: exercise intolerance, palpitations; electrocardiography (QTc interval); echocardiography scheduled based on age, dose, and radiation exposure; Holter monitor; exercise electrocardiography; exercise nuclear angiography
- Bleomycin
 - Pulmonary: fibrosis, impaired diffusion capacity, exacerbated by increased oxygen (eg, anesthesia)
 - History: shortness of breath, dyspnea on exertion, cough; chest radiograph and pulmonary function tests (with diffusion capacity) at baseline and with symptoms
- Cyclophosphamide, ifosfamide
 - Gonadal: infertility, sterility, early menopause
 - History: menses, question of fertility; luteinizing hormone (LH), follicle-stimulating hormone (FSH), testosterone or estradiol during pubertal development or if fertility problems or amenorrhea (or both) exists; semen analysis (as required to conceive)
 - Bladder: hemorrhagic cystitis
 - Urinalysis annually
 - Marrow: secondary acute myeloblastic leukemia
 - Complete blood cell count annually

- Lomustine
 - Pulmonary, gonadal
 - Pulmonary and gonadal evaluation
 - Cisplatin
 - Kidney: decreased glomerular filtration rate
 - Serum creatinine at baseline and per guidelines
 - Creatinine clearance at baseline and per guidelines
 - Ears: hearing loss (high frequency)
 - Audiography at baseline and per guidelines
 - Methotrexate
 - Liver dysfunction
 - Central nervous system (CNS): learning impairment (high intravenous dose)
 - Liver function tests
 - 6-Mercaptopurine, 6-thioguanine, actinomycin D
 - Liver dysfunction
 - Liver function tests
- Long-term side effects of radiation**
- The site of side effects, risks, and monitoring techniques are listed.
 - Cranium and nasopharynx
 - Cataracts
 - Physical examination
 - Impaired growth
 - Growth charts (bone age, growth hormone, organ system function as appropriate)
 - Learning impairment
 - Monitoring school function; neuropsychological evaluation
 - Abnormal dentition formation
 - Dental evaluation
 - Overt or compensated hypothyroidism
 - Free thyroxine and thyroid-stimulating hormone
 - Hypothalamic dysfunction (decreased growth hormone; decreased gonadotropin, hyperprolactinemia)
 - Growth; pubertal, menstrual, and fertility history (growth hormone, LH, testosterone, estrogen, prolactin levels)
 - Hearing (especially with cisplatin)
 - Audiography
 - Neck and mandible
 - Hypoplasia of bone or soft tissues
 - Examination of area
 - Dentition: abnormal formation, abnormal salivary function
 - Dental evaluation
 - Hypothyroidism
 - Free thyroxine and thyroid-stimulation hormone
 - Thorax
 - Hypoplasia (includes impaired chest wall growth)
 - Examination of area
 - Lungs: fibrosis, decreased capacity
 - History, pulmonary function tests, chest radiograph at baseline and as appropriate
 - Cardiac: pericardial and valvular thickening; possibility of early myocardial infarction
 - History, electrocardiography, and echocardiography are scheduled on the basis of age, dose, and radiation exposure.
 - Breasts: impaired growth, possibility of increased malignancy
 - Breast self-examination and early mammograms start 8 years after therapy or at age 25 years.
 - Abdomen/pelvis
 - Hypoplasia (including scoliosis)
 - Examination of area, radiograph of spine during puberty
 - Liver (if in field)
 - Liver function tests
 - Kidney (if in field)
 - Serum creatinine, urinalysis protein (24-hour collection for creatinine, protein)
 - Gonads (if in field)
 - Pubertal, menstrual, and fertility history, LH, FSH, estradiol or testosterone levels during puberty; if fertility is doubtful, semen analysis
 - GI tract
 - Nutritional history
 - Extremities
 - Hypoplasia
 - Examination
- Other risks**
- The most prominent toxicity from chemotherapy is myelosuppression, which can rapidly result in septic shock.
 - Recognize the risk of fever and refer to a pediatric oncologist immediately.
 - If the cancer center is at a distance, be prepared to obtain proper culture specimens and initiate antibiotic therapy (usually aminoglycoside and semisynthetic penicillin or a fourth-generation cephalosporin).

- Patients with indwelling central venous catheters have increased risk for septicemia.
 - Have blood drawn for culture, and consider therapy with antibiotics if fever develops.
- Varicella is a major threat to immunocompromised patients.
 - If exposed by a sibling or close playmate, the patient should receive varicella-zoster immunoglobulin within 4 days of the exposure.
 - Should chickenpox occur, treat with acyclovir or related new-generation antiviral drugs, often as an inpatient, and withhold chemotherapy.

PROGNOSIS

Wilms tumor

- Prognosis is determined by histopathologic factors of the tumor.
- Prognosis also depends on stage of disease at diagnosis.
 - More patients with UH tumors die compared with those with FH tumors.
 - UH tumors, particularly diffuse anaplasia, confer worse prognosis.
 - Most relapses occur within 2 years of diagnosis.
 - The 2-year relapse-free survival for stage I–III disease with FH findings is approximately 91%.
 - The 2-year relapse-free survival rate is 84% for stage IV disease and FH features.
 - Patients with diffuse anaplasia have a poor prognosis, with survival rates 4 years after diagnosis of:
 - 59% with stage II disease
 - 45% with stage III disease
 - 7% with stage IV disease
 - 4-year event-free survival is 74.9% for patients with focal anaplasia.
- Patients who relapse have a better prognosis if initial management did not include radiotherapy or doxorubicin.
- Fertility is preserved in most patients, although a risk of ovarian failure exists with whole-abdomen radiotherapy.

Neuroblastoma

- Patients <1 year of age do much better than those >2 years of age.
- Patients who have stage 1, 2, or 4S neuroblastoma with favorable biological features have survival rates >90%.
- Long-term survival for patients with stage 3 neuroblastoma:
 - Patients <1 year of age have survival rate of 100% at 4 years.
 - Patients with favorable biology have survival rate of 90% at 4 years.
- Intensive multiagent chemotherapy appears to result in improved cure rates.

- In studies of patients with stage 4 disease treated with stem cell transplants, event-free survival is 23–47% at 3–6 years.
- Skeletal disease and persisting bone marrow involvement are predictive of poorer outcome; patients who have complete response to chemotherapy benefit most from transplantation.

Retinoblastoma

- Survival is excellent; >85% have no recurrence, and survival from primary tumor is >95%.
- Hereditary retinoblastoma carries a high incidence of second cancer.
 - 50% of cases occur within the radiation field.
 - Osteosarcoma or other sarcomas are particularly common.
 - Patients irradiated when <1 year are at increased risk.
 - One-third have a second cancer within 15 years.
 - Two-thirds have a second cancer by 30 years.
 - Avoiding radiotherapy may reduce but not eliminate this risk.

Rhabdomyosarcoma

- Survival is determined by site and stage.
- Overall survival: 73% at 5 years from diagnosis.
- Prognosis is particularly good (90–95% long-term survivors) for:
 - Orbital tumors
 - Nonbladder and nonprostate GU tract tumors
 - Localized tumors that can be resected fully
- Patients with stage IV (metastatic) disease who are <10 years and have embryonal histology have a better prognosis than older patients who have stage IV disease.
- 80% of recurrences occur within 2 years of treatment.
 - Local relapse is most common, although distant spread to the lungs, CNS, lymph nodes, bone, liver, bone marrow, and soft tissues does occur.
- Metastatic disease at diagnosis
 - 25–30% of these patients will survive 5 years from diagnosis.
 - Hematopoietic stem cell transplant or the use of new agents may offer hope to these patients.
- 20% who experienced relapse have favorable features, with 50% 5-year survival; the other 80% of patients have only 10% 5-year survival (if poor stage).

Germ cell tumors/teratomas

- 3 prognostic groups for patients >1 year:
 - Stage III disease (more than microscopic residual disease), sacrococcygeal or mediastinal primaries, and AFP level >10,000 ng/mL: 43% 3-year disease-free survival

- Stage I disease (complete resection) or stage II disease (microscopic residual), testicular, ovarian, perineal, or retroperitoneal primary tumor, and AFP level <10,000 ng/mL: 100% 3-year disease-free survival
- The remaining patients were in an intermediate-prognosis group and had 81% disease-free survival.
- Prognosis is improved for patients treated with cisplatin versus carboplatin.
- Event-free survival rates >80% and up to 100%
- Teratoma prognosis depends on its degree of maturity and age.
 - Sacrococcygeal teratomas are usually benign in children <2 months; thereafter, likelihood of malignant evolution increases rapidly.
 - This may be the reason that intrapelvic teratomas that are not detected early often are found to be malignant.
 - Mediastinal teratomas behave benignly in children and young teenagers; in older patients, they are more aggressive.
 - Cervical and intracranial teratomas in infants are usually benign; those in adolescents and adults are often malignant.
 - Immature teratomas can be treated with surgery alone, with event-free survival rates of 97.8%, 100%, and 80% for patients who have ovarian, testicular, and extragonadal tumors, respectively.
- For patients who experience relapse, cisplatin-based chemotherapy offers an excellent chance of cure.

Ewing sarcoma

- Older age is associated with worse prognosis.
- Metastatic disease is present in 20–25%.
- Histologic response of marked tissue necrosis after chemotherapy indicates better prognosis.
- 5-year disease-free survival is approximately 75% for non-metastatic disease.
- Event-free survival of 12–24% is seen in patients with metastatic disease.
- Outcome after relapse is very poor; there are few survivors among patients who have relapse >2 years from initial diagnosis or who have relapse with lung metastases only.

Osteosarcoma

- Adjuvant chemotherapy improves long-term disease-free survival if osteosarcoma is nonmetastatic (survival rates of 65–75%).
- Outcome after preoperative chemotherapy is similar to or better than with immediate surgical excision.
- The alkaline phosphatase level has been shown to have independent prognostic significance.
- Other factors
 - Patients who have distal tumors may have better outcomes than those who have proximal or central-axis tumors.
 - Age (outcome improves with older patients)

- Presence of metastatic disease
 - Pulmonary metastases are associated with better prognosis than bone metastases.
 - Unilateral disease or <8 nodules may carry a better prognosis; survival of 65–75%, compared with 25–35% for other patients with pulmonary involvement.
 - Prognosis for bone metastases at diagnosis or relapse is grim.

NHL

- Prognosis is excellent for most children: >95% survival for those with localized disease and 80–90% survival for patients who have high-risk disease (advanced stage, a large mediastinal mass, more than 4 sites of involvement, and B symptoms).
- Worse prognosis with Burkitt and bone marrow and CNS involvement, mediastinal diffuse large B-cell lymphoma, and some patients with widespread anaplastic large-cell lymphoma
- Histologic findings are of prognostic significance for outcome.
- Age and sex may affect prognosis, even within histologic subtypes.
- Other prognostic factors include lactic dehydrogenase and, as with other types of cancer, response to therapy.
- New intensive chemotherapy or bone marrow transplantation regimens should improve survival in patients whose prognosis is poor or who experience relapse.

Hodgkin disease

- Radiotherapy alone may cure up to 70% with stage I or IIA disease and 50% with IIB or IIIA disease.
- Subsequent chemotherapy enables 50% who experience relapse after radiotherapy.
- With combined-modality therapy, 5-year disease-free survival is 90–100% for localized disease and 80–90% for advanced-stage disease.
- High-risk features
 - Advanced-stage disease
 - Large mediastinal mass
 - ≥4 sites of involvement
 - B symptoms
- Patients whose disease progresses or relapses
 - Cure may be accomplished with intensive chemotherapy and radiation or with stem cell transplantation.
 - Salvage rates >60%
 - Patients whose diseases progress while in therapy have a poorer prognosis than those who experience relapse after treatment.

PREVENTION

- Diet, particularly folic acid intake, and breastfeeding may protect against development of neuroblastoma.

Cardiac Arrhythmias

DEFINITION

- Cardiac arrhythmias comprise a spectrum of variations to normal heartbeat.
- Normal rhythm variations
 - A wide range of normal heart rates is present in young persons.
- Premature (early) beats
 - Usually benign arrhythmias that occur as:
 - Premature atrial contractions (PACs)
 - Premature ventricular contractions (PVCs)
 - Couplet
 - 2 premature beats in a row
 - Bigeminal or trigeminal rhythm
 - Every second or third beat is a premature impulse.
- Supraventricular tachycardia (SVT)
 - Tachycardia with origin above the ventricles
- Atrial flutter
 - Primary atrial reentrant tachycardia
 - Atypical form (intraatrial reentrant tachycardia)
- Atrial fibrillation
 - Irregular tachycardia with variable atrioventricular conduction
 - Types
 - Lone (idiopathic, no underlying cause)
 - Underlying heart disease
- Ventricular tachycardia (VT)
 - ≥ 3 repetitive excitations arising from the ventricles
- Conduction abnormalities
 - First-degree atrioventricular (AV) block
 - Second-degree AV block
 - Wenckebach block or Mobitz type I
 - Mobitz type II
 - Complete AV block
- Sudden cardiac death

EPIDEMIOLOGY

- Prevalence
 - PACs
 - Seen in 50–75% of pediatric patients
 - PVCs
 - Less common than PACs
 - On Holter monitoring, seen in up to 25% of healthy infants, children, and adolescents
 - SVT
 - Up to 1 in 250 children
 - Reentrant: >90% of pediatric SVT
 - Automatic: <10% of pediatric SVT

- Wolff-Parkinson-White (WPW) syndrome:
 - 0.15% in the general population with or without SVT
- Atrial flutter
 - Bimodal distribution in newborn infants and in older children
- Atrial fibrillation
 - Less common than other arrhythmias
 - Incidence in adolescence may be underestimated.
- VT
 - Rare in the newborn and young infant
- Sudden cardiac death
 - 1:100,000
 - Beyond infancy, 25% of sudden deaths in the young occur during exercise.
- Long QT syndrome (LQTS)
 - 10:100,000
 - May be underestimated because of incomplete genetic ascertainment
- Age
 - Arrhythmias in the young are common.
 - Usually benign
 - May be life-altering or fatal
 - Arrhythmias may begin at any age.
 - In utero up to the later teenage years
 - Higher incidence in early infancy and mid-adolescence
 - Sudden cardiac death
 - Most common in mid-adolescence
- Sex
 - No sex preference

MECHANISM

- Premature beats
 - May arise in the atria, the AV junction, or the ventricles
- SVT
 - Early infancy
 - Usually initiated by PAC or sinus tachycardia
 - AV reentry tachycardia through an accessory pathway (preexcitation)
 - Childhood and adolescence
 - PVCs and sinus pauses with junctional escape beats are additional initiators.
 - AV nodal reentry tachycardia using the fast and slow pathways in the AV nodal region
 - Primary atrial tachycardias
 - Automatic SVT
 - Atrial flutter
 - Atrial fibrillation

- Conduction abnormalities
 - Second-degree AV block
 - Type I
 - Predominance of vagal tone
 - Block is in the AV node.
 - Type II
 - Block is more distally located in the bundle of His.
 - Complete AV block
 - Acquired
 - Usually results from conduction system injury
 - Congenital complete atrioventricular block (CCAVB)
 - Fetus exposed to antibodies in a mother with autoimmune disease between 15 and 24 weeks of gestation
 - Sudden cardiac death
 - Ion channel cardiac disorder that prolongs repolarization
 - Genetic basis
 - Romano-Ward form (95% of patients)
 - Jervell and Lange-Nielsen syndrome (5%)
- HISTORY**
- Thorough family history focuses on:
 - Sudden death
 - Premature death
 - Syncope
 - Recurrent arrhythmias
 - Typical symptoms of cardiac dysfunction
 - Palpitations
 - Lightheadedness
 - Syncope
 - Visceral chest pain
 - Dyspnea
 - Nonspecific signs and symptoms of arrhythmia
 - Depend on age of the patient and the rate and type of rhythm disturbance
 - Fatigue
 - Malaise
 - Poor feeding
 - Nausea
 - Pallor
 - Premature beats
 - The majority have no obvious incitant.
 - Observed most often in healthy children and adolescents
 - Associated with:
 - Myocarditis
 - Hypertrophic cardiomyopathy
 - Dilated cardiomyopathy
 - Ventricular dysfunction
 - Congenital cardiac malformations
 - Sympathomimetics
 - Stimulant drugs
 - Electrolyte imbalances
 - Intracardiac catheters
 - SVT
 - Onset
 - First 4 months of life (~50%)
 - 1–5 years : usually electrically quiescent
 - >5 years: associated with high probability of recurrence
 - WPW syndrome
 - May be inherited in an autosomal-dominant fashion
 - Risk factors for atrial flutter
 - Cardiomyopathy
 - Previous repair of complex congenital heart malformations lesions (Fontan procedure) (see Figure 10 on page F3)
 - Risk factors for atrial fibrillation:
 - Structural heart disease
 - Cardiomyopathies
 - VT
 - Risk factors
 - Myocarditis
 - Repaired and unrepaired congenital cardiac lesions
 - Cardiomyopathies
 - LQTS, short QT syndrome
 - Catecholamine use
 - Exercise-induced VT
 - Marked electrolyte imbalances
 - Use of street drugs (eg, cocaine)
 - Associated conditions
 - Ventricular tumor
 - Mitochondrial fatty acid beta-oxidation disorders in neonates
 - In general, VT is a marker for myocardial disease.
 - Conduction abnormalities
 - Risk factors in acquired conduction abnormalities
 - Conduction system injury during repair of congenital cardiac malformations (most commonly)
 - Myocarditis
 - Lyme disease
 - Risk factors in CCAVB
 - Complex structural heart disease (~50% of affected patients)
 - Levo-transposition of the great vessels
 - Complex AV septal defects

- Immune-mediated block in utero from mother with overt or occult autoimmune disease (~50% of affected patients)
 - <5% of infants born to mothers who have autoimmune disease develop CCAVB
 - If a mother bears 1 child who has CCAVB, the risk in future pregnancies is 15%.
- Prolonged QT interval (up to 25%)
- Fetal hydrops
- Premature birth
- Congestive heart failure
- Ventricular ectopy
- Atrioventricular valve insufficiency
- Low or decreasing ventricular rate (≤ 55 bpm in a neonate)
- Risk factors in sudden cardiac death
 - Repaired complex congenital heart malformations
 - Cardiomyopathies
 - Myocarditis
 - Drugs that prolong the QT interval
 - Cisapride
 - Imipramine
 - Pentamidine
 - Congenital coronary artery anomalies
 - Especially origin of the left main coronary artery from the right sinus of Valsalva
 - Acquired coronary artery anomalies
- Kawasaki disease
- Primary arrhythmias
 - LQTS
 - WPW syndrome
 - Catecholamine-sensitive polymorphic VT
- Associated conditions
 - Congenital deafness (Romano-Ward form)

PHYSICAL EXAM

Normal rhythm variations in childhood

- Sinus arrhythmia (phasic respiratory variations of sinus rate with inspiratory slowing and expiratory acceleration)
- Fast heart rates
 - Sinus tachycardia at rates of 230–250 bpm during infancy have been documented.
 - A rate >200 bpm in a teenager who is not involved in maximal exertion would be abnormal.
- Slow heart rates/sinus bradycardia
 - Sinus rate below that expected for a patient's age
 - Greater reason for alarm than fast rates
 - Sinus rate below 100 bpm in an awake neonate is abnormal.
 - During sleep, rates down to 80 bpm are common.

- Brief dips into the 60–80 bpm range are also observed in sleeping neonates during normal, vagally induced episodes of junctional rhythm.
- A highly conditioned adolescent endurance athlete may have a resting heart rate ≤ 40 bpm.

Premature beats

■ PACs

- Usually asymptomatic to the patient
- Characterized by premature P waves with an axis and morphology different from the sinus P waves
- Usually occur with normally conducted QRS complexes
- If wide beats are also noted, the apparently prolonged QRS beats are likely to be aberrant PACs.
 - Premature atrial and ventricular contractions rarely occur together, especially in the newborn period.
- Sign of blocked atrial bigeminy in a newborn infant
 - Slowing of the heart rate sufficient to alter feeding and arousal time

■ PVCs

- Benign if:
 - No evidence for heart disease
 - QTc is normal (≤ 0.44 seconds)
 - Family history is not adverse
 - PVCs are uniform in appearance
 - PVCs are either suppressed or not aggravated with exercise
- Worrisome if:
 - Answer to any of the above questions is positive
- New appearance of PVCs in the setting of a febrile illness should raise the question of myocarditis.

SVT

- May be noted incidentally
- Commonly associated with signs and symptoms of congestive-heart failure
 - Tachycardia
 - Tachypnea
 - Dyspnea
 - Truncal diaphoresis
 - Diminished pulses
 - Pallor
 - Hepatomegaly
 - Poor feeding
 - Palpitations
 - Chest pain
 - Nausea
 - Respiratory distress
 - Syncope (rarely)

■ Infants

- 25% of infants are in congestive heart failure with tachycardia of 24 hours' duration.
- 50% of infants have heart failure after SVT for 48 hours.

■ Children >5 years

- Usually can communicate their distress soon after onset of SVT
- Hence, the relative paucity of congestive heart failure caused by SVT in older pediatric patients

■ Duration

- Ranges from a few seconds to several hours

■ Heart rate

- Infants: 230–300 bpm but usually between 260 and 280 bpm
- Older patients: 180–240 bpm

Atrial flutter

■ Newborn infants

- Atrial rate typically between 350 and 500 bpm
- 2:1 atrioventricular conduction and brief interruptions caused by higher degrees of AV block
- Congestive heart failure may be seen.
- Not as dramatic as in infants who have the usual variety of SVT
- Structural cardiac problems are uncommon.

■ Onset in utero

- Fetal hydrops may develop.

■ Atypical form (intraatrial reentrant tachycardia)

- Slower atrial rate
- Heart rate of 100–140 bpm in a patient with risk factors should prompt investigation.

VT

■ Signs and symptoms

- Rate >120 bpm or 25% faster than sinus rate
- Congestive heart failure
- Chest pain
- Dyspnea
- Palpitations
- Fatigue
- Reduced exercise capacity
- Pallor
- Presyncope
- Syncope

■ VT is confirmed by the presence of atrioventricular dissociation.

- Similar but isolated PVCs and fusion beats in sinus rhythm assist in establishing the diagnosis
- Cardiac output frequently is compromised to a greater degree than in SVT.

- Heart rate may be extremely rapid (up to 500 bpm) and slightly irregular.
- All wide QRS tachycardias should be considered VT until proven otherwise

■ Benign forms of VT

- Accelerated ventricular rhythm
 - ≤120 bpm, or <25% faster than the basic sinus rate
- Right ventricular outflow tract
- Idiopathic left VT

Conduction abnormalities

■ First-degree AV block

- Prolongation of the PR interval beyond the upper limit of normal for age, with all impulses conducted
- Benign finding
- Seen with:
 - Congenital cardiac malformations (especially AV septal defects)
 - Electrolyte disorders
 - Rheumatic fever
 - Myocarditis
 - Congenital muscular disorders
 - Patients receiving antiarrhythmic drugs

■ Second-degree AV block

- Type I
 - Progressive prolongation of the PR interval until a dropped ventricular beat (nonconducted P wave) occurs
 - Generally benign unless syncope occurs
 - Normal finding in:
 - Healthy children during sleep
 - Highly conditioned athletes at rest
- Type II
 - Intermittent loss of AV conduction without preceding lengthening of the PR interval
 - Implies an abnormal conduction system
- Complete AV block
 - No atrial impulses are conducted to the ventricles

Sudden cardiac death

■ Exertion or emotional stress triggers 1 of the following:

- Syncope
- Atypical seizures
- Cardiac arrest

■ Long QT3 subtype events

- Predominantly occur at rest
- Physical examination is usually normal.
- Bradycardia may be the only sign.

DIFFERENTIAL DIAGNOSIS

■ Premature beats

- Escape or late beats occurring when higher pacemaker cells fail to produce an impulse at the expected interval

■ VT

- SVT with persistent aberrancy (see Figure 11 on page F3) is uncommon.
- SVT with antegrade conduction across an accessory pathway (see Figure 12 on page F4) is uncommon.

■ LQTS

- Electrolyte abnormalities
 - Hypokalemia
 - Hypocalcemia
 - Hypomagnesemia
- Myocardial ischemia or injury
- Acute central nervous system events
- Cardiomyopathy

IMAGING

■ Echocardiography

- Used to assess cardiac structure and function when new PVCs are seen in the setting of a febrile illness where underlying disease may be subtle
- Used in SVT to identify:
 - Subtle congenital cardiac defects in patients with WPW syndrome
 - Ebstein malformation of the tricuspid valve
 - Levo-transposition of the great vessels

DIAGNOSTIC PROCEDURES

12-lead electrocardiography (ECG)

- Must be obtained when an arrhythmia is being considered
 - Rhythm alterations may be quite subtle and not always identified on a rhythm strip.
 - ECG will detect chamber enlargement.
 - Calculate corrected QT interval: $QTc = QT \text{ interval (seconds)} / \sqrt{\text{preceding RR interval (seconds)}}$
- Analyze arrhythmia in an organized fashion.
 - Is the rhythm fast or slow?
 - Is the rhythm regular or irregular?
 - Are the QRS complexes narrow or wide?
 - What is the relationship between the P waves and the QRS complexes?
- Sinus bradycardia
 - Neonates and infants: <100 bpm, awake
 - Children to 3 years: <100 bpm
 - Children 3–9 years: <60 bpm

- Adolescents 9–16 years: <50 bpm
- Adolescents >16 years: <40 bpm

■ PACs

- If PAC occurs when 1 of the bundle branches is refractory:
 - The premature beat will be conducted down the other bundle branch.
 - The result is an aberrant PAC with QRS morphology wider than and different from sinus QRS complexes (see Figure 13 on page F4).
- If both bundle branches are refractory:
 - PAC will not be conducted to the ventricles (blocked PAC).
 - PAC may reset the sinus node, with a resultant pause greater than the previous RR interval.
- T waves
 - Usually smoothly inscribed
 - Consistent sharp deflections in the T waves may represent P waves (see Figure 14 on page F4).

■ Wandering atrial pacemaker related to alterations in vagal tone

- Usually noted with slower heart rates and characterized by different P wave morphologies

■ QRS morphology of PVCs

- Different from sinus QRS beats
- Occur before the next expected sinus beat
- Not preceded by a premature P wave
- QRS duration may be only slightly prolonged.
- Uniform PVCs
 - Similar morphology in contrast to multiform beats
- Late PVCs
 - Hybrid or fusion beat with morphology intermediate between the sinus QRS and PVC

■ SVT

- QRS complexes are usually narrow but may be transiently wide at initiation, especially with aberrant left bundle branch morphology in early infancy (see Figure 11 on page F3).
- Wide QRS tachycardias should be considered ventricular in origin until proven otherwise.
- Careful attention should be paid to the T waves for sharp deflections representing retrograde conduction from the ventricles to the atria via an accessory pathway (see Figure 15 on page F4).
- WPW syndrome warrants further (echocardiographic) investigation.
 - Shortened PR interval
 - Delta wave
 - Wide QRS

- Atrial flutter
 - Newborn infants
 - Rapid saw-tooth pattern with inverted P waves in the inferior limb leads
 - Atypical form (intraatrial reentrant tachycardia)
 - Distinct P waves separated by isoelectric periods
- VT
 - QRS complexes differ from the sinus QRS complexes
 - Typically wide
 - Young infants are an exception; minimal QRS prolongation (0.08–0.09 seconds) may be seen.
- Sudden cardiac death
 - Marked prolongation of QTc intervals
 - QTc interval >460 ms = LQTS
 - QTc interval 440–460 = borderline
- During administration of adenosine
 - Detect rare conversion to a more malignant arrhythmia
 - Once conversion to a sinus rhythm is achieved, 12-lead ECG should be repeated to look for evidence of preexcitation.

Ambulatory (Holter) monitoring

- Criteria for diagnosis of sinus bradycardia
 - Neonates and infants: <60 bpm, sleeping, <80 bpm, awake, quiet
 - Children 2–6 years: <60 bpm
 - Children 7–11 years: <45 bpm
 - Adolescents >11 years: <40 bpm
 - Athletes: <30 bpm

TREATMENT APPROACH

- Empirical therapy without detecting arrhythmia does not meet the current standard of practice.
- Young children
 - Drug treatment for 6–12 months followed by observation
 - Pacemaker implantation for complete AV block
- Older children and adolescents
 - Depending on clinical and nonclinical factors
 - No therapy
 - Drug therapy
 - Ablation
 - Pacemaker

SPECIFIC TREATMENT

Premature beats

- PACs
 - Therapy not necessary unless:
 - PACs initiate SVT.
 - PACs block impulses in a newborn infant dependent on heart rate to maintain adequate cardiac output.
 - If suppressive therapy is required:
 - Digoxin
 - Propranolol
- PVCs
 - Neither treatment nor curtailment of exercise is required, even if a bigeminal rhythm is present.
 - If worrisome PVCs are present, the need for therapy should be determined by a pediatric cardiologist.

SVT

- Young children
 - Cardiogenic shock:
 - Direct current synchronized cardioversion
 - 0.5–2 watt-seconds or J/kg with the largest paddles allowing effective chest contact
 - Adenosine
 - Administered via intravenous bolus, if venous access is available
 - Follow with a second doubled if the first dose is ineffective.
 - Should be administered with ECG monitoring
 - Effective in approximately 90% of episodes
 - Procainamide
 - Use if adenosine is ineffective, or if SVT quickly recurs
 - Can be administered intravenously to infants and young children after appropriate loading, with a subsequent repeat trial of adenosine.
 - If conversion does not ensue, procainamide level should be obtained 4 hours into the infusion (therapeutic range, 4–8 µg/mL).
 - Intravenous verapamil and propranolol
 - Suppressive therapy with propranolol is appropriate in WPW syndrome.
 - These agents are contraindicated in children <1 year.
 - Digoxin and verapamil
 - Should be avoided in SVT
 - May shorten the antegrade refractory period of the accessory pathway, allowing more rapid conduction to the ventricles
 - Potentially fatal if atrial fibrillation develops
 - If preexcitation is not present, either agent can be used to prevent recurrence.

- β -Blockers
 - Should be avoided in the presence of congestive heart failure, sick sinus syndrome, or a history of bronchospasm
 - Other medical therapies
 - Use if the above agents are ineffective.
 - All require hospitalization for drug initiation.
 - Flecainide
 - Sotalol
 - Amiodarone
 - Ablation
 - Not recommended during the first 2 years of life
 - Resultant myocardial scar may grow with the patient and become a subsequent nidus for malignant, often drug-refractory arrhythmias.
 - Older children and adolescents
 - Therapeutic choices depend on:
 - Frequency
 - Ease of conversion of episodes
 - No therapy other than self-conversion via a Valsalva maneuver or headstand
 - Drug therapy with consideration of:
 - Duration
 - Compliance
 - Cost
 - Radiofrequency ablation
 - At least 90% successful, but with a chance of a later recurrence
 - If the patient with SVT will undergo surgery for a cardiac defect, preoperative assessment and ablation should be considered to reduce arrhythmia-related postoperative morbidity and potential mortality.
- Atrial flutter**
- Digoxin
 - One-third of very young patients respond in utero or postnatally.
 - Electrical cardioversion
 - Required in about two-thirds of patients
 - Long-term therapy
 - Usually unnecessary because recurrences are rare
- VT**
- Acute management
 - Depends on the patient's clinical status
 - Rate and duration of VT
 - Presence of structural cardiac lesions
 - Prior myocardial dysfunction
 - Hemodynamic compromise
 - Electrical cardioversion with 1–2 watt-seconds/kg
 - If reasonable clinical stability is present:
 - Intravenous lidocaine
 - Procainamide
 - Magnesium
 - Amiodarone
 - Long-term suppressive therapy
 - Predicated on:
 - Risk of recurrence
 - Morbidity and mortality of the type of VT
 - Risk-benefit ratio of treatment
 - Common antiarrhythmic agents to prevent VT recurrence:
 - β -Blockers
 - Sotalol
 - Amiodarone
 - Other treatments:
 - Implantation of an automatic cardioverter-defibrillator
 - VT ablation
 - Benign forms of VT
 - Accelerated ventricular rhythm
 - Requires observation only (see Figure 16 on page F5).
 - Right ventricular outflow tract tachycardia
- Conduction abnormalities**
- First-degree AV block
 - No therapy is required.
 - Second-degree AV block
 - Type I
 - No therapy is required in most cases.
 - Type II
 - Ongoing medical surveillance
 - Potential need for pacemaker implantation
 - Complete AV block
 - Early pacemaker implantation is advised in infants with:
 - Risk factors
 - Symptoms of inadequate cardiac output
 - Isoproterenol
 - Infuse if necessary to increase the heart rate while awaiting pacemaker therapy
 - Should not delay implantation
 - If not in infancy, pacemaker insertion in adolescence is usually necessary depending on:
 - Symptoms
 - Ventricular rate
 - Stability of the ventricular escape rhythm

Sudden cardiac death**■ LQTS**

- For any child or adolescent who collapses suddenly with no discernible cardiac output:
 - Rapid resuscitation
 - Early defibrillation
- β -Blocker therapy
- Cardiac pacing
- Left stellate ganglionectomy
- Implantation of cardioverter-defibrillator
- Avoidance of:
 - Competitive sports
 - Drugs capable of prolonging the QTc
 - Sympathomimetics
 - Rapid correction of electrolyte abnormalities

WHEN TO REFER

- Arrhythmias associated with presyncope, syncope, chest pain, or a sense of doom
- Underlying heart disease
- Family history of premature (before age 35 years) sudden cardiac death
- Persistent or repetitive bradycardias or tachycardias
- Premature ventricular beats that increase with exercise

WHEN TO ADMIT

- Arrhythmias associated with syncope or low cardiac output
- Symptomatic high-grade AV block
- Difficult-to-control SVT, atrial flutter
- VT
- LQTS with syncope, aborted sudden death

FOLLOW-UP

- Premature beats
 - Frequent PVCs
 - Long-term yearly follow-up
 - Watch for arrhythmia-induced ventricular dilatation.
 - Watch for ventricular dysfunction.
- SVT
 - Infants should be observed after treatment in view of the risk of later recurrence.

PROGNOSIS**■ SVT**

- SVT onset during the first 4 months of life
 - 60% will have recurrences.
 - >90% will be free of clinical episodes of tachycardia by 1 year of age.
 - As many as one-third of these children may have a recurrence at a mean age of 8 years.
- SVT onset at ≥ 5 years
 - Chance of recurrent episodes of tachycardia is 75–80%.
- WPW syndrome/preexcitation
 - Substantially increased risk of sudden death
- Automatic ectopic tachycardias
 - Often incessant and relatively drug resistant
 - Tachycardia-induced cardiomyopathy is possible if conversion is not achieved.

■ Atrial flutter

- Atypical form
 - If conversion to and maintenance in a sinus rhythm cannot be achieved, morbidity is substantial, with 4- to 5-fold increase in risk for sudden death

■ VT

- Benign forms
 - Substantial incidence of spontaneous resolution in childhood

■ Conduction abnormalities

- Second-degree AV block
 - Type I: little risk of progression to complete block
 - Type II: progression to higher levels of AV block occurs
- Complete AV block
 - 20% mortality risk

■ Sudden cardiac death

- Annual mortality after onset of symptoms in untreated young patients
 - 1–5%
 - Nearly 10% risk of sudden death as the initial symptom
- Highest risk for sudden death in patients with:
 - History of syncope
 - QTc more than 530 ms
- LQTS
 - Cumulative probability of a cardiac event (predominantly syncope) in patients who are genotyped LQT1, 2, and 3 by 15 years of age
 - 10% LQT3
 - 69% LQT1

- Jervell and Lange-Nielsen syndrome
 - Substantially higher incidence of sudden death compared with Romano-Ward variant
- Rarely, may be a cause of sudden infant death syndrome

PREVENTION

■ Conduction abnormalities

- LQTS
 - Automatic external defibrillators
 - Availability in some school systems has already begun to decrease the incidence of sudden cardiac death in the young.

- Risk reduction may be achieved by asking 2 critical questions in pre-sports clearance evaluations.
 - Has the patient ever passed out, had visceral chest pain, or experienced symptomatic palpitations during strenuous exercise?
 - Has any family member died suddenly and unexpectedly before the age of 35 years?
 - An affirmative answer to either question should prompt a cardiologic referral before participation in competitive sports.

Cardiovascular Screening

BACKGROUND

- Congenital and acquired heart diseases are common chronic disorders in children.
- Heart disease in children is often undetected until a child develops symptoms.
 - Heart failure
 - Sudden death
 - Exception: diseases contracted shortly after birth that produce severe symptoms
- Pediatric heart diseases are a heterogeneous group of conditions.
 - Individual diseases are not common.
- However, as a group, pediatric heart diseases raise questions about need for universal screening.
- Congenital structural lesions, when undetected, often result in sudden death.
 - Screening may be most important for lesions associated with sudden death.
 - Occur in 0.8–1% of all births
- Improved screening strategies have resulted in higher incidence of cardiomyopathies (1.13 new cases per 100,000 births).
- Hypertrophic cardiomyopathy (HCM) is:
 - Defined as unexplained left-ventricular hypertrophy in the absence of a hemodynamic cause
 - The most common cause of sudden cardiac death in healthy, often athletic adolescents
- Rhythm disturbances of concern are:
 - Long QT syndrome (LQTS)
 - Inherited disorder of cardiac ion channels
 - Brugada syndrome
 - Both syndromes predispose affected individuals to sudden death from ventricular tachycardia.
- Arrhythmogenic right-ventricular dysplasia (ARVD)
 - Also referred to as *arrhythmogenic right-ventricular cardiomyopathy*
 - Includes rhythm abnormality and cardiomyopathy
 - Accounts for 5% of cases of sudden death in North America.
- Acquired conditions can also be severe and lead to sudden death or heart failure.
 - Infectious
 - Myocarditis
 - Vasculitis
 - Pericarditis
 - Endocarditis

- Toxic
 - Adriamycin
 - Thalassemias
 - Medications
- Vascular
 - Atherosclerosis
- No overall incidence and prevalence data are available for acquired conditions.
- Incidence of sudden cardiac death
 - Approximately 1 death in 200,000 high school athletes per year
 - Devastating effect on public and survivors when a young person in dies unexpectedly
 - An even larger number of youth with these conditions will be disabled by heart failure.

GOALS

- Clinicians should maintain a high level of alertness in their practices for these potentially life-threatening cardiac conditions by conducting a thorough history, physical examination, and laboratory evaluation.
- Cardiovascular screening depends on a high index of suspicion of disease in young children.
 - Those who appear healthy and fit, with normal clinical examinations, are the most difficult to refer for further assessment.
 - The risk of sudden cardiac death associated with many of the clinically relevant cardiac diseases is not known.
- Some subpopulations may be particularly vulnerable or require additional consideration.
 - Screening methods include:
 - Fetal screening
 - Infant screening
 - Hypertension screening
 - Screening of young athletes

GENERAL APPROACH

- Many recommend wide-scale screening for cardiovascular disease in childhood, because of:
 - Devastating consequences
 - Hidden nature of the disease
 - Relatively common occurrence of different cardiovascular conditions
 - Prolonged asymptomatic period

- To identify the many types of cardiac conditions, echocardiography and electrocardiography (ECG) would be necessary for all children and adolescents.
 - Cost would be prohibitive.
 - ECG may generate a large number of false-positive results.
 - Comprehensive assessments such as these are probably not indicated.
- Office tools readily available to all practitioners for evaluating cardiovascular health in children
 - Positive communication skills
 - Growth curves and documentation of normal developmental milestones
 - Accurate scales and a stadiometer (or a tape measure) to measure height
 - Tape measure for head circumference and wing span
 - Accurate blood pressure cuffs, with a range of appropriate-size cuffs
 - An oscillometric cuff is easier to use on infants and small children.
 - Aneroid cuffs are portable.
 - May be more reliable, particularly in older children who may be hypertensive
 - Pulse oximeter
 - Body mass index (BMI) calculator
 - US Centers for Disease Control and Prevention (CDC) guidelines for the normal range of BMI by sex and age
 - To calculate BMI: weight (in kilograms) divided by height (in meters) squared
 - Printed tables are available from the CDC.
 - Clinical examination by observation, palpation, and auscultation
 - Access to radiographs, ECG, and echocardiography
 - Blood biomarkers may be useful in distinguishing heart diseases from other causes of distress.
 - Interpretation of results may require discussion with a subspecialist who uses these tests with greater frequency.
 - In some tertiary care centers, thorough clinical screening may allow the identification of the affected individual and genotype.
 - Genetic testing of individual family members may be necessary.
 - Should provide sufficient clues to heart disease to prompt referrals to a pediatric heart specialist
- These tools and a high index of suspicion can identify some cases of occult cardiovascular disease in children and adolescents.

SPECIFIC INTERVENTIONS

Fetal screening

- A fetal diagnosis of complex congenital heart disease may prompt delivery at a tertiary care center.
 - Cost/benefit ratio is unknown.
- Advance knowledge of an infant's cardiac defect may allow the family more time to process the disease emotionally.
 - The emotional effect of this advance knowledge is difficult to assess.
- Indications for fetal echocardiography include:
 - Obvious structural abnormality visualized on routine fetal sonography
 - Perceived rhythm abnormality
 - Sibling with congenital heart defect or cardiomyopathy
 - Known fetal chromosomal abnormality
 - Family history of syndromes or heart disease
 - Maternal lupus or phospholipid antibodies
 - Maternal diabetes
 - Maternal exposure to infectious diseases
 - Multiple spontaneous abortions
 - Known teratogens and toxins

Neonatal and infant screening (general)

- Most neonates have not been screened by fetal echocardiography.
 - Screening all fetuses is presently not cost effective.
 - Current efforts rely on standard tools to make a diagnosis.
 - An abnormal screening result should prompt referral to a pediatric heart specialist.
- Pediatricians screen most infants in the immediate newborn period.
 - First 2 weeks and again at 2 months of life
- Detecting lesions that are dependent on the ductus arteriosus is critical.
 - Critical coarctation
 - Pulmonary atresia
 - Hypoplastic and left-heart syndrome
 - Presentation is often nonspecific.
 - Coarctation may occur surreptitiously with a cranky infant who is mildly tachypneic and diaphoretic.
 - The infant may appear septic.
 - Other ductal-dependent lesions lend themselves to cyanosis.
 - May be readily apparent
 - Less so in the darker-skinned infant and anemic infant

- The 2-month screening is particularly important in detecting left-to-right shunts.
 - The patient's pulmonary vascular resistance drops maximally at that point.
 - A detailed family history is important.
 - Pregnancy history
 - Known heart disease before age 50 years
 - Heart murmur that required treatment
 - Sudden infant death in prior pregnancies
 - Abrupt deaths under the age of 50 years
 - Ask about automobile crashes or swimming deaths.
 - May give clues to a family history of LQTS or Brugada syndrome
 - Deafness at birth
 - An association exists with the Jervell and Lange-Nielsen form of LQTS and abnormalities of ion flux into the organ of Corti.
 - Seizures
 - Possibly caused by ventricular tachycardia
 - Potassium abnormalities
 - Associated with LQTS
 - Developmental delays, physical handicaps, or syndromes
 - Diabetes
 - Thyroid disease, lupus, rheumatoid arthritis
 - May have associations with pericarditis, cardiomyopathies, and atrioventricular block
 - Enlarged heart
 - Cardiomyopathy
 - Use of a pacemaker or antiarrhythmic
 - Tall family members
 - Indicates connective tissue disease
 - Deaths due to aneurysm
 - Indicates connective tissue disease and familial aortic aneurysm
 - Obesity
 - Kidney disease or kidney transplantation
 - Applicable when screening for systemic hypertension
- Screening infants using the medical history and review of systems**
- Signs of a possible cardiac lesion, although nonspecific:
 - Poor Apgar score
 - Tachypnea
 - Cyanosis at birth
 - In the review of systems, indications that cardiac disease and congestive heart failure (CHF) are present
 - Any indications of poor or lengthy feeding
 - Tachypnea
 - Dyspnea
 - Diaphoresis with feeding
 - Reflux
 - Common in infants
 - Persistent reflux with sweating and pallor or cyanosis may be indication that a heart lesion is present with associated CHF caused by:
 - Diminished gut perfusion
 - Hepatosplenomegaly
 - Or both
 - Cranky, colicky infant who is also pale, tachypneic, or not growing may have CHF or intermittent arrhythmia.
 - Frequent upper respiratory symptoms are often an indication of pulmonary edema.
 - Dyspnea
 - Tachypnea
 - Wheezing
 - Caused by CHF or congenital heart disease associated with immune deficiency
 - The clinician should ask how well the patient sleeps.
 - An infant with heart failure or arrhythmia may sleep restlessly.
- Screening infants using the physical examination**
- Vital signs are crucial.
 - If the infant is cyanotic or dusky, obtain pulse oximetry.
 - Assess upper- and lower-extremity pulses, including the femoral pulse, to assess for coarctation of aorta.
 - Comparing upper- and lower-extremity pulses simultaneously during the physical examination may increase accuracy.
 - Coarctation is the most frequently missed cardiac lesion.
 - 4-extremity blood pressures are less sensitive and specific for diagnosis of coarctation of aorta than formerly thought.
 - Obtaining 4-extremity blood pressures at least once in all infants is still good practice.
 - A flat or declining growth curve may indicate failure to thrive.
 - May be a sign of CHF
 - Infants and children with cyanotic and valvular heart disease may continue to grow along a normal curve.

■ Head, ears, eyes, nose, and throat

- Should be referred to a pediatric cardiologist if:
 - Any jugular venous distention
 - Brisk carotid upstroke
 - Cranial bruit
 - Neck webbing prompts suspicion of Noonan or Turner syndrome.
 - A bifid uvula prompts suspicion of Loeys-Dietz syndrome.
 - With a predilection toward bicommissural aortic valves, aortic root dilatation and, ultimately, dissection

■ Chest

- A precordial bulge can indicate cardiomegaly.
- Pectus excavatum and carinatum may signal the presence of a connective tissue disorder.
- Marfan syndrome

■ Lungs

- Pulmonary edema
 - Persistent, recalcitrant wheezing
 - Frequent respiratory symptoms

■ Cardiac system

- Many children have innocent murmurs.
 - Soft or musical and systolic in nature
 - Some of these murmurs are even continuous.
 - Disappear when the child is supine
 - Murmurs that require referral
 - Present in diastole or continuously
 - Harsh and loud
 - Persistent systolic murmurs
 - Clicks
 - Snaps
 - Rubs
 - Third and fourth heart sound gallop rhythms

■ Abdomen

- Organomegaly is suspicious for CHF and storage diseases.
 - Associated with cardiomyopathy

■ Extremities

- Clubbing is a sequela of cyanotic disease.
- Arachnodactyly is associated with Marfan syndrome.
- Genetic syndromes
 - Polydactyly
 - Clinodactyly
 - Absent radii

Appearance as a screening tool in infants

- Is the child dysmorphic?
- Does the child have similarities in appearance to either parent?
 - The clinician should not use this look-alike phenomenon to exclude syndromes.
 - Parents may not realize they have a syndrome if it has never been diagnosed.
 - A parent with bad acne may in fact have tuberous sclerosis.
 - If the child is dysmorphic, and if a syndrome is suspected:
 - Heart disease should be considered as an associated issue
 - A very strong association exists between structural heart abnormalities or cardiomyopathies and syndromes or chromosomal abnormalities.

Screening infants with noninvasive tools

Chest radiography

- Allows assessment of:
 - Visceral situs
 - Pulmonary blood flow patterns
 - The shape and size of the cardiac silhouette
- The following are associated with some forms of cardiac disease.
 - Dextrocardia
 - Situs inversus
 - Increased cardiopulmonary blood flow
 - Cardiomegaly
 - Volume or pressure overload lesions
 - Cardiomyopathies
 - Myocarditis
 - Ebstein anomaly
 - Pericardial effusions
- The side of the aortic arch may be inferred.
 - A right-sided aortic arch is seen in 10% of the population.
 - More common with conotruncal defects, such as tetralogy of Fallot
 - A right-sided arch may also be seen in persons with a double aortic arch.
 - Produces a vascular ring
- The thymic sail should be obvious in newborns and neonates.
 - If it is absent, consider:
 - DiGeorge syndrome
 - Conotruncal defects

- The pulmonary blood flow pattern is important because Kerly B lines may confirm the suspicion of:
 - Pulmonary edema consistent with shunt lesions
 - Cardiomyopathy
 - Myocarditis
 - Chronic lesions may produce hyperinflation and flattened diaphragms.

Barium esophagography (barium swallow)

- Readily accessible
- Does not require sedation
- Excellent screening tool for vascular rings and slings
- Less expensive than magnetic resonance imaging
- Indentation of the esophagus indicates abnormal vasculature.
- The test is indicated for:
 - Stridorous infants
 - Infants with reflux
 - Any infant in whom the suspicion of right-sided aortic arch is raised
- Direct imaging techniques are required to make a definitive diagnosis.
- In all cases, requires further investigation by a pediatric cardiologist

ECG

- Relatively insensitive, nonspecific screening tool for structural heart defects
- Important screening tool for rhythm disturbances
- Inexpensive
- Readily accessible
- Provides baseline information regarding heart lesions
- Use of the ECG as a routine screening tool is not universally established.
 - Has been adopted in some parts of Europe
- In newborns suspected of having heart disease, attention must be paid to the QRS axis and the T-wave morphology.
 - A superior axis may suggest the presence of major cardiac defects.
 - Atrioventricular septal defect
 - Tricuspid atresia
 - Some forms of double-outlet right ventricle
 - The persistence of an upright T wave in V1 beyond the first week of life usually indicates significant right-ventricular hypertrophy.
 - In the context of cardiac or pulmonary disease

- If the heart rhythm is not sinus, heart disease should be considered.
- If degrees of atrioventricular block are found, maternal systemic lupus must be considered.
- Greatly elevated (sinus) heart rates may be present in patients with CHF.
- Extremely low heart rates (not sinus) may be consistent with atrioventricular block.
- If a superior QRS vector is found, it may be:
 - Normal variant
 - Sign of preexcitation
 - Indication of Noonan syndrome
 - Indication of a more complex lesion
 - Atrioventricular canal
 - Tricuspid atresia
- Configuration of the P waves and QRS complexes is important.
 - Ventricular preexcitation patterns may be present within families.
 - Wolff-Parkinson-White syndrome
 - Ebstein anomaly
 - Wolff-Parkinson-White syndrome is also seen with left-ventricular noncompaction-type cardiomyopathy.
- Diagnosis of Brugada syndrome depends on the appropriate analysis of the QRS complex.
 - Including ST-segment elevation in the right precordial leads
- rSR' patterns may be a normal variant evident of:
 - Right-ventricular hypertrophy
 - Initial sign of atrial septal defect
 - More pronounced right bundle-branch block patterns, which are not surgically induced, may be present in:
 - Mitochondrial dystrophies (Kearns-Sayre syndrome)
 - Arrhythmogenic right-ventricular dysplasia
 - Beckwith-Wiedemann syndrome
 - Some septal defects
 - May also be present in familial right bundle-branch block
 - Generally benign
- Ventricular hypertrophy as indicated by ECG should prompt referral for echocardiography.
- Right- and left-ventricular hypertrophy may be signs of:
 - Cardiomyopathy lesions
 - Shunt lesions
 - Pressure overload lesions
 - However, voltage is not uniformly accurate in predicting disease.
 - If increased voltage is combined with a strain pattern, cardiac disease is likely.

- Certain ECGs are considered pathognomonic for disease.
 - Pompe disease
 - Massively increased voltage
 - Strain pattern
 - Shortened PR interval
 - Many patients with severe left-ventricular noncompaction-type cardiomyopathy have a similar pattern of severe ventricular hypertrophy on ECG.
 - Pathognomonic for this disease and of strain
 - With or without evidence of preexcitation

Serum markers of heart disease

- Cardiac enzymes and B-type natriuretic peptide (BNP) levels are routinely used in screening symptomatic adults for cardiac ischemia or heart failure.
 - Their use as screening tools has not been established for diagnosing heart disease in children.
 - They serve as secondary tools that aid in defining the severity of the disease.
- Troponin I and troponin T are components of the cardiomyocyte.
 - May be released during myocyte degradation
 - Have been useful in identifying adults with ischemic heart disease
 - Use of troponin analysis in children is less clear.
 - Active release of troponins may be more consistent with acute myocarditis than chronic dilated cardiomyopathy.
- BNP is released from the ventricle during times of cardiac stress.
 - Appears to correlate well with heart failure in adults and children
 - A linear correlation of BNP with degree of heart failure appears to exist.
 - The specific level of BNP may be predictive of adverse cardiac events in children.
- Other biomarkers are presently being investigated as possible indications of heart disease.
- More conventional markers of disease are nonspecific and not very useful in screening for heart disease.
 - C-reactive protein
 - Sedimentation rate
 - Blood chemistry
 - Complete blood counts

Echocardiography

- Echocardiographic screening in every newborn is not cost effective.
- Expensive

- Time consuming
- Indiscriminate performance of echocardiography may create more anxiety than comfort among practitioners and parents.
 - The finding of a tiny patent ductus arteriosus or patent foramen ovale on routine echocardiography often results in:
 - Unnecessary follow-up
 - Increased parental anxiety
 - Increased medical expenditures
- Appropriate echocardiographic screening of children with heart murmurs is determined by a thorough clinical examination.
 - Reported to be 80% sensitive in identifying pathologic heart disease when performed by general pediatricians
 - Sensitivity increases to 96% when a pediatric cardiologist performs the examination.
- Screening echocardiography may be warranted:
 - In neonates with siblings with complex congenital heart disease
 - If maternal exposure to toxins or potential teratogens is suspected
 - For infants born to mothers with gestational diabetes
 - Any neonate with genetic syndrome

Screening for cardiovascular disease in children in adolescents

- In the US, structural heart disease is frequently diagnosed early in life.
 - Some occult cardiac defects and cardiomyopathies may not come to light until children grow and their physiologic features change.
 - Bicuspid aortic valve
 - HCM
 - ASDs
 - Partial anomalous pulmonary veins
 - Coronary artery anomalies

History

- History of present illness
- Family history
- Medical history
- Review of systems
- History of multiple family members with diabetes may indicate a predisposition for:
 - Acquired heart disease
 - Metabolic or mitochondrial cardiomyopathy

- Underlying heart defect may be suspected if a patient:
 - Is hospitalized yearly for respiratory infections
 - A frequent presentation of:
 - ASDs
 - Pulmonary vein anomalies
 - Dilated cardiomyopathies
 - Has sedentary lifestyle (doesn't have the energy to play)
- Symptoms of chest pain and palpitations are often nonspecific in growing children and adolescents.
 - Warrant evaluation for heart disease in appropriate cases
- Presyncope should be thoroughly evaluated.
 - A history of syncope warrants screening for cardiovascular disease.
- In a child with a heart murmur, ask whether this murmur is new.
 - May help differentiate between innocent and pathologic murmurs
- Coarctation of the aorta may sometimes occur beyond infancy.
 - Physical examination in suspected cases should include:
 - Palpation of femoral pulses
 - Measurement of upper- and lower-extremity blood pressure
- In addition to the history, questions to ask of children and adolescents include:
 - What grade are you in, and how are you doing in school?
 - Chronically ill children tend to have more difficulty concentrating on school activities.
 - Do you participate in activities outside of school? What type?
 - Some children do not have the energy to participate in activities.
 - How well do you sleep at night? How many pillows do you use for sleeping? Has anyone ever told you that you snore? Are you sleepy during the day? Do you nap?
 - These questions are useful in identifying sleep apnea, which has been linked with:
 - Systemic hypertension
 - Severe sinus bradycardia with obstruction
 - Cor pulmonale
 - How often and how much do you eat?
 - This question may be difficult for some children and adolescents to answer.
 - The question may be further refined by asking what the patient has had to eat today.
 - A chronically ill child may have high caloric needs.
 - A patient with organomegaly caused by CHF, storage disease, or both may have early satiety and abdominal pain.

Screening for systemic hypertension, obesity, and metabolic syndrome as precursors to cardiovascular disease

- Cardiac risk factors are additive risk factors for future cardiac disease.
 - Systemic hypertension
 - Obesity
 - With or without metabolic syndrome
 - Obstructive sleep apnea caused by obesity

Blood pressure screening

- Mass screening is important but may produce a variety of false-positive results.
- Repeated testing and questioning may be necessary to obtain true-positive results.
- Additional questions for patients
 - How and when were you diagnosed with high blood pressure?
 - Have you had any tests for your high blood pressure?
 - Have you gained or lost weight recently? How much and over what period?
 - What are your favorite foods? How often do you eat out?
 - What are your favorite drinks? How much water do you drink in a day?
 - What medicines (prescription and over the counter) are you taking?
 - Do you take any dietary supplements, such as creatine, protein shakes, or MetRx?
 - Anabolic steroids will cause acne and blood pressure elevation.
 - How active are you? Is your exercise limited? By what?
 - Do other people in your family have high blood pressure? Does anyone have kidney dialysis, transplants, or diabetes?
 - How do you sleep at night? Do you snore? How many pillows do you use under your head when sleeping?
 - Do you ever have trouble with palpitations, breathing difficulties, fainting, or dizziness?
- If the initial blood pressure is taken in an outer room and it is elevated:
 - The patient should be allowed to lie down in the examining room for at least 5 minutes.
 - Blood pressure assessment is then repeated.
- The readings are compared with those recently established by the Task Force for Systemic Hypertension in Children.
 - Using sex, height, and weight percentiles
- If 3 readings on different visits are consistently >97th percentile:
 - The patient should be referred to a subspecialist.
 - Pediatric cardiologist
 - Nephrologist

Obesity and comorbid conditions

- Childhood obesity has become increasingly prevalent.
- Once an individual has been identified as obese by BMI:
 - Associated comorbid conditions should be assessed by history and physical examination.
 - Appropriate referrals can be made.
 - Nutritionists
 - Behavioral modification specialists
 - Physical therapists
 - Exercise or rehabilitative programs
 - Pulmonology or sleep specialists
 - Endocrinologists
- ECGs should be obtained in obese children with:
 - Systemic hypertension
 - Obstructive sleep apnea
 - Hyperlipidemia
 - Any obese child who is seeking exercise clearance
 - The presence of obesity may preclude a reliable ECG.
 - The layer of adipose may provide voltage insulation, arbitrarily decreasing the total voltage.
 - The presence of any of the following should prompt further investigation.
 - Right-ventricular hypertrophy (may be seen with cor pulmonale caused by obstructive sleep apnea)
 - Left-ventricular hypertrophy
 - Bundle-branch blocks
 - Ischemic changes
- Obese children with systemic hypertension and obstructive sleep apnea should have echocardiography.
 - Echocardiography is technically challenging in obese individuals.
 - Resolution is often poor.
 - Although some studies have reported increased left-ventricle mass in obese individuals, obese children have not been thoroughly assessed.
 - Lack of increased left-ventricle mass or left-ventricle hypertrophy on the echocardiogram should not be a measure of comfort.
- Obesity may first occur as an endothelial disease.
 - Therefore, newer noninvasive imaging modalities may be in order.
 - Carotid or intimal thickening
 - Vascular reactivity studies

- Individuals with obesity or systemic hypertension should have blood tests, including:
 - Metabolic profile
 - Liver function tests
 - Complete blood cell count with differential
 - Thyroid function tests
 - Aldosterone, uric acid testing
 - If systemic hypertension or as a baseline marker
 - Insulin level testing (likely to be elevated)
 - Glycated hemoglobin test
 - Glucose tolerance testing if diabetes is suspected
 - C-reactive protein testing as a nonspecific marker for cardiac inflammatory disease
 - Fasting lipid profile
 - BNP assessment: often performed at baseline
 - Serial follow-up in patients with suspected or proven cardiomyopathy
 - Obese individuals have been documented to have lower BNP levels.
 - A false-negative result may occur.

Athletic screening: ruling out sudden death

- Genetic diseases, such as HCM, Marfan syndrome, and ARVD, may be suspected in individuals on the basis of family history, medical history, and current illness history.
- However, many diseases that cause sudden cardiac death are relatively silent.
 - History and physical examination alone cannot guarantee identification of many critical cardiovascular abnormalities that may occur in young athletes.
 - Even with the addition of noninvasive screening (echocardiography and ECG performed in populations of 250–2000 athletes, followed up over 1 year), very few definitive examples of lethal cardiovascular abnormalities have been detected.
 - Given the expense, time, and labor intensiveness of genetic molecular screening for the widely heterogeneous cardiovascular diseases, screening blood testing for mutations is untenable.

Echocardiography

- Can diagnose HCM in young athletes
 - Most common cause of sudden cardiovascular death in young athletes
 - Other relevant abnormalities associated with sudden cardiac death may also be identified.
 - Valvar heart disease (mitral valve prolapse, aortic valve stenosis)
 - Aortic root dilatation
 - Left-ventricular dysfunction (myocarditis or dilated cardiomyopathy)

- Some relevant diseases may occasionally be missed even with echocardiographic assessment.
 - Coronary anomalies
 - Early coronary diseases
 - ARVD
 - Cost efficiency must be considered in mass screening.
 - Cost range: \$600–\$2000
 - Institutions cannot be expected to bear the expense of these screening programs.
 - Additional emotional, financial, and medical burdens exist because of false-negative and false-positive results
- ECG**
- More practical and cost-efficient than echocardiography for population-based screening
 - Is abnormal in 75–95% of patients with HCM
 - Will usually assist in identifying LQTS and Brugada syndrome
 - Not all affected relatives within a family with LQTS will exhibit an ECG abnormality.
- Some patients with coronary anomalies have normal ECGs; therefore, ECG does not have the same power as the echocardiogram as a preliminary screening tool.
 - It has a relatively low specificity because of the frequency with which ECG alterations may occur in normal athletic physiologic circumstances.
 - False-positive results complicate its use as a primary screening tool, anticipating that 20–25% of all athletes will exhibit these abnormalities, prompting further echocardiographic study.
 - Elite athletes without structural cardiac abnormalities are likely to exhibit ECG abnormalities most consistent with HCM and ARVD.
 - If an abnormality is identified, refer for a full evaluation by a pediatric cardiologist.

Cerebral Palsy

DEFINITION

- Cerebral palsy (CP) is a clinical descriptive term for a heterogeneous group of conditions classified according to type, distribution, and severity of motor abnormality.
- Describes a group of disorders of the development of movement, posture, and coordination
 - Motor disorder often accompanied by disturbances of any of the following, alone or in combination:
 - Sensation
 - Cognition
 - Communication
 - Perception
 - Behavior
 - Can also be accompanied by a seizure disorder
 - Can include impairment in the musculoskeletal system, most commonly:
 - Contractures (eg, equinus deformity)
 - Torsional changes in long bones (eg, femoral and tibial torsion)
 - Joint instability (eg, hip displacement)

EPIDEMIOLOGY

- Prevalence
 - Approximately 2–2.5 cases/1000 live births in developed countries
 - Has generally remained stable over the past 20 years
 - More common with lower birth weight and lower gestational age
 - In 1 survey, children born weighing <1000 g constituted 0.2% of survivors but accounted for 8% of children who had CP.
 - Prevalence of CP in very low birth weight infants and those born at <32 weeks' gestation decreased from 6% of live births in 1980 to 4% in 1996.
- In the US, 59% of children with CP attend a special school versus 0.5% without CP.
- Use of health care services for children with CP versus without (over 12 months; 100 children each group)
 - 16 versus 3 visits to a physician
 - 29 versus 4 hospital admissions
 - 108 versus 20 hospital days

ETIOLOGY

- A definite cause cannot be identified for many cases.
 - When a cause can be identified, it is usually of prenatal origin.
 - Intrapartum events play a limited role.
 - Neither sophisticated fetal monitoring nor a higher rate of cesarean deliveries has reduced the occurrence of CP.

- Each form of CP can be caused by a multitude of conditions, and a single etiologic factor (eg, meningitis) can lead to different forms of CP.
- Caused by nonprogressive disturbances affecting the brain in its early development (fetal, infantile, and early childhood)
- The timing of insult to the brain may affect manifestation.
 - Disturbances between 24 and 28 weeks' gestation are more likely to produce spastic diplegia or tetraplegia (quadriplegia).
 - Those occurring at term are more likely to produce dyskinesia.
- In approximately 10%, the cause is thought to be postneonatal (after 28 days).
 - Infection (eg, meningitis, encephalitis)
 - Asphyxia
 - Unintentional injury

RISK FACTORS

- Associated conditions
 - Periventricular leukomalacia (necrosis of white matter near the lateral ventricles)
 - Hydrocephalus
 - Congenital malformations
 - Newborn encephalopathy (recurrent seizures, hypotonia, coma)
- Low birth weight
- Low gestational age
- Multiple pregnancies (in mother)
- Isolated risk factors are poor predictors of CP, especially in full-term infants.
 - Fetal bradycardia
 - Neonatal acidosis
 - Intraventricular hemorrhage in the absence of periventricular leukomalacia
 - Low Apgar scores
 - Prenatal maternal chorioamnionitis

SIGNS AND SYMPTOMS

- Although the brain lesion or anomaly, once recognized in early childhood, is no longer progressive, clinical signs change, especially in the first several years of life.
 - Abnormal patterns emerge as the damaged nervous system matures.
 - For example, a child destined to have spastic quadriplegia:
 - Is often hypotonic in early infancy
 - At 6 months, may develop adduction of the thumb (palmar thumb)

- Followed in a month or 2 by scissoring of the legs when held upright
- By 9 months, may have diffuse spasticity and hyperactive deep-tendon reflexes
- Dyskinetic patterns may not be obvious until approximately 18 months.
- Ataxia may be apparent even later.
- Early signs
 - Difficulty feeding because of abnormal oral-motor patterns
 - Tongue thrusting
 - Tonic bite
 - Oral hypersensitivity
 - Irritability
 - Delayed milestones, such as head control

DIFFERENTIAL DIAGNOSIS

Possible diagnoses

- Neurodegenerative disorders
- Inborn errors of metabolism
 - Some rare inborn errors of metabolism (arginase deficiency and glutaric aciduria) may mimic CP.
 - These cause progressive deterioration, whereas CP does not.
- Developmental or traumatic lesions of the spinal cord
- Severe neuromuscular disease
 - Hypotonia in association with weak muscles and depressed tendon reflexes suggests a neuromuscular disease.
 - Many children with both spastic and extrapyramidal CP are hypotonic in early infancy.
- Movement disorders
- Spinocerebellar degeneration
 - Repeated examinations are necessary to rule out a progressive degenerative condition.
- Neoplasms
- Hydrocephalus
- Subdural hematoma
- Dopa-responsive dystonia
 - Rare but treatable form of dystonia
 - May begin with toe-walking and difficulties with gait
 - Responds dramatically to administration of levodopa
 - In most instances, no history can be found of a preexisting condition that would be consistent with CP.
- Hereditary spastic diplegia
 - Consider in a child with a parent who has CP and has late-onset spastic diplegia with no preceding history of prenatal or neonatal problems

Categorization by type, distribution, and severity of motor abnormality

- CP can be simplified into 3 categories.
 - Spastic (involving the pyramidal tracts)
 - Dyskinetic (involving the extrapyramidal tracts)
 - Mixed (involving both)
- Spastic CP
 - Associated with neurologic signs, including:
 - Hyperreflexia
 - Clonus
 - Extensor plantar response
 - Co-contractions
 - Persistent primitive reflexes
 - Abnormal postural control
 - Abnormalities impair normal movements, such as gait and the manipulation of objects, in complex ways.
 - Movement is often stiff, and patterns of movement, such as fisting of hands, retraction of shoulders, scissoring of legs, and toe-walking are often abnormal.
 - Hypotonia of the trunk and neck is common.
 - 3 types of spasticity
 - Diplegia
 - The legs are affected with general sparing of the arms.
 - Children with hydrocephalus are more likely to develop spastic diplegia.
 - Quadriplegia
 - All 4 limbs are significantly and functionally impaired, with the legs more severely involved than the arms.
 - More likely to be intellectually disabled (64% have an IQ <50) and have seizures (56%)
 - More likely to have feeding difficulties, severe joint contractures, and scoliosis
 - Hemiplegia
 - Only 1 side is involved, with the arm usually more impaired than the leg.
- Dyskinetic CP
 - Dyskinesia includes the involuntary movements of athetosis, chorea.
 - Dystonia
 - Sustained muscle contractures that lead to abnormal posture and twisting
 - Ataxia
 - Incoordination of movement and impaired balance and may be associated with an intention tremor

DIAGNOSTIC APPROACH

- A direct link between the type of CP and its cause cannot be established without using diagnostic evaluations, such as cranial ultrasonography or magnetic resonance imaging (MRI), and even then, one is often not found.
- The mean age at which CP is diagnosed is 10 months.
 - Therefore, in addition to formal developmental screening recommended for all children, those at risk for CP should have:
 - Regular careful physical examinations
 - Special attention to neurologic status
- Early diagnosis is aided by:
 - History of abnormal pregnancy, labor, delivery, or neonatal period
 - Report of serious acute illness and trauma
- Should evaluate:
 - Primitive reflexes (eg, the asymmetric tonic neck response)
 - Postural responses
 - Delayed
 - Righting the head when tilted to the side
 - Muscle tone (abnormal)
 - Motor milestones
 - Neurobehavioral responsiveness
- Routine screening for metabolic and genetic disorders is not recommended unless the child has atypical features, such as unusual facial features, or a progressive condition.

IMAGING

- Neuroimaging techniques may aid in understanding of structural abnormalities and timing of lesions.
 - Ultrasonography
 - Computed tomography
 - MRI
- Neuroimaging may demonstrate:
 - Periventricular leukomalacia
 - Postischemic necrosis
 - Cerebral dysgenesis
 - Hydrocephalus
 - Porencephaly
 - Tumor
 - Prenatal ischemic injury
 - Leukodystrophy

DIAGNOSTIC PROCEDURES

- Electroencephalography
 - Important part of diagnosis and management of associated seizures
 - Continuous electroencephalographic monitoring with videography may help differentiate seizures from other movement disorders.
 - Not helpful in diagnosis of CP
- Evaluation of altered gait and feeding disorders may require special diagnostic studies.
 - Gait analysis
 - Using videography, electromyography, and sensors
 - Has improved the orthopedic care given to these children
 - Videofluoroscopic swallowing studies

CLASSIFICATION

- Gross motor function classification system
 - Most common system for classifying severity
 - 5-level system to classify severity of motor involvement based on functional abilities and need for assistive technology and wheeled mobility

TREATMENT APPROACH

- The goal is for the patient to be as independent as possible and to participate in family and community activities with nonaffected peers.
 - Opportunities for participation may be limited, but the physician should:
 - Try to identify opportunities
 - Encourage child to participate in any and all activities that are available
- Multiple interventions are possible.
 - Muscle strengthening
 - Orthotics (eg, ankle-foot orthoses)
 - Oral medication
 - Botulinum toxin injections (with or without serial casting)
 - Intrathecal baclofen pump
 - Selective dorsal rhizotomy
 - Orthopedic surgery
- The best approach requires input of child and family with a team of clinicians (therapists, orthotists, surgeons, nurses, physicians, and social workers).
- Families often turn to alternative therapies.
 - The primary care physician should inquire about them and be aware of:
 - Their nature
 - Possible interactions with medications
 - Potential for harm

- Adults with CP
 - The 3 most important issues are:
 - Communication skills
 - Self-care
 - Mobility
 - Interventions (eg, medications, surgery, braces, or adaptive equipment) should focus on these issues.

SPECIFIC TREATMENTS

Medications

- Oral medications can reduce spasticity but have potential adverse effects.
 - Diazepam
 - Oral baclofen
 - Tizanidine
 - Dantrolene
- No controlled studies have documented improvement in functioning from these medications.
- Intramuscular botulinum toxin is effective in children with functional spasticity in transiently reducing spasticity in individual limbs.
- Drooling can be treated with:
 - Scopolamine (available as transdermal patch and tablet)
 - Glycopyrrolate
 - Botulinum toxin injections into salivary glands

Surgical procedures

- Selective dorsal rhizotomy and intrathecal baclofen reduce spasticity and increase range of motion.
- Orthopedic procedures, such as tenotomies, tendon releases, and transfers, are necessary to address soft-tissue and bone problems.
- Drooling may be managed with surgical removal of the salivary glands.

Physical modalities

- Constraint therapy produces anatomic changes in the brain on functional MRI.
 - Cannot improve selective motor control, difficulties with balance, and weakness
 - Immobilizing the better upper extremity in children with hemiplegia while providing therapy to enhance the function of the affected/worse arm and hand improves function.
- Strength training can improve function.
- Various casting and splinting techniques to maintain muscle length and inhibit increased tone may be helpful.
- After orthopedic surgery, therapy should be started to maximize range of motion and skills.

Assistive devices

- To assist motor activities
 - Switches that improve ability to control the environment
 - Computers
 - Small electric motors
- Communication augmentation
 - Speech synthesizers
 - Symbol charts
 - Spelling boards
- Simple enhancements to improve quality of life
 - Ramps
 - Accessible showers
 - Assistive devices, such as a pencil holder or mouth-activated switch
- The Individuals with Disabilities Education Act requires that school-aged children with disabilities be assessed for the utility of assistive devices and be given the support needed to use them effectively.
- Gaining access to these services requires:
 - Coordination of care
 - Knowledge of the resources available in the community
 - Referral to experts
 - Financial assets
- The physician is obliged to ensure that these services are available to the patient and the family.

Alternative treatments

- The following may offer functional benefits.
 - Equine-assisted therapy (hippotherapy)
 - Acupuncture
- Hyperbaric oxygen
 - Does not appear to improve function
- Electrical stimulation
 - Evidence for effectiveness is inconclusive.

Treatment for specific conditions

Impaired growth

- Evaluating growth impairment includes:
 - Evaluation of dietary intake and feeding
 - Assess the child's seating and posture during meals.
 - Assess swallowing mechanism.
 - Can be aided by a videofluoroscopic swallow study using foods of different consistencies
 - Videofluoroscopic swallow study can assess risk of aspiration.
 - Assistance of feeding specialists is invaluable.

- Evaluation for gastroesophageal reflux using:
 - pH probe
 - Endoscopy with biopsy
 - Barium swallow or radionuclide gastric-emptying study
- Provide special seating devices to maintain the child in an upright, neutral position.
- Thickened feedings
- Gastrostomy tube, with or without fundoplication
 - Usually improves weight gain and general health
 - May not improve longitudinal growth

Impaired communication

- Augmentative communication aids have been used, but few studies on these have been done.

Impaired cognition

- Early intervention referral for young children
- Special education program for school age
- Formal educational testing

Weakness or impaired mobility

- Orthoses/braces
- Walker
- Wheeled mobility and strength training
- Constraint therapy for hemiplegia

Joint contractures

- Range of motion
- Orthoses
- Surgery

Scoliosis

- Orthoses
- Surgery

Sexual functioning

- Education
- Adaptive devices

Dental caries, malocclusion

- Repair of dental caries
- Orthodontia

Seizures

- Medication
- Surgery

Impaired vision/hearing

- Assistive devices
- Surgery

WHEN TO ADMIT

- Children who aspirate food or saliva or have inadequate nutrition:
 - Demonstrate increased susceptibility to acute illnesses (eg, pneumonia)
 - Should be hospitalized if severely ill or cannot be managed at home
- Hospitalize for most major surgeries, such as complex orthopedic procedures.

WHEN TO REFER

- In US, all infants with CP between birth and 3 years of age should be referred to an early intervention program.
 - Mandated under the Individuals with Disabilities Education Act
 - Special education
 - Physical, occupational, and speech therapies
 - Adaptive equipment
 - Training for mobility and living skills
 - Communication
 - Therapies may not change the basic disorder significantly.
 - However, therapists may help the families by:
 - Teaching them how to position and handle their infant
 - Providing more opportunity for play and learning
 - Facilitating feeding and the parent-child relationship
- Children with moderate or severe CP:
 - Should be referred to an interdisciplinary clinic, if one exists
 - If not, referral to an orthopedist, physical therapist, and health care provider (developmental pediatrician, neurologist, pediatric rehabilitation specialist) who can manage spasticity, other abnormalities of tone, and optimize functioning
- The primary care physician should coordinate referrals.
 - Ensure that the child is receiving coordinated, comprehensive care.
- The family should have early professional support to help them cope with the crisis of diagnosis.
- Specific referrals
 - Speech therapist, audiologist
 - Augmentative communication aids
 - Education specialist, psychologist, school advocate
 - Early intervention
 - Special education
 - Formal educational testing

- Orthopedist, orthotist, physical therapist, equine specialist, occupational therapist
 - Orthoses/braces
 - Walker
 - Wheeled mobility and strength training
 - Hippotherapy
 - Constraint therapy for hemiplegia
- Physical therapist, orthopedist, orthotist
 - Range of motion, orthoses, surgery
- Orthopedist, orthotist
 - Orthoses, surgery
- Gynecologist, urologist, psychologist
 - Sex education
 - Adaptive devices
- Dentist, pedodontist, orthodontist
 - Repair of dental caries, orthodontia
- Neurologist
 - Seizure medication, surgery
- Ophthalmologist, otolaryngologist
 - Vision/hearing assistive devices, surgery
- Financial counselor, care coordinator, specialty program
 - Financial counseling, care coordination, transportation
- Social worker, psychologist, specialty program, care coordinator
 - Parent support group, counseling, support

FOLLOW-UP

- Careful monitoring of physical growth is critical.
 - Monitoring weight for length rather than weight alone is important.
 - Reliable measures are often impossible to obtain.
 - Tibial length is used as a proxy for height.
- Long-term planning and preparation are required to help children make the transition from adolescence to adulthood, particularly when the child has multiple needs.

COMPLICATIONS

- Osteoporosis
 - Common in patients with severe quadriplegia and immobility
- Impaired self-care/hygiene
 - Due to gross motor and fine-motor abnormalities and associated conditions, such as drooling
- Dental disease
 - Malocclusion
 - Dental caries

- Seizures
 - Often, onset in first 2 years of life
- Inhibited physical growth
- Failure to thrive
 - Especially those with dyskinesia or spastic quadriplegia
 - Feeding difficulties/recurrent vomiting may be associated with aspiration.
- Language abnormality (from aphasia to poor articulation)
- Specific learning disabilities, such as visuospatial impairment, are common in a child with a normal range of intelligence.
- Cognitive impairment (75% of cases)
 - 40% are intellectually disabled.
 - Mildly in approximately one-third of cases
 - Moderately or worse in one-third
- Impaired mobility
- Impairment in gastrointestinal functioning, such as gastroesophageal reflux disease
- Impairment in growth
- Impaired vision
 - Strabismus
 - Refractive error
 - Nystagmus
- Behavioral problems

PROGNOSIS

- Survival depends on the severity of CP.
 - A 2-year-old child with severe CP is expected to have a 40% chance of living to age 20 years.
 - A child with mild CP has a 99% chance.
- Greatest risk for early death if child has all of the following:
 - Intellectual disability
 - No independent mobility (ie, rolling), limited spontaneous movement
 - Can be fed only by gastrostomy tube
- Prognostication before child's second birthday may be difficult, except at the extremes of involvement.
- Prognosis for functioning is related to:
 - Clinical type of CP
 - Pace of motor development
 - Evolution of infantile reflexes
 - Intellectual abilities
 - Sensory impairment
 - Emotional-social adjustment

■ Prognosis for walking

- Patients who sit unsupported by 24 months and crawl by 30 months are more likely to walk independently.
- Retention of obligatory primitive reflexes at 18 months of age makes independent ambulation unlikely.
- Virtually all with hemiplegia learn to walk, as do many with dyskinesia or ataxia.

■ Individual achievement is related to many factors.

- Intelligence
- Physical functioning
- Ability to communicate
- Personality attributes
- Major factors in adjustment as adults
 - Availability of training, jobs, sheltered employment
 - Counseling
- A supportive family and availability of specialist medical care are other important factors.

PREVENTION

■ Prevention of prematurity

■ In some instances, CP may be prevented by:

- Reducing occurrence of injuries during childhood
- Minimizing periventricular leukomalacia in premature infants
 - Improving circulation
 - Countering effects of excitatory neurotransmitters (eg, head cooling in newborn who has had a hypoxic or ischemic event)

Chest Pain

DEFINITION

- Chest pain is defined as discomfort in the thoracic region.

EPIDEMIOLOGY

- Most cases are due to trauma to the musculoskeletal wall.
- Pulmonary disease accounts for one-fifth of cases.
- The rest are due to psychiatric causes, gastrointestinal disorders, or cardiac disease.
 - Undiagnosed cardiac disease causes chest pain in <5% of patients.
 - Excluding children with preexisting heart disease, cardiac abnormalities are found in <1% of patients.
- Approximately 15% of cases remain idiopathic.

MECHANISM

- Pulmonary conditions
 - Children with asthma may have chest pain from excessive coughing and overuse of their intercostal muscles.
- Gastrointestinal conditions
 - Acid reflux to the esophagus can mimic the pain of angina and can cause both acute and chronic chest pain.
- Cardiac conditions
 - Aortic stenosis and idiopathic hypertrophic cardiomyopathy can cause chest pain as a result of the heart's inability to increase the cardiac output with exercise.
 - These are the most important lesions that cause left ventricular outflow obstruction.
 - These disorders cause syncope and chest pain with exertion.
 - Mild aortic stenosis does not cause chest pain.
 - Pericarditis can result from either an infectious agent or an autoimmune process.

HISTORY

- A detailed history includes:
 - The child's response to the pain.
 - If possible, children should describe the pain in their own words.
 - They should be asked what they think is causing the pain.
 - The location, duration, radiation, and quality of the pain.
 - Aggravating and alleviating factors
 - Any associated signs and symptoms
 - Any history of trauma, even if it occurred 1–3 months earlier
- To many adolescents, chest pain is synonymous with heart disease; therefore, this issue should be addressed.
 - If no cardiac cause is discovered, the physician should unequivocally state to the adolescent and the family that the heart is normal.

- The quality of pain can help determine its source.
 - Deep, poorly localized pain that radiates to the neck or shoulders is characteristic of visceral pain.
 - Superficial sharp pain that is exacerbated by lifting or movements of the torso suggests musculoskeletal pain.
 - Peripheral pain that increases with inspiratory efforts originates from pleural inflammation.
 - Sharp pain that decreases when the child leans forward is characteristic of pericardial inflammation.
 - Pain that occurs with exercise points toward respiratory or cardiac conditions.
 - Pain that awakens the child from sleep is never psychological.
- Common, uncommon, and rare causes of chest pain and associated signs and symptoms
 - Musculoskeletal
 - Costochondritis (common): localized, superficial, reproducible pain over costochondral junction
 - Exercise, overuse, muscle strain (common): reproducible pain with use of involved muscle group
 - Protracted coughing or vomiting (common): intercostal muscle tenderness
 - Trauma: localized pain; pain with movement of involved areas
 - Stitch (common): sharp, crampy costal pain that occurs with running
 - Precordial catch (uncommon): transient, stabbing pain at left sternal border; relieved by forced inspiration
 - Pulmonary
 - Asthma (common): associated with cough, shortness of breath, wheezing, abnormal pulmonary function tests; relief with inhaled bronchodilators
 - Exercise-induced bronchospasm (common): abnormal findings on exercise tests; improvement with bronchodilators
 - Pneumonia (common): crackles, fever, cough
 - Pleural effusion (uncommon): pleural rub, fever, decreased breath sounds
 - Pneumothorax (uncommon): sudden pain, referred shoulder pain, dyspnea
 - Pulmonary embolus (rare): contraceptive use or recent abortion, pleuritic pain
 - Gastrointestinal
 - Esophagitis (common): retrosternal pain; relief with antacids
 - Gastroesophageal reflux (common): retrosternal burning pain; worse after eating and when reclining; relief with antacids

- Cardiac
 - Hypertrophic cardiomyopathy (rare): syncope, family history, systolic ejection murmur
 - Pericarditis (rare): associated fever with acute onset of pain; pain increases with movement; narrow pulse pressure, distant heart sounds; alleviated by leaning forward
 - Myocarditis (rare): precedent viral illness, anorexia, shortness of breath, third heart sound or gallop, cardiomegaly
- Nonorganic
 - Psychogenic (common): normal physical examination, trouble sleeping, family or school problems, life stresses, family history of chest pain, other somatic symptoms
 - Hyperventilation (common): associated light-headedness, paresthesias, underlying anxiety

PHYSICAL EXAM

- Findings that suggest musculoskeletal and chest wall conditions
 - Signs of trauma, such as bruising
 - Swelling over joints
 - Splinting or an abnormal breathing pattern
 - Reproduction of point tenderness at the origin of the spontaneous pain is the strongest evidence favoring the diagnosis of chest wall disease.
 - Each rib cartilage should be palpated with only 1 finger or with the child's finger.
 - Pain from the thoracic cage that can be elicited by movements of the torso or by flexion of the arms is highly suggestive of a musculoskeletal chest wall injury.
- Findings that suggest a parapneumonic effusion
 - Fever, tachypnea, tachycardia, pleural friction rub and/or crackles, and dullness to percussion
- Findings that suggest a spontaneous pneumothorax
 - Dyspnea, shoulder pain, and tachypnea
- Findings that suggest a cardiac source
 - Any new clicks, rubs, or systolic murmur or change in a previous murmur
- Findings that suggest myocarditis or pericarditis
 - An ill appearance, fever, dyspnea, changes in the pain associated with the respiratory cycle
 - A third heart sound or gallop can be heard in myocarditis and congestive heart failure.
- Findings that suggest a hyperventilation syndrome
 - Carpopedal spasm
 - Paresthesias
- Adolescents with gynecomastia or breast pain may experience chest pain that is easily discernible on inspection and palpation of the developing breast tissue.

DIFFERENTIAL DIAGNOSIS

Musculoskeletal conditions

- Costochondritis (common)
- Exercise, overuse, muscle strain (common)
- Protracted cough or vomiting (common)
- Trauma
- Stitch (common)
- Precordial catch (uncommon)

Pulmonary conditions

- Asthma (common)
- Exercise-induced bronchospasm (common)
- Pneumonia (common)
- Pleural effusion (uncommon)
- Pneumothorax (uncommon)
- Pulmonary embolus (rare)

Gastrointestinal conditions

- Esophagitis (common)
- Gastroesophageal reflux (common)

Cardiac conditions

- Hypertrophic cardiomyopathy (rare)
- Pericarditis (rare)
- Myocarditis (rare)

Nonorganic

- Psychogenic (common)
- Hyperventilation (common)

LABORATORY EVALUATION

- Screening laboratory tests are usually not helpful in establishing a specific diagnosis.
- A thorough history and physical examination should guide the clinician in ordering tests.

IMAGING

- In most cases, chest radiographs will only confirm what is suspected clinically.
- A chest radiograph is indicated if the provider suspects:
 - Pericarditis
 - Pneumonia
 - Pleural effusion
 - Other pulmonary disease

DIAGNOSTIC PROCEDURES

- In most cases, electrocardiography will only confirm what is suspected clinically.
- If the pain occurs with exercise, exercise testing or spirometry may help uncover underlying asthma or exercise-induced bronchospasm.

- To confirm the diagnosis of exercise-induced or cold air-induced bronchospasm:
 - Exercise testing
 - Cold air challenge
 - A therapeutic trial of bronchodilators

TREATMENT APPROACH

- It is important to define whether the chest pain is secondary to an underlying abnormality, psychogenic, or idiopathic.
- Treatment of psychogenic chest pain should be focused on:
 - The family's understanding of the cause of the pain
 - Reassurance that no long-term sequelae exist
 - Acknowledging that the pain is real to the child
- Children with idiopathic chest pain may benefit from a trial of antacids or histamine₂-blockers because the clinical presentation of esophagitis can be nonspecific.

SPECIFIC TREATMENT

- Exercise-induced bronchospasm
 - Treatment with bronchodilators will help these children participate in sports and allow them to lead normal, active lives.
- Hyperventilation syndrome
 - For a child with an acute episode, the treatment is to have the child breathe into a paper bag to relieve the hypocapnia.
 - Resolution of the chronic problem is based on techniques to allow children to understand the nature of their anxiety and regain control of their emotional state.

WHEN TO REFER

- Signs and symptoms that accompany chest pain and warrant referral or hospitalization
 - Symptoms
 - Chest pain with exercise
 - Palpitation
 - Syncope
 - Fever, chills, weight loss, malaise, anorexia
 - History of Kawasaki disease, Turner syndrome, Marfan syndrome, sickle cell disease, or cystic fibrosis
 - Recent elective abortion, calf pain, oral contraceptive use
 - Family history of hypertrophic obstructive cardiomyopathy or unexplained syncope
 - Pica, foreign body aspiration
 - Conversion disorder

- Signs
 - Cyanosis, toxic appearance, or respiratory distress
 - Murmur that increases with Valsalva maneuver
 - Pleural or pericardial friction rub
 - Pulsus paradoxus
 - Cardiac clicks, thrills, gallop, or third heart sound
- A pediatric cardiologist should see children with chest pain and a family history of sudden death.
- If palpitations or chest pain occur infrequently or are not associated with exercise, referral for Holter monitoring is indicated.
- For children with severe psychiatric problems, referral to a psychiatrist may be necessary.

WHEN TO ADMIT

- Children with chest pain rarely require hospitalization because chest pain is usually benign, self-limited, and not associated with severe intrathoracic illness.
- Children with the following should be hospitalized:
 - Myocarditis
 - Pericarditis
 - Empyema
 - Pneumothorax
 - Significant thoracic trauma
 - Acute chest syndrome
 - Esophageal foreign bodies
 - Coronary artery anomalies or other cardiac lesions
 - Myocardial ischemia
 - Chest pain and palpitations
 - Cyanosis
 - Distress

FOLLOW-UP

- Patients with psychogenic or idiopathic chest pain should be followed up at regular intervals.

PROGNOSIS

- Prognosis depends on the cause of the chest pain.

Chickenpox

DEFINITION

- Chickenpox (varicella) is a childhood viral disease characterized by a pruritic vesicular rash that appears in crops.
 - “Chicken” is believed by some to derive from a likeness to the chickpea *Cicer arietinum*, or from the French for chickpea, *pois chiche*.
 - Others postulate that the name may come from the Old English word for itch, *gican*.
- It is highly contagious and has been regarded as relatively benign, inasmuch as complications are rare in healthy children.

EPIDEMIOLOGY

■ Incidence

- Until 1995 (before the vaccine era), ~4 million chickenpox cases occurred yearly in the US
- By 2000
 - Incidence decreased overall by 71–84% in populations with varicella immunization coverage rates for 1- to 3-year-olds of 74–84%.
 - Incidence decreased in every age group, with the greatest decrease (83–90%) seen in the 1-to 4-year-old group.
 - Incidence continued to be highest in children age 1–4 years and those age 5–9 years.
- By 2001
 - The rate of varicella-related hospitalizations in the US had declined by 75% overall, with <3800 such hospitalizations.
 - A reduction was seen in all age groups but was greatest for young children.
 - Deaths in the US caused by varicella dropped by 66% overall to an all-time low of 26.
 - The drop in mortality rates was most pronounced in children age 1 to 4 years (92%) and those age 5 to 9 years (89%) but was evident in all age groups, except for persons >50 years.
- Epidemics occur every 2–3 years and are distributed worldwide.

■ Prevalence

- Historically, 80–90% of children are infected by 9–10 years of age.
- In tropical climates, 40–90% of children enter adulthood without contracting the disease.
 - Much larger pool of susceptible persons in older age groups

■ Seasonality

- Occurs throughout the year, with most cases during the winter and spring months

■ Historic case-fatality rates from chickenpox (pre-vaccine era)

- 5 per 100,000 infants
- 1 per 100,000 1- to 14-year-olds

- 3 per 100,000 15- to 19-year-olds
- 25 per 100,000 30- to 49-year-olds
- Higher rates in neonates, immunocompromised patients, and older adults
- 10,000 hospitalizations annually, predominantly in children
- Annual deaths ranged from 40–150.
 - Most (80%) occurred in children in the early 1970s.
 - The majority (54%) occurred in adults in the early 1990s.
- From 1990–1994, an average of 50 annual pediatric deaths were attributed to varicella.
 - >90% of deaths occurred in children with no risk factors for severe varicella.

ETIOLOGY

- Caused by the varicella-zoster virus, a DNA virus and member of the herpesvirus family
 - The virus causes both chickenpox and herpes zoster.
 - Herpes zoster is a reactivation (after a latent phase) of the initial varicella infection.
- One of the most contagious viral infections to cause disease in humans (only known natural host).
 - Slightly less contagious than measles and smallpox
- Varicella virus
 - Gains entry into the susceptible individual through respiratory tract or conjunctiva via droplet or airborne transmission
 - Migrates to regional lymph nodes, where primary replication occurs
 - Primary viremia spreads the virus to internal organs approximately 4–6 days later, where secondary replication occurs.
 - Secondary viremia spreads the organism to the skin and is followed by clinical chickenpox.
 - Viremia has been documented in blood-borne monocytes 9–12 days after exposure, 1–5 days before onset of the rash.
 - Appearance of the rash in crops may be the result of intermittent secondary viremia.

RISK FACTORS

- Exposure to varicella-zoster virus
- Infection is thought to be spread by:
 - Respiratory secretions
 - Airborne particles from patients can transmit infection before onset of rash.
 - Contact with the vesicular fluid of chickenpox or herpes zoster
 - Indirect contact (fomite transmission)
 - Rare because of the lability of the varicella-zoster virus

- Transmission from pregnant woman to her fetus or newborn
 - Transplacentally acquired antibody to varicella-zoster virus is partially protective.
 - Chickenpox can occur in young infants born to immune mothers.
- Communicability period
 - From 1 or 2 days before the onset of the rash until 5 days after the onset or until all vesicles have crusted
 - Most vesicles have lost virus particles after 5 days.
 - Incubation period is between 10 and 21 days and averages 14–15 days.
- With household exposure, clinical disease will develop in approximately 90% of susceptible contacts after 1 incubation period.
 - Secondary household cases are often more severe.

SIGNS AND SYMPTOMS

Young children

- Mild malaise
- Low-grade fever (varies from none to 102°F [38.9°C])
 - May continue until vesicles cease to appear
- Fever followed in a few hours to days by a macular rash
 - Usually begins on the scalp, neck, or upper portion of the trunk
- Macules progress to a papular, vesicular, pruritic rash (usually within 12–24 hours).
 - Rash spreads centrifugally and involves all areas of the skin in severe cases.
 - Lesions occur more frequently in areas of irritation or dermatitis or in skin folds.
 - Occasionally appears as a macular rash in the diaper area or on the trunk and remains for 1 or 2 days before becoming vesicular.
 - Papular lesion contains a minute vacuole.
 - Fluid accumulates in the vacuole.
 - Causes vesicle to appear on a reddened base
 - Produces the classic “dewdrop on a rose petal” lesion
- Vesicles appear in crops.
 - A new crop occurs every 1–2 days over the next 2–5 days.
 - 2–4 crops during the illness
 - Typically produces a total of 250–500 lesions
- Vesicles turn to pustules and then crust over.
 - Crusts develop and may remain attached for 1–2 weeks.
 - Vesicles are pruritic, and excoriations are common.
 - Vesicles may occur on the mucous membranes.
 - Mouth
 - Conjunctiva
 - Esophagus
 - Trachea
 - Rectum
 - Vagina
 - On mucous membranes, the roof of the vesicle sloughs to leave a shallow ulcer.
- Total length of illness: 5–10 days

In older children and adults

- Irritability
- Listlessness
- Headache
- Chills
- Anorexia
- Myalgia
- Fever
 - Usually present
 - Higher and more prolonged than in young children
- More severe rash than in young children

In immunized children

- Milder systemic symptoms
- Lesions
 - Fewer (usually <50)
 - Less pruritic
 - Crust over faster
- Lesions may appear only as papules that never vesiculate.
- Children with typical, mild breakthrough varicella are also approximately half as likely to transmit the disease to household contacts.

DIFFERENTIAL DIAGNOSIS

- Smallpox (variola)
 - Historically the most important disease to be differentiated from chickenpox
 - Has again become a concern because of its possible use in bioterrorism
 - Clinical smallpox prodrome is typically more severe than that of chickenpox.
 - In varicella lesions, all stages of evolution are present at once.
 - In smallpox, most of the lesions are present in a uniform stage of development.
 - Lesions progress together from macules to papules to deep-seated vesicles and crusting.
 - Involvement of palms and soles is much more typical of smallpox.

- Vaccinia (cowpox)
 - Produces a vesicular rash resulting from exposure to infected livestock
 - When smallpox vaccine use was commonplace, resulted from direct contact with a smallpox vaccination
- Disseminated herpes simplex
 - History and progression of the diseases usually differentiate these 2 entities.
 - Confusion ordinarily arises only in newborns.
 - Disseminated herpes is rare in normal children.
 - Tzanck test will be positive in both diseases, but direct fluorescent antibody testing, culture, and polymerase chain reaction are specific.
- Rickettsialpox
 - Vesicles are deeper and are at a uniform stage of development.
 - Prodrome is more severe.
- Other viruses (especially coxsackievirus and echovirus)
 - Can produce vesicular exanthema that usually do not crust
 - Course is distinctly different.
 - Tzanck test is negative in these infections.
- Stevens-Johnson syndrome
 - Clinical course is different.
 - Rashes develop differently.
 - Tzanck test will be negative.
- Contact dermatitis
 - May produce a rash similar to that of chickenpox (including pruritus)
 - Different distribution and evolution
- Insect bites and scabies
 - May cause confusion if they are vesicular
- Bullous impetigo (especially staphylococcal skin infection)
 - May produce bullae that resemble chickenpox

DIAGNOSTIC APPROACH

- Chickenpox is usually diagnosed clinically.
 - History of exposure in the previous 10–21 days

LABORATORY FINDINGS

- Leukocyte counts and other laboratory test results are usually normal in uncomplicated varicella.
- Tzanck test (scraping of the base of a vesicle and staining with Giemsa or Wright stain)
 - Positive for multinucleated giant cells in varicella-zoster virus infections.
 - Herpes simplex types 1 and 2 also produce a positive Tzanck test.

- Varicella-zoster virus–specific direct fluorescent antibody testing of vesicle scrapings
 - Can provide specific diagnostic confirmation within hours
- Vesicle fluid can also be cultured for varicella-zoster virus.
 - Growth may take weeks.
- Polymerase chain reaction
 - Superior to viral culture in identification of varicella virus from vesicles
 - Can distinguish eruptions due to wild-type and vaccine virus
- Viral titers during acute and convalescent stages
 - Can document a recent infection if obtained early in the illness (preferably day 1 or 2)
 - Higher titers are noted during convalescence 2–6 weeks later.
- Commercially available antibody tests
 - Perform well for detection of serologic responses to infection
 - Not as sensitive for detecting vaccine-induced antibody response

TREATMENT APPROACH

- In most cases, treatment focuses on:
 - Control of fever
 - Relief of prodromal symptoms
 - Measures to control pruritus

SPECIFIC TREATMENTS

Fever and prodromal symptoms

- Acetaminophen
- Ibuprofen may increase risk of necrotizing fasciitis and other secondary bacterial infections.
 - This association has not been firmly established.
- Aspirin
 - Should be avoided in any child with chickenpox because of its association with Reye syndrome

Pruritus

- Oral antihistamine (eg, diphenhydramine)
 - Uncommon but reported encephalopathic side effects of diphenhydramine may mimic neurologic complications of varicella.
- Calamine lotion
- Cetaphil lotion
- 0.25% menthol lotion
- Baking soda or oatmeal preparations (Aveeno) in a warm bath to relieve discomfort
 - Daily baths also help prevent bacterial superinfection.

- Children's nails should be kept clean and trimmed to help discourage scratching.
 - Gloves or socks on the hands may be required.

Superinfection

- Usually a result of group A streptococci or *Staphylococcus aureus*
- Superinfection of a few lesions can be treated topically with mupirocin ointment.
- Superinfection of many lesions or of lesions in difficult areas (eg, around nares or the mouth) can be treated systemically.
 - First-generation cephalosporin (eg, cephalexin, cefadroxil) or other antibiotics that are active against streptococci and staphylococci
 - Where clindamycin-susceptible, methicillin-resistant *S aureus* is endemic, clindamycin may be an appropriate choice.

Antiviral agents

- Acyclovir
 - Effective in treating varicella infections in healthy children and adolescents
 - Not routinely recommended in healthy preadolescent children
 - Recommended (by intravenous route) for treatment of immunocompromised children who develop varicella infection
 - Increasingly, children infected with HIV, particularly those who have higher CD4 percentages, have been treated successfully for primary varicella with oral acyclovir.
 - When instituted within 24 hours of the onset of rash, treatment has resulted in modest reductions in:
 - Duration of illness
 - Number of cutaneous lesions
 - Fever
 - Systemic symptoms
 - Should be considered in adolescents because they are at greater risk for more severe disease
 - Can be considered for other nonimmunocompromised children who are at increased risk of more severe varicella, including:
 - Chronic lung disease
 - Chronic skin disorders
 - Those on salicylate therapy
 - Those taking aerosolized or low-dose systemic corticosteroids
 - Secondary household cases
 - In 1 study, treatment of the index case with acyclovir did not change the transmission rate to other susceptible household contacts.

- Valacyclovir and famciclovir
 - Licensed for treatment of zoster in adults
 - No studies and no pediatric formulations exist on which to base recommendations for use in children.

Hospitalization

- Should be avoided whenever possible because hospital epidemics can occur even when the strictest isolation procedures are followed
- Generally, disease is spread by:
 - Infection of staff members who were thought to be immune
 - Airborne spread of the virus through ventilation systems
- When unavoidable, hospitalization requires strict isolation.
- Hospitalization on an adult ward that has no immunosuppressed patients may reduce chance of spread where effective strict isolation is not available.
- All health care workers should have immunity to varicella verified at the time of hire.

WHEN TO ADMIT

- Varicella pneumonia
- Moderately to severely immunosuppressed host
- Moderate to severe bacterial complications
- Chickenpox in neonates
- Encephalopathy

WHEN TO REFER

- Immunodeficient children
- Pregnant women

COMPLICATIONS

Secondary bacterial infection

- Most common complication of chickenpox
- Children <5 years appear to be at increased risk.
- Symptoms begin, on average, 4 days after appearance of the varicella rash, often with a secondary fever.
- Superficial bacterial skin infections remain most common, but invasive group A streptococcal infections have become increasingly important.
- Infections are usually caused by group A streptococci or *S aureus* and include:
 - Impetigo
 - Cellulitis
 - Abscess
 - Necrotizing fasciitis
 - Myositis
 - Gangrene
 - Arthritis

- Osteomyelitis
- Pneumonia
- Empyema
- Conjunctivitis
- Toxic shock syndrome (usually streptococcal)
- Sepsis
- Erysipelas
- Occasionally, lesions are bullous as a variant of the disease itself, but these are more often caused by staphylococcal superinfection.
 - Can lead to complications in neonates, immunocompromised children, older adults
 - Bullous lesions caused by *S aureus* may begin on the second or third day of the rash and show as bullous impetigo.

Neurologic complications

- Second most common complication of varicella
- Mortality from neurologic complications reached approximately 10% overall.
- Most deaths occurred among cases of encephalitis, some of which may have represented unrecognized Reye syndrome.
- Acute cerebellar ataxia (ACA)
 - Most common neurologic complication
 - Occurs in 1 in 4000 cases of chickenpox
 - The average age is 4 years; the great majority of cases is seen in those <5 years.
 - Onset of symptoms usually occurs 1–2 weeks after onset of varicella, from 2–21 days after the appearance of the rash.
 - May precede the rash (rare)
 - Clinical features of varicella-related ACA are:
 - Acute onset of vomiting
 - Ataxic gait disturbance without major disturbance in mental status
 - Dysmetria (68%)
 - Trunk ataxia (74%)
 - Fever (5–10%)
 - Nystagmus (5–10%)
 - Laboratory studies usually reveal:
 - Normal peripheral leukocyte count
 - Normal to mildly elevated cerebrospinal fluid protein level
 - Cerebrospinal fluid pleocytosis in 50%
 - Between 95% and 100% of normal children who have varicella-related ACA recover completely with only supportive care.
 - Many cases are mild enough that hospitalization is not necessary.
 - Recovery usually takes place within the first 3 months.

- Some concern exists for longer-lasting subtle behavioral and learning difficulties.
- These need further study with controlled comparisons.

■ Encephalitis

■ Seizures

- Many may be febrile seizures.
 - In 1 series, 12 of 23 patients who had varicella and seizures had concomitant fever.
 - In older series

■ Aseptic meningitis

■ Myelitis

■ Peripheral neuropathy

Immunocompromised children

- Usually have the most severe symptoms
 - Higher fever and more prolonged vesicular eruption
- Neonates are at greatest risk of death from chickenpox.
- All complications are increased in this population.
 - Varicella pneumonia is the most common cause of death.
- Progressive varicella
 - Seen in immunocompromised children or those being treated with immunosuppressive therapy
 - Develops in up to 30% of immunocompromised children
 - Varicella-zoster virus spreads to the:
 - Lungs
 - Liver
 - Pancreas
 - Central nervous system
 - Vesicles may be larger and hemorrhagic.
- Children with HIV (especially those with very low CD4 percentages)
 - Most do not develop severe acute varicella.
 - Many experts use high-dose oral acyclovir to manage selected children infected with HIV and who have relatively normal CD4 values.
 - Others manage all children with HIV as being at increased risk of severe disease.
- Children who receive systemic steroid therapy for diseases other than cancer
 - Children who receive >2 mg/kg or 20 mg prednisone (or equivalent) for >2 weeks should be considered at increased risk for more severe involvement and complications.
 - Possibly attributable to the potentially immunocompromising effect of non-oncologic conditions for which steroids are prescribed
 - Inhaled corticosteroids do not appear to increase risk, but definitive data are lacking.

Congenital and neonatal varicella

- In primary maternal varicella during the first 2 trimesters of pregnancy
 - Varicella-zoster virus can cross the placenta.
 - Leads to congenital varicella syndrome in 2%
 - Affected infants have:
 - Skin lesions in a dermatomal distribution (76%)
 - Neurologic defects (60%)
 - Eye diseases (51%)
 - Skeletal anomalies (49%)
- Maternal infection during the late third trimester of pregnancy
 - May result in transplacentally acquired varicella in the newborn
 - Neonatal varicella is seen in 24% of infants of mothers with chickenpox in the 2 weeks before delivery.
 - Risk of death seems to be small if:
 - Onset of maternal rash occurs >5 days before delivery.
 - Rash initiates in infants <4 days.
 - This reprieve is probably attributable to maternally transferred immunity.
 - 20–30% neonatal mortality occurs if:
 - Maternal rash emerges between 4 days before and 2 days after delivery,
 - Newborn rash begins at 5–10 days of age
- Risk is uncertain for infants who are nursing when the mother contracts chickenpox.
- Herpes zoster in pregnant women appears to confer minimal risk of infection to the fetus.
 - In 1 series of 366 women with herpes zoster in pregnancy, no infants had evidence of intrauterine infection.

Reye syndrome

- Acute illness occurring almost exclusively in children, characterized by encephalopathy and fatty degeneration of the liver
- Case-fatality rate is 30% overall.
 - Reaches 43% for children <5 years
- In 1980, the association between Reye syndrome and use of aspirin during varicella or influenza illnesses was first reported.
 - This report led to:
 - 1980—advisory from the Centers for Disease Control and Prevention (CDC)
 - 1982—Surgeon General advisory
 - 1986—mandatory warning labels of all aspirin-containing medications, cautioning physicians and parents to avoid using salicylates in children with varicella or influenza-like illnesses

- The annual number of reported cases of Reye syndrome in the US has decreased.
 - 555 cases in 1980
 - No more than 36 cases per year from 1987–1993
 - No more than 2 cases per year from 1994–1997

- Given its rare occurrence, any child suspected of Reye syndrome should be evaluated thoroughly for the presence of another metabolic disorder.
- Aspirin should be avoided in any child who has chickenpox.

Varicella pneumonia

- Occurs most often among adults, adolescents, and immunocompromised children
 - In children, occurs in <1 per 10,000 cases of chickenpox
 - In adults, it may be present in 30–50% of cases of varicella.
 - More recent studies estimate 5–10%
- One of the more common causes of death from varicella
 - Mortality is 10–20%, higher among severely immunodeficient patients.
- Onset typically occurs:
 - 5–6 days after onset of rash in immunodeficient persons
 - Within the first 3 days of rash onset in immunocompetent hosts (adults)
- Manifestations include:
 - Abnormal chest radiograph findings
 - Cough
 - Rales
 - Tachypnea
 - Hemoptysis
 - Chest pain
 - Cyanosis
 - Respiratory failure
- Chest radiographs typically show diffuse, reticulonodular densities of various sizes, best viewed in the lung periphery.
 - As disease progresses, nodules may enlarge and coalesce into extensive infiltrates.
- Treatment with intravenous acyclovir is recommended.

Hematologic complications

- Thrombocytopenia
 - Most common hematologic abnormality seen with varicella
 - May occur with:
 - Invasive secondary bacterial infection
 - Sepsis, where it is associated with more severe illness and worse outcome

- In the absence of secondary bacterial infections, varicella may produce thrombocytopenia (or pancytopenia) that is attributed to:
 - Infection-related suppression
 - Antibody-mediated destruction (idiopathic thrombocytopenic purpura) of platelets
- Onset occurs from 3 days to 3 weeks after the chickenpox rash appears.

■ The following have been described with varicella infection:

- Febrile purpura
- Malignant chickenpox with purpura
- Postinfectious purpura
- Purpura fulminans
- Henoch-Schönlein purpura

Hepatitis

- Hepatitis may appear on second to fourth day after rash appears; marked by:
 - Onset of abdominal pain
 - Vomiting
 - Continued fever
- Liver function tests become abnormal but return to normal with resolution of abdominal symptoms.
- No progression to classic Reye syndrome
- Blood ammonia level is normal.
 - Some experts believe that some of these cases may represent low-grade Reye syndrome.
 - A study of 39 children who had uncomplicated chickenpox found:
 - 47% had a mildly increased level of aspartate aminotransferase (serum glutamic-oxaloacetic transaminase).
 - 29% had significantly increased aspartate aminotransferase levels.

Zoster (shingles)

- Reactivation of varicella-zoster virus that has remained dormant after clinical chickenpox
 - Virus resides in the dorsal nerve ganglia.
 - Virus is reactivated by periods of decreased host immunity or other unknown stimuli.
 - During reactivation, rash covers the dermatome corresponding to infected nerve root.
 - Disseminated zoster can occur, involving multiple dermatomes.
- Has been described in all age groups, including in infancy after prenatal exposure to varicella from maternal chickenpox
- Young children, especially those <1 year of age, have increased incidence of zoster later in life.

- Immunocompromised children are at greater risk.
 - 27% of children infected with HIV with primary varicella after 1 year of age; zoster an average of 2 years later
 - Significantly fewer children with leukemia (25 cases per 1000 person-years)
 - 70% of children whose CD4 percentage was <15% at the time of varicella infection

Other complications

- Appendicitis
- Myocarditis
- Arthritis (viral)
- Nephritis
- Orchitis
- Splenic hemorrhage and rupture
- Pancreatitis
- Pericarditis
- Parotitis (rare)
- Papillary conjunctivitis (most common ophthalmologic complication)
- Keratitis
- Uveitis
- Optic neuritis
- Chorioretinitis

PROGNOSIS

- Complications are rare in healthy children.
- Little scarring occurs unless the lesions become superinfected or are continually traumatized.
- Areas where chickenpox lesions have occurred may remain hypo- or hyperpigmented months after rash has resolved.

PREVENTION

Varicella vaccine

- A live-attenuated varicella virus vaccine licensed by the US Food and Drug Administration in 1995 is effective in preventing varicella infection in most recipients.
- Recommended doses
 - Susceptible immunocompetent children ≥ 1 year should receive 2 doses: one at 12 months and one at 4–6 years.
 - Susceptible adolescents ≥ 13 years should receive 2 doses of the vaccine at least 1 month apart.
 - *Susceptible* is defined as a lack of reliable history of chickenpox.
 - A positive serologic result excludes the need for vaccination.
 - Routine serologic confirmation of susceptibility in adolescents is not likely to be cost effective.

■ Effectiveness

- Studies have suggested vaccine effectiveness as follows:
 - 44–88% complete prevention of chickenpox
 - 86–90% prevention of moderate or severe chickenpox
- Risk factors for breakthrough disease included:
 - Immunization at <15 months of age
 - Longer elapsed time since immunization
 - Oral steroid use
 - Receipt of measles-mumps-rubella vaccine <28 days before varicella vaccine
- Limited data (from Japan) demonstrate persistence of humoral and cell-mediated immunity following vaccination for up to 20 years.
- The contribution of boosting by continued circulation of wild-type varicella to maintaining immunity is unknown.

■ Adverse events

- Mild (2–5 lesions on average) maculopapular or varicelliform rash at the injection site or other sites in the month following vaccination
 - Seen in 7–8% of vaccinated healthy children
 - When tested by polymerase chain reaction, the majority of rashes occurring within 2 weeks of varicella immunization are determined to be from natural infection.
- Modified chickenpox (shorter duration, fewer lesions, less fever) occurs at a rate of approximately 2–3% per year among vaccinees.
 - Associated with low 6-week postvaccination varicella zoster virus antibody titers
- Other, more serious but much less common adverse events occur at lower frequencies than would be expected following natural infection.
 - Encephalitis
 - Ataxia
 - Erythema multiforme
 - Pneumonia
 - Thrombocytopenia
 - Seizures
 - Herpes zoster

■ Precautions

- Transmission of vaccine virus to susceptible contacts is extremely rare and has occurred only in the presence of a vaccine-associated rash.
- Vaccinees who develop a rash should avoid direct contact.
- Immune globulin or other blood products (except washed red blood cells) may interfere with the immune response to varicella vaccination.
 - Vaccine should be deferred for 3–11 months after receipt of blood products, depending on the dose and type of blood product use.

- Salicylates should not be given for 6 weeks following vaccination; there is a theoretical risk of Reye syndrome.
- Measles-mumps-rubella vaccine and varicella vaccine should not be given <28 days apart; it may be given simultaneously, eg, as MMR-V, without reducing efficacy.

■ Contraindications

- Because the varicella vaccine is an attenuated-live virus vaccine, it is not generally recommended for use in pregnant women or in immunocompromised children, including those with:
 - Congenital immunodeficiencies
 - Severely symptomatic HIV infection
 - HIV infection with CD4 percentages <15%
 - Blood dyscrasias
 - Leukemia
 - Lymphoma
 - Immunosuppressive therapy for cancer
 - High-dose steroid therapy (equivalent of prednisone 2 mg/kg/day or 20 mg/day)

■ Special considerations

- Children with leukemia
 - For children whose leukemia is in remission and with a break in chemotherapy before and after vaccination, the 2-dose varicella vaccine was safe, immunogenic, and completely effective in clinical trials.
 - 50% developed a mild rash in the month following vaccination.
 - They were less likely to develop zoster than were comparable leukemic children who had natural varicella infection.
 - Not currently licensed or routinely recommended for susceptible children who have leukemia, but children may be eligible to receive the vaccine through a research protocol.
- Children with HIV
 - Varicella vaccine should be considered for children who have asymptomatic (CDC class N) or mildly symptomatic (CDC class A) HIV infection and whose CD4 percentages are $\geq 25\%$.
 - Eligible children infected with HIV should receive 2 doses of varicella vaccine ≥ 3 months apart.
 - The Advisory Committee on Immunization Practices has made provisional recommendations to broaden the group of eligible HIV-infected children who should receive the 2-dose varicella vaccine series to include:
 - Symptomatic involvement ranging from asymptomatic to moderately symptomatic (class N, A, or B) and
 - CD4 percentages $\geq 15\%$

■ Varicella vaccine after exposure

- Nonpregnant, healthy adults and children ≥ 1 year of age (without contraindication to the vaccine)
 - May be vaccinated within 3 days and perhaps up to 5 days after exposure
- Recommended for vaccine-eligible patients who received VariZIG, intravenous immunoglobulin, or acyclovir prophylaxis unless varicella disease has occurred
- To minimize potential interference with vaccine response by passive antibody from these products, delay vaccine by:
 - 5 months after VariZIG
 - 8 months after 400-mg/kg intravenous immunoglobulin

MMR-V vaccination

- In 2005, varicella vaccine with the measles-mumps-rubella vaccine as a combination product (MMR-V) was licensed for use based on its safety and immunogenicity in children.
- In 2007, the Provisional Advisory Committee on Immunization Practices recommended a routine second dose of varicella vaccine for all children to help reduce breakthrough disease.
 - The second dose to be routinely given between 4 and 6 years of age
 - Single injection of MMR-V at 12–15 months
 - Repeated at 4–6 years for optimal protection against all 4 viral exanthema
 - The second varicella vaccine dose can be given as soon as 3 months after the initial dose.
 - The dose does not need to be repeated if 2 doses are given at least 28 days apart.

Public health

- Easiest prevention strategy in institutions, such as hospitals, schools, or child care facilities
 - Isolation or exclusion of the child who has chickenpox
 - Not always effective because the disease is contagious 1–2 days before the appearance of the rash
 - Generally, isolation is not feasible for preventing household contamination.

Immunoglobulin

- Varicella-zoster immunoglobulin (VZIG)
- Until recently, the most common and recommended method of postexposure prophylaxis for susceptible, high-risk patients
- When administered within 72–96 hours of a known or anticipated exposure, can prevent or modify disease in children and adults
- Despite VZIG prophylaxis, varicella may occur up to 28 days after exposure.
- Because widespread vaccine use has reduced the need for VZIG, the manufacturer halted production in 2005.

■ VariZIG (investigational)

- A purified human immune globulin preparation with high antiviral antibody titers (similar to VZIG)
- Recommended in place of VZIG
- Can be obtained through an expanded access protocol

■ IVIg

- Recommended dose: 400 mg/kg intravenously
- If VariZIG cannot be obtained, IVIg is the best alternative for:
 - Exposed neonates
 - Immunocompromised patients
 - Susceptible pregnant women
 - Other susceptible patients

■ Postexposure prophylaxis with VariZIG or IVIg

- Recommended for susceptible individuals at high risk of severe varicella, including:
 - Children who are infected with HIV
 - Other immunocompromised children
 - Pregnant women
 - Newborn infants whose mothers develop varicella eruption from 5 days before until 2 days after delivery.
 - Hospitalized premature infants >28 weeks' gestation whose mothers are susceptible (these infants have been deprived of active transport of maternal antibody that takes place in the final trimester)
 - Hospitalized premature infants <28 weeks or <1000 g, regardless of maternal susceptibility
- May be repeated following reexposure to varicella >3 weeks after initial dose (if varicella has not developed)
- May be considered for susceptible adolescents and adults because these age groups are at higher risk of severe disease compared with younger children
 - Alternative preventive strategies (immunization or acyclovir) may be more appropriate for this group.

Acyclovir

■ Acyclovir

- 10-day course at a dose of 40–80 mg/kg/day (divided into 4–5 doses) up to adult dose of 800 mg 5 times daily, beginning 10 days after exposure
- Can be used to prevent or attenuate chickenpox in high-risk outpatients beyond the newborn period
- This use is not approved by the US Food and Drug Administration.
 - Use is based on small studies.
 - Potential effect on the immune response has not been fully evaluated.

Chronic Fatigue Syndrome

DEFINITION

- Chronic fatigue syndrome (CFS) describes an illness characterized by prolonged periods of debilitating fatigue for which no definitive cause is known.
- Although the Centers for Disease Control and Prevention has created a working definition of CFS, it is not a well-defined clinical entity.

EPIDEMIOLOGY

- Prevalence
 - 20–200 cases of CFS-like illness per 100,000 persons
 - Cases of CFS have been reported to occur both sporadically and epidemically.
- Age
 - The majority of reported cases are in persons 35–40 years of age.
 - Adolescents with CFS have been described.
- Sex
 - Predominantly seen in females
- Race
 - White women from upper socioeconomic groups are most commonly affected.
 - Minorities, the indigent, and people living in developing countries are strikingly underrepresented.
 - Whether this reflects a bias in patient selection or predisposing factors remains to be determined.

ETIOLOGY

- No specific causative agents or characteristic pathophysiologic models have been identified.
- Causative factors under consideration for CFS are likely to interact in differing degrees in each individual.
 - Infectious agents
 - Other medical and immunologic conditions
 - Psychological factors

RISK FACTORS

- Depression
 - Both a risk factor and a reaction to CFS
- Additional adolescent-specific risk factors include:
 - School performance anxiety
 - Overprotection and overindulgence associated with difficulty in mother-teen separation
 - Infection or other stressor serves as a model for persistent symptoms that may become a mechanism to maintain overprotective environment or avoid school.
- Other possible risk factors
 - Low blood pressure (postural orthostatic tachycardia syndrome [POTS])
 - Hormonal factors (eg, depressed cortisol responses)

SIGNS AND SYMPTOMS

- Primary manifestation is severe fatigue.
 - >6 months in duration
 - Limits individual to activity <50% of the premorbid level
- Associated symptoms
 - Sore throat
 - Low-grade fever (oral temperatures of 37.5°C to 38.6°C)
 - Painful lymph nodes
 - Unexplained generalized weakness, myalgias, or arthralgias (or both)
 - Prolonged fatigue after exercise
 - Headache
 - Difficulty concentrating or memory loss
 - Sleep disturbances (hypersomnia or insomnia)
- Onset
 - Most patients describe sudden onset with an initial mono-nucleosis- or influenza-like illness.
 - Many describe a history of atopy, multiple allergies, or both.
- History
 - Question the patient about the nature and duration of symptoms.
 - Identify possible exposures to ill persons that might suggest an alternative diagnosis.
 - Obtain personal and social history.
 - Family dynamics
 - Prior level of functioning
 - Response to illness
 - Family history of psychiatric illness
 - Psychological or marital problems
 - Common psychological issues include internalizing symptoms and feeling different from others.
- Physical examination, with a goal of eliminating other causes of the patient's symptoms
 - Mild inflammation of the pharynx
 - Cervical or axillary lymphadenopathy
 - Low-grade temperature elevation in up to 50% of cases

DIFFERENTIAL DIAGNOSIS

- The following should suggest an alternative diagnosis.
 - Enlarged lymph nodes (>2 cm)
 - Weight loss >10% of body mass index without dieting
 - Focal neurologic abnormalities
- Differential diagnoses
 - Cancer
 - Autoimmune disease
 - Localized infection (eg, sinusitis, occult abscess)

- Chronic or subacute infection (eg, Lyme disease, endocarditis, tuberculosis, mononucleosis)
- HIV infection
- Fungal disease (eg, candidiasis, histoplasmosis, coccidioidomycosis, blastomycosis)
- Parasitic disease (eg, toxoplasmosis, giardiasis)
- Chronic inflammatory disease (eg, sarcoidosis, Wegener granulomatosis)
- Endocrine disease (eg, hypothyroidism, Addison disease, diabetes, hypoglycemia)
- Neuromuscular disease (eg, myasthenia gravis, multiple sclerosis)
- Drug dependency
- Side effects of chronic medications or other toxic agents (eg, chemical solvent, heavy metal, pesticide)
- Psychiatric disorder
- Total allergy syndrome
- Other poorly defined CFS-like conditions
 - Neurasthenia, myalgic encephalomyelitis, postviral syndrome, fibromyalgia

DIAGNOSTIC APPROACH

- Focus on excluding all other diagnoses and making an extensive differential diagnosis.
 - Physical examination
 - Laboratory tests
 - Chest and sinus radiographs
 - Cardiologic evaluation may be useful in patients with dizziness.

LABORATORY FINDINGS

- No specific laboratory tests exist that can be used to diagnose CFS.
- Primary aim of laboratory evaluations is to eliminate other conditions.
- Suggested battery of screening tests
 - Complete blood count and differential
 - Erythrocyte sedimentation rate
 - Serum electrolytes
 - Creatinine
 - Blood urea nitrogen
 - Glucose
 - Liver enzyme and function tests
 - Thyroid function tests
 - Tuberculin skin test with controls

- Alkaline phosphatase
- Antinuclear antibodies
- Rheumatoid factor
- HIV antibody

- Additional tests (eg, Lyme disease test, viral serologies) may be indicated based on history and physical examination.
- Immunologic testing is generally not warranted.
 - Abnormalities are rare and opportunistic infections do not occur in CFS.

IMAGING

- Chest and sinus radiography
 - Used to eliminate other causes of symptoms
- Magnetic resonance imaging
 - In some patients with CFS, increased white matter on T2-weighted scans suggestive of:
 - Possible infiltration of the perivascular spaces
 - Focal demyelination
 - Disease of the small blood vessels of the cerebral white matter
 - The significance of these finding is uncertain.

DIAGNOSTIC PROCEDURES

- Head-upright or tilt-table testing
 - Used to assess the role of POTS
 - Appropriate for the subset of patients in whom dizziness is a significant symptom

TREATMENT APPROACH

- A coordinated approach minimizes doctor shopping, unnecessary testing, and unconventional therapies.
 - Provide counseling and symptomatic relief for depression, sleep disorders, and musculoskeletal pains.
 - Offer emotional support with involvement of a social worker, psychologist, or psychiatrist as needed.
 - Identify and eliminate secondary gain from continuing to contribute to the illness.
 - Devise programs with the patient to increase school (or work) attendance and exercise capability gradually.
- No specific therapy for CFS has been proven to be effective.

SPECIFIC TREATMENTS

- Confirm the diagnosis of CFS and acknowledge the symptoms as real.
- Explain and explore the potential relationship to psychological symptoms.
 - Use team approach and coordinate services.

- Stress-coping skills
 - Modify lifestyle.
 - Develop a realistic schedule.
 - Work with school on gradual return to classes, home tutoring, and neuropsychometric testing.
 - Develop a graduated exercise program.
- Cognitive-behavioral approaches
 - Pay attention to sleep patterns and nutrition.
 - Increase activity gradually.
- Psychological support
 - Individual therapy and family therapy
 - Decrease secondary gain
- Symptom-based management
 - In documented POTS, dietary (eg, increased salt intake) or pharmacologic management (or both) may be beneficial.
 - Medications, such as fludrocortisone, propranolol, or midodrine
 - Therapy for neurally mediated hypotension has been only of partial benefit, even in adolescents whose tilt-table tests are abnormal.
 - Immunoglobulin injections have been reported to be beneficial in a study of patients with CFS.
 - Subsequent studies failed to confirm this observation.

WHEN TO REFER

- To resolve issues relating to possibility of ongoing infection or inflammation
- Multiple specialists may become involved and multiple laboratory tests may be ordered.
 - Symptoms are often extensive and varied.
 - Coordinate a team approach to avoid redundant or unnecessary testing.

- To provide a higher level of supportive care or counseling than can be provided in the office setting
 - Especially if the individual is cannot attend school or participate in normal activities

FOLLOW-UP

- Periodic physical examinations
 - Monitor for other possible conditions.
 - Monitor physical symptoms and psychological issues.
- Provide ongoing guidance and continued reassurance.
- Be aware of untested fad therapies that the patient may investigate.
 - Megavitamin treatment
 - Immune modifiers (eg, Ampligen, thymic extract, interleukin-2)
 - Magnesium sulfate
 - Liver extract injections
 - Anti-*Candida* diets
 - Colonic irrigation
 - Removal of dental fillings

PROGNOSIS

- Most patients report improvement or resolution of symptoms over 2–3 years.
- Few patients report progressive symptoms, although symptoms may wax and wane.
- With better definition of the nature of CFS, additional therapeutic approaches may become available.

Cleft Lip and Cleft Palate

DEFINITION

- Clefts of the lip and/or palate
 - May occur in isolation or may have several associated anomalies representing a syndrome
- Clefts are divided into 4 groups by an early classification system.
 - Soft palate clefts alone
 - Clefts of both the hard and soft palate
 - Complete unilateral clefts of the lip and palate
 - Complete bilateral clefts of the lip and palate
- Complete cleft of the primary palate with a degree of skin bridging the superior aspect of the lip is termed a *Simonart band*.
- Pierre Robin sequence consists of micrognathia, glossoptosis, and upper airway obstruction, with or without cleft palate, or any combination.

EPIDEMIOLOGY

- Prevalence
 - Cleft lip with or without cleft palate occurs in ~1 in 700 new births.
 - Isolated cleft palate occurs in ~1 in 1000 new births.
- Race/ethnicity
 - Patients of Asian descent: 2.1 in 1000
 - Black patients: 0.41 in 1000
 - White patients: 1.3 in 1000
- Sex
 - Cleft lip and palate are more common in boys than girls (2:1).
 - Isolated cleft palate occurs twice as often in girls than boys.
- Location
 - Clefts are more common on the left side.
 - Unilateral cleft lips occur much more commonly than bilateral cleft lips (4:1).
 - Frequency of orofacial clefting between cleft lip to cleft palate and cleft lip and palate is 1:1.2:2.5.

ETIOLOGY

- Cleft is caused by failure of penetration or fusion of the mesenchymal masses of the 5 facial prominences.
 - Isolated failure of fusion of the medial nasal prominence with the maxillary prominence on 1 side results in a unilateral cleft lip.
 - Bilateral cleft lip results from failure of both medial nasal prominences to fuse with the maxillary prominence.
 - Palatal clefts result from incomplete fusion of the lateral palatine processes with the nasal septum.
- Clefting may be associated with other conditions meeting the criteria of a syndrome; >300 syndromes are associated with clefting.

- Most common syndromes
 - Van der Woude syndrome
 - Velocardiofacial syndrome
 - Pierre Robin sequence
 - Goldenhar syndrome
 - Treacher Collins syndrome
 - Down syndrome
 - Stickler syndrome
- Most clefts are nonsyndromic and multifactorial in nature or a result of changes at a major single-gene locus.
 - Candidate genes
 - TGF alpha and beta
 - *MSX-1*
 - Retinoic acid receptor alpha
 - Homeobox gene
 - Distal-less homeobox 2
 - B-cell leukemia or lymphoma 3

RISK FACTORS

- Environmental agent exposure
 - Agents found to increase rate of clefting during first trimester of pregnancy
 - Corticosteroids
 - Ethanol
 - Ionizing radiation
 - Phenytoin
 - Isotretinoin
 - Diazepam
 - Methotrexate
 - Exposures to caffeine and tobacco are theorized to increase risk.
- Infections in first trimester of pregnancy, including rubella and toxoplasmosis
- Family risk for cleft lip/cleft palate
 - No family history of cleft lip or cleft palate: 0.1%/0.04%
 - Unaffected parents with 1 previously affected child: 4%/2%
 - Unaffected parents with 2 previously affected children: 9%/1%
 - 1 affected parent: 4%/6%
 - 1 affected parent and 1 previously affected child: 17%/15%

IMAGING

- Diagnosis of cleft lip or palate can be reliably established by prenatal ultrasonography.
 - Transvaginal ultrasonography can detect a cleft lip by 13–16 weeks of gestation.
 - Clefts of secondary palate can be diagnosed at 19 weeks of gestation using real-time magnetic resonance imaging.

TREATMENT APPROACH

■ Treatment by age

- Repair in utero: no current safety and ethical standards
- Newborn: Establish airway stability and feeding optimization.
- First 3–4 months of age:
 - Audiologic evaluation
 - Ear-nose-throat evaluation for middle ear abnormalities
 - Possible orthodontic evaluation for use of presurgical orthopedics
- 3–4 months of age: surgical management with lip repair
- Around 1 year of age: palate repair
- 2–4 years of age: speech evaluation and therapy, with or without possible surgical management of velopharyngeal insufficiency
- Late childhood and teen years, on as-needed basis:
 - Alveolar bone grafting
 - Lip and nose revisions
 - Orthodontics
 - Orthognathic surgery

■ Care is usually coordinated through multidisciplinary team following guidelines of the American Cleft Palate-Craniofacial Association.

- Plastic surgeon
- Speech therapist
- Audiologist
- Otolaryngologist
- Oral surgeon
- Dentist, orthodontist
- Nurse
- Social worker or psychologist

■ Nutritional care

- A nurse is usually the feeding expert who monitors the nutritional status of the infant carefully to ensure adequate caloric intake.
- Other feeding specialists may include:
 - Occupational therapists
 - Lactation consultants
 - Speech therapists
- Neonates with cleft of the primary palate (lip and alveolar ridge) can usually feed using a regular bottle or breastfeed without significant difficulty.
- Infants with a cleft of the secondary palate (hard and soft palate) usually require special bottles.
 - Haberman feeder (Medela)
 - Pigeon nurser (Respironics)

- Mead Johnson nurser
- Infant may have to be fed with a syringe (Breck feeder) or nasogastric tube.
- Infants with cleft of the secondary palate are unlikely to be able to breastfeed.
 - If the mother wishes to attempt breastfeeding, a lactation consultant with experience in cleft feeding should be consulted.
 - Infants should be monitored closely by a primary care physician, cleft-team nurse, and surgeon, with frequent weight checks.
 - Receiving human milk is desirable, even if by bottle; a hospital-grade breast pump (Medela) can be provided.
- Many centers fit infants with cleft of the secondary palate with a feeding plate that is custom fabricated by a dentist or orthodontist.
 - Decreases nasal regurgitation and irritation

■ Evaluation/treatment for middle ear disease

- Common (90%) with secondary palate cleft; results in limited drainage of middle ear through the eustachian tube and potentially causing conductive hearing loss (50%)
- Patients are monitored closely for middle ear effusion and hearing impairment.
- Almost universally treated with myringotomy tubes to prevent chronic hearing loss and cholesteatoma
 - Tubes are generally placed at around 3 months of age.

■ Presurgical orthopedics to align the alveolar segments and facilitate the lip repair

- Passive (nasalveolar molding appliance)
 - Many centers use a standard in which the cleft of the lip is narrowed, the cleft nostril is elevated into a more normal configuration, and the alveolar ridges become aligned.
- Active (Latham appliance)
 - Performed by a pediatric dentist or orthodontist who monitors the child weekly, progressively modifying the appliance from birth to the time of lip repair as the child grows

SPECIFIC TREATMENTS

Primary lip repair

- Usually performed between 3 and 4 months of age
- Timing of lip repair, 10-10-10 rule:
 - 10 weeks of age
 - 10 g of hemoglobin
 - Weight of 10 lb
- Surgical techniques include:
 - Rotation advancement repair (Millard)
 - Triangular flap repair (Tennison-Randall; less common)

- Additional primary cleft rhinoplasty at the time of the lip repair results in enhanced nasal aesthetic outcomes.
- The alveolus may also be repaired at time of the lip repair (gingivoperiosteoplasty), providing the framework/potential for ossification of the cleft alveolar arch.
- Lip adhesion in the first few weeks of life, before formal lip repair, molds the alveolar ridges, especially when used with a dental plate, in preparation for lip repair several weeks later.

Cleft palate repair (palatoplasty)

- Usually performed between 9 and 12 months of age (although protocols vary widely).
- Repair around 1 year of age is desirable to maximize normal speech development; however, repairing too early might result in poor maxillary growth.
- 2 most common procedures
 - Furlow double-opposing Z-plasty
 - Intravelar veloplasty technique of levator muscle reorientation
- Flaps used to repair the hard palate include the von Langenbeck and Veau-Wardill-Kilner techniques.
- Subperiosteal release of the floor of the mouth
- Tracheostomy for the most severe cases

Pierre Robin sequence

- Infants with a small mandible and upper airway obstruction:
 - Should be placed in the prone position to allow the tongue to fall forward out of the pharynx
 - Should be kept on a pulse oximeter to assess oxygen saturation level in the blood
 - If this is not adequate to alleviate obstruction/maintain saturations >94%:
 - A nasal trumpet may be placed (12 or 14 French).
 - If necessary, the infant may be bag ventilated with a jaw thrust, nasal trumpet, or oral airway in place and endotracheal or nasotracheal intubation carried out in a controlled environment by medical staff.
 - If necessary, the tongue may be pulled forward with a piece of gauze between the fingers or, rarely, a towel clamp.
- Further workup
 - 3-dimensional craniofacial computed tomography to evaluate the size of the mandible and the position of the tongue in the pharynx and to rule out choanal atresia and other anomalies
 - Nasoendoscopy to evaluate the position of the tongue in the pharynx with spontaneous respirations
 - Direct laryngobronchoscopy to rule out other airway anomalies (laryngomalacia or tracheomalacia)
 - Evaluation for gastroesophageal reflux disease and treatment as necessary

- Polysomnography, if the child is stable enough
- Feeding assessment: Children may have to be fed via nasogastric tube or syringe until more definitive treatment is carried out.

■ Indications for surgical intervention

- Continued upper airway obstruction/oxygen desaturation such that the baby cannot be taken out of the prone position
- Need for nasal trumpet or intubation
- Abnormal apnea-hypopnea index on sleep study
- Inability to be fed with a bottle
- Failure to thrive

■ Surgery

- Mandibular distraction osteogenesis
 - Involves lengthening the mandible using internal or external devices
 - The mandible is distracted 1.0–1.5 mm/day until in a normal or overcorrected position and airway obstruction/feeding difficulties are alleviated.
 - Regenerated bone consolidates in 6–8 weeks, and distractors are removed.
 - Complications
 - Device failure
 - Possible tooth bud damage
 - Possible inferior alveolar nerve paresis
 - Poor scar formation
 - Future mandible growth is unknown at this time.
- Tongue-lip adhesion
 - Suturing a flap of muscle and mucosa from undersurface of the tongue to a similar flap on the inner surface of the lower lip
 - Complications include dehiscence, inability to feed with a bottle, and failure to alleviate upper airway obstruction.
 - Reversed at 9–12 months of age to allow normal oral-motor coordination for speech and swallowing, once the mandible has grown sufficiently so that the tongue base no longer obstructs the airway
 - Cleft palate is repaired during tongue-lip adhesion reversal operation as well.

WHEN TO ADMIT

- Poor weight gain and dehydration in an infant who has feeding difficulty due to cleft palate

WHEN TO REFER

- Prenatally
 - Refer to plastic surgery, otolaryngology, genetics, and nursing specialists to provide appropriate council for what is to be expected postnatally.

- From birth until 3–4 months of age
 - Audiologic evaluation
 - Ear-nose-throat evaluation for middle ear disease
 - Possible orthodontic evaluation for the use of presurgical orthopedics
 - Surgical management follows with lip and nose repair
- 1 year of age
 - Palate repair
- 3–6 years of age
 - Speech evaluation and therapy with or without possible surgical management of velopharyngeal insufficiency
- Late childhood and teen years
 - Alveolar bone grafting as needed
 - Lip and nose revisions as needed
 - Orthodontics and orthognathic surgery as needed

FOLLOW-UP

- A child with a cleft should be followed up closely from before birth through adulthood by a multidisciplinary team.
 - Evaluate annually and until the management plan is completed in the child's late teens/early twenties.
 - The goal is to achieve normal function, characterized by:
 - Normal occlusion
 - Normal speech and hearing
 - Growth that is as normal as possible and optimal form, characterized by normal lip, nose, and facial aesthetics
- Speech
 - Even after palatoplasty, some children will have velopharyngeal insufficiency or incompetence (cleft palate speech), due to either:
 - Muscular incoordination (as is frequently the case in velocardiofacial syndrome)
 - Short palate
 - Speech should be assessed by a speech therapist in children 18–24 months of age to establish a diagnosis of velopharyngeal insufficiency.
 - Velopharyngeal insufficiency is often treated with speech therapy with or without surgical management.
 - The most common surgical techniques include a pharyngeal flap or sphincter pharyngoplasty, when the patient is 3–6 years of age.
 - These partly obturate the oronasopharynx, resulting in decreased air escape through the nose and thus necessitating careful monitoring of the airway.

- Lip and nose revisions
 - Before starting school (4–5 years): intermediate revisions
 - When growth is completed (14 years for girls, 16 years for boys)
 - A final septorhinoplasty or lip revision, or both
 - Reconstruction of deviated nasal septum and asymmetric nasal bones or lip (or both)
- Orthodontics/cleft alveolus management
 - May be started as early as 4 years and continued through the teen years
 - Teeth adjacent to the cleft site may be missing, misshapen, or misaligned; teeth may need to be passively molded or extracted.
 - If no gingivoperiosteoplasty was performed or gingivoperiosteoplasty failed, orthodontics are performed before secondary alveolar bone grafting.
 - Involves harvest of cancellous bone from the iliac crest, grafted into the alveolar cleft site
 - Allows complete ossification of the alveolar arch
 - Allows eruption of the canine tooth
 - Some surgeons advocate primary bone grafting in infancy (using a small piece of rib), although most perform alveolar bone graft as needed, between 7 and 9 years (mixed dentition period).
- Orthognathic (jaw) surgery
 - Sometimes needed to align the jaws in a normal occlusal relationship
 - Maxillary advancement (LeFort I osteotomy)
 - School-aged children, by distraction osteogenesis
 - Teenagers, advancement osteotomy with rigid titanium plate fixation
 - In some cases the mandible is set back to meet the maxilla.
 - Factors considered in timing orthognathic surgery
 - Upper airway obstruction
 - Sleep apnea
 - Malocclusion
 - Articulation errors
 - Masticatory problems caused by malocclusion
 - Psychosocial effects of facial disharmony
 - Final prosthodontic care, including dental implants or bridges, may be needed for missing or malformed teeth around the cleft site in the late teenage years.

PROGNOSIS

- Successful treatments result in a well-adjusted child with normal facial appearance, dental occlusion, speech, and hearing.

Colic

DEFINITION

- Inconsolable crying that:
 - Occurs for >3 hours per day **and**
 - Occurs >3 days per week **and**
 - Lasts >3 weeks

EPIDEMIOLOGY

- Prevalence
 - Colic is extremely common, affecting 20% of babies.

ETIOLOGY

- The exact cause of colic is unknown.
- Various causative theories have been suggested, including:
 - Food allergy
 - Gastrointestinal tract immaturity
 - Parental stress
 - Infant temperament

RISK FACTORS

- Parental stress or anxiety may lead to, or aggravate, colic.
- Family history of colic in a sibling.

SIGNS AND SYMPTOMS

- Colic presents as bouts of crying, fussing, or irritability that may develop into agonized screaming.
- The infant may draw up his/her knees against the abdomen, as if in pain.
- Symptoms follow the typical crying curve.
 - Crying bouts begin in the second week.
 - Crying peaks at 6 weeks.
 - Usually resolves by 4 months of age
 - Crying bouts are more common in the evening hours.
- It has been suggested that colic represents the upper end of the continuum of normal crying.
- Babies seem inconsolable during these crying periods.
 - Feeding, diaper changes, and soothing techniques are not effective in halting the crying.

DIFFERENTIAL DIAGNOSIS

- Crying in the newborn can be a sign of any number of disease processes; thus, they must be excluded before colic can be diagnosed.
- Gastroesophageal reflux disease
 - Presents with episodes of fussiness
 - Often accompanied by emesis which occurs soon after feeding
- Milk protein intolerance
 - Crying accompanied by diarrhea or hematochezia

- If the mother used alcohol or other drugs during pregnancy, the infant may be excessively fussy.
- All of the following typically present with persistent, rather than paroxysmal, symptoms.
 - Corneal abrasion
 - Hair tourniquet
 - Acute abdominal processes that constitute medical emergencies and symptoms including anorexia or vomiting
 - Volvulus
 - Intussusception
 - Incarcerated hernia
 - Infectious processes, usually accompanied by fever
 - Otitis media
 - Urinary tract infection
 - Meningitis
 - Inflicted injuries
 - Fractures
 - Intracranial bleeding

DIAGNOSTIC APPROACH

- A complete history is essential.
 - Parents may state that the baby is fussy and has excessive gas.
 - They may be concerned that the infant is in pain.
 - Ask:
 - When did symptoms begin?
 - How often do they occur?
 - During what part of the day do the symptoms occur?
 - How long do the symptoms last?
 - What have you done to try to ameliorate the symptoms?
 - What interventions, if any, are effective?
 - Obtain a history of the pregnancy.
 - Determine whether there was any maternal alcohol or drug use.
 - Determine whether there were any infections during pregnancy.
 - Family history
 - Metabolic or allergic disorders
 - Sibling with colic
 - Social history
 - Assess parental anxiety regarding real or perceived health concerns.
 - Ask who in the family is responsible for caregiving.
 - Ask what types of supports for caregiving are available to the family.

- Review of systems
 - Inquire about organic signs and symptoms of irritability, including:
 - Fever
 - Lethargy
 - Vomiting
 - Diarrhea
 - Hematochezia
- Review feeding techniques and history.
 - For formula-fed infants
 - Ensure that formula is being prepared correctly.
 - Assess whether the baby is being overfed or underfed.
 - For breastfed infants
 - Assess the mother's supply of milk.
 - Review how often and for how long the baby is fed.
- Physical examination
 - Generally serves to exclude pathologic abnormalities
 - In most cases, physical examination will be normal.
 - Acute abdominal processes, otitis media, and hair tourniquet can all be excluded by physical examination.
 - Determine weight, length, and head circumference and plot on a growth chart.
 - Poor growth suggests inadequate nutrition or other organic causes for crying.
 - Increasing head circumference suggests hydrocephalus or abuse.

LABORATORY FINDINGS

- Laboratory testing is seldom indicated.
 - Should be reserved for cases in which an organic cause is suspected
- Unnecessary laboratory testing should be avoided because it may convey to the parents the message that the baby is ill.

TREATMENT APPROACH

- Management primarily involves parental education and support.
 - Teach the parents that the baby is not sick.
 - Excessive crying is not harmful.
 - Use the baby's normal growth and results from the physical examination to reinforce this.
 - Reassure parents about their abilities as caregivers.
 - Emphasize that they are not to blame for the baby's symptoms.
- Acknowledge the parents' frustration.
 - Inform them that the office will provide support.

SPECIFIC TREATMENTS

- Teach parents to respond to the baby's fussiness with a predictable set of responses.
 - Having a plan to use during fussy periods can be reassuring.
- First, make sure the baby is not hungry, soiled, or tired.
 - Soothe the baby by encouraging:
 - Nonnutritive sucking
 - Swaddling
 - Gentle rocking or swinging
- It is acceptable to allow the infant to cry for a short period.
 - Allows the parents to regroup
 - Provides the baby with some time to blow off steam
- Educate parents about infant crying.
 - Most parents are surprised to learn how much healthy babies cry.
 - Highlight the differences among healthy babies.
 - Some babies are just naturally fussier.
 - The mnemonic PURPLE, from the Period of PURPLE Crying program (aimed at preventing shaken baby syndrome), can be used to remind parents of the pattern of normal, healthy infant crying that can cause stress and frustration in caregivers.
 - **P**: peak pattern
 - **U**: unexpected timing of episodes
 - **R**: resistance to soothing
 - **P**: pain-like face, even though baby is not in pain
 - **L**: long bouts of crying
 - **E**: evening cluster of symptoms
- Parents should be encouraged to:
 - Take care of themselves
 - Get adequate rest
 - Enlist family members or friends to take over from time to time to reduce caregiver stress
- Few medical interventions are helpful for colic.
 - If indicated by history, changing to hypoallergenic formula may be considered.
 - For breastfeeding mothers, consider an elimination diet.
 - If symptoms suggest reflux, treat for gastroesophageal reflux disease.
- Pharmacologic therapies have been found to be unhelpful, and possibly harmful.
 - Simethicone is not effective in symptom reduction.
 - Dicyclomine, an anticholinergic, is effective.
 - The manufacturer has advised against its use in children <6 months of age.

- Herbal tea made of chamomile, vervain, licorice, fennel, and balm-mint has been shown to be effective.
 - Large volume of fluid, 120 mL/3 times a day
 - May cause potential harm, such as hyponatremia or decreased milk intake

WHEN TO ADMIT

- In the vast majority of cases, colic can be successfully managed in the outpatient setting.
- If the history is confusing or suggests more serious symptoms, admission for observation may be necessary.

WHEN TO REFER

- Referral to specialists in developmental or behavioral medicine may be useful if the parents are extremely anxious or in need of additional reassurance.
- Be alert to parents who are overwhelmed by the infant's crying and may be in danger of harming the infant.
 - In this case, referral to children's services may be necessary.

FOLLOW-UP

- Support the parents until they are comfortable managing their child's symptoms.
- Very anxious parents may be offered a return office visit in 1 week.

- Provide support through telephone contact a few days after the initial visit.
- Excessive crying may be a stimulus for shaken baby syndrome.
 - Provide support and education to the parents, and carefully assess the baby at follow-up visits.

PROGNOSIS

- Prognosis is generally good.
- Symptoms usually decrease dramatically by 4 months of age.
- The presence of colic in an infant does not necessarily predict a more difficult temperament in an older baby.
- Excessive parental anxiety and frustration may lead to later parent-child interaction problems, such as:
 - Prolonged night waking
 - Overfeeding
 - Vulnerable child syndrome

Common Cold

DEFINITION

- Colds are viral infections of the upper respiratory tract.
- Mucosal surfaces that are lined with respiratory epithelium are involved.
 - Potentially affected areas include:
 - Nasal passages
 - Sinuses
 - Eustachian tubes
 - Middle ear spaces
 - Conjunctivae
 - Nasopharynx

EPIDEMIOLOGY

- Distribution
 - Worldwide
- Incidence
 - More frequent during cooler months in temperate climates
 - Northern hemisphere
 - Peaks in early fall
 - Remains high during winter
 - Decreases in spring
- Age
 - Adults and children
 - Most common in preschool-age children, who experience 6–8 colds per year (4 times adult rate)
 - Frequent infection in the preschool years might decrease the frequency of colds in the school years.
- Race or ethnicity
 - All ethnic groups

ETIOLOGY

- >100 different infectious agents can cause cold symptoms.
 - Most frequent cause
 - Rhinoviruses and small RNA viruses of the picornavirus family (autumn)
 - Frequent cause
 - Coronavirus (winter)
 - Less frequent causes
 - Influenza virus (winter)
 - Respiratory syncytial virus (winter)
 - Parainfluenza virus (winter)
 - Occasional causes
 - Enterovirus (all seasons)
 - *Mycoplasma pneumoniae* (all seasons)
 - Metapneumovirus (autumn and winter)

- Exposure to a cold environment:
 - Does not cause a cold
 - Does not decrease immunity that may potentially allow a viral infection to begin
- Infection begins most commonly after self-inoculation of a virus onto the individual's own nasal or conjunctival mucosa.

RISK FACTORS

- Exposure to nasal secretions
 - Virus easily spread by way of fingers and hands to objects, such as clothing or environmental surfaces
 - Children then acquire and self-inoculate their respiratory tracts by picking their noses or rubbing their eyes.
 - Inhalation of virus-containing aerosols
 - An effective means of virus acquisition
- Chronic stress
 - Colds are more likely in chronically stressed adults after inoculation by rhinovirus.
 - Whether this is the case in children is unknown.
- Crowds
 - Colds occur more commonly in children who:
 - Attend child care centers
 - Are exposed to other school-aged children versus those who spend most of their time at home

SIGNS AND SYMPTOMS

- Infants
 - Fever
 - Irritability
 - Changes in feeding pattern
 - Changes in sleep patterns
 - Mild diarrhea occasionally
 - Respiratory syncytial virus and parainfluenza viruses
 - Croupy cough
 - Bronchiolitis
- Children
 - Usually afebrile
 - Stuffy nose
 - Watery nasal discharge
 - Becomes more purulent within 3–4 days
 - Sneezing after a few days
 - Dry cough by third or fourth day
 - Rhinovirus infection
 - Generalized symptoms are uncommon.

- Adenoviral and other viral infections
 - Headache
 - Malaise
 - Myalgia
 - Pharyngitis
 - Gastrointestinal symptoms
- Duration of symptoms
 - Generally ~1 week
 - However, mild rhinorrhea and dry cough may persist for 2–3 weeks.
 - Cilia necessary for proper function of the respiratory epithelium may take as long as 3 weeks to return to their normal state.
 - When the symptoms are prolonged, a secondary infection may be present if:
 - Fever persists or is prominent.
 - Ear pain or a productive cough develops.
- Ear and lung examinations are essential for a child whose cold has persisted longer than expected.

DIFFERENTIAL DIAGNOSIS

- Allergy
 - Similar symptoms may be caused by seasonal allergy or allergy associated with nasal eosinophilia.
- Non-cold-causing viruses
 - Cold symptoms are associated with significant:
 - Pharyngitis
 - Rash
 - Other systemic symptoms
 - Streptococcal pharyngitis
 - Not usually associated with rhinorrhea or cough
- β -Hemolytic streptococcal infection
 - Occasionally causes persistent purulent nasal discharge in children <2 years
 - Usually associated with mild excoriations around the nares
- Nasal foreign body
 - Unilateral nasal discharge must be evaluated carefully to exclude nasal foreign body.
- Drug use
 - Older children with persistent symptoms
 - Irritation and swelling of the nasal passages from inhalation of:
 - Cocaine
 - Medicated nasal sprays

- *Bordetella pertussis* infection
 - Should be considered in a child with persistent cough
 - Children who have been partially immunized may not have the characteristic whoop.
- Concurrent bacterial infection
 - If a cold causes the usual symptoms for 5–7 days:
 - Concurrent bacterial infection is unlikely.
 - Purulence used to be interpreted as indicating a bacterial infection (eg, sinusitis).
 - Little evidence is available to support this impression.

DIAGNOSTIC APPROACH

- Diagnosis is based on clinical grounds.
- No routine tests exist to diagnose the common cold.

LABORATORY FINDINGS

- Viral cultures
 - Expensive and generally unnecessary

IMAGING

- Routine use of imaging is unnecessary.
 - Radiologic finding of opacification of the sinuses has not correlated with the clinical indications of sinusitis in adults.
- Chest radiograph
 - Confirms diagnosis of pneumonia as a complication of a protracted cold

TREATMENT APPROACH

- Most remedies give marginal, if any, symptomatic relief.
 - In many cases, they are potentially quite harmful.
 - Acetaminophen or ibuprofen can be used to treat fever in older children.
 - Oral decongestants may be used in older children.
- Infants should receive nothing more than saline nose drops.

SPECIFIC TREATMENTS

Infants

- Most pediatricians advise against using any cold remedies for infants.
 - At most:
 - Saline nose drops and bulb syringe to aspirate secretions
 - Cool-mist vaporizer to humidify room air

Children

- Acetaminophen or ibuprofen for malaise and fever
 - Some studies suggest that ibuprofen may lead to:
 - Shorter period of viral shedding
 - Better neutralizing antibody response

- Aspirin should be avoided; it is associated with Reye syndrome.
- Decongestants or antihistamines
 - Preschoolers
 - Studies have not demonstrated a beneficial effect singly or in combination.
 - Older children and adolescents
 - May use an oral decongestant (eg, pseudoephedrine hydrochloride) alone or with an antihistamine
 - Provides symptomatic relief with low possibility of side effects
 - Nasal spray or drops containing vasoconstrictors, such as oxymetazoline hydrochloride
 - Use should be discouraged.
 - High incidence of rebound nasal congestion after only a few days of use.
 - Corticosteroid or atropine-like nasal sprays
 - Have not been evaluated in children
- Mast-cell stabilizers (eg, nedocromil, sodium cromoglycate)
 - Their place in pediatric care is not clear.
- Zinc lozenges
 - Efficacy to reduce the duration of cold remains controversial.
- Antirhinoviral drugs
 - Studies are still too preliminary to judge their therapeutic potential.
- Vitamin C supplementation
 - Has not been proven efficacious; should be discouraged
- Antibiotics
 - Many parents will request that the physician prescribe antibiotics.
 - Discouraging antibiotic use is particularly important when bacterial infection is unlikely.
 - Evidence indicates increasing drug resistance among some bacterial pathogens.
- Alternative therapies
 - *Echinacea*
 - A recent randomized clinical trial showed no benefit to the use of extract of *Echinacea purpura* in treating children 2–11 years of age at the onset of their colds.
 - *Echinacea angustifolia*
 - A randomized clinical trial in adults using *E angustifolia* extract showed no benefit in treating experimental rhinovirus infection.

WHEN TO ADMIT

- Patients who develop pneumonia secondary to bacterial infection may need to be hospitalized if home therapy is ineffective or inappropriate.

COMPLICATIONS

- Otitis media
 - Most common in younger children
 - May be acute
 - Common cold can cause eustachian tube dysfunction.
- Pneumonia
- Secondary bacterial sinusitis
 - Uncommon and overdiagnosed
 - Fever
 - Headache
 - Purulent nasal discharge
- Lower respiratory tract infection (rare)
 - May progress to pneumonia
 - Cough
 - Tachypnea
 - Fever (usually)
 - Origin may be viral or a secondary bacterial infection.
- Reactive airway disease
 - Role of rhinovirus infection as a trigger of exacerbation is well documented.
 - Wheezing or a prolonged cough after a cold should alert the clinician to this possibility.

PREVENTION

- Frequent hand washing with soap and water by the patients and their caregivers may prevent the spread of infection.

Complementary and Alternative Medicine

BACKGROUND

- Interest in complementary and alternative medicine (CAM) has redefined modern Western medicine.
 - Widely used by the public and increasingly available at conventional hospitals:
 - Acupuncture
 - Biofeedback
 - Guided imagery
 - Hypnotherapy
 - Herbs
 - Dietary supplements
 - Massage
 - Chiropractic
 - Formal definitions of health care quality now acknowledge the importance of respecting:
 - Spirituality
 - Culturally based healing traditions
- CAM includes all of the following that are not considered part of conventional medicine as practiced in the US
 - Health care systems
 - Therapies
 - Products
 - These can be used:
 - To supplement conventional care (complementary)
 - In place of conventional care (alternative)
- *Integrative medicine* is the preferred term.
 - Incorporates both conventional medicine and complementary and alternative therapies for which sufficient evidence of safety and efficacy exists
- Consortium of Academic Health Centers for Integrative Medicine
 - Consists of 36 prominent medical schools
 - Further defines integrative medicine as “the practice of medicine that reaffirms the importance of the relationship between practitioner and patient, focuses on the whole person, is informed by evidence, and makes use of all appropriate therapeutic approaches, health care professionals and disciplines to achieve optimal health and healing.”

GOALS

- New competencies in pediatric care are necessary because of:
 - Tremendous growth in demand for CAM
 - Parental use of the Internet and mass media for health information
- Pediatricians should be able to:
 - Inquire regarding CAM use
 - Counsel on CAM from an evidence-based perspective
 - Partner with and refer appropriately to CAM practitioners

- Pediatricians do not need to:
 - Be content experts on CAM
 - Reject their training in biomedicine or critical thinking
- CAM emphasizes the:
 - Centrality of the therapeutic relationship
 - Importance of prevention
 - Healing power of nature

GENERAL APPROACH

- Strengthen the physician-patient relationship with:
 - Honest dialogue
 - Nonjudgmental manner
 - Compassion
 - Attention
- Use the best of scientifically based medical therapies whenever appropriate.
- Use appropriate complementary and alternative approaches when they enhance conventional medicine.

SPECIFIC INTERVENTIONS

Mind-body medicine

- Includes all therapies that activate the following factors, which can have significant mediating effects (positive and negative) on health outcomes
 - Emotional
 - Mental
 - Social
 - Spiritual
 - Behavioral
- Therapies include:
 - Relaxation
 - Stress management
 - Yoga
 - Hypnosis
 - Guided imagery
 - Biofeedback
 - Spirituality/prayer
 - The most prevalent complementary therapies in the US
 - May or may not involve formal religion
 - Frequently important in medical decisions
 - Closely linked to successful coping, faster recovery, and higher quality of life
 - Many patients may want help with meaning, hope, or overcoming fears.
 - Unmet spiritual needs are associated with despair and increased mortality.
 - Parents often have significant spiritual needs around the life-threatening illness or death of a child.

- Meditation
- Music therapy
 - Increases oxygen saturation and weight gain, decreases salivary cortisol and distress behaviors in premature infants
 - Intraoperative and postoperative music reduces pain and pharmaceutical requirements in surgical patients, including the use of sedatives and analgesics.
 - Reduces pain and suffering, improves mood and attitude in pediatric oncology patients
 - Reduces patient anxiety and depression in intensive care units
 - Improves the quality of life in dying patients
- Support groups
- Psychological therapies
 - Cognitive-behavioral therapy
- Mind-body therapies are recognized as safe and effective for many pediatric conditions, including:
 - Headaches
 - Asthma
 - Enuresis
 - Sleep problems
 - Pain
 - Stress
- Nonphysician providers of mind-body therapies
 - Psychologists
 - Nurses
 - Social workers
 - Chaplains
 - Music therapists
- Biologically based therapies**
- Includes all therapies that use natural products to modulate physiologic function
 - Herbs
 - Vitamins
 - Other supplements
- Dietary supplements can be sold without premarket approval and do not require a specific postmarketing study.
 - Only functional foods can claim specific health benefits.
 - Such approvals require significant supporting clinical data and US Food and Drug Administration approval.
- Commonly used herbal therapies and their uses
 - Aloe (*Aloe vera*)
 - Burns
 - Minor wounds
 - Skin irritations
 - Aphthous stomatitis
 - Constipation
 - Gastric and duodenal ulcers
 - Astragalus (*Astragalus* species)
 - Immune booster
 - Calendula (*Calendula officinalis*)
 - Skin soother
 - Cascara (*Rhamnus purshiana*)
 - Constipation
 - Cayenne (*Capsicum frutescens*)
 - Pain (topical)
 - Postherpetic neuralgia (topical)
 - Migraine (nasal spray)
 - Cluster headache (nasal spray)
 - Chamomile (*Matricaria recutita*)
 - Sedative
 - Colic
 - Antiinflammatory
 - Antispasmodic
 - Clove oil (*Syzygium aromaticum*)
 - Teething pain
 - Coffee (*Coffea* species)
 - Stimulant
 - Attention-deficit/hyperactivity disorder
 - Bronchodilator
 - Dandelion (*Taraxacum officinale*)
 - Mild diuretic
 - Liver tonic
 - Dill (*Anethum graveolens*)
 - Antispasmodic
 - Colic
 - Flatulence
 - Echinacea (*Echinacea* species)
 - Immune stimulation
 - Antiinflammatory
 - Ephedra (ma huang) (*Ephedra* species)
 - Vasoconstriction
 - Allergy
 - Upper respiratory infection
 - Asthma
 - Appetite suppressant
 - Evening primrose oil (*Oenothera biennis*)
 - Eczema
 - Premenstrual syndrome
 - Feverfew (*Tanacetum parthenium*)

- Migraine
- Rheumatoid arthritis
- Garlic (*Allium sativum*)
 - Antimicrobial
 - Cholesterol lowering
- Ginger (*Zingiber officinale*)
 - Antiemetic
 - Antinausea
- Ginkgo (*Ginkgo biloba*)
 - Enhances blood flow past clogged arteries
 - Prevents memory loss
 - Attention-deficit/hyperactivity disorder
- Ginseng (*Panax* species)
 - Stimulant
 - Adaptogen
 - Enhances endurance and performance
- Hawthorn (*Crataegus oxyacantha*)
 - Cardiac stimulant; enhances cardiac contractility
- Hops (*Humulus lupulus*)
 - Sedative
- Kava kava (*Piper methysticum*)
 - Anxiolytic
- Lavender (*Lavendula* species)
 - Sedative
- Licorice (*Glycyrrhiza* species)
 - Antiinflammatory
 - Antiviral
 - Demulcent
- Milk thistle (*Silybum marianum*)
 - Hepatoprotection against cirrhosis, hepatitis
- Oats (*Avena sativa*)
 - Antipruritic
 - Eczema
 - Varicella
- Pine bark extract (*Pinus* species)
 - Antioxidant
 - Attention-deficit/hyperactivity disorder
- Rhubarb root (*Rheum officinale*)
 - Constipation
 - Chronic renal failure
- St John's wort (*Hypericum perforatum*)
 - Depression
 - Antiviral

- Skullcap (*Scutellaria* species)
 - Sedative
- Slippery elm bark (*Ulmus fulva*)
 - Demulcent
 - Pharyngitis
- Tea tree oil (*Melaleuca alternifolia*)
 - Topical antimicrobial
 - Acne
 - Minor skin infections, eg, fungal and yeast infections
- Thyme (*Thymus vulgaris*)
 - Antimicrobial
 - Expectorant
 - Colds
 - Sore throat
 - Cough
- Valerian (*Valeriana officinalis*)
 - Sedative
- Witch hazel (*Hamamelis virginiana*)
 - Topical antiseptic
 - Antiinflammatory
- Licensed practitioners who promote use of herbal medicine:
 - Naturopaths
 - Not all naturopaths are graduates of accredited naturopathic medical schools.
 - International Board Certified Lactation Consultants frequently prescribe herbs to nursing mothers, eg, galactagogues to stimulate milk production.
 - Chiropractors

Manipulative and body-based methods

- Includes all therapies that focus on:
 - Manipulation
 - Compression
 - Stretching of skin, muscles, joints
 - Touch
- Activates a variety of mechanisms that support and promote health, including:
 - Mechanical
 - Enhances blood flow to the muscles and soft tissues and enhances lymphatic flow
 - Immunologic
 - Enhances specific immune cell functions, such as natural killer cell activity
 - Neurologic
 - Triggers relaxation response
 - Lowers sympathetic nervous system arousal, reduces serum cortisol

- Enhances endogenous serotonin and dopamine levels
 - Modulates pain perception
 - Energetic
 - Provides balance
 - Improves the flow of life force energy (*chi*)
 - Chiropractic
 - Chiropractors are licensed in all 50 US states.
 - Their services are widely covered by insurance, including Medicaid.
 - Most chiropractic schools now offer courses in pediatric care.
 - In children, chiropractors tend to use:
 - Few radiographs
 - Lighter force when making adjustments
 - A device called an *activator* to make adjustments
 - Special pediatric tables or treat the children in their parents' laps
 - Osteopathy
 - Osteopaths are licensed in all 50 US states.
 - Their services are widely covered by insurance, including Medicaid.
 - Doctors of osteopathy are considered mainstream physician practitioners.
 - Graduates of osteopathic medical schools can enter pediatric residency programs.
 - Massage
 - One of the oldest health care practices
 - Among the most popular options selected by pediatric and adolescent patients
 - Can include many different techniques and forms that require more substantial training
 - Structural integration (Rolfing)
 - Movement integration (Feldenkrais technique, Alexander technique)
 - Pressure point techniques (shiatsu, acupressure)
 - Craniosacral therapy
 - Reflexology
 - May be enhanced through the use of clinical aromatherapy
 - Therapeutic application of essential oils distilled from plants
 - Topical oils that enhance blood flow and engender a sense of warmth are often added (eg, lemongrass, black pepper oil).
 - Specific scents can have application to specific symptoms, such as lavender or chamomile for relaxation, ginger or spearmint for nausea, and peppermint or lemon for fatigue.
 - The appropriate amount of massage has not yet been measured.
 - Therapy is provided most often by parents or other family members.
 - Family members frequently appreciate the chance to learn a skill that can contribute to the comfort and well-being of the patient.
 - Massage therapists are licensed in all 50 US states.
 - Training and licensure requirements vary.
 - The largest professional national organization is the American Massage Therapy Association.
- Alternative medical systems**
- Based on comprehensive theories and healing traditions found outside conventional Western biomedicine
 - Restoration of the body and mind through:
 - Lifestyle
 - Diet
 - Exercise
 - Herbal medicines
 - Spiritual practices
 - Ayurveda
 - From the Indian subcontinent
 - Acupuncture
 - One component of traditional Asian medicine systems
 - Vital energy, *chi* (*qi*), is thought to circulate through the body in channels called *meridians*.
 - When the circulation of *chi* is blocked or disrupted, disease is present.
 - When the flow is balanced, harmonized, and restored, the patient returns to health.
 - Acupuncture—insertion of needles into key points on known meridians—is one means of restoring flow of *chi*.
 - Among major teaching hospitals with a pediatric pain service, 33% offer acupuncture therapy to treat chronic pain.
 - Therapy can be taught to and performed by parents and children for home treatments.
 - Care must be taken to present it in a nonthreatening light.
 - Use of the term *acupoint stimulation* avoids eliciting fear of needles.
 - Acupoint stimulation can be achieved by:
 - Massage
 - Comfortable electrical stimulation
 - Stickers with beads
 - Very thin (>30 gauge) nonhollow acupuncture needles

- After comfort and trust is established with a noninvasive approach, many children and teens will agree to needle insertion.
 - Performed correctly, acupoint stimulation is virtually painless and well tolerated by older children.
 - Immediate benefits are rarely seen.
 - Acupuncturists often ask patients to commit to 4 to 6 visits before deciding to stop treatment.

■ Homeopathy

- System of medical treatment invented in the early 1800s by Samuel Hahnemann, for whom Hahnemann Medical School was named.
 - Homeopathy was frequently taught and practiced in US medical schools until rigorously criticized in the Flexner Report (1910).
 - Almost 2 million visits were made to homeopathic practitioners in the US in 1997.
- Homeopathy is based on 2 principles.
 - Law of Similars
 - A remedy that would cause a symptom in a healthy person is used to treat the same symptom in a sick person.
 - Example: A remedy made from the poison ivy plant (*Rhus toxicum*) might be used to treat a child with eczema.
 - Law of Dilutions
 - The more a remedy is diluted, the more powerful it becomes.
 - Homeopaths think that these highly diluted solutions contain an energy, or information, that the patient uses to heal symptoms.
 - They report that the right remedy may worsen symptoms briefly before they improve.
 - Many physicians think that the remedies are simply placebos that trigger the patient's psychoneuroimmunologic healing systems.
 - Randomized controlled trials suggest activity exists for remedies for diarrhea and otitis media but not for attention-deficit/hyperactivity disorder.
- Side effects
 - Serious side effects from homeopathic treatment are exceedingly rare.
 - Far less common than side effects from standard over-the-counter and prescription medications
- An estimated 12,000 homeopaths practice in the US
 - 50% lay practitioners
 - 35% chiropractors
 - 10% physicians
 - 5% other health professionals

- Most states allow certified health professionals to practice acupuncture or homeopathy.
 - Certification boards for health care professionals:
 - Physicians and doctors of osteopathy (American Institute of Homeopathy)
 - Chiropractors (National Board of Homeopathic Education)
 - Naturopaths (Naturopathic Academy of Homeopathic Physicians)
 - Non-health care professionals
 - Registered with the North American Society of Homeopaths

Energy therapies

- Includes all therapies that affect physiologic function by the modulation of hypothesized energy fields
 - Spirit
 - Chi
 - Energy
 - Life force
- Practitioners transmit bioenergetic healing energy through their hands to foster healing.
 - Actual touching does not always take place.
 - Includes therapies that use measurable electromagnetic fields to relieve the underlying causes of unexplained pain, eg, magnet therapies
- Therapeutic Touch
 - 5-step process of healing outside of a specific religious faith or belief
 - Having a clear and conscious intent to be helpful and heal
 - Being centered in a peaceful state of mind
 - Using hands to assess the patient's energy (typically moving the hands 1–3 inches away from the body in a slow downward sweep from the head to the toes)
 - Using hands to help restore the patient's energy to a balanced, harmonious, peaceful state
 - Releasing the patient to complete the healing process while the healer returns to the healer's own centered, peaceful state of mind
 - Primary clinical benefits
 - Increased relaxation
 - Diminished anxiety
 - Diminished pain
 - Enhanced sense of well-being
 - Therapeutic Touch is taught in nursing schools across the US
 - Nursing practice in many hospitals, including children's hospitals, includes policies and procedures for performing Therapeutic Touch.

- Healing Touch
- Reiki
 - Similar to Therapeutic Touch; from a Japanese tradition
 - Typically provided by lay practitioners outside of medical settings
 - Practitioners are trained by a Reiki master through apprenticeship and spiritual and energetic initiation.

How to talk with patients about CAM

Concerns

- Physicians
 - Families who use CAM may be dissatisfied with main-stream medical care.
 - Patients may abandon effective therapies in favor of unproved alternatives.
 - Data do not support these concerns.
 - Families who seek out CAM rarely abandon their pediatrician.
- Families
 - Therapies that are consistent with their:
 - Values
 - Worldview
 - Culture
 - Therapists who:
 - Respect them as individuals
 - Offer time and attention
 - Offer compassion and hope
 - Provide comprehensive primary care
 - Additional information in areas over which they may exert some control:
 - Healthy lifestyles
 - Dietary supplements
 - Environmental therapies

The medical interview

- Ask all patients about CAM.
 - Use a manner that is:
 - Seamless
 - Structured
 - Positive
 - Nonjudgmental
 - Begin new patient interviews with questions, such as:
 - Number of meals eaten together as a family
 - Fun things the family does together
 - Hopes and dreams for the child
 - Aspects of the child of which they are most proud

- At each return visit, a helpful question would be to also ask:
 - “Since the last visit, which other health professionals has your child visited?”
- Listen for understanding rather than agreement or disagreement.

Social history

- Diet
- Exercise
- Environment
 - ACHHOO mnemonic for potential exposure site to known toxins
 - **A**ctivities
 - **C**ommunity
 - **H**ousehold
 - **H**obbies
 - **O**ccupation
 - **O**ral behaviors
- Illness care at home
 - Foods
 - Teas
 - Rubs
 - Prayers or rituals that are helpful for the patient’s family
- Any mind-body therapies used to:
 - Manage stress
 - Reduce chronic symptoms
 - Promote well-being
- Academic history, including:
 - Learning style
 - Friends
 - Hobbies
 - Extracurricular activities
- Questions regarding spirituality as appropriate and ethical:
 - FICA mnemonic:
 - **F**aith or belief—What is your faith or belief?
 - **I**mportance and influence—Is faith important in your life? How?
 - **C**ommunity—Are you part of a religious community?
 - **A**wareness and addressing—What would you want me as your physician to be aware of? How would you like me to address these issues in your care?
 - HOPE mnemonic:
 - **H**ope—What are your sources of hope, meaning, strength, peace, love, and connectedness?
 - **O**rganization—Do you consider yourself part of an organized religion?

- **Personal spirituality and practices**—What aspects of your spirituality or spiritual practices do you find most helpful?
- **Effects**—How do your beliefs affect the kind of medical care you would like me to provide?
- **SPIRIT mnemonic:**
 - **Spiritual belief system**—What is your formal religious affiliation?
 - **Personal spirituality**—Describe the beliefs and practices of your religion or spiritual system that you personally accept or do not accept.
 - **Integration within a spiritual community**—Do you belong to a spiritual or religious group or community? What importance does this group have for you?
 - **Ritualized practices and Restrictions**—Are there specific practices that you carry out as part of your religion/spirituality (eg, prayer or meditation)?
 - **Implications for medical care**—Would you like to discuss religious or spiritual implications of health care?
 - **Terminal events planning**—As we plan for your care near the end of life, how does your faith affect your decisions? Are there particular aspects of care that you wish to forgo or have withheld because of your faith?
- The following guidelines should be kept in mind when discussing spirituality:
 - The physician's role is not to provide answers but to support the search for answers.
 - Anticipate the presence of spiritual concerns with every illness—those of the patient, the family, and care team members.
 - Comprehend how the patient's and the family's faith or spirituality can be a resource during illness.
 - Seek to understand how the patient's or the family's cultural and spiritual worldview influence understanding of the disease, the appropriate treatment, and the recovery process.
 - Determine what effect, positive or negative, the patient's or the family's spiritual orientation or interpretation has on perceived needs.
 - Partner with, and refer to, chaplains or the patient's or the family's preferred spiritual care provider for assistance with significant spiritual concerns.
- **Medical history**
 - Do you use multivitamins?
 - Do you use over-the-counter medications?
 - Example: for pain
 - Do you use herbal medicines?
 - Example: *Echinacea* or chamomile
 - Do you take specific vitamins and minerals?
 - Example: Vitamin C or calcium
- Do you take dietary supplements?
 - Example: fish oil
- Follow-up questions:
 - What brand?
 - What dose?
 - How often?
 - What directions are you following?
 - What goals are you hoping to achieve by taking it?
 - Are you using any other remedies now?
- Identify patients at risk for:
 - Interactions with prescription medications
 - Excessive bleeding during surgery
 - Highest risk associated with:
 - Anticoagulants
 - Hypoglycemics
 - Antidepressants
 - Sedative-hypnotics
 - Antihypertensives
 - Medications with narrow therapeutic windows (eg, digoxin, theophylline)
- Ask patients to bring all remedies with them to every visit, so that:
 - Chart can be updated
 - Use is monitored

How to counsel families about CAM

■ Goals

- Strengthen the physician-patient relationship through honest dialogue that is:
 - Clinically responsible
 - Ethically appropriate
 - Legally defensible

■ Follow 3 steps when patients or families report seeing other health professionals and describe current CAM use.

- 1—Determine whether the use of CAM:
 - Represents a rejection of standard care for a serious or life-threatening disease for which a reasonable chance exists of cure or will delay proven treatment
 - In such cases, the first step is to protect the child while understanding the parents' goals.
 - Reporting requirements for abuse and neglect may apply.
 - Parental inclusion of CAM does not in itself constitute neglect.
- 2—Determine whether the CAM therapies used are known to be unsafe or ineffective.

- If yes:
 - The physician's responsibility is to counsel from the documented evidence that the therapy should be stopped.
 - Resistance to such advice may place the parents at risk for charges of neglect or abuse.
 - If no:
 - Monitor as clinically appropriate.
 - Offer to talk with other therapists involved in the child's care to maintain coordinated, comprehensive care.
 - Offer to learn more to help answer the family's questions.
 - Offer additional information and resources to address family's questions about CAM.
 - Document the following in the medical record:
 - Therapy used and the goal of the therapy
 - Patient or family preferences and expectations regarding the therapy
 - Provider of the therapy, location, contact information, and treatment plan (as known by the family)
 - Review of the safety and efficacy issues of the therapy from the medical literature
 - Results of counseling including plan for monitoring CAM treatment and its results
 - Advice provided or resources recommended for further information
 - 3—Ensure that the patient and family's decision to use CAM without a referral is:
 - Based on a fully informed judgment
 - Documented as verbal consent, including what options have been discussed, offered, tried, refused
- How to partner with and refer to CAM practitioners**
- Document the following in the medical record.
 - Parity of evaluation
 - Medical history and physical examination as thorough as for conventional care
 - Informed consent
 - Review of diagnosis
 - All medical options for that diagnosis
 - Discussion of risks and benefits of recommended treatments, including potential interference with ongoing conventional care
 - Any applicable financial interests
 - Treatment plan objectives and goals (expected favorable outcomes and monitoring plan for duration of treatment)
 - Physicians must be able to demonstrate a basic understanding of the medical scientific knowledge connected with the CAM.
 - Physicians should only refer to:
 - Licensed or otherwise state-regulated health care practitioners
 - CAM practitioners with the requisite training and skills
 - Some credentialed practitioners exist in conventional settings.
 - When making referrals for children with complex chronic illness or chronic pain:
 - Carefully prioritize and schedule necessary conventional therapies.
 - Coordinate care with all subspecialists.
 - Consider time and expenses of families who are vulnerable as they seek any available therapies for children.
 - Set appropriate expectations.
 - Support appropriate hope.
 - Avoid overscheduling and overtreating children.
 - Physicians are not liable for negligence on the part of a CAM provider unless the physician:
 - Delayed necessary conventional treatment
 - Knew the provider was not competent to provide the therapy
 - Hired the CAM provider or provided joint treatment with the provider

Conduct Disorders

DEFINITION

- Conduct disorders encompass a range of repetitive and persistent patterns of behavior.
 - In all, basic rights of others or major age-appropriate societal norms or rules are violated.
- Terms used and misused for children and adolescents with these behaviors
 - Conduct disorder
 - Oppositional
 - Conduct disorder is more serious than oppositional behavior.
 - Violent
 - Delinquent
 - Sociopathic
 - Psychopathic
 - Antisocial

EPIDEMIOLOGY

- Conduct disorder
 - Prevalence: approximately 5% (5000 per 100,000)
 - Sex: 3:1–4:1 ratio of boys to girls
- Oppositional disorder
 - Prevalence: higher than that of conduct disorder but declines substantially between early childhood and school age compared with other age groups
 - Sex: 3:1 or 4:1 ratio of boys to girls

ETIOLOGY

- Genetics seem to play a role that has not been defined specifically.
 - The genetics of alcohol and substance use, depression, and impulsivity are better defined by and relate to aspects of conduct disorder.
 - Other neuronal substrates to these behaviors, such as autonomic underarousal, may also have genetic roots.

RISK FACTORS

- Comorbid or co-occurring conditions
 - Learning disabilities
 - Increased risk of school dropout and running away when coexisting with oppositional or conduct disorder
 - Attention deficit/hyperactivity disorder (ADHD)
 - Increased risk of unintentional injury when oppositional or conduct disorder coexists with the impulsivity of ADHD
 - Depression
 - Increased risk of suicidal behavior when coexisting with oppositional or conduct disorder

- Substance use
 - Increased risk of unintentional injury when oppositional or conduct disorder coexists with alcohol use, especially in adolescence
- Anxiety
- Familial factors
 - Insecure early attachment between young child and caretaker
 - Harsh discipline, abuse, or neglect
 - Family dysfunction, marital conflict, domestic violence
 - Mental illness in parents, especially depression
 - Paternal criminality
 - Financial stresses, low income
 - Frequent family moves
 - Birth of a sibling
- Characteristics of the child
 - Rigid temperament
 - Poor fit between child's temperament and parenting styles
 - Academic difficulties
 - Struggles concerning autonomy
- Poor social environment, negative peer group influences (such as gangs)

SIGNS AND SYMPTOMS

- Pediatricians commonly hear about conduct-disordered and oppositional children from parents who are frustrated and angry.
 - Examples of parental behavioral concerns
 - “Jimmy runs out of the house while I am telling him not to.”
 - “Sally will not stay in her room for a time out.”
 - “My husband and I cannot get Billy to sit down and start his homework.”
 - “Jason lied to me about where he was.”
 - “Peter used my credit card to buy a violent video game on the Internet.”
 - “Tom drove the car, despite having only a learner's permit, to see his girlfriend, even though he was grounded.”
 - “Mike may be using and even selling marijuana to his friends.”
 - “Jared is getting into fistfights at school.”
 - A wide range of behaviors can raise the concern of oppositional or conduct disorder.
 - Even the simplest symptoms require thoughtful assessment.
 - Is refusing to go to school an issue of anxiety, emerging learning disabilities, fear of a bully, a consequence of rejection by peers, oppositional behavior, or a reaction to parental conflict?

- Thorough history assessment of each behavior and its circumstances is critical.
 - For many children, the behavior is not the core problem but is the solution that emerges to the child feeling overwhelmed, frustrated, or angry.
 - Although parents will have worries of delinquency or even criminality, the focus of primary care efforts will be a review of risk factors.
 - Pediatricians should assess the severity, frequency, and context of the behavior.
 - What family, personal, and social risk factors may be underlying the behavior?
 - What is the parental reaction, and do any legal ramifications exist?
 - Given the complexity of the behavior and likely contributing circumstances, no easy questionnaires or tools have been developed that substitute for interviews of the child and family.
 - Hierarchy of behavior severity: reactive, nonviolent, proactive nonviolent, reactive violent, and proactive violent
 - In general, reactive behavior, such as arguing or losing one's temper after feeling unfairly punished or exhausted by a long school day, is less serious than proactive anger.
 - A younger child occasionally blaming others or even lying as a means of coping is not as serious as a more consistent pattern of annoying or blaming others.
 - Reacting to bullying with violence or destroying property as part of a group prank is very different from proactively initiating fights, using weapons, or acting out cruelty.
 - Behaviors exhibited as part of a group are, in general, not as serious as acts performed alone.
 - Problem behaviors can be conceptualized as related to:
 - Property (vandalism, theft, fire setting)
 - Interpersonal aggression (bullying, cruelty, fighting, assault)
 - High personal risk (truancy, substance use, running away from home)
 - Comprehensive mental health evaluation
 - Required in a patient with persistent, escalating, violent, and remorseless behavior
 - Behaviors are most worrisome if they are severe, repeated, done alone, and done without remorse.
- DIFFERENTIAL DIAGNOSIS**
- Differential diagnosis focuses on separating common behaviors from serious disorders that portend long-term risk.
 - Some forms of aggressiveness are part of a developmental trajectory to autonomy and independence.
 - They are often socially sanctioned, as in competitive sports, academics, and dating.
 - Such aggression is often socially accepted and achievement oriented.
 - Oppositional behavior for many children is a sign of or a solution to a hidden problem.
 - Disrupting a class may be:
 - A solution to an underlying fear of appearing stupid, a sign that the child needs treatment for learning problems or ADHD
 - A reaction to tension or violence in the home
 - Violating rules to see a girlfriend or boyfriend may be:
 - Simply oppositional
 - A reasonable attempt to assert autonomy in the face of overly restrictive parents
 - Sensible in the context of a private adolescent crisis
 - Diagnostic criteria for conduct disorder
 - Presence of ≥ 3 of the following criteria in the past 12 months, with ≥ 1 criterion present in the past 6 months:
 - Often bullies, threatens, or intimidates others
 - Often initiates physical fights
 - Has used a weapon that can cause serious physical harm to others (eg, a bat, brick, broken bottle, knife, gun)
 - Has been physically cruel to people
 - Has been physically cruel to animals
 - Has stolen while confronting a victim (eg, mugging, purse snatching, extortion, armed robbery)
 - Has forced someone into sexual activity
 - Has deliberately engaged in fire setting with the intention of causing serious damage
 - Has deliberately destroyed others' property (other than fire setting)
 - Has broken into someone else's house, building, or car
 - Often lies to obtain goods or favors or to avoid obligations (ie, cons others)
 - Has stolen items of nontrivial value without confronting a victim (eg, shoplifting, but without breaking and entering; forgery)
 - Often stays out at night despite parental prohibitions, beginning before age 13 years
 - Has run away from home overnight at least twice while living in parental or parental surrogate home (or once without returning for a lengthy period)
 - Is often truant from school, beginning before age 13 years
 - The disturbance in behavior causes clinically significant impairment in social, academic, or occupational functioning.

- Specify the severity.
 - Mild: few, if any, conduct problems in excess of those required to make the diagnosis and conduct problems cause only minor harm to others
 - Moderate: the number of conduct problems and effect on others is between mild and severe
 - Severe: many conduct problems in excess of those required to make the diagnostic or conduct disorder problems that cause considerable harm to others
- Diagnostic criteria for oppositional defiant disorder
 - A pattern of negativistic, hostile, and defiant behavior lasting ≥ 6 months, during which ≥ 4 of the following are present:
 - Patient often:
 - Loses temper
 - Argues with adults
 - Actively defies or refuses to comply with adults' requests or rules
 - Deliberately annoys people
 - Blames others for his or her mistakes or misbehavior
 - Is touchy or easily annoyed by others
 - Is angry and resentful
 - Is spiteful or vindictive
 - A criterion is met only if the behavior occurs more frequently than typically observed in individuals of similar age and developmental level.
 - The disturbance in behavior causes clinically significant impairment in social, academic, or occupational functioning.

DIAGNOSTIC APPROACH

- Thorough history that includes assessment of each behavior and its circumstances
 - Severity
 - Frequency
 - Context
- Close analysis of risk factors
 - Concomitant conditions
 - Family dynamics and social issues
- Comprehensive mental evaluation in the face of persistent, escalating, violent, and remorseless behavior

TREATMENT APPROACH

- Initial goals
 - Increase safety.
 - Seek to have guns or life-threatening medications removed from the home.

- Decrease the level of tension, discord, and stress.
 - Consider structured family agreements or having the child stay with another caretaker.
 - Involve social services if immediate threat to family, child, or others.
- Long-term goals
 - Family and behavior interventions (especially parent training) to:
 - Eliminate the conduct disordered behavior
 - Help the patient make amends
 - Relieve underlying stressors or comorbid conditions
 - Restore trust
 - Build on the child's adaptive strengths in school, activities, with friends, and in the family
- Conduct disorder is more serious than oppositional behavior.
 - Maintaining an appropriate sense of optimism is important because most adolescents with disturbing behaviors emerge as productive adults.
 - However, the risks for self-injury, injury to others, academic discipline, and intervention by legal authorities are real, with serious consequences.
- Mild-to-moderate, short-term defiant behaviors
 - These may yield to the pediatrician's assessment and recommendations.
- Persistent, escalating, violent, and remorseless behaviors
 - Psychosocial and behavioral treatments
 - Appropriate use of medication to treat associated conditions, such as depression, ADHD, or anxiety

SPECIFIC TREATMENTS

Non-pharmacologic management

- Actions and considerations that may be helpful in initial management if conduct-disordered behavior is a serious concern:
 - Patient safety
 - Does the child experience abuse or violence from peers or gang members?
 - Does the child exhibit self-destructive behaviors, including use of substances?
 - Does the child exhibit suicidal risk caused by depression, severe embarrassment, or shame, intensified by a sense of being trapped with no escape and no solution?
 - Does the child have access to guns or life-threatening medications?
 - Family safety
 - Does the home have guns, patterns of domestic violence, or patient-initiated violence to parents or peers?
 - Does the child's home life have escalating, physical confrontations between the child and the parent as part of the emerging behavior?

- Consider structured family agreements or having the child stay with a relative or friend.
- Support structure
 - Provide access to mental health consultation for patient, parent, or family work.
 - Determine the need for other urgently needed services, such as legal representation, liaison with school guidance or probation officer, or state department of social services.
- Limit setting and negotiation
 - Suggest limit setting that decreases stress, for example:
 - Limiting contact to provocative peers
 - Limiting access to substances (or substance abuse treatment)
 - Tracking where the patient is when not in school
- Building on strengths
 - Reinforce any positive supports, such as:
 - Areas of competence
 - Relationship with a caring adult (coach, teacher, parent, sibling, grandparent)
 - Behaviors that will elicit parental praise
- Establishing rules
 - Encourage consistency and unanimity of parental discipline and overall response to conduct-disordered behaviors.
 - Support by a behavioral psychologist is often critical.
- School interventions
 - Help the child reduce academic stress with the help of the school psychologist or guidance counselor, through a teacher conference, by eliminating a stressful class, or by implementing an education plan.
 - Consider whether school-based peer pressures, such as bullying, threats, humiliation, or clique or gang group behavior, are contributing factors.
 - If others are involved, the clinician should support contacting the relevant parents.
- Legal interventions
 - Facilitate parents contacting a lawyer or public defender to deal with potential legal issues, arrests, or pressure from local law enforcement.
 - Lawyers may appropriately engage police who are assigned as youth officers, work with probation departments, or negotiate with the court and local agencies to ensure the availability of services in the context of legal proceedings.
- Specialty mental health interventions: parent training
- Department of social services referral if there is danger to child or family
 - A comprehensive plan often must be mobilized to provide safety.

- Consider referral to the local department of social services to coordinate legal, mental health, and school resources.

Drug treatment

- Risperidone
 - Antipsychotic drug prescribed off-label to address violent conduct-disordered behavior
 - Use of this potent and complex medication should not be initiated without a comprehensive treatment plan and collaboration with a child and adolescent psychiatrist.
- Treat underlying concomitant conditions/risk factors, such as ADHD.

PROGNOSIS

- We do not know which patients will have lifelong problems.
 - The specific profile of causes and symptoms that are prognostic for a persistent course is not well defined.
 - Oppositional and conduct-disordered symptoms at any age cause dysfunction in the child and family and are potentially dangerous to others.
 - Most children who demonstrate oppositional behavior do not progress to conduct disorder as adolescents.
 - More serious conduct disorders do not necessarily lead to criminality, addiction, or lifelong disorders.
- Early childhood
 - Oppositional disorder declines substantially between early childhood and school age compared with other age groups.
- School age and adolescence
 - Aggressive behavior seems to decline after early childhood but is more stable and worrisome when evident in school age and adolescence.
 - The younger the patient, the more violent the behavior, and the less the child experiences remorse or guilt, the more serious the eventual prognosis.
 - Adolescents who demonstrate a sense of feeling connected to a school, team, peers, or family probably have a better prognosis than those who are isolated, unfeeling, or alone.
- Late adolescence
 - Period of another substantial decline in conduct disorder
 - A distinct subsample becomes criminal.
- Protective factors that probably improve prognosis
 - Adaptable temperament
 - Higher IQ
 - Competence in ≥ 1 area (eg, academic, social, athletic)
 - Warm relationship with a parent or adult
 - Opportunities to connect to the community (eg, clubs, teams)
 - Financial resources to facilitate opportunities

PREVENTION

- Encouraging efforts focused on high-risk populations
 - Early identification of at-risk infants
 - Postpartum home visits or screening in child care settings for young mothers who are vulnerable to depression, domestic violence, conflictual relationships, or using harsh disciplinary techniques
 - Identifying and providing services for school-aged children who demonstrate aggression, bullying, learning disabilities, and ADHD
 - Identifying high-risk adolescents who might be failing in school, depressed, using substances, or fighting
 - Broad-based prevention efforts
 - Comprehensive services for abused and neglected children
 - Community efforts directed against substance use or development of gangs
 - Adequate opportunities for connecting children and adolescents to their community through sports, activities, and religious affiliation
 - Access to mental health services when needed
 - Financial pressures on community services and schools have decreased preventive services.
 - Pressures to control health care spending have lowered the priority of mental health services for children and families.
 - An adolescent with conduct disorder who elicits mental health, social service, school-based, and legal attention costs the community \$70,000 over a 7-year period.
 - Despite this high cost, prevention, early intervention, and mental health services in most communities are poorly funded.
 - Primary care pediatricians shoulder more of the burden for mental health problems, such as oppositional and conduct disorders.
-

Congenital and Acquired Heart Disease

DEFINITION

Congenital defects

- Intracardiac shunting lesions
 - A defect or hole in the septum separating the 2 ventricles that allows blood to traverse from one side of the heart to the other
 - Shunting can be:
 - Left side of the heart to the right
 - Right side of the heart to the left
 - Bidirectional
 - Right heart
 - Systemic veins, inferior vena cava (IVC), and superior vena cava (SVC)
 - Atrium
 - Ventricle
 - Great artery/pulmonary artery
 - Left heart
 - Pulmonary veins
 - Atrium
 - Ventricle
 - Great artery/aorta
- Left-to-right shunting lesions
 - Ventricular septal defect (VSD)
 - Atrial septal defect (ASD)
 - Patent ductus arteriosus (PDA)
 - Atrioventricular septal defects (AVSDs)
 - Arteriovenous malformations
- Right-to-left shunting lesions
 - Tetralogy of Fallot
 - Eisenmenger syndrome
 - Untreated septal defect
 - Pulmonary hypertension
 - Pulmonary atresia
 - No prograde flow across the pulmonary valve
 - Ebstein anomaly
 - Anomalous pulmonary venous return (PVR)
 - Total
 - Partial
 - Dextrorotation
 - Rightward transposition of the great arteries
- Left-sided obstructive lesions
 - Characterized by impedance to blood flow from the systemic ventricle (generally the left) to the body
 - Aortic stenosis
 - Coarctation of the aorta

- Complete mixing lesion/single-ventricle heart
 - Arterial oxygen saturation (SaO₂) is the same in both the aorta and the pulmonary artery.
 - Hypoplastic left heart syndrome
 - Tricuspid atresia

Acquired heart disease

- Infectious
 - Infectious endocarditis (IE)
 - Bacterial infection of the endocardium or endothelium of the heart
 - Myocarditis
 - Generalized inflammation of the cardiac muscular walls
 - Pericarditis
 - Inflammation of the pericardium
 - Both the parietal and the visceral layers of the pericardium are inflamed.
- Cardiomyopathies
 - Any structural or functional abnormality of the ventricular myocardium that is not associated with congenital heart disease or diseases of the coronary arteries, cardiac valves, or pulmonary vasculature
 - Dilated cardiomyopathy (DCM)
 - Hypertrophic cardiomyopathy (HCM)
 - Restrictive cardiomyopathy (RCM)
 - Miscellaneous cardiomyopathies

EPIDEMIOLOGY

Congenital defects

- Only 5–8 of 1000 live births are affected by a congenital heart lesion.
- Left-to-right shunting lesions
 - Ventricular septal defects (VSD)
 - One of the most common types of congenital heart disease
 - Nearly 20% of patients in heart disease registries have a solitary VSD.
 - PDA
 - Most commonly encountered in premature infants
 - AVSDs
 - Nearly 50% of all patients with trisomy 21 have congenital heart disease.
 - Nearly 50% are AVSDs (also known as *atrioventricular canal defects* or *endocardial cushion defects*).
- Right-to-left shunting lesions
 - Tetralogy of Fallot
 - One of the most commonly encountered cyanotic heart defects, occurring in 0.33 per 1000 live births and comprising approximately 7% of heart defects

- Dextrorotation
 - The most common type of cyanotic heart disease

Acquired heart disease

■ Infectious

- IE
 - Prevalence has increased substantially over the past 2 decades.
- Myocarditis
 - In a 10-year study of 14,000 cardiac patients between 1954 and 1977, myocarditis was diagnosed in 0.5% of patients at presentation and another 2–5% at autopsy.
 - Nearly 20% of pediatric sudden deaths may be related to myocarditis.

■ Cardiomyopathies

- DCM
 - Accounts for 60–70% of pediatric cardiomyopathies
 - Prevalence: 5–20 cases/1,000,000 persons
- HCM
 - Second most common form of cardiomyopathy (20–30%) in children
 - Prevalence: 4–6/1,000,000 persons
- RCM
 - Rarest form of cardiomyopathy in children
- Miscellaneous cardiomyopathies
 - Arrhythmogenic right-ventricular dysplasia (ARVD) and mitochondrial and noncompaction cardiomyopathies comprise only 2–3% of pediatric cardiomyopathies.

ETIOLOGY

Intracardiac shunting lesions

- In all shunting lesions, the volume of shunted blood depends on the size of the defect.

Left-to-right shunting lesions

- VSD
 - Left-sided heart pressure generally exceeds that on the right side.
 - Blood will preferentially shunt from left to right and is added directly to the pulmonary circulation.
 - In the case of large VSDs, this addition of blood results in left-ventricle volume overload.
 - Over time, the left heart will dilate to accommodate this increased volume.
 - Abnormal mechanical stresses inherent in the chronically volume-loaded, dilated ventricle can lead to myocyte dysfunction and heart failure.

■ ASD

- In addition to pressure, a difference in chamber compliance is the dominant force directing blood from left to right.
- The highly compliant right atrium becomes a sink for blood draining into the smaller, less-compliant left atrium by the pulmonary veins.
 - This additional blood volume is routed into the right ventricle, resulting in right-heart dilation over time.

■ PDA

- When the ductus arteriosus does not involute shortly after birth, it is a potential source of shunting from the aorta to the pulmonary arteries once PVR decreases.

■ AVSDs

- Partial type (primum type ASD with a cleft mitral valve)
- Complete type (single atrioventricular valve spanning the entire width of the heart)
 - Variability in the attachment of the atrioventricular valve leaflets to the interventricular septum
 - Can result in a significant left-to-right shunt volume

■ Arteriovenous malformations

- Direct connection between the arterial and venous vascular systems results in:
 - Shunting of blood to the right heart
 - Possible high-output, left-sided heart failure
- Common locations in children
 - Cerebral
 - Abdominal

Right-to-left shunting lesions

- Oxygen-poor blood is shunted to the oxygen-rich systemic blood.
 - Systemic peripheral cyanosis is the key difference between left-to-right and right-to-left shunting lesions.
 - As with left-to-right shunting lesions, the volume of shunted blood depends on:
 - Size of the defect
 - Pressure gradient across it
- Tetralogy of Fallot
 - May occur as a result of disproportionate segregation of the truncus arteriosus into the pulmonary artery and aorta
 - Shunting of right-ventricular blood through the VSD into the aorta produces systemic, peripheral cyanosis.
 - Tetralogy spell (Tet spell), a hypercyanotic event, occurs when systemic vascular resistance decreases, resulting in an increased right-to-left shunt.
- Eisenmenger syndrome
 - Unrepaired VSDs or large ASDs with secondary pulmonary hypertension

- Significant shunting and progressive cyanosis occur once the pulmonary artery, and therefore right-ventricular, pressures are higher than the systemic blood pressure.
- Pulmonary hypertension
 - Isolated or idiopathic pulmonary hypertension
 - No septal defects through which blood can shunt right to left
 - Pulmonary hypertensive crisis (transient, severe elevation of pulmonary artery pressures) causes markedly decreased right-ventricular and then left-ventricular output.
- Pulmonary atresia
 - Blood entering the right ventricle is regurgitated through the tricuspid valve back into the right atrium, where it mixes with SVC and IVC blood.
 - The increase in blood volume increases right atrial pressure, resulting in shunting of blood across the patent foramen ovale to the left atrium.
- Ebstein anomaly
 - Tricuspid valve insufficiency
 - Course of blood flow is much the same as in pulmonary atresia with intact ventricular septum.
 - With worsening tricuspid valve incompetence, the effectively smaller right ventricle is less able to propel blood across the pulmonary valve, which is usually narrowed or stenotic, or both.
 - Blood instead returns to the right atrium and crosses the patent foramen ovale.
- Total anomalous PVR
 - Occurs when the pulmonary veins do not connect with the posterior wall of the left atrium but instead form a confluence that then drains via a vertical vein indirectly to the right atrium
 - Within the heart, blood is shunted from the right atrium across an obligate ASD into the left atrium.
 - This provides the only source of systemic cardiac output.
- Partial anomalous PVR
 - Anomalous return of ≥ 1 pulmonary veins to the right heart
- Dextrorotation
 - Embryologic defect of the conotruncus
 - The aortic valve lies rightward and anterior of the pulmonary valve instead of rightward and posterior, as in the normal heart.
 - Pulmonary and systemic circulations are in parallel rather than in series.
 - The body relies on both intra- and extracardiac shunting to provide oxygenated blood to the tissues.

Left-sided obstructive lesions

- Aortic stenosis
 - A large portion of fetal cardiac output is provided by ductal flow from the pulmonary artery to the descending aorta.
 - The transition to postnatal circulation occurs with closure of the ductus arteriosus.
 - In the newborn with severe or critical aortic stenosis, this process is associated with a significant decrease in systemic blood flow.
- Coarctation of the aorta
 - In neonates, occurs as either a discrete narrowing or a diffuse hypoplasia of the transverse and isthmus aortic arch
 - Discrete coarctation can occur in virtually any portion of the aorta but is typically found near the insertion of the ductus arteriosus (juxta-ductal).
 - In adolescents, a discrete, relatively undersized segment of the aorta that did not continue to grow at a rate commensurate with the remainder of the aorta
 - The coarctation is bypassed by collateral arteries.
- Complete mixing lesion/single-ventricle heart
 - Systemic and pulmonary venous blood volumes drain into a single ventricle to produce a partially desaturated blood volume perfusing both the body and the lungs.
 - The same physiologic mechanism and management is applicable to essentially all variations of the single-ventricle heart.
 - Hypoplastic left-heart syndrome (HLHS)
 - Group of cardiac anomalies characterized by underdevelopment of the aortic arch, aortic valve, mitral valve, and left ventricle
 - Used herein as the prototype for single-ventricle heart
 - Tricuspid atresia
 - The single ventricle is a left ventricle generally connected to the aorta.

Acquired heart disease

- Infectious
 - IE
 - Generally associated with a procedural or surgical intervention
 - Spontaneous IE does occur but is exceedingly rare without predisposing risk factors.
 - Staphylococci, streptococci, and enterococci are the most common pathogens because of their ability to interact with platelets and resist the host's immune response.
 - Myocarditis
 - Viral infiltration of myocytes and the associated immune-mediated cell lysis
 - Enteroviruses, particularly the coxsackievirus B3 and B4 serotypes, and adenovirus are most frequently involved.

- Pericarditis
 - Infectious causes: enteroviruses (especially coxsackievirus B), influenza, cytomegalovirus, Epstein-Barr virus; *Staphylococcus aureus*, *Streptococcus pyogenes*, *Streptococcus pneumoniae*
 - Noninfectious causes: rheumatic fever, autoimmune diseases, postcardiac surgery, uremia, cancer
- Cardiomyopathies
 - DCM
 - A viral cause is identified in 2–15% of cases of biopsy-proven myocarditis.
 - The remaining cases are classified as idiopathic but are probably genetic.
 - Regardless of cause, the progressive cardiac dysfunction associated with DCM is probably related to the remodeling response of the heart after an inciting injury.
 - HCM
 - Genetic basis; multiple familial forms
 - 40–50% have a point mutation on chromosome 14q1.
 - RCM
 - Thought to have both genetic and nongenetic causes
 - Miscellaneous cardiomyopathies
 - ARVD: dysplasia of the right ventricle develops from fatty deposits within the ventricular walls.
 - Mitochondrial cardiomyopathies: maternally inherited
 - Left-ventricular noncompaction cardiomyopathy: deep crevices or trabeculations within the left ventricle reduce cardiac function.

RISK FACTORS

Congenital defects

- Down syndrome
 - 40–60% of children with Down syndrome are born with some form of congenital heart disease.
 - Patients with Down syndrome comprise ~9% of the pediatric cardiologist's practice.
- Williams syndrome
 - Supravalvar obstruction
- Turner syndrome
- Coarctation of aorta
- Noonan syndrome
- Pulmonary valvular stenosis

Acquired heart disease

- IE
 - Congenital heart defects (~90% of cases)
 - Risks of IE in the preoperative state of congenital heart defects
 - Tetralogy of Fallot: >30%

- VSD: 12–14%
 - PDA: 8%
 - Aortic stenosis: 2%
 - Pulmonary stenosis: 1%
- Indwelling venous catheters without associated structural heart disease
- Myocarditis
 - Frequently associated with infectious pericarditis
 - More so with viral than with bacterial agents
- Pericarditis
 - Autoimmune disease
 - Uremia
- HCM
 - Noonan syndrome
 - Friedreich ataxia
- RCM
 - Sarcoidosis
 - Amyloidosis
- Mitochondrial cardiomyopathies
 - Other muscle, liver, neurologic, and developmental abnormalities
- Left-ventricular noncompaction cardiomyopathy
 - Mitochondrial, metabolic, and systemic (Barth syndrome) disorders

SIGNS AND SYMPTOMS

Cardiac murmur

- Audible blood flow through the heart or vascular system that can be auscultated in a normal heart, resulting from hyperdynamic function or a thin chest wall
- Diastolic murmur
 - Generally indicates an abnormality
- Systolic murmur
 - May be either:
 - Normal (functional)
 - Pathologic
- Regardless of the timing, location, or cause of the murmur, its frequency and pitch depend on:
 - Size of the opening through which the blood flows
 - Pressure gradient across it

VSDs and ASDs

- Smaller ASDs and VSDs
 - May not be detected prenatally
 - Usually detected by the presence of a murmur, with or without the signs of heart failure

- The timing of presentation depends on the size of the defect and whether the infant has fully transitioned from fetal circulation.
- A small VSD will produce a high-pitched, holosystolic murmur that continues from the onset of ventricular systole through the closure of the atrioventricular valves (obscuring the first heart sound), to the closure of the semilunar valves.
- In some patients, PVR never decreases after birth or decreases at a slower rate and then increases.
 - These patients will have few or no symptoms of pulmonary overcirculation.
 - As a result, they may not be brought to a physician's attention.
 - Elevated PVR produces elevated pulmonary artery pressures and commensurate pulmonary hypertension (mean pulmonary pressures >25 mm Hg at rest).
- Large VSDs
 - Produce a softer holosystolic murmur because the pressures of the 2 ventricles more closely approximate one another
 - This murmur will be loudest at the left lower sternal border and may be best described as a mid-frequency blowing murmur.
 - A neonate with a large VSD may demonstrate poor weight gain and lethargy as PVR decreases, increasing the gradient for shunting from the left ventricle to the right
 - If untreated, heart failure (marked pulmonary over-circulation) may ensue.
- ASD
 - Auscultation differs significantly from that of a VSD.
 - The lack of a marked pressure gradient between the 2 atria does not produce a murmur at the site of shunting.
 - Rather, the murmur of an ASD is due to excess volume traversing the pulmonary valve, commonly described as a relative pulmonary stenosis.
 - It is described as a mid-frequency systolic ejection murmur best auscultated at the upper left sternal border and will commonly radiate to the lung fields bilaterally.
 - ASD may remain asymptomatic for many years.
 - Pulmonary edema symptoms
 - Typically do not develop until the pulmonary artery blood flow has doubled in volume

PDA

- Auscultation
 - Machinery murmur (continuous, undulating)
 - Heard during both systole and diastole
 - As the ductus arteriosus begins to close, the murmur is higher in pitch
 - Murmur is best auscultated in the left upper sternal border of the chest; it may radiate to both lung fields.

- Other signs
 - Worsening chronic lung disease
 - Poor renal perfusion
 - Hemodynamic instability
 - Intraventricular hemorrhage
 - Necrotizing enterocolitis

Tetralogy of Fallot

- Commonly detected by prenatal ultrasonography between 18 and 22 weeks' gestation
- Clinical presentation can vary greatly, depending on:
 - Degree of pulmonary stenosis
 - Presence of pulmonary atresia
- Newborns
 - Cyanosis
 - Audible murmur
 - Systolic murmur may be appreciated at the left upper sternal border and is produced by the narrowing of the right-ventricular outflow tract (RVOT).
 - Grade (I–VI/VI) and quality (harsh or soft) depend on the degree of obstruction.
 - In the newborn with tetralogy of Fallot and pulmonary atresia:
 - RVOT murmur is replaced by a flow murmur through the ductus arteriosus, the only source of pulmonary blood flow.

Eisenmenger syndrome

- Physical examination of patient with pulmonary hypertension caused by Eisenmenger syndrome may be virtually indistinguishable from that of a simple ASD or VSD.
 - A subtle difference may be a loud pulmonary valve component of the second heart sound.

Pulmonary hypertension

- Idiopathic pulmonary hypertension or pulmonary hypertension secondary to bronchopulmonary dysplasia
 - Cyanosis (from intrapulmonary or right-left atrial level cardiac shunting)
 - Loud pulmonary valve component of the second heart sound without an associated cardiac murmur
 - In the absence of pulmonary or tricuspid insufficiency
 - Equal ventricular pressures in Eisenmenger syndrome secondary to a VSD will not produce an audible murmur.

Dextrorotation

- Can be diagnosed prenatally
 - Neonates are cyanotic at birth without associated respiratory distress.
 - Physical examination will be remarkable for cyanosis and possibly a ductal murmur.
 - Should otherwise be normal for a newborn

- SaO₂ will not increase significantly with supplemental oxygen (failed hyperoxia challenge test).
- Care should be taken to assess lower-extremity pulses.
 - Coarctation of the aorta can be associated with dextro-looped transposition of the great arteries (d-TGA).
 - Prostaglandin E₁ infusion should be initiated once this defect is suspected.

Aortic stenosis

- Valvar aortic stenosis can occur in isolation or be associated with either subvalvar or supra-valvar obstruction.
- With few exceptions, the presentation and alteration of cardiovascular physiologic characteristics are very similar among the 3 defects.
- Mild to moderate stenosis
 - Cardiac murmur may be the only sign of an abnormality in the newborn.
 - Ejection click followed by a harsh systolic ejection murmur
 - Best auscultated at the right upper sternal border
 - Additional signs and symptoms may not develop until childhood.
 - Particularly in the pediatric population, mild to moderate aortic stenosis will not produce exercise intolerance, chest pain, syncope, or shock.
 - As a result, these patients are often referred to a pediatric cardiologist after the characteristic murmur is heard during a routine physical examination.
- Severe or critical aortic stenosis will develop in the newborn as heart failure or clinical extremus.
 - Signs and symptoms of congestive heart failure will ensue.
 - Diaphoresis with feeding
 - Irritability
 - Lethargy
 - Fatigue
 - Acyanotic, but ashen pallor
 - Harsh cardiac murmur
 - Diminished or absent peripheral pulses

Coarctation of the aorta

- Auscultation
 - Systolic murmur is loudest at the left upper sternal border.
 - Murmur generally radiates to the back, medial to the left scapula.
- Neonates
 - Patient presentation tends to have a bimodal distribution.
 - Cases with diffuse arch hypoplasia are typically diagnosed shortly after birth.
 - Cases with an isolated discrete narrowing may not be diagnosed until later in infancy or childhood.

- This lesion may not be detected by prenatal ultrasonography.
 - Therefore, palpation of the femoral pulses becomes a crucial part of the newborn examination.
 - When not palpable in an otherwise healthy-appearing infant, both upper-extremity and 1 lower-extremity blood pressure should be obtained.
- Blood pressure
 - Must be checked in both arms; the left subclavian artery may arise either proximal or (more rarely) distal to the coarctation site.
 - In the legs, a single-leg blood pressure should be adequate.
- Determining presence of a PDA is of critical importance.
 - Because of the presence of ductal tissue in the aorta, coarctation cannot definitively be ruled out until the ductus has closed.
 - If the ductus is closed and a blood pressure gradient on cuff or narrowing on echocardiography is not found, then a hemodynamically significant coarctation does not exist.
 - If there is concern about the existence of a coarctation, the patient should not be discharged until the ductus arteriosus has completely closed or close follow-up has been arranged.
- Adolescents
 - Distinctly different presentation from that in infants
 - Multiple collateral arteries connect the aorta proximal and distal to the obstruction, thus bypassing the coarctation.
 - Intercostal arteries supplying the collateral artery system can become extensive and produce indentations or notching of the ribs.
 - Patients exhibit systolic murmur, upper-extremity hypertension, or both.
 - Upper- and lower-extremity blood pressures
 - May be a more accurate modality than Doppler flow for determining the clinical coarctation gradient

HLHS

- Newborns with HLHS can achieve normal birth weight and gestational age.
 - Fetal circulation can be adequately supplied by the right ventricle.
- Timing of diagnosis
 - Unless HLHS is diagnosed prenatally, the newborn with HLHS may not be immediately recognized.
 - Some of these patients do not receive a diagnosis for several weeks.
 - Such patients typically present with pulmonary over-circulation and systemic shock.

- Profound systemic cyanosis may not occur until the SaO_2 falls below approximately 85% (possibly lower in dark-skinned children).

■ Auscultation

- Cardiac murmur is commonly not present or appreciated.

■ Palpation of femoral pulses

- Critical step in every newborn's routine evaluation
- Commonly decreased in the newborn with HLHS
 - These pulses will become progressively weaker as the ductus arteriosus closes.
 - If aortic atresia exists, then all 4 extremity pulses will diminish with ductal closure.

Tricuspid atresia

■ Patients have a similar physiologic display to those with HLHS.

- Several anatomic variants exist.

IE

■ Clinical course

- Typically indolent
- In rare cases, can cause cardiogenic shock

■ Patients may have:

- Recurrent low-grade fever (90%)
- Arthralgia (25%)
- Gastrointestinal discomfort (15%)
- Fatigue
- Rigors
- Other nonspecific findings

■ Physical examination may be significant for:

- New cardiac murmur (rare)
 - Splenomegaly (55%)
 - Neurologic changes (20%)
- #### ■ Classically described findings are rare in children.
- Osler nodes (tender subcutaneous nodules on pads of fingers)
 - Janeway lesions (nontender hemorrhagic macules on palms or soles)
 - Roth spots (pale centered oval hemorrhages on retina)
 - Splinter hemorrhages in the nail beds

■ Duke criteria for diagnosis of IE

- Criteria are met if a patient demonstrates:
 - Both major criteria
 - 5 of the 6 minor criteria
 - 1 major and 3 minor criteria
 - Overall, the minor criteria are often used when diagnosing pediatric IE

Myocarditis

■ Clinical presentation

- Ranges from mild electrocardiographic (ECG) abnormalities in an otherwise asymptomatic child to fulminant congestive heart failure

■ Less fulminant presentations

- More typical in older children
- 7–10 days after a viral upper respiratory infection or gastroenteritis

■ Severe, fulminant onset

- Cardiogenic shock may be present.

■ Signs and symptoms

- Fever
- Malaise
- Chest pain
- Dyspnea
- Pallor
- Poor perfusion

■ Auscultation

- Muffled heart sounds
- Gallop rhythm
- Suggestive of congestive heart failure

Pericarditis

■ History

- Viral upper respiratory infection 10–14 days before the development of pericarditis is common.

■ Physical examination

- Pain in the left side of the chest
 - Worse in the supine position or with deep breathing
 - Relieved on sitting or leaning forward
 - May radiate to the left shoulder or to the neck
- Fever (especially with bacterial pericarditis)
- Signs of low cardiac output
 - Hypotension
 - Tachypnea
 - Tachycardia
 - Dyspnea
 - Pale, gray (sometimes mottled) pallor
 - Clammy skin
- Auscultation
 - Pericardial friction rub (a biphasic sound) is the cardinal sign of early pericarditis.
 - With further accumulation of pericardial fluid, the friction rub may disappear and the heart sounds may become muffled.

- With the onset of cardiac tamponade:
 - Venous return during inspiration is compromised, resulting in a paradoxical rise in the jugular venous pressure (Kussmaul sign).
 - Cardiac output and systolic blood pressure decreases (pulses paradoxicus).
- Symptoms and signs depend on:
 - Fluid volume within the pericardial space
 - The pericardial fluid can be serous, serofibrinous, hemorrhagic, or purulent in nature.
 - Rapidity with which the fluid collects
 - Rapid collection of fluid, as occurs in bacterial infections, may cause severe circulatory compromise (cardiac tamponade).
 - A gradually developing pericardial effusion allows the pericardium to stretch, and therefore the increase in the pericardial pressure is slower and more readily tolerated.
 - Myocardial function
 - If myocardial function is depressed, even a gradual increase in pericardial fluid and pressure may cause significant circulatory compromise.

DCM

- Clinical presentation
 - Varies from progressive exercise intolerance with pulmonary congestion to systemic decompensation with complete cardiovascular collapse
 - Diagnosis typically does not occur until the cardiac reserve is exhausted or is nearly exhausted.
 - Often diagnosed after the patient experiences an acute viral illness that elevates resting metabolism enough to exceed the failing heart's compensatory mechanisms
- Physical examination
 - Consistent with congestive heart failure in symptomatic patients
 - Tachycardia
 - Cachexia
 - Sallow color
 - Tachypnea
 - Orthopnea (older children)
 - Hepatomegaly and weakened peripheral pulses may be found with severe cardiac dysfunction.
 - Auscultation
 - Gallop
 - Early systolic, regurgitant murmur of mitral regurgitation

HCM

- Presentation
 - Variable
 - Asymptomatic to congestive heart failure

- Classic presentation
 - Syncopal patient with a loud cardiac murmur
- Physical examination
 - Typically normal
 - Progressive exercise intolerance
- Auscultation
 - Harsh systolic ejection murmur at the left sternal border with radiation to the neck
 - If present, this murmur is accentuated when a squatting patient is asked to stand.
- History
 - Family history is critical.
 - Nearly one-half of all patients with HCM will have a first-degree relative with HCM or with a history of syncope or sudden death.

Miscellaneous cardiomyopathies

- ARVD
 - Patients typically present with dysrhythmias.
- Mitochondrial cardiomyopathies
 - Often present early in life
 - Hypertrophied or (less commonly) dilated, poorly functioning heart
- Left-ventricular noncompaction cardiomyopathy
 - Cardiac dysfunction has a varying age of onset.
 - Newborn period to adulthood

DIFFERENTIAL DIAGNOSIS

- Peripheral pulmonary branch stenosis
 - Accompanied by a physiologic murmur
 - Short, relatively high-pitched II/VI systolic ejection murmur
 - Auscultated equally on both sides of the sternum with diffuse radiation to both lung fields
 - Characteristic of the natural transition period from fetal to postnatal circulation
 - Does not require urgent consultation
 - Most physicians are concerned that they may be missing the murmur produced by pulmonary stenosis.
 - This murmur is distinct from that of peripheral pulmonary stenosis in both its severity and focality.
 - Peripheral pulmonary branch stenosis is a softer, less intense murmur that is equally audible throughout the chest.
 - A murmur produced by significant valvar pulmonary stenosis will be:
 - Harsh in character
 - At least grade III on a severity scale of I to VI
 - Often preceded by a valve click

- Best auscultated at the left sternal border, but will radiate to both lung fields

■ Cyanosis

- In most of these situations, a cardiac lesion is not the cause.
 - Pulmonary disease is more commonly the culprit.
- Verify that cyanosis is truly present.
 - Acrocyanosis is a frequent occurrence in newborns, particularly in the setting of volume depletion or cool extremities.
 - Full-body cyanosis can occur in several scenarios, including respiratory distress syndrome.

■ Pediatric hypertension

- Any evaluation should include investigation for coarctation of the aorta.

■ RCM

- Care must be taken to distinguish RCM from constrictive pericarditis.

DIAGNOSTIC APPROACH

■ In all heart lesions, the severity of the obstruction determines:

- Age at presentation
- Clinical manifestations

■ Foremost diagnostic tools

- History and physical examination
 - Signs of low cardiac output
- Imaging
 - Electrocardiography
 - Chest radiography
 - Echocardiography

■ All patients with Down syndrome should be evaluated by a pediatric cardiologist within the first month of life.

LABORATORY FINDINGS

■ IE

- Blood cultures
 - Identical bacterial pathogens are identified before IE is diagnosed.

■ Myocarditis

- The following may be elevated.
 - Erythrocyte sedimentation rates
 - C-reactive protein
 - Leukocyte count
 - Platelet count
- Measures of cardiac cell damage to establish that myocyte injury has occurred and monitor progress
 - Troponin-I
 - Creatinine kinase–MB fraction

• Verify the cause.

- Serum viral cultures
- Serologic titer assays
- Polymerase chain reaction amplification of the viral genome

■ Pericarditis

• Determine the cause with:

- Total cell count
- Differential cell count
- Glucose
- Protein concentration
- Gram stain
- Acid-fast stain
- Cultures (with viral polymerase chain reaction as indicated)
- Cytologic assays

IMAGING

■ Chest radiography

- VSD and ASD
 - Generally noncontributory in diagnosing left-to-right shunt lesions before the onset of pulmonary overcirculation and the resulting pulmonary edema
 - Once pulmonary overcirculation has developed, the cardiac silhouette will gradually increase in area and pulmonary vascular markings will become substantially more prominent.
 - Can also be used to help assess effectiveness of medical management, such as diuretic therapy.
- Tetralogy of Fallot
 - The classic radiographic finding is the boot-shaped cardiac silhouette.
 - Relative right-ventricular hypertrophy in the healthy newborn often results in the erroneous reading of a boot-shaped cardiac silhouette on initial chest radiographic examination.
- Ebstein anomaly
 - Marked cardiomegaly from right-atrial dilation
- Dextrorotation
 - The classic radiographic finding for d-TGA is the *egg on a string*.
 - The great arteries are often oriented parallel (the string) instead of perpendicular, removing the aortic and pulmonary knobs.
 - This great artery orientation can also create a mesocardiac orientation of the cardiac silhouette producing an egg-shaped silhouette.

- Aortic stenosis
 - Chest radiography is helpful only if pulmonary edema has developed because of left-heart failure.
 - The anteroposterior projection of the cardiac silhouette is usually not particularly helpful.
- Coarctation of the aorta
 - In the adolescent with long-standing, unrepaired coarctation, rib notching may be seen from engorgement of the intercostal blood vessels.
- HLHS
 - Unless pulmonary overcirculation occurs, radiography is unlikely to contribute to the diagnosis, except possibly to differentiate a cardiac from a pulmonary source of cyanosis.
- Myocarditis
 - Global cardiac enlargement and increased pulmonary vascularity with varying degrees of edema
- Pericarditis
 - May be normal when the pericardial effusion is small
 - With a large effusion, the heart looks enlarged and has a globular appearance.
 - The pulmonary vascular marking may be prominent in patients with tamponade.
- Dilated cardiomyopathy
 - Cardiomegaly with or without increased pulmonary vascular markings
- Echocardiography
 - VSD and ASD
 - Two-dimensional echocardiography will show a defect in the interatrial or interventricular septum and allow for determination of cardiac function.
 - Doppler flow velocities across the defect can estimate pressure differences between the respective chambers.
 - Together, this information can help guide timing and type of surgical correction, if indicated.
 - Right-to-left shunting lesions
 - Two-dimensional and Doppler echocardiograms define cardiac anatomy, function, and direction of blood flow across any cardiac defects.
 - Doppler flow velocity across the RVOT allows estimation of outflow gradient, degree of obstruction, and any evidence of branch pulmonary artery stenosis.
 - Dextrorotation
 - Two-dimensional echocardiography will confirm the diagnosis and can evaluate the extent of intra- and extracardiac shunting.
 - ASD size, direction of ductus arteriosus shunting, and presence of a VSD are important components of intercirculatory mixing.
 - Aortic stenosis
 - Two-dimensional echocardiography is adequate to diagnose aortic stenosis.
 - Hyperdynamic systolic function of a hypertrophied left-sided ventricle may be found.
 - A bicuspid aortic valve will be present in nearly 60% of cases.
 - Doppler flow can approximate the systolic flow gradient across the obstructed region.
 - In the setting of subvalvar aortic stenosis, flow acceleration begins below the valve and can be associated with aortic regurgitation.
 - Supravalvar aortic stenosis is commonly seen with Williams syndrome and should prompt a search for the associated lesion of pulmonary branch stenosis.
 - In the neonate with aortic stenosis, patency of the ductus arteriosus and its direction of flow are important to help plan an appropriate management strategy.
 - Coarctation of the aorta
 - To determine whether the coarctation is ductal dependent and to evaluate for other left-sided obstructive lesions
 - Used to diagnose the presence of a hypoplastic aortic arch or discrete narrowing of the aorta
 - HLHS
 - Confirmatory study
 - The sonographer should document presence or absence of PDA and flow through aortic and mitral valves, estimate the left-ventricular volume, determine size of the ascending aorta and ASD, and characterize the aortic arch and coarctation.
 - Size and competency of the pulmonary and tricuspid valves, and right-ventricular function are critical information to obtain to stratify surgical morbidity and mortality risks.
 - IE
 - Transthoracic echocardiography
 - Excellent specificity, but poor sensitivity limits its role in the diagnosis of IE
 - Transesophageal echocardiography
 - Preferred visual diagnostic modality
 - Sensitivity of 80–90%
 - Should be strongly considered in highly suggestive cases even if transthoracic echocardiography is negative
 - Myocarditis
 - Global cardiac chamber enlargement with atrioventricular valve regurgitation and poorly contracting ventricles

- Pericarditis
 - Most frequently used to assess the size of a pericardial effusion, which can occur with pericarditis
 - Very useful in detecting evidence for cardiac tamponade and associated conditions (ie, myocarditis)
 - DCM
 - Confirms diagnosis
 - Dilated cardiac chambers, atrioventricular valve regurgitation, and depressed systolic function are nearly universal findings.
 - HCM
 - Diagnostic method of choice
 - Type of hypertrophy (concentric versus asymmetric)
 - Ratio of interventricular septum to left-ventricular posterior wall thickness (>1.5 is diagnostic)
 - Presence of LVOT or RVOT obstruction
 - Systolic anterior motion of the anterior mitral valve leaflet
 - RCM
 - Distinguish RCM from constrictive pericarditis
 - Echocardiogram shows normal ventricular size and function associated with dilated atria caused by the ventricular diastolic dysfunction.
 - ARVD
 - Echocardiogram is diagnostic.
 - Kawasaki disease
 - Evaluate for coronary artery aneurysms
 - Confirm diagnosis
 - Computed tomography, magnetic resonance imaging
 - Pericarditis
 - If echocardiogram is inconclusive
 - Pericardial effusion is suspected to be loculated or hemorrhagic
 - Distinguish from RCM
- ## DIAGNOSTIC PROCEDURES
- ECG
 - VSD and ASD
 - ECG can be normal for age in patients with both ASDs and VSDs.
 - As chamber dilation or hypertrophy occurs, however, signs of ventricular or atrial enlargement may develop.
 - Classic finding for patients with ASDs is an rSR' in lead V1 from volume overload of the right ventricle.
 - ECG may be helpful for identifying the onset of pulmonary hypertension by the gradual development of right-ventricular hypertrophy.
 - Patients with complete ASD defect generally demonstrate a northwest, superior QRS axis and some element of ventricular hypertrophy.
 - AVSD
 - Left axis deviation
 - Northwest QRS axis
 - Small Q wave in lead aVL
 - Tetralogy of Fallot and pulmonary hypertension
 - Right-axis deviation
 - Tall R waves in the early or right-sided precordial leads
 - Pulmonary atresia
 - Hypoplastic ventricles
 - Decreased voltage in left or right precordial leads
 - Abnormal QRS axes
 - Ebstein anomaly
 - Right atrial enlargement
 - Dextrorotation
 - ECG generally unremarkable for a newborn
 - Will not offer added information unless other cardiac defects exist
 - Aortic stenosis
 - ECG findings depend on disease severity.
 - In the newborn with critical stenosis:
 - ST-segment elevation or depression, T-wave inversion, and sinus tachycardia may be present.
 - Right-ventricular hypertrophy is usually noted.
 - Voltage criteria for left-ventricular hypertrophy may already be present or develop quickly.
 - Mild-to-moderate disease will probably demonstrate voltage criteria for left-ventricular hypertrophy, but ST- or T-wave changes are less likely.
 - Coarctation of the aorta
 - ECG is unlikely to contribute to the diagnosis unless left-ventricular hypertrophy or strain is present.
 - HLHS
 - A healthy newborn pattern of right-ventricular hypertrophy with a right-axis deviation may be more pronounced.
 - A distinguishing feature may be a relative paucity of left-ventricular forces.
 - Myocarditis
 - A pathognomonic electrocardiographic finding is decreased precordial voltages consistent with a loss of functioning myocardium.
 - This finding can generally be differentiated from pericarditis by the absence of diffuse ST-segment elevation commonly present.
 - First-, second-, and third-degree atrioventricular block may develop, as well as wide-complex ventricular tachycardias.

- Pericarditis
 - Low-voltage QRS complexes with substantial pericardial effusion
 - Changes caused by associated myocarditis, such as diffuse ST elevation in initial stages
 - Gradually, the ST segment begins to normalize, with decrease in the T-wave amplitude eventually leading to T-wave inversion.
 - These ECG changes may resolve completely, with the exception of T-wave abnormalities, which may persist for long periods.
- DCM
 - May show biventricular hypertrophy by voltage criteria with ST-segment and T-wave abnormalities
- HCM
 - ECG is abnormal in 90–95% of cases.
 - Large voltages in the precordial leads suggest biventricular hypertrophy, ST-segment elevation and depression, T-wave inversion, and abnormally deep Q waves.
 - Occasional delta wave of Wolff-Parkinson-White syndrome
 - Tendency for frequent episodes of ventricular tachycardia and ST-segment elevation on ECG during exercise

■ Cardiac catheterization

- May be required with total anomalous PVR or partial anomalous PVR
 - Particularly in cases of complex anatomy
- The diagnosis can be difficult to confirm by echocardiography.
- Distinguishes RCM from constrictive pericarditis

■ Endomyocardial biopsy

- Required for the definitive diagnosis of myocarditis

■ Pericardiocentesis

- Diagnostic and therapeutic
 - Pericardial fluid collection is large or rapidly increasing.
 - Bacterial pericarditis or when tuberculous pericarditis is suspected
- Drains the fluid to minimize the potential for clinical decompensation from tamponade
- Allows possible etiologic diagnosis

CLASSIFICATION

■ 6 grades of systolic or diastolic murmur severity

- Grade I
 - Barely audible and may require several cardiac cycles to detect
- Grade II
 - Soft, but easily audible

- Grade III
 - Moderately loud murmur without a thrill
- Grade IV
 - Loud murmur with a thrill
- Grade V
 - Loud murmur heard with the stethoscope barely off the chest
- Grade VI
 - Loud murmur heard without the stethoscope touching the chest

TREATMENT APPROACH

- Prevention of disease progression
 - Consultation with a pediatric cardiologist if pathologic entity is suspected
- Determining whether surgical intervention is required
 - Preoperative management to maximize survival and minimize morbidity and mortality
 - Maintaining cardiovascular stability
 - End-organ perfusion and oxygen delivery
 - Multidisciplinary approach

SPECIFIC TREATMENTS

VSD and ASD

- Patients with known septal defects should be monitored closely for:
 - Weight gain
 - Development
 - Clinical status
- Any signs of respiratory distress or failure to thrive will generally occur during the first 6 months of life.
 - Reevaluation by the pediatric cardiologist is indicated.

■ Medical management

- Temporary improvement of complications may be achieved with:
 - Diuretics
 - Afterload reduction
- Definitive prompt closure of an ASD or VSD
 - Indicated when signs of pulmonary overcirculation develop

PDA

- In a healthy infant
 - Outpatient follow-up
 - Most PDAs close within days to months postnatally.
- Indocin
 - Standard treatment
 - If contraindicated or unsuccessful, PDA can often be ligated in the neonatal intensive care unit.

- Coil embolization
 - Indicated if persistent into childhood
 - Performed in the catheterization laboratory
- Surgical closure
 - In the presence of decreased renal perfusion or pulmonary overcirculation

AVSD

- Surgical repair
 - Indicated for complete AVSD, includes:
 - Patch closure of the ASD and VSD
 - Creation of 2 functioning atrioventricular valves from the single, frequently regurgitant common atrioventricular valve
 - Performed between 3 and 6 months of age to minimize the potential for irreversible pulmonary hypertension
 - Postoperative outcomes depend on:
 - Severity of any residual atrioventricular valve regurgitation
 - Presence of pulmonary vascular disease
 - Partial AVSD
 - Can generally be repaired later in life (first few years)
 - Low risk of pulmonary vascular obstructive disease

Arteriovenous malformations

- Coil embolization
 - May reduce or reverse heart failure in many cases

Tetralogy of Fallot

- Tet spell (hypercyanotic spell)
 - Uncommon, but can be fatal if not treated urgently
 - Supplemental oxygen
 - Fluid boluses
 - Anxiolytics
 - Sedatives
 - Knee-to-chest positioning
 - Phenylephrine
- Tetralogy of Fallot without pulmonary atresia
 - Neonatal intensive care unit monitoring
 - Until ductus arteriosus (if present) closes
 - Patients who can produce pulmonary blood flow to maintain $\text{SaO}_2 > 80\%$ may be discharged from the hospital and allowed to grow.
 - Surgical repair
 - Tet spell is a semi-urgent indication for repair.
 - In the absence of earlier unacceptable cyanosis ($\text{SaO}_2 < 75\%$), elective repair is performed at age 4–6 months.
 - Operative correction consists of patching the VSD and correcting the obstruction to pulmonary blood flow.

- Resection or division (or both) of RVOT muscle bundles is performed first through the right atrium to remove this source of impedance.
- The VSD is then patched.
- Finally, depending on pulmonary artery anatomy, a patch is placed:
 - Supravalvar (main pulmonary artery)
 - Subvalvar (infundibular or outflow region)
 - Transvalvar (across the pulmonary valve annulus and extending into the supra and subvalvar regions)
- In many cases, a pulmonary valvectomy is performed during these repairs.
 - Patients are left with some degree of pulmonary insufficiency.

■ Tetralogy of Fallot with pulmonary atresia

- Prostaglandin E_1 infusion
 - Maintains ductal patency until surgical repair
- Surgical repair
 - If pulmonary artery size is favorable (> 3 mm in diameter):
 - Complete repair can be performed in the neonate.
 - If pulmonary artery size is unfavorable (< 3 mm in diameter):
 - An aortopulmonary shunt is placed to allow pulmonary artery growth until complete repair is performed later.
 - Patients without confluent pulmonary arteries who rely instead on multiple aortopulmonary collaterals
 - The collateral arteries can be unifocalized through a single or staged procedure to a conduit arising from the right ventricle.

Eisenmenger syndrome

- Surgical closure of the septal defect
 - Will worsen the outcome if pulmonary hypertension is not addressed first
 - If not reversed, pulmonary hypertension can be fatal.
- Multiple approaches to decreasing pulmonary artery pressure and right-to-left shunting
 - Calcium-channel blockers
 - Nitric oxide donors
 - Endothelin receptor antagonists
 - Inhaled oxygen therapy
 - Continuous infusions of prostacyclin (severe cases)
 - If the pulmonary vasculature proves to be reactive with these measures, surgical intervention may be considered.
- Lung transplantation
 - May be the only other therapeutic option if the pulmonary vasculature does not respond to medications to decrease pulmonary hypertension

Pulmonary atresia

- Opening pulmonary valve
 - Balloon dilation or radiofrequency ablation to perforate through the valve cusps.
 - This approach is controversial and, in many institutions, surgical valvotomy is preferred.
 - If right-heart structures are significantly affected, the single-ventricle treatment route must be used.
 - Surgical specifics will be determined by the presence or absence of sinusoids.

Ebstein anomaly

- Treatment consists of monitoring until the ductus arteriosus closes and PVR decreases.
 - At that time, the degree of forward pulmonary blood flow can be reassessed.
 - If pulmonary blood flow is adequate to produce $\text{SaO}_2 > 75\text{--}80\%$, the infant may be discharged from the hospital.
 - PVR should continue to decrease with a commensurate increase in systemic SaO_2 .
- Single-ventricle palliative surgery
 - Consider in infants with insufficient pulmonary blood flow.

Total anomalous PVR

- Surgical correction
 - Infracardiac drainage frequently becomes obstructed at some point along the extended, tortuous course of the vertical vein into the liver.
 - When present, constitutes a surgical emergency
 - Surgical correction for uncomplicated total anomalous PVR consists of reanastomosis of the pulmonary venous confluence to the posterior wall of the left atrium.
 - Common postoperative complications
 - Obstruction at the site of the anastomosis
 - Pulmonary vein stenosis
 - Left-atrial dysrhythmias

Partial anomalous PVR

- Surgical correction may not be necessary unless symptoms develop (ie, exercise intolerance).
 - Unless ≥ 1 of the pulmonary veins returns anomalously, this anomaly rarely becomes hemodynamically significant.

Dextrorotation

- Preoperative management
 - Complex to manage in the newborn period
 - The most important component is maintaining adequate atrial-level shunting.
 - Although the presence of a VSD is important when considering surgical options, ventricular-level shunting does not usually contribute a significant amount of intracardiac mixing in the newborn period.

- Prostaglandin E_1 infusions
 - Many patients with d-TGA have already begun receiving prostaglandin E_1 infusions at the time of diagnosis after failing the hyperoxia challenge.
 - Dosing ranges from 0.02–0.2 mcg/kg per minute.
 - Higher doses inherently increase the side effect profile.
 - PDA diameter cannot generally be titrated by changing infusion doses.
 - Once open, only doses of 0.01–0.02 mcg/kg per minute are usually required to maintain patency.
 - May be discontinued after assessing for paradoxical cyanosis (as seen with persistent fetal circulation), SaO_2 , and arterial oxygen content
 - Arterial oxygen content > 30 mm Hg (typical fetal partial pressure of oxygen in arterial blood) with a corresponding $\text{SaO}_2 > 75\text{--}80\%$, in the absence of metabolic acidosis, is predictive of adequate atrial-level mixing.
 - If these conditions are not met and the newborn demonstrates any signs of respiratory distress or pulmonary edema with marked cyanosis, the ASD is probably restrictive and needs to be enlarged.
 - Side effects of prostaglandin E_1
 - Apnea (prophylaxis with caffeine or aminophylline may decrease risk)
 - Irritability
 - Hyperthermia
 - Jitteriness
 - Decreased leukocyte function
 - High probability of intubation
- Catheterization procedures
 - Balloon septostomy (Rashkind procedure)
 - Blade septostomy
 - Radiofrequency ablation of the atrial septum
 - These procedures increase blood exchange and systemic oxygen delivery.
 - These life-saving interventions can be associated with significant risks of morbidity and mortality.
- Surgical correction
 - Arterial switch (Jantene) operation
 - Surgical option of choice for most patients with d-TGA
 - Technically complex operation
 - Once the patient is placed on cardiopulmonary bypass, the aortic and pulmonary arteries are transected above their native valves.
 - The surgeon removes the coronary arteries from the aortic root (arising from the right ventricle) by cutting small buttons of tissue surrounding the coronary artery's ostium.

- Similar-sized buttons of tissue are removed from the pulmonary artery (arising from the left ventricle), and the coronary arteries are sutured into the native pulmonary artery root (arising from the left ventricle).
 - The aorta is freely mobile within the thorax and is easily sutured to the exposed pulmonary artery root.
 - The main and branch pulmonary arteries remain attached to the lungs and are subsequently more restricted in their range of motion.
 - To minimize surgical stretch and subsequent obstruction, the Lecompte maneuver is performed, which drapes the main and branch pulmonary arteries over the ascending aorta instead of underneath.
 - Abnormal coronary artery anatomic configuration
 - Occurs in ~30% of all patients with d-TGA
 - This abnormality can produce one of the major complications of the arterial switch operation.
 - A single coronary artery origin necessitates flipping of the button before reimplantation and is often associated with kinking and compromise of coronary artery flow.
 - Although no coronary pattern precludes a switch, transmural (coursing through the arterial wall) coronary artery anatomy and others may increase the risk of the procedure.
 - Alternative surgical approaches may be necessary.
 - Discordant annulus size of the great arteries can also produce difficulty.
 - Not usually a contraindication to an arterial switch
 - Surgical outcomes
 - An overall mortality rate of 7% was reported in 1 study of 223 patients with d-TGA after the arterial switch operation.
 - Coronary artery pattern was not associated with an increased risk of death.
 - However, 2 studies with a total of 1263 patients demonstrated a rate of coronary artery events between 7% and 8% over 15 years of follow-up.
 - Abnormal coronary artery vasomotor function has been demonstrated in asymptomatic children after arterial switch.
 - Patients require close postoperative follow-up.
- Aortic stenosis**
- If diagnosed prenatally or shortly after birth in an otherwise healthy, stable newborn:
 - Careful monitoring alone is justified.
 - Timely intervention on rapidly progressive stenosis can be planned before congestive heart failure and systemic shock occur.
 - Right-to-left shunting through the ductus arteriosus suggests ductal-dependent systemic cardiac output (in the absence of persistent fetal circulation).
 - Patient should remain monitored in the hospital until a final decision regarding the need for intervention is reached.
 - Balloon valvuloplasty
 - Standard of care for valvar aortic stenosis
 - Equally effective with less morbidity and mortality vs surgical valvotomy
 - In most cases, aortic valvotomy results in some degree of aortic insufficiency.
 - Degree of insufficiency is usually mild and is well tolerated for many years.
 - Indications for nonemergent balloon valvuloplasty
 - Progressively severe left-ventricular hypertrophy with a transvalvar gradient >50 mm Hg
 - Most cardiologists would also intervene in the presence of:
 - Syncope
 - Exercise intolerance
 - Chest pain
 - Abnormal exercise stress test
 - Surgical intervention
 - Indications
 - Stenosis is accompanied by significant valvar insufficiency.
 - More than moderate insufficiency develops after a balloon procedure.
 - Surgical options
 - Valve replacement with a prosthetic mechanical valve
 - Cadaveric homograft
 - Porcine xenograft
 - Pulmonary valve autograft (Ross procedure)
 - Important considerations
 - Patient age
 - Size
 - Lifestyle
 - Future adherence to an anticoagulation regimen
 - Subaortic stenosis
 - With the exception of an absent valve click, subaortic stenosis is clinically indistinguishable from valvar stenosis.
 - However, blood flow velocity becomes accelerated before reaching the aortic valve and gradually damages the leaflets over time, which can result in progressive valvar regurgitation.

- Surgical resection of this subaortic region is indicated to:
 - Relieve obstruction
 - Prevent progressive aortic valve damage and resultant insufficiency
 - In general, surgical resection is performed with the onset of any degree of aortic insufficiency or gradients between 20 and 40 mm Hg.
- The decision to intervene is difficult.
 - Recurrence after resection is common.
 - Significant valve damage cannot be accurately predicted.
 - The rate of progression of subaortic stenosis is insidious and is not associated with acute cardiovascular decompensation.
- Progressive valvar damage may ultimately require valve repair or replacement.
 - Homograft valve
 - Artificial valve
 - Autograft valve via the Ross procedure

■ Supravalvar aortic stenosis (least common form)

- When surgery is indicated:
 - Patch aortoplasty of the narrowed region is corrective.
 - Reduces the coronary artery perfusion pressure and can produce coronary artery ischemia

Coarctation of the aorta

■ Initial treatment

- Infusion of prostaglandin E₁ to maintain ductal patency or regain it
- Patient should receive no enteral feeds.
 - Possible intestinal underperfusion
- Renal function should be monitored closely.

■ Discharged newborn or ductus closed at home insidiously, resulting in a coarctation

- Shock is likely to be present from poor lower-body perfusion.
- Patients should be treated similarly but will also require:
 - Frequent blood gas monitoring for assessment and correction of acidosis
 - Possible mechanical ventilation
 - Upper- and lower-extremity blood pressures to track the success of the prostaglandin infusion in regaining ductal patency
- If the clinician cannot reestablish adequate lower-body perfusion:
 - Emergent intervention may be required.

■ Balloon dilation

- Gradient >20 mm Hg is generally considered the clinical indication for intervention.

- Balloon dilatation results in splitting or tearing of intimal or proximal medial tissue planes.
 - Will often be repeated 2–3 times to ensure adequate luminal diameter
- Stent placement during balloon dilatation reduces the rate of restenosis and provides significant relief from obstruction in adults.
- Metallic stent placement is not recommended in young children; the artificial stent will not grow with the rapidly growing patient.

■ Surgical management (standard of care)

- Discrete coarctations
 - Subclavian flap repair
 - The subclavian artery closest to the coarctation (generally the left) is ligated distally and filleted open.
 - The coarctation region is also filleted open.
 - The flap of subclavian artery tissue is then rotated and sutured in place.
 - Less likely to result in aneurysmal dilatation of the segment of aorta, but can be associated with a mild growth retardation and loss of strength in the respective arm
 - Patch aortoplasty
 - Use of a Dacron patch to open the coarctation
- Coarctation associated with isthmic hypoplasia
 - Coarctation segment resection with extended end-to-end reanastomosis
- Coarctation associated with a diffuse segment of transverse arch hypoplasia
 - Not generally amenable to an extended end-to-end reanastomosis, except in specific circumstances

HLHS

■ Prostaglandin E₁ infusion

- Should be started immediately if HLHS is suspected
 - Starting doses can vary widely based on clinical status, but all can result in apnea.
- If cardiac lesion is strongly suspected, beginning prostaglandin E₁ infusion should not be held until a pediatric cardiology consult can be obtained.

■ Arterial and venous catheters

- Should be inserted if possible, when diagnosis is confirmed

■ Parameters directing management:

- Renal function (assessed by urine output and serum creatinine)
- Blood pressure
- SaO₂
- Arterial blood gases

■ Strategies to provide adequate pulmonary and systemic blood flow

- Hypoxia
 - Producing subambient oxygen by increased nitrogen infusion into the inhaled gas mixture
- Hypercarbia
 - Increasing carbon dioxide content of inhaled gas mixture
- Permissive hypercapnia
 - When patient is intubated, decreasing minute ventilation with resultant pulmonary vasoconstriction
- Decreasing systemic vascular resistance with vasodilatory medications
 - Milrinone
 - Phenoxybenzamine

■ Surgical intervention

- Surgical options depend on how blood flow is provided to the lungs and body.
- The strategy for all single-ventricle hearts is based on 2 simple premises, regardless of which ventricle is hypoplastic.
 - A single ventricle cannot perform the function of 2 ventricles indefinitely.
 - PVR is elevated initially after birth and, in most cases, does not decrease completely until 2–6 months of age.
 - The physiologic characteristic does not change regardless of which ventricle is hypoplastic.
- First-stage palliative surgery (Norwood procedure)
 - Produces a neo-aorta from the main pulmonary artery and the hypoplastic ascending aorta
 - Necessary but suboptimal
 - PVR does not fully decrease for several months and requires systemic blood pressures to overcome elevated pulmonary artery pressures.
 - The right ventricle is then obligated to perform as both a right and a left ventricle and is also volume overloaded from shunt-mediated pulmonary overcirculation.
- Second-stage palliative surgery
 - Performed once PVR decreases
 - Decreases the work of the single ventricle by removing the need for active pumping of the pulmonary blood supply
 - The Glenn procedure connects the SVC to the pulmonary artery, and the previously placed shunt or conduit is ligated.
 - Pulmonary blood flow is provided passively from the SVC into the low-resistance and low-pressure pulmonary arteries.
 - Systemic SaO₂ after the Norwood and Glenn procedures will generally remain 75–85%, and patients typically have a higher hemoglobin concentration than acyanotic children.

- Third-stage palliative surgery
 - Fontan procedure
 - Baffles the IVC to the pulmonary artery, routing all systemic venous return directly into the lungs
 - Oxygen-rich blood is separated from oxygen-poor blood.
 - Systemic SaO₂ is typically near normal (>90%).

Tricuspid atresia

■ Surgical correction

- Less complicated than with HLHS correction because it does not require formation of a neo-aorta
 - Aortopulmonary shunt is placed to provide pulmonary blood flow.
- Glenn and Fontan surgeries are the same as for HLHS.

IE

- A prolonged course of intravenous antibiotics given to eradicate the high concentration of organisms deeply embedded in the fibrin-platelet matrix.
 - Duration of intravenous therapy will vary between 2 and 6 weeks, depending on bacterial speciation and antimicrobial sensitivity.
 - Blood cultures should be repeated during and after antibiotic therapy to ensure proper choice and duration.
 - For a complete review of the suggested regimen of antibiotic therapy, see the American Heart Association's recommendations for IE therapy in adults.
- Once the patient has received adequate therapy and demonstrated several negative blood cultures, the infection can generally be considered cleared.
 - If no evidence exists of congenital heart disease or significant valvar derangement, then continued evaluation by a pediatric cardiologist may not be indicated.

Myocarditis

■ Treatment is largely supportive.

- Although antiviral medications, corticosteroids, and intravenous γ -globulin are administered, limited and somewhat controversial data exist to support their use.

■ Milder cases

- Bed rest
- Hospitalization until the patient's cardiac status returns to baseline

■ More severe cases

- Aggressive diuresis
- Inotropy
- Chronotropy
- Afterload-reducing medications
- Antiarrhythmic agents
- Ventilator support

- Mechanical circulatory support
 - Extracorporeal membrane oxygenation
 - Ventricular assist devices
- Patients who survive the initial phase
 - Many will require long-term medical therapy.
 - Diuresis
 - Afterload reduction
 - Long-term antiarrhythmic medications
 - Automatic implantable cardioverter defibrillators (ICDs)
 - β -Blockers (experimental)
- When patients do not respond adequately to medical or mechanical support
 - Cardiac transplantation is the only alternative for long-term survival in appropriately selected patients.

Pericarditis

- Management of pericarditis depends on:
 - Size and cause of the effusion
 - Effect on cardiac function
- Purulent pericarditis
 - Urgent decompression
 - Life-saving in patients with cardiac tamponade
 - Necessary for suspected purulent pericardial effusion
 - Percutaneous pericardiocentesis or surgical drainage
 - Large-bore pericardial drain or a surgically created pericardial window
 - Permits continuous drainage of purulent material
 - Prevents development of tamponade
 - Intrapericardial infusion of a fibrinolytic agent
 - Streptokinase decreases the recurrence of pericardial effusion.
 - Antibiotics
 - Given intravenously for 4–6 weeks
 - Partial or total pericardiectomy
 - Often necessary after treatment of purulent effusions to prevent development of constrictive pericarditis
- Viral pericarditis
 - No treatment other than a short course of antiinflammatory medication, such as ibuprofen.
- Pericarditis associated with other conditions
 - Treatment of the underlying condition leads to the resolution of the pericardial effusion.
 - Patients should be treated aggressively for all episodes of strep pharyngitis and receive appropriate procedural antibiotic prophylaxis.
 - Corticosteroids
 - Can be considered for persistent or refractory viral or secondary pericarditis

DCM

- Pharmacologic intervention
 - Treats the symptoms of congestive heart failure
 - Blunts the neurohumoral cascade
 - Aggressive diuresis
 - Spironolactone
 - Reduces pulmonary edema, hepatic congestion, excessive intravascular volume expansion
 - Angiotensin-converting enzyme inhibitors, angiotensin receptor blockers
 - Decrease morbidity and mortality
 - Use is discouraged in the acute, decompensated period.
 - β -Blocker therapy
 - One of the few medical interventions for congestive heart failure that has evidence supporting its use in both adults and children
 - Anticoagulation therapy
 - Aspirin
 - Warfarin
 - Commonly used to reduce the risk of thrombus formation
 - Cardiac resynchronization therapy
 - Pacing modality used in patients with DCM and heart failure refractory to conventional medical management
 - Synchronizes ventricular wall motion
 - Improves diastolic filling and systolic ejection fraction
 - Reduces symptoms
 - Further research is needed to determine efficacy in patients without intraventricular conduction delay or with nonsinus rhythms.
 - Use in children is limited by lack of controlled study data.
 - Severe cases
 - Ventricular assist devices
 - Extracorporeal membrane oxygenation
 - Cardiac transplantation
 - May be indicated in appropriately selected patients if other treatment regimens are unsuccessful
- ### HCM
- Symptomatic relief
 - Minimizing the risk of fatal arrhythmias
 - Exercise stress tests
 - 24-hour Holter monitoring to help stratify risk of ventricular tachycardia and sudden death
 - Asymptomatic, nonsustained ventricular tachycardia on Holter monitor increases risk of sudden death 8–10 times.

■ Pharmacologic intervention

- β -Blockers
 - Indicated for patients who have symptoms or left-ventricular outflow tract obstruction at rest.
- If β -blockers are poorly tolerated:
 - Calcium-channel blockers have been shown to produce similar effects.
- Amiodarone
 - Indicated when tachycardia is present
- Prophylactic implantation of an automatic ICD is strongly recommended for patients with:
 - Left ventricular wall thickness >3.0 cm
 - Family history of death related to HCM
 - Unexplained syncope
 - Nonsustained ventricular tachycardia on Holter monitor
- Automatic ICD implantation as secondary prevention in patients with:
 - Aborted sudden death
 - Documented ventricular tachycardia or fibrillation
 - Malignant ventricular ectopy
 - Now considered the standard of care

■ Surgical myomectomy

- Reduction of flow gradient in patients whose symptoms are related to their degree of left-ventricular outflow tract obstruction
- Brock or Morrow procedure
 - Reserved for symptomatic, medically refractory patients with an ventricular outflow tract gradient >50–60 mm Hg
 - 10-year survival rate approximately 86%
 - Intraoperative mortality rate can approach 5%.

■ Medical septal reduction

- Alternative to surgical myomectomy to improve left-ventricular outflow tract obstruction
 - Infusion of desiccated alcohol into the septal perforating coronary vessels in the interventricular septum
- Performed under transesophageal echocardiographic guidance in the cardiac catheterization laboratory
- Advocated for patients with HCM who are failing medical management
 - Has been used with a resting ventricular outflow tract gradient as low as 40 mm Hg
- Reduces the morbidity and mortality compared with surgery; however, risk is increased in:
 - Coronary artery dissection
 - Uncontrolled myocardial infarction
 - Complete heart block (5–10% risk) requiring pacemaker placement

RCM

- Generally unresponsive to conventional medical therapy
- Patients should be referred for heart transplantation once the diagnosis is made.
 - Pulmonary hypertension that is unresponsive to pulmonary vasodilators is the most commonly cited problem preventing heart transplantation in these patients.

Miscellaneous cardiomyopathies

■ ARVD

- Treatment is directed at preventing life-threatening arrhythmias
 - Medications
 - Automatic ICDs

■ Kawasaki disease

- In the absence of cardiac involvement at either presentation or a 2- to 4-week follow-up appointment, further evaluation by a pediatric cardiologist is probably unnecessary.

Orthotopic heart transplantation (OHT)

- Standard therapy for end-stage congenital and acquired heart disease
- Indications for OHT
 - Infants
 - >75% of all recipients <1 year undergo OHT because of surgically irreparable congenital heart disease.
 - 17% of cardiomyopathy-related heart failure and dysrhythmias unresponsive to medical therapy result in OHT.
 - Adolescents
 - ~25% of 11- to 17-year-old OHT recipients have surgically irreparable congenital heart disease.
 - 62% of cardiomyopathy-related heart failure and dysrhythmias unresponsive to medical therapy result in OHT.
- Contraindications
 - Absolute
 - Significantly elevated PVR
 - Elevated PVR unresponsive to vasodilatory therapy (ie, oxygen and nitric oxide)
 - Active cancer
 - Hepatic cirrhosis
 - Relative
 - Bacterial or viral infection
- The decision to proceed with OHT should be made on the basis of the individual patient's clinical status.
 - Cardiac catheterization
 - Determine hemodynamics and PVR.

- Complete antiviral antibody titer panel
 - Exclude infection and guide use of antiviral medications postoperatively.
 - Herpes simplex virus
 - Cytomegalovirus
 - HIV
 - Epstein-Barr virus
 - Hepatitis A, B, and C
- Panel reactive antibody testing
 - Assess the amount of circulating preformed antibodies in the recipient's serum.
 - May limit acceptable donor organs
- Social screening
 - Evaluate a potential recipient's emotional coping skills.
- Financial screening
 - Verify that the financial burden of transplantation is minimized.
- Transplant status classification
 - Strongly influences the expected waiting time for the recipient
 - Transplant status can change at any time if the clinical condition improves or worsens.
 - UNOS (United Network for Organ Sharing) status Ia
 - Generally several days to months before receiving a heart transplant, assuming survival is possible for this period
 - Patient must be inotrope dependent and hospitalized.
 - UNOS status II
 - Depending on weight and blood type, infants >6 months can expect to wait up to several months.
 - Adolescents may require as long as 2 years before a suitable heart is located.
- Surgical procedure
 - The donor heart is harvested in its entirety, with the exception of a cuff of posterior left atrial wall, which contains the pulmonary veins.
 - Once the recipient is placed on cardiopulmonary bypass, the heart is removed in a reciprocal fashion.
 - Anastomosis of the donor heart to the recipient is performed by either a biatrial or a bicaval (SVC-IVC) connection.
- Postoperative management
 - Unique challenge of managing a patient with a denervated heart that has been ischemic for as long as 4 hours
 - Heart rate
 - Dependent on the intrinsic sinoatrial nodal rate
 - Not influenced by the Valsalva maneuver, carotid massage, or atropine
 - The resting heart rate of a transplanted heart is typically higher than that in normal controls.
 - However, it is frequently abnormally slow in the immediate postoperative period.
 - Isoproterenol
 - Can be titrated to produce the desired heart rate
 - As the transplanted heart begins to recuperate from the surgical insult, heart rate and cardiac output will increase to meet the patient's needs.
- Immunosuppressive medications
 - Typically started soon after the transplantation is complete
 - The dosage is gradually decreased with time after transplantation.
 - Calcineurin inhibitor (ie, tacrolimus or cyclosporine) plus
 - Antimetabolite (ie, mycophenolate mofetil or azathioprine) plus
 - Corticosteroids
 - Side effects
 - Cyclosporine and tacrolimus: hypertension, nephrotoxicity, and derangement of the lipid profile (especially cyclosporine)
 - Azathioprine: neutropenia and hepatotoxicity
 - Mycophenolate: lymphopenia and gastrointestinal distress (may require dose adjustment)
 - Side effects of corticosteroids have been well described.

WHEN TO ADMIT

- Same as when to refer (see next section)

WHEN TO REFER

- Diminished or absent femoral pulses
- PDA murmur in the presence of decreased renal perfusion or pulmonary overcirculation
- Coarctation of the aorta
 - Pulses absent or thready
 - Lower-extremity blood pressures >15 mm Hg less than upper extremities
- Cyanotic heart lesion is suspected
 - Persistent hypoxemia (<70–80 mm Hg) despite adequate oxygen therapy
 - Failure of the hyperoxia challenge
- Progression of cardiomyopathy
 - Murmur
 - New gallop
 - Abnormal ECG or chest radiograph

- Indicators of declining cardiac function
 - Weight loss or a plateau in weight gain
 - Missed developmental milestones
 - Fatigue
 - Activity intolerance
 - Personality changes
- OHT recipients who:
 - Are febrile, immunosuppressed without obvious, treatable cause
 - The transplant cardiologist should be involved to minimize the chance that graft rejection will be misinterpreted as a common, benign infectious illness.
 - Show signs of rejection
 - New-onset fatigue
 - Shortness of breath
 - Exercise intolerance
 - Low-grade fever
 - Vomiting
 - Diarrhea
 - Have unexplained abdominal distention, pain, or vomiting
 - Should prompt evaluation for an ileus or intussusception
 - May also be a sign of intestinal angina caused by decreased cardiac output
 - Have no chest pain
 - Absence of pain should not be comforting to the physician.
 - A denervated transplanted heart will not become significantly tachycardic in response to fever or pain.
 - A heart rate increase of only 10 beats per minute may indicate imminent cardiovascular collapse.
- When hypertension persists beyond the first few post-operative days, an angiotensin-converting enzyme inhibitors offset the renin-mediated phase of hypertension.
- Monitoring for rejection after OHT
 - Potentially life-threatening situation
 - Cellular rejection can begin within the first 5–7 days after transplantation
 - Highest incidence during the first 3 post-OHT months
 - Patients may exhibit:
 - Malaise
 - Anorexia
 - Gastrointestinal distress
 - Low-grade fever
 - Nonspecific changes in sleeping patterns
 - If significant rejection is present, physical examination will reveal:
 - Hepatomegaly
 - Mild elevation in heart rate from baseline
 - Possibly a new murmur or gallop
 - Patients require prompt evaluation and assessment.
 - Echocardiography to assess cardiac function
 - Endomyocardial biopsy if indicated
 - If disease proves the presence of rejection:
 - Pulse steroids are administered.
 - Maintenance immunosuppressive regimen will usually be augmented.
 - Repeat biopsy
 - Necessary to verify effective treatment for the rejection episode
 - Interventions (ie, scheduled vaccinations) that might upregulate the immune response
 - Delay for approximately 3 months after resolution of the episode.
 - Frequent blood monitoring of OHT recipients
 - Immunosuppressive agent side effects, such as neutropenia and hepatotoxicity

FOLLOW-UP

- Aortic stenosis
 - Once the infant is home, most pediatric cardiologists will arrange biweekly or monthly visits for the first 6 months of life.
 - During this rapid phase of somatic growth, changes in clinical status or aortic stenosis gradient can occur quickly.
 - When neonatal intervention is required, frequent return visits may occur for at least the first 6 months of life.
- After valve repair
 - Patients must be proactively managed in the postoperative cardiac intensive care unit.
- Coarctation repair
 - Complications include paradoxical hypertension or systemic blood pressure higher than preoperative measures.
 - β -Blockers are often used to treat hypertension in the immediate postoperative period.

COMPLICATIONS

- Complications of OHT
 - First 6 months
 - Bacterial infections in 52% of patients
 - Opportunistic infections in 15% of patients
 - After 6 months
 - Immunosuppressive medications are decreased to maintenance dosing.
 - Predominant infectious organisms shift from bacterial to viral (83% of infections).

- Specific microbes parallel those afflicting the general, nonimmunosuppressed pediatric population.
- Long-term complications
 - Posttransplantation lymphoproliferative disease
 - Abnormal growth of lymphoreticular cells in immunosuppressed patients
 - Occurs in approximately 5–10% of pediatric OHT recipients
 - Has been linked to primary posttransplant Epstein-Barr virus infection
 - Most forms can be treated solely by a decrease in immunosuppression.
 - Some forms will require chemotherapy and possibly surgical resection.
 - Posttransplantation coronary vasculopathy
 - Progressive intimal and medial thickening of the transplanted heart's coronary arteries, with loss of coronary flow reserve and eventual luminal obliteration
 - Risk increases with each episode of rejection, certain infections (ie, cytomegalovirus), original harvest time, and associated donor ischemic time; it is also increased in the presence of abnormal lipid profiles.
 - Statins (ie, pravastatin, atorvastatin) have been recommended in OHT recipients.
 - Freedom from posttransplantation coronary vasculopathy decreases with time from transplantation and with each decade of life after which transplantation occurs.
 - Newer immunosuppressant agents (ie, sirolimus) have shown initial promise as potential treatments for posttransplantation coronary vasculopathy; however, retransplantation is the only definitive therapy.
- Immunization
 - Live viral vaccines
 - Should not be given
 - The immunosuppressed patient's response to vaccinations will be blunted, particularly during the early post-OHT period.
 - Any systemic antigenic response may precipitate a rejection episode.
 - Nonlive vaccinations
 - Should be given approximately 3 months after transplantation to minimize rejection
- Immunosuppression
 - Predisposes these patients to serious infectious complications
 - However, deficiency in these medications places them at significant risk for rejection.

PROGNOSIS

■ VSDs and ASDs

- Natural history
 - Regardless of the mechanism, the PVR will reflexively increase in proportion to the degree of shunt volume (in ASD and VSD) and pressure (in VSD) to reduce stress on the arteriolar walls.
 - Over time, these pulmonary arterioles can become quite hypertrophied and cannot vasodilate.
 - This irreversible state of pulmonary arteriolar vasoconstriction results in pulmonary hypertension and eventual pulmonary vascular obstructive disease.
 - Small defects in the muscular portion of the interventricular septum often close spontaneously.
 - VSDs in other regions of the interventricular septum close less commonly.
 - The natural history of secundum-type ASDs depends largely on the initial defect size.
 - Nearly 85% <5 mm in diameter resolve spontaneously.
 - <2% resolve when they are >8 mm in diameter.
- Patients at risk for pulmonary vascular obstructive disease
 - Those in whom VSDs neither close spontaneously nor are associated with pulmonary overcirculation
 - Those with an unrepaired defect and persistently elevated PVR (eventually can become irreversible)
 - As early as 6 months of age, particularly in patients with trisomy 21 syndrome
 - As early as 1 year in children without Down syndrome
 - When pulmonary artery pressures exceed those of the left ventricle, the direction of shunted blood will become right to left, producing peripheral cyanosis (Eisenmenger syndrome).
- Surgical mortality rates
 - <1% for both ASDs and VSDs
 - Device closure vs surgical correction of ASDs
 - Failure rate requiring surgical repair occurs in 4% of patients with devices.
 - Device-related complication rate, 7.2%; surgical complication rate, 24%
 - Device closure of VSDs
 - Currently being performed in limited situations
 - Success rates have been reported to be 99% but have been associated with a nearly 50% serious complication rate.

- Tetralogy of Fallot
 - Surgical outcomes
 - Pulmonary valvectomy performed during repairs leaves patients with some degree of pulmonary insufficiency.
 - Progressive RV dilation associated with pulmonary insufficiency is one of the sources of long-term morbidity in these patients.
 - Unifocalization of collateral arteries
 - 10- and 20-year actuarial survival rates of 86% and 75%, respectively
 - Freedom from repeat surgery is 55% and 29% at 10 and 20 years, respectively.
- Pulmonary hypertension
 - Can be fatal if not reversed
 - Patients are at a significantly elevated risk for right-ventricular failure and sudden death.
- Ebstein anomaly
 - Long-term outcomes are related to severity of disease (degree of cyanosis) at presentation.
 - Severely hypoplastic lungs will preclude cardiac palliation.
 - Most of these infants die shortly after birth.
- Anomalous pulmonary venous return
 - Natural history of prolonged untreated obstruction of the anastomosis or pulmonary veins
 - Irreversible pulmonary venous obstructive disease
 - Pulmonary vascular disease
 - Eventual right-heart failure
- Aortic stenosis
 - Progression rate
 - Unpredictable during the first 6 months of life
 - Final valvar gradients are poorly predicted by initial gradients.
 - Slower and more predictable after the first year
 - Patients not requiring intervention before 6 months of life are less likely to:
 - Develop heart failure
 - Become critically ill during the follow-up period
 - After neonatal intervention:
 - Frequency of restenosis is 15–30%.
 - Aortic valvotomy results in mild aortic insufficiency, which is well tolerated for many years.
 - Subaortic stenosis
 - Recurrence rate is 20–30% after resection.
 - Supravalvar aortic stenosis
 - Insidious disease progression marked by significantly elevated coronary artery perfusion pressures
- Coarctation of the aorta
 - 5–25% rate of recoarctation, depending on surgical procedure
 - The restenosis rate is <20% after balloon dilation.
 - Associated transverse arch hypoplasia is associated with a higher rate of reintervention.
 - Repair during or after adolescence is associated with a higher rate of persistent hypertension.
- HLHS
 - Sequelae include:
 - Cardiac dysrhythmias
 - Cerebrovascular accidents with seizures
 - Myocardial ischemia
 - Pleural effusions
 - Patients may require multiple cardiac catheterizations.
 - Survival
 - Improved survival after the Fontan procedure has been shown to be strongly correlated with shorter cardiopulmonary bypass and aortic cross-clamp times.
 - When the condition results in end-organ damage or a delay in surgical intervention, morbidity and mortality increase significantly.
 - Long-term prognostic data are lacking.
 - A palliative approach for single-ventricle physiological arrangement may ultimately serve as an extended bridge to cardiac transplantation.
 - 20–30% of patients after undergoing the Fontan procedure develop heart failure, resulting either in successful OHT or death.
 - Neurodevelopmental outcomes
 - A majority of postoperative 8- to 9-year-olds had cognitive scores similar to those in the general population, but approximately 18% had IQ scores <70.
 - Some children have also had developmental motor delay and behavioral problems, including obsessive-compulsive disorder and attention-deficit/hyperactivity disorder.
- Tricuspid atresia
 - A single left ventricle is intuitively advantageous over a single right ventricle.
 - However, the data have failed to demonstrate any differences in long-term survival.
- IE
 - Survival
 - Before the era of antibiotics, IE was universally fatal.
 - Today, survival has increased by 70–80%.

- Long-term prognosis
 - Primarily determined by the presence of complications
 - If treatment is initiated early, valvar damage, heart failure, embolic events, and heart block can be prevented.
 - Prognosis is more guarded if IE involves a prosthetic valve or *Staphylococcus*.
- Myocarditis
 - Although its incidence is low in the pediatric population, accurate and timely diagnosis is critical for improving the related morbidity and mortality.
 - Mortality rates vary inversely with age of onset.
 - Nearly 75% of all newborns and infants who develop myocarditis will die of it.
 - In older children with less fulminant disease, the mortality rate is approximately 25%, with 50% exhibiting a complete recovery and another 25% becoming asymptomatic but having persistent abnormal cardiac function.
- Pericarditis
 - The pathologic course depends on the virulence of the offending organism.
- DCM
 - If unchecked, this change in myocardial structure and function can become irreversible.
- HCM
 - Morbidity
 - Ischemia-induced arrhythmias are the most likely source.
 - Mortality
 - Ventricular fibrillation is the most common cause of death in undiagnosed adolescents and young adults.
 - Overall risk of sudden death, 1–2% per year (may be as high as 4–5% in adolescents)
- RCM
 - Prognosis is poor.
 - Elevated left-ventricle end-diastolic pressures usually result in pulmonary hypertension and pulmonary vascular disease.
 - Death occurs within 1–4 years of diagnosis in symptomatic patients.
 - Pulmonary hypertensive crisis
 - Sudden death
- ARVD
 - Patients <30 years are at high risk for life-threatening ventricular tachycardias.
- OHT
 - Survival
 - Overall 50% survival at 13 years after transplantation
 - Younger age at transplantation is associated with longer survival and decreased need for retransplantation.
 - Quality of life
 - Although transplantation is a formidable treatment strategy for most patients and their parents, approximately 90% of OHT recipients surveyed at 1, 3, and 5 years after transplantation report excellent quality of life with no activity limitations.
 - Transplantation seems to be an acceptable treatment for patients with irreparable congenital or acquired heart disease.
 - Access to treatment
 - OHT is limited by the number of available donor hearts.
 - Approximately 20–30% of patients die while awaiting a suitable donor.

PREVENTION

- To ensure that no unnecessary or unknown risks are taken, exercise intensity, duration, and participation in any type of athletic event must be discussed among the:
 - Health care team (including cardiologist and pediatrician)
 - Patient
 - Family
- IE
 - Prevention is an integral step in caring for persons at risk.
 - Good oral hygiene
 - Appropriate antibiotic prophylaxis
 - Inappropriate prophylaxis can pose more risk than benefit when considering hypersensitivity reactions to antibiotics.
 - Avoid unnecessary interventions.

Constipation

DEFINITION

■ Constipation

- Infrequent elimination of large or hard stools that cause straining or pain

■ Chronic constipation in childhood not caused by an organic lesion may also be called:

- Dysfunctional stool retention
- Psychogenic constipation
- Idiopathic constipation
- Functional constipation

■ One expert consensus defined constipation as any of the following:

- Passage of hard, scybalous, pebblelike, or cylindrical cracked stools
- Straining or painful defecation
- Passage of large stool that may clog the toilet
- Stool frequency <3 times per week, unless breastfed

■ Can present as pain, fecal soiling, urinary tract infection, or enuresis

EPIDEMIOLOGY

■ Prevalence

- Common among children of the industrialized world
- Among referral populations
 - >90% of childhood constipation is functional.
 - 50–90% will be cured.

■ Age

- Of toddlers, 16–37% suffer constipation at some time.

MECHANISM

Normal colonic function

■ Focal circular contractions

- Impede progress of luminal contents
- Allow solutes and water to be absorbed from liquid ileal effluent

■ Progress of a relatively dehydrated fecal stream is achieved by contractile waves.

■ Bolus of stool

- Propelled to next colonic segment
- Ultimately, stool arrives at the rectum.

■ Defecation

- Coordinated sequence of neuromuscular events
- Involves reflexive and conscious components
- At rest, continence is maintained by:
 - Involuntary resting tonic contraction of smooth muscle cuff of internal anal sphincter
 - Posterior turn of anal canal in relation to anterior angulation of rectal vault

- When stool arrives in rectal ampulla, it causes:
 - Distention of rectal walls
 - Relaxation of internal anal sphincter, which lowers the pressure of the anal canal and allows the stool bolus to descend to the anal canal (rectoanal inhibitory reflex)
- Control of defecation is a critically important social achievement in early childhood.
- Voluntary (and learned) contraction of striated muscle of external sphincter and puborectalis sling muscles increases pressure in anal canal and makes the exiting angle more acute.
- The Valsalva maneuver in combination with relaxation of the external anal sphincter and puborectalis sling permits defecation to proceed.

Constipation

■ Functional

- Stool is most often withheld in response to the rectoanal inhibitory reflex.
- The cause is not clear, but functional constipation may result from several distinct pathophysiologic events, including:
 - Disorder of dynamics of defecation
 - Problem with rectal sensation
 - Disorder of colonic transit, leading to impacted, overly desiccated stool in colon

■ Withholding

- Commonly recognized clinical scenarios that result in constipation include:
 - Painful anal fissures
 - Perianal streptococcal cellulitis
 - Traumatic toilet-training experiences
 - Transient periods of dehydration, illness, or immobility
- Stool withholding may figure prominently in the perpetuation of constipation after pain or an aversive experience.
- Withholding behavior in the toddler or child is strongly self-reinforcing.
 - Avoidance of painful bowel movements makes the stool harder and more painful to pass.
 - Parental concern may unwittingly reinforce withholding behavior
- Lack of privacy commonly found in some school lavatories can engender withholding by older children.
- Studies have documented abnormalities in the dynamics of defecation.
 - Most common is paradoxical contraction of the external anal sphincter and the puborectalis sling in response to the rectoanal inhibitory reflex, also called:
 - Rectoanal pelvic floor dyssynergia
 - Abnormal defecation dynamics

- Anismus
 - Dyssynergia is considered to be a learned phenomenon.
 - Painful defecation and withholding antedate the clinical presentation of constipation by 1–5 years.
 - In a significant subset of children who experience persistent constipation, withholding becomes entrenched and particularly difficult to unlearn.
- Sensory abnormalities
 - Megarectum
 - The rectum is dilated, with chronic impaction.
 - Associated with increase in sensory threshold to minimal rectal distention
 - Associated with increase in minimal volume required to initiate the urge to defecate
 - May persist for several years
 - May contribute to relapses
- Slow transit of fecal stream through colon
 - Occurs predominantly in young women
 - Can occur in children
 - Unclear whether this is a primary problem or acquired epiphenomenon of more distal difficulties with defecation
 - Not easily differentiated clinically from normal-transit constipation
 - A unique therapeutic approach has not emerged.
- Dietary factors
 - Dietary fiber is believed to have an important role in promoting regular bowel habit.
 - Decreased fiber intake as a risk factor for childhood constipation has been documented, but overlap exists in fiber intake between cases and controls.
 - In infancy, the transition from breast milk or formula to whole cow's milk or periods of excess protein intake are associated with constipation.
 - It is a myth that iron-containing formulas cause constipation.

HISTORY

- Description of stools that child passes
 - Frequency
 - Consistency
 - Caliber
- History of stool withholding (a positive history strongly supports functional constipation)
- Age of child at onset
 - If a newborn, whether child passed meconium in first day of life
- Toilet-training experience
 - Whether traumatic
 - Critical in toddlers and preschool children

- Diet history—how constipation began
 - With transition to cow's milk
 - During periods of high protein intake
 - With excessive cow's whole milk consumption
- Complications
 - Fissures
 - Bleeding
 - Abdominal pain
 - Anorexia
 - Enuresis
 - Urinary tract infection
 - Distention and vomiting (not caused by functional constipation)
- Prior evaluation and treatment
 - Over-the-counter medicines
 - Home remedies
 - Alternative therapies
 - Culturally specific therapies
 - Can be part of treatment plan if they pose no harm
- Change in urinary voiding pattern (possible occult spinal process affecting sacral nerves)
 - Stream
 - Continence
- Family history of:
 - Heritable conditions
 - Functional constipation
- Specific questions to address differential diagnosis of:
 - Hirschsprung disease
 - Endocrine, metabolic, and neurologic disease
- In infants
 - Delayed passage of meconium

PHYSICAL EXAM

Infants

- An empty rectum raises the possibility of Hirschsprung disease, particularly in conjunction with any or all of following:
 - History of delayed passage of meconium
 - Explosive gush of stool on withdrawal
 - Hard impacted mass palpated in the pelvis or lower abdomen
- In infants with delayed passage of meconium
 - Anorectal manometry
 - Rectal suction biopsy
 - Unprepared barium enema
 - Sweat test

- Impactions
 - Unusual
 - May indicate Hirschsprung disease
 - External examination of perineal area
 - Establish the normal placement of anal orifice.
 - Look for:
 - Anal fissure
 - Skin tag
 - Normal anal wink
 - Examine lower extremities for:
 - Tone
 - Strength
 - Symmetry
 - Reflexes
 - Examine spine for:
 - Dimple
 - Hair tuft
 - Vertebral anomalies
- Children**
- Check the child's growth parameters.
 - Recent growth velocity
 - For growth failure, failure to thrive, or short stature, consider:
 - Thyroid function tests
 - Celiac panel
 - Sweat test
 - Assess physical appearance.
 - The child should appear well and not wasted or malnourished.
 - Abdomen should not be distended.
 - Examination should establish presence or absence of fecal impaction in lower quadrants or the hypogastric area.
 - External examination of perineal area
 - Establish normal placement of anal orifice.
 - Look for:
 - Soiling
 - Fissures
 - Skin tags
 - Normal anal wink in response to touch
 - Rectal examination, with patient's cooperation
 - With functional constipation, desiccated stool is found in the rectal vault.
 - Megarectum
 - In older children with long-standing constipation:
 - Anal canal will feel foreshortened.
 - In children who soil from chronic constipation:
 - The disorder is sensory.
 - Tone of the internal sphincter should be normal.
 - Older child with functional constipation
 - The rectum may be empty if the child has just defecated.
 - Carefully consider the possibility of Hirschsprung disease.
 - Be alert for extrinsic mass compressing the rectum (rare).
 - Patulous anus is indicative of a neurologic lesion or sexual abuse.
 - Neurologic examination
 - Explicitly assess lower extremities for:
 - Tone
 - Strength
 - Symmetry
 - Reflexes
 - Analyze the patient's gait.
 - Examine spine for:
 - Signs of spina bifida occulta
 - Dimple
 - Hair tuft
 - Palpable vertebral deformity
- DIFFERENTIAL DIAGNOSIS**
- Functional constipation**
- Despite the large number of possible diagnoses, at least 90% of affected children have functional constipation.
 - Infants
 - Parental definition of constipation in the first 6 months may be incorrect.
 - In otherwise healthy breastfed infants:
 - Stool consistency rather than frequency is a critical determinant of constipation.
 - Straining and grunting (turning deep red) in producing a soft stool of average caliber is normal.
 - Mushy stool once a week requires no intervention.
 - Functioning rectoanal inhibitory reflex
 - Manometric studies have documented this at birth.
 - Likely represents unsuccessful attempts to coordinate voluntary with involuntary defecation
 - Treatment is required for the constipated infant who:
 - Strains with production of a desiccated plug of stool followed by loose stool
 - Produces consistently desiccated stool of pebbly consistency

■ Toddlers

- History of stool withholding is critical for both diagnostic and therapeutic purposes.
- Parents of toddlers are:
 - Usually aware the child is constipated
 - Frequently do not recognize stool withholding
- During typical withholding, the child may:
 - Hide quietly
 - Cling to an inanimate object
 - Squeeze buttocks together
- Variations of stool-withholding behavior
 - Crouching
 - Dancing or walking on tiptoes
 - Crying out in anticipation of pain
- Episodes of withholding:
 - Are misinterpreted by the parents as attempts to defecate
 - Generate great concern in the parent

■ Children

- Once the child has attained privacy in the bathroom:
 - Parents are not likely to be involved in toilet routine.
 - Constipation becomes occult.
- Incomplete evacuation is common in school-age children; typical scenario:
 - Child goes to the bathroom with regular or increased frequency.
 - Child passes only a small, hard piece of desiccated stool.
 - Child emerges from bathroom not terribly bothered.
 - Parent inquires, “Did you go?” Child answers, “Yes.” Thus both parties are happy.
 - Pattern is punctuated episodically by the passage of massive bowel movements.
- Many children do not seem terribly bothered by their constipation.
- Children are often brought in, not for constipation itself, but for:
 - Soiling
 - Recurrent abdominal pain
 - Blood streaks seen on stool
 - Excessive flatus
 - Anorexia
- Pelvic floor dyssynergia in children with stool withholding:
 - Can affect urinary voiding dynamics
 - Predisposes child to enuresis or urinary tract infection

■ Findings that support the diagnosis of functional constipation

- Onset after infancy
- Presence of stool-withholding behavior
- Episodic passage of large-caliber stools

- Absence of red flags
 - Failure to thrive (weight loss, poor growth)
 - Vomiting
 - Abdominal distention
 - Persistent anal fissures, perianal disease
 - Persistent blood in stool or guaiac-positive stool
 - Delayed passage of meconium
 - Weak urinary stream, diurnal enuresis

Anal and rectal disorders

■ Anal fissure

- May induce self-perpetuating cycle of withholding, worsening constipation, and reinjury

■ Anterior ectopic anus

- Occasionally, the anal orifice is misplaced anteriorly, so that the stool bolus must turn anteriorly at the perineum.
- Parents may report seeing a perineal bulge when the infant attempts to defecate.
- Consider surgical reconstruction in children who fail to improve with medical therapy.

■ Anal stenosis

- Characterized by straining during the production of small-caliber stools
- Frequently diagnosed during infancy
- Digital examination shows that the anal canal is narrow and not distensible.

■ Rectal duplication

■ Anal trauma (abuse)

■ Extrinsic masses, though rare, may intermittently or partially obstruct the rectum.

■ Rectal duplication cyst

■ Pelvic mass, such as neuroblastoma, presacral teratoma, ovarian tumor, hematocolpos

Neurologic

■ Hirschsprung disease

- The most common reason to consider Hirschsprung disease is failure of treatment for functional constipation.
 - Appropriate in early infancy, when functional constipation is unusual and easily treatable
 - In the toddler and the school-age child, more likely to reflect the complexity and duration of intervention required rather than a missed diagnosis of Hirschsprung disease
 - Findings with a very high negative predictive value for Hirschsprung disease:
 - Almost all children with functional constipation withhold stool in response to the rectoanal inhibitory reflex.
 - This reflex is absent with Hirschsprung disease.

- Hirschsprung disease should be considered in any child with refractory constipation who has had any of the following:
 - Failure to pass meconium in the first 24 hours of life
 - Onset of constipation before 3 months of age
 - Symptoms of intestinal obstruction at any time (distention, pernicious emesis)
 - Lifelong dependence on laxatives, enemas, or mechanical manipulation to initiate defecation
 - History of enterocolitis in early infancy (sometimes misdiagnosed as gastroenteritis)
- Spinal cord lesions
 - Affect the second, third, and fourth sacral nerves
 - Associated with both sensory and motor deficits affecting defecation
 - Trauma to sacral cord, intraspinal and extraspinal tumors, and congenital malformations can tether the spinal cord.
 - Consider when constipation is accompanied by abnormalities in bladder function or gait.
 - Consider when visible abnormalities or palpable deformities of the lumbosacral spine exist.
- Cerebral palsy
- Neuromuscular diseases with hypotonia
- Refractory constipation
 - Frequently multifactorial and difficult to treat
 - Prevalent in children with:
 - Cerebral palsy
 - Muscular dystrophy
 - Generalized hypotonia
- Pseudo-obstruction syndromes
 - Characterized by intermittent episodes of functional intestinal obstruction
 - Affects the neuromuscular function of the colon

Metabolic and endocrine

- Hypothyroidism
- Diabetes insipidus
- Hypercalcemia
- Hypokalemia

Medication and toxin related

- Antihistamines
- Anticholinergics
- Anticonvulsants
- Opioids
- Bismuth, aluminum hydroxide
- Tricyclic antidepressants
- Iron preparations (**not** iron-fortified formulas)

- Plumbism
- Infant botulism

Miscellaneous

- Celiac disease and cystic fibrosis should be considered in children with:
 - Poor growth in weight or height
 - Recurrent respiratory symptoms
 - Anemia
 - Hypoproteinemia
- Cow's milk allergy
 - For treatment-resistant chronic constipation, soy milk has been used as a substitute.
 - In study of 65 children, 44 had a positive response when soy milk replaced cow milk.
 - Replacing cow milk with soy milk is controversial.
- Scleroderma
- Systemic lupus erythematosus

LABORATORY EVALUATION

- Routine laboratory tests
 - Not indicated in evaluating for functional constipation
- Tests to consider
 - Thyroid function tests
 - Serum calcium
 - Potassium
 - Lead
 - Celiac panel
 - Sweat test

IMAGING

- Plain abdominal radiographs:
 - Often do not have significant diagnostic value
 - In functional constipation, should show dilated, enlarged rectum
 - In Hirschsprung disease, should show empty rectum
 - Can be used:
 - Selectively for confirmation that palpable abdominal mass is a fecal impaction
 - For a questionable diagnosis in a child unable to cooperate with rectal examination
- Barium enema:
 - In functional constipation, should reveal diffusely dilated colon and rectum
 - In Hirschsprung disease, should reveal distal spasm, proximal dilatation

- Magnetic resonance imaging of lumbosacral spinal cord for:
 - Hair tufts, lipomas, hemangiomas overlying the lumbosacral spine
 - Abnormalities of gait
 - Abnormalities of urination
 - Absent anal wink
 - Absent cremaster reflex

DIAGNOSTIC PROCEDURES

- Rectal manometry
 - Functional constipation: rectoanal reflex present
 - Hirschsprung disease: rectoanal reflex absent

TREATMENT APPROACH

- Goals of treatment
 - Establish a pattern of soft bowel movements with ≥ 3 per week.
 - Wean the child from pharmacotherapy.
 - Have the child and family manage problem on their own with diet and behavioral modification.
- Involves parental education, laxatives, diet, behavioral modification
- Considerations
 - Age of patient
 - Duration of symptoms and treatment
 - Transient constipation lasting several days
 - Typically can be managed with 1 to a few days of laxative use and dietary change
 - Functional constipation
 - Patients are affected for weeks to months before seeking medical attention.
 - Requires a phased approach and months of treatment
 - In older children, may require 1–2 years of laxative therapy

SPECIFIC TREATMENT

Infants

- Before the introduction of solids, add undigestible, osmotically active carbohydrates to formula/breast milk.
 - Dark corn syrup or malt soup extract
 - Dose: 2–6 teaspoons per day, divided among several bottles
- Once juice and infant food are introduced:
 - Give apple or prune juice and fruits.
- Infant glycerin suppositories
 - Can be used at the beginning of therapy to remove a desiccated rectal plug
 - Should not be the mainstay of therapy because infants can become dependent on rectal stimulation

- 2 studies have established the efficacy of polyethylene glycol (PEG).
- Constipated infants should not be treated with mineral oil: risk of pneumonia from aspiration
- Treat externally visible anal fissures with petroleum jelly.

Toddlers and older children

- Functional constipation
 - Highly successful treatment adopted widely by pediatric gastroenterologists with published guidelines
 - Divided into 3 phases
 - Education and disimpaction
 - Maintenance
 - Weaning
 - Controlled studies have not documented greater improvement with biofeedback training than with standard treatment regimens.
- Education
 - Parents need to know:
 - Constipation frequently engenders withholding.
 - Withholding is self-perpetuating.
 - Toddlers may require several months of laxative that produces soft stools before they abandon withholding.
 - Long-term nonstimulant laxatives are safe, based on innumerable studies.
 - Nonstimulant laxatives that do not engender laxative dependence include:
 - Mineral oil
 - Milk of magnesia
 - PEG
 - Lactulose
 - Reluctance to medicate children leads to premature discontinuation of therapy.
 - The limited use of senna, an anthraquinone-stimulant laxative, is acceptable as:
 - Adjunct to an osmotic agent
 - Rescue therapy for children who have transient relapses
 - Experts discourage the prolonged use of stimulant laxatives (senna, bisacodyl).
 - No proof exists that prolonged use of mineral oil impairs fat-soluble vitamin absorption.
 - Parents should be instructed to:
 - Ignore withholding events as they would a temper tantrum
 - Talk directly to toddlers and engage them in the therapeutic program.
 - Say, “I want you to push the poo-poo out of your body; don’t hold it in. That’s how you will get better, and it will stop hurting.”

■ Disimpaction

- The goal of disimpaction is to remove all hard-formed stools throughout colon.
- Treatment begins with disimpaction for the patient who:
 - Has had months to years of symptoms
 - Has an impaction on examination
- For older children:
 - Defer disimpaction until the weekend.
 - Treat with mineral oil to lubricate impacted stool.
- Fiber is withheld during the disimpaction phase.
- Enemas
 - Once a day for 3–6 days
 - Simple, effective, and safe (with important caveats)
 - Dose guidelines should be followed.
 - In the rare event of failure to pass stool following an enema, the child needs medical attention.
 - Sodium phosphate enemas are contraindicated in children who:
 - Weigh <10 kg
 - Have cardiac or renal impairment or electrolyte disorders
 - May have any form of intestinal obstruction
- Oral route versus enemas
 - Oral PEG has been used successfully for disimpaction.
 - Choice should be made with the child's and family's input.
- Laxative doses
 - Rectal
 - Hypertonic sodium phosphate enema: 3 mL/kg/dose, once daily via rectum for 1–6 days
 - Mineral oil enema: 30–60 mL, once daily via rectum for 1–6 days
 - Oral
 - PEG electrolyte-free: 1.5 g/kg/day, maximum 100 g for 3 days
 - Mineral oil: 30 mL/year of age to maximum 8 oz twice daily for 3 days
 - PEG with electrolytes: 10–40 mL/kg/hr, via nasogastric tube (maximum 2 L/h) until stool effluent clear

■ Maintenance

- Follows disimpaction and incorporates laxative use, dietary advice, behavioral modification
- Laxative choice
 - Less important than close follow-up for dose adjustment
 - Mineral oil

- Contraindicated for children <2 years or at risk for pulmonary aspiration
- Parents should be counseled explicitly never to force a child to take mineral oil.
- PEG
 - Cautions for mineral oil also apply for PEG.
 - PEG is an osmotic laxative widely used to treat functional constipation.
 - Polymer of ethylene glycol that is not absorbed or fermented by colonic bacteria
 - Fairly tasteless, water-soluble powder that can be disguised when mixed into a child's drink
 - Pediatric studies have established clinical tolerance, effective dose, and absence of unanticipated or serious adverse effects.
 - In a study comparing low-dose PEG with lactulose, no difference was found between the prevalence of abnormal electrolyte or nutritional parameters.
 - Despite its popularity, it is unclear whether PEG is better and safer than other commonly used laxatives.
 - For severe pulmonary edema from PEG aspiration, bronchoalveolar lavage has been used successfully.
- Dietary fiber
 - Addition of fiber is widely advocated as an adjunct.
 - A randomized controlled trial has shown benefits of fiber supplement when prescribed with laxative.
 - Dietary changes that increase child's fiber intake
 - Whole-grain breads and cereals
 - Increased fruit and vegetable intake
- Behavioral modification
 - Toddlers
 - Focus on replacing stool-withholding behavior with deliberate attempts to defecate.
 - Defer toilet-training efforts until the child stops withholding.
 - Older children
 - Have the child sit on the toilet after meals for 5–10 minutes to capitalize on the gastrocolic reflex
 - Reward success by use of a star chart.
 - Child should be rewarded for the targeted behavior: sitting
 - Physician
 - Titrate laxative dose to achieve desired effect (soft bowel movement every day)
 - Work in partnership with the child and parents, who should report to physician frequently

- Laxative Doses (oral)
 - PEG electrolyte-free powder: 0.8g–1.5g/kg/day
 - Mineral oil: 1–3 mL/kg/day
 - Milk of magnesia: 1–3 mL/kg/day
 - Lactulose 10 g/15 mL: 1 mL–2 mL/kg/day
 - Senna syrup 218 mg/5 mL: 10–20 mg/kg/dose at bedtime
- Weaning
 - Laxative therapy should not be stopped abruptly.
 - Some toddlers can be weaned after 6–12 weeks of maintenance treatment.
 - In older children, weaning may take 6–12 months.
 - Daily laxative dose can be decreased in 1 of 2 ways.
 - Decrease to 75%, 50%, and 25% of initial dose over successive months
 - Give a full dose every second day for 6–8 weeks, then every third day for another 6–8 weeks.
 - Efforts should be redoubled to:
 - Increase fiber intake
 - Foster compliance with behavioral program
 - Older school-age children should:
 - Be encouraged to practice self-monitoring of frequency and adequacy of bowel movements
 - Have a rescue plan (enema, suppository, or stimulant laxative) for a transient relapse
 - Consider no stool for >3 days a transient relapse
- Common reasons for treatment failure of functional constipation
 - Inadequate disimpaction
 - Failure to escalate laxative dose to achieve 1–2 soft stools per day
 - Premature discontinuation because of the widely held notion that laxatives are addictive
 - Relying on dietary fiber alone

WHEN TO REFER

- Abnormal diagnostic studies
- Findings that are inconsistent with functional constipation
 - Growth failure
 - Distention
 - Vomiting
 - Bleeding
- Treatment is complicated by other significant problems.
 - Behavioral
 - Emotional

- Parenting
- Mental health issues
- Toileting is the focus of a power struggle.
- Refer to pediatric gastroenterologist
 - Infant who is refractory to treatment
 - Child who is refractory to treatment or cannot wean from laxative therapy after 12 months
- If Hirschsprung disease is suspected:
 - Consult with surgeon and radiologist
 - Decide on initial diagnostic test (rectal biopsy is the gold standard)

WHEN TO ADMIT

- Constipation associated with obstruction or enterocolitis
- Failure of disimpaction as an outpatient

FOLLOW-UP

- Toddlers and older children
 - Follow-up by phone within 2 days of starting therapy.
 - Ascertain whether the child is still passing hard stools.
 - Titrate laxative dose to induce a daily soft bowel movement.
 - Determine whether disimpaction is complete.
 - Question to determine whether disimpaction was thorough.
 - Disimpaction failure is a common therapeutic mistake.
 - Initial disimpaction failure undermines successful treatment because maintenance-dose laxatives will not penetrate or remove impaction.
 - Failure should prompt a revisit to consider:
 - Abdominal or rectal examination *and/or*
 - Abdominal radiography
 - Children who have extremely hard or treatment-resistant impactions can be admitted for nasogastric administration of PEG.
 - Remain optimistic and involved, because improvement beyond 12 months of therapy is well documented.

PREVENTION

- Dietary fiber is believed to have an important role in promoting regular bowel habit.
- Sufficient fluid intake to prevent dehydration

Contact Dermatitis

DEFINITION

- Contact dermatitis is inflammation of the skin secondary to contact with an offending agent.
- 2 broad types
 - Irritant contact dermatitis
 - Allergic contact dermatitis

EPIDEMIOLOGY

- Prevalence
 - Represents 6–10% of visits to dermatologists' offices
 - Allergic contact dermatitis may account for at least 20% of all childhood dermatitis.
- Affects both sexes, all ages, and all races
 - Irritant contact dermatitis is more common than allergic contact dermatitis in very young children.
- Regional differences can exist, depending on the allergens or irritants in the environment.

ETIOLOGY

- Irritant contact dermatitis
 - Result of skin exposure to substances that cause an inflammatory reaction that is not immune mediated
 - Irritant agents may be present in the home, child care center, or school (eg, harsh detergents and cleaning materials).
 - Diaper dermatitis is common.
 - Urine, feces, and persistent moisture macerate the occluded skin of the perineum.
 - Typically does not involve the infant's skin creases
 - If the femoral creases or anal area is involved, infection is likely to be candidal.
 - Can be caused by airborne agents (dust or volatile chemicals)
 - These are often missed but must be considered in all cases.
 - Solvent/aerosol sniffers are susceptible to irritant contact dermatitis secondary to the airborne agent.
- Allergic contact dermatitis
 - Delayed hypersensitivity reaction, caused by primed T cells, producing a cascade of cytokines and chemotactic factors leading to dermatitis
 - *Anacardiaceae* is a family of plants that cause allergic contact dermatitis.
 - Poison ivy
 - Poison oak
 - Poison sumac
 - Japanese lacquer tree

- Cashew nut tree (allergen in the nutshell)
- Mango (allergen in rind, leaves, or sap)
- Rengas tree
- Dermatitis appears within 48 hours of exposure in a previously sensitized individual.
- Allergic reaction to nickel is common and the most frequently positive patch test allergen in North America.
 - Body piercing
 - Metallic areas of clothing, such as snaps and zippers
- Other allergens are becoming more important.
 - Topical antibiotic preparations, such as those containing neomycin
 - Hair dye products that contain paraphenylenediamine
 - Latex (eg, in children who have repeated exposure to latex in the clinical settings)

RISK FACTORS

- Patients with a history of atopic dermatitis are likely to have contact dermatitis.

SIGNS AND SYMPTOMS

- Clinical presentation of both types of contact dermatitis can be similar.
 - Range of responses:
 - Eczematous changes of the skin
 - Pink, scaling, irritated plaques
 - Severe vesiculobullous eruptions characterized by blistering changes of the skin and severe pruritus
- Irritant contact dermatitis
 - Can lead to lichenification
 - Accentuation of skin lines, often with hyperpigmentation, and an almost hardening of the skin
 - Acute irritant dermatitis occurs minutes to hours after exposure.
 - Intensity of the reaction, related to:
 - Nature of the chemical
 - Concentration
 - Duration of contact
 - Conditions that foster a more severe reaction
 - Wet skin
 - Skin under friction, occlusion, or pressure
 - Solvent sniffers
 - Irritant dermatitis of the arms and chest
 - Eczematous changes found mostly around the nose and mouth

- Allergic contact dermatitis—reactions can be:
 - Bullous
 - Purpuric
 - Lichenoid
 - Papular
 - Urticarial
 - Pigmented
 - Hypopigmented
 - From plants, ie, poison ivy
 - Linear arrays of vesicles where plant has come in contact with the skin
 - The genitals in young boys may be affected, because they transfer the allergen to this area when voiding.

DIFFERENTIAL DIAGNOSIS

- Atopic dermatitis
- Seborrheic dermatitis
- Tinea
- Psoriasis
- Rare conditions that can mimic diaper dermatitis
 - Acrodermatitis enteropathica from zinc deficiency
 - Letterer-Siwe disease

DIAGNOSTIC APPROACH

- The child or parent may be aware immediately of an offending agent.
- Use of a diary to chart symptoms and associated activities and exposures is recommended.
- If the irritant dermatitis is acute, identifying the culprit is often easy, given that it may be only a single agent.
- In chronic cases, multiple offenders are often present.
- Initial episode of allergic contact dermatitis may be easily identified because:
 - The rash usually is localized to a specific area.
 - The history of the offending agent can be ascertained.

DIAGNOSTIC PROCEDURES

- Patch testing
 - Application of suspected allergens to intact uninflamed skin
 - Substances are usually applied to the back and left on for 48 hours.
 - After 48 hours, patches are removed and coded sites are evaluated for the presence of a reaction.
 - Erythema *or*
 - Bullae
 - Some positive reactions may not show for up to 7 days; reevaluate at 5 and 7 days.

- Commercially available patch testing system (23 common allergens) can be performed easily in the dermatologist's office.
- In more extensive patch testing, individually prepared aluminum chambers with multiple allergens can be placed and then applied with hypoallergenic tape to the back.
- Photopatch testing to detect contact photoallergy is available.
 - The patch is applied, and after 24 hours the area is exposed to ultraviolet A light.
 - The patch is read 48 hours later.

TREATMENT APPROACH

- Uncomplicated cases (for both irritant and allergic contact dermatitis)
 - Topical steroids and emollients for milder disease
 - Elimination of the offending agent and liberal application of emollients is curative for mild irritant contact dermatitis.
 - Systemic medications, including oral corticosteroids and antihistamines for more dramatic presentations
 - Topical steroids are effective in allergic contact dermatitis, but less so for irritant dermatitis.
- Identifying the causative factors so that they may be avoided is accomplished by good history taking.
 - In chronic cases, a parent or older patient may need to keep a diary.
- Complicated cases that may require skin biopsy
 - Patient who has not responded to treatment in 1 month
 - Patient with involvement of a large body surface
 - Patient displays severe reactions (such as bullae)

SPECIFIC TREATMENTS

- Treatment of diaper dermatitis
 - Gentle application of protective barrier ointments, eg, zinc oxide and petrolatum
 - Lowest-potency corticosteroids
 - Can be used in severe cases 2–3 times daily for a limited time (3 days, no longer than 2 weeks)
 - Long-term exposure should be avoided in the occluded diaper area.
 - Care of diaper area
 - Bathing in water with minimal use of nondetergent soaps, followed by liberal use of emollients
 - Barrier ointments should be used with each diaper change, with care not to produce excess friction.
 - Involved areas should be kept dry and free of urine and stool.
 - Caregivers should be encouraged to change the diaper frequently, as often as every ≥ 2 hours.

- Commercial cleansing wipes, if used, should be fragrance-free and alcohol-free.
- Topical antifungal agents
 - Work well for secondary candidal infection of the diaper area
 - Should be considered in irritant rashes that are present for >3 days.
- Treatment of allergic contact dermatitis, specifically, *Rhus* dermatitis
 - Washing the skin and other items that may have come in contact with the plant
 - If patient develops skin lesions, systemic antihistamines are usually needed.
 - Topically, mild to moderate strength (class 7 to 4) steroids are appropriate
 - Topical pramoxine (an antihistamine) is safe and can be used over large areas of the body 2–3 times a day.
 - If lesions are limited but very pruritic, a more potent topical steroid cream (class 1 or 2) can be applied for no more than 2 weeks.
 - If lesions are more extensive, systemic steroid therapy for 2 weeks at a beginning dose of 0.5–1.0 mg/kg, followed by a rapid taper over the subsequent 2 weeks, is justifiable.
 - Should not have quick bursts of systemic steroids, because this is often associated with rebound of the rash
- In rare or severe cases, systemic steroids can be given for 2 weeks at a dose of 0.5–1.0 mg/kg with a rapid wean.

WHEN TO ADMIT

- If contact dermatitis is severe, such as seen in a generalized contact dermatitis or systemic contact dermatitis
 - Generalized contact dermatitis may occur if a patient is exposed to the smoke of a burning antigen (ie, various plants, such as those from the *Rhus* family).
 - Systemic contact dermatitis occurs when a patient is repeatedly exposed to a substance via an oral, intramuscular, or intravenous route that cross-reacts with an allergen.
- Patients experiencing any:
 - Fever
 - Chills
 - Nausea
 - Vomiting
 - Hypotension

- Secondary bacterial infection may require intravenous antibiotics if large body-surface involvement exists.
- Although rare, secondary infection with herpes virus may require intravenous antivirals.

WHEN TO REFER

- Presumed irritant contact dermatitis (including diaper dermatitis) that has persisted for ≥ 1 month despite aggressive topical treatment
 - Refer to a dermatologist.
- Involvement of a large body surface area or severe reactions (eg, bullae) or an atypical presentation
 - Refer to a dermatologist for skin biopsy.
- Patients in need of patch testing
 - Refer to a dermatologist or qualified pediatric allergist.

COMPLICATIONS

- Repeated episodes of irritant contact dermatitis that compromises the protective skin barrier may create a fertile environment for subsequent allergic contact dermatitis.

PREVENTION

- Irritant contact dermatitis
 - Maintain the skin barrier.
 - By maintaining a healthy stratum corneum
 - By keeping skin well hydrated (but not overly) and well moisturized
 - Avoid irritants.
 - Parents and older children must be educated about common irritants (soaps/detergents, especially those with fragrance and dyes).
 - Formaldehyde, formaldehyde releasers, and other clothing treatments can aggravate the skin; clothing should be washed before wearing.
- Allergic contact dermatitis
 - Identify trigger factors.
 - Educate the parent and older child about avoidance of triggers.
 - Patients and their families should be taught to identify a poison ivy plant so that it can be avoided and removed, if possible.
 - Commercial nickel spot tests are available from several sources.
 - Patients may identify the presence of nickel in metal items with which they may come in contact.

Contagious Exanthematous Diseases

DEFINITION

- Exanthem, meaning to bloom or to break out, refers to an eruption or rash that is usually associated with fever.
 - Generally implies that the eruption is infectious in origin
- These eruptions are extremely common in children, and rashes for different diseases may appear similar.

EPIDEMIOLOGY

- Enteroviral exanthems
 - The most common cause of exanthems in children
 - Typically occur in the late summer and early fall
 - Associated with epidemics of aseptic meningitis
- Roseola (exanthem subitum)
 - Occurs year-round
 - Limited to children between 6 months and 3 years of age
- Infectious mononucleosis
 - Occurs in approximately 15% of children
- *Mycoplasma pneumoniae* infection
 - Cutaneous signs are a minor manifestation of mycoplasmal infections.
- Mumps
 - Exanthem develops in <10% of persons infected.
 - Clinical mumps develops in approximately 60% of infected persons.
 - The remaining 40% have inapparent infections, without salivary gland swelling.

ETIOLOGY

- Exanthems may be caused by infection with:
 - Viruses
 - Bacteria
 - *Rickettsia* species
 - *Mycoplasma* species
 - Fungi
- Many serotypes of echoviruses and coxsackieviruses are associated with rashes.
 - Transmission is via the fecal-oral route.
- Roseola transmission is via secretions, usually from an asymptomatic contact.
- Erythema infectiosum is caused by infection with human parvovirus-B19.
 - Infection is spread by respiratory tract droplets.
- Rubella is transmitted through direct or droplet contact from nasopharyngeal secretions.
- Infectious mononucleosis is the exanthem of the Epstein-Barr virus.

- Measles (rubeola) is highly contagious and transmitted via respiratory droplets.
- Mumps transmission is through direct contact via the respiratory route.

SIGNS AND SYMPTOMS

Enteroviral exanthems

- Typically, these rashes are generalized maculopapular types that have discrete lesions similar to those of rubella or roseola.
- 2–3 days of fever precedes eruption.
 - Generally, prodromal fever is much lower than that of roseola.
- Vesicular lesions have been observed in coxsackievirus A5, A9, and A16 infections.
 - Hand-foot-mouth disease commonly is seen with coxsackievirus A16 infection.
 - Manifests as vesicles on the palms and soles
 - Oral ulcerations of enteroviral herpangina typically occur in the back of the mouth; this feature can distinguish it from the more diffuse lesions of primary herpes stomatitis.

Roseola (exanthem subitum)

- Human herpesvirus-6 is the infectious agent.
- 3 or 4 days of high fever (104–105°F [40–40.6°C])
- Abrupt resolution of fever
- Eruption of a pink maculopapular rash
 - Begins on the neck and spreads to the trunk and extremities
 - Face usually spared
- Lesions are discrete and last for 1 or 2 days.
- Usually, the child has no other manifestation of illness.
- The child does not appear as ill as the severity of the fever might imply.

Erythema infectiosum (fifth disease)

- Rash without fever or other systemic signs
- Fever can occur in 15–30% of patients.
- Rash occurs 7–10 days after nonspecific symptoms.
 - Malaise
 - Myalgias
 - Headache
- Rash erupts as a bright-red erythema of the cheeks (“slapped-cheek”) and forehead.
 - Many large maculopapular lesions coalesce to form a confluent red rash.
 - Lesions are hot to the touch, palpable, and nontender.
 - Circumoral pallor

- Second stage: after 1 day, maculopapular rash appears on the proximal extremities.
 - Spreads gradually to the trunk and distal extremities
 - Leaves a lacelike appearance as it clears
 - Lasts 2–4 days
- Third stage: rash may reappear transiently when the skin is traumatized by pressure, sunlight, or extremes of hot and cold.
- Arthritis and arthralgia, which often occur in adults, are infrequent findings in children.
- Mild myelosuppression typically goes unnoticed in normal individuals.
 - A life-threatening aplastic crisis may occur in patients with shortened red cell survival, such as occurs in sickle cell disease or hereditary spherocytosis.

Rubella

- Also known as *German measles* or *3-day measles*
- The period of maximal communicability is just before and up to 1 week after onset of the rash.
- Incubation period is 2–3 weeks; disease peaks at 16–18 days.
- Clinical illness is mild and brief.
- Rash is the first sign of infection.
 - A pink, maculopapular eruption begins on the face and spreads downward to the trunk and extremities.
 - Lesions remain discrete and pink, in contrast with the raised, confluent, and deep-red lesions of rubeola.
- Facial rash clears as the extremity rash erupts.
- Rash has cleared by the third to the fifth day.
- Fever is very mild, between 99°F and 101°F (37.2°C and 38.3°C).
 - Lymphadenopathy
 - Posterior auricular and suboccipital chains are most commonly involved.
 - Tender at the onset of rash, with tenderness resolving rapidly over 2–3 days
 - Although lymphadenopathy is an important sign of rubella infection, it is not specific.
 - Tiny reddish spots may occur on the soft palate, which are indistinguishable from those of scarlet fever or rubeola.

Infectious mononucleosis

- The rash is pink to red and macular or maculopapular.
- The lesions are discrete and have no specific distinguishing characteristic.
 - Disease is most often diagnosed on the basis of other signs of infectious mononucleosis and confirmed by the peripheral blood smear and serologic tests.

- Administration of ampicillin (and sometimes other penicillins) results in approximately 50% of patients developing a much more intense rash.
 - This ampicillin-associated rash is deep red and confluent, giving it a morbilliform appearance.
 - Rash resolves spontaneously within a week.
 - The appearance of such a rash in a patient treated for presumptive group A streptococcal pharyngitis is cause to reconsider the diagnosis.
 - Reassure parents that rash does not represent penicillin hypersensitivity.

Measles (rubeola)

- The most serious of the childhood exanthems because of morbidity of the acute infection and potential for producing permanent sequelae.
- Incubation period: 10–11 days
- Prodromal illness
 - Increasing fever
 - Cough
 - Conjunctivitis
 - Coryza
- By the fourth day
 - Fever is high (104°F [40°C]).
 - A deep-red macular rash erupts, beginning on the face and neck and spreading down the trunk and extremities.
 - Appearance is similar to that of rubella.
 - The lesions on the face and upper portion of the trunk soon become confluent to produce the characteristic morbilliform rash.
 - Rash in rubella tends to remain discrete.
- By the sixth day
 - Fever subsides.
 - The rash begins to fade, leaving a faint brown stain in the skin.
 - A fine desquamation ensues.
- Children are usually very ill but recover rapidly after the eighth or ninth day and are most often back to normal in a few days; hence, the moniker *10-day measles*.

Atypical measles

- Occurs in some children who were exposed to wild measles virus and had been immunized with inactivated measles vaccine
- May have 2–3 days of fever and headache followed by a rash erupting on wrists and ankles
- Rash may be maculopapular, purpuric, petechial, or vesicular.
- Marked myalgia, with swelling of the hands and feet, may also occur.
- Pneumonia is common.
- Inactivated measles vaccine is no longer available in the US

M pneumoniae infection

- A maculopapular eruption may appear on the trunk and extremities of 10–15% of persons infected with *M pneumoniae*.
- These infections are more commonly associated with allergic-type eruptions.
 - Urticaria
 - Erythema multiforme
 - Vesicles
 - Bullae
- Patients frequently have had a prodromal illness of fever, headache, malaise, and cough.
- Disease may escape physical diagnosis, only to crop up on the chest radiograph as an incidental finding.

Mumps

- Exanthem is uncommon, but when present, lesions are maculopapular, pale pink, discrete, and concentrated on the trunk.
- Virus more typically involves salivary glands, testicles (after puberty), pancreas, and meninges.
- Incubation period of 16–18 days
- Illness begins with 1 or 2 days of anorexia, headache, and mild to moderate fever that usually lasts 2–5 days.
- This is followed by discomfort when chewing and pain around the ear.
- Diffuse but noticeable enlargement and tenderness of the parotid gland is usually present.
 - Swelling extends anterior to the ear and below the ramus of the mandible posteriorly to the mastoid bone, usually obliterating the angle of the jaw.
 - Rarely, only 1 parotid gland is involved.
 - Submandibular salivary glands rather than the parotids may be involved.
 - Lymph nodes are more discrete and generally submandibular in location.
 - Erythema accompanying the parotitis is commonly seen around the opening of the Stensen duct.

Scarlet fever

- Rash (scarlatina) is caused by a circulating erythrotoxin produced by certain strains of streptococci and staphylococci.
 - Characterized by a fine papular eruption on an erythematous base
- Generalized erythema of the skin is present, even including areas that are not yet involved with the papular rash.
 - Concentrated on the trunk and proximal extremities
 - Feels rough to the touch, similar to fine sandpaper
 - Commonly associated with prominent erythema of the lips, soles, and palms

- Transverse red streaks (Pastia lines) are sometimes present, usually in the antecubital space.
- Desquamation of involved skin typically occurs in the recovery phase.
- On the tongue, prominent papillae appear on a very red base, giving a “strawberry tongue” appearance.
- If streptococci are the source of the erythrogenic toxin, the pharynx is the usual site of focal infection.
 - Other focal infections (eg, vaginitis, cellulitis) may also be found.
- When staphylococci are the source of erythrogenic toxin, the infective focus is usually some site other than the pharynx, eg, infected surgical or traumatic wounds.

DIFFERENTIAL DIAGNOSIS

- Clinical manifestations other than the rash must often be explored to distinguish one disease from another.
 - Incubation period
 - Prodromal symptoms and signs
 - Patient age
 - Immunization history
 - Contact history
 - Distribution and progression of the rash
 - Evidence of other organ involvement
 - Pathognomonic signs, such as peeling or Koplik spots
- Certain allergic and immune-complex diseases, such as childhood arthritis, can mimic infectious exanthems.
- Kawasaki disease must be carefully differentiated from scarlet fever.
 - Coronary artery disease may complicate untreated Kawasaki disease.
 - Cutaneous manifestations overlap those of scarlet fever.
 - Can usually be distinguished by additional signs
 - Discrete bulbar conjunctivitis without exudate
 - Cracking of the lips
 - Lymphadenopathy, usually solitary, unilateral, and >1.5 cm in diameter
 - Induration with erythema of palms and soles
 - Meatitis
 - Children are profoundly irritable.
 - Fever persists for more than 1 week (5 days of fever is necessary for diagnosis).
 - As in scarlet fever, patients have erythema of the palms and soles.
 - Striking desquamation is evident during the second and third weeks of the disease.

- Measles (rubeola)
 - The exanthem of measles is pathognomonic.
 - Koplik spots begin approximately 2 days before the rash erupts and increase in number until the first or second day of the exanthem.
 - Tiny bluish-white spots on an erythematous base
 - Cluster adjacent to the molars on the buccal mucosa
 - The combination of Koplik spots, fever, cough, conjunctivitis, and morbilliform rash is sufficient to make a firm clinical diagnosis of measles.

LABORATORY FINDINGS

- Clinical suspicion of erythema infectiosum (fifth disease) confirmed by
 - Testing for anti-parvovirus B19 immunoglobulin M in the immunocompetent patient
 - Through polymerase chain reaction testing in the immunocompromised patient
 - Dot-blot hybridization of serum specimens may have adequate sensitivity for patients with HIV.
- Rubella
 - Virus grown from the pharynx within 5 days of the onset of the rash
 - Serological diagnosis is made by demonstrating antibody titer increase between acute and convalescent serum samples obtained 2 weeks apart.
 - Serologic tests
 - Traditional hemagglutination-inhibition antibody titers
 - Enzyme immunoassays

SPECIFIC TREATMENTS

Erythema infectiosum (fifth disease)

- Supportive care is sufficient for most patients.
- Patients in aplastic crises may require transfusion.
- In immunodeficient patients with chronic infection, intravenous immune globulin therapy should be considered.
- Transmission of parvovirus B19 may be decreased through the use of routine infection control measures.

M pneumoniae infection

- Macrolide antibiotics may be used to treat *M pneumoniae* infections.

Measles and its complications

- Vitamin A supplementation should be considered for patients 6 months to 2 years of age who are hospitalized

Scarlet fever

- Treatment should be directed toward eradication of the focal infection.

- Streptococcal infections
 - Penicillin
 - Erythromycin
- Staphylococcal infections
 - Cephalexin
 - Amoxicillin-clavulanate
 - Dicloxacillin
 - Oxacillin

WHEN TO ADMIT

- Patients with measles may need to be hospitalized in an isolation room.
- Patients who have developed severe complications such as pancreatitis in mumps, pneumonia in measles due to contagious exanthematous diseases.

FOLLOW-UP

- All children who have measles should have careful follow-up, and the examiner should have a high degree of suspicion for secondary bacterial pneumonia.

COMPLICATIONS

- Rubella
 - The major serious complications of rubella virus result from fetal infection.
 - High probability that infection in the first trimester of gestation will result in fetal infection with multiorgan involvement
 - Complications are rare in children.
 - Transient arthritis develops in approximately 15% of adolescents and young adults that rarely becomes chronic.
- Measles (rubeola)
 - Induces inflammation throughout the respiratory tract and respiratory complications are common
 - Otitis media (treat as usual)
 - Pneumonia may be either a primary measles pneumonia or a superimposed bacterial pneumonia.
 - Croup
 - Subacute sclerosing panencephalitis, also known as *Dawson encephalitis*, is the major complication of persistent measles virus infection.
 - Occurs in approximately 1 per 1000 cases
 - Commonly results in death or permanent neurologic sequelae
 - Signs and symptoms of subacute sclerosing panencephalitis
 - Headache
 - Vomiting
 - Drowsiness

- Personality changes
- Seizures
- Coma
- Cerebrospinal fluid reveals pleocytosis and elevated protein levels
- Some have only mild disease and recover in a few days; others have a fulminant course
- Mumps
 - Meningoencephalitis is estimated to occur in 10% of all cases of mumps.
 - Characterized by
 - Headache
 - Nausea
 - Vomiting
 - Mild nuchal rigidity
 - It may occur before, during, or after the parotitis phase of the disease.
 - Follows a course similar to the aseptic meningitis that is caused by other viruses.
 - Usually has no sequelae.
 - Orchitis is uncommon in children.
 - Unilateral involvement of the testes and epididymis is observed in approximately 25% of male patients who are infected with mumps virus after puberty.
 - Patients who have orchitis are usually quite ill.
 - Sterility rarely occurs.
 - The pancreas and other exocrine glands are rarely involved.
 - Late neurologic complications include nerve deafness and very rare postinfectious encephalitis.

PREVENTION

- Prevention can be achieved by utilizing appropriate infection control procedures.
 - Many of the contagious exanthematous diseases such as measles, mumps, and rubella can be prevented by vaccination.
-

Conversion Reactions and Hysteria

DEFINITION

- Conversion reactions are medical complaints or symptoms associated with unconscious distress.
- They are a way of communicating the uncomfortable, or “a psychic mechanism whereby an idea, fantasy, or wish is expressed in bodily rather than in verbal terms and is experienced by the patient as a physical symptom rather than as a mental symptom.”
- The terms *conversion symptom*, *conversion reaction*, and *conversion disorder* often are used interchangeably.
- Somatic or functional complaints differ from conversion symptoms.
 - Patients with somatic or functional complaints are aware of emotional distress associated with the symptom.
 - Patients with conversion symptoms are not cognizant of any associated emotional distress.

EPIDEMIOLOGY

- Prevalence
 - Specific overall prevalence of conversion symptoms in children and adolescents is not known.
 - 5–13% suggested by available data
 - Lack of more definitive data reflects the difficulty in ascertaining whether a somatic complaint represents a conversion symptom.
- Gender
 - 2 to 3 times more common in girls
- Age
 - May appear as early as 7 or 8 years of age
 - Appears to be more common among adolescents than among younger children
 - Adolescents more often have alarming somatic complaints, such as chest pains and fainting spells.
 - Younger children frequently suffer from more indolent complaints, such as sporadic abdominal pains.
- Socioeconomic status
 - No correlation apparent
- Less sophisticated patients tend to have rare or very unusual and physiologically unexplained symptoms.
 - Therefore, the more classic conversion symptoms (eg, paralysis, blindness) are less likely to be seen in Western societies.
 - Practitioners in Western societies are more likely to diagnose conversion symptoms in patients presenting with chronic abdominal pain or chronic headaches.
- Can appear as a group phenomenon, often referred to as *epidemic hysteria*.
 - Episodes of epidemic hysteria appear to have several characteristics in common:

- Audiovisual cues (eg, seeing ambulances arrive to care for accident victims) seem to be important precipitators.
- Adolescent girls are involved more often than adolescent boys.
- Reaction is more likely if it is initiated by a group member identified either as a leader (of a large subgroup) or an authoritative outsider.
- Episodes are likely to involve larger numbers of adolescents if adults are not present.
- For example, adolescent girls swooning and fainting at rock concerts
 - In this situation, the unacceptable wish relates to sexualized thoughts involving rock stars.
- Other examples are explained less easily.
- Entire school populations may be involved in mass conversion reactions.

ETIOLOGY

- A conversion symptom serves as a form of decompression whereby unpleasant effects associated with acknowledgment of the wish are dissipated through the use of a somatic symptom.
 - The idea or wish is psychologically threatening to individuals or unacceptable for them to express directly.
 - Because the wish is completely unconscious, patients in no way relate any psychological stigmata to the somatic complaint.
- Conversion symptoms have no organic basis by themselves.
 - May be perpetuated by biochemical or physiological body changes, known as *conversion complications*
 - Can include changes such as
 - Muscle atrophy caused by longstanding paralysis
 - Respiratory alkalosis secondary to acute hyperventilation
 - Body activity (ie, gestures) used to express ideas during verbal interaction
- Some somatic complaints can result directly from emotional upsets:
 - Headaches
 - Nausea
 - Vomiting
- Anxiety often is associated with
 - Palpitations
 - Sweating
 - Tremulousness
- Depression often is exhibited by
 - Fatigue
 - Weakness

SIGNS AND SYMPTOMS

- All body systems may be invoked in a conversion reaction.
 - Any bodily process that can be perceived by the individual can serve as the focus for conversion symptoms.
 - Body activity (ie, gestures) is used to express ideas during verbal interaction.
 - Developmentally, infants express feelings and communicate through visible behavior long before spoken language becomes their dominant mode of communication.
 - Common conversational phrases frequently allude, metaphorically, to the intermixing of emotion and body functioning.
 - “I’m fed up.”
 - “He is a pain in the neck.”
- Typical symptoms include:
 - Paresthesia
 - Anesthesia
 - Diffuse pain
 - Paralysis
 - Tremors
 - Weakness of an extremity
 - Hyperventilation
 - Dizziness
 - Vomiting
 - Nausea
 - Visual problems
- Sensory system symptoms typically are not distributed in the correct pattern of innervation of the implicated cutaneous nerves.
- Abdominal pain
 - Common conversion symptom in children and young adolescents
 - An extensive investigation of 100 children who had abdominal pain showed an organic cause in only 8 cases.
 - Another study revealed abdominal pain in 14% of the children studied.
 - Highest incidence in children 9 years of age
 - Lowest incidence in those 16–17 years of age
 - Recurrent abdominal pain and its causes remain controversial.
 - Recurrent abdominal pain may indicate emotional concerns of which patient is unaware.
- Somatic symptoms of relatives or close friends can serve as the source of a patients’ complaints.
 - Patients’ interpretation of another person’s symptom provides a model.
 - When the symptom is adapted from one observed in another person, that person frequently evokes strong feelings in patients.

- Patients express guilt about their feelings or impulses toward that person and may take the other’s symptoms.
 - A form of self-punishment and psychological expression of the patient’s forbidden idea or wish.
- Adolescents who have conversion symptoms frequently display characteristic patterns of behavior, sometimes designated as traits of the hysterical personality, including
 - Egocentricity
 - Labile emotional states (quick shifts from sadness to elation or from anger to passivity)
 - Dramatic, attention-seeking behavior
 - Sexual provocativeness (displayed in gestures and in dress)
- Patients who have such characteristics also
 - Usually are demanding
 - Display an air of pseudomaturity
 - Are dependent in personal interactions
- Their personal relationships, however, are rarely intimate or satisfying.
- Many aspects of the hysterical personality are seen in adolescent patients who have conversion symptoms, but also are demonstrable in adolescents who do not have such symptoms.
 - Therefore hysterical behavior traits alone in adolescents are not synonymous with conversion symptoms.
 - In isolation, these traits are not indicative of a psychopathologic condition.

DIFFERENTIAL DIAGNOSIS

- Other psychosomatic disorders at times may be confused with conversion symptoms.
- Hypochondriasis
 - Common, especially in adolescents
 - Patients view their symptoms with extreme concern.
 - Patients lack the apparent indifference seen in those who have conversion symptoms.
 - Patients who have conversion symptoms frequently seem relieved by consideration of an organic cause.
 - Patients who have hypochondriasis become more concerned if an organic diagnosis is suggested; they suspect and fear a serious or fatal disease.
 - Neither type is reassured more than transiently by being informed that there is no disease.
- Malingering
 - Uncommon in adolescents
 - May be seen in institutionalized adolescents
 - May be seen in adolescents in restrictive situations (eg, military service)
 - May be seen as an appropriate means of avoiding threatening or unpleasant circumstances

- Attempts to feign illness often are naive, especially in younger patients.
- Many of these individuals appear to be accident prone.
- May submit to painful procedures readily and without objection
- Malingering adolescents are aloof and hostile to the physician, delaying discovery of their deception.
- Patients who have conversion symptoms are often normal in their fear of invasive medical procedures.
 - May appear charming and garrulous with the physician
- Both malingerers and patients who have conversion symptoms may have parents with an unconscious psychological need to have their children be ill, therefore reinforcing symptoms.
- Somatic delusions
 - Symptoms of psychosis
 - Usually not confused with conversion symptoms
 - Other signs of severe mental illness usually are present:
 - Inability to relate to peers
 - Visual or auditory hallucinations
 - Stereotypical behaviors
 - The symptoms described sometimes are intermittent and often extremely bizarre.
 - For example, patients who have somatic delusions may express the conviction that their heart is shriveling or that something is wrong with the blood that is running from the head to the leg.
- Psychophysiological symptoms
 - May occur when conversion symptoms have failed to dissipate anxiety
 - Continuing anxiety activates biological systems (especially the autonomic nervous system), resulting in physiological changes such as
 - Tachycardia
 - Hyperperistalsis
 - Vasoconstriction
 - Patient's cognizance of these changes is exhibited by
 - Palpitations
 - Diarrhea
 - Sweating
 - In this situation, the symptom itself has no organic symbolic meaning and results from a reaction to actual body changes.
 - Therefore psychophysiological symptoms can occur when conversion symptoms have failed.
 - Similarly, conversion symptoms can replace psychophysiological symptoms.

DIAGNOSTIC APPROACH

Evaluating somatic complaints

- Evaluation of any patient who has a somatic complaint not easily explained by another medical condition should always include consideration of the possibility of a conversion symptom.
- Evaluation of any somatic complaint should involve inquiry into areas that reveal the patient's baseline emotional functioning:
 - Family
 - School attendance and performance
 - Peer relationships
- Advise both parents and patient that having feelings about somatic complaints is acceptable.
 - If the physician communicates an appreciation of the role of emotions in physical disease, then the family may volunteer information more readily about psychosocial functioning.
 - Both family and patient may be more accepting of primary emotional involvement if permission for expressing feelings is given early in the physician-patient relationship.
 - Eventual diagnosis involving emotional aspects of health may be more acceptable if the family has been prepared for the possibility.
 - Focusing only on physical diagnosis intimates to parents that psychological involvement is unlikely, unimportant, and improbable.
 - Turning to psychological issues after all physical tests prove unremarkable implies to parents that this tack was chosen as a last resort because the physician was unable to ascertain an organic cause.
 - A concurrent physical-psychological diagnostic approach not only prepares the physician to consider the problem with some psychotherapeutic intent, but also may save the family time and money by avoiding multiple laboratory tests.
- From the outset, parents and patient should
 - Be told that the body has physical ways of responding to emotional stress.
 - Be encouraged to suggest diagnostic tests and possible diagnoses for consideration by the physician.
 - Understand that the goal is to help maintain normal daily functioning in school and with peers even though symptoms may persist.
 - Understand that referral to a trained psychiatric professional may be necessary if progress is not made.
- A thorough history may not only elicit symptom inconsistencies in the present illness, but may also reveal a record of inexplicable or recurrent bouts of illness associated with life events, such as
 - Chronic abdominal pain that occurs only on school days

- Somatic complaints associated with stressful social events
- Documentation of abdominal surgery with equivocal findings

Diagnostic criteria

- Diagnosis of a conversion reaction should never be one of exclusion and should follow specific diagnostic criteria:
 - The symptom has symbolic meaning to the patient.
 - The patient frequently exhibits characteristic interpersonal behaviors.
 - Reporting symptom has a characteristic style.
 - The symptom helps patients cope with their environment (secondary gain).
 - Health issues and symptoms frequently are used in family communication.
 - Symptoms occur at times of stress.
 - The symptom has a model or representation in the patient's life.
 - History and physical findings often are inconsistent with anatomic and physiological concepts.
 - No one criterion can be confirmatory; each patient who has a conversion symptom may not display every criterion.

Approach to patient interview

- Nondirective interviewing proves more rewarding than direct questioning.
 - For example, asking patients to describe the pain ("Tell me how it feels.") almost always provides insight into the emotions that patients associate with symptoms.
 - Suggestions ("Is it dull or sharp pain?") limit possible responses.
- If patients spontaneously offer information about recent events, then the interviewer should look for relationship of changes to patient's life.
 - However, care should be taken to avoid suggesting a cause-and-effect relationship between feelings and symptoms.
 - Patients who have conversion symptoms have no conscious knowledge of such an association, so the suggestion may alienate them and prevent establishment of trust.
- Patients who have a conversion symptom often describe their problem in a distinctive way.
 - The account frequently is dramatic.
 - Pain may be described as "thousands of burning needles thrust into my leg" or "a giant spike being driven into my chest."
 - Because they are suggestible, any symptom description alluded to by the physician may be adopted readily and thereafter reported.

- The conversion symptom has a specific, but unconscious, symbolic meaning to the patient.
 - Often related to an unconscious wish, and physical impairment serves to prevent acting out the wish
 - For example, the adolescent boy who has hand paralysis may have anxieties about masturbating.
 - The family or clinician may not always be aware of the symbolic meaning of the symptom.
 - Cognizance of the presence of the symbolic meaning may be intellectually rewarding for the physician; ignorance of the specific symbolism does not prevent adequate treatment.
- Conversion symptoms are adopted unconsciously in an attempt to reduce unpleasant affects such as
 - Anxiety
 - Depression
 - Guilt
- Therefore, although patients may describe incapacitating pain, they often affect an air of unconcern.
 - Psychiatrists refer to this as *la belle indifférence*.

Primary and secondary gain

- The extent to which the conversion symptom diminishes the unpleasant affect and symbolically communicates the forbidden wish for the patient is referred to as the *primary gain*.
- Patients who have conversion reactions are often stubborn in their belief that the symptom is caused by organic problems, reflecting denial of the underlying emotional problem.
 - Conversely, insistence (especially by an adolescent) that a symptom is psychological in origin may indicate denial of a physical problem.
 - Therefore, differentiating between conversion symptoms and physical disease in adolescent patients cannot depend solely on the patient's emotional response.
- Conversion symptoms not only effect a primary gain for patients, but also help them cope with the environment.
- The conversion symptom achieves a secondary gain for patients.
 - For example, a conversion symptom defending against homosexual thoughts may be an excuse from attending school, where anxiety may have been intensified.
- Limitations imposed by symptom may contradict verbalized wishes to participate in activities but, nevertheless, remove the patient from potentially threatening social interactions.
- Interference with daily activities may provide secondary gain of attention and more frequent expressions of love from parents and friends.
 - The situation may be resistant to change, not only because the symptom is reinforced continually, but also because the symptom meets parents' psychological needs.

- Symptom may provide the parents with a reason for inappropriately attending to or infantilizing their child.
- Consequently, patients and entire families may fall into a vicious circle of dependence on the symptom.
- Demonstration of a secondary gain does not ensure a diagnosis of conversion.
 - To an extent, all illness is involved with some secondary gain.
 - Bedridden patients must accept increased attention to cope with their physical confinement.
 - Therefore, a degree of secondary gain is necessary for adequate adaptation to disability.
 - In conversion symptoms, secondary gain not only intensifies symptoms, but may also be associated with further occurrence of a somatic complaint.
 - Perpetuation depends on concern from others, thus conversion symptom is more readily exhibited in the presence of individuals meaningful to the patient.
- Children and adolescents who develop conversion symptoms are often overprotected and become extremely dependent on their parents.
 - Daily familial communication may have been invested heavily in somatic complaints.
 - Children may recognize how often activities may have been canceled because of health complaints by other family members.
 - Therefore, patient's symptoms may conform to the unspoken interactional family rules.
 - Family members indirectly reinforce patient problems, although parents may assume an air of indifference with respect to the patient's symptoms.
- Because the association between conflict and conversion reaction is unconscious, a history is helpful only if the interviewer elicits details about daily activities.
 - The stressful event precipitating a conversion symptom often becomes apparent only after many visits.
- Symptom selection is based on the unconscious remembrance of the patient's own body function or understanding of symptoms in others.
 - The patient's conversion symptom may appear quite dissimilar to that displayed by the other (often a parent or a close relative) because the patient's perception of disease governs the display of symptoms.
 - Parents and relatives often misinform children and adolescents about diseases, fearing that the truth would be too frightening.
 - Such misinformation may actually potentiate fantasies and result in the development of a symptom quite different from the model.
- Choice of symptom may be based on a previous physical illness.
 - Thus patients who have a history of seizures may, after many years of adequate anticonvulsant control, have atypical and physiologically unexplainable seizures.
 - Because the somatic complaint expressed by the patient is based on a model symptom, a physical disease often is mimicked.
 - Close scrutiny of the symptom's history and description often reveals anatomic and physiological discrepancies.
 - The child or adolescent who has a stocking anesthesia—an anesthesia confined to a specific area of an extremity without any relationship to cutaneous nerve innervation—demonstrates an example of symptom inaccuracy.
 - It is based on the concept of the patient's own body rather than on anatomic principles.

Identifying precipitating events

- Precipitation of a conversion symptom may be related to specific stressful events, such as
 - A change of school
 - Final examinations
 - New social experiences
 - Parental conflict
 - Unresolved grief reactions
 - For instance, loss of a parent through death, divorce, or moving
- Both adolescent and adult patients experience pseudo-seizures more often in families in which an unspeakable dilemma was present.
 - Often associated with a fear of physical or sexual assault
 - Even though other family members were aware of the specific problem, they often underestimated the severity of trauma.

TREATMENT APPROACH

- In essence, treatment of the patient begins before a definitive diagnosis is made.
- The initial interaction between the physician and the patient is critical to the degree of success achieved.
- Before embarking on a treatment plan, the physician must be satisfied with the completeness of the medical evaluation.
 - Common sense should dictate when the physician believes that further organic tests will be futile.
 - Patient and family can often sense physician uncertainty, especially if the family is averse to accepting a psychological diagnosis.
 - A prudent step is to ask the family what additional tests they expect and what other diagnoses they have considered.

- Treatment goals must be realistic.
 - Conversion symptoms seldom disappear completely.
 - However, adolescents often acquire increased coping skills so that
 - Daily function is unimpaired.
 - Dependence on secondary gain is minimized.
- Care of the adolescent patient who has a conversion reaction involves
 - Establishing a renegotiable number of regular visits
 - Encouraging the patient to discuss daily activities and interrelated feelings
 - Meeting with parents regularly to provide emotional support and counseling
 - Knowing that palliation rather than a cure may be the end goal
- Although patients who have conversion symptoms are suggestible, reassurance that the symptom will go away rarely is effective and does not contribute to psychological investigation of the symptom.
- On the contrary, suggesting that the symptom will persist allows time to work out a therapeutic relationship and sometimes has a paradoxical effect.
 - Because the symptom is unlikely to disappear after 2 or 3 visits, patients will retrospectively view the physician's suggestion as sound.
 - Trust in the physician will be reinforced, and patients may be more comfortable communicating information about their feelings.
 - Anxiolytic medications may reduce transiently attendant anxiety in some cases; however, medication as the sole therapy rarely results in lasting improvement.
 - Medication does not relieve the underlying conflict responsible for the symptom and another symptom eventually may appear.
 - There is a risk that medication side effects may become the model for new conversion symptoms, or new symptoms may be confused with side effects.
 - When physicians feel comfortable acting as both therapist and provider of acute medical care, occasions may arise when a teenager has a new physical symptom or complaint that requires attention.
 - If the physician suspects a physical illness unrelated to the conversion symptom, then whatever evaluation that is indicated must be performed, including a full or partial physical examination.
 - Overzealous search for disease should be avoided.
- The patient who has a conversion symptom usually will not outgrow it in the short term.

WHEN TO REFER

- Referral to mental health professionals is indicated
 - If symptoms continue to interfere with the patient's daily activities or functioning, such as
 - School attendance
 - Participation in extracurricular activities
 - Involvement with peers
 - If the family believes that inadequate progress has been made after an agreed-on duration of therapy
 - If the patient's symptom creates uncomfortable feelings in the pediatrician
 - For example, situations involving seductive adolescent behavior in association with a conversion symptom
 - If the patient or family member is a social acquaintance or a relative of the pediatrician
 - Dealing with the emotional problems of friends' or relatives' children is inappropriate.
 - Personal details of family or sexual functioning often may be required in the evaluation and may jeopardize the social relationship.
 - Failure or hesitancy to obtain appropriate data may jeopardize subsequent resolution of the problem.
- In all cases when referral is suggested, parental and patient compliance with the referral is improved if the possibility has been mentioned as a contingency early in the evaluation.
- The pediatrician should help families understand that seeing a psychiatrically trained professional does not connote "craziness."
 - Suggest that a mental health professional can help teenagers understand feelings about prolonged or unusual symptoms better than can most pediatricians.
 - Recommend a specific counselor rather than offering a list of suggested therapists.
 - Before the name of the therapist is given, verify that the counselor feels comfortable with the referral and has time available.
- After the referral is made, continued contact with the family concerning the conversion symptom promotes adherence with therapy.

FOLLOW-UP

- The number of anticipated follow-up sessions should be discussed with the family.
 - The number of sessions should be flexible so that it can be renegotiated if necessary.
 - Follow-up sessions with teenagers can usually be limited to 15–20 minutes every 2–4 weeks.
 - More frequent visits may be necessary if symptoms interfere with school attendance, peer relationships, or family functioning.

- During follow-up sessions, teenagers should be encouraged to talk about their daily life (eg, school, friends, family, dating).
 - If the teenager volunteers information about recurrence of the somatic complaint, the physician should inquire about events that were transpiring concurrently and feelings that accompanied these events.
- Having the adolescent keep a symptom diary may be helpful.
 - The patient records
 - When the symptom occurred
 - What was happening at the time the symptom began
 - This record may illustrate the association of the symptom with feelings or emotionally charged life events.
- For physicians with sufficient expertise, follow-up visits with parents should take place every 4 to 6 weeks.
 - Such meetings may
 - Elicit persistent or new concerns that parents may have
 - Attempt to assess the parents' reaction to continuing complaints
 - Emphasize the validity of the teenager's concerns so that misconceptions about the symptom being faked are dispelled.
 - Offer positive reinforcement so that parents believe they are doing what is best for their child.
- Selected follow-up sessions with parents should include the teenager to
 - Demonstrate to the patient that confidentiality is not being violated
 - Offer the physician an opportunity to observe parent-adolescent interaction

PROGNOSIS

- The prognosis for patients who have conversion reactions is unknown.
- Many patients who have conversion symptoms have an encouraging future.
- For some patients, adolescent conversion symptoms mark the beginning of a lifelong course of conversion illness.
- In a report of 74 children who had psychogenic pain, many were judged to be improved after several years regardless of whether professional intervention took place.
- In a 7-year follow-up of patients hospitalized with conversion, 23 of 41 patients
 - No longer suffered from presenting physical symptom
 - Were free of underlying stress
 - Had experienced no symptom substitution or new associated complaint

Cough

DEFINITION

- Cough can be described as a forceful exhalation.
 - Generally results from acute viral infection and is therefore self-limited
 - May be the harbinger of a more serious problem
- Cough can be exceedingly disruptive to the child and family.
 - It can lead to significant anxiety for all involved parties.
 - Allaying this anxiety through appropriate diagnosis and management is of prime importance.

EPIDEMIOLOGY

- Cough is one of the most common complaints of children.

MECHANISM

- The primary purpose of cough is to facilitate removal of inhaled irritants and secretions from the airway.
- 3 classic phases of the cough sequence
 - Inspiratory phase
 - Deep inspiration ending in glottic closure
 - Compressive phase
 - Intrathoracic pressure increases as a result of coordinated contraction of the expiratory muscles.
 - Expiratory phase
 - Glottis opens rapidly, leading to the sudden, sometimes explosive, release of the pent-up intrathoracic air (ie, cough).
 - Secretions and irritants are expelled from the airway.
 - Incomplete or inefficient removal of these materials will result in recurrence of the cough sequence, as will ongoing irritation or inflammation.

HISTORY

Accurate description of the cough

- Pattern and progression of symptoms
 - Duration
 - Frequency of discrete cough episodes
 - Quiet periods between cough (daily cough vs days or weeks between cough episodes)
 - Quality
 - Timing
 - Triggers

Age at onset

- Chronic or recurrent cough that begins in early infancy, especially in children <3 months
 - Congenital or anatomic origin
 - Requires a more aggressive approach toward evaluation

- Cough that begins relatively suddenly in toddlers
 - Foreign body aspiration
 - Requires active approach toward testing (bronchoscopy)
- Cough beginning at >6 months of age
 - May suggest airway hyperreactivity
- Cough beginning relatively suddenly in adolescents
 - Especially at times of psychosocial stress, might indicate a psychogenic origin

Family history

- Especially helpful with chronic symptoms
- Allergies, atopy, or asthma
 - Makes these diagnoses far more likely in the child with chronic or recurrent cough
 - History of asthma or atopy in first-degree relatives increases the risk of asthma in the child by 2-fold to 4-fold.
- Family history of early childhood death related to infection
 - Makes an immune deficiency more likely

Neonatal history

- Preterm infants are more likely than full-term infants to have:
 - Persistent airways hyperreactivity
 - Laryngotracheomalacia
 - Gastroesophageal reflux
- Central nervous system sequelae are likely in infants with:
 - Poor Apgar scores
 - Perinatal hypoxia
 - Difficult postnatal course
 - Suck or swallow dysfunction increases the risk of aspiration.
- Congenital abnormalities (eg, diaphragmatic hernia)
 - Pulmonary hypoplasia
 - Chronic respiratory dysfunction
 - Recurrent pneumonia

Environmental history

- Smokers in the household
 - Associated with significantly more respiratory infections and asthma symptoms in children
- Exposure to molds
 - Household water leaks
 - Decaying garbage
 - Ineffective cleaning of bathroom tile
- Dust mites
 - Old mattresses
 - Stuffed animals
 - Forced air heating systems
- Roaches

- Mice
- Pets
- Exposure to other children
 - At school
 - At child care
 - Babysitters
 - Siblings

PHYSICAL EXAM

- Physical examination plays a critical role in:
 - Pinpointing the origin of the cough
 - Identifying signs of a more serious underlying chronic condition
- Nasal mucosa
 - Nasal speculum examination
 - Color and quality of mucosa
 - Presence or absence of nasal secretions helps determine whether the cause of the cough is upper airway disease.
 - Rhinitis
 - Pale, boggy, swollen nasal mucosa
 - Sinusitis (when symptoms are prolonged)
 - Associated maxillary or frontal sinus tenderness
 - Pharyngeal drip with a cobblestone appearance (lymphoid hyperplasia) further supports the diagnosis of sinusitis.
 - Halitosis may also be present.
 - Chronic pharyngeal inflammation
 - In the absence of other signs of acute infection, suggests gastroesophageal reflux
- Oral mucosa
 - Ulcerations or thrush suggest an immune deficiency.
 - Cough paroxysms triggered by a tongue depressor support the diagnosis of pertussis.
- Signs of an acute infectious process
 - Fever
 - Adenopathy
 - Pharyngitis
 - Rash
 - These do not necessarily rule out a predisposing condition, especially when the pattern of illness suggests chronicity or frequent recurrence.
- Thorough assessment of other body systems
 - Important in judging whether a more global workup is necessary
 - Clues to a more severe underlying process
 - Growth failure
 - Poor developmental milestone achievement

- Clubbing
- Heart murmur
- Hepatosplenomegaly
- Chronic lymphadenopathy

■ Respiratory system

- Stridor, inspiratory rhonchi, or wheeze
 - Suggest upper and large central airway disease
- Rales, expiratory rhonchi, and wheeze
 - Indicative of lower or distal airway inflammation
- Change in the quality of air exchange
 - Can be an early finding in asthma and other diseases of airway obstruction
- Accurate lower airway examination depends on the cooperation of the patient.
 - Wheeze and distal airway sounds can be masked by a patient's vocalization or crying.
 - A force of airflow insufficient to uncover milder changes may mask both inspiratory and expiratory findings in infants and children who do not take deep breaths on command.
- Every effort should be made to place the child at ease during the examination.
 - Game-playing can be helpful.
 - Blowing on a feather
 - Blowing up a balloon
 - In younger children and infants:
 - The examiner can mimic a forced expiratory maneuver by firmly but gently compressing the anterior-posterior chest wall inward once the child has begun voluntary exhalation.
 - This approach will frequently uncover milder degrees of wheezing not appreciated with passive breathing.
 - The examiner should allow the child to begin exhalation passively before performing this maneuver to ensure that the glottis is relaxed.

DIFFERENTIAL DIAGNOSIS

- Acute vs chronic (>3 weeks' duration) cough
 - Chronic cough requires a more extensive evaluation plan.
- Upper, lower, or mixed airway origin
 - Upper airway cough
 - Croupy
 - Young children with asthma (disease of the lower airway) may initially exhibit a croupy cough.
 - Throaty
 - Honking
 - Foghorn

- Lower airway cough
 - Productive with expectoration of sputum is classically the result of bacterial pneumonia.
 - Children with severe chronic sinusitis (disease of the upper airway) will frequently cough and expectorate or swallow thick sputum that may be blood tinged.
- Cough character can be a useful starting point.
 - Paroxysmal
 - Pertussis
 - Staccato
 - *Chlamydia* infection
 - Barking
 - Laryngotracheal infection
 - Throat clearing
 - Postnasal secretions
 - Honking
 - Psychogenic cough
 - Occurs during the daytime
 - Increases when more attention is paid to it
 - Does not limit or change with physical activity
 - Cough during feeding
 - Suggests swallowing dysfunction
 - Tracheoesophageal fistula with aspiration
 - Cough after feeding
 - Spitting up, retching, or arching of the back
 - Gastroesophageal reflux
 - Associated fever
 - Respiratory tract infection
 - Cough worsening with exercise
 - Suggests reactive airway disease
 - Asthma
 - Night cough
 - Postnasal drip
 - Allergy
 - Sinusitis
 - Previous episodes, especially with seasonal variation
 - Allergy
 - Chronic cough with poor weight gain
 - More severe systemic illness
 - Cystic fibrosis
 - Immune deficiency

LABORATORY EVALUATION

- Acute cough rarely needs extensive laboratory assessment.
- Hematologic tests
 - Complete blood count with differential
 - May help distinguish a bacterial from a viral cause if infection is suspected
 - Localized infections, such as sinusitis, are not always accompanied by an elevated leukocyte count with a left shift.
 - Total eosinophil count may be an important clue to the atopy.
 - Elevated immunoglobulin E level further corroborates the diagnosis of allergy and suggests the possibility of asthma.
- Nasal smear
 - Positive for eosinophils
 - Corroborates the diagnosis of allergy and suggests the possibility of asthma
 - Increased polymorphonuclear leukocytes on nasal smear may suggest rhinosinusitis.
 - However, the result is difficult to quantify, and test may be misleading.
- Tuberculin skin test
- Immunologic studies
- α_1 -Antitrypsin levels
- Sweat chloride

IMAGING

- Computed tomography of the sinuses
 - Confirms the diagnosis of sinusitis
- Chest radiography
- Barium swallow
 - In infants
 - Anatomic causes of partial obstruction
 - Tracheoesophageal fistulae
 - Vascular rings
 - Modified for aspiration
 - Standard for gastroesophageal reflux
 - ~40% false-negative rate

DIAGNOSTIC PROCEDURES

- Pulmonary function tests
 - Distinguish between:
 - Upper and lower airways disease
 - Obstructive vs restrictive changes

- Children must be old enough to exhale fully and inhale forcefully on command.
- Test should be reproducible to ensure accuracy and reliability of results.
- Airway tests
 - Changes on the inspiratory loop of the flow-volume curve
 - Upper airway obstruction
 - Changes in the FEV₁/FVC ratio or the forced midexpiratory flow rate over the middle half of the FVC (FEF 25–75%)
 - Airway obstruction consistent with distal disease
 - Reversibility of these changes (20% improvement) with a β_2 -agonist confirms asthma and leads to effective therapy.
- pH probe monitoring
 - The gold standard for diagnosing gastroesophageal reflux
 - Reserve for patients in whom primary empiric treatment fails
- Bronchoscopy
 - Cough that begins relatively suddenly in toddlers
 - To confirm foreign body aspiration
 - Useful to diagnose structural abnormalities of both the upper and lower airways
 - Should be considered in patients with chronic symptoms not responsive to empiric treatment
 - If an upper airway origin is likely, flexible bronchoscopy can make a definitive diagnosis.
 - The bronchoscopist must always look beyond the vocal cords in this setting.
 - Lesions at the level of the thoracic inlet can exhibit as findings suggestive of upper airway obstruction.
- Sweat test

TREATMENT APPROACH

- Treatment is based on the underlying disorder.
 - Empiric therapy, based on primary assessment, can be a reasonable starting point.
- Detailed history and physical examination are usually sufficient to reach an accurate presumptive diagnosis.
 - Response to empiric therapy will confirm this assessment.
- The cough as a symptom of an underlying condition should be discussed with the patient and family.
 - Treatment of the underlying disorder (if necessary) should always be the primary focus.
 - In some conditions, cough is an important component of the body's natural response to the primary illness.
 - Suppressing the cough, in the absence of effective therapy for the primary disorder, may worsen the problem.
- The decision to use a cough medicine as an adjunct to the treatment of the primary disease is left to the primary care physician and family.
 - When cough is limiting or otherwise debilitating the patient, symptomatic treatment may be reasonable.
 - Cold and cough medicines should not be used in children <2 years of age because of serious side effects. Further, they are generally ineffective in children <6 years.

SPECIFIC TREATMENT

Expectorants

- Despite widespread use, expectorants have not been shown to decrease cough in children.
- Guaifenesin (formerly glyceryl guaiacolate)
 - May be used to make secretions more fluid and reduce sputum thickness
 - Useful when drainage of secretions is important, as with sinusitis
- Saline solutions
 - Safe adjunct to primary therapy
 - Water is the most effective expectorant because expectorants work by increasing the fluid content of secretions.
 - Administration via nasal spray, inhalation, or orally
- Older expectorants
 - Potassium iodide
 - Ammonium chloride
 - No longer prescribed to children because of their adverse effects when used at effective doses

Mucolytic agents

- Acetylcysteine
 - Previously used as a mucolytic agent to help liquefy thick secretions, especially in such diseases as cystic fibrosis
 - Its propensity for inducing airway reactivity and inflammation has made it less popular.

Cough suppressants

- Peripheral agents
 - Can be effective in transiently decreasing cough severity and frequency
 - Demulcents (eg, throat lozenges) soothe the throat.
 - Topical anesthetics can be sprayed or swallowed; effects are short-lived, as oral secretions rapidly wash them away.
- Centrally acting agents
 - Narcotics
 - Effective narcotic agents commonly used in children include hydrocodone and codeine.
 - The metabolic clearance pathway of codeine in infants is immature and data for adults should not be extrapolated to children, particularly those <2 years.

- Hydrocodone has a greater risk of dependency and no demonstrated advantage.
- They should be used in older children with appropriate instructions and caution to avoid overuse or abuse.
- Nonnarcotic medications
 - Dextromethorphan
 - Despite evidence in adults, proven efficacy data in children are lacking.

Decongestants (pseudoephedrine)

- Topical or systemic
- Decreases nasal mucosal swelling
- Facilitates sinus drainage
- May work well in combination with expectorants to optimize treatment of chronic sinusitis
- Care should be taken in the use of these agents because:
 - When used in excess, they have been shown to lead to tachyarrhythmias.
 - Topical nasal decongestants can cause rhinitis medicamentosa.
 - They have not been studied in younger children.
 - They should be avoided in children <2 years.
 - Use should always be limited to short periods to minimize these risks.

Antihistamines

- Can be helpful in the treatment of cough triggered by allergy
- Minimal effect when cough is the result of viral or bacterial infection

- May be detrimental because they can increase the thickness of secretions.
 - First-generation histamine₁-receptor antagonists may decrease nasal drip by exerting an anticholinergic effect.
- Diphenhydramine may have a modest direct effect on the medullary cough center.
 - The clinical benefits of these findings are unclear.

Bronchodilators

- Therapeutic trial of treatment with a β_2 -agonist may be a reasonable first step in suspected airway hyperreactivity.

WHEN TO REFER

- When cough persists despite adequate therapy
- When cough recurs more than every 6–8 weeks
- When associated with failure to thrive
- When associated with other systemic illness

WHEN TO ADMIT

- When the patient has respiratory distress
- When the infant cannot feed
- When associated with bacterial pneumonia not responsive to an oral antibiotic trial

Cross-Sex Behavior and Gender Identity Disorder

DEFINITION

■ Gender-variant behavior

- Display of behaviors, attitudes, or interests outside the cultural norm for the child's biological (genetic/anatomic) sex
 - Boys who prefer playing house, enjoy dressing up in their mother's clothes or trying on their makeup, prefer long hair, and are more stereotypically feminine in their mannerisms and speech
 - Girls who avoid wearing girls' clothes, enjoy more physically aggressive play with boys, prefer short hair, and have the stereotypic mannerisms of a tomboy

■ Gender identity is a person's deepest inner sense of being female or male, often established by age 2–3 years.

- Incongruent with biological sex for some
- Different concept from sexual orientation

■ *Transsexual* or *transgender* refers to an inner identity of the opposite gender or a sense of gender separate from female or male.

- Transsexual persons
 - Gender identity does not match biological gender.
 - Seek to physically change their bodies to be consistent with their inner sense of gender
- Cross-dressers (transvestites), drag kings and queens, and persons who perceive themselves to be of both genders
- Individuals who are simply gender nonconforming in terms of attitudes, interests, and behaviors
- Transgender individuals often refer to themselves as *trans*, *TG*, or *T*.
- Many experience significant gender dysphoria: persistent discomfort with the gender assigned at birth and accompanying societal gender role expectations.
- Transition occurs when transgender individuals gradually let go of the need to conform to societal expectations of their biological gender and increasingly present themselves in a manner consistent with their gender identity.
 - Male-to-female (MTF) and female-to-male (FTM) transgender describe the direction of transition from biological gender to gender identity.
 - The transition process may include hormone treatment and sex-reassignment surgery.

■ One of the most debated issues related to gender expression and gender identity during childhood and adolescence is whether gender nonconformity, gender-variant behaviors, and transgenderism are causes for concern.

- Is it a pathological abnormality or simply part of the continuum of normal human development?
 - Similar debates occurred around homosexuality until it was officially removed from the American Psychiatric Association's list of mental disorders in 1973.

- Gender identity disorder (GID): Although controversial, transsexualism is listed in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* under the diagnostic category of *gender identity disorder*. See Diagnosis for listing of 4 criteria for diagnosis of GID.

EPIDEMIOLOGY

■ Prevalence

- Occasional or single gender-variant behaviors among elementary school children are common.
- During development of the Child Behavior Checklist, mothers of 4- to 5-year-old children reported:
 - 6% of boys and 11.8% of girls sometimes or frequently behaved in a manner more typical of the opposite sex.
 - 1.3% of boys and 5.0% of girls sometimes or frequently wished to be the opposite sex.
- The prevalence of transgenderism is uncertain.
 - Few people seek hormonal and surgical sex reassignment.
 - Some transgender individuals do not have access to, or do not want, sex-reassignment treatments.

ETIOLOGY

- No clear biological marker for GID has yet been found.
- Possible causes for development of gender-variant behavior and transgender identity
 - Animal studies suggest an influence of prenatal hormones.
 - Studies of girls exposed to large levels of androgens prenatally (congenital adrenal hyperplasia) found that the girls had more masculine gender roles than those of peers.
 - Exposure to subtle changes in prenatal androgens during fetal psychosexual development may result in gender-variant behavior and transgender identity.
 - Some studies, mostly in boys, have found an association between GID and:
 - Handedness
 - Sibling sex ratio
 - Birth order
 - Birth weight
- Psychosocial theories (controversial)
 - Familial, particularly parental, psychopathology
 - Predisposal because of aberrant parenting practices
 - These theories are criticized because they appear to identify presumed negative factors (eg, parental failure to discourage a son's feminine behaviors) that might be modified through family therapy to prevent undesirable gender-variant behaviors in a child.

RISK FACTORS

- Any gender-variant child or adolescent raised in a society that enforces a binary view of gender will predictably experience discomfort related to gender expression and identity.
- Given the overt discrimination and violence against transgender individuals in US society, distress or impairment in social and other areas of function should be expected.
- Evidence suggests that transgender individuals growing up in more accepting societies experience less discomfort and distress related to gender identity and gender role than those in the US.

SIGNS AND SYMPTOMS

- 4 criteria for diagnosis of GID
 - Evidence of strong and persistent cross-gender identification (eg, desire to be or insistence that one is of the other sex)
 - Persistent discomfort with assigned sex or a sense of inappropriateness of assigned gender role for that sex
 - No concurrent physical intersex condition (eg, androgen insensitivity syndrome, congenital adrenal hyperplasia)
 - Evidence of clinically significant distress or impairment in social, occupational, or other important areas of functioning
- Based on these criteria, GID would not be diagnosed in a child or adolescent with gender-variant behaviors who identifies with the gender assigned at birth.
- Some signs include:
 - Wearing clothes or exhibiting behaviors or interests typical of the opposite gender
 - This may or may not relate to the child's gender identity.
 - Some may have begun the transition process.
 - Come to the clinic displaying dress, hairstyles, makeup, and mannerisms usually associated with the opposite gender but consistent with gender identity
 - Occasionally wear non-gender-defining street clothes but underwear appropriate for gender identity
 - Patients who have begun transition hormone treatment may show:
 - Evidence of breast development (MTF)
 - Appearance of facial hair (FTM)
 - Other expected changes of estrogen and testosterone treatment (see Specific Treatments)
 - Significant discomfort related to pubertal changes, which feel alien to gender identity
 - MTF-transgender adolescents may tuck their genitals, placing them between their legs so they are less visible.
 - FTM-transgender youths may wear chest binders or baggy tops to make their breasts less visible.

- Comorbid mental health problems, including:
 - Depression
 - Separation anxiety
 - Behavior problems
 - Distress/mental health problems that may result from stigmatization, peer rejection, and discrimination
- Results of violence/fear for own safety
- Sexually transmitted infections (STIs)
 - Can result from promiscuity (eg, in runaways)
- Multisubstance use

DIAGNOSTIC APPROACH

- Physicians should not presume the sexual orientation or gender identity of any patient.
- Many transgender youths hide their true gender identity; the physician must watch for:
 - Fears of primary care physician (PCP) disapproval
 - Uncertainty about confidentiality
 - Confusion about the meaning of their emerging feelings
- Mistaken assumptions
 - That no children in a practice are dealing with issues of gender identity
 - That significant gender-variant behavior in childhood accurately predicts sexual orientation
 - That transgender youths are gay, lesbian, or bisexual
 - An MTF-transgender adolescent who falls in love with a boy is considered heterosexual.
 - That gender identity predicts sexual orientation
- It is important to make distinctions between sexual orientation and gender identity for the provision of care.
- PCPs should reflect on their own feelings about gender-variant behaviors/gender identity issues.
 - Discomfort or disapproval will diminish the ability to care for these patients.
 - Should receive training about transgender health issues
 - Need to provide care that addresses the patient's needs in a compassionate and comprehensive manner
- At a well-child visit, beginning in early childhood:
 - Ask parents how they think their child is developing compared with other children.
 - Ask parents and child how the child is getting along with siblings and peers.
 - See whether the child appears happy.
 - All parents should be asked whether they have concerns with child's sexual development or gender expression.
 - Many parents are hesitant but relieved when the PCP brings the topic up.

- If a child with gender-variant behavior is happy and safe and parents have no concerns, no reason exists to question further.
- If parents express concerns, the PCP should ask what they have noticed or heard from the child and what their concerns or fears might be.
- PCPs may gently question a gender-variant child:
 - To see whether the child feels safe from teasing at home and school
 - About the child's feelings of being more like a girl or a boy inside
- Care must be taken to avoid conveying that anything is wrong with a child because of gender variance.
- At each well-teen visit
 - Initiate a discussion of sexuality, including sexual orientation and gender identity.
 - In broader context of HEEADSSS (home, education, eating, activities, drugs, sexuality, safety, and suicide) interview
 - Acknowledge that sexual feelings can be confusing.
 - Ask about attractions (sexual orientation), and ask, “And how about inside? Does it seem to feel more like a girl or a boy or maybe somewhere in between?”
 - Let the patient know that you are available to talk.
- For adolescents who acknowledge transgender identity:
 - Thank them for their trust.
 - Reassure them about confidentiality.
 - Ask what they know about gender identity and what it means to be transgender.
 - Ask if they have told others about their inner feelings of gender.
 - Have they been scolded, teased, harassed, or ridiculed?
 - With whom do they spend time, and what kinds of things do they do together?
 - Have they been in relationships, and have they been healthy ones?
 - Have they been sexually active, and do they use safe-sex practices?
 - Ever been pregnant
 - Ever impregnated anyone
 - Ever had an STI
 - How many different sexual partners and their gender
 - Ever been touched sexually or forced to have sex without permission
- Recommendations for examination
 - Prior to examination, discuss the rationale for suggesting areas that might be uncomfortable for a transgender adolescent, eg, breast and genital examinations.
 - Explain that the intent is to make the examination as comfortable as possible and to elicit the patient's guidance in how best to accomplish this task.
 - Inform patients that they have a right to refuse any part of the examination.
 - Ask transgender patients what words they would like used in referring to various body parts.
 - *Genitals* instead of *penis* or *vagina*
 - FTM-transgender patient, *chest* rather than *breast*
 - MTF-transgender patients should be treated like other female patients.
 - FTM-transgender patients should be treated like other male patients.
 - Drape the patient in a gown to minimize exposure.
 - Acknowledge that anatomic gender may suggest gender-specific evaluation, such as breast, testicular, or pelvic examination, is appropriate.
 - Most transgender patients agree to a suggested examination if the medical rationale is presented in a factual and respectful manner.
 - Invite questions/input on how to make the examination as comfortable as possible.
- Questions to ask transgender individuals
 - Have you run away from home or dropped out of school?
 - Have you needed to sell your body, deal drugs, or engage in other illegal activities to survive?
 - Have you been involved with child welfare or juvenile justice system, and how have you been treated within that system?
 - Have you ever used drugs or contemplated suicide?
 - How has your physical health been, and do you have any health needs you believe are not being addressed?
 - Finally, have you begun transition process, MTF or FTM?
 - Have you chosen a new name, and would you like the PCP to call you by that name?
 - Have you begun to cross-dress?
 - Have you begun hormone therapy?
 - If so, where have you obtained hormones?
 - Have you injected silicone?
 - Have you thought about sex-reassignment surgery or other transition-related procedures?

LABORATORY FINDINGS

- No special laboratory evaluation is needed when there is an unremarkable history and normal physical examination.
- Laboratory evaluation of transgender adolescents should be based on:
 - Accurate and comprehensive history, including sexual and other risk behaviors
 - Physical examination
- Evaluation for STIs if engaged in sexual activity

TREATMENT APPROACH

- There is a growing belief that gender-variant children should be permitted to express gender-variant behaviors and identities freely and without shame.
 - Some investigators believe that a GID diagnosis has been used as an indirect means of treating children to prevent development of a later homosexual orientation.
 - Much research pathologizes gender-variant behavior and transgenderism.
 - Has not invited study subjects into a discussion of what research questions are important and how study results are to be interpreted and used
 - By trying to answer the question, “What went wrong?” the focus on individuals and their families is likely misdirected.
 - The most important questions may be found by observing gender-variant children and families within the context of a disapproving and often violently retributive society.
- The goal of care is to promote optimal:
 - Physical development
 - Emotional development
 - Social development
 - Well-being
 - PCPs are challenged to achieve this goal within a context of nonacceptance and stigmatization by many in society.
- PCPs should focus on risks that transgender youths face, but also identify specific strengths.
- Listen carefully to understand patients’ unique experience and needs; counseling of gender-variant and transgender youths will address:
 - Self-acceptance and validation of gender expression and identity
 - Safety
 - Ways to connect to support groups
 - Self-disclosure or coming out
 - Healthy relationships and sexual decision making
 - Optimism for the future

- Acknowledge the controversy around the use of GID as a diagnostic category.
 - Inform the patient that many professionals disagree that being transsexual or transgender is a disorder.
 - Reassurance of health rather than disorder
- Provide transgender youths with information on sexual orientation, gender identity, and being transgender.
 - Assure that confusion about being gay, bisexual, straight, transgender, or a combination of these is normal.
 - Connect ethnic and other minority youths who are transgender to appropriate supportive resources within their communities.
- Check on safety.
 - At home, school, or church; within the peer group; and within the broader community
 - Work to help identify and implement appropriate strategies to end violence.
 - Tell patients they should expect safety and respect.
 - Offer to join with them where they experience violence, including the home and school, to work out a plan to end violence immediately and completely.
 - If necessary, call on state child protective services or advocacy organizations, such as the American Civil Liberties Union.
- Never reveal gender identity to the parents without the permission of the child unless risk of harm exists.
- Help adolescents decide whether they are ready to come out to family or friends, and help them choose:
 - Appropriate time
 - Appropriate place
 - Approach for disclosure
- Create a safe, accepting clinical setting where patients and families know they can discuss gender identity/expression.
 - Specific messages can be provided through clinic posters and brochures.
 - History taking and anticipatory guidance should include issues of child and adolescent sexuality and gender.
 - After patients have identified themselves as transgender, use pronouns consistent with patients’ gender identity; ask what name they would like to be called by clinic staff.
 - Medical records must retain patients’ legal names, but add “Also Known As [preferred name]” to front of the chart; staff members should use these names with patients.
 - Patients should use either a unisex restroom or a restroom consistent with their gender identity while in the clinic.
 - Transgender patients should be seen alone and their confidentiality respected.

- Ask patients how they want gender identity recorded in the chart, if at all, because records containing confidential information may be accessible to parents.

SPECIFIC TREATMENTS

Suppression of puberty

- In cases where physical changes of puberty are very distressing to transgender youths, protocols exist to suppress progression of puberty.
 - Allows time for later decisions about hormone therapy or surgery
 - Gonadotropin-releasing hormone analogue
 - For patients ≥ 12 years of age with a sexual maturity rating of 2 or 3
 - If the adolescent later decides not to pursue hormone therapy or surgical sex reassignment, suppression can be discontinued.
 - If at age 16 years adolescent wishes hormone treatment, estrogen or testosterone can be added to gonadotropin-releasing hormone analogue to initiate pubertal changes consistent with gender identity.

Elective process for transition after GID diagnosis

- Transition represents emotional, psychological, social, physical, and legal processes that transgender persons experience to assume a body and role consistent with gender identity.
- PCPs play an important role in facilitating the patient's transition FTM or MTF, either by referring patients or by providing transition medical care and counseling themselves.
 - Pediatric PCPs generally refer transgender patients for transition-related care and counseling but retain a central role as PCP.
 - Providers of transition medical care and supportive counseling to transgender patients can be located through local gay, lesbian, bisexual, and transgender centers or national organizations, such as the Gay and Lesbian Medical Association.
 - Adolescent medicine
 - Family practice
 - Internal medicine physicians
 - Mental health care providers
- 3 stages
 - Real-life experience consistent with gender identity
 - Hormones of the desired gender
 - Surgery to change genitalia and other sexual characteristics
- Requirements for initiating hormone treatment
 - Minimum age of 16 years (preferably with parental consent if < 18 years)

- Involvement of mental health professional with both patient and family for ≥ 6 months
- Letter authorizing hormone treatment from patient's therapist to physician
- Plan for monitoring by physician and therapist of adaptation to physical and psychosocial changes

- Transition is not the same for everyone.
 - Some individuals are satisfied to live their lives consistent with their gender identity in a social sense but have no urge to initiate hormone therapy or undergo surgery.
 - Others seek hormone treatment but think that surgical alteration is unnecessary.
 - Others choose partial surgical gender reassignment.
 - Many FTM transgender individuals choose mastectomy but not genital reconstruction.
 - The transition process is not necessarily linear.
 - Some individuals move back and forth between feeling more feminine or masculine.
 - May present themselves differently to the world at different times
 - This fluidity of identity should be expected and supported by the PCP.

Hormone treatments for transition

MTF transition

- Estrogen
 - Oral, injectable, transdermal forms
 - Expected changes
 - Breast development
 - Softening of skin
 - Increase in subcutaneous fat and its redistribution to the thighs and buttocks
 - Diminished body hair
 - Fewer erections
 - Testicular atrophy
 - Possible infertility
 - Possible, sometimes permanent changes
 - Decreased libido
 - Weight gain
 - Emotional changes
 - Medical contraindications to estrogen treatment in adolescents are rare.
- Antiandrogens, such as spironolactone, may be added to:
 - Suppress the action of endogenous testosterone
 - Augment breast development
 - Soften facial and body hair

FTM transition

■ Testosterone

- Injection, patch, and topical gel forms
- Expected changes
 - Increased facial and body hair
 - Clitoral enlargement
 - Cessation of menses
 - Possible infertility
 - Increased acne
 - Male-pattern baldness
 - Deepening of voice
 - Redistribution of fat and increased muscle mass
- Possible changes
 - Increased libido
 - Mood changes
 - Increased weight
 - More prominent veins
 - Coarser skin
 - Mild breast atrophy

Other treatments

- Occur post-adolescence (expensive and seldom covered by insurance)
 - MTF-transgender individuals
 - Reconstructive surgery
 - Orchiectomy
 - Vaginoplasty
 - Breast augmentation
 - Tracheal shaving
 - Facial reconstruction
 - Electrolysis or other hair-removal procedures
 - FTM-transgender individuals
 - Chest reconstruction surgery
 - Hysterectomy, oophorectomy
 - Genital reconstruction
 - Voice therapy
 - Professional guidance in how to present themselves to the world
 - Discussing these or making appropriate referrals should be part of the PCP's anticipatory guidance.

WHEN TO REFER

- When an adolescent has acute or recurrent suicidal ideation
- When an adolescent is engaged in multiple high-risk behaviors

- When the PCP believes that time, expertise, or comfort is insufficient to provide care and counseling to gender-variant children and transgender youths
- Referral should be made only to health care providers and counselors who have:
 - Experience in working with gender-variant children and transgender youths *and*
 - Who accept gender variance as normal
- Referrals for therapy to change a child's or adolescent's gender expression or gender identity are unethical and potentially harmful.

FOLLOW-UP

- Refer parents to Web sites, mailing lists, and brochures geared to parents of gender-variant children.
- Discuss gender variance and its possible causes with parents.
 - Many, but not all, boys with gender-variant behaviors identify themselves as homosexual as they grow older.
 - Most, but not all, girls with gender-variant behaviors identify themselves as heterosexual or bisexual as they grow older.
 - A few may eventually seek hormone therapy or surgery to make their biological gender more consistent with their inner gender identity.
 - Recommend that parents avoid efforts to change a child's behavior to conform to stereotypic notions of appropriate behaviors.
- Review the Children's National Medical Center Guidelines with parents.
 - Love and accept your child.
 - Do not allow societal expectations to come between you and your child.
 - Create a safe space, especially in the child's home.
 - Seek out socially accepted activities (sports, arts, hobbies) that respect the child's interests while helping the child fit in socially.
 - Validate the child's interests.
 - Speak openly and calmly about gender variance in positive terms, and listen as child expresses feelings of being different.
 - Seek out supportive resources (books, videos, Web sites, support groups).
 - Talk about gender variance with other significant people in the child's life.
 - Siblings
 - Extended family members
 - Babysitters
 - Family friends

- Prepare for bullying.
 - Let the child know that he or she does not deserve to be hurt.
 - Be aware of behaviors that suggest that bullying may be occurring.
 - School refusal
 - Crying excessively
 - Complaining of aches and pains
- Be the child's advocate.
 - Parents should insist on acceptance, respect, and safety wherever their child is.
 - Parents may need to educate school staff and others about the special experience and needs of gender-variant children.
- Advise parents to avoid these pitfalls.
 - Avoid finding fault.
 - No blame exists.
 - The child's gender variance came from within, not from them as parents.
 - Blame will get in the way of enjoying their child.
 - Do not pressure the child to change, because this will cause much pain and harm.
 - Do not accept bullying as just the way things are.
 - No one has the right to torment or criticize others because they are different.

COMPLICATIONS

- Many transgender individuals experience daily verbal, physical, and sexual harassment.
 - Often not addressed, or even encouraged, by teachers, counselors, or school staff
 - Most schools have no policies prohibiting harassment or bullying based on gender identity.
- Broader societal forms of discrimination
 - Common forms of identification and personal records usually reflect biological sex rather than gender identity.
 - Fear, embarrassment, and potential humiliation accompanying presentation of these documents to others may prevent transgender individuals from applying for school, a job, or health care.
- Rejection or violence within families lead many to be thrown of the home out or to run away.
 - Youths often survive by exchanging sex for money, drugs, or shelter.
 - At high risk for STIs, infection with HIV, physical and sexual assault
 - Multisubstance use

- May be sheltered by transgender adults; often a conduit to:
 - Commercial sex work
 - Substance use
 - Underground acquisition of transition hormones or injectable silicone
- Many attempt suicide.

PROGNOSIS

- Boys with GID
 - Most eventually self-identify as homosexual or bisexual and no longer report gender dysphoria.
 - A small percentage later self-identify as heterosexual and report no gender dysphoria.
 - Approximately 15% continue to experience discomfort with their biological sex and self-identify as transgender.
- Girls with GID
 - Most eventually self-identify as heterosexual or bisexual.
 - A small percentage report being homosexual.
 - Only a small percentage continue to have gender dysphoria.
- Most children with significant gender-variant behaviors eventually identify themselves as gay, lesbian, or bisexual.
 - Most experience significant confusion and distress.
 - In our society, many feel overwhelming shame, anger, self-hatred, and despair.
 - Often experience profound isolation that intensifies feelings of confusion and distress
- Discrimination, stigma, violence
 - Completing the developmental tasks of childhood/adolescence related to identity and self-esteem is enormously difficult.
 - Many are viewed by their families with shame and disgust; they often are forced to renounce their declared inner sense of being female or male.
 - Many run away from or are thrown out of their homes.
 - Many end up in the child welfare or juvenile justice systems.
 - Harassment/abuse often continues in these settings, perpetrated by other youths and by staff members.
- PCPs should challenge the belief of many transgender adolescents that their futures will be significantly limited by their gender identity.
 - Although some communities are more accepting of transgender people than others, many transgender adults lead happy, healthy, and productive lives.
 - Although growing up transgender is often challenging, the future should be seen as hopeful and exciting.
 - If provided with loving, supportive validation, they can expect to grow into happy, healthy, and productive adults.

Croup (Acute Laryngotracheobronchitis)

DEFINITION

- Viral croup, also known as *acute laryngotracheobronchitis*, is an age-specific viral syndrome characterized by acute laryngeal and subglottic swelling, resulting in:
 - Hoarseness
 - Cough
 - Respiratory distress
 - Inspiratory stridor
- *Spasmodic croup* is a term sometimes used to denote afebrile episodes of croup that may be recurrent.
- In the past, membranous croup was commonly referred to as *diphtheria*.
 - Until the 20th century, considered the cause of most croup cases
 - Occasionally, the term *membranous croup* is still used for croup-like cases caused by bacteria.

EPIDEMIOLOGY

- Prevalence
 - Accounts for approximately 10–15% of respiratory tract disease in children
- Incidence
 - 7 per 1000 children <6 years of age annually in a prepaid group practice in Seattle
 - Between 1 and 2 years of age, this incidence approximately doubled.
 - In a Chapel Hill, North Carolina, practice, the annual incidence per 100 children for all ages was 1.82 for boys and 1.27 for girls
 - The attack rate during the 2nd year of life was 4.7 per 100 children per year.
 - Hospital admissions from croup in the US have been declining since the 1990s, despite concurrent increase in the population of young children.
 - Most likely explained by the improved and more widely used therapeutic modalities of corticosteroids and nebulized epinephrine
- Age
 - Primarily in children between 3 months and 3 years of age
 - Peak incidence between 6 and 24 months
 - A 14-year Canadian study showed that the rates of hospitalization for croup were highest in the 1st year of life.
- Sex
 - Boys seem to be more susceptible to croup than girls.
 - Among both hospitalized and ambulatory croup cases, the ratio of boys to girls is approximately 2:1.
- Seasonality
 - Seasonal patterns of croup correlate closely with activity of the major viral agents causing the syndrome (see Etiology).

ETIOLOGY

- Inflammation at the subglottic area can cause marked airflow obstruction.
- The anatomy of the cricoid and thyroid cartilage make this area the narrowest and least distensible part of the larynx.
- Inflammation, however, commonly affects the conducting airways at all levels.
- Airway hyperreactivity resulting from allergens may play a role in predisposing these children to repetitive bouts of croup.
- Most frequent cause
 - Parainfluenza types 1 and 2: biennial epidemics in the fall
 - Parainfluenza type 3: annual spring outbreaks, extending into summer, early fall
- Frequent cause
 - Influenza A: epidemic, winter
 - Influenza B: epidemic, winter
 - Respiratory syncytial virus: epidemic, winter and spring
- Less common
 - Human metapneumovirus: winter and spring
 - Adenoviruses: endemic
 - Picornaviruses: fall, spring-summer
 - Coronaviruses: winter and spring
- The age predilection of viral croup can be partly explained by the anatomic features of the airway.
 - Smaller airways are prone to greater degrees of obstruction from inflammation of the lining membranes.
 - Resistance to airflow is inversely related to the 4th power of the radius of the airway.
 - Subglottic trachea of a young child is relatively smaller and more pliable than that of an older individual.
 - Narrowing that occurs with inspiratory effort may therefore be exaggerated in a young child with croup.
 - In addition, obstruction above the subglottic area, as may occur with nasal congestion, increases collapsing force, and increased respiratory rate associated with crying or anxiety may compromise ventilation further.

RISK FACTORS

- Respiratory syncytial virus tends to cause croup in younger children, primarily in the 1st year of life.
 - Often results in prolonged symptoms and hospitalization
- Parainfluenza viruses cause croup predominately in toddlers but may infect younger or school-age children.
- Genetic, immunologic, and other mechanisms are likely to contribute to the development and severity of croup.
 - Atopy or hyperreactivity of the airways has been suggested as playing a role in spasmodic or recurrent croup.
 - Higher incidence of a family history of allergy and positive skin tests for allergens in such children.

- The role of genetic and anatomic factors is supported by studies of lower respiratory tract disease, in which children enrolled at birth were monitored through 13 years of age with periodic pulmonary function tests and markers of atopy.
 - The group with wheezing had significantly lower indices of intrapulmonary airway function as infants, before any lower respiratory tract illness, and increased risk of persistent wheezing in later life.
 - Among children who subsequently developed croup without wheezing or those who never developed croup, premorbid inspiratory resistance was significantly higher.

SIGNS AND SYMPTOMS

- Viral croup typically includes signs of an upper respiratory tract infection for 1–2 days.
- This period is followed by characteristic cough, indicating the progression of infection.
 - Cough may be spasmodic, with a deep brassy or harsh barking quality.
- Laryngitis with a raspy-sounding voice may develop.
- Fever is commonly present, particularly with influenza and parainfluenza viral infections.
 - Temperature often reaches 103°F–104°F.
 - Patients with higher temperatures and more toxic appearance should be suspected of having bacterial tracheitis.
- Child may awaken at night with:
 - Spasms of the cough
 - Acute onset of respiratory distress and inspiratory stridor
- On physical examination, distress is most evident during inspiration.
 - Each inspiratory effort is marked audibly by the stridulous sound and accentuated visibly by retractions of accessory chest wall muscles.
 - Suprasternal, supraclavicular, and particularly substernal retractions are characteristic of the inspiratory obstruction.
 - Distress may be marked by asynchronous movements of the chest wall and abdomen.
- Respiratory rate is increased but usually not >50 breaths/min.
 - Unlike bronchiolitis, in which respiratory distress may be accompanied by respirations of 80–90 breaths/min
- Auscultation of the chest reveals prolonged inspiration, often accompanied by coarse crackles.
 - Wheezes and rhonchi may also be heard on expiration.
 - With more severe obstruction, breath sounds may be diminished.
- Cyanosis may occasionally be noted, particularly around the lips and nail beds.

- Varying intensity of respiratory distress is characteristic.
 - In some children, the symptoms appear to abate on waking in the morning but may worsen again as the day progresses.
 - For most, signs of croup extend over 3 or 4 days, but upper respiratory tract signs and cough may last longer.
 - In a few children, respiratory distress may be unremitting or associated with significant pneumonitis and hypoxemia.

DIFFERENTIAL DIAGNOSIS

- Viral croup must be differentiated from the 2 bacterial causes of stridor.
 - Bacterial tracheitis
 - Epiglottitis, which may be fatal without immediate therapy
 - Rare since conjugated *Haemophilus influenzae* type b vaccines became available
- Differentiating characteristics of epiglottitis
 - Rapidly progressive and unrelenting course, drooling, toxic appearance
 - Coryza and barking cough characteristic of viral croup usually are not present with epiglottitis.
- Infectious causes of stridor
 - Epiglottitis
 - Bacterial tracheitis
 - The second emergent entity that needs to be differentiated from viral croup
 - Relatively uncommon and may affect children of any age, sometimes occurring after an episode of viral croup
 - Onset is acute with respiratory stridor, high fever and, often, copious and purulent secretions.
 - The child appears toxic, and respiratory obstruction rapidly progresses, often necessitating tracheal intubation.
 - Most often involved are *Staphylococcus aureus* and group A β -hemolytic streptococci.
 - Diagnosis may be confirmed by direct laryngoscopy, which shows purulent secretions and inflammation in the subglottic area.
 - Sometimes, lateral neck radiography reveals an area of subglottic narrowing with a shaggy membrane.
 - Human papillomavirus (acquired perinatally)
 - Retropharyngeal and parapharyngeal abscess
 - May occasionally have features similar to croup
 - Should be especially considered in a child with a history of a penetrating pharyngeal injury, eg, by a fishbone
 - Usually preceded by mild pharyngitis and more gradual in onset than croup
 - The child may be febrile, with sore throat and difficulty in swallowing.

- Stridor is not usually present until disease has markedly progressed.
- Important differential findings include muffled voice, head held in a position allowing extension of the neck, resistance to oropharyngeal examination, and progressive drooling and visible asymmetry to the wall of the posterior oropharynx.
- Diphtheria may be excluded by:
 - History of adequate immunizations
 - Absence of characteristic gray pharyngeal or laryngeal diphtheritic membrane
- Other infectious agents that may mimic croup are now rare.
- Noninfectious causes of stridor, many of which can be differentiated by thorough history
 - Foreign body aspiration
 - Abrupt onset of stridor
 - Respiratory distress
 - Lack of preceding respiratory symptoms
 - Fever
 - History of previous choking on food or foreign body
 - Acute edema of upper respiratory tract caused by an allergic reaction
 - May cause abrupt swelling and severe respiratory distress with stridor
 - Lack of previous respiratory signs
 - Concurrent onset of other manifestations of allergic reaction, eg, swollen lips and tongue and urticaria
 - Vocal cord paralysis
 - Angioneurotic edema of upper airway
 - Hypocalcemic tetany
 - Congenital malformations of upper airway
 - Laryngotracheal malacia, web, cleft
 - Vascular ring
 - Tracheal stenosis
 - Hemangioma, cyst of larynx or trachea
 - Cystic hygroma
 - Trauma

DIAGNOSTIC APPROACH

- Croup is usually diagnosed on the basis of characteristic clinical findings and a compatible history.
- History is integral in:
 - Diagnosing viral croup
 - Assessing the severity of the illness on which the management depends

- Carefully obtain:
 - Prodromal signs
 - Characteristics of the onset of illness
 - Course of the development of the respiratory signs
- A child may be at an increased risk for severe disease if there is evidence of:
 - Atypical onset
 - Rapidly progressive illness
 - History of recurrent episodes of illness with respiratory distress
 - Underlying condition

LABORATORY FINDINGS

- Laboratory testing is usually not necessary for most outpatients.
- Testing may upset the child, causing an increased respiratory effort, further subglottic narrowing, and obstruction to airflow.
- In severe cases, measurement of oxygen saturation may detect hypoxemia.
- If the child's appearance or history, suggests dehydration, serum chemistries may be warranted.
- Leukocyte count and differential are not usually helpful.
 - Total leukocyte count may be normal or low from viral infection.
 - However, a shift to the left with increased number of neutrophils and band forms may also occur in more distressed and hypoxemic children or, infrequently, may suggest bacterial infection.
- Multiple laboratory assays are available to determine the specific viral agent; however, specific diagnosis of the viral agent usually is not necessary.
 - Viral isolation
 - Rapid antigen detection techniques, such as immunofluorescence assays and enzyme immunoassays
 - Methods to detect viral RNA, as by reverse transcriptase polymerase chain reaction
- In some instances, determination of the specific viral cause may help determine infection control procedures or need for antiviral therapy.

IMAGING

- Imaging is not usually necessary in diagnosing or managing children with viral croup.
- In some atypical cases or those likely to be confused with other syndromes characterized by stridor, diagnosis may be aided by:
 - Lateral inspiratory and expiratory radiography
 - May show distension of the hypopharynx

- Posteroanterior radiography of the neck
 - The air shadow of the larynx narrows, resembling an hourglass or a steeple, in the subglottic region as a result of the characteristic inflammation inspiratory lateral view.
 - However, in some instances, the radiograph is not interpretable, or the classic signs may not be evident.

TREATMENT APPROACH

- The first phase of management is to evaluate which children may be managed at home and which require hospitalization.
- Severity is often difficult to determine in this fluctuating disease, and no clinical signs are consistently prognostic of a complicated course.
- Clinical scoring systems, such as the Westley croup score, have been used to aid in the decision as to which children should be hospitalized (see table Clinical Scoring System for Croup).
- Toxic appearance, dehydration, and fatigue are indications for hospitalization.

SPECIFIC TREATMENTS

Supportive care

- Supportive care is of prime importance for both outpatients and hospitalized patients.
- The child should be made comfortable to avoid unnecessary anxiety and fatigue.
- Fluids should be encouraged.
- Antipyretics may be given for fever and to diminish the associated increased respiratory rate and fluid requirements.
- Few other home therapies have proved beneficial; however, because of the variable nature of croup, several unverified therapies may appear to work.

Humidified air

- Water particles from such devices as vaporizers, home-devised mist tents, and showers are generally too large to reach the lower respiratory tract.
 - They generally humidify primarily the anterior nares and oropharynx.
 - Hot water poses the potential hazard of accidental burns
- Cool mist may help cool the airway and may be beneficial to some children with croup.
- Studies in children of the efficacy of humidified air in treating croup are few and involve small numbers of patients; nevertheless, no significant benefit has been shown.

Nebulized epinephrine

- Nebulized epinephrine has been shown to be beneficial for children with more severe croup.

Clinical Scoring System for Croup^a

Category		Score
Level of Consciousness	Normal (including sleep)	0
	Disoriented	5
Cyanosis	None	0
	Cyanosis with agitation	1
	Cyanosis at rest	2
Stridor	None	0
	When agitated	1
	At rest	2
Air Entry	Normal	0
	Decreased	1
	Markedly decreased	2
Retractions	None	0
	Mild	1
	Moderate	2
	Severe	3

^aFrom: Westley CR, Cotton EK, Brooks JG. Nebulized racemic epinephrine by IPPB for the treatment of croup: a double-blind study. *Am J Dis Child.* 1978;132(5):484–487. Copyright ©1978 American Medical Association. All rights reserved.

- Clinical improvement occurs in most cases by reducing degree of stridor and retractions.
- Epinephrine causes diminished subglottic swelling via stimulus of α - and β -adrenergic receptors.
 - Results in decreased blood flow and swelling in the upper respiratory tract
- Racemic epinephrine, which contains both D and L isomers, has been preferably used because it was believed to reduce adverse effects.
 - However, controlled evaluation of the 2 isomers indicated no difference in effect or in adverse reactions.
- Nebulized epinephrine should be used with the understanding that:
 - Amelioration of the clinical signs is transient, and the child again may worsen within 2 to 3 hours.
 - Arterial oxygen saturation is not affected.
 - Nebulized epinephrine should be used only for children with moderately severe or severe croup.
 - These children should usually be concurrently treated with corticosteroids.

Corticosteroid therapy

- The major advance and mainstay in the management of both ambulatory and hospitalized children with viral croup is the use of systemic or nebulized corticosteroids.
 - Multiple well-designed trials have shown that both systemic and nebulized corticosteroid therapy has resulted in significant clinical improvement, decreased hospitalization, and fewer follow-up visits.
 - A recent Cochrane systematic review of 31 studies involving 3736 children found:
 - Significant clinical improvement in the Westley score at 6–12 hours.
 - Benefit by 24 hours was no longer significant.
 - Clinical efficacy did not differ significantly according to the agent or route of administration.
 - Conclusion
 - Dexamethasone and budesonide show clinical benefit as early as 6 hours after administration.
 - Treatment was associated with fewer and shorter hospital stays, return visits, and need for other therapies.
 - Dexamethasone was also effective for mild cases of croup.

Antibiotic therapy

- Because croup is of viral etiology, antibiotics are rarely indicated.
- Secondary or concurrent bacterial infection is unusual, and antibiotics should be reserved for such documented cases.

WHEN TO ADMIT

- When the child appears toxic, lethargic, in respiratory distress, or dehydrated
- When the onset of illness was sudden, with rapid progression of symptoms
- When signs of respiratory distress are unresponsive to outpatient drug therapy

WHEN TO REFER

- When the child has a wheezing condition predisposing to more severe croup
- When the child has history of recurrent episodes of croup
- When the episode of croup occurs during the neonatal period
- When symptoms progress despite supportive care at home

Cystic and Solid Masses of the Face and Neck

DEFINITION

- Cystic lesions are either congenital cysts or vascular malformations.
 - Traumatic hematomas and abscesses may appear to be cystic.
- Solid neck masses usually consist of inflammatory lymph nodes or, rarely, neoplastic lesions.

ETIOLOGY

- Thyroglossal duct cysts
 - Result from failure of the embryologic thyroglossal duct to degenerate during the fifth week of gestation, leaving a fistula, sinus tract, or cyst at the midline of the neck just below the hyoid bone.
- Branchial cleft cysts
 - Congenital remnants of the lateral 4 branchial pouches and clefts
- Causes of cervical lymphadenopathy include:
 - Viral infections of the upper respiratory tract
 - Bacterial infections
 - HIV infection
 - Kawasaki disease
 - Systemic disorders, such as systemic lupus erythematosus, juvenile idiopathic arthritis, sarcoidosis, and histoplasmosis

SIGNS AND SYMPTOMS

History

- The physician should determine:
 - Whether the neck mass was observed at birth
 - Lymph nodes >1 cm rarely appear at birth, whereas many congenital cysts are noted in the newborn period.
 - Some congenital cysts may not be noted until childhood or beyond and are detected only when they become infected.
 - Whether it has increased or decreased in size
 - Whether it has changed color
 - Whether the lesion has drained or opened
- Any history of pain or tenderness is important.
 - Congenital cysts are nontender unless they become infected.
 - Inflamed lymph nodes are tender and painful.
 - Pain during eating suggests parotid gland involvement.
- Infectious processes and cancer may be suggested by:
 - History of fever
 - Other systemic symptoms such as loss of appetite, weight, fatigue, etc.

Physical examination

- The first step in the physical examination is to determine whether abnormalities exist in other parts of the body.
 - Other cysts
 - Lymphadenopathy
 - Hepatosplenomegaly
 - Skin lesions
 - Signs of infection
- The exact anatomic location of the neck mass must be determined.
 - Midline masses usually are associated with a thyroid abnormality.
 - A mass along the anterior edge of the sternocleidomastoid muscle that moves with swallowing or that has a sinus opening to the surface of the overlying skin is likely to be a branchial cleft cyst.
 - The clinician should note whether the mass is in a typical location of a lymph node (see Figure 17 on page F5).
- Characteristics of the mass must be determined.
 - Consistency, color, and firmness
 - Presence of tenderness
 - Size
 - Whether the mass moves or is fixed
 - Masses that move with swallowing or with tongue protrusion suggest a thyroglossal duct cyst.
 - These lesions may be tethered to the foramen cecum by the thyroglossal duct remnant.
 - Both cysts and benign lymph nodes are freely mobile.
 - Malignant lesions are more likely to be fixed to underlying structures.
- Neoplasms may be suspected.
 - Rapidly growing, painless neck masses are worrisome because they may be neoplastic.
 - Additional signs associated with a neoplastic process include:
 - Fixation of the mass to subcutaneous tissue
 - Firm consistency
 - Size >3 cm
 - Presence of constitutional symptoms
 - Supraclavicular nodes are the most likely neck mass to be malignant and should always be investigated.

DIFFERENTIAL DIAGNOSIS

- Major challenges in the differential diagnosis are:
 - Differentiating congenital masses from lymph nodes
 - Determining the type of congenital lesion
- Most neck masses encountered by pediatricians are lymph nodes, not cysts.

- Knowing the location of the different groups of lymph nodes within the anterior and posterior anatomic triangles of the neck is crucial.
- Figure 17 on page F5 shows the location of the major groups of lymph nodes, the sternocleidomastoid muscle, and the typical locations of congenital cysts encountered most frequently.

Congenital cysts

Thyroglossal duct cysts

- Account for >70% of congenital cysts of the neck
- Are not often detected at birth but usually are noted first after 2 years of age
- May show initially as an inflamed, tender mass
- When not infected, they are smooth, firm, mobile, and nontender and move upward with tongue protrusion or with swallowing.
- Differential diagnosis includes:
 - Sebaceous cysts
 - Epidermal cysts
 - Submandibular lymph nodes
 - Lipomas

Branchial cleft cysts

- Account for >20% of congenital cysts of the neck
- Most branchial cleft cysts arise from the second cleft or pharyngeal pouch.
- They appear as a small dimple or opening anterior to the middle portion of the sternocleidomastoid muscle.
- The cyst, located just under the skin, is nontender, firm, and mobile.
- A small sinus, which occasionally drains fluid to the surface of the overlying skin, may be present; a long fistulous tract may extend from it to the tonsil bed.
- Branchial cleft cysts without sinuses often are unnoticed until later childhood, when they become infected.
- Infected cysts can easily be confused with lymphadenitis.

Vascular malformations and other lesions

- Account for 4–5% of congenital cysts of the neck

Other lesions

- Other lesions included in the differential diagnosis
 - Sternocleidomastoid muscle masses associated with torticollis
 - Small cystic hygromas
 - Epidermoid cysts
 - Neurofibromas
 - Lipomas
 - Ectopic thyroid gland
- Other congenital masses occur rarely in the head and neck.

Cystic hygromas

- Congenital, avascular masses derived from congenital obstruction of lymphatic vessels
- Usually multilocular, fluid-filled, soft, compressible, painless masses located in the posterior triangle just behind the sternocleidomastoid muscle and in the supraclavicular fossa
- Occur infrequently in the axilla, on the trunk, or on the extremities
- In older children, when they occur within the subcutaneous tissues, they may be mistaken for a lipoma or a hemangioma.
- Usually can be transilluminated
- May grow rapidly because of accumulation of lymph
 - Can reach an enormous size, compressing important structures and obstructing the airway
- Although diagnosis usually is obvious during the physical examination, smaller cystic hygromas may resemble hemangiomas or other cysts.

Cavernous hemangiomas

- Vascular lesions within the subcutaneous tissues
 - May appear in any part of the body
 - May be difficult to differentiate from congenital cysts
- Often noted in the newborn period
- Enlarge, sometimes rapidly, during the first year of life
- Usually regress spontaneously by school age
- The skin overlying these vascular lesions often is bluish.
- Less firm, more diffuse, and more easily compressible than cystic masses (except for cystic hygromas)
- Unlike cystic hygromas, cavernous hemangiomas do not transilluminate, and their size may increase with crying or straining.

Epidermoid cysts

- Relatively common masses that may arise from an embryologic or fusional defect
- Usually located at midline on the face, most often at the level of the eyebrows
- These small cysts feel doughy and smooth and contain sebaceous material, sometimes even hair, cartilage, or bone.
- One-third are present at birth; the remaining two-thirds appear by school age.

Preauricular cysts and sinuses

- The most common anomalies arising from an embryologic fusion failure of precursor tissues that develop into the external ear
- The sinuses are pinhole-size pits.
 - Usually located anterior to the helix
 - May contain a short sinus tract

- Preauricular cysts often are bilateral.
- They are inherited in an autosomal-dominant manner, with incomplete penetrance, and are found more commonly in blacks than in whites.
- They are a far more common cause of preauricular lesions than are first branchial cleft cysts and sinuses, which are located in the same area.
- Hearing deficit may be associated with these lesions, but their prevalence is unknown.

Solid neck masses

- Cervical lymph nodes
 - Often palpable in normal children
 - Can be distinguished by location, size, shape, consistency, and mobility
 - Enlarged cervical lymph nodes (>1 cm) should be defined further by:
 - Their association with surrounding nodes or generalized adenopathy
 - The presence of an infection of the head or pharynx
 - Localized signs of inflammation and erythema
 - Cervical adenitis typically develops as a swollen, tender, erythematous mass in a child with fever.
 - *Staphylococcus aureus* and *Streptococcus pyogenes* account for 80% of acute unilateral cervical adenitis and usually respond to oral antibiotics, such as a penicillin or cephalosporin.
 - Chronic inflammation of the lymph nodes can be seen with infections such as cat-scratch disease, atypical mycobacterium, and toxoplasmosis.
- Cancer
 - Malignant tumors often are found as a single supraclavicular mass or as multiple or matted masses crossing into both the anterior and the posterior triangles.
 - >25% of children with cancer have a tumor of the head or neck.
 - The most common neck cancers include:
 - Hodgkin and non-Hodgkin lymphoma
 - Lymphosarcoma
 - Rhabdomyosarcoma
 - Fibrosarcoma
 - Thyroid tumors
 - Neuroblastoma

DIAGNOSTIC APPROACH

- Because the causes of neck masses range widely from common inflamed lymph nodes and cysts to rare neoplasms, an orderly approach to the workup and management of a neck mass is needed.
 - The mass must be defined as lateral or midline.

- The exact anatomic position of the mass must be determined.
- Localizing a lateral neck mass further into either the anterior cervical triangle (anterior to the sternocleidomastoid muscle) or the posterior cervical triangle is helpful.

LABORATORY FINDINGS

- A complete blood count and blood culture can sometimes be helpful in assessing a tender, erythematous mass.
- Erythrocyte sedimentation rate may be helpful in differentiating inflammatory or malignant lesions from other lesions, such as cysts.
- Thyroid hormone should be measured if the thyroid gland is enlarged.

IMAGING

- Ultrasonography or computed tomography can determine whether the mass is cystic or solid or whether it extends to deeper structures within the neck.
- Thyroglossal duct cysts
 - Unless normal thyroid tissue is palpable, the presence of the thyroid gland should be confirmed by ultrasonography or technetium scan.
 - What may seem to be a thyroglossal duct cyst may actually be an ectopic thyroid gland; removal would leave the child dependent on thyroid hormone supplementation for life.
- Cystic hygromas
 - Ultrasonography reveals fluid and multiple cystic components, confirming the diagnosis.

DIAGNOSTIC PROCEDURES

- Biopsy (needle or excision) of the lesion may be necessary to establish the diagnosis, especially when a malignant lesion is being considered.

TREATMENT APPROACH

- For children with enlarged cervical lymph nodes and evidence of infection, antibiotic therapy is recommended.
 - The child should be evaluated further and monitored closely until the enlarged node has resolved if:
 - Adenopathy is persistent
 - Inflammation is not present
 - Any characteristics are worrisome (eg, the node is >3 cm, immobile, associated with systemic symptoms, or in an abnormal location)
- Congenital cysts and masses
 - Should be monitored closely by the primary care physician
 - Acute bacterial infections should be treated with systemic antibiotics.

- Thyroglossal duct cysts, branchial cleft cysts, cystic hygromas, and epidermal cysts should be referred to a surgeon who is experienced at excising these congenital lesions.
- Elective surgery before an infection develops is preferable because excision of an entire sinus tract, fistula, or embryologic connection is more difficult after an infection.
- However, many primary care physicians and surgeons prefer to delay surgery until the child is beyond infancy and can better tolerate the procedure.
- Hemangiomas can be observed without referral unless they begin to impinge on vital structures.
 - Hemangiomas that interfere with physiologic functions (eg, blocking the vision, interfering with eating) may be:
 - Treated with glucocorticoid steroids
 - Referred to a surgeon for management

SPECIFIC TREATMENTS

- Thyroglossal duct cysts
 - Because the likelihood of infection is high, thyroglossal duct cysts should be removed surgically.
- Cystic hygromas
 - Because spontaneous regression is rare and the risk of compression of vital upper airway structures is high, surgical removal is indicated.
 - Several procedures often are necessary to remove large lesions completely.
- Cavernous hemangioma
 - Surgery is indicated only for masses that compress vital structures or that cause severe disfigurement.
- Epidermoid cysts
 - Because these cysts may become infected and may form deep tracts, surgical excision is indicated.
- Cervical lymph nodes
 - Lymph node aspiration usually is reserved for patients whose disease does not respond to initial therapy.
 - Incision and drainage may be needed for masses that become fluctuant.

WHEN TO ADMIT

- Infected mass that is unresponsive to oral antibiotics
- Worrisome mass requiring immediate intervention and imaging
- Mass that compromises the airway or other vital structures

WHEN TO REFER

- Congenital cysts or tracts
 - All congenital cysts or tracts should be removed.
- Mass that does not resolve with antibiotic therapy (≥ 2 weeks)
- Mass in the thyroid gland
- Mass in the parotid gland
- Rapidly enlarging mass (>3 cm)
- Mass that is fixed or lymph nodes that are matted
- Mass in an area that causes concern (eg, supraclavicular)
- Abnormal chest radiograph
- Systemic signs and symptoms (eg, fever, weight loss, easy fatigability, hepatosplenomegaly)

FOLLOW-UP

- All cystic and solid masses of neck require close follow-up to make sure that they are not enlarging rapidly and interfering with physiologic functions, such as vision, eating, and speaking.

COMPLICATIONS

- Interference with physiologic functions, such as vision, eating, or speaking
- Compromise of vital structures, such as airways or the carotid artery

PROGNOSIS

- For children with enlarged cervical lymph nodes and evidence of infection:
 - Antibiotic therapy should improve the condition within 7 days.
 - The condition should resolve completely over the next few weeks.
- Cystic lesions have a good prognosis after surgical removal.
- Prognosis for malignant diseases depends on the type of disease and the extent of spread.

Cystic Fibrosis

DEFINITION

- Cystic fibrosis (CF) is an autosomal-recessive disease.
 - Involves both exocrine and endocrine gland dysfunction
 - Involves multiple organ systems, especially the pancreas and lungs

EPIDEMIOLOGY

- Prevalence
 - CF occurs with a frequency of approximately 1:3600 live births in the white population.
 - It is the most common inherited fatal disease in this group.
 - Frequency in other ethnic groups
 - 1:29,000 in black persons
 - 1:6500 in Hispanic persons
- Age
 - The mean age at diagnosis is 3.3 years.
 - The median age at diagnosis is 6 months.
 - 75% of children with CF receive a diagnosis by 2 years of age.
 - When CF was first described in 1938, the median survival for children with CF was <1 year.
 - Today, the predicted median survival for people with CF in the US is >36 years.
 - This demonstrates how dramatically the face of this disease has changed over a relatively short period.

ETIOLOGY

- Mutation of the cystic fibrosis transmembrane-conductance regulator (CFTR) gene causes a change in structure of the CFTR glycoprotein and results in the development of CF.
- The CFTR glycoprotein is located in numerous organs throughout the body, including:
 - Lungs
 - Upper respiratory tract
 - Sweat glands
 - Pancreas
 - Intestines
 - Liver
 - Reproductive tract
- Ineffective mucociliary clearance and other changes predispose CF airways to infection.
- *Pseudomonas aeruginosa* has become the primary pathogen in this disease.
- *Staphylococcus aureus* and *Haemophilus influenzae* are important bacterial pathogens.

- Initially, nonmucoid environmental strains of *P aeruginosa* are detected in patients.
 - The CF airway environment leads to a transition to mucoidy and to a biofilm mode of growth.
 - Accelerates the rate of decline in lung function
- Despite the chronic nature of the airway infection, ongoing neutrophilic inflammation is typical.
 - DNA released from dying neutrophils increases the viscosity of the airway secretions.
 - Impaired ciliary function and tenacious secretions lead to stasis, and the distal airways become plugged.

RISK FACTORS

- Mutation of the CFTR gene
 - >1000 known mutations of the CFTR gene have been found.
 - The birth of a child with CF is often the first knowledge parents have that they carry a mutation.
- Those in the carrier state are asymptomatic.

SIGNS AND SYMPTOMS

Respiratory symptoms

- Patients with CF most commonly have respiratory symptoms.
- Recurrent pulmonary infections in 49% of patients at presentation
- Failure to thrive or malnutrition in 40%
- Steatorrhea or abnormal stools in 32%
- Meconium ileus or intestinal obstruction in 20%
- Family history of CF in 15%

Pulmonary symptoms

- The common pulmonary symptoms at presentation include:
 - A recurrent cough (most common) that is productive of purulent sputum
 - The cough may initially be dry but becomes progressively productive of purulent sputum.
 - Over-the-counter therapies are generally ineffective.
 - Antibiotic treatment produces only transient, partial improvement in the cough.
 - The cough is present both day and night and may be exacerbated by physical activity or by crying in infants.
 - Difficult-to-control wheezing
 - Some children with CF also have asthma.
 - Nasal polyps
 - Recurrent otitis media
 - Sinusitis
 - Pneumonia
- Vitamin deficiency, specifically deficiencies in the fat-soluble vitamins A, D, E, and K

■ Other manifestations of CF that may trigger initial patient encounters include:

- Salt loss syndrome
- Nasal polyps
- Hepatobiliary disease
- Impaired fertility
- Failure to thrive
- Irritability
- Vomiting
- Salt crystals are sometimes caked on the skin

Gastrointestinal manifestations

■ In the pancreas, abnormal electrolyte secretion from the epithelial cells lining the pancreatic ducts results in:

- Dehydration of the ductal secretions
- Blockage of the pancreatic ducts
- Destruction of the pancreatic acini
 - Pancreatic enzyme secretion is significantly decreased.
- Bicarbonate secretion from the pancreatic ducts is also reduced.
 - In 85–90% of patients with CF, this further decreases the effectiveness of the pancreatic enzymes, known as *pancreatic insufficiency* (PI).
- PI results in the malabsorption of:
 - Fat
 - Proteins
 - Carbohydrates
 - The fat-soluble vitamins A, D, E, and K
- Children with PI have difficulty growing and gaining weight.
- Optimization of nutritional status is also essential to maintaining pulmonary function.

■ Patients with PI are at risk for intestinal dysfunction.

- 20% of infants with CF have meconium ileus.
 - Obstruction of the distal ileum with thick, inspissated, poorly hydrated material
- Clinically, newborns exhibit:
 - Delayed passage of meconium
 - Abdominal distention
 - A bubbly or granular-appearing material in the region of the terminal ileum on radiography
- In older children and adults partial or complete obstruction of the small or large intestine may be caused by:
 - Poor hydration of intestinal contents
 - Decreased secretion of pancreatic enzymes
 - Inspissated intestinal secretions
 - Fecal stasis

– Distal intestinal obstruction syndrome (DIOS) may develop as an acute event or may occur chronically, with the following symptoms:

- Vomiting
- Abdominal distention
- Crampy abdominal pain
- Possibly, a mass in the abdomen, most often in the right lower quadrant.
- Patients may continue to pass stool around a partial obstruction.
- Regions of stool retention may serve as lead points for intussusception.
- Some patients experience rectal prolapse secondary to difficulty passing stool and from increased intraabdominal pressure from coughing.

■ Symptomatic liver disease is an uncommon manifestation of CF, with characteristic pathologic findings of:

- Focal biliary cirrhosis with edema
- Chronic inflammatory cell infiltration
- Bile duct proliferation with patchy accumulation of eosinophilic material in the intrahepatic ducts

■ The localization of CFTR to the apical membrane of the intrahepatic bile duct cells suggests that a reduction in CFTR activity in CF may result in dehydration and increased viscosity of the bile.

- May be a key factor in the pathophysiological features of the hepatic disease
- Prolonged jaundice can occur in neonates.
- Some patients may develop fatty infiltration of the liver.
- The characteristic liver lesion in CF is focal or multilobular cirrhosis.
 - Hepatomegaly is detected on examination.
 - The secondary development of splenomegaly suggests the possibility of portal hypertension.
 - Other features of portal hypertension, such as variceal bleeding, have been reported in CF but are relatively rare.

DIFFERENTIAL DIAGNOSIS

■ The differential diagnosis includes:

- Asthma
- Environmental allergies
- Immunodeficiency syndromes
- Ciliary agenesis or dyskinesia
- α_1 -Antitrypsin deficiency
- Foreign body aspiration

DIAGNOSTIC APPROACH

General

- In the majority of cases, no known family history of CF is found.
- Parents often report that their child has had:
 - Recurrent pneumonia
 - Sinusitis
 - Bronchitis
 - Otitis media
 - Pneumonia and atelectasis may have occurred repeatedly in the same area of the lung.
 - A history of nasal polyps without a concomitant history of nasal allergies
 - Changes to the child's nail beds consistent with clubbing
- From the gastrointestinal standpoint, infants with CF are often voracious feeders despite having poor weight gain.
 - The infants' stools are frequent, bulky, loose, and foul-smelling.
 - The stools are so voluminous that they may overflow the diaper.
 - Grease may be seen in the stool; absorbed in the diaper; or, in the case of older children, seen in the toilet bowl.
 - Abdominal cramping and bloating after eating are common.
 - Foul-smelling flatulence may be described.
- Test for CF:
 - Any neonate born with meconium ileus with delayed passage of meconium
 - Any infant or child with rectal prolapse

Vital signs

- Respiratory rates and heart rates should be monitored relative to age-appropriate normal values.
- Fever and exacerbation or progression of the underlying lung disease may elevate both values.
- Oxygen saturation should be assessed at each visit.
- Overnight pulse oximetry or polysomnography should be considered to evaluate for nocturnal hypoxemia and hypercarbia in patients with more advanced disease.

Growth parameters

- At all ages, pay particular attention to growth parameters.
 - Weight, height, head circumference, and weight for length in children ≤ 2 years
 - Weight, height, and body mass index in children >2 years
 - The child's height percentile should be compared with the height percentile predicted from the parental height.

- Concern should arise whenever a child:
 - Fails to gain weight
 - Loses weight
 - Crosses percentiles for height or weight

Head and neck

- Ooscopic examination should be performed at all visits to assess for otitis media.
- Audiometry should periodically be performed if a child has recurrent otitis media or is exposed to frequent doses of aminoglycosides.
- Nasal mucosa should be inspected for discharge, swelling of the tissue, or polypoid tissue.
- Palpation of the sinuses should be performed.
- Examination of the oropharynx should include assessment of the tonsils and the posterior pharynx.
 - Children with CF have similar risk for adenotonsillar hypertrophy as children without CF.
- The posterior pharynx should be checked for exudates emanating from the nasopharynx.

Chest and lungs

- Coughing frequency and the productivity of the cough should be assessed.
 - The child's ability to communicate without coughing, becoming dyspneic, and using accessory muscles is indicative of the status of the lung disease.
 - Auscultation of the lungs may reveal clear breath sounds.
 - With exacerbation of the underlying lung disease, wheezing, rhonchi, or crackles may be heard.
 - As the patient's pulmonary status worsens, these findings may not change with antibiotic therapy.
 - Any clearing that does occur may be short lived.
 - As the lung disease progresses, breath sounds may become globally decreased.
 - Tubular breath sounds may be heard in areas of severe tissue destruction or bronchiectasis and fibrosis.
 - Unilaterally decreased breath sounds should raise concern about development of pneumothorax, particularly in association with an acute onset of dyspnea.
 - Progression of the obstructive component of CF lung disease is increasing hyperinflation of the lungs.
 - The chest may take on a barrel shape with an increased anterior–posterior diameter.
 - Progression of the fibrotic component of the lung disease results in tachypnea and decreased vital capacity.
- ### Heart
- Fixed splitting of the first and second heart sounds, with increased loudness of the second heart sound, may be heard with progression of the lung disease and development of cor pulmonale.

Abdomen

- Infants often have protuberant abdomens.
 - Distention of the abdomen with pain on palpation may be noted in children with acute intestinal obstructions.
- The frequency and distribution of bowel sounds should be assessed by auscultation.
- Palpation should be performed to assess for:
 - Retention of stool, most commonly in the left lower quadrant
 - Tenderness
 - Hepatomegaly
 - Splenomegaly

Genitourinary tract

- Tanner staging should be performed:
 - By direct inspection
 - By having the child indicate his or her developmental status from a series of pictures
- Girls should be questioned about:
 - Onset of menstruation
 - Regularity of cycles
 - Associated symptoms
- All sexually active girls should undergo annual pelvic examination.

Extremities

- Joints should be examined for swelling that may be caused by CF-related arthropathy.
- The digits and nail beds should be examined for clubbing and cyanosis.
- Edema may arise from hypoproteinemia, especially in:
 - Newly diagnosed malnourished infants
 - Patients with end-stage lung disease
 - Patients with cor pulmonale

LABORATORY FINDINGS**General**

- Laboratory tests
 - Increased:
 - Serum pH
 - Bicarbonate levels
 - Decreased serum levels of:
 - Sodium
 - Chloride
 - Potassium
- The diagnosis of CF requires:
 - Either 2 positive sweat tests *or*
 - Genotype analysis revealing 2 CFTR mutations known to cause CF

- Plus 1 of the following:
 - Chronic sinopulmonary disease
 - Gastrointestinal or nutritional abnormalities
 - Obstructive azoospermia in boys
 - Salt loss syndrome
 - CF in a first-degree relative

Sweat testing

- The pilocarpine iontophoresis technique of Gibson and Cooke is the gold standard for the diagnosis of CF.
 - Pilocarpine stimulates the secretion of sweat.
 - The volume of sweat and concentration of chloride secreted are then measured.
 - Sweat testing should be performed in accordance with the Clinical and Laboratory Standards Institute (formerly National Committee for Clinical Laboratory Standards) guidelines.
 - Normal chloride values are <40 mEq/L.
 - Values of 40–60 mEq/L are considered borderline.
 - Repeat sweat testing or genetic testing is required to make a definitive diagnosis.
- For some borderline cases, referral to specialized centers may be needed to confirm or rule out CF.
 - For example, a borderline sweat test result with identification of only 1 CFTR mutation
 - Assess CFTR function by measuring nasal potential difference.
 - Abnormal results on 2 nasal potential difference tests are indicative of CF.
- Chloride values >60 mEq/L are considered diagnostic of CF.
 - Many possible causes of false-positive sweat tests exist.
 - Laboratory error
 - Untreated adrenal insufficiency
 - Autonomic dysfunction
 - Ectodermal dysplasia
 - Glucose-6-phosphate deficiency
 - Hypothyroidism
 - Malnutrition
 - Mucopolysaccharidosis
 - Glycogen storage disease (type 1)
 - Fucosidosis
 - Hereditary nephrogenic diabetes insipidus
 - Mauriac syndrome
 - Pseudohypoaldosteronism
 - Familial cholestasis
 - A repeat confirmatory sweat test should be performed together with genetic mutation analysis.
 - Sweat testing should not be performed before 48 hours of age.

- False-negative values can result from edema, malnutrition, and laboratory error.
- Several CFTR mutations that cause CF can also result in a false-negative sweat test.
- When genetic testing is done to resolve borderline sweat testing or when genetic testing alone is performed:
 - The presence of 2 mutations known to cause CF is required to make the diagnosis.
 - DNA from blood or buccal swabs can be used for genetic testing.

Newborn screening

- Newborn screening for CF is being widely adopted in the US.
 - Evidence of moderate benefits and low risk of harm are justification for screening.
 - Recommended by an expert panel convened by the Centers for Disease Control and Prevention and the Cystic Fibrosis Foundation
 - Evidence exists to support the efficacy of newborn screening in the areas of:
 - Improved nutritional status
 - Cognitive development
 - Economic benefit
 - Improved survival
 - The impact of newborn screening on pulmonary status varies.
 - The benefit of improved height and weight status on pulmonary status is well known.
 - Believed to outweigh variability in data concerning pulmonary outcomes for newborn screening
- Newborn screening for CF is typically a 2-tier test.
 - The first tier involves measuring serum immunoreactive trypsinogen (IRT) levels.
 - IRT values are elevated in newborns with CF.
 - Except in infants with meconium ileus, when IRT levels are low
 - All infants with meconium ileus should undergo sweat testing or genetic analysis.
 - The second tier of testing varies among states.
 - May use either repeat IRT measurement or limited genetic mutation analysis.
 - Sweat to confirm results of newborn screening.
- If the child has signs and symptoms consistent with CF, sweat testing or genetic analysis should be performed regardless of newborn screening results.

Microbiological assessment

- Cultures to assess lower respiratory tract flora should be obtained at least quarterly in clinically stable patients and when there is any change in clinical status.
 - An expectorated sputum sample is the usual source.
 - Throat swab or cough swab is often obtained in infants and young children who cannot expectorate.
 - Not necessarily predictive of lower-airway pathogens
- In young children, *S aureus* and *H influenzae* are the most common organisms.
- With advancing age, *P aeruginosa* becomes the predominant pathogen.
- Other pathogens can also infect the lungs in CF.
 - *Burkholderia cepacia* complex
 - *Stenotrophomonas maltophilia*
 - The prevalence of methicillin-resistant *S aureus* has been increasing over the past decade.
- Specialized media are recommended to ensure isolation of pathogens.
 - *P aeruginosa* is best detected using MacConkey agar.
 - *S aureus* on mannitol salt agar or Columbia or colistin–nalidixic acid
 - *H influenzae* on horse blood or chocolate agar
 - *B cepacia* complex is best determined using *B cepacia*–selective agar, oxidation–fermentation polymyxin bacitracin lactose agar, or *Pseudomonas cepacia* agar.
- Antimicrobial susceptibility testing should be determined using an agar-based diffusion assay.
 - Use E-tests (antibiotic-impregnated strips) or antibiotic discs rather than automated commercial systems.
 - Organisms in the *B cepacia* complex and other unidentified gram-negative rods should be further evaluated at a reference laboratory.
 - For instance, Cystic Fibrosis Foundation–sponsored *B cepacia* laboratory at the University of Michigan

IMAGING

- Chest radiography should be performed every 2–4 years in clinically stable patients.
 - Annually in patients with declining pulmonary function
 - As clinically indicated at times of pulmonary exacerbation in all patients
 - Bronchial wall thickening, together with hyperinflation caused by small-airway obstruction, are the first changes noted.
 - Bronchiectasis develops with time.
 - Acute or chronic infiltrates may be noted depending on the patient's clinical status.

- The progression of radiographic changes varies among patients and does not necessarily correlate with abnormalities in lung function tests.
 - Pulmonary function may be relatively well maintained even as radiographic changes may be fairly advanced.
- Lateral chest radiographs should be examined for fractures at least annually if patients are ≥ 8 years of age and at risk for bone disease because these patients are:
 - Malnourished
 - Have severe pulmonary disease
 - On chronic glucocorticoid therapy
 - Have delayed puberty
 - Have low levels of 25-hydroxy vitamin D
- Children with these risk factors for bone disease who are ≥ 8 years of age should undergo a dual-radiograph absorptiometric scan to measure bone density.
- All children with CF should have bone densitometry performed by their 18th birthday.
- Chest CT may detect structural changes in the lung before symptoms are present.
 - Enthusiasm for periodic chest CT has been limited by concerns about the radiation exposure.
 - No current formal recommendations have been made for routine CT in patients with CF.
- Abdominal ultrasonography should be performed:
 - If liver function test results change
 - If hepatomegaly or splenomegaly is detected
- Fetal ultrasonography may reveal hyperechoic bowel.
 - Intestinal manifestations of CF may be present even before birth.
 - Suggests retention of mucus material in the intestine.
- In older patients, as in meconium ileus, bubbly, granular material can be detected by radiography in the region of intestinal obstruction.

DIAGNOSTIC PROCEDURES

- Bronchoscopic studies of infants with CF reveal that neutrophil and proinflammatory (interleukin-8) mediator levels are increased even though children appear clinically well.
- Spirometry should be performed every 3–6 months and as needed on the basis of the patient's pulmonary status.
 - Most children < 6 years cannot perform the test reliably.
 - Infant pulmonary function testing is available at many CF centers.
 - It may be difficult to get a reliable, reproducible effort, especially when the child is first learning to perform the test.
 - Best performed with supervision of a certified respiratory therapist trained to work with children.

- The changes seen in pulmonary function are obstructive in nature secondary to plugging of the small airways with thick secretions.
- Severity of pulmonary disease is categorized on the basis of percentage predicted forced expiratory volume in 1 second (FEV_1).
 - Normal lung function is defined as an $FEV_1 > 90\%$.
 - Mild disease is 70–89%.
 - Moderate disease is 40–69%.
 - Severe disease is $< 40\%$.
- $< 20\%$ of children have moderate to severe lung disease.
- One measure of the health of the small airways is a forced expiratory flow of 25–75%.
 - The average amount of air expelled over the middle half of all the air expelled during spirometry
 - Clinicians should consider this value, particularly in younger children.
 - Researchers have suggested that changes may be seen in a forced expiratory flow of 25–75% before FEV_1 .

TREATMENT APPROACH

- The improved survival for patients with CF seen over recent decades is likely to continue.
 - Greater understanding of the pathobiological characteristics of the disease
 - Significant increase in therapeutic options
- The challenge to the practitioner treating CF is in choosing the best, most appropriate combination of therapies for the individual patient that are aimed at maintaining optimal health status.
- Consultation with a regional CF care center and physicians who are experienced with the nuances of CF care is strongly recommended.
- More specific therapies aimed at the basic defect in CF are being developed.
 - The ultimate goal is delivery of a therapy to infants with CF that will provide them with long and healthy lives.
- All children with diagnosed CF and those who have clinical stigmata of CF but equivocal diagnostic test results should be referred to a local CF care center for evaluation by professionals who are highly experienced in the management of CF.
- A team of individuals that can provide counseling, support, and education to families of newly diagnosed children comprises:
 - Pediatrician, most often a pediatric pulmonologist
 - Nurse
 - Respiratory therapist
 - Dietician
 - Social worker

- Pulmonary and gastrointestinal therapies can be initiated.
- Children should be seen at least quarterly in the CF care center.
 - The adequacy of their therapies, as well as their growth, nutrition, and pulmonary function, can be assessed and therapies adjusted accordingly.
- CF social workers are an invaluable resource for families.
 - Help families deal with the psychological and financial aspects of raising a child with CF
 - Work with the child over the years to help him or her develop into an adult capable of managing the disease independently
- CF centers also can make available to patients clinical trials of novel therapies.
 - The CF center should not be considered a replacement for the general pediatrician.
 - The child absolutely must continue to receive routine well-child care.
 - CF centers generally have physicians available at all times to consult on medical management issues relating to CF.
 - A list of accredited CF care centers in the US can be accessed at www.cff.org.
- Clearance techniques are designed to shear the mucus off the airways and provide back-pressure to stent the airways open so that secretions may be expelled.
- Each technique has specific advantages; no single technique is superior.
- To optimize adherence, choice of therapy should be based on the method that is:
 - The most effective for that patient
 - The best fit for the family's lifestyle
- Physical activity and regular exercise should be recommended as an integral part of the regimen.
- Bronchodilators are often given before CPT to maximally dilate the airways and help facilitate clearance of the secretions.
 - Patients with CF have a variable response to β -agonists.
 - Some patients exhibit a transient decline in pulmonary function, most likely secondary to collapse of bronchiectatic airways.
 - Patients with CF should be assessed for bronchodilator response by pulmonary function testing.
 - Therapy should be adjusted accordingly.
 - Long-acting β -agonists, however, may be beneficial in some patients with CF and asthma.

SPECIFIC TREATMENTS

Pulmonary therapy

- From the moment that CF is diagnosed in a child, the family should be counseled to minimize environmental tobacco smoke exposure.
- Children, especially adolescents, should be educated about the detrimental effects of tobacco smoke and illegal inhalants on their lungs.
- Annual influenza vaccination is recommended for children with CF who are >6 months of age and for their families.
- The cornerstone of pulmonary therapy for children and adults with CF is chest physiotherapy (CPT).
 - Patients are prescribed a daily regimen of CPT to help them mobilize and expectorate the thick, tenacious secretions in their airways.
 - Frequency of therapy is generally increased during times of acute exacerbations.
 - Numerous airway clearance techniques are available for CPT.
 - Manual percussion with postural drainage
 - Autogenic drainage
 - An inflatable vest that vibrates the chest at different frequencies
 - Several handheld devices (eg, Flutter/Acapella) and therapies (eg, positive expiratory pressure) are also available.
- Alternate-day prednisone therapy has been shown to improve lung function in patients with chronic *P aeruginosa* infection.
 - An increased incidence of growth retardation, glucose abnormalities, and cataracts have dampened enthusiasm for this therapeutic approach.
- Inhaled steroids and leukotriene modifiers are attractive alternatives and are widely prescribed.
 - Their use should be limited to patients with concomitant asthma, because evidence of efficacy for CF treatment is lacking.
- High-dose ibuprofen has been shown to decrease the rate of decline in lung function and the need for hospitalization, primarily in patients with CF who have mild lung disease.
 - The requirements for a pharmacokinetic study to determine the optimal dose of ibuprofen and concerns about safety have limited penetration of this therapy into clinical practice.
- Dornase alpha, a recombinant human deoxyribonuclease, was developed for nebulization into the airways.
 - It cleaves the viscous DNA released by dying neutrophils as part of the exaggerated inflammatory response characteristic of CF lung disease.

- Deoxyribonuclease treatment improves the rheologic properties of the sputum.
 - It enables the patient to expectorate the sputum more easily.
 - It is generally administered once a day.
- A multicenter study of dornase alpha revealed an improvement in lung function and a decrease in the frequency of pulmonary exacerbations with chronic use.
 - This therapy has been widely adopted in the treatment of CF.
- Inhaled hypertonic saline is the newest therapy in the CF armamentarium.
 - Inhaling a highly concentrated (7%) saline solution may increase the osmotic load and stimulate water movement into the airways.
 - Improved hydration of the secretions results in better mucociliary clearance.
 - A 48-month trial of 7% saline inhaled twice daily revealed improved pulmonary function and fewer pulmonary exacerbations compared with controls who inhaled 0.9% saline twice daily.
 - Some patients may experience wheezing with the medication; this can be attenuated by pretreatment with a bronchodilator.
- Long-term daily antibiotic therapy is not well supported by evidence in the literature.
 - Either to prevent the initial infection or to treat chronic bacterial infection
 - Generally recommended for treating acute exacerbations when bacterial burden increases and patients develop associated symptoms, such as:
 - Increased cough frequency and sputum production
 - Declining pulmonary function with or without radiographic changes
 - Macrolide antibiotics and inhaled tobramycin are used for treating chronic *P aeruginosa* infection.
 - Research has shown that 3-times-weekly administration of azithromycin has a positive impact on lung function, weight, and the frequency of pulmonary exacerbations in older children and adults.
 - A high-dose preparation of tobramycin given twice daily in alternating months reduced the need for hospitalization and improved pulmonary function.
 - These therapies are widely used in CF.
- When patients experience an exacerbation of bronchopneumonia or an apparent viral respiratory illness, antibiotic therapy directed against the most recently cultured pathogen is recommended.
 - If the patient does not have respiratory distress or hypoxemia, then oral outpatient therapy may be initiated.
- Hospitalization, intravenous antibiotics, and aggressive chest physiotherapy are recommended when patients show an acute worsening of their respiratory status, hypoxemia, or respiratory distress.
- *P aeruginosa* is routinely treated with 2 antipseudomonal antibiotics.
- Duration of antibiotic therapy depends on the severity of the exacerbation.
 - Generally 10 days or longer, based on the response to treatment
- As lung disease progresses, intervals of stability between exacerbations may become shorter.
 - Patients may require supplemental oxygen therapy because of progressive hypoxemia.
 - Noninvasive ventilation may be instituted when evidence exists of carbon dioxide retention or sleep-disordered breathing.
- Lung transplantation is a final therapeutic option for the treatment of progressive, severe lung disease.
 - It is an inherently risky procedure with a 5-year posttransplantation survival rate of approximately 50–60%.
 - Referral for lung transplantation should be made when other therapeutic options are exhausted.
 - Survival models have been developed that facilitate calculation of a patient's predicted survival without transplantation.
 - Aids selection of patients most likely to gain a survival advantage from the procedure
 - Patients should be made aware that the complicated medical regimen they follow to treat their CF-related lung disease will be replaced by a transplant medical regimen that is often equally complicated.
 - Contraindications to lung transplantation
 - Active tuberculosis
 - HIV
 - Hepatitis B
 - Significant psychosocial dysfunction that precludes adherence to the posttransplantation medical regimen

Gastrointestinal therapy

- Nutritional therapy is a cornerstone of good CF therapy.
- Patients should be evaluated at least annually by a dietitian who is knowledgeable about CF.
- Frequent nutritional problems faced by both adults and children with CF
 - Lack of appetite caused by intercurrent illness
 - Inability to consume the increased number of calories needed to:
 - Sustain normal growth
 - Make up for lost weight
 - Achieve catch-up growth

- Infants and children with CF who have PI should receive at least 120–130% of the recommended daily allowance of age-appropriate calories.
 - Fat intake should make up 35–40% of the daily required calories, compared with <30% in people without CF.
 - Caloric requirements are higher when acute illness or exacerbation of the pulmonary disease is present and when catch-up growth is needed.
 - Modifications are initially made to increase the caloric density of the child's regular diet.
 - High-calorie, high-fat supplements in the forms of shakes and formulas are also recommended.
 - Supplementation via nasogastric or gastrostomy tube is recommended, if the child cannot orally consume the daily requirement of calories.
 - The following are usually adequate to prevent salt loss syndrome:
 - Increased consumption of salty foods in older children
 - Addition of salt to the formula for infants
 - Patients with CF-related diabetes (CFRD) should *not* be placed on a diabetic diet.
 - A significant reduction in caloric intake might compromise the patient's overall nutritional status.
 - Patients are taught how to distribute carbohydrates more equally throughout the day.
 - Pancreatic enzyme supplements are given with each fat-containing meal or snack.
 - The recommended dose for infants is 2000–4000 units of lipase per 120 mL of formula or per breastfeeding.
 - A powdered enzyme preparation is often used for infants, but it is not enteric coated.
 - Much of the dose may be destroyed in the stomach.
 - Infants are at risk for ulceration of oral mucosa if enzymes are not completely cleared from the oral cavity.
 - Low-dose, enteric-coated enzyme preparations can be administered to infants.
 - Mix with a small amount of applesauce or other nonalkaline food.
 - Brand-name enteric-coated enzymes should be used exclusively.
 - Enteric coating keeps enzymes from being destroyed by stomach acids.
 - Generic preparations should be avoided.
 - Lack of standardization of the enzyme dose
 - Enzyme dosing is initially based on the patient's weight.
 - Subsequently adjusted based on clinical symptoms of continued malabsorption.
 - Frequency and consistency of stools
 - Perceived greasiness of stools
 - Abdominal cramping
 - Enzyme therapy for children <4 years should be initiated at a dose of 1000 units of lipase per kilogram per meal.
 - Therapy for children ≥4 years should be initiated at a dose of 500 units of lipase per kilogram per meal.
 - To reduce the risk of fibrosing colonopathy, doses should generally be kept to:
 - <2500 units of lipase per kilogram per meal *or*
 - <4000 units of lipase per gram-fat per day
- Vitamin supplements**
- Children with CF should receive a standard, age-appropriate dose of non-fat-soluble multivitamins.
 - Children with PI should also receive supplements of vitamins A, D, E, and K.
 - Vitamin K is supplemented at higher levels in patients:
 - With liver disease with abnormalities in clotting
 - Receiving prolonged antibiotic therapy
 - Special high-dose preparations of these vitamins are available for patients with CF.
 - Dosages for vitamin supplementation
 - 0–12 months:
 - Vitamin A: 1500 IU
 - Vitamin E: 40–50 IU
 - Vitamin D: 400 IU
 - Vitamin K: ≥0.3 mg
 - 1–3 years:
 - Vitamin A: 5000 IU
 - Vitamin E: 80–150 IU
 - Vitamin D: 400–800 IU
 - Vitamin K: ≥0.3 mg
 - 4–8 years:
 - Vitamin A: 5000–10,000 IU
 - Vitamin E: 100–200 IU
 - Vitamin D: 400–800 IU
 - Vitamin K: ≥0.3 mg
 - >8 years:
 - Vitamin A: 10,000 IU
 - Vitamin E: 200–400 IU
 - Vitamin D: 400–800 IU
 - Vitamin K: ≥0.3 mg
 - Acid blockers should be used as needed to treat gastroesophageal reflux.
 - Common in patients with CF
 - Acid suppression may be beneficial for optimization of pancreatic enzyme function.

- Findings during examination should raise concern about the possible development of cirrhosis.
 - Elevated liver enzyme levels and abnormal liver function tests
 - Detection of hepatomegaly or splenomegaly (or both)
 - Order abdominal ultrasonography.
 - Ursodeoxycholic acid has been shown to benefit patients with cholestatic diseases.
 - For example, primary biliary cirrhosis
 - Often administered in patients with CF who have hepatobiliary disease:
 - In an effort to improve bile flow and to limit further liver damage
- Liver transplantation is a therapeutic option when end-stage liver disease develops.

WHEN TO ADMIT

- Pulmonary exacerbations
 - Characterized by:
 - Increased cough
 - Sputum production
 - Decline in pulmonary function
 - Associated symptoms may include:
 - Fever
 - Wheezing
 - Dyspnea
 - Malaise
 - Weight loss
 - Acute changes in the chest radiograph may or may not be seen.
 - The patient should be admitted for intravenous antibiotic therapy if response to oral antibiotic therapy is inadequate.
 - If the patient is hypoxemic, he or she should be admitted to the hospital for further management.
- Major hemoptysis
 - Hemoptysis over 3–7 days of more than:
 - 240 mL in 24 hours
 - >100 mL per day
- Pneumothorax
 - Patients will likely require a chest tube if:
 - Respiratory distress or
 - Pneumothorax occupying at least 20% of the pleural space
 - Other patients should be observed until the pneumothorax is clearly stable or resolving.

- Hospitalized patients should have frequent blood glucose measurements.
 - Altered glucose metabolism may be present only during times of acute illness or stress, particularly in patients receiving supplemental feedings via gastrostomy tube.

WHEN TO REFER

- All children with CF should be referred to a local CF center for ongoing care.

FOLLOW-UP

- Recommended monitoring of patients with an established diagnosis of CF.
- The Cystic Fibrosis Foundation recommends that patients with CF should have annually:
 - A complete blood count with:
 - Differential
 - Fat-soluble vitamins
 - Retinol
 - α -Tocopherol
 - 25-hydroxy vitamin D
 - Albumin and prealbumin
 - Prothrombin time
 - Liver enzymes
 - Patients ≥ 14 years should be screened for CFRD on an annual basis.
 - Patients should have at least annual measurement of renal function, particularly those who:
 - Are receiving long-term inhaled aminoglycoside therapy
 - Receive frequent courses of intravenous aminoglycosides
- All patients should receive a complete physical examination annually.
 - Including hearing and vision screening
 - Particularly relevant for patients receiving multiple courses of aminoglycosides because of potential ototoxicity

COMPLICATIONS

Respiratory

- Hemoptysis and pneumothorax are both common complications of CF lung disease.
 - Patients with CF may have blood-streaked sputum.
 - If the volume of blood expectorated is large, treatment should be initiated.
 - Bed rest
 - Intravenous antibiotics
 - Cessation of any medications with anticoagulant properties

- Bronchial artery embolization may be required if the bleeding does not resolve or becomes life threatening.
- Resection of the bleeding segment is the therapeutic option of last resort.
- Pneumothorax occurs annually in approximately 1% of patients with CF.
 - Patients with respiratory distress or with a pneumothorax occupying at least 20% of the pleural space will likely require a chest tube.
 - If the pneumothorax does not resolve with chest tube placement, pleurodesis may be required.
- Children with CF are predisposed to recurrent and chronic sinusitis despite normal nasal mucociliary clearance.
 - Hypoplasia of the sinuses is a common finding.
 - Polyps may obstruct the nasal passages and contribute to the development of sinusitis.
 - The etiology of polyposis is unknown; it does not appear to be associated with allergies.
- Death most commonly results from respiratory failure and cor pulmonale caused by recurrent or chronic pulmonary infections.

Gastrointestinal

- In newborns, complications may occur because of meconium ileus.
 - Volvulus
 - Intestinal atresia
 - Meconium peritonitis
- DIOS is a common complication of CF.
 - Patients with vomiting, crampy abdominal pain, and decreased stool output should be evaluated for intestinal obstruction by imaging.
 - If DIOS is diagnosed:
 - Oral intake should be withheld.
 - Intravenous fluids or total parenteral nutrition should be initiated.
 - Obstruction may be relieved with a Gastrografin enema or oral or nasogastric administration of osmotic laxatives (polyethylene glycol).
 - Surgical intervention may be needed.
 - Other diagnostic considerations for these symptoms include:
 - Appendicitis
 - Pancreatitis
 - Cholecystitis
 - Intussusceptions
 - *Clostridium difficile* colitis
- Liver disease leads to death in a small minority of the patient population.

Nutritional

- Patients with CF are prone to the development of CFRD, particularly in their late teens and adulthood.
 - CFRD results primarily from a relative insulin deficiency caused by gradual destruction of the islet cells in the pancreas.
 - CFRD is associated with increased morbidity and mortality.
 - Patients may have the classic symptoms of diabetes.
 - Polyuria
 - Polydipsia
 - Weight loss
 - Many have minimal symptoms.
 - An element of insulin resistance has been reported.
- Patients with CFRD:
 - Rarely develop diabetic ketoacidosis.
 - But are at risk for other complications of diabetes.
 - Retinopathy
 - Renal dysfunction
 - Neuropathy
- CFRD should be considered as a possible cause of:
 - Poor growth
 - Delayed puberty
 - Increased frequency of pulmonary exacerbations
 - Unexplained decline in pulmonary function

Bone density

- Osteopenia and osteoporosis are relatively common in adolescents and adults with CF, for several reasons.
 - Failure to thrive
 - Delayed pubertal development
 - Liver disease
 - Physical inactivity
 - Malabsorption of:
 - Calcium
 - Magnesium
 - Vitamins D and K
 - Steroid use may further exacerbate these problems.
- Patients with decreased bone mineral density are predisposed to atraumatic fractures, especially of spine and ribs.
- Patients may experience transient arthritis.
 - Monoarticular, pauciarticular, or polyarticular
 - Knees, ankles, wrists, and proximal interphalangeal joints of the hands are most often affected.

Endocrine

- Pubertal development is often delayed in both boys and girls with CF.
 - Delayed or blunted pubertal development results from:
 - Poor nutrition and decrease in glucose tolerance, accompanied by delayed increase in sex hormone levels
- Female infants with CF have excessive cytoplasmic and extracellular mucus.
 - Can continue into childhood
 - Thickened cervical secretions may reduce fertility.
- Girls may have abnormal menstrual cycles.
 - Possible primary and secondary amenorrhea
 - Increasing numbers of successful pregnancies are occurring as the population with CF ages.
- Boys with CF may have reduced testicular and epididymal size and reduced testosterone levels.
 - In most boys, bilateral absence of the vas deferens occurs secondary to obstruction and subsequent resorption of the structure.
 - Results in infertility
 - Assisted reproductive technologies have been developed and used to treat infertility in men with CF.

PROGNOSIS

- A vicious cycle of infection and inflammation develops in the lungs of patients with CF.
 - Typically punctuated by acute exacerbation, eventually leading to bronchiectasis
 - Damages and destroys the airways
- In general, a good correlation exists between pancreatic status and genotype.
 - Patients with 2 severe mutations, such as $\Delta F_{508}/\Delta F_{508}$, are generally pancreatic insufficient.
 - Patients with 1 or 2 mild mutations are much more likely to be pancreatic sufficient; they are at increased risk of pancreatitis.
 - Individuals who are pancreatic sufficient generally have better clinical outcomes than patients with PI.

Dehydration

DEFINITION

- Dehydration is a condition in which pure water loss occurs.
- Volume depletion or hypovolemia is a condition in which extracellular fluid is lost.
- These terms are used interchangeably.

EPIDEMIOLOGY

- Incidence
 - Diarrheal illness, the most common cause of dehydration
 - Globally, 2.5 million deaths annually from diarrheal illnesses
 - Gastroenteritis
 - >200,000 hospital admissions annually in the US
 - >1.5 million outpatient visits annually in the US

ETIOLOGY

- Infectious processes include:
 - Viral agents
 - Rotavirus
 - Norwalk agent
 - Enteric adenovirus
 - Uncommon viral agents
 - Calicivirus
 - Astrovirus
 - Bacterial agents
 - *Salmonella* spp
 - *Shigella* spp
 - *Campylobacter jejuni*
 - Uncommon bacterial agents
 - *Yersinia enterocolitica*
 - *Vibrio cholerae*
 - *Escherichia coli*
 - *Clostridium difficile*
 - Parasitic agents
 - *Giardia lamblia*
 - Uncommon parasitic agents
 - *Entamoeba histolytica*
 - *Cryptosporidium*
- Noninfectious causes include:
 - Osmotic agents
 - Laxatives or cathartics that contain high concentrations of sugars
 - Obstructive processes in the gastrointestinal tract
 - Occasionally, vomiting as a sign of elevated intracranial pressure

- Nondiarrheal causes of water and electrolyte loss
 - Losses through the skin
 - Losses with fever usually are in the range of a 10–15% increase in insensible losses for each 1°C rise in temperature above 38°C
 - Losses through the respiratory system (ie, increase in insensible losses)
 - Renal losses
 - Diuretic use or abuse
 - Diabetes mellitus
 - Chronic renal disease, obstructive uropathy
 - Water deficit
 - Nephrogenic diabetes insipidus
 - Central diabetes insipidus
 - Increased insensible losses
 - Premature infants
 - Radiant warmers
 - Phototherapy
 - Tracheostomy, tachypnea
 - Inadequate intake of water
 - Ineffective breastfeeding
 - Child abuse
 - Water and sodium deficits
 - Burns
 - Excessive sweating
 - Miscellaneous
 - Surgical drains
 - Third spacing

RISK FACTORS

- Very young children are at risk because of:
 - Higher surface area-to-volume ratio
 - Proportionally higher rate of insensible losses
 - Inability to communicate
 - Inability to actively seek fluids to replenish their losses

SIGNS AND SYMPTOMS

- Volume depletion (see table Degree of Dehydration)
 - Measured as change in body weight from baseline
 - Pre-illness weight is used to determine degree of weight loss due to the fluid deficit.
 - If pre-illness weight is unavailable, use:
 - Pulse rate
 - Blood pressure
 - Urine output
 - Skin turgor

Degree of Dehydration

Parameter	Degree of Dehydration		
	Mild	Moderate	Severe
Weight loss (%)—infants	5	10	15
Weight loss (%)—children	3	6	>9
Skin color	Pale	Gray	Mottled
Skin turgor	May be normal	Decreased	Tenting
Mucous membranes	Slightly dry	Dry	Dry, parched, collapse of sublingual veins
Eyes	Normal	Decreased tears	Sunken, absence of tears
Central nervous system	Alert but thirsty	Irritable	Lethargic, grunting, coma
Pulse	Normal and strong	Rapid and slightly weak	Significantly tachycardic, and very weak to not palpable
Capillary refill	Normal (<2 sec)	2–4 sec	>4 sec
Blood pressure	No change	Orthostatic decrease	Shock
Urine	Normal to mildly reduced	Significantly reduced	Anuria
Volume of deficit—infants	50 mL/kg	100 mL/kg	150 mL/kg
Volume of deficit—children	30 mL/kg	60 mL/kg	>90 mL/k

■ Dehydration is categorized as:

- Mild (3–5% volume loss)
- Moderate (6–9% volume loss)
- Severe dehydration ($\geq 10\%$ volume loss)

• Renal function

- Blood urea nitrogen
- Creatinine
- Urine specific gravity

DIFFERENTIAL DIAGNOSIS

■ In children who only have vomiting (without diarrhea)

- Appendicitis
- Intussusception
- Volvulus
- Pyloric stenosis

DIAGNOSTIC APPROACH

■ 5-point assessment

- Volume deficit
 - History
 - Physical examination
- Osmolar disturbance
 - Serum sodium
 - Serum osmolality
- Acid-base disturbance
 - Blood pH
 - Partial pressure of carbon dioxide
 - Serum bicarbonate
- Potassium
 - Serum potassium

LABORATORY FINDINGS

■ Laboratory tests to assess clinical condition and origin of dehydration are usually not needed in children with mild or moderate dehydration.

■ For moderate to severe dehydration

- Serum electrolytes
 - Sodium
 - Potassium
 - Chloride
 - Bicarbonate
- Blood urea nitrogen
- Serum creatinine
- Urine specific gravity
- Serum glucose (finger-prick at the bedside)

■ Laboratory testing is less useful in assessing the degree of volume depletion.

■ Serum bicarbonate (<17 mEq/L) differentiates moderate or severe hypovolemia from mild hypovolemia.

■ Serum sodium measurements to determine type of dehydration

- Isonatremic (135–145 mEq/L)

- Hyponatremic (<130 mEq/L)
- Hypernatremic (>150 mEq/L)
- Serum potassium
 - Falsely elevated when acidosis causes a shift from the intracellular compartment
 - Low because of losses in the gastrointestinal tract
- Urine osmolality and specific gravity
 - May be high (often >450 mOsm/kg)
 - May be low if the patient has lost renal concentrating ability
 - Osmotic diuresis
 - Diabetes insipidus
- Bacterial cultures for children with:
 - Ill appearance
 - Fever
 - $\geq 38^{\circ}\text{C}$ in infants <3 months
 - 39°C in children >3 months
 - Bloody or mucoid stools
 - Travel or exposure history suggestive of enteric pathogens
- Routine stool cultures should be discouraged.
- Studies for rotavirus antigen are needed only rarely.

CLASSIFICATION

- Dehydration is categorized as:
 - Mild (3–5% volume loss)
 - Moderate (6–9% volume loss)
 - Severe dehydration ($\geq 10\%$ volume loss)

TREATMENT APPROACH

- Rapid repletion of fluids:
 - Restores circulating volume
 - Reverses acidosis
 - Improves perfusion and end-organ function
 - Administer fluid rapidly and with the intent to restore the entire deficit in 4–6 hours.
- Dehydration resulting from gastroenteritis
 - Oral rehydration on an outpatient basis
 - Little laboratory evaluation is necessary.
- Proper dietary management is essential to minimize:
 - Severity of symptoms
 - Duration of symptoms
- Most dehydrated children can be rehydrated successfully without resorting to parenteral (intravenous or intraosseous) therapy.
 - Parenteral therapy is reserved for severe or unusual cases.

- Combined use of an oral rehydration solution (ORS) and an appropriate regimen of refeeding is referred to as *oral rehydration therapy* (ORT).

SPECIFIC TREATMENTS

Oral rehydration

- First choice for the conscious child who has mild or moderate dehydration (see table Fluid Therapy for Dehydration).
- Fluid absorption can be promoted by enteral administration of properly designed fluids, even in the face of ongoing losses.
- ORS
 - Fluid designed to promote water and electrolyte absorption through the co-transport system in the gut
 - A physiologically appropriate ORS contains:
 - 70–90 mEq/L sodium
 - ≤ 25 g/L glucose
 - An ORS typically contains:
 - 20 mEq/L potassium
 - 30 mEq/L of base in the form of citrate
 - The World Health Organization formula published in 2002 specifies:
 - 13.5 g/L carbohydrates
 - 75 mEq/L sodium
 - 20 mEq/L potassium
 - 30 mEq/L of bicarbonate base
 - Osmolarity of 245 mOsm/kg of water
 - The World Health Organization and the United Nations Children's Fund recommend the following properties for an ORS for global use:
 - Total osmolality 200–310 mmol/L
 - Equimolar concentrations of glucose and sodium
 - Glucose concentration ≤ 20 g/L (111 mmol/L)
 - Sodium concentration 60–90 mEq/L
 - Potassium concentration 15–25 mEq/L
 - Citrate concentration 8–12 mmol/L
 - Chloride concentration 50–80 mEq/L
 - Juices, soft drinks, and punches usually contain much higher concentrations of sugars and almost no sodium; they are inappropriate for use as an ORS.
 - The higher sugar concentrations in these fluids may exacerbate diarrhea by presenting a large osmotic load in the intestinal lumen.
 - An ORS can be used to restore both fluid and electrolyte balance in children who have a wide range of initial serum sodium values.

Fluid Therapy for Dehydration

Degree of Dehydration ^a	Signs	Rehydration Phase (First 4 Hours; Repeat Until No Signs of Dehydration Remain)	Maintenance Phase ^b (Until Illness Resolves)
Mild (3–5%)	Slightly dry mucous membranes, increased thirst	ORS, 60 mL/kg ^c	Breastfeeding, undiluted lactose-free formula, half-strength cow's milk, or lactose-containing formula
Moderate (6–9%)	Sunken eyes, sunken fontanelle, loss of skin turgor, dry mucous membranes, decreased urine output	ORS, 80 mL/kg	Same as above
Severe (>10%)	Signs of moderate dehydration, plus ≥ 1 of the following: rapid thready pulse, hypotension, cyanosis, rapid breathing, delayed capillary refill, markedly reduced or absent urine output, lethargy, coma	Intravenous or intraosseous isotonic fluids (0.9% saline or lactated Ringer's solution), 20 mL/kg over 1 hr; repeat until pulse and state of consciousness return to normal, then 50–100 mL/kg of ORS based on remaining degree of dehydration ^d	Same as above

Abbreviation: ORS, oral rehydration solution.

^a Percent of total body weight lost.

^b In addition to the rehydration amounts shown, replace ongoing stool losses and vomitus with ORS, 10 mL/kg for each diarrheal stool and 5 mL/kg for each episode of vomitus.

^c If no signs of dehydration are present, the rehydration phase may be omitted. Proceed with maintenance therapy and replacement of ongoing losses.

^d While parenteral access is being sought, nasogastric infusion of ORS may be begun at 30 mL/kg per hour, provided that airway protective reflexes remain intact.

■ Types of ORS

- Premixed liquids
 - Most widely available commercially in the industrialized world
 - Contain 50–70 mEq/L sodium
 - Appropriate for the mildly dehydrated child
- Significantly dehydrated infants and children need a solution with 70–90 mEq/L.
- Packets of oral rehydration salts for preparation of a solution containing 90 mEq/L of sodium are available for mixing with 1 L of water to provide an inexpensive and reliable alternative.
 - These packets always should be distributed with a 1-L bottle to promote proper mixing.
- Juices, punches, and other soft drinks are inappropriate for children who have diarrhea because of the high osmotic load they introduce into the intestines.
- See table Solutions Commonly Used in Children Who Have Diarrhea for commonly available solutions and their compositions.

■ Rehydration phase

- Fluids are best administered initially by a parent using a needleless syringe to introduce the solution into the child's mouth.
 - Infants: 1 tsp (5 mL) per minute

– Toddlers: 10 mL per minute

– Older children: 15 mL per minute

- At a steady rate of administration, provides 300, 600, and 900 mL/h, respectively
- Generally replaces the calculated deficit within 4–6 hours
- The child should be reassessed frequently.
- Rehydration phase should be completed in the office, clinic, or emergency department before the child is sent home.

■ Vomiting

- Usually not a contraindication to ORT
- Even when vomiting occurs, steady fluid replacement is continued orally.
- Children usually do not discharge their entire stomach contents when they vomit.
- As dehydration and tissue acidosis are corrected, the frequency and severity of vomiting are generally reduced.

■ Maintenance

- After 4 hours, reassess the child's state of hydration using the original clinical criteria.
 - If dehydration is still detectable, repeat the rehydration phase based on the remaining calculated volume deficit.
 - If rehydration is complete, begin the maintenance phase.
- Continued administration of ORS in ad libitum quantities

- Alternate between ORS and breast milk, formula, or other appropriate feedings.
- Resume regular feedings.
- Strong evidence suggests that both the volume and duration of diarrhea are reduced when children are fed immediately following rehydration.

Parenteral and enteral rehydration

- Parenteral administration of initial rehydration fluids
 - For patients who have severe dehydration (shock) fluids are administered
 - Intravenously
 - Intraosseously when line placement proves difficult
 - Rapid boluses of 0.9% sodium chloride in initial volumes of 20 mL/kg for ≤20 minutes
 - Severely dehydrated patients may require 60–100 mL/kg before the restoration of circulating volume is apparent.
- Enteral fluid therapy may begin immediately if:
 - The patient is conscious
 - Airway protective reflexes are intact
- Fluids are given either by mouth or nasogastric tube.

Emergency department

- Children who seek treatment at emergency departments may represent a distinct group of patients.
 - Often have seen a primary care physician earlier in the illness
 - Physician may have attempted oral rehydration.
- Use of ORT in the emergency department is strongly encouraged.
 - Should always be attempted in the mild and moderately dehydrated child

- ORT in children who are sick enough to come to the emergency department is likely to be unsuccessful.
 - Intravenous treatment probably will be required, especially in the older (school-age) child in whom vomiting is the most prominent feature.
 - Such children are often too exhausted to continue with efforts to drink.
 - Reasonable to approach with a brief trial of ORT followed, if necessary, by a brief course of intravenous fluids and subsequent reintroduction of liquids and solids

WHEN TO ADMIT

- Persistently abnormal mental status
- Persistently abnormal electrolyte levels
- Chronic diarrhea (>14 days)
- Other medical problems, eg, short-gut and inflammatory bowel disease
- Hydration status that cannot be restored or maintained after 6 hours of outpatient treatment

COMPLICATIONS

- Inadequately treated dehydration can lead to:
 - Full-blown shock
 - Multiorgan dysfunction syndrome
 - End-organ damage to the kidneys, liver, and brain
 - Death
- Mild overhydration results from aggressive oral hydration.
 - Some transient periorbital puffiness
 - 2–3% weight gain
 - These complications are self-limited and of no clinical consequence.

Solutions Commonly Used in Children Who Have Diarrhea

Solution	Glucose/Phenol (g/L)	Sodium (mEq/L)	Base (mEq/L; Citrate or Bicarbonate)	Potassium (mEq/L)	Osmolality (mmol/L)
Physiologically Appropriate Solutions					
Pedialyte	25	45	30	20	270
Ricelyte	30 ^a	50	30	25	200
Rehydralyte	25	75	30	20	310
WHO and UNICEF oral replacement solution	20	90	30	20	310
Physiologically Inappropriate Solutions					
Cola	700	2	13	0.1	750
Apple juice	690	3	0	32	730
Gatorade	255	20	3	3	330

Abbreviations: UNICEF, United Nations Children's Fund; WHO, World Health Organization.

^aRice syrup solids.

- Hypokalemia results from the loss of total body potassium as a consequence of the increased aldosterone activity in the kidney.
 - Common in severe dehydration
 - As sodium is avidly retained, potassium is lost in the urine.
 - Hypokalemia can result in ileus.
 - May impair fluid and electrolyte absorption from the intestines
 - ORS containing 20 mEq/L potassium chloride can restore potassium balance.
- Elevated aldosterone levels caused by hypovolemia may cause:
 - Renal potassium loss
 - Circulatory collapse
 - Shock
 - Irreversible organ damage
 - Death

PROGNOSIS

- Prognosis is excellent for appropriately treated diarrheal dehydration.
- Typical episodes of gastroenteritis last 3–7 days.

PREVENTION

- Extreme consequences may be prevented by early and aggressive fluid therapy.
- Risking overhydration is better than being exceptionally cautious with fluid administration.

Dental Stains

DEFINITION

■ Extrinsic stains

- Teeth stained from external deposits on their surface layer
- Usually removable by careful daily brushing and professional oral prophylaxis (scaling)

■ Intrinsic stains

- Staining substance is incorporated into the deep structures of the tooth (enamel, dentin, or both).
- Cannot be removed by scaling

MECHANISM

Green color

■ Several teeth; gingival third of crowns; extrinsic stain

- Chromogenic bacteria in plaque biofilm
- Associated with poor oral hygiene

Orange color

■ Less common than green stain

■ Several teeth; gingival third of crowns; extrinsic stain

- Chromogenic bacteria in plaque biofilm
- Associated with poor oral hygiene

Black color

■ Less common than green and orange stains

■ Several teeth; gingival third of crowns; extrinsic stain

- Chromogenic bacteria in plaque biofilm
- Associated with poor oral hygiene

■ Several teeth; extrinsic stain

- Oral medications, especially iron

■ ≥1 teeth; occlusal or interproximal surfaces; hard, shiny

- Arrested dental caries

Brown/black color

■ Several teeth; occlusal pits and fissures or smooth surfaces

- Accumulation of tin or staining of demineralized enamel after strontium fluoride topical treatment

Pink color

■ Single tooth; entire crown

- Posttraumatic change
- Within 1–2 days, bleeding into dentin; changes to gray in 1–3 weeks
- After several months: internal resorption of dentin

Gray color

■ Several teeth; linear pattern or entire crown, depending on stage of tooth development

- Tetracycline incorporation in tooth and subsequent oxidation by sunlight
- Exhibits other colors

■ All primary and permanent teeth; entire crown

- Dose-dependent and duration-linked
- Caused by the incorporation of tetracycline into the mineral complex at the dentinoenamel junction during odontogenesis
- If tetracycline was ingested by the mother during pregnancy or by the child in the first months after birth, the primary teeth will be affected.
- Permanent teeth will be stained if drug ingestion occurs between 3 months and 7–8 years of age.
 - The result may be yellow, gray, or brown tooth discoloration in a linear pattern that, without restoration, may be quite disfiguring.

■ All primary and permanent teeth; entire crown

- Dentinogenesis imperfecta (autosomal dominant)

■ Single tooth; entire crown

- Posttraumatic change
- Within 1–3 weeks: hemosiderin pigment in dentin
- After several months: pulpal necrosis

Yellow color

■ Several teeth; entire crown

- Natural color of permanent compared with primary teeth

■ Several teeth; linear pattern or entire crown

- Tetracycline
- Systemic infection

■ All primary and permanent teeth; entire crown

- Amelogenesis imperfecta (various inheritance patterns)

■ Single tooth; entire crown

- Posttraumatic change
- Pulpal obliteration by dentin

■ Several teeth; gingival third of crown; extrinsic stain

- Food debris and chromogenic bacteria in plaque biofilm
- Associated with poor oral hygiene

■ Several teeth; extrinsic stain; part of or entire crown

- Tea
- Coffee
- Cola
- Tobacco

Yellow/brown color

■ Several teeth

- Premature birth; enamel disturbance
- Hypoplasia and hypocalcification

■ ≥1 teeth; ≥1 surfaces with cavitations

- Advanced active dental caries

■ Brown color

- Several teeth; entire crown
 - Amelogenesis imperfecta
 - Dentinogenesis imperfecta
 - Premature birth
 - Jaundice
- Individual teeth; localized area
 - Turner hypoplasia secondary to infection
 - Brown or yellow/brown discoloration of a single tooth associated with hypoplasia of the enamel
 - Occurs in a tooth undergoing odontogenesis at the time of illness
 - Hypocalcified or hypoplastic area
 - Traumatized primary tooth affecting permanent crown
- Several teeth; linear or generalized distribution; associated hypoplasia
 - Fluorosis; systemic infections
 - Especially with high fever; nutritional deficiencies
- Several teeth; generalized or linear
 - Tetracycline
- Several teeth; ≥ 1 surfaces; loss of tooth structure
 - Advanced active dental caries

Red/brown color

- Several teeth; primary and permanent; generalized
 - Porphyria

Blue color

- Several teeth; extrinsic stain; part of or entire crown
 - Berries

Blue/green or yellow/green color

- All primary teeth; entire crown
 - Bilirubin pigments incorporated into dentin
 - Erythroblastosis fetalis
 - Biliary atresia
 - Neonatal hepatitis

White or cream color

- Several teeth; linear or entire crown
 - Fluorosis
 - Systemic infection
- All primary and permanent teeth; entire crown
 - Amelogenesis imperfecta
- Individual teeth; localized area
 - Turner hypoplasia
- ≥ 1 teeth; occlusal or gingival third of smooth surface
 - Early active dental caries
 - Demineralization of enamel

■ Several teeth; any surface; extrinsic stain

- Plaque biofilm and food debris (materia alba)
- Removed easily with gauze

HISTORY

■ Parental concerns

- Changes in tooth color are often the cause of much anxiety.
- Concerns are frequently first brought to the pediatrician.

■ Extrinsic stains

- Oral hygiene habits
- Ingestion of staining substances, especially liquid iron preparations
- Frequent prolonged exposure to chlorinated swimming pools

■ Intrinsic stains

- Medical history: neonatal
 - Erythroblastosis fetalis
 - Biliary atresia
 - Hepatitis
- Medical history: childhood
 - Porphyria
 - Tooth trauma and associated bleeding into dentin
 - Active dental caries
 - Local infection
 - Excessive fluoride intake
 - Tetracycline exposure

PHYSICAL EXAM

- Erythrodonia caused by deposition of red-brown porphyrin pigments into the tooth structure is readily apparent in ultra-violet light, if not in daylight.

DIFFERENTIAL DIAGNOSIS

■ Normal tooth color varies greatly:

- From 1 tooth to another
- From 1 individual to another
- Between the usual blue-white of primary dentition and the yellowish ivory of permanent teeth

■ Cyanotic congenital heart disease

- As many as 50% of such children may have dull, pale, bluish-white teeth.
 - Color of teeth resembles skim milk.

■ Amelogenesis imperfecta, dentinogenesis imperfecta

- Inherited disorders associated with hypoplastic enamel and yellow, opalescent, blue-gray, or brown-violet tooth color

TREATMENT APPROACH

- Allay parental anxieties.
- Consider referring a child with extrinsic or intrinsic stains.

SPECIFIC TREATMENT

Chromogenic bacteria in plaque biofilm

- Oral prophylaxis
- Preventive education

Discoloration from oral medications

- Oral prophylaxis after discontinuing medication

Dental caries

- Arrested
 - Dental evaluation, observation, or restoration
- Advanced, active
 - Restoration

Accumulation of tin

- No treatment, or aesthetic restoration

Staining of demineralized enamel after topical fluoride treatment

- No treatment, or aesthetic restoration

Posttraumatic change

- None, or observation
- Minor resorption
 - Endodontics
- Severe resorption
 - Extraction
- Pulpal necrosis
 - Endodontic treatment or extraction
- Pulpal obliteration by dentin
 - Observation or esthetic restoration

Tetracycline incorporation in tooth

- Esthetic restoration
- Endodontic therapy and bleaching

Fluorosis

- Esthetic restoration

Systemic infections

- Esthetic restoration

Nutritional deficiencies

- Esthetic restoration

Dentinogenesis imperfecta

- Esthetic improvement
- Protection from wear—prosthetic coverage

Amelogenesis imperfecta

- Esthetic restoration
- Protection from occlusal wear

Tea, coffee, cola, tobacco use

- Oral prophylaxis
- Avoid excessive use of substance

Premature birth; enamel disturbance

- Hypoplasia and hypocalcification
- No treatment

Turner hypoplasia secondary to infection

- No treatment, or esthetic restoration

Hypocalcified or hypoplastic area

- No treatment, or esthetic restoration

Porphyria

- No treatment, or esthetic restoration

Bilirubin pigments incorporated into dentin

- No treatment
- Generally fades
- Permanent teeth are not affected if the condition does not continue.

WHEN TO REFER

- Consider referring a child with extrinsic or intrinsic stains.
 - Simple office dental procedures and preventive education can resolve all extrinsic staining problems.
 - Esthetic improvement is possible with the majority of intrinsic discoloration.

PROGNOSIS

- Extrinsic stains
 - Discoloration will usually resolve with:
 - Oral prophylaxis
 - Avoidance of the staining substance
- Intrinsic stains
 - Major restoration of dental surfaces may be required to restore normal appearance.

PREVENTION

- Extrinsic stains
 - Good oral hygiene
 - Oral prophylaxis
 - Avoidance of staining food and beverages
 - Children who are receiving liquid medications, especially iron preparations
 - Staining may be completely prevented if medication is administered through a straw from the onset.

- Competitive swimmers
 - Professional oral prophylaxis is protective.
- Intrinsic stains
 - Avoidance of excessive fluoride intake
 - Fluoride content >1.5 parts per million (ppm) results in hypoplastic enamel, with characteristic dull, opaque, white mottled patches in the permanent teeth.
 - Tetracycline should be avoided in:
 - Pregnant or lactating women
 - Children <8 years of age
 - If the amount of fluoride consumed is >5 ppm, the teeth will show a blotchy brown or black/brown color that is highly disfiguring and requires extensive restoration of dental surfaces.

Developmental Surveillance and Intervention

BACKGROUND

- Developmental screening and surveillance helps families:
 - Optimize their children's acquisition of skills
 - Understand behavior
 - Facilitate learning
- For children with developmental differences or delays, universal or focused screening provides an opportunity for:
 - Early identification
 - Referral for intervention
- Growth, development, and behavior are inextricably linked.
 - Screening needs to consider the whole child.
 - Social and emotional development in the context of family and community
- Approximately 16% of children have developmental or behavioral disabilities.
 - Speech and language delays
 - Intellectual disabilities or deficits
 - Learning disabilities
 - Emotional problems
 - Even at preschool age, 13% of children have mental health problems.
 - 5% of 4- to 17-year-olds in the US (2.7 million children) have severe emotional or behavioral difficulties.
- Risk factors for developmental delay or behavioral disabilities
 - Poverty
 - Maternal depression
 - Substance abuse
 - Domestic violence
 - Foster care placement
 - Premature birth or prolonged neonatal intensive care unit course
- Despite the medical community's knowledge of prevalence and risk, detection of developmental and behavioral problems before school age is very poor (~30%).
 - Lack of detection eliminates the possibility of early intervention.
 - By contrast, 70–80% of children with developmental disabilities are correctly identified when standardized screening tests are used.
 - Reasons given for not screening include:
 - Screening takes too long.
 - Tools are difficult to administer.
 - Children may not cooperate.
 - Reimbursement is limited.
 - Perceived barriers to screening
 - Time
 - Cost

- Staff
- Language availability
- Practicality
- Waiting to screen until a problem is observable is pointless.
 - Time for intervention has been lost.
 - Informal checklists, used by many primary care physicians, have no validated criteria for referral and result in missed referral opportunities.

GOALS

- Creating collaborative relationships that link the:
 - Family
 - Practice
 - Community
 - Counselors
 - Agencies
 - Early intervention programs
 - Child care
 - Head Start
 - Schools
- Early identification:
 - Allows referral and early intervention even for children with developmental diagnoses that cannot be cured or completely remediated
 - Improves function for the child and family
 - Can save up to \$100,000 per student in special-education costs over the course of the child's education
- The primary care physician does not need to become an expert at diagnosing and managing developmental and behavioral disorders.
 - However, the physician is a:
 - Resource for referrals for further assessment and interventions
 - Partner in finding information
 - Sounding board
 - Facilitator to negotiate the system
- If a screen has an at-risk score:
 - For more detailed assessment to confirm or rule out a diagnosis, the primary care physician refers (generally outside the practice) to:
 - Developmental and behavioral pediatrician
 - Infant-toddler specialist
 - Psychologist
 - Speech and language pathologist
 - Physical therapist

- The primary care physician screens periodically (surveillance).
 - Surveillance increases the sensitivity and accuracy of the assessment of the child's skills and progress.

GENERAL APPROACH

- Developmental and behavioral screening
 - Early identification of potential problems or delays
 - Review of appropriate expectations at a given developmental age
 - Facilitates understanding of the child's behavior
 - Potentially facilitates use of appropriate discipline by parents
 - Leads to referring children with at-risk scores to early intervention services
- Psychosocial screening can cover risk factors.
 - Family relationships
 - Maternal depression
 - Domestic violence
 - Substance abuse
 - Unstable housing
 - Financial resources
 - Must be considered individually for a realistic care plan
- The screen:
 - Provides a template for anticipatory guidance
 - Facilitates patient flow
 - Reduces “doorknob concerns” as the physician leaves the examination room
 - Improves patient and physician satisfaction

SPECIFIC INTERVENTIONS

Screening tools for primary care practice

- Types of developmental screening tools
 - Direct elicitation
 - Interview
 - Parent questionnaires
- Advantages of parent questionnaire
 - Family-centered process
 - Does not require staff administration; only scoring and recording
 - Can be completed while the parent is in the waiting room or examination room
 - Some tools are available in an online version that can be completed by the family before the visit.
 - Removes the problem of trying to elicit skills from young child in a foreign environment

- Parents' concerns are accurate indicators of true problems, particularly for:
 - Speech and language
 - Fine-motor skills
 - Hearing
 - General function
- Parent estimations correlate well with developmental quotients for:
 - Cognitive skills
 - Motor skills
 - Self-help skills
 - Academic skills
- Disadvantages to a parent questionnaire
 - Recall (eg, milestones) is unreliable.
 - Staff time for scoring, transcribing, and filing depends on how the questionnaire is administered.
 - Parental reading skills may be a concern.
 - Parents can be asked if they would like to complete the screen independently.
 - The provider can offer to have someone go through the screen with the parent.

Screening schedule

- Screens can be interwoven into the schedule of well-child visits and the growing relationship with the family.
 - Primary screens should be routine for all families.
 - Secondary screens are used as indicated.
- 1-week, 1-month visits
 - Primary screen
 - Psychosocial
 - Pertinent issues
 - Support
 - Housing
 - Transportation
 - Peak crying in second month
 - Parenting
 - Newborn care
 - Feeding
 - Sleep
 - Reading cues
 - Soothing strategies
- 2-month visit
 - Primary screen
 - Maternal depression (Edinburgh Postnatal Depression Scale)

- Pertinent issues
 - Socioeconomic
 - Family relationships
 - Attachment
- Parenting
 - Sleep
 - Reading cues
- 4-month visit
 - Primary screen
 - Maternal depression
 - Pertinent issues
 - Socioeconomic
 - Family relationships
 - Attachment
 - Reaching
 - Rolling
 - Social smile
 - Parenting
 - Sleep
 - Reading cues
- 6-month visit
 - Primary screens
 - Mental health
 - Substance abuse
 - Domestic violence
 - Pertinent issues
 - Emergent motor skills
 - Emergent social skills
 - Mobility
 - Parenting
 - Sleep
 - Book sharing
 - Age-appropriate expectations
 - Secondary screen
 - Ages and Stages Questionnaire Social-Emotional (ASQ SE), if indicated
- 9-month visit
 - Primary screens
 - ASQ
 - Parents' Evaluation of Developmental Status (PEDS)
 - Pertinent issues
 - Emerging stranger anxiety
 - Mobility
 - Feeding self
- Parenting
 - Sleep
 - Book sharing
 - Discipline
- 12-month visit
 - Primary screens
 - ASQ
 - PEDS (if not at 9 months)
 - Pertinent issues
 - Emerging language
 - Joint attention
 - Mobility
 - Parenting
 - Sleep
 - Book sharing
 - Discipline
 - Toilet training
 - Secondary screens
 - ASQ SE
 - Temperament and Atypical Behavior Scale (TABS)
 - Brief Infant Toddler Social Emotional Assessment (BITSEA)
- 15-month visit
 - Primary screens
 - Psychosocial mental health
 - Substance abuse
 - Domestic violence
 - Pertinent issues
 - Language
 - Home environment
 - Parenting
 - Sleep
 - Book sharing
 - Discipline
 - Toilet training
- 18-month visit
 - Primary screen
 - ASQ
 - PEDS
 - Pertinent issues
 - Language
 - Independence
 - Ambivalence

- Parenting
 - Sleep
 - Book sharing
 - Discipline
 - Toilet training
- Secondary screens
 - ASQ SE
 - TABS
 - BITSEA
 - Modified Checklist for Autism in Toddlers (MCHAT)
- 24-month visit
 - Primary screen
 - ASQ/PEDS (if not at 18 months)
 - Psychosocial
 - Pertinent issues
 - Language
 - Independence
 - Ambivalence
 - Parenting
 - Interaction with peers
 - Discipline
 - Toilet training
 - Book sharing
 - Secondary screens
 - ASQ SE
 - TABS
 - BITSEA
 - Eyberg Child Behavior Inventory
 - MCHAT
- 30- or 36-month visit
 - Primary screen
 - ASQ
 - PEDS (if not at 30 months)
 - Pertinent issues
 - Communication
 - Social skills
 - Parenting
 - Book sharing
 - Secondary screens
 - ASQ SE, etc
- 48-month visit
 - Primary screen
 - ASQ
 - PEDS
- Pertinent issues
 - School readiness
 - Communication
 - Social skills
 - Early graphomotor
- Parenting
 - Book sharing
- Secondary screens
 - ASQ SE
 - TABS
 - Eyberg Child Behavior Inventory
 - Pediatric Symptom Checklist (PSC)
- 60-month visit
 - Primary screen
 - ASQ
 - PEDS
 - Pertinent issues
 - School readiness
 - Communication
 - Social skills
 - Early graphomotor
 - Parenting
 - Book sharing
 - Secondary screens
 - ASQ SE
 - TABS
 - Eyberg Child Behavior Inventory
 - PSC
- 6- to 18-year visits
 - Primary screen
 - PSC
 - Pertinent issues
 - Learning
 - Peers
 - Self-esteem
 - Parenting
 - Building self-esteem
 - Making good choices
 - Secondary screens
 - Attention-deficit/hyperactivity disorder
 - Depression
 - Anxiety

Developmental and behavioral screens

■ Excluded tests

- Poor validation or sensitivity and specificity
 - Prescreening Developmental Questionnaire
 - Denver Developmental Screening Test II
 - Developmental Indicators for the Assessment of Learning III
 - Gesell Developmental Observation Test

■ Effective screens, with sensitivity and specificity of at least 70–80% (details below subject to change)

- ASQ
 - Type: parent questionnaire
 - Age: 4 mo–5 yr
 - Staff required: paraprofessional
 - Cost: \$199.00/kit
 - Refills, copies: ok to copy
 - Time: 3 min to score
 - Languages: English, Spanish, French, Korean
 - Reading level: 4th–6th grade
- Bayley Infant Neurodevelopmental Screener (BINS)
 - Type: direct elicitation
 - Age: 3–24 mo
 - Staff required: master's or equivalent
 - Cost: \$195.00/kit
 - Refills, copies: refills of score sheet
 - Time
 - 20–30 min to administer
 - 10 min to score
 - Languages: English
- PEDS
 - Type: parent questionnaire
 - Age: 0–8 yr
 - Staff required: paraprofessional
 - Cost
 - \$69.95 manual
 - \$30.00 kit
 - Refills, copies: refills at \$30.00/50 sheets
 - Time: 5 min to score
 - Languages: English, Spanish, Vietnamese, Hmong, Somali
 - Reading level: 5th grade
- PEDS DM
 - Type: parent questionnaire
 - Age: 0–7 to 11 yr
 - Staff required: paraprofessional

- Cost
 - \$275.00/starter kit
 - Extra: laminated questionnaire book \$110.00 each
- Refills, copies: refills for record form \$32/100 sheets
- Time: 5–10 min to score
- Languages: English, Spanish
- Reading level: 3rd–4th grade
- IDI
 - Type: parent questionnaire
 - Age: 3–18 mo
 - Staff required: paraprofessional
 - Cost: \$14.00/pad (25 sheets)
 - Refills, copies
 - Refills: \$14.00
 - Time: 10 min to score
 - Languages: English, Spanish
- BRIGANCE
 - Type: direct elicitation
 - Ages
 - 0–23 mo
 - 2–2.5 yr
 - 3–4 yr
 - Staff required: professional
 - Cost: for each age range: \$110.00/manual, \$148.00/120 data sheets
 - Refills, copies: refills at \$148.00/120 sheets
 - Time: 10–15 min to administer
 - Languages: English, Spanish

Social-emotional screens

- Secondary screens help the primary care physician make decisions about referrals and types of interventions.
 - The primary care practice may opt not to do secondary screening.
 - Patients can be referred for further assessment when the primary screen indicates an at-risk area.
- A secondary screen can be performed at a follow-up visit:
 - With the primary physician
 - By a care manager
 - By a social worker in the practice
 - For example, MCHAT can be used if a child has indicators of risk on the communication portion of the primary screen.

■ ASQ SE

- Type: parent questionnaire or interview
- Age: 6–60 mo
- Cost: \$125/kit
- Refills, copies: free to copy
- Time: 10 min
- Languages: English, Spanish
- Reading level: 4th–6th grade

■ TABS

- Type: parent questionnaire or interview
- Age: 11–71 mo
- Cost: \$85/kit
- Refills, copies: \$25 for pad of 50 sheets
- Time: 5 min
- Languages: English, Spanish
- Reading level: 3rd grade

■ BITSEA

- Type: parent questionnaire or interview
- Age: 12–36 mo
- Cost: \$99.00/kit
- Refills, copies: \$35 for 25 sheets
- Time: 7–10 min
- Languages: English, Spanish, French, Dutch, Hebrew

■ Eyberg Child Behavior Inventory

- Type: parent questionnaire or interview
- Age: 2–16 yr
- Cost: \$147/kit
- Refills, copies: \$29 for pad of 25 sheets
- Time: 5 min
- Languages: English
- Reading level: 6th grade

■ PSC

- Type: parent questionnaire or interview
- Age: 4–18 yr
- Cost: free, downloadable

- Refills, copies: free to copy
- Time: 5 min
- Languages: English, Spanish, Chinese

Office process

- Assess protocols for developmental screening already in use in the practice.
- Map the workflow to include:
 - Physician
 - Nursing staff
 - Office manager
 - Tailor the workflow to the practice.
- Select tool or tools.
- Identify system supports for:
 - Parent education
 - Referral
 - Community services
- Meet with key partners.
 - Invite community partners to a lunch meeting at the practice.
 - Share screening plans.
 - Align goals.
- Establish a process for:
 - Referral
 - Communication
 - Orient all staff members to new procedures.
- Billing issues
 - The American Medical Association *Current Procedural Terminology* code for screening tools is 96110.
 - Can be billed with a well-visit code
 - Can be billed with an evaluation and management code
 - 0.36 relative value units

Diabetes Mellitus

DEFINITION

- Diabetes mellitus
 - Heterogeneous group of conditions with diverse underlying pathophysiologic factors that result in elevated blood glucose levels
- Type 1 diabetes (T1D)
 - Elevated blood glucose level caused by an absolute insulin deficiency
 - Type 1A
 - Classic form caused by autoimmune destruction of the pancreatic β cells
 - Type 1B
 - Non-immune-mediated severe insulin deficiency caused by such conditions as cystic fibrosis or pancreatotomy
- Type 2 diabetes (T2D)
 - Caused by a relative insulin deficiency, peripheral resistance to the action of insulin, or both
- Maturity-onset diabetes of the young (MODY): defect in pancreatic β cells

EPIDEMIOLOGY

- Prevalence
 - T1D
 - 12 per 100,000 person-years for individuals <20 years
 - Worldwide incidence of T1D increasing
 - T2D
 - Increasing in recent years, especially among specific ethnic groups
 - MODY
 - 5% of all cases of diabetes
- Race or ethnicity
 - T1D
 - Northern Europeans have a much higher risk than individuals from most Asian countries.
 - T2D
 - Incidence in African Americans, Hispanics, and Native Americans is increasing.
- Age
 - T1D
 - Occurs at any age, including in the neonatal period
 - T2D
 - Occurring in younger children as obesity becomes more common
 - Most common in children during puberty, a time of relative insulin resistance

ETIOLOGY

- T1D: absolute deficiency of insulin
 - Precise cause is elusive; probably a combination of:
 - Genetic factors
 - Strongest associations have been found with the genes encoding human leukocyte antigen (HLA) molecules on chromosome 6.
 - Other HLA molecules appear to offer protection against the development of diabetes.
 - Genetic factors do not account for all of the risk, and other factors must play a role.
 - Environmental factors
 - Environmental exposures have been implicated in the development of T1D in genetically susceptible individuals.
 - Congenital rubella syndrome confers added risk to the development of T1D.
 - A link with viral infections has not been proved.
 - There is no association between T1D and immunization status.
 - Dietary factors
 - Definitive data regarding dietary antigen exposure are lacking.
 - Antibodies
 - Islet cell antigens
 - Glutamic acid decarboxylase
 - Insulin
 - Whether these antibodies are causal or simply a marker of disease is unclear.
- T2D: relative deficiency of insulin or peripheral resistance to insulin, or both
 - The definite etiology is not known.
 - Environment (increased prevalence of obesity)
 - Genetic (strong family history)
- MODY
 - Defect in pancreatic β cells
 - Autosomal-dominant inheritance

RISK FACTORS

- T1D
 - Genetic factors
 - Strongest associations have been found with the genes encoding HLA molecules on chromosome 6.
 - Environmental factors
 - Environmental exposures
 - Congenital rubella syndrome

- T2D
 - Obesity
 - Family history of T2D

SIGNS AND SYMPTOMS

- T1D
 - Acute or subacute onset of symptoms (days to weeks)
 - Abdominal pain
 - Headache
 - Nausea
 - Polyuria
 - Polydipsia
 - Significant weight loss despite an increasing appetite
- Severe ketoacidosis
 - Tachypnea
 - Fruity odor to the breath
- Severe diabetic ketoacidosis
 - Altered mental status
 - Seizures
- Physical examination
 - May be helpful in the case of suspected diabetes but will not substitute for laboratory confirmation of the diagnosis
 - T1D and T2D have no pathognomonic physical findings.
 - Physical findings are consistent with the degree of insulin deficiency and the duration of the disorder.
 - Dehydration
 - Tachycardia in some cases
- T2D
 - More insidious than T1D in onset
 - Patients may be asymptomatic.
 - Polyuria
 - Polydipsia
 - Signs of insulin resistance
 - Acanthosis nigricans
 - Weight loss may be apparent, but patients are invariably obese at the time of diagnosis.
 - Hypertension
- MODY
 - Clinical course varies considerably among the different forms.
 - Suspect if:
 - T2D develops at a young age in a thin individual.
 - Family history is suggestive of autosomal-dominant inheritance.
 - The specific type of MODY should be characterized if the diagnosis is made or suspected.

DIFFERENTIAL DIAGNOSIS

- Hyperglycemia from any cause can lead to symptoms related to an osmotic diuresis.
- Glycosuria: Glucose may be seen in the urine of some normoglycemic individuals, and glycosuria alone should not be used to diagnose diabetes mellitus.
- Causes other than diabetes mellitus that may lead to glycosuria
 - Diabetes
 - Neonatal diabetes
 - Gestational diabetes
 - Endocrinopathies
 - Cushing syndrome
 - Growth hormone excess
 - Pheochromocytoma
 - Glucagonoma
 - Somatostatinoma
 - Drugs
 - Glucocorticoids
 - Diazoxide
 - Glucagon
 - Cyclosporin
 - Phenytoin
 - Niacin
 - Antipsychotics
 - Calcium-channel blockers
 - Pentamidine
 - L-Asparaginase
 - Other
 - Cystic fibrosis
 - Pancreatitis
 - Pancreatectomy
 - Wolfram syndrome
 - Stiff man syndrome
 - Anti-insulin receptor antibodies

DIAGNOSTIC APPROACH

- Criteria for diagnosis
 - Symptoms of diabetes
 - Polyuria
 - Polydipsia
 - Unexplained weight loss
 - Causal (ie, any time of day without regard to time since the last meal) plasma glucose level ≥ 200 mg/dL *or*
 - Fasting (≥ 8 hours) plasma glucose level ≥ 126 mg/dL *or*

- Plasma glucose level ≥ 200 mg/dL 2 hours after an oral glucose challenge
 - Glucose load should contain 75 g of glucose for adults or 1.75 g/kg in children (maximal dose, 75 g).
- T2D can be asymptomatic, and the diagnosis may be made only as a result of screening.

LABORATORY FINDINGS

- Plasma glucose level
 - ≥ 126 mg/dL after an 8-hour fast is diagnostic.
- Oral glucose tolerance test
 - More costly and labor intensive than plasma glucose level
 - May identify some individuals with diabetes who have a fasting plasma glucose level < 126 mg/dL
- Blood and urine ketone levels
 - Traditionally associated with T1D but occasionally present in patients with T2D
- Insulin and C-peptide concentrations
 - Generally low in established T1D
 - Elevated in T2D
- Antibody measurements (T1D)
 - Sensitivity and specificity are not sufficient to warrant routine clinical use.
 - Antibodies can be elevated in patients who may not develop disease for many years or ever.

CLASSIFICATION

- T1D
 - Type 1A
 - Type 1B
- T2D
- MODY
 - Type 1
 - Hepatocyte nuclear factor-4- α defect
 - Type 2
 - Glucokinase defect
 - Type 3
 - Hepatocyte nuclear factor-1- α defect
 - Type 4
 - Insulin promoter factor-1 defect
 - Type 5
 - Hepatic transcription factor-2 defect
 - Type 6
 - Neurogenic differentiation factor defect

TREATMENT APPROACH

- Therapy must be tailored to the specific underlying pathophysiologic condition.
 - Individualized patient education and support is imperative for success.
- T1D requires an integrated multidisciplinary team.
 - Physicians
 - Nurses
 - Diabetes educators
 - Dietitians
 - Social workers
 - Psychologists
- Insulin therapy
 - Required in patients with T1D
 - May not always be necessary for children with T2D
 - Safe and effective choice if it is not initially clear whether the patient has T1D or T2D
- Diabetes caused by excess glucocorticoids or other medications
 - Dose reduction or elimination of the drug (if possible) may be all that is required.

SPECIFIC TREATMENTS

Patient education

- Critical to safe and successful diabetes management
- Must be developmentally appropriate
 - Teenagers should be able to assume more responsibility for their care than young children.

T1D

- The goal is to safely achieve as near euglycemia as possible while minimizing adverse events, primarily hypoglycemia.
 - Glycemic control improves outcomes with regard to:
 - Microvascular complications
 - Macrovascular complications
 - Reduction in progression of diabetic retinopathy
- American Diabetes Association (ADA) age-adjusted guidelines for glycemic control
 - Age 0–6 years
 - Premeal plasma glucose 100–180 mg/dL
 - Bedtime or overnight plasma glucose 110–200 mg/dL
 - Hemoglobin (Hb) A_{1c} $< 8.5\%$ (but $> 7.5\%$)
 - Less tight control is recommended for younger children.
 - Risks of hypoglycemia may be greater.
 - Advantages of very tight control have not been proven.
 - Age 6–12 years
 - Premeal plasma glucose 90–180 mg/dL
 - Bedtime or overnight plasma glucose 100–180 mg/dL
 - HbA_{1c} $< 8\%$

- Age 13–19 years
 - Premeal plasma glucose 90–130 mg/dL
 - Bedtime or overnight plasma glucose 90–150 mg/dL
 - HbA_{1c} <8%
- Adults
 - Premeal plasma glucose 90–130 mg/dL
 - HbA_{1c} <7%
- Lower HbA_{1c} values may be safely obtained in select patients in whom the risk of severe hypoglycemia is deemed low.
- Pregnancy
 - Postprandial glucose targets are widely used in the management of diabetes during pregnancy.
 - These targets are not commonly used outside pregnancy because their value has not been studied rigorously in children.

T2D

- Treatment options available for patients with T2D are more diverse than for those with T1D.
 - Although many effective medications with a variety of mechanisms of action are available, few are indicated for the treatment of T2D in children.
 - Therapy must be tailored to fit the clinical situation of the patient.
- Weight loss and exercise
 - Can significantly improve insulin sensitivity in T2D
 - Appropriate in the asymptomatic patient with a normal or near-normal HbA_{1c} level
 - May be adequate for maintenance of glycemic goals in patients who will adhere to dietary and exercise guidelines
 - Lifestyle modification intervention has been shown to reduce development of T2D in adults by 58% over 2.8 years of follow-up.
- Pharmacologic intervention
 - Consider for patient with:
 - Symptomatic hyperglycemia
 - Significantly elevated HbA_{1c} level
 - No pharmacologic intervention is a substitute for lifestyle intervention and medical nutrition therapy.
 - Insulin
 - The only medication approved for the treatment of diabetes in children at all ages
 - Most children with T2D can improve glycemic control with less intensive programs than are needed for patients with T1D.
 - Once- or twice-daily, intermediate- or long-acting insulin may be sufficient.

- Metformin
 - The only oral agent approved for use in children
 - Advantages
 - Safe and effective in lowering HbA_{1c} levels when used appropriately
 - Does not induce hypoglycemia when used alone
 - Weight stabilization or mild weight loss
 - Gastrointestinal disturbance is the major side effect.
 - Largely prevented by slow titration of the dose
 - Contraindications
 - Significant liver disease or renal impairment

Specific insulin programs

- All patients taking insulin will need to have an individualized plan for:
 - Type and dose of insulin
 - Timing of injections
 - Frequency of home glucose monitoring
- Typical doses of insulin in children
 - 0.5–1 unit of insulin per kg per day
 - During puberty, children require higher insulin doses to achieve the same control.
 - For patients with T1D
 - Intermediate- or long-acting insulin is used as the basal insulin.
 - A short-acting insulin bolus is used to control the post-meal glucose increase (see Figure 18 on page F5).
- Short-acting
 - Regular
 - Onset: 30 minutes
 - Peak: 2–4 hours
 - Duration: 4–6 hours
 - Lispro
 - Onset: <15 minutes
 - Peak: 1 hour
 - Duration: 3–4 hours
 - Aspart
 - Onset: <15 minutes
 - Peak: 1 hour
 - Duration: 3–4 hours
 - Glulisine
 - Onset: <15 minutes
 - Peak: 1 hour
 - Duration: 3–4 hours

- Intermediate-acting
 - NPH
 - Onset: 2–4 hours
 - Peak: 4–6 hours
 - Duration: 10–16 hours
 - Lente
 - Onset: 3–4 hours
 - Peak: 6–10 hours
 - Duration: 10–20 hours
- Long-acting
 - Glargine
 - Onset: 2–3 hours
 - Peak: none
 - Duration: ≥ 24 hours
 - Detemir
 - Onset: 1–2 hours
 - Peak: 3–9 hours
 - Higher doses result in delayed peak and longer duration of action.
 - Duration: 6–23 hours
 - Higher doses result in delayed peak and longer duration of action.
- Split-mixed program
 - Commonly used in younger patients in whom fewer injections may be desirable
 - A short-acting and an intermediate-acting insulin are mixed.
 - Given as a single injection before breakfast and again before the evening meal
 - Higher doses are required in the morning compared with the evening.
 - Typical ratio
 - 2/3 to 3/4 of the total daily dose given in the morning and the remainder in the evening
 - $\sim 2/3$ of the morning dose is intermediate-acting insulin.
 - The rest is short-acting insulin.
 - Equal amounts of intermediate- and short-acting insulin are given with the evening meal.
 - Prevention of hypoglycemia
 - A snack at bedtime can prevent nighttime hypoglycemia.
 - The intermediate-acting insulin will have its peak action in the early morning hours.
 - The evening dose of intermediate-acting insulin can be given at bedtime to help prevent this complication.
- Limitations
 - Achieving adequate glycemic goals is sometimes not possible.
 - Program requires patients to be on a fixed diet with respect to timing and nutrient content at each meal.
- Multiple daily injection (MDI) program
 - Intermediate- or long-acting insulin as the basal insulin
 - Short-acting insulin as a bolus with each meal
 - Requires 3–4 (or more) injections each day.
 - More flexibility in timing and content of meals than split-mixed programs
 - Basal insulin
 - Constitutes approximately half of the total daily dose
 - Usually given in the evening
 - The amount of short-acting insulin given with each meal depends on the amount of carbohydrate consumed at that meal.
 - If the patient has been prescribed an exchange diet with a fixed amount of carbohydrate for each meal, the dose of insulin will be the same from day to day.
 - Patients who vary carbohydrate consumption will need to adjust insulin accordingly.
- Continuous subcutaneous insulin injection (CSII) program
 - Cartridge filled with short-acting insulin serves as both the basal and bolus insulin.
 - Insulin is delivered through tubing connected to a flexible plastic cannula, which is inserted subcutaneously.
 - Advantages
 - Pump can be concealed under a person's clothing.
 - Multiple basal rates can be programmed for patients whose basal insulin requirements are not constant throughout the day.
 - This feature is not available with a split-mixed or MDI program.
 - Tubing and cannula are changed every 2–3 days, significantly reducing the number of injections required.
 - There may be a slight improvement in HbA_{1c} in patients treated with CSII compared with MDI.

Meal plan

- Carbohydrate ingestion is a major determinant of blood glucose concentration.
- Matching the amount of food intake with the appropriate amount of insulin requires knowledge of:
 - Onset
 - Peak
 - Duration of action of the various types of insulin available

■ No single meal plan has been shown to be superior.

- As children grow and vary their activity levels, caloric requirements can change significantly.
- Advice from a dietitian experienced in the management of children with diabetes is necessary.
 - Plans require specific education.
 - Patients must be able to assess the nutrient content of foods.
 - Patients must understand how nutrition affects the management of their disease.

■ Exchange diet

- Patient eats a consistent amount of nutrients at a consistent time of day.
 - Example: 45 g of carbohydrate for breakfast, 60 g for lunch, and 60 g for dinner
 - Fat and protein may also be prescribed for each meal.
 - The patient is expected to eat according to this pattern each day.
- Foods are categorized according to nutrient content.
 - This list is used to create a meal.
 - Foods with equivalent nutrient content can be exchanged for each other to introduce variety in the diet.
 - Snacks are usually incorporated into this diet depending on the individual patient's needs and preferences.
- Advantages
 - Nutrient intake is consistent.
 - Allows insulin dosing also to be consistent
 - Can be used for patients on split-mixed, MDI, or CSII programs

■ Carbohydrate counting

- More complex than exchange diet, but increasingly popular
 - Patients must be familiar with the carbohydrate content of each food.
- For each unit of carbohydrate taken, a specific amount of insulin must be given to maintain euglycemia.
 - Typical ratio may be 1 unit of short-acting insulin for each 15 g of carbohydrate eaten.
 - Ratio is adjusted for each patient.
 - Ratio may vary based on time of day for a given individual.
- Advantages
 - Can be used for patients on an MDI or CSII insulin regimen
 - Carbohydrate counting allows more flexibility in the timing and content of each meal.
- Caveats
 - Patients can take more insulin to maintain glycemic control while overeating.

- Carbohydrate counting must be a part of an overall meal plan so that overeating does not lead to obesity or contribute to hyperlipidemia.

- Carbohydrate counting requires specific education and a motivated patient and family to be implemented correctly.

• Contraindications

- Patients on a split-mixed insulin program
- Insulin doses in a split-mixed program cannot easily be adjusted to account for the dietary variability of carbohydrate counting.

Exercise

■ Exercise can be performed safely.

- Children should not be discouraged from participating in sports because of diabetes.
- However:
 - Attention to the effects of activity on glucose levels can assist in preventing hypoglycemia during or after exercise.
 - Hypoglycemia may occur if changes are not made in the amount of food eaten or insulin taken.
 - The effect of exercise may be sustained and lead to delayed hypoglycemia.

■ Planned activity—2 methods of preventing hypoglycemia:

- Reduce the dose of short-acting insulin given at the previous meal.
- A snack can be given just before or during the activity.

■ Unplanned activity

- A snack is the only option.

■ Blood glucose level

- Should be checked before and again after exercise to determine the effect of the activity on glucose concentrations
- If the activity is prolonged (>45–60 minutes), level should be checked:
 - Periodically during the activity
 - Again at night
- Documenting the effect of exercise on the patient's glucose level is the only way to make appropriate decisions to prevent hypoglycemia.

Illness

■ Illness can have a notable affect on blood glucose values.

- Hypoglycemia or hyperglycemia may result.
 - Dependent on the severity of the illness and the amount of food eaten

■ Regardless of food intake, insulin is necessary in health or illness.

- A common error made is the omission of insulin injections because the child is not eating.

- Although the dose may change, some insulin should be given even if the child cannot eat.
- Practical guidelines can assist in appropriate care during illness and avoidance of hospitalization.
 - Never completely omit insulin.
 - Monitor and record blood glucose concentrations every 2–4 hours.
 - Monitor urine ketone concentrations frequently, even if the blood glucose level is not significantly elevated (>250 mg/dL).
 - Some patients with T1D can develop ketosis in the absence of hyperglycemia when ill.
 - Encourage adequate hydration.

WHEN TO ADMIT

- Admit when diabetic ketoacidosis present.
- Consider admitting patients with:
 - Newly diagnosed T1D
 - Severe hypoglycemia or dehydration

WHEN TO REFER

- Refer when:
 - T1D is newly diagnosed
 - A multidisciplinary diabetes program is needed and not available

FOLLOW-UP

- Monitoring
 - Appropriate insulin dosing cannot be accomplished without adequate blood glucose monitoring.
 - Simply checking the glucose concentration is not enough.
 - Glucose values must be recorded in a log and reviewed on a regular basis to determine whether insulin doses need to be adjusted.
 - Frequency
 - Patients with T1D and some patients with T2D treated with insulin
 - Before meals
 - Bedtime
 - Occasionally at night
 - T2D treated with lifestyle modification or oral agents
 - Less frequent monitoring is required.
 - Additional glucose determinations may be needed during:
 - Illness
 - Exercise
 - Symptoms of hyperglycemia or hypoglycemia

- Home management
 - Many good home glucose monitors are available.
 - All of these monitors should be checked periodically for accuracy.
 - Patients should receive training on proper technique.
 - Data from many home glucose meters and insulin pumps can be transferred to a computer to assist in tracking glycemic control.
- Adjusting
 - Adjusting insulin doses is necessary to maintain good glycemic control.
 - Adjustment is based on patterns of blood glucose concentrations recorded in the log
 - Generally made as a 10% increase or decrease.
 - The purpose of an adjustment is to prevent future abnormal glucose levels.
 - Primary care physicians should commonly ask patients to look for a 3-day trend of hyperglycemia before making an adjustment.
 - Example: A patient consistently has glucose values before his or her evening meal that are higher than the goal range.
 - An increase in the short-acting insulin before the noon meal would be made.
 - Many variables exist that cannot be accounted for, therefore:
 - Patients should be informed that their blood glucose concentration will not always fall in the normal range.
 - For some people, this circumstance can be discouraging and lead to improper insulin adjustments.
 - For others, lack of education or fear of hypoglycemia leads to improper dose adjusting.
 - Primary care physicians must be clear about the difference between insulin adjustments and supplements.
- Supplementing
 - Used to correct a glucose concentration outside the goal range
 - The supplement (either adding or subtracting insulin) is used to correct the abnormal glucose.
 - The bolus dose of short-acting insulin is used to account for the food that will be eaten at a meal.
 - Example: A patient has a blood glucose level that is below the goal range before breakfast.
 - Insulin would be subtracted from the morning bolus dose of short-acting insulin.
 - Example: Glucose is above the goal range before a meal.
 - Supplemental insulin may be added to the bolus dose of short-acting insulin at that meal to correct the hyperglycemia.

COMPLICATIONS

- Both T1D and T2D greatly increase the risk of:
 - Blindness
 - Chronic kidney disease
 - Neuropathy
 - Cardiovascular disease
 - Stroke
 - Risks can be attenuated in adolescents and adults treated with intensive diabetes management.
 - Screening for chronic complications must be performed to intervene early to reverse or slow disease progression.
- Hypoglycemia
 - Common complication of treatment
 - Blood glucose levels should be checked to confirm symptoms are due to low blood glucose level.
 - Some symptoms of hypoglycemia are nonspecific.
 - Unnecessary treatment should be avoided.
 - Children <5 or 6 years at the time of diagnosis:
 - At particularly high risk of frequent hypoglycemia, cognitive impairment
 - Mild hypoglycemia
 - Symptoms
 - Shakiness
 - Nervousness
 - Tachycardia
 - Sweating
- Older children are generally able to recognize symptoms.
- Younger children may not be able to recognize or effectively communicate these symptoms.
- Primary care physicians must be responsible for identifying hypoglycemia.
- Parents frequently report unusual behavior and irritability as signs of hypoglycemia in younger children.
- Management of mild hypoglycemia
 - 10–15 g of carbohydrate will correct the situation.
 - Glucose level should be rechecked in 15–20 minutes to be certain hypoglycemia has resolved.
 - Glucose tablets and gels are available and easy to carry.
 - Some form of carbohydrate should always be available to the patient.
- Severe hypoglycemia
 - Defined as an episode requiring assistance for treatment
 - Symptoms
 - Neurologic symptoms can include confusion or loss of consciousness.
 - Symptoms markedly increase with lowering of the HbA_{1c} level (see Figure 19 on page F5).
- Management of severe hypoglycemia
 - In an unconscious patient, severe hypoglycemia may be treated with glucagon or intravenous glucose.
 - Training on proper use of glucagon should be provided to individuals caring for the patient (parents, school nurses, older siblings, others).
 - Glucagon is reserved for patients with severe hypoglycemia who cannot ingest carbohydrates.
 - Response is short-lived; as soon as practical, the patient should eat.
 - Nausea frequently accompanies glucagon administration.
- After hypoglycemia treatment, cause of hypoglycemia should be considered.
 - If no cause is readily apparent, the insulin dose should be adjusted the next day to avoid additional hypoglycemia.
 - This advice is in contrast to monitoring glucose trends before making adjustments to prevent hyperglycemia.
 - One episode of unexplained hypoglycemia should prompt an insulin adjustment.
 - Less tight glycemic control should be considered for patients with frequent severe hypoglycemia and associated long-term neurologic consequences.
- Diabetic retinopathy
 - Screening is recommended for all individuals with diabetes.
 - Retinopathy within the first 3 years of diagnosis is unusual for a child.
 - Especially if the child is <10 years
 - Ophthalmologic evaluation for patients with T1D
 - Starts between 3 and 5 years after the initial diagnosis
 - Annual follow-up thereafter
- Diabetic nephropathy
 - Leading cause of chronic kidney disease and need for dialysis
 - Uncommon in the young patient or the patient with newly diagnosed T1D
 - Screening should start at age 10 years in children who have had T1D for ≥5 years.
 - Random urine sample to determine the microalbumin-to-creatinine ratio
 - Ratio of ≥30 mg/g (albumin to creatinine) is considered abnormal, and further testing may be indicated.
 - Because other factors may contribute to albuminuria, including exercise, 2–3 abnormal determinations may need to be obtained to confirm the diagnosis.
- Hyperlipidemia
 - Screening is also recommended at or shortly after the initial diagnosis of T1D in all patients.
 - Lifestyle and pharmacologic intervention may be required.
 - Depending on the lipid profile and additional risk factors

■ Autoimmune disorders

- Thyroid disease (~17% of patients)
 - Screening should begin at or shortly after diagnosis of T1D.
 - Measurement of sensitive thyroid-stimulating hormone
 - Annual screening thereafter
- Celiac disease
 - Patients with T1D are at risk.
 - Screening by measuring tissue transglutaminase antibodies or endomysial antibodies
 - Normal total immunoglobulin A concentrations should also be documented.

PROGNOSIS

■ T1D

- Fatal disease until the discovery of insulin
 - Progressive metabolic abnormalities, including ketoacidosis, would eventually lead to death.
 - With the availability of insulin for clinical use in the early 1920s, patients were able to survive the more immediate threat of severe acidosis.
- Uncorrected severe hyperglycemia and metabolic acidosis can lead to neurologic sequelae.
 - Seizures
 - Coma
- Antibodies predict progression in high-risk individuals with HLA susceptibility or a family history of diabetes.
 - Islet cell antigens
 - Glutamic acid decarboxylase
 - Insulin

■ MODY

- Clinical course can range from mild to progressive disease with the development of microvascular complications.

PREVENTION

■ Recognizing early symptoms of diabetes may help prevent:

- Severe diabetic ketoacidosis
- Potentially fatal outcomes

■ Criteria for Screening High-Risk Children for Diabetes

- Overweight (body mass index >85th percentile for age and sex)
- *Plus* any 2 risk factors:
 - Family history of T2D in a first- or second-degree relative
 - High-risk race or ethnicity (Native American, African American, Latino, Asian American, or Pacific Islander)
 - Signs of insulin resistance or associated conditions
 - Acanthosis nigricans
 - Hypertension
 - Dyslipidemia
 - Polycystic ovarian syndrome
 - Maternal history of diabetes or gestational diabetes
- Age to initiate screening
 - 10 years
 - Onset of puberty if <10 years
- Frequency: every 2 years
- Preferred screening test: plasma glucose after an 8-hour fast

Diabetic Ketoacidosis

DEFINITION

- Diabetic ketoacidosis (DKA) is the metabolic consequence of insulin deficiency.
 - Biochemical hallmarks of DKA
 - Hyperglycemia
 - Acidosis

EPIDEMIOLOGY

- Age
 - Adolescents
- Sex
 - More prevalent in girls
- Race and ethnicity
 - Although DKA is more common with type 1 diabetes (T1D) than type 2 diabetes (T2D), Hispanic and African-American youths are more prone than other populations with T2D to develop DKA.

ETIOLOGY

- DKA results from a lack of insulin.
- The following counterregulatory hormones may have elevated levels and contribute to hyperglycemia:
 - Glucagon
 - Catecholamines
 - Cortisol
- Fat stores are broken down in the absence of adequate insulin action, leading to:
 - Ketone body formation
 - Metabolic acidosis

RISK FACTORS

- Diabetes
 - T1D
 - Poor glycemic control (higher hemoglobin A_{1c} level)
 - High reported daily insulin doses
 - Omission of insulin
 - Previous episode of DKA (frequently)
 - Coexisting psychiatric disorders
 - Lower socioeconomic status (underinsured)
 - Adolescent age (especially girls)
 - T2D
 - Historically, less commonly associated than T1D with DKA
 - However, patients with T2D may have DKA.

- Other factors
 - Illness
 - Trauma
 - Alcohol
 - Medications
 - Pancreatitis
- Family history
 - Positive in most patients with T2D
 - Negative in most patients with T1D

SIGNS AND SYMPTOMS

- Symptoms vary and are consistent with the degree of metabolic disturbance.
 - Polyuria
 - Polydipsia
 - Enuresis in previously continent children
 - Dehydration
 - Can be severe if the child has limited access to fluids or is vomiting
 - Signs include tachycardia and weight loss.
 - Most patients with moderate to severe DKA are at least 5–10% dehydrated.
 - True dehydration (intracellular and extracellular fluid loss) rather than simple hypovolemia (intravascular fluid loss) is the rule.
 - Few patients become hypotensive.
 - Fatigue
 - May be evident even before significant dehydration and acidosis
 - Weight loss
 - May be difficult to quantify unless a recent accurate weight is available
 - Polyphagia may be evident early but is typically replaced with a loss of appetite as ketosis and metabolic acidosis worsen.
 - Abdominal pain
 - Vomiting
- Initial assessment
 - Cardiovascular status (heart rate, blood pressure, perfusion)
 - Respiratory status
 - Address immediately if compromise is present.
 - Rapid, deep respirations (Kussmaul breathing)
 - Fruity breath odor may be detected with release of acetone.

- Signs of neurologic dysfunction
 - Confusion
 - Altered sensorium
 - Cerebral edema: consider in all patients with DKA who exhibit signs or symptoms of neurologic compromise
- Severity of disease assessment
 - Sensorium
 - Mild: alert
 - Moderate: drowsy, lethargic
 - Severe: obtundation, coma
 - Hyperpnea
 - Mild: normal respiration
 - Moderate: modest increased respiration
 - Severe: frank Kussmaul respiration
 - Hydration
 - Mild: no dehydration
 - Moderate: mild to moderate dehydration (3–5%)
 - Severe: severe dehydration (>5%)
 - Plasma bicarbonate level
 - Mild: >16–18 mEq/L
 - Moderate: 10–16 mEq/L
 - Severe: <10 mEq/L
 - Anion gap
 - Mild: <20 mEq/L
 - Moderate: 20–25 mEq/L
 - Severe: >25 mEq/L
- Special considerations in infants and young children
 - Young patients cannot verbalize symptoms.
 - Infants' inability to access fluids freely may mask polyuria.
 - Increased urine production may be difficult to judge on the basis of how wet infants' diapers are or how frequently the diapers need to be changed.
 - Parents are less likely to recognize symptoms of hyperglycemia and DKA in children <2 years.
 - May delay diagnosis of diabetes
 - More children in this age group have DKA at initial diagnosis compared with older children.

DIFFERENTIAL DIAGNOSIS

- Coexisting illness should be considered if:
 - The patient is in shock.
 - Lactic acidosis or hemodynamic instability is present.
 - Sepsis or poor perfusion may coexist with DKA.
 - Ketoacidosis does not improve or worsens with insulin administration.

DIAGNOSTIC APPROACH

- 2 biochemical requirements for diagnosis of DKA
 - Blood glucose level >200 mg/dL
 - Metabolic acidosis with a venous pH <7.3 or bicarbonate level <15 mEq/L
 - Although these criteria will identify most patients, glucose concentration ≤200 mg/dL does not always rule out DKA.
- During initial assessment, precipitating factors associated with the episode should be identified.
- DKA is present at the time of initial diagnosis in many patients with T1D.

LABORATORY FINDINGS

- Sodium
 - Estimated depletion per kg body weight
 - 6 mEq/kg (range, 5–13 mEq/kg)
 - Accurate assessment of sodium concentration is necessary to determine appropriate fluid management.
 - Apparent hyponatremia (pseudohyponatremia)
 - Some laboratory methods take this into account when measuring sodium (eg, direct potentiometry using an ion-selective electrode).
 - Primary care physicians need to know the method being used by the laboratory to determine whether pseudohyponatremia is contributing to this biochemical abnormality.
- Potassium
 - Estimated depletion per kg body weight
 - 5 mEq/kg (range, 4–6)
 - Must be monitored closely and replaced appropriately
 - At initial evaluation, potassium levels are typically normal or elevated because of acidemia.
 - When treatment begins, total body potassium is depleted, even with hyperkalemia
 - Profound hyperkalemia or hypokalemia may lead to cardiac arrhythmias.
- Phosphorus
 - Estimated depletion per kg body weight
 - 3 mEq/kg (range, 2–5)
 - Patients with DKA may have profound hypophosphatemia.
 - This may become apparent only during therapy.
- Other biochemical features of DKA
 - Estimated water depletion per kg body weight
 - 60–100 mL/kg
 - Estimated chloride depletion per kg body weight
 - 4 mEq/kg (range, 3–9)

- Other laboratory tests
 - Renal function
 - Blood urea nitrogen (BUN)
 - Creatinine
 - Values are typically elevated in a pattern consistent with a prerenal state.
 - Insulin and C-peptide concentrations are generally low in patients with newly diagnosed T1D.
 - Antibody levels against islet cell antigens and insulin
 - Frequently elevated at time of diagnosis
 - Not useful in diagnosis or management of DKA

IMAGING

- Brain imaging
 - Order promptly if symptoms of cerebral edema are encountered at any time during the treatment of DKA.

DIAGNOSTIC PROCEDURES

- Cultures
 - Blood
 - Urine
 - Glucose
 - Ketones
 - Cerebrospinal fluid
- Electrocardiography
 - Obtain in patients with significantly elevated potassium concentrations to determine whether cardiac abnormalities are present.

TREATMENT APPROACH

- Treatment approach depends on severity of DKA.
 - Mild
 - Patients with established diabetes can be managed in the outpatient setting if they can maintain oral intake.
 - Moderate to severe
 - Medical emergency requiring meticulous attention to optimize outcomes
 - Early recognition and appropriate intervention are imperative.
- Principles of managing DKA are the same whether the underlying diagnosis is T1D or T2D.
 - Correction of metabolic disturbances
 - Prevention of potential complications
 - Mandatory insulin administration
 - Fluid and electrolyte replacement
 - Treatment of concomitant conditions
- No single protocol will be appropriate for all patients.

SPECIFIC TREATMENTS

Fluid replacement

- Initial fluid replacement
 - Patients with moderate to severe DKA are generally considered to be 5–10% dehydrated.
 - 10–20 mL/kg intravenous (IV) fluid is suggested for initial fluid replacement.
 - Isotonic solutions such as lactated Ringer's solution or 0.9% saline
 - Additional fluid resuscitation may be required in some patients.
 - Caution must be used, especially in patients with possible cerebral edema.
 - Aggressive fluid resuscitation is rarely required.
 - The goal of initial fluid resuscitation is not to replace the entire fluid deficit.
 - Rehydration should take place over 36–48 hours.
 - Less aggressive rates of fluid replacement have been associated with more rapid correction of acidosis.
 - Gradual rehydration may reduce the risk of cerebral edema compared with more aggressive fluid administration.
 - Fluid therapy (even before insulin) will reduce the blood glucose concentration.
- After initial fluid bolus
 - Content of IV fluid should be changed to:
 - Address additional electrolyte abnormalities
 - Prevent hyperchloremic metabolic acidosis that may occur if isotonic saline solutions are continued
 - Add potassium to the IV solution when:
 - Potassium concentration is normal or low *and*
 - Urine flow has been established.
 - Rehydration should take place over ≥ 48 hours.
 - Rate of fluid administration should rarely exceed 1.5–2 times the maintenance fluids.
 - Urinary losses should not be added to the calculated fluid requirement.
- Transition to oral intake after correction of acidosis
 - IV fluids should be reduced or discontinued.

Insulin therapy

- IV insulin
 - Preferred route of administration for regular insulin
 - Subcutaneous (SC) and intramuscular delivery are used initially only if IV access is impossible.
 - Can be titrated frequently if necessary

■ SC delivery

- Consider converting to SC insulin when:
 - The serum bicarbonate level is >16 – 18 mmol/L (or pH >7.3).
 - The patient can begin oral intake.
- Child with previous diagnosis of diabetes
 - Home insulin regimen may serve as a guide in choosing:
 - Initial SC insulin doses
 - Type of program to use (split-mixed vs multiple daily injection)
- Child with newly diagnosed diabetes
 - 0.5 – 1.0 units/kg per day in divided doses
- Adjust dose on the basis of:
 - Meal plan
 - Level of activity
 - Pubertal status (insulin requirement is increased during puberty)

■ Dosing

- Initial infusion rate
 - 0.1 unit/kg per hour of IV regular insulin
 - Ketosis and metabolic acidosis will not correct without adequate insulin administration.
 - A constant insulin infusion rate should be used.
 - Rate of insulin infusion may need to be increased in some children if ketoacidosis does not improve or worsens.
 - Metabolic acidosis often corrects many hours after euglycemia has been restored.
- Blood glucose concentration
 - Should not be used alone to determine when to discontinue or decrease rate of infusion
- Addition of glucose to IV fluids
 - When blood glucose level falls below 250 – 300 mg/dL
 - An infusion of 5% dextrose may be sufficient for many patients.
 - Higher rates of dextrose infusion may be required to prevent hypoglycemia while ketoacidosis is resolving.

Electrolytes

■ Sodium

- Sodium depletion is addressed with isotonic solutions suggested for initial fluid management.
- Correction factors for hyponatremia
 - Add 1.6 mEq/L to the measured sodium concentration for every 100 mg/dL that the glucose concentration is over the normal range.
 - Other researchers have suggested that a correction factor of 2.4 mEq/L is more appropriate than 1.6 mEq/L.
 - Excessive isotonic sodium chloride should not be given; hyperchloremic metabolic acidosis may result.

- Sodium concentrations should be monitored closely.
 - Failure of the sodium concentration to increase during treatment of DKA may be associated with higher risk of cerebral edema.

■ Potassium

- Before insulin therapy, potassium concentrations may be elevated, normal, or low, depending on:
 - Severity of DKA
 - Duration of DKA
 - Gastrointestinal losses caused by vomiting
- After initiation of insulin therapy, potassium concentrations invariably decline as acidosis resolves and may become normal or low.
- Potassium should be replaced after:
 - Initial isotonic fluid bolus has been given.
 - Serum potassium concentration becomes normal or low.
 - Urine output is established.
- Dosing
 - Add 20 mEq/L potassium acetate and 20 mEq/L potassium phosphateto 0.45% saline.
 - The combination of salts prevents excess chloride while replacing potassium and phosphorus.
 - This solution is safe and an effective means to prevent profound hypokalemia.
- Potassium levels should be monitored closely and therapy adjusted according to individual patient needs.

■ Phosphorus

- Phosphate concentrations may vary before initiation of insulin therapy.
- Phosphate replacement in patients with DKA has *not* been shown to:
 - Provide clinically important improvements in outcome
 - Eliminate significant complications
- However, possibility of a decrease in oxygen delivery to tissues is present.
- Dosing
 - Add 20 mEq/L potassium acetate and 20 mEq/L potassium phosphateto 0.45% saline (as for potassium replacement).
 - The combination of salts prevents excess chloride while replacing potassium and phosphorus.
- If phosphate therapy is used:
 - Serum calcium concentrations should be monitored because hypocalcemia may occur.

■ Bicarbonate

- Data are lacking to support use of bicarbonate therapy for patients with mild to moderate DKA.
- Even for patients with severe DKA, bicarbonate therapy has not been proven beneficial.
- Use of bicarbonate in patients with DKA may not be appropriate because:
 - Ketoacidosis can be completely corrected by the administration of IV fluids and insulin.
 - Bicarbonate will add sodium that may not be required.
 - Bicarbonate therapy may cause paradoxical central nervous system acidosis.
 - Bicarbonate therapy has been associated with an increased risk of cerebral edema.
- Despite these concerns, some patients may benefit from cautious alkali administration.
 - Patients with cardiovascular dysfunction caused by severe acidosis and/or hyperkalemia

WHEN TO ADMIT

- Patients with moderate to severe DKA
- Patients with dehydration or those who cannot maintain adequate oral intake
- All patients with newly diagnosed diabetes regardless of severity of ketoacidosis

WHEN TO REFER

- When facilities to provide frequent patient assessment (clinical and laboratory) are not available
- When a physician experienced in the diagnosis and treatment of DKA is not available

FOLLOW-UP

- Monitoring
 - Frequent monitoring of patient's response to therapy is imperative to assess whether change in treatment is required.
 - Hourly measurement
 - Glucose
 - Measure every 2–4 hours:
 - Electrolytes
 - Bicarbonate
 - Ketones
 - pH
 - Severe DKA
 - More frequent monitoring (every 2 hours)
 - When improvement in ketoacidosis has been established
 - Less frequent monitoring (every 4 hours)

COMPLICATIONS

■ Cerebral edema

- Affects ~1% of children
 - Some studies suggest an increased incidence of sub-clinical cerebral edema when imaging criteria are used to diagnose the condition.
- Consequences are severe.
 - 20–25% mortality rate
 - A significant proportion of survivors will have permanent neurologic consequences.
- High index of suspicion should be maintained for early identification of this potentially fatal condition.
 - Clinical findings suggestive of cerebral edema should prompt emergent assessment.
 - Frequent neurologic examinations should be performed in children with DKA in an attempt to identify and intervene early.
 - Cerebral edema can be present before therapy for DKA.
 - Prevention of DKA may be the only effective strategy to prevent this potentially devastating complication.
- Symptoms of cerebral edema attributed to increased intracranial pressure
 - Decreased level of consciousness
 - Elevated blood pressure
 - Bradycardia
 - Nonspecific symptoms, such as headache
- Risk factors for cerebral edema:
 - Lower partial pressure of arterial carbon dioxide at presentation
 - Severity of dehydration (higher initial BUN)
 - Smaller increase in serum sodium during treatment
 - New-onset diabetes
 - Treatment with bicarbonate
 - Younger age
 - Longer duration of symptoms before presentation
- Management of cerebral edema associated with DKA
 - Reduce rate of fluid administration.
 - IV mannitol may be given and repeated after 2 hours if clinically indicated.
 - Hypertonic saline has been suggested as an alternative to mannitol.
 - If intubation is required, hyperventilation should be avoided.
 - Has been associated with worse outcomes

- Hypoglycemia
- Venous thrombosis
 - Especially in children with a central venous catheter
- Seizures
- Coma

PROGNOSIS

- The reported mortality rate in children with DKA is low (<0.5%).
 - Most deaths occur in patients who develop clinically apparent cerebral edema.
 - In adults, coexisting conditions, such as myocardial infarction, contribute to a larger percentage of the mortality associated with DKA.

PREVENTION

- Most children with established diabetes develop DKA because of omission of insulin.
 - Failure to recognize the need for insulin during illness
 - This common mistake can be prevented by providing adequate education to the patient and family.
 - Insulin need may be greater during illness.
 - Financial constraints
 - A small percentage of patients with diabetes accounts for a disproportionate number of episodes of DKA.
 - Interventions targeted at this high-risk population would seem appropriate.
- Patients with newly diagnosed diabetes
 - Raising public awareness of symptoms of diabetes may be a cost-effective way to prevent DKA.

Diaper Rash

DEFINITION

- Diaper rash is not a single disorder, but rather a reaction of the skin to a host of factors, both local and systemic.
- On occasion, it may result from serious illness.

EPIDEMIOLOGY

- Prevalence
 - The most common skin disorder of infants and toddlers
 - Occurs in 1 of 4 infants
 - In a survey of suburban infants, 25% had some diaper dermatitis and 4% had a severe rash.
- Age
 - The greatest frequency occurs between 9 and 12 months of age.

ETIOLOGY

- 4 factors have been associated with the occurrence of diaper rash (see Figure 20 on page F6).
 - Wetness of the skin
 - Elevated pH of the skin
 - Fecal enzymes (especially proteases and lipases)
 - Microorganisms, especially *Candida albicans*
- Wet skin
 - Has a reduced ability to withstand frictional forces
- Elevated pH and fecal enzymes
 - Increase permeability
 - The normal pH of the skin is between 4.5 and 5.5.
 - Elevated pH:
 - Has been associated with more severe diaper rash
 - Increases activity of fecal proteases and lipases
 - Decreases normal skin microflora
 - Ammonia once was believed to be the primary irritant causing diaper rash but is no longer considered to be the major factor.
 - Fecal proteases and lipases along with moisture:
 - Lead to maceration of the skin
 - Increase permeability to such substances as bile salts, which worsen the inflammation
- *Candida albicans*
 - The most important microorganism found on the skin of infants who have diaper rash
 - Produces a protease that penetrates the skin and can:
 - Cause a primary infection
 - Be a secondary invader in systemic conditions, such as seborrheic dermatitis
 - Be found in many infants who have nonspecific diaper rash

- Even a small number of *Candida* organisms can cause significant infection.
- In 1 survey, candidal species were isolated from one-half of the mouths of healthy infants.
 - Infants who routinely sucked a pacifier had a higher rate of oral candidal carriage.
- Use of oral or parenteral antibiotics
 - Can increase the number of *Candida* organisms on the skin and frequency of stools
- *Staphylococcus aureus*
 - Has been isolated as a secondary invader of systemic illness, such as atopic dermatitis
 - Although present on skin, it does not appear to be a common primary pathogen in other forms of diaper rashes.

RISK FACTORS

- Historical factors that may help determine the contributors to diaper rash include:
 - Duration of the rash
 - Frequent bowel movements, eg, in infants with gastroenteritis or taking antibiotics
 - Presence of increased enzymes, yeast, pathogenic bacteria
 - Type of diaper
 - Diapers made of water-absorbent gel material keep skin drier and decrease the occurrence of diaper rash.
 - Frequency of changing: wet skin
 - In 1 study, infants whose diapers had been changed ≥ 8 times during the day had fewer rashes than those changed less often.
 - Method of laundering cloth diapers
 - Use of outer coverings, such as plastic or rubber pants
 - Past illness (especially dermatologic, allergic, and infectious)
 - Medication use (eg, antibiotics) that include the therapy for the rash
 - Exposure to contagious disease (eg, scabies, varicella)
 - Presence of systemic symptoms
 - Family history of illness (eg, psoriasis, allergy)

SIGNS AND SYMPTOMS

- Diaper rashes can be classified into 3 distribution patterns by appearance and location.
 - This approach has limitations.
 - A single agent (eg, *C albicans*) can lead to different presentations.
 - A single presentation may be caused by many agents (either alone or in concert).

- Diaper dermatitis from any cause
 - Can become secondarily infected with *Staphylococcus* or *Streptococcus*, leading to impetigo, bullous impetigo, or staphylococcal scalded skin
- Some diaper rashes do not fit any of these patterns, eg, that due to herpes simplex virus infection
- First pattern
 - Chafing or irritant dermatitis (see Figure 21 on page F6)
 - Erythematous desquamative rash involving the convex surfaces that touch the diaper and spare the inguinal folds
 - Erythema is mild, with or without papules.
 - Skin has a shiny, glazed appearance.
 - Meatitis may be seen in boys.
 - Rashes that have persisted for >72 hours are usually found to have significant *Candida* involvement.
 - Atopic dermatitis
 - Eczematoid appearance with lichenification (thickening), pruritus, and atopic dermatitis elsewhere should help substantiate this diagnosis.
 - Uncommon in children <6 months
- Second pattern
 - Involves skinfolds and spares convex surfaces (see Figure 22 on page F7)
 - Rashes involving the perianal area only
 - Are common in the neonatal period
 - May result from irritation by diarrhea
 - Are especially common in children whose diarrhea is secondary to disaccharidase deficiency
 - May be caused by infection with *C albicans*
 - Intertrigo
 - Causes moist, macerated symmetric eruptions in skinfolds and creases
 - Commonly becomes infected secondarily by *C albicans*, especially when satellite lesions are present
 - Classic primary candidal (monilial) diaper rash
 - Bright red confluent lesions, often with raised borders
 - Occasional pustular-vesicular satellite lesions on the trunk and legs
 - Other areas, eg folds of the neck, the postauricular area, and the oral mucosa (thrush), may be involved.
 - Usually painful and tender
 - In 1 study, rashes least like that shown in Figure 22 on page F7 were more likely to be associated with *Candida* organisms.
- Langerhans cell histiocytosis
 - May have the same distribution as *Candida* infection but is more papular, hemorrhagic, and more likely to be eroded
 - Fails to respond to conventional therapy
 - Constitutional symptoms (such as malaise) and abnormal physical findings (such as hepatosplenomegaly) may be present.
- Seborrheic dermatitis
 - Characterized by erythematous, often salmon-colored, patches with greasy scale that involve the convexities and creases (see Figure 23 on page F7)
 - May be difficult to distinguish from psoriasis, which has a deeper red color
- Third pattern (see Figure 24 on page F7)
 - Erythema in this distribution has been termed *tide mark dermatitis*.
 - Believed to be related to frequent cycles of wetting and drying
 - Irritation from diapers that are too tight (constrictive) and that may have an elastic band can lead to a similar rash.

DIFFERENTIAL DIAGNOSIS

- Serious, systemic illness must always be considered in the child with:
 - An atypical or a severe rash
 - Failure to respond to customary therapy
- Some conditions may occur or begin with greater intensity in the diaper area and may change morphologically.
 - Such predilections probably represent the Koebner (isomorphic) response.
 - Skin lesions of a systemic illness concentrate on areas previously inflamed by other factors, such as friction.
 - Conditions include:
 - Seborrhea
 - Atopic dermatitis
 - Hand-foot-and-mouth disease
 - Primary herpes simplex virus infection
 - Psoriasis
 - Varicella
 - Miliaria
 - Scabies
- Less common causes of diaper rash include:
 - Infectious or presumed infectious
 - Herpes simplex virus: Vesicular; may be associated with immunosuppression
 - Cytomegalovirus: Usually associated with immunosuppression

- Kawasaki disease: red, desquamating perineal eruption associated with fever, often during the first week after syndrome onset
- Syphilis: May have other manifestations of secondary syphilis
- Trichophyton: Extremely uncommon; annular scaly patches
- Neoplastic
 - Histiocytosis (Letterer-Siwe disease): Resembles seborrhea plus reddish-brown papules
- Nutritional and metabolic
 - Zinc deficiency (acrodermatitis enteropathica): Mimics monilial rash; vesicular eruptions elsewhere
- Presumed iatrogenic
 - Granuloma gluteale infantum: May be secondary to use of halogenated steroid creams
- Genetic
 - Wiskott Aldrich syndrome: Thrombocytopenia and recurrent infections in boys
- Severe, persistent, and recurrent infections with *Candida* organisms
 - May (rarely) result from immunodeficiency, including HIV infection or diabetes mellitus
- Children who are immunosuppressed from HIV infection or neoplasia (or its treatment):
 - May have diaper rash from such organisms as herpes simplex virus or cytomegalovirus
 - If an immunosuppressed child has a serious or unresponsive diaper rash, then aggressive pursuit of an etiologic agent, including skin biopsy, should be considered.
- Child abuse (including sexual abuse) or neglect
 - Should be suspected in the child who has lesions in the diaper area (especially burns) that are inconsistent with the history provided.

LABORATORY FINDINGS

- Laboratory tests are not indicated for most diaper rashes.
- Tests that may be helpful in identifying the cause of a diaper rash include:
 - Potassium hydroxide preparation and a fungal culture of skin scrapings for *Candida* organisms
 - Bacterial culture for *Staphylococcus* organisms
 - Mineral oil slide preparation for scabies
 - Serum zinc level (to rule out acrodermatitis enteropathica)
 - Serologic tests for syphilis

IMAGING

- Radiography of the skull and long bones may be helpful for evidence of child abuse.

DIAGNOSTIC PROCEDURES

- Skin biopsy
 - Rarely, may be useful in cases in which the diaper rash is atypical or unresponsive to therapy

TREATMENT APPROACH

- The initial step should be to minimize contact with soiled diapers.
 - Most clinicians recommend that during therapy:
 - Diapers should be changed frequently (≥ 8 times a day), using breathable diapers with absorbent gel material.
 - Stool should be wiped off the skin as soon as possible.
 - Plastic pants that retain water should not be used.
 - Breaks from wearing diapers should be offered as much as possible.
- Commercial disposable baby wipes, which typically contain water, an emollient, and surfactants:
 - Are less irritating than cotton washcloths
 - May be better for cleaning intertriginous areas
 - Are well tolerated by children with atopic dermatitis
- Systemic conditions such as scabies, atopic dermatitis, and varicella
 - Most can be managed as they are for other parts of the skin.
 - Seborrheic dermatitis is an exception (see Specific Treatments).
- Many more children have been harmed by well-intended diaper rash therapies than have ever been harmed by the rash itself.
 - Boric acid, mercury compounds, and pentachlorophenol have led to illness and death in infants.
 - Talcum powder never should be used.
 - Provides no protection
 - Is abrasive
 - Inhalation of a large quantity can produce serious or fatal pulmonary damage.
 - Topical steroids present numerous dangers.
 - In a nationally representative survey, 16% of diaper rashes were treated with a combination of nystatin and triamcinolone, a mid-potency steroid that should not be used in the diaper area.
 - In a survey of pediatricians, 23% who prescribed clotrimazole-betamethasone dipropionate (Lotrisone) did so for diaper dermatitis.
 - Betamethasone dipropionate is a high-potency steroid and is not indicated for the diaper area.
 - Hair dryers may cause perineal burns and should never be recommended to dry the skin in the diaper area.

- Products containing iodochlorhydroxyquin, such as Vioform or Iodo Plain, should never be used.
 - Systemic absorption may lead to optic atrophy and neuropathy.

SPECIFIC TREATMENTS

Irritant diaper dermatitis

- Usually, the only interventions needed are:
 - Frequent diaper changes
 - Skin washing with plain water or disposable baby wipes
 - Allowing the skin to dry between diaper changes
- Scrubbing the rash or diaper area should be discouraged.
- Diapers with absorbent gel materials:
 - Have been shown to decrease wetness in the diaper area
 - May hasten the disappearance of a diaper dermatitis
- Barrier pastes and ointments
 - Form a resistant covering over the skin surface and decrease friction
 - Insufficient evidence available to support use of one product over another.
- Cloth diapers
 - Rinsing in methylbenzethonium chloride (Diaparene), a bacteriostatic agent, or in a vinegar solution (1 ounce in 1 gallon of water) has been shown to reduce recurrences.
 - Elimination of fabric softeners and changing detergents
 - May be effective in some cases
 - Is not scientifically documented as beneficial
- 1% hydrocortisone
 - May promote healing in cases of significant inflammation
 - Steroids that are more potent than 1% hydrocortisone should never be used in the diaper area because diapers form an occlusive dressing.
 - Long-term use may lead to skin atrophy, telangiectasis, granuloma gluteale, striae and, possibly, Cushing syndrome.
- Topical antibiotics
 - May be used to prevent stricture in meatitis
 - Antibiotic solutions available in ophthalmologic containers can be used.
- Miconazole in a zinc oxide-petrolatum base
 - One study showed it was more effective in eliminating moderate to severe diaper rashes (even without direct evidence of candidiasis) than the base alone.
- Agents to acidify urine (cranberry juice, vitamin C), cornstarch, and ointments that contain vitamins A and D
 - Widely used
 - No experimental evidence supports their efficacy.

Seborrheic dermatitis

- Because the diaper area is often infected secondarily with *Candida* organisms, measures to treat yeast must be undertaken as well.
- For this and other diaper rashes in which *Candida* organisms are present
 - Topical nystatin, miconazole, clotrimazole, haloprogin, or ketoconazole should be applied for 5–10 days.
 - Such agent as miconazole and clotrimazole have the advantage of requiring only twice-daily application.
 - 1% hydrocortisone may be used simultaneously to decrease inflammation.
 - Steroids that are more potent than 1% hydrocortisone should never be used in the diaper area because diapers form an occlusive dressing.
 - Long-term use may lead to skin atrophy, telangiectasis, granuloma gluteale, striae and, possibly, Cushing syndrome.
- Gentian violet
 - Effective, but is extremely messy
 - Rarely if ever indicated
- Oral nystatin
 - Effectiveness in the therapy of candidal diaper rash is uncertain.
 - In a controlled study, recurrence of candidal diaper rash was not decreased significantly.
 - In another controlled trial, oral fluconazole was more effective than nystatin in eliminating oral *Candida* in infants who had oral thrush.
- Oral fluconazole
 - Effective for candidal diaper rash in the absence of thrush
 - Can be used if other therapies have failed

WHEN TO ADMIT

- Systemic illness that cannot be treated safely at home
- Severe illness, such as septicemia

WHEN TO REFER

- The rash has not responded to conventional treatment in several weeks or is worsening.
- The rash is nodular.
- Abuse is suspected.

PREVENTION

- The following measures should prevent many diaper rashes.
 - Frequent diaper changes
 - Cleansing the diaper area promptly
 - Avoidance of plastic or rubber pants

- Airing the diaper area
 - Careful diaper selection
 - Disposable diapers that contain absorbent gel are associated with the lowest incidence of diaper rashes in otherwise healthy children and those who have atopic dermatitis.
 - Breathable covers are associated with lower counts of *Candida* and reduced occurrence of diaper rash.
 - A recent Cochrane review concluded that not enough evidence from quality randomized controlled trials exists to choose one type of disposable diapers over another.
 - Use of barrier creams and ointments
 - Breastfeeding
 - Lower levels of enzymes in infant stools, lower urinary pH, and fewer diaper rashes
 - Educating caregivers
 - Physician should educate parents about commonly used home remedies that might be harmful.
 - Parents who usually use cloth diapers may consider using commercial diapers:
 - That contain absorbent gel materials when their children are at increased risk for diaper rash
 - During travel away from home
-

Diarrhea and Steatorrhea

DEFINITION

■ Diarrhea

- Increased stool frequency
- Stools with increased water content

■ Steatorrhea

- Excess fat in the stool

EPIDEMIOLOGY

■ Incidence

- 1 or 2 episodes per year in US children in the first few years of life, on average

MECHANISM

■ The pathophysiologic mechanisms for diarrhea fall into 4 basic groups.

- Osmotic diarrhea
 - The ingestion of a poorly absorbable, osmotically active substance and its presence in the bowel lumen create an osmotic gradient that encourages movement of water into the lumen and subsequently into the stool.
 - Diarrhea resulting from secretion or altered absorption of electrolytes
 - Secretory diarrhea occurs when a physiologic electrolyte secretory process is pathologically stimulated.
 - A net increase in luminal electrolytes and, subsequently, a secondary increase in water occur.
 - Diarrhea also may result from a decrease in active electrolyte absorption in the absence of any change in secretory function.
 - Exudative diarrhea
 - A break in the integrity of the mucosal surface of the intestine can result in water and electrolyte loss, driven by hydrostatic pressure in blood vessels and lymphatics.
 - Diarrhea resulting from abnormal intestinal motility
 - The intestine has a cyclical, orderly pattern of motility.
 - Increased, decreased, or disordered movement can lead to diarrhea.
- Each mechanism has unique clinical characteristics and requires a different therapeutic approach.
- Frequently, >1 mechanism of diarrhea will be involved in an episode of diarrhea.
 - This variation will be apparent in the evaluation.
- Steatorrhea signifies an excess of fat in the stool and is a symptom of malabsorption.
- Absorption of fat by young infants varies with the type of fat that is fed and with the maturity of the infant.
 - Normal premature infant: as little as 65–75% of dietary fat
 - Term infants: 90% of dietary fat

- Neonates absorb vegetable fat much more efficiently than butterfat.
- Neonates absorb human milk fat best of all.
- By comparison, older children and adults typically absorb $\geq 95\%$ of the fat in a normal diet.

HISTORY

■ During initial evaluation, establish:

- Length of illness
- Characterization of stools
 - Frequency
 - Looseness (watery vs mushy)
 - Presence of gross blood
- Oral intake
 - Diet
 - Quantity of fluids and solids taken
- Presence of vomiting
- Associated symptoms
 - Fever
 - Rash
 - Arthralgia
- Urine output
 - Frequency
 - Qualitative amount
- Possible exposure to diarrheal illness

PHYSICAL EXAM

■ Determine hydration status.

- Mild dehydration: 3% in infants and 5% in older children
 - Dry mouth
 - Absence of tears
- Moderate dehydration: 6% in infants and 10% in older children
 - Dry mouth
 - Absence of tears
 - Sunken eyes
 - Sunken fontanelle
 - Poor skin turgor
- Severe dehydration: >9% in infants and $\geq 15\%$ in older children
 - Shock

■ Assess body weight.

- A recorded weight is essential.
 - Can be compared with previous weights
 - Can be used to reevaluate the child's state of hydration during the illness
- Infants should be weighed at least daily.

- Assess:
 - Vital signs
 - Alertness
 - In infants, vigor of suck
- Measurement of stool output
 - If the urine is collected in a urine bag, diapers can be weighed before and after stools to give an accurate measure of stool output.

DIFFERENTIAL DIAGNOSIS

Steatorrhea

- Cystic fibrosis
- Congenital pancreatic insufficiency with cyclic neutropenia (Shwachman-Diamond syndrome)
- Intestinal lymphangiectasia
- Abetalipoproteinemia
- Transient steatorrhea following acute enteritis
- Celiac disease
- Pancreatic insufficiency, as detected by measurement of stool elastase or serum trypsinogen

Acute diarrhea

Neonates

- Neonates with acute diarrhea must be considered differently from older infants and children.
 - Lower tolerance to associated fluid shifts
 - Greater likelihood of severe infection or congenital anomaly
- Signs of necrotizing enterocolitis should raise concern.
 - Gastric retention (frequently bilious)
 - Distention
 - Occult or bright-red blood in the stool
 - More common in premature infants
 - The presence of pneumatosis intestinalis, gas in the portal vein, or free intraperitoneal gas seen on abdominal radiographs supports the diagnosis.
- Epidemics of diarrhea associated with rotavirus, enteropathogenic *Escherichia coli*, *Salmonella*, and other organisms, including *Klebsiella* organisms, have been reported in nurseries.
- Onset of diarrhea associated with initial feedings
 - Consider congenital digestive defects, especially sugar intolerance.
- Hirschsprung disease
 - May produce acute diarrhea and enterocolitis in the neonatal period
 - Should be considered, especially in the infant who has not passed meconium in the first 24 hours

- Bloody diarrhea
 - May result from cow's milk or soy protein intolerance
 - May develop as early as the first few days of life
 - Resolution and exacerbation on removal and reintroduction of cow's milk or soy formula, as well as an atopic family history, are clues to the diagnosis.

Older infants and children

- Enteric infection
 - *Salmonella* organisms
 - *Yersinia enterocolitica*
 - *Campylobacter*, *Giardia*, *Cryptosporidium*, and *Cyclospora* organisms
 - *Clostridium difficile* toxin
 - The cause of most cases of pseudomembranous colitis
 - May be associated with chronic childhood diarrhea in the absence of colitis
 - Enterotoxin C *E coli*
 - In older infants and children, associated with watery stools
 - No evidence of mucosal invasion (ie, no high fever or blood in the stool)
 - Rotavirus
 - Adenovirus
- Parenteral diarrhea
 - Diarrhea in association with extraintestinal infections, most notably otitis media and pyelonephritis
 - The mechanism is obscure.
 - Associated viral enteritis in some cases of otitis media
 - Certain antibiotics, especially ampicillin, have been associated with transient diarrhea.
 - Less common but of greater danger is antibiotic-associated pseudomembranous colitis.
 - May occur acutely or as a more chronic illness lasting 1–2 months
- Bacteria
 - *Shigella*
 - Patients appear severely ill.
 - May have meningismus or seizures
 - Stools tend to be foul smelling.
 - Hemolytic-uremic syndrome (although *E coli* is the more common cause)
 - *Campylobacter*
 - Evidence of infection before the onset of neurologic symptom in up to 40% of cases of Guillain-Barré syndrome
 - *Yersinia* (less common in the US)

- *E coli*
 - Produces diarrhea by several pathogenic mechanisms
 - Enteroadherent, enteroinvasive, enterohemorrhagic, and enteroaggregative forms can all be associated with blood in the stool.
 - Hemolytic-uremic syndrome results largely from enterohemorrhagic *E coli* (especially serotype O157:H7).

■ Parasites

- *Entamoeba histolytica*
- *Giardia lamblia*

■ Food-borne spread of organisms or toxins

- Improperly prepared poultry and eggs are the major source for both campylobacteriosis and salmonellosis.
- The major source for *E coli* O157:H7 infection is ground beef.
- Preventive measures include:
 - Safe food-handling practices
 - Pasteurization of in-shell eggs
 - Irradiation of ground meat and raw poultry
- Explosive diarrhea after ingesting seafood is likely to be due to infection with *Vibrio* species.

Chronic diarrhea

Infants

■ Chronic nonspecific diarrhea (toddler's diarrhea, irritable colon of childhood)

■ Protracted diarrhea of infancy

- Poorly understood
- Previously called *intractable diarrhea of infancy*
- Probably represents the final pathway for multiple causes
 - Gastrointestinal infections
 - Food intolerances
- Defined somewhat arbitrarily as occurring in infants younger than 3 months and persisting for longer than 2 weeks
- In the past, associated with high mortality from irreversible diarrhea and related malnutrition
 - Outcome has improved markedly with the advent of elemental diets and total parenteral nutrition.
- Now rare and related to more specific causes, such as microvillus inclusion disease

■ *C difficile* infection

■ Hirschsprung disease

- Accounts for approximately 25% of intestinal obstructions in newborns
 - Almost invariably fail to pass meconium early
 - Persistent obstipation and recurrent abdominal distention

- Usually have a history of the absence of stools in the first 24 hours of life

- These features may be overlooked, and infants may subsequently have chronic diarrhea.
- The diarrhea is secondary to enterocolitis.
 - The enterocolitis can be a surgical emergency that demands rapid diagnosis and treatment.
- Infants with Hirschsprung disease require decompression colostomy to remove risk of perforation of the colon.

■ Cystic fibrosis

- Although cystic fibrosis is thought of primarily as a respiratory disease, some infants and children have malabsorption and little history of respiratory symptoms.
- Patients typically have voracious appetites.
- Diagnosis must be confirmed by sweat electrolyte studies or genetic testing.

■ Celiac disease (gluten-sensitive enteropathy)

- Much more common than previously recognized
- In infancy, celiac disease becomes apparent 1 to several months after the introduction of gluten-containing products (eg, wheat, rye, barley) into the diet.
- Diagnosis should be confirmed by small-bowel biopsy.
- *Giardia* infection can produce small-bowel malabsorption that mimics celiac disease.

■ Carbohydrate (monosaccharide or disaccharide) intolerance

- Usually secondary to other gastrointestinal disorders
- Extent of symptoms varies in response to quantity of the offending sugar in the diet.
- Age at presentation varies with the age at which the sugar is introduced into the diet.

■ Congenital deficiency of trypsinogen, the zymogen precursor of the pancreatic protease trypsin (very rare)

■ Infection

- Urinary tract infection
- *Candida*
 - Rare cause of diarrhea in immunocompetent individuals
 - The incidental finding of *Candida* is so common that the clinician must be cautious before identifying it as the cause of diarrhea.
 - A dramatic response to treatment for *Candida* would support this diagnosis.
- *Salmonella* infection may be associated with persistent diarrhea in infants.
- *Yersinia enterocolitica* enteritis has been associated with a chronic relapsing diarrhea, although not commonly in the US.
 - The microbiology laboratory must look specifically for this organism, or it will be missed.

- *Campylobacter* enteritis also may have a protracted course.
 - Persistence of rotavirus excretion has been identified in immunocompromised individuals but also rarely in immunocompetent children after severe gastroenteritis.
- Parasites
- *G lamblia*
 - Principal parasitic cause in US
 - May be associated with watery diarrhea and crampy abdominal pain
 - May be epidemic
 - *Cryptosporidium*
 - Causes diarrhea in immunocompetent individuals
 - *Cyclospora*
 - *Blastocystis hominis*
 - *Dientamoeba fragili*
 - Amebic dysentery may be indistinguishable from colitis of inflammatory bowel disease and must be considered along with bacterial colitis before inflammatory bowel disease can be diagnosed.
- Food allergy
- 6–8% of children have dietary protein hypersensitivity during the first 5 years of life.
 - Hypersensitivity to cow's milk protein is most common.
 - Symptoms resolve by 3 years of age in 85% of children.
 - Consider in an infant with chronic diarrhea with any of the following manifestations
 - Occult or gross blood in the stool (colitis)
 - Protein-losing enteropathy
 - Peripheral eosinophilia
 - Other extraintestinal manifestations of allergy (eg, eczema, hives, or asthma)
 - Most food allergic reactions include immediate gastrointestinal hypersensitivity.
 - Nausea
 - Abdominal pain
 - Vomiting within 1–2 hours
 - Diarrhea in 2 hours
 - Implicated food proteins include:
 - Milk
 - Egg
 - Peanut
 - Soy
 - Cereal
 - Fish
 - Eosinophilic (allergic) gastroenteropathy
 - Characterized by infiltration of the stomach and intestine with eosinophils and often a peripheral eosinophilia
- Symptoms include vomiting, abdominal pain, growth failure, and diarrhea (often with gross blood).
 - May respond to elimination diet, but corticosteroid treatment may be necessary
 - Dietary protein enterocolitis is most common in the first year of life.
- Diet-induced proctitis
 - Gross blood in stool
 - Diarrhea in the first few days to months of life
 - Symptoms usually resolve within 72 hours with removal of the offending food allergen.
 - Bloody diarrhea can develop in some infants while they are nursing.
 - Resolution when cow's milk is removed from the mother's diet or when a protein hydrolysate formula is substituted for nursing suggests an allergic basis.
- Short-bowel syndrome
- Chronic malabsorption and diarrhea follow extensive resection of the small intestine.
 - Begins most commonly in the newborn period in association with necrotizing enterocolitis or a congenital anomaly involving small intestine (eg, gastroschisis, intestinal atresia, malrotation with secondary midgut volvulus)
 - Total parenteral nutrition (TPN) may be required for the first several years of life.
- Intestinal lymphangiectasia
- Protein-losing enteropathy
 - Steatorrhea
 - Lymphocytopenia
 - Chronic diarrhea
 - Sometimes, hypogammaglobulinemia and hypoalbuminemia, usually with peripheral edema
 - Primary intestinal lymphangiectasia
 - Appears to be a developmental anomaly of unknown origin
 - Often associated with lymphatic abnormalities of the extremities
 - Secondary lymphangiectasia may result from:
 - Chronic volvulus secondary to malrotation with malfixation of the bowel
 - Constrictive pericarditis
 - Tumor
 - Lymphatic malformation
 - Elevated right atrial pressure associated with the Fontan procedure for congenital heart disease
 - Any other factor that leads to obstruction of intestinal lymphatic flow

- The diagnosis is suggested by:
 - History of chronic diarrhea and poor growth
 - Peripheral edema
 - Hypoalbuminemia
 - Hypogammaglobulinemia
 - Lymphocytopenia
- Acrodermatitis enteropathica
 - Rare familial disease
 - Typically appears when breastfed infants are weaned
 - Associated with a zinc deficiency, possibly secondary to malabsorption
 - Nutritional zinc deficiency (eg, TPN without zinc supplementation or cystic fibrosis) may produce a syndrome similar to acrodermatitis enteropathica.
- Factitious diarrhea
 - More common than pediatricians recognize
 - Laxative abuse may be suspected when an infant has persistent diarrhea that does not seem to fit any known pattern.
 - Surreptitious administration of laxative to an infant indicates the caretaker's psychosocial dysfunction.
 - Stool osmolality well below 290 mOsm/L can occur only by surreptitious dilution of stool with water.
 - Factitious diarrhea occurs among teenage girls who take laxatives surreptitiously to lose weight.
- Hormonal
 - Adrenal insufficiency
 - Adrenogenital syndrome
 - Adrenal hemorrhage
 - Hyperthyroidism
 - Vasoactive intestinal polypeptide–secreting tumors of the pancreas (rare)
 - Congenital thyrotoxicosis
 - Ganglioneuroma and ganglioneuroblastoma
 - Associated with chronic secretory diarrhea
 - Usually abdominal but also reported in the mediastinum
 - Catecholamine-secreting, but prostaglandins or vasoactive intestinal polypeptide may be the mediator of the diarrhea
 - Diarrhea usually resolves abruptly when a tumor is found and is completely excised.
- Immunodeficiency states
 - AIDS
 - A major cause of immunodeficiency in childhood
 - Its first manifestation may be diarrhea.
 - In addition to the organisms the clinician usually considers in individuals with persistent diarrhea (especially *Giardia*), cytomegalovirus, *Mycobacterium avium-intracellulare*, *Cryptosporidium parvum*, *Isospora belli*, and *Enterocytozoon bieneusi* must also be considered.
 - Astrovirus, calicivirus, and adenovirus have been associated with diarrhea in HIV-infected individuals and may be more important than rotavirus as agents of AIDS diarrhea.
 - HIV may be a primary pathogen in the bowel of these patients as well.
 - Lactose intolerance occurs commonly in individuals with AIDS, presumably as a result of injury to small-bowel mucosa.
 - Pancreatic insufficiency with steatorrhea also has been noted in these patients.
- Cytomegalovirus
- Inborn disorders of immunity
 - Severe combined immunodeficiency
 - Wiskott-Aldrich syndrome
- Late-onset, variable hypogammaglobulinemia
- Pure T-cell abnormalities (DiGeorge syndrome and other T-cell deficiencies)
- Selective IgA deficiency
 - Patients have an increased risk of celiac disease.
- Chronic parasitic, adenovirus, or rotavirus infection can be seen with immunodeficiencies.
- Chronic granulomatous disease of childhood
 - Perianal fistulas or gastric outlet obstruction may be seen.
 - May initially be mistaken for Crohn disease
- Children who have received organ transplants
 - The clinician must consider the full range of enteric infections associated with immunosuppression.
 - Tacrolimus toxicity
 - Lymphoproliferative disease
- Graft-versus-host disease
 - Common cause of diarrhea in bone marrow transplant recipients
- Autoimmune enteropathy
 - Chronic diarrhea beginning in the first year of life
 - Often associated with failure to thrive
 - Extraintestinal autoimmune disorders (eg, diabetes mellitus, arthritis, thrombocytopenia, hemolytic anemia) are common.
 - Rule out celiac disease, food allergy, and gastrointestinal infection.
 - Response to immunosuppressive therapy confirms the diagnosis.

- Immunodysregulation, polyendocrinopathy, enteropathy, X-linked syndrome (IPEX)
- Idiopathic intestinal pseudoobstruction
 - A group of rare disorders characterized by widespread gastrointestinal dysmotility
 - In early infancy
 - Vomiting and diarrhea
 - Diarrhea may alternate with constipation.
 - In older children
 - More insidious presentation
 - A long history of constipation may precede the onset of diarrhea.
 - Intermittent or constant abdominal distention
 - Roentgenographic findings of bowel dilation with disordered motility
 - Urinary bladder dysfunction often is present.
 - Bacterial overgrowth is an important cause of diarrhea in this disorder.
- Microvillus inclusion disease (rare)
 - Familial enteropathy
 - Present from birth
 - Causes severe intractable secretory diarrhea with malabsorption
 - The most common cause of intractable diarrhea in the neonatal period
 - Several families have been identified with >1 child with this disorder.
- Tufting enteropathy
- Congenital disorders of electrolyte absorption
 - Congenital chloride-losing diarrhea and congenital sodium-secretory diarrhea (very rare)
 - Autosomal-recessive
 - Associated with maternal polyhydramnios
- Congenital disorders of glycosylation
 - Exhibit in the first year of life, often with multisystem dysfunction
 - Hepatic, neurologic, cardiac, and optic manifestations
 - Can be associated with chronic diarrhea or severe protein-losing enteropathy, or both
 - Screening for this diagnosis has been performed with serum transferrin isoelectric focusing.
- Lactase deficiency
- Disaccharide intolerance
- Chronic constipation with overflow diarrhea
- Monosaccharide intolerance
- Eosinophilic (allergic) gastroenteritis

- Postenteritis bile acid malabsorption
- Congenital deficiency of enterokinase
- Neural crest tumor and carcinoid
- Intestinal stricture or blind loop
- Pancreatic insufficiency with neutropenia
- Trypsinogen or enterokinase deficiency
- Congenital chloride-losing diarrhea
- Congenital sodium-secretory diarrhea
- Abetalipoproteinemia
- Intestinal pseudoobstruction
- Ileal bile salt receptor defect

Infant of a drug-addicted mother

- Diarrhea may be a prominent manifestation of neonatal drug abstinence syndrome.
- This diagnosis should be considered in newborns with persistent diarrhea, especially when other symptoms of neonatal drug withdrawal are present.

Older children

- Irritable bowel syndrome
- Inflammatory bowel disease: Crohn disease or ulcerative colitis
- Chronic constipation

Diarrhea that usually occurs without blood in stool

- Viral enteritis C rotavirus
- Orbivirus
- Noroviruses (includes Norwalk virus)
- Other caliciviruses
- Enteric adenovirus
- Astrovirus
- Sapoviruses
- Enterotoxin C *E coli*
- *Klebsiella* organisms
- Cholera
- *Clostridium perfringens*
- *Staphylococcus* organisms
- *Bacillus cereus*
- *Vibrio* species
- Parasitic *Giardia*, *Cryptosporidium*, *Cyclospora*, *Dientamoeba fragilis*, and *Blastocystis hominis* organisms
- Extraintestinal infection C
- Otitis media
- Urinary tract infection
- Antibiotic-induced
- *C difficile* toxin (without pseudomembranous colitis)

Diarrhea that commonly is associated with blood in stool

- *Shigella*, *Salmonella*, and *Campylobacter* organisms
 - With symptoms of colonic involvement (tenesmus, urgency, and crampy lower abdominal pain)
 - With *C difficile* toxin-associated pseudomembranous colitis
 - Symptoms of dysentery may be less striking with *Salmonella*.
 - When the *Shigella* is an enterotoxin-producing organism, watery diarrhea may precede the onset of dysentery.
- *Yersinia enterocolitica*
- Invasive *E coli*
- Gonococcus (venereal spread)
- Enteroadherent *E coli*
- Enteroaggregative *E coli*
- *Aeromonas hydrophilia*
- *Plesiomonas shigelloides*
- Cytomegalovirus (especially in immunocompromised individuals)
- Amebic dysentery
- *Trichuris trichiura* (whipworm)
- Hemolytic-uremic syndrome (enterohemorrhagic *E coli*—*E coli* O157:H7 and other Shiga toxin-producing *E coli*)
- Henoch-Schönlein purpura
- Pseudomembranous enterocolitis (*C difficile* toxin)
- Ulcerative or granulomatous colitis (acute presentation)
- Necrotizing enterocolitis (neonates)

LABORATORY EVALUATION**Stool evaluation**

- Smear for leukocytes to establish presence of colitis
- Polymorphonuclear leukocytes
 - Usually account for at least 60–80% of the cells
 - The presence of only occasional cells is considered a negative finding.
- Leukocytes are found in high numbers, frequently in sheets, in both infectious and noninfectious colitis.
- Absence of leukocytes in grossly bloody diarrheal stool occurs with enterohemorrhagic *E coli* infection but should also direct attention to such entities as intussusception and Meckel diverticulum when these diagnoses seem clinically appropriate.
- Amebic colitis also may not be associated with leukocytes in the stool, although the trophozoites and numerous red blood cells may be visible on a saline wet mount preparation of the stool.
- Invasive bacterial diarrhea frequently is associated with a peripheral blood leukocytosis.

- Culture stool if blood or leukocytes are noted in the stool and the child is severely ill.
- Ova and parasites
- *C difficile* toxin assay
- Occult blood
- Reducing substances
- Urine specific gravity and volume
 - May be deceptive because of poor concentration by the kidneys in the presence of malnutrition and total body hypokalemia
- Complete blood count
- Blood urea nitrogen and serum electrolyte levels if hydration status is in question
- Urinalysis
- If the child is lethargic or has had a seizure
 - Culture for sepsis
 - Blood urea nitrogen and creatinine
 - Serum electrolyte and glucose levels
 - Cerebrospinal fluid
- For a child with chronic diarrhea who has been fed recently, the presence of reducing substance or an acid stool pH (<5.3) suggests carbohydrate malabsorption.
- Stool pH is not a good measure of the effect of diarrhea on total body acid-base balance.
- If stool concentration of sodium and potassium minus chloride is greater than the plasma bicarbonate level, then the infant is losing bicarbonate.
- Leukocytes or gross blood in stool usually indicates colonic inflammation.
- Occult blood in stool suggests loss of blood across the mucosa anywhere in the gastrointestinal tract.
- Hyponatremia indicates more severe dehydration than suggested on physical examination.

IMAGING

- Flat-plate radiograph of the abdomen
 - In Hirschsprung disease, may show a dilated colon with absence of air in the rectum
 - Toxic megacolon may also be seen in infectious colitis or in chronic inflammatory bowel disease in infancy.
 - Air-fluid levels throughout the bowel
 - Common in infants with gastroenteritis
 - Not helpful in defining a cause
- Barium enema under low pressure in the unprepared patient may show the narrow distal segment of rectum.
 - Delayed radiograph (24–48 hours after the barium enema) may show the transition zone of Hirschsprung disease.

DIAGNOSTIC PROCEDURES

- Protracted diarrhea of infancy
 - Small-bowel biopsy specimen may show patchy villous shortening with a decreased villus/crypt ratio and marked inflammation, as well as a damaged surface epithelium.
 - However, the results of the small-bowel biopsy also may be normal.
 - Similarly, a rectal biopsy specimen may show evidence of inflammation, including crypt abscesses, or it may be normal.
 - Presence or absence of these biopsy findings may not correlate with severity of the clinical syndrome.
 - Affected infants are severely malnourished and have low serum protein and hemoglobin levels.
 - Several stools should be collected for culture, examination for parasites, and *C difficile* toxin assay when indicated.
 - Blood and urine cultures should also be ordered.

TREATMENT APPROACH

- Fluid and electrolyte management
 - Commercial oral rehydration solutions (ORS) provide more sodium and lower carbohydrate concentration than traditional clear liquids.
 - Human milk contains low concentrations of sodium (6–7 mEq/L).
 - Supplemental rehydration solution should be used when diarrhea is persistent or severe.
 - Electrolyte content in diarrheal stool varies widely.
 - Highest concentrations occur in secretory diarrheas, such as cholera.
 - Fecal sodium levels
 - Range from 40–100 mEq/L
 - Occasionally as high as 150 mEq/L.
 - In rotavirus diarrhea, fecal sodium concentration typically is 20–40 mEq/L.
- ORS
 - Infants with diarrhea can usually drink large volumes of salty-tasting liquids ad libitum appropriate for the stool output.
 - Episodes of diarrhea in previously healthy, well-nourished children are often mild.
 - Nevertheless, use of ORS to replace diarrheal loss is encouraged in infants.
- Liquids can be offered ad libitum.
 - Smaller volumes per feeding may be tolerated better when diarrhea is associated with vomiting.

- Guidelines for rehydration
 - The most recent World Health Organization recommendation is for a lower osmolarity (245 mOsm/L) solution for rehydration (containing 75 mEq/L sodium and 75 mmol/L glucose).
 - Continuing regular feedings with supplemental ORS is generally tolerated and thought to lead to quicker recovery.
 - Vomiting usually is not a contraindication for oral rehydration.

SPECIFIC TREATMENT

Fluid and electrolyte management of acute diarrhea

General rules

- Oral rehydration therapy with ORS containing glucose-electrolytes is the preferred treatment of fluid and electrolyte loss, except as noted below.
 - These solutions generally contain 25 g/L glucose (or ≥ 30 g/L rice starch), 45–90 mEq/L sodium, 20–25 mEq/L potassium, and 30 mEq/L bicarbonate.
 - The higher sodium concentration is appropriate for rehydration.
 - The lower concentration is usually adequate for rehydration with mild diarrhea and is appropriate for maintenance.
- Moderate-to-large stool output should be replaced with ORS at 10 mL/kg per stool, if losses cannot be estimated.
- Losses from emesis should be replaced with ORS at 2 mL/kg per episode of emesis or replace estimated losses.
- The use of ORS is labor intensive.
 - If a caregiver is not available to give small amounts of fluid frequently, then intravenous therapy may be necessary.
 - If the child is not severely dehydrated, oral rehydration may be completed at home with close follow-up.
 - Otherwise, intravenous fluids should include replacement of deficit, ongoing losses, and maintenance fluids.
- ORS therapy is effective for hypernatremic dehydration, as well as for hyponatremic and isotonic dehydration.
- Age-appropriate feedings should be continued during acute diarrhea, except as noted below.
 - Formula should be offered full strength.
 - Diet may be better tolerated if fatty foods and foods high in simple sugars (eg, undiluted juices and soft drinks) are avoided.
- Breastfeeding should be continued when possible.
- A lactose-free diet is generally unnecessary.
 - If stools worsen on reintroduction of lactose (human milk, cow's milk, or lactose-containing formula), lactose intolerance should be considered.
 - If stools become acidic and contain reducing substances, lactose intolerance is likely.

No dehydration

- Continue age-appropriate feeding.
- Use ORS only to replace excessive stool output.

Mild-to-moderate dehydration (3–10% of body weight)

- Correct dehydration with 50–100 mL/kg ORS over 3–4 hours.
- Replace continuing losses from stool and emesis with additional ORS. (See section below on special considerations for vomiting.)
- Reevaluate hydration and replacement of losses at least every 1–2 hours.
 - This process may require medical supervision (emergency department, hospital outpatient unit, or physician's office).
- Once dehydration is corrected, begin feeding and continue to correct losses as above.

Severe dehydration (>10%)

- Resuscitate with intravenous or intraosseous normal saline or lactated Ringer's solution 20 mL/kg of body weight over 1 hour.
 - Monitor vital signs closely.
 - Repeat until pulse and state of consciousness return to normal.
 - Larger volumes and shorter periods of administration may be required.
 - Delay giving intravenous potassium until urine output is established.
- Determine serum electrolyte levels.
- Lack of response to initial resuscitation suggests an underlying problem, such as:
 - Septic shock
 - Toxic shock syndrome
 - Myocarditis
 - Myocardioathy
 - Pericarditis
 - Persistently poor urine output may be a sign of hemolytic-uremic syndrome.
- ORS may be initiated when the child's condition has stabilized and mental status is satisfactory.
 - An intravenous line should be maintained until no longer needed. (See section below on special considerations for vomiting.)
- Feeding may be restarted when rehydration is complete.

Special considerations

- Vomiting
 - Vomiting occurs commonly during acute gastroenteritis.
 - Children who are dehydrated and vomit usually tolerate ORS.
 - Intractable, severe vomiting, unconsciousness, and ileus are contraindications to ORS.
 - ORS should be started at 5 mL every 1–2 minutes.

- Vomiting usually decreases as dehydration improves.
 - Larger amounts can be given at less frequent intervals.
- A nasogastric tube can be used for continuous ORS infusion for persistent vomiting or feeding refusal secondary to mouth ulcers.
 - Do not use in a comatose child or one who has ileus or intestinal obstruction.
- Intravenous fluids should be used if ORS treatment is unsuccessful.
- Refusal to take ORS
 - Children who are not dehydrated may not take ORS because of the salty taste.
 - However, dehydrated children generally take it well.
 - Giving ORS in small amounts at first allows child to become accustomed to the taste.
 - ORS can be frozen in ice-pop form.
- Hyponatremia and hypernatremia must be corrected slowly to prevent complications of the central nervous system.
- Oral solutions are better tolerated and result in fewer central nervous system complications than intravenous solutions in infants with hypernatremia.
- Potassium should not be added to intravenous fluids until adequate urine output is established.

Acute gastroenteritis

- Indications for medications in the treatment of acute gastroenteritis in infants and children are limited.
- There is no apparent rationale for medications that slow gut motility (diphenoxylate, loperamide, anticholinergics).
- Slowing intestinal transit with drugs may allow greater mucosal contact with pathogens and thereby permit local mucosal invasion.
- Bismuth subsalicylate, which may decrease the duration of diarrhea, has been shown to be a safe adjunct to oral rehydration but is not used routinely.
- Antibiotics are useful in specific situations.
 - *Shigella* dysentery
 - *Yersinia* or *Campylobacter* gastroenteritis
 - Pseudomembranous colitis
 - *Salmonella* infections in infants <6 months
 - *Salmonella* infections in older patients who have enteric fever, typhoid fever, or complications of bacteremia
 - *Campylobacter* gastroenteritis must be identified very early for antibiotics to shorten the illness.
 - For the individual patient, the presence of an *E coli* serotype previously labeled enteropathogenic correlates poorly with the presence of diarrhea and is not alone an indication for antibiotic treatment.
- *Lactobacillus* or other probiotics may be useful to prevent infectious diarrhea but are probably not effective as treatment.

Rotavirus

- The current approach to treatment is to restart the previous full-strength formula and solids early after the onset of diarrhea.
- If diarrhea recurs on the introduction of lactose-containing formula, then the child may have transient lactose intolerance.
 - In this situation, a lactose-free formula should be offered.
 - Transient lactose intolerance usually lasts only ≤ 1 week but can, at times, persist for months.

Severe dehydration and shock

- Rapid intravenous administration of 10–20 mL/kg of isotonic fluid or colloid is required initially.
- May need to be repeated early

Chronic diarrhea**Infants (general)**

- Restrict frequency of feedings, whether liquids or solids, in an effort to decrease stimulation of the gastrocolic reflex.
 - In the toddler, 3 meals and a bedtime snack with nothing by mouth in between
- Restrict volumes of fluids ingested when excessive.
- Avoid excessive intake of juices.
- Reassure parents of the benign nature of this entity.
- High-fat diet may be helpful in some children.
 - Probably is of less importance
- Cholestyramine (2 g by mouth 1–3 times daily) is also effective at times.
 - Duration of use should be restricted because of potential for interference with fat-soluble vitamin absorption.
- This condition is self-limited and typically resolves by 3.5 years of age.
 - The only danger is that well-intentioned parents may restrict oral intake to clear liquids repeatedly in an effort to treat the child; this action may result in poor weight gain.
- Bile acid malabsorption is an occasional sequela of gastroenteritis that can produce persistent, watery diarrhea.
 - Will respond to cholestyramine therapy

Protracted diarrhea of infancy

- Nutritional rehabilitation should begin at once.
 - The best choices are either enteral alimentation with an elemental or modular formula or TPN, peripheral or central.
 - Elemental formulas are composed of predigested components in fixed proportions.
 - Modular formulas allow the clinician to vary the components.

- In many instances, enteral nutrition is tolerated best by the continuous drip method, and recovery may be more rapid when enteral alimentation is used.
 - Nevertheless, unsuccessful attempts at enteral feeding necessitate initiation of TPN in some infants.
- Initial treatment with TPN and a gradually increasing, continuous enteral drip is a good approach to patients who do not tolerate an elemental diet alone.
- Stool output and weight gain may be measured to assess the infant's response.
- During treatment, further workup as indicated
 - Upper gastrointestinal series with small-bowel radiography
 - Barium enema
 - Small-bowel biopsy
 - If disaccharidase levels are abnormal on small-bowel biopsy, then disaccharides should be avoided.
 - Proctoscopy

Malabsorption syndromes

- Oral enzyme supplements are available for both lactase and sucrase deficiency.
- Congenital deficiency of enterokinase is reversed with very small amounts of pancreatic replacement.

Intestinal lymphangiectasia

- Treatment includes the dietary use of medium-chain triglycerides and avoidance of long-chain fat.
- Protection from and early treatment of infection also are important.

Autoimmune enteropathy

- Immunosuppressive therapy

Irritable bowel syndrome

- Increased fiber in the diet
- Anticholinergics
- Amitriptyline for diarrhea-predominant irritable bowel syndrome

WHEN TO REFER

- Persistent diarrhea when the workup for routine infectious causes is negative
- Steatorrhea
- Diarrhea or steatorrhea (or both) causing weight loss or failure to thrive
- Diarrhea associated with fever, chronic anemia, or abdominal pain without an obvious explanation

WHEN TO ADMIT

- Acute or chronic diarrhea with mild to moderate dehydration that cannot be managed successfully with outpatient rehydration solution
- Dehydration >10% of body weight
- Diarrhea with intractable vomiting
- Severe electrolyte imbalance, including hypernatremic dehydration or serum potassium level <3.0 mEq/L
- Laboratory evidence suggesting hemolytic-uremic syndrome
- Chronic diarrhea or steatorrhea (or both) with persistent signs of malnutrition that is unresolved with outpatient management

FOLLOW-UP

- Patients undergoing rehydration therapy should be monitored frequently and need close follow-up.

COMPLICATIONS

- Chronic diarrhea can lead to failure to thrive.

PREVENTION

- Acute gastroenteritis caused by rotavirus can be prevented by oral rotavirus vaccine during infancy.

Disorders of Sexual Development

DEFINITION

- Patients with ambiguous genitalia have *disorders of sexual development* (DSD).
 - Previously termed *intersex conditions*
- The nomenclature used to describe atypical sexual differentiation has changed.
 - Patient advocacy groups were concerned that the terminology was pejorative
- Historically, the term *male pseudohermaphrodite* was used to describe the patient with incompletely masculinized external genitalia possessing XY chromosomes and a typical number of autosomes (also known as *46, XY karyotype*).
 - These conditions are now denoted as *46, XY DSD*.
- The term *female pseudohermaphrodite* was used to describe the patient with *46, XX karyotype* and with masculinized external genitalia.
 - Currently, these disorders are denoted as *46, XX DSD*.
- In some rare cases, a patient has both ovarian and testicular tissue.
 - These patients had been called *true hermaphrodites* in the past.
 - They are now considered to have *ovotesticular DSD*.

EPIDEMIOLOGY

- *46, XX disorders of sexual development*
 - Occurs in 1 in 14,000 white infant births
 - Late-onset, or nonclassical, 21-hydroxylase deficiency usually occurs in childhood or the teenage years.
 - Defects in 11 β -hydroxylation are rarer than defects in 21-hydroxylation, occurring in roughly 1 in 100,000 white infant births.
 - Occurs more frequently in children of Middle Eastern descent
- Disorders of gonadal differentiation (sex chromosome disorders of sexual development)
 - Klinefelter syndrome
 - Most common form of primary hypogonadism in males
 - Incidence of 1 in 1000 males
 - Turner syndrome (syndrome of gonadal dysgenesis)
 - Occurs in 1 in 2500 live-born female infants
 - Occurs in a greater percentage of conceived pregnancies
 - ~15% of first-trimester spontaneous abortions have an XO karyotype.
 - Cardiac involvement is common.
 - ~10% of patients have coarctation of the aorta leading to hypertension in the upper extremities.
 - An even greater percentage of patients have bicuspid aortic valves, which increases their risk for subacute bacterial endocarditis.

- In some cases, short stature may be the sole phenotypic manifestation of the syndrome.
- 90% of infants with ambiguous genitalia have congenital adrenal hyperplasia.
 - >50% of these patients experience significant sodium loss.
- Rarely, disorders of either testicular or ovarian differentiation may lead to gonadal dysgenesis and thus anomalous sexual development.

ETIOLOGY

- Disorders of sexual development arise from chromosomal, gonadal, or anatomic abnormalities in the pathway of sexual differentiation.
- Incomplete masculinization of a fetus with testes may result from
 - Decreased synthesis or secretion of testosterone or dihydrotestosterone (DHT)
 - Peripheral tissue resistance to androgen action
 - Defective production or action of antimüllerian hormone (AMH)
- *46, XX DSD* may result from abnormally high levels of androgen from either a fetal or exogenous source.

46, XX disorders of sexual development

- ~90% of cases of congenital adrenal hyperplasia (CAH) are caused by 21-hydroxylase deficiency.
- Virilization of a female fetus results from excess androgen exposure from either a fetal or maternal source.
- Timing is important.
 - If the female fetus is exposed to elevated androgen levels after the 8th week of gestation but before the 13th week, the vaginal opening may fuse posteriorly and appear slitlike.
 - Females with CAH will have posterior fusion of the labia and not clitoromegaly, given their high circulating androgen levels between weeks 8 and 12.
 - Exposure to androgen after the 12th week of gestation (eg, exogenous administration to the mother) will result in clitoromegaly without fusion of the labioscrotal folds.
- Fetal sources of androgen excess
 - CAH
 - Overproduction of adrenal androgens by the female fetus may occur in virilizing CAH.
 - Group of disorders in which a biochemical defect in cortisol synthesis leads to hyperplasia of the adrenal gland resulting from compensatory elevation in adrenocorticotrophic hormone (ACTH)
 - These disorders are inherited in an autosomal-recessive manner.
 - The degree and timing of virilization, as well as the presence or absence of salt wasting, depend on the specific genetic lesion (see table Differential Diagnosis of Adrenal Enzyme Defects).

Differential Diagnosis of Adrenal Enzyme Defects^a

Deficiency	Newborn Phenotype	Postnatal Virilization	Other
StAR (also called lipid congenital adrenal hyperplasia)	Infantile female	–	Salt loss
3 β -Hydroxylase	Ambiguous in XY and XX	+	Salt loss
17 α -Hydroxylase (P450c17)	Infantile female	–	Delayed puberty
11 β -Hydroxylase (P450c11 β)	Male in XY, ambiguous in XX	+	Hypertension
21 Hydroxylase (P450c21)	Male in XY, ambiguous in XX	+	Salt loss
18 Hydroxylase (P450c11B2)	Normal	–	Salt loss

Abbreviations: HT, hypertension; StAR, steroidogenic acute regulatory protein function.

^a From: Styne D. *Pediatric Endocrinology*. Philadelphia, PA: Lippincott Williams & Wilkins; 2004.

- P450c21 hydroxylase converts 17-hydroxyprogesterone (17-OHP) to 11-deoxycortisol.
 - Deficiency in this enzyme leads to extreme elevation in 17-OHP levels.
 - Defects in 21-hydroxylase will lead to low aldosterone and cause renal salt wasting and potassium retention in approximately 50% of patients.
 - P450c11 hydroxylase deficiency typically results in:
 - Hypertension in either gender as a result of elevated levels of 11-deoxycorticosterone
 - Virilization of the female fetus as a result of increased adrenal androgen production
 - 3 β -Hydroxysteroid-dehydrogenase deficiency causes mineralocorticoid, glucocorticoid, and sex-steroid deficiency.
 - Genetic females may be phenotypically normal or have varying levels of clitoromegaly or labial fusion.
 - Virilization occurs in genetic females because of increased levels of dehydroepiandrosterone (DHEA) and its sulfate (DHEA-S).
 - Peripheral conversion of DHEA to testosterone may cause virilization in females.
 - May be a common cause of late-onset CAH
 - Salt loss, as a result of aldosterone deficiency, occurs to varying degrees.
 - Aromatase deficiency
 - In rare cases, deficiency in the enzyme aromatase caused by mutations in the *CYP19* gene may lead to virilization of the female fetus and often of the mother during pregnancy.
 - Aromatase catalyzes the conversion of androgen to estradiol.
 - Deficiency leads to elevated levels of androstenedione and testosterone and low levels of estrogens.
 - Maternal or exogenous sources of elevated androgen levels
 - Maternal use of androgenic steroids, such as danazol or certain progesterone compounds, during pregnancy may lead to virilization of the female fetus.
 - Exposure to these compounds during weeks 8–12 of gestation may lead to significant ambiguity.
 - Later exposure may result only in an enlarged clitoris.
 - In rare instances, maternal CAH or a virilizing maternal tumor of ovarian or adrenal origin may lead to masculinization of the fetus.
 - Luteomas of pregnancy have been reported to cause genital ambiguity in the newborn.
 - More commonly, result only in maternal virilization
- 46, XY disorders of sexual development**
- Luteinizing hormone (LH) receptor defects
 - Testosterone secretion is controlled by human chorionic gonadotropin (hCG) early in gestation and LH from the fetal pituitary later in gestation.
 - Failure of hCG or LH to stimulate testosterone production at the critical times is due to mutations in the LH/hCG receptor. This will result in incomplete masculinization of a male fetus.
 - This failure may occur in the situation of Leydig cell agenesis or hypoplasia.
 - Stimulation testing with hCG will result in little or no increase in androgen levels.
 - Basal and stimulated LH levels are typically elevated.
 - Androgen biosynthesis defects
 - Enzyme defects in the pathways of testosterone biosynthesis may result in incomplete virilization of the male fetus.
 - Some of the defects affect synthesis of corticosteroids and are thus forms of CAH.

- The initial conversion of cholesterol to delta-5-pregnenolone requires the enzyme P450_{scc} (side chain cleavage), as well as the steroidogenic acute regulatory protein, which transports cholesterol to the inner mitochondrial membrane where P450_{scc} is located.
 - Owing to low testosterone levels, patients with steroidogenic acute regulatory protein or P450_{scc} enzyme deficiencies have:
 - Lipid-laden adrenal glands
 - Adrenal insufficiency
 - Sexual infantilism in males
- 3 β -Hydroxysteroid dehydrogenase deficiency may result in:
 - Mineralocorticoid
 - Glucocorticoid
 - Sex-steroid deficiencies
- 17-Hydroxylase deficiency caused by a defect in the *CPY17* gene results in deficiencies in cortisol and testosterone and thus can result in an incompletely masculinized 46, XY fetus.
 - Excess of the mineralocorticoid deoxycorticosterone leads to:
 - Hypertension in both sexes (caused by increased salt and water resorption)
 - Hypokalemia
 - Suppression of aldosterone production
- Enzyme defects affecting testosterone biosynthesis without affecting corticosteroid production are described.
 - In a male fetus, 17,20 lyase (also called 17,20 *desmolase*) deficiency and 17 β -hydroxysteroid dehydrogenase-3 deficiency will lead to an incompletely masculinized phenotype without any abnormalities related to mineralocorticoid or glucocorticoid effects.
 - Virilization may occur at puberty in either condition.
 - Gynecomastia may occur at puberty in those with 17,20 lyase deficiency.

Defects in androgen action

- Syndrome of complete androgen resistance (androgen insensitivity syndrome or testicular feminization) results from a defect in the androgen receptor.
- Affected individuals are phenotypic females with a 46, XY karyotype and bilateral testes that secrete elevated levels of testosterone.
- At puberty, LH increases and leads to elevations in testosterone, some of which is converted peripherally to estrogens.
- Incomplete forms of androgen resistance are caused by mutations in the androgen receptor.

5 α -reductase-2 deficiency

- Mutations in the *SRD5A2* gene coding for 5 α -reductase-2, an enzyme that converts testosterone to dihydrotestosterone, lead to deficiency of DHT.
 - At birth, affected males may have ambiguous genitalia or be phenotypically female as a result of decreased conversion of testosterone to DHT in the sexual skin during the critical times of male genital development.
 - These patients have well-developed wolffian ducts (given that these structures are testosterone and not DHT responsive) and absent müllerian structures (given that AMH is produced from the normal testes).
 - During puberty, virilization occurs with growth of the phallus and testes, probably secondary to expression of a different form of the 5 α -reductase enzyme (type 1) in the liver and other tissues at that time, with subsequent increases in circulating DHT levels.

Disorders of gonadal differentiation (sex chromosome disorders of sexual development)

- Turner syndrome (syndrome of gonadal dysgenesis)
 - Classic manifestations of Turner syndrome are linked to the absence of the *SHOX* gene on the X chromosome.
- Other disorders of gonadal development
 - Additional disorders of testicular development may be caused by:
 - Complete XY gonadal dysgenesis (Swyer syndrome)
 - Partial gonadal dysgenesis
 - Gonadal regression
 - *Gonadal dysgenesis* is descriptive and bears no etiologic relationship to the syndrome of gonadal dysgenesis or Turner syndrome.
 - 15–20% of these cases are caused by mutations in the *SRY* gene.
 - Partial gonadal dysgenesis in 46, XY individuals leads to variable amount of testosterone and AMH production.
 - Anorchia must be considered in all phenotypic male patients with bilaterally nonpalpable testes.
 - Gonadal dysgenesis may occur in patients with a 46, XX karyotype who may have streak gonads and sexual infantilism, but none of the other characteristics of Turner syndrome.
 - Genetic abnormalities, such as translocation of the *SRY* gene, can result in a 46, XX genotypic patient developing testicular instead of ovarian tissue.

SIGNS AND SYMPTOMS

History

- Evaluation of an infant with a disorder of sexual differentiation must include a detailed obstetric and family history.
- The patient's mother should be asked about medication use and symptoms of virilization during pregnancy.
 - May occur in aromatase deficiency or with androgen-secreting maternal ovarian or adrenal tumors
- Family history should not focus solely on genital abnormalities but should include
 - History of consanguinity
 - Unexplained neonatal deaths, especially in apparently phenotypic males
 - Infertility
 - Disorders of puberty
- Many conditions associated with ambiguous genitalia are sporadic or inherited in an autosomal-recessive manner.

Physical examination

- Initial physical examination should begin with an assessment of the general health of the patient and an evaluation for malformations or dysmorphic features.
- Physical findings in patients with DSD may range from an apparently normal phenotype to complete ambiguity.
- Unstable vital signs or hypoglycemia with no apparent cause should raise concern about cortisol deficiency associated with CAH.
- Typically, shock in patients with CAH does not develop until day 4–5 of life.
- Patients with ambiguous genitalia may benefit from earlier diagnosis of salt loss and signs of cortisol deficiency than phenotypically normal patients.
- Midline abnormalities, such as cleft palate, may be associated with hypopituitarism and low gonadotropin levels, leading to microphallus.
- Increased skin pigmentation caused by elevated levels of ACTH occurs well after the newborn period and thus is not helpful in early diagnosis.
- Stretched penile length in a term male infant should be >2 cm.
 - Average length is ~3.5 cm.
- A normally formed phallus and scrotum indicate that testosterone production in the critical window of male differentiation was appropriate.
- Micropenis (penile length <2 cm) often indicates gonadotropin deficiency and may be a sign of hypopituitarism.
 - Congenital growth hormone deficiency can also cause microphallus.

- Proper examination technique is critical, as an infant with chordee or a generous suprapubic fat pad may be thought mistakenly to have micropenis.
- Position of the urethral meatus should be noted.
 - Sometimes requires observation of urination
 - A urogenital sinus can be mistaken for the urethra.
 - Indentation at the end of the glans penis can be mistaken for the penile urethra.
- The labioscrotal folds should be examined for:
 - Degree of fusion
 - Symmetry
 - Rugosity
 - Color
- Presence or absence of a vaginal opening should be established.
- Gonads, when palpable bilaterally, are most often testes, but might be ovaries or ovotestes as well.
- A unilaterally palpable and symmetrical gonad may be a testis, an ovotestis, or an ovary.
- Sweeping the fingers down the path of the inguinal canal with soap may allow palpation of gonads that might not otherwise be located.
- If gonads are palpable, then the infant is not a virilized female with CAH, because these patients have nonpalpable gonads (ovaries) that are normally situated in the pelvis.

DIFFERENTIAL DIAGNOSIS

- Differential diagnosis of the infant born with developmental anomalies of the external genitalia is extensive, given the complicated process of human sexual differentiation.
- See table Differential Diagnosis of Adrenal Enzyme Defects.

46, XX disorders of sexual development

- Late-onset, or nonclassical, 21-hydroxylase deficiency begins with excessive or premature acne and sexual hair.
 - May be associated with increased growth and bone age advancement
- 17-Hydroxylase deficiency
 - Females are phenotypically normal at birth but will not progress through pubertal changes.
 - Primary amenorrhea may be the presenting feature.
- 3 β -Hydroxysteroid dehydrogenase deficiency
 - Genetic females may be phenotypically normal or have varying levels of clitoromegaly or labial fusion.
 - Varying degrees of salt loss, as a result of aldosterone deficiency
- Aromatase deficiency
 - Females may exhibit mild virilization in addition to osteopenia and delayed bone age (given the estrogen deficiency).

46, XY disorders of sexual development■ 3 β -Hydroxysteroid dehydrogenase deficiency

- Affected males may be incompletely masculinized at birth.
- Often experience salt loss or adrenal crisis in infancy
- May experience gynecomastia around the time of puberty
- Elevated levels of enzyme substrates, such as DHEA and delta-5-pregnenolone

■ Aromatase deficiency

- Males with aromatase deficiency will be tall and have delayed bone age and osteoporosis caused by estrogen deficiency.

Defects in androgen action

■ Development of female secondary sexual characteristics

- Pubic and axillary hair is sparse, if present at all.
- Menarche cannot occur.

■ Incomplete forms of androgen resistance have great phenotypic variability.

- External genitalia may range in appearance from completely ambiguous to mildly hypoplastic male genitalia with a small but normally formed phallus.
- Hypoplastic wolffian duct structures are typically present.
- Müllerian derivatives are absent because of production of AMH.
- At puberty, virilization is usually incomplete.
- Gynecomastia often becomes apparent.
- Axillary and pubic hair is normal in amount and distribution.

■ External genitalia are phenotypically female, given the inability of the tissue to respond to dihydrotestosterone.

■ Müllerian structures, such as the cervix and uterus, are absent or hypoplastic.

- Production of AMH by the fetal Sertoli cells is normal.
- The vagina ends in a blind pouch.

5 α -reductase-2 deficiency

■ Secondary sexual characteristics, such as increased muscle mass and voice deepening

Disorders of gonadal differentiation (sex chromosome disorders of sexual development)

■ Klinefelter syndrome

- Before puberty, patients have:
 - Decreased upper segment to lower segment ratios
 - Small testes
 - Increased incidence of developmental delay (mainly in the areas of speech and language)
 - Behavioral problems
- Puberty is not usually delayed because Leydig cell function is characteristically less affected than seminiferous tubule function.

- Testosterone is often adequate to stimulate pubertal development.

- Serum gonadotropin levels increase after the onset of puberty, as the testes become firm and rarely grow >3.5 cm in diameter.

- After the onset of puberty, histologic changes of seminiferous tubule hyalinization and fibrosis, adenomatous changes of the Leydig cells, and impaired spermatogenesis occur.

- Gynecomastia is common.

- Variable degrees of male secondary sexual development

■ Turner syndrome (syndrome of gonadal dysgenesis)

- Turner syndrome (45, XO karyotype) is associated with:

- Sexual infantilism
- Short stature
- Characteristic female phenotype often includes webbing of the neck

- Patients have streak gonads consisting of fibrous tissue without germ cells.

- Pubic hair may appear late and is usually sparse.

- Adrenarche progresses even in the absence of gonadarche.

- Serum gonadotropin concentrations are extremely high between birth and age 4 years.

- Decrease toward the normal range in prepubertal patients and then increase again dramatically after age 10 years

- Because of decreased ovarian secretion of estrogens, puberty does not usually begin spontaneously.

- Patients have no pubertal growth spurt and reach a mean final height of 143 cm.

- Growth hormone function is usually normal.

- Various mosaic forms have been identified, with such karyotypes as 45, X/46, XX, or 45, X/46, XY.

- These patients may have any phenotype varying from normal female to normal male to manifestations of many of the features of Turner syndrome.

- Some have apparently normal gonadal function.

- Others have abnormality of 1 X chromosome, such as a ring X, or other abnormalities, which are out of the scope of this chapter.

■ Other disorders of gonadal development

- In complete gonadal dysgenesis, 46, XY karyotype individuals fail to develop normal testes.

- Instead, they have:

- Gonadal streaks
- Müllerian duct development
- Wolffian duct regression
- Female external genitalia

- Usually associated with ambiguous genitalia and partial development of both the wolffian and müllerian ducts

- In gonadal regression or vanishing testes syndrome, the testes are lost after the external genitalia and internal structures have formed.
- These 46, XY individuals will be phenotypically male except for absence of both testes.
- Patients may phenotypically resemble those with Klinefelter syndrome.
- Ovotesticular disorders of sexual development
 - Patients with ovotesticular DSD have both ovarian and testicular tissue present.
 - The majority of patients have a 46, XX phenotype, and the remainder have a 46, XY karyotype or 46, XX/46, XY chimerism.
 - Great phenotypic variability exists in both the internal and external genitalia in these patients.

DIAGNOSTIC APPROACH

- Diagnostic algorithms for evaluation of infants with indeterminate gender, as well as some infants with relatively subtle genital findings are shown in Figures 25 and 26 on page F8 and F9.
- In males, even very mild hypospadias can be considered to represent incomplete masculinization.
 - Most uncomplicated cases do not need diagnostic evaluation.
 - More severe degrees of hypospadias, especially when a testis is not palpable, should raise concern about an identifiable abnormality.
 - In an apparently phenotypic female, mild clitoromegaly may represent
 - Severe undervirilization in a genetic male who has undescended testes
 - Masculinization of a female fetus
- Specific recommendations for which genital findings should elicit concern for a sexual development disorder
 - An apparent male born at term with the following characteristics:
 - Bilateral nonpalpable testes
 - Micropenis
 - Perineal hypospadias
 - Single undescended testis with hypospadias of any degree
 - An apparent female with the following characteristics:
 - Clitoral hypertrophy of any degree
 - Posterior labial fusion (but not just labial adhesions)
 - Inguinal or labial mass
 - All infants with truly ambiguous genitalia and thus indeterminate gender
 - Infants with family history of DSD or discordance between apparent gender and a previously obtained prenatal karyotype

- Because the testes do not normally descend until ~34 weeks of gestation, significantly preterm males with nonpalpable testes alone do not necessarily require evaluation.
- No individual patient should be assumed to have virilizing adrenal hyperplasia.
- Newborn screening should eliminate cortisol and aldosterone deficiency in diagnostic time.
- Diagnosis of P450c11 hydroxylase deficiency is usually made after the discovery of elevated levels of 11-deoxycortisol (compound S).
- Diagnosis of aromatase deficiency is made around the time of puberty.
- Defects in androgen action are suggested by elevated levels of testosterone.
- 5 α -reductase-2 deficiency
 - Ovotesticular disorders of sexual development
 - Ovotesticular DSD should be considered in all patients with DSD.
 - A 46, XX/46, XY karyotype or a bilobate gonad in the inguinal region or labioscrotal folds should raise suspicion.

LABORATORY FINDINGS

- Basic serum chemistries should be obtained immediately to evaluate for salt wasting or hyperkalemia associated with CAH.
 - Abnormalities may take days to become apparent.
- Normal electrolyte values in the few days after birth do not exclude salt losing.
- Karyotype will establish whether the patient is genotypically XX or XY (or other) and should always be performed.
 - Results from an urgently ordered karyotype can be available within ~3 days in some cytogenetics laboratories.
- Endocrine testing generally consists of measurement of:
 - 17-OHP
 - Testosterone
 - DHT
 - Androstenedione
 - Follicle-stimulating hormone
 - LH
 - AMH
- Tests should be performed in a national specialty laboratory with pediatric standards rather than the local laboratory.
 - Most local laboratories are unlikely to have pediatric standards or appropriately sensitive techniques.
 - On the basis of these results, additional tests may be performed.
- In the first weeks after birth, measurement of testosterone may reveal the amplitude of the episodic spike of testosterone.

- After this period, hCG administration will help determine whether functional Leydig cells are present (given that functional cells will secrete testosterone in response to the hCG).
- Serum testing of the steroid hormones involved in the pathways for cortisol and testosterone is indicated in many cases because the forms of CAH rarer than 21-hydroxylase deficiency will not cause elevations in 17-OHP levels.
- In some cases, stimulatory testing with ACTH is necessary.
- Newborn screening for 21-hydroxylase deficiency (but not other forms of CAH) is currently done in 46 states.
 - Testing is required but not yet implemented in 3 of the 4 remaining states.
 - Results can be returned several days after the specimens are drawn.
 - Available within the first week of life, but not always before clinical symptoms develop
 - This screening test is most helpful in diagnosing the condition in males who appear normal but are affected.
- 5 α -reductase-2 deficiency
 - Laboratory testing reveals abnormally high testosterone/DHT ratios with normal to elevated testosterone and low to undetectable DHT.
- Confirmatory testing via mutation analysis of the 5 α -reductase-2 gene is currently only available as a research tool.

IMAGING

- Imaging is useful to determine internal anatomy.
- Ultrasonography
 - Determination of the presence and appearance of müllerian structures
 - Lack of müllerian structures implies that AMH was produced from testicular tissue and that the underlying problem is an abnormality of testosterone or DHT synthesis or action.
 - Renal problems (eg, in Frasier syndrome)
 - Visualization of the adrenal glands
 - Visualization of the gonads
 - Magnetic resonance imaging may be required, particularly if the gonads are intraabdominal.
 - Defects in androgen action
 - Shown by absence of the corpus and cervix and the presence of testes

TREATMENT APPROACH

- A team to address the multiple issues surrounding management of patients with DSD may include:
 - Endocrinologist
 - Urologist and/or pediatric surgeon and/or plastic surgeon
 - Gynecologist

- Neonatologist
- Geneticist
- Ethics specialist
- Psychologist or psychiatrist
- Social worker
- Gender assignment should be avoided after delivery and during evaluation.
 - The infant should be referred to using gender-neutral terms such as *your baby* or *the baby* rather than *he* or *she*.
- Goal is to establish a diagnosis as rapidly as possible.
- Gender assignment should occur with the participation of the family.
 - The family must realize that not all patients with a given abnormality identify themselves in the same way.
 - Considerations may need to include cultural practices.
- Factors to consider include:
 - Underlying diagnosis
 - Fertility
 - Capacity for sexual function
 - Appearance of the genitalia
 - Surgical options
 - Potential hormonal therapies
- Surgical issues include:
 - Preventing patient dissatisfaction with genital reconstruction discordant with his/her gender identity
 - Timing and feasibility of surgery
 - Potential for malignant degeneration of a gonad in certain disorders of sexual development involving Y chromosome material
 - In the case of a streak gonad of an XY cell line, the gonad should be removed at the time of diagnosis.
 - In androgen resistance syndrome, the testis may be brought into the scrotum, where it can be observed for potential cancer.
- Long-term psychological support is required for the majority of patients with DSD.
 - Help should be provided by a mental health professional, preferably experienced in DSD.
 - National and local support groups are available for families.
- *Gender identity* is the personal conception of oneself as male or female.
 - It is distinct from sexual orientation and gender role.
 - Influences on gender identity include:
 - Hormonal effects (specifically androgen effect on the prenatal brain)
 - Brain structural differences
 - Assigned sex of rearing
 - Sex-steroid effects at the time of puberty

- Some patients who are assigned a particular gender are later dissatisfied.
- Outcome data for gender identity in DSD are relatively sparse; the largest study to date showed that:
 - Genetic males with active prenatal androgen effects should be raised as males.
 - Female infants virilized as a result of CAH should be given a female gender assignment.
- Gender identity outcomes are more difficult to predict in other disorders.

SPECIFIC TREATMENTS

Equivocal cases

- A trial of testosterone injections (eg, 25 mg of testosterone enanthate intramuscularly every month for 3 months) is given in some equivocal cases to assess whether phallus size responds to androgen, eliminating substantial androgen resistance.
 - The effect of this cannot be assessed for several months.

Defects in androgen action

- Removal of the testicular tissue is indicated, given the increased risk of neoplasm after puberty.
 - The timing of removal is controversial.
 - After removal of the testes, estrogen replacement is provided.

5 α -reductase-2 deficiency

- Some patients change gender identity from female to male at the time of puberty.

Disorders of gonadal differentiation (sex chromosome disorders of sexual development)

- Turner syndrome (syndrome of gonadal dysgenesis)
 - Growth hormone treatment increases growth rate and adult stature.
 - Estrogen treatment is initiated in adolescence in these patients to allow feminization.

WHEN TO ADMIT

- Patients with significant electrolyte abnormalities, such as hyponatremia and hyperkalemia
- Patients with dehydration
- Patients with hypoglycemia

WHEN TO REFER

- All patients with ambiguity of the external genitalia should be evaluated immediately by an experienced multidisciplinary team that includes a pediatric endocrinologist.
- This process necessitates transfer of the patient to a medical center with a neonatal intensive care unit and the appropriate pediatric subspecialists.

- The patient should never be sent home and referred to subspecialty care as an outpatient.
- Indications for referral include:
 - In a male infant born at term
 - Bilateral nonpalpable testes
 - Micropenis
 - Perineal hypospadias
 - Single undescended testes with hypospadias of any degree
 - In a female infant
 - Clitoral hypertrophy of any degree
 - Posterior labial fusion (not adhesion)
 - Inguinal or labial mass

COMPLICATIONS

- DSD is considered an endocrine emergency.
 - In the majority of cases, the genital findings may be accompanied by:
 - Life-threatening electrolyte abnormalities
 - Hypotension
 - Shock
- The psychological stress to the family cannot be overstated.
- In its most serious form, cortisol and aldosterone deficiency are severe enough to result in:
 - Severe hyponatremia
 - Hyperkalemia
 - Dehydration
 - Hypotension
 - Shock
 - Death
- Male infants die more frequently than female infants.
 - As a result of their visibly normal phenotype at birth, the condition is not suspected.
- Female infants with virilization are usually evaluated quickly.
- Disorders of gonadal differentiation (sex chromosome disorders of sexual development)
 - In Klinefelter syndrome, the risk of breast cancer is increased.

Disseminated Intravascular Coagulation

DEFINITION

- Disseminated intravascular coagulation (DIC) is a pathologic syndrome that arises from a heterogeneous group of medical disorders.
 - Simultaneous activation of both clotting and fibrinolysis, resulting in severe bleeding
 - DIC is always a secondary phenomenon and not a disease entity in its own right.
- Because of variable clinical manifestations and heterogeneity of primary disorders, DIC is also known as:
 - Consumptive coagulopathy
 - Hemorrhagic syndrome
 - Defibrination syndrome
 - Consumptive thrombohemorrhagic disorder

EPIDEMIOLOGY

- Prevalence
 - Seen in ~0.4–1% of hospitalized children
 - Infection is a contributing factor in almost 95% of children with DIC.
 - Multiorgan dysfunction is present in almost 85%.
- Incidence by underlying disease process is unknown.

ETIOLOGY

- The normal physiology of coagulation is disturbed by the simultaneous action of 4 mechanisms.
 - Increased thrombin generation
 - Suppressed physiologic anticoagulant pathways
 - Activation and subsequent impairment of fibrinolysis
 - Activation of the inflammatory pathway
- Steps in DIC
 - During an inciting event (eg, sepsis), monocytes and endothelial cells are injured by toxic substances elaborated during the disease process.
 - They generate tissue factor, which activates the coagulation cascade.
 - Continuous activation of coagulation leads to unregulated or explosive generation of thrombin.
 - Depletes clotting factors and platelets
 - Activates the fibrinolytic system
 - Activation of clotting leads to generalized fibrin deposition and microthrombi formation.
 - Microthrombi deposit in various organs, leading to tissue ischemia and multiorgan failure.
 - Deposition of fibrin in microvasculature leads to mechanical fragmentation of erythrocytes, causing microangiopathic hemolytic anemia.

- Impaired anticoagulant pathway function can amplify thrombin generation and contribute to fibrin formation.
 - Plasma levels of antithrombin are reduced in patients with sepsis, and significant depression of the activated protein C system may occur.
 - Initial hyperfibrinolytic response causes clot lysis, contributing to cutaneous hemorrhages and bleeding into internal organs.

RISK FACTORS

- Sepsis
- Trauma
- Systemic inflammatory syndrome

SIGNS AND SYMPTOMS

- Clinical manifestations are bleeding and/or thrombosis
- Bleeding
 - Typically acute and occurs from multiple sites
 - Bleeding from venipuncture sites and intravascular access sites (intraarterial lines or surgical wounds) is an important early indication of DIC.
 - Mucocutaneous bleeding is common.
 - Petechiae
 - Purpura
 - Epistaxis
 - Gum bleeding
 - Bleeding after tracheal suctioning
 - Gastrointestinal bleeding
 - Hematuria
 - In advanced cases, internal bleeding in the brain, lung, heart, and gastrointestinal system may constitute a medical emergency.
 - Increased intracranial pressure
 - Brain herniation
 - Respiratory compromise
 - Possibly, shock
- Thrombosis
 - Generalized microvascular thrombosis may produce:
 - Purpura fulminans
 - Peripheral acrocyanosis
 - Pregangrenous changes in digits, genitalia, and nose
 - Microvascular thrombosis further contributes to multi-organ failure and hemodynamic instability.

DIFFERENTIAL DIAGNOSIS**■ Fulminant hepatic failure**

- Synthesis of coagulation proteins and inhibitors of coagulation is affected.
- Associated hypersplenism contributes to thrombocytopenia.
- Bleeding manifestations predominate.
- The main treatment strategy is supportive care and blood component therapy.

■ HELLP (hemolysis, elevated liver function tests, and low platelets) syndrome

- Commonly associated with pregnancy
- Clinical and laboratory features are similar to DIC, but hypertension is relatively common.

■ Chronic DIC (Trousseau syndrome)

- Rare in children
- Commonly associated with certain types of cancer
 - Mucinous adenocarcinomas
 - Ovarian cancer
 - Pancreatic tumors
- Exhibits as migratory thrombophlebitis, arterial and venous thrombosis, hemorrhagic diathesis, and laboratory values consistent with DIC
- Treated with long-term anticoagulation with heparin therapy

■ Massive transfusion

- Defined as replacement of >1 blood volume in 24 hours or replacement of 50% of total blood volume within 3 hours
- Prolonged prothrombin time (PT) and partial thromboplastin time (PTT), decreased fibrinogen level, and thrombocytopenia are seen.
- Management
 - Bleeding associated with hemostatic failure can be managed first with prompt transfusion with cryoprecipitate and fresh-frozen plasma (FFP).
 - Platelet transfusion may be required if bleeding persists.
 - Recombinant factor VIIa is effective in management of excessive perioperative bleeding.

■ Thrombotic thrombocytopenic purpura (TTP)

- Symptoms
 - Fever
 - Thrombocytopenia
 - Microangiopathic hemolytic anemia
 - Renal failure
 - Neurologic signs

- Tests (PT, activated PTT [aPTT]) and fibrin degradation products are usually normal.
- Treated with plasmapheresis and supplementation of ADAMTS13 protease through FFP infusion
- Hemolytic-uremic syndrome is a triad of microangiopathic hemolytic anemia, thrombocytopenia, and renal insufficiency.
 - Clinically similar to TTP and is often confused with DIC
 - Occurs in children <3 years; acute mortality, 3–5%
 - Laboratory findings include microangiopathic hemolytic anemia (hemoglobin level <10 g/dL) and negative direct antiglobulin (Coombs) test.
 - Presence of schistocytes and helmet cells on a blood smear suggests mechanical trauma.
 - Typical findings accompanying hemolysis
 - Increased indirect bilirubin
 - Decreased haptoglobin
 - Increased lactate dehydrogenase values
 - Thrombocytopenia, approximately 40×10^3 cells/mcL (40×10^9 cells/L)
 - Urinalysis shows hematuria and proteinuria.
 - Elevated blood urea nitrogen and creatinine concentrations
 - Albumin level may be decreased.
 - Management is primarily supportive and includes renal replacement therapy.

DIAGNOSTIC APPROACH

- DIC is a clinical diagnosis based on laboratory results in a patient with a clinical condition known to be associated with DIC (listed below).
- A practical approach is to categorize and understand the clinical presentations of DIC, by:
 - Rate of progression (acute or chronic)
 - Extent (localized or systemic)
 - Chief clinical manifestations (thrombotic or hemorrhagic, with or without progressive organ dysfunction)
- Conditions associated with DIC
 - Sepsis or severe infection
 - Viruses (eg, HIV, cytomegalovirus, varicella, hepatitis)
 - Fungal (eg, *Histoplasma*)
 - Parasitic (eg, malaria)
 - Trauma
 - Polytrauma
 - Neurotrauma
 - Fat embolism
 - Organ failure
 - Severe pancreatitis
 - Liver cell failure

- Cancer
 - Acute promyelocytic leukemia
 - Lymphoproliferative disorders
 - Hemophagocytic lymphohistiocytosis
 - Solid tumors
- Obstetric calamities
 - Dead fetus syndrome
 - Abruptio placentae
 - Amniotic fluid embolism
- Vascular abnormalities
 - Kasabach-Merritt syndrome
 - Large vascular aneurysms
- Immunologic conditions
 - Systemic lupus erythematosus
 - Autoimmune hemolytic anemia
 - Crohn disease
 - Ulcerative colitis
 - Transfusion reactions
 - Transplant rejections
- Miscellaneous
 - Snake bites
 - Recreational drugs
 - Poisoning
 - Burns
 - Massive transfusions

LABORATORY FINDINGS

- Laboratory tests should show evidence of consumptive coagulopathy with activation of the fibrinolytic cascade.
 - Laboratory values change rapidly based on clinical status and may create confusion in patient management.
 - Such changes make diagnosis at an early stage particularly difficult.
- Complete blood cell count may show moderate or severe thrombocytopenia with or without anemia.
 - Thrombocytopenia
 - Present in approximately 50% of patients
 - Suggests consumption of platelets
- Blood smear
 - Presence of fragmented erythrocytes (schistocytes) confirms the diagnosis of microvascular angiopathy.
- Screening tests for extrinsic/intrinsic coagulation cascade
 - PT and aPTT are prolonged in 50–60% of patients.
 - Concentrations of fibrinogen-fibrin degradation products and D-dimers are increased in most patients.

- Prothrombin fragment 1.2 and TAT complexes are the most sensitive tests for diagnosis.
- The International Society for Thrombosis and Hemostasis Scientific Standardization, Subcommittee on DIC, proposed a scoring system based on a 5-step algorithm, assigning a score based on severity of abnormality for each of the following.
 - Platelet count
 - $>100 \times 10^9$ cells/L = 0
 - $<100 \times 10^9$ cells/L = 1
 - $<50 \times 10^9$ cells/L = 2
 - Elevated levels of fibrin-related markers
 - No increase = 0
 - Moderate increase = 2
 - Strong increase = 3
 - Prolonged PT
 - <3 seconds = 0
 - ≥ 3 seconds but <6 seconds = 1
 - ≥ 6 seconds = 2
 - Fibrinogen level
 - >1 g/L = 0
 - <1 g/L = 1
 - Total score of 5 or more is considered compatible with DIC.
 - The algorithm should be applied only if an underlying disorder known to be associated with DIC is present.

TREATMENT APPROACH

- The fundamental principal of DIC treatment is the specific and vigorous treatment of the underlying disorder.
 - In some cases, DIC completely resolves within hours after resolution of the underlying condition, eg:
 - Placental abruption
 - Intrauterine fetal death
 - In some cases, supportive measures are required to control DIC until the underlying condition is resolved, eg:
 - Use of all-trans-retinoic acid and chemotherapy for treating acute promyelocytic leukemia and DIC

SPECIFIC TREATMENTS

Blood component treatment

- Low levels of platelets and coagulation factors may increase risk of bleeding.
- Rational therapy in bleeding patients or patients at risk for bleeding who have significant depletion of the following substances is treatment with:
 - FFP
 - Fibrinogen
 - Cryoprecipitate *or*
 - Platelets

- Blood component therapy should not be instituted on the basis of laboratory results alone; it is indicated only if:
 - Active bleeding is present.
 - The patient requires an invasive procedure.
 - The patient is otherwise at risk for bleeding complications.
- Large volumes of plasma may be necessary to correct the coagulation defect.

Anticoagulants

- Heparin or other anticoagulants to inhibit thrombin generation
- However, the beneficial effect of heparin on clinically important outcomes has never been demonstrated.
- Safety is debatable.
- Therapeutic doses of heparin are indicated in:
 - Clinically overt thromboembolism
 - Chronic DIC
 - Extensive fibrin deposition, as seen in purpura fulminans or acral ischemia

Restoration of coagulation pathways

- Recombinant activated protein C has been used in patients with sepsis.
 - Bleeding is the only recognized adverse effect.
 - Maintaining the platelet count above 30×10^9 cells/L is prudent during this therapy.
 - The dose is 24 mcg/kg/hour.

Other agents

- Recombinant factor VIIa is effective for certain situations.
 - Volume overload, persistent bleeding: give 75 mcg/kg every 2 hours
 - To inhibit fibrinolysis in patients with severe hemophilia A with inhibitors: high doses of recombinant factor VIIa (250 mcg/kg every 2–4 hours)

Supportive therapy

- Multiorgan support may be required.
 - Ventilatory support
 - Circulatory resuscitation or inotropic agents
 - Hemodialysis
- Blood product support may be needed if there is evidence of active bleeding.
 - Platelets if platelet count is $<50 \times 10^9$ cells/L.

- FFP if clotting times are prolonged
 - Dose: 15 mL/kg
- Cryoprecipitate to keep fibrinogen level >100 mg/dL
 - Dose: 1–1.5 bags/10 kg
- Packed red blood cell transfusion
 - Dose: 10 mL/kg
- Recombinant VIIa for intractable bleeding or volume overload
 - Dose: 75 mcg/kg every 2 hours
- Recombinant human activated protein C in desperate situations
 - Severe sepsis and multiple organ failure
 - Platelet count must be $>50 \times 10^9$ cells/L.
 - Dose: 24 mcg/kg/hour for 24–72 hours

WHEN TO ADMIT

- Most children with DIC:
 - Are already in the intensive care unit because of their underlying disease *or*
 - Require admission because of the disease complications that can occur

WHEN TO REFER

- All patients with DIC need to be treated with the help of hematologists.
- They also need to be treated in critical care units, where they can be monitored closely.

FOLLOW-UP

- Frequent monitoring is needed.
 - Clinical monitoring
 - Monitoring of PT, aPTT, fibrinogen level, and platelet count up to several times per day
 - Monitoring of D-dimer levels daily is usually adequate.

PROGNOSIS

- Associated comorbid conditions that determine outcome
 - Multiorgan dysfunction
 - Respiratory failure

Dizziness and Vertigo

DEFINITION

- Dizziness and vertigo are very different symptoms with different clinical implications.
- Dizziness
 - Term commonly used by patients to describe subjective symptoms such as faintness, giddiness, light-headedness, or unsteadiness
 - Patients with simple dizziness do not describe the room spinning around them, and do not have nystagmus.
- Vertigo
 - Sensation of rotation, spinning or whirling motion
 - True vertigo is accompanied by nystagmus.

EPIDEMIOLOGY

- The causes of vertigo in children are very different from those in adults.
 - Acute episodic vertigo
 - The type most commonly encountered by pediatricians
 - Usually not accompanied by hearing loss
 - Benign paroxysmal positional vertigo (BPPV)
 - Extremely common in adults but rare in children
 - Benign paroxysmal torticollis of infancy
 - Begins in infancy, and generally resolves spontaneously by 2–3 years of age
 - Benign paroxysmal vertigo of childhood
 - Considered a migraine variant
 - Typically seen in children <5 years
 - Ménière disease
 - Rare in young children
 - Usually occurs after 11 years of age

MECHANISM

- The mechanisms for dizziness and vertigo depend on their underlying etiology.

HISTORY

- Vertigo can be differentiated from dizziness based on 3 elements in the history:
 - Whether the vertigo is acute or chronic
 - Whether episodes are recurrent
 - Whether it is accompanied by hearing loss
- History should ascertain:
 - Description of events
 - Onset/precipitating event (eg, trauma, standing up, change in head position, excessive strain/exertion such as flying, diving, coughing, sneezing)

- Characterization in patient's words (eg, "room spinning")
- Context (eg, vision changes, hearing changes, medicine or toxin exposure)
- Associated events
 - Aura
 - Scintillating scotomas
 - Oral paresthesias
 - Tinnitus
 - Drop attacks
 - Seizures
 - Loss of consciousness
 - Altered mental status
- Observations from others, including:
 - Eye deviations
 - Nystagmus
 - Unsteady gait or evidence of dysequilibrium
 - Loss of consciousness
- When young children cannot describe dizziness or vertigo, observers tend to apply these terms to a child who is unsteady while standing
- Medical history/review of systems
 - Hearing loss, recent illnesses, history of trauma or blood loss
 - Medication history
 - Cardiac symptoms, including:
 - Palpitations
 - Chest pain
 - Neurologic symptoms, including:
 - Headache
 - Motion sickness
 - Family history, including:
 - Neurofibromatosis
 - Seizures
 - Migraines
 - Syncope
 - Sudden death
 - In adolescents, as indicated, consider a full HEADSSS assessment
 - **H**ome
 - **E**ducation
 - **A**ctivities
 - **D**rugs
 - **S**exuality

- Suicide/Depression
- Safety
- Alternatively, at a minimum, the following:
 - Home situation
 - Educational status
 - Sexual history and last menstrual period
 - Stressors

PHYSICAL EXAM

- Vital signs
 - Temperature
 - Heart rate
 - Blood pressure
 - Orthostatic vital signs
 - It may be useful to compare weight with previous weights when assessing hydration status
- Physical exam
 - Mental status
 - Volume status
 - Assess for anemia (eg, pale conjunctiva)
 - Examine head and neck, and pay particular attention to ears.
 - Vesicles may suggest herpes zoster (Ramsay-Hunt syndrome).
 - A distorted tympanic membrane may be seen with otitis media, cholesteatoma, and perilymph fistula.
 - Two useful maneuvers that may help in the diagnosis of perilymph fistula are:
 - Application of pressure to the tragus to occlude the external auditory canal
 - Pneumatic otoscopy
 - Both may induce nystagmus or vertigo and transiently worsen hearing loss.
 - Complete examination of the cardiac and neurologic systems
 - The Dix-Hallpike maneuver (Nylan-Barany test) can help localize the source of nystagmus or vertigo.
 - To provoke an episode, the child is moved rapidly from a sitting to supine position with the head 45 degrees below the edge of the table and turned 45 degrees to 1 side.
 - The ear that is facing the floor when the nystagmus is elicited is the affected side.
 - Nystagmus that resolves when the child fixates on an object is suggestive of a peripheral or vestibular disease.
 - Persistent nystagmus suggests central nervous system disorders.

DIFFERENTIAL DIAGNOSIS

- Most episodes of dizziness and vertigo can be diagnosed by history and physical examination alone.
- See table Differential Diagnoses of Dizziness and Vertigo for suggested diagnoses based on history.

Dizziness

- See Figure 27 on page F10 for suggested evaluation.
- Middle ear disease
 - Middle ear effusion may cause deterioration in vestibular balance and motor function.
 - If not self-limited, symptoms usually resolve after placement of tympanostomy tubes.
- Pre-syncope and syncope related to:
 - Fever
 - Dehydration
 - Orthostatic hypotension
 - Vasovagal episodes
 - Cardiac arrhythmias
- Anemia
 - From acute or chronic blood loss
 - From a congenital condition such as sickle cell disease
- Cardiovascular
 - Any heart disease or arrhythmia that affects cardiac output
 - Hypertension
- Hypoglycemia
- Endocrine cause, such as:
 - Hyperthyroidism
 - Hypothyroidism
 - Addison disease
- Ocular disorders, such as:
 - Refractive errors
 - Astigmatism
 - Amblyopia
 - Strabismus
- Acute cerebellar problems, especially in young children
 - Postviral acute cerebellar ataxia
 - Posterior fossa tumors
- Medications such as:
 - Aminoglycosides
 - Phenytoin
 - Loop diuretics
 - Nonsteroidal antiinflammatory drugs
- Pregnancy
- Anxiety or panic attacks

Differential Diagnoses of Dizziness and Vertigo

Information		Possible Diagnoses
Family History	Neurofibromatosis	– Acoustic neuroma
	Seizure disorder	– Seizure
	Migraine	– Benign paroxysmal torticollis of infancy – Benign paroxysmal vertigo of childhood – Migraine
	Unexplained syncope or sudden cardiac death	– Dysrhythmias
	Anxiety, panic disorders	– Anxiety
Medication History	Aminoglycosides, loop diuretics, phenytoin, nonsteroidal antiinflammatory drugs, chemotherapeutic agents, quinine	– Ototoxicity – Intoxication
Medical History	Acute or chronic blood loss	– Anemia
	Palpitation or chest pain	– Dysrhythmias – Anxiety, panic disorder
	Recent life stressor	– Anxiety
	Last menstrual period	– Pregnancy
	Motion sickness	– Benign paroxysmal vertigo of childhood – Migraine
	Recent upper respiratory infection	– Vestibular neuritis
	Fever	– Otitis media – Labyrinthitis
	Ear trauma, barotrauma	– Perilymph fistula
	Headache	– Migraine – CNS disease
	Head trauma	– Temporal bone fracture – Labyrinth or brain stem concussion – Cerebellar contusion – Perilymph fistula
	Neurologic deficits	– CNS tumor – Multiple sclerosis
	Hearing loss	– Cholesteatoma – Acoustic neuroma – Temporal bone fracture – Perilymph fistula – Labyrinth concussion – Labyrinthitis – Ramsay-Hunt syndrome – Menière disease
	Triggered by change in head position	– Benign paroxysmal positional vertigo – Perilymph fistula – Vestibular neuritis – Acute labyrinthitis
	Loss of consciousness or altered mental status	– Seizure – Dysrhythmias – Vasovagal syncope – CNS disease – Hypoglycemia

Abbreviation: CNS, central nervous system.

Vertigo

- See Figure 28 on page F11 for suggested evaluation.
 - Acute episodic or recurrent vertigo
 - Usually not accompanied by hearing loss
 - Migraine headaches and related syndromes
 - Benign paroxysmal torticollis of infancy is thought to be a migraine variant.
 - Episodes of recurrent head tilt for hours or days, often associated with vomiting, agitation, pallor, and ataxia
 - Benign paroxysmal vertigo of childhood also is considered a migraine variant.
 - Sudden onset of extreme unsteadiness and inability to stand, usually with nystagmus and sometimes with vomiting
 - Episodes last seconds to minutes
 - Family history of migraines; many develop typical migraines later in life.
 - Basilar artery migraines
 - Scintillating scotomas or visual obscuration, oral paresthesias, tinnitus
 - Occasionally *drop attacks* with or without loss of consciousness
 - Often followed by a pounding headache
 - Seizures that are associated with vertigo are followed by an alteration in or loss of consciousness.
 - Perilymph fistula
 - Abnormal connection between inner and middle ear spaces, which may be congenital or acquired by trauma
 - Benign paroxysmal positional vertigo
 - Acute episodes of severe vertigo precipitated by a change in head position
 - Associated with nystagmus, nausea, and vomiting, but not hearing loss
- Acute febrile vertigo
 - Usually associated with severe otitis media leading to labyrinthitis.
 - Patients uncomfortable, with ear pain and severe vertigo
 - Usually with nausea, vomiting, and nystagmus
 - Vestibular neuritis
 - Consider if vertigo preceded by viral illness.
 - Not associated with hearing loss
- Acute vertigo related to head or ear trauma
 - May be associated with hearing loss
 - May create perilymph fistula
- Chronic persistent vertigo
 - Especially if accompanied by neurologic signs
 - Usually is indicative of central nervous system disease

- Menière disease
 - Vertigo
 - Fluctuating hearing loss
 - Pressure in the ear
 - Tinnitus
- Central nervous system tumors
- Acoustic neuromas (seen in neurofibromatosis type II)
- Demyelinating disorders
- Degenerative disorders
- Multiple sclerosis
 - In adolescents, particularly girls, ataxia as part of multiple sclerosis may be described as dizziness.

LABORATORY EVALUATION

- Laboratory testing has a limited role in the evaluation of dizziness and vertigo.
- Evaluation is guided by clinical suspicion, and may include:
 - Blood glucose and chemistries
 - Complete blood count
 - Metabolic panel
 - Thyroid function tests
 - Medication levels
 - In girls, pregnancy testing

IMAGING

- Imaging is guided by clinical suspicion.
 - MRI of brain or other neuroimaging may be helpful.

DIAGNOSTIC PROCEDURES

- Diagnostic procedures may be obtained as guided by clinical suspicion.
 - Electrocardiogram
 - Consider especially if history suggests syncope or pre-syncope.
 - Electroencephalogram
 - Audiometry and electronystagmogram
 - Consider in evaluation of vertigo

TREATMENT APPROACH

- Treatment is aimed at the underlying disease entity.

SPECIFIC TREATMENT

- Vestibular suppressants may be used to relieve the symptoms of vertigo and nausea.
 - Diazepam
 - Meclizine (for children >12 years)
 - Dimenhydrinate

- Orthostatic hypotension with dizziness
 - Hydrate appropriately with IV fluids as needed.
 - Provide reassurance and education.
 - Caution against rising suddenly.
 - Educate about necessity of putting the head lower than the heart when symptoms occur.
- Labyrinthitis
 - Treat with antibiotics
- Migrainous vertigo
 - Treatment is symptomatic and targeted to the treatment of migraines.
- Panic attack or significant stress presenting with dizziness
 - Further history should be obtained, including any suicidal ideation.
 - Referral for counseling should be considered.
- Postinfectious vestibular neuritis
 - Treatment is symptomatic and supportive.
 - Evidence suggests that prednisone may be helpful.

WHEN TO REFER

- Acute ataxia
- A clear history of vertigo, especially with other neurologic signs or after head or barotrauma
- Suspected perilymph fistula or cholesteatoma
- Suspected seizure
- Complicated migraine

WHEN TO ADMIT

- Bacterial or suppurative labyrinthitis
 - Head trauma with temporal bone fracture
 - Space-occupying lesions
 - Potentially life-threatening cardiac dysrhythmias
 - Labile hypertension
-

Down Syndrome

DEFINITION

- Down syndrome (DS) is a constellation of abnormalities caused by triplication or translocation of chromosome 21.

EPIDEMIOLOGY

- Prevalence
 - ~1 in 732 births in the US

ETIOLOGY

- DS is caused by a chromosomal aberration, trisomy 21.
 - Most individuals (95%) with trisomy 21 have 3 free copies of chromosome 21.
 - In approximately 5% of patients, 1 copy of chromosome 21 is translocated to another chromosome, most often chromosome 14 or 21.
 - The DNA sequence of chromosome 21 is now known, and >100 genes have been identified.

RISK FACTORS

- Advanced maternal age
 - The likelihood of bearing a fetus with DS increases with maternal age >35 years.

SIGNS AND SYMPTOMS

Common features

- All characteristic features may or may not be present.
 - Presence of 8 of the features is diagnostic for DS.
 - A child can have fewer characteristics and still have DS.
 - A child can have some of the characteristics and not have DS.
- Head
 - Brachycephaly (flat occiput)
- Eyes
 - Inner epicanthal folds
 - Upward slanting palpebral fissures
- Face
 - Flat appearing, low nasal bridge
 - Small shell-like ears with small or no earlobes
 - Brushfield spots (speckling of the iris)
- Fingers and toes
 - Single-flexion crease on fifth finger and incurving of the fifth finger
 - 4-finger sign (simian crease)
 - Present in 50% of children with DS and 15% without DS
 - Transverse palmar lines
 - Brachydactyly (short fingers)
 - Wide space between the first and second toes

- Heart (commonly, congenital defects)
 - Endocardial cushion defects
 - Ventricular septal defects

- Neck
 - Short
 - Superabundant skin at nape

- Neuromuscular system
 - Absent or diminished Moro reflex
 - Muscular hypotonia
 - Joint hyperflexibility

- Tongue
 - Excessive protrusion

History and physical examination, by age

- Newborn to 1 month of age
 - History
 - Feeding pattern
 - Stooling pattern
 - Physical examination
 - General physical examination
 - Neurologic examination
 - Signs of congenital heart defects:
 - Ocular examination for congenital cataracts
 - Signs of gastrointestinal malformation:
 - Vomiting
 - Weight loss
 - Absence of stools
 - Signs of cardiac malformation:
 - Cyanosis
 - Murmur
 - Irregular heart rate
 - Signs of cataracts:
 - Absent red reflex
- Infants 1–12 months of age
 - History
 - Parents' concerns
 - Otitis media
 - Upper respiratory tract infection
 - Nutritional intake/feeding
 - Physical examination
 - Plot growth on a DS growth chart; consider possibility of celiac disease in infants with DS, failure to thrive, or diarrhea.
 - Cardiac assessment
 - Neurologic examination

- Ocular examination: strabismus, cataract, nystagmus
- Tympanic membranes: otitis media, upper respiratory tract infection
- Audiologic screening
- Administer age-appropriate immunizations.
- Children 1–5 years of age
 - History
 - Parental concerns about the child’s behavior and school program.
 - Symptoms of a vision or hearing disorder
 - Snoring, restless sleep, and sleeping positions
 - The primary care physician should ask about the child’s snacks and the amount of time the child spends watching television.
 - Physical examination
 - Height and weight plotted on a DS growth chart
 - Obesity may become a problem at ~5 years of age.
 - Ears should be examined for impacted cerumen that can cause moderate hearing loss.
 - Eye examination should be performed to detect cataracts.
 - Vision screening should be performed yearly or more often, if indicated.
- Children 5–13 years of age
 - History
 - Parental concerns about the child’s behavior and school program
 - Symptoms of a vision or hearing disorder
 - Snoring, restless sleep, sleeping positions, sleep apnea
 - Skin problems, such as dryness
 - Physical examination
 - Height and weight plotted on a DS growth chart
 - Body mass index/obesity
 - Neurologic examination
 - Vision screening
 - Hearing screening
- Adolescents 13–21 years of age
 - History
 - Answer the parents’ questions.
 - Education or behavioral problems
 - Ensure that the child is up to date on immunizations.
 - Physical examination
 - Height and weight plotted on a DS growth chart
 - Body mass index/obesity
 - Gynecologic examination (consider referral)
 - Neurologic examination for long-tract signs
 - Vision screening
 - Hearing screening

- Young adults
 - History
 - Evaluate the family’s concerns.
 - Ask about symptoms of dementia and mental disorders.
 - Physical examination
 - Gynecologic examination, Papanicolaou smear
 - Testicular and breast examination
 - Neurologic examination

DIAGNOSTIC APPROACH

- Accurate and prompt diagnosis can often be accomplished at the bedside.
 - When 8 of the many characteristics commonly associated with DS are present, the diagnosis is relatively simple.
 - 1 or 2 physical findings are not diagnostic of DS.
- Chromosomal analysis is required to confirm diagnosis.
 - Every newborn clinically suspected of having DS requires chromosomal analysis.
 - Confirmation of DS diagnosis by chromosomal analysis helps the parents accept the clinical diagnosis.
 - Physicians should share the suspected diagnosis of DS with the family as soon as possible.

LABORATORY FINDINGS

- Chromosomal analysis
 - Required to confirm DS diagnosis
 - Complements a detailed family history
 - Forms the basis of genetic counseling of the parents on the risk of recurrence
- Thyroid screening
 - Newborn and annually thereafter
 - Serum-free thyroxine
 - Free triiodothyronine
 - Thyroid-stimulating hormone
- Serum immunoglobulin A antigliadin antibody and anti-tissue transglutaminase antibody levels
 - Screen for celiac disease.
- Complete blood count
 - Newborns
 - Blast cells in the peripheral blood smear and normal neutrophil and hemoglobin levels indicate transient leukemia.
 - All newborns with transient leukemia need follow-up with the hematologist every 3 months for review of the peripheral blood smear.
 - Adolescents

IMAGING

- Cervical spine radiography (flexion and extension)
 - Should be interpreted by an experienced radiologist
 - Indicated in:
 - Children with signs of atlantoaxial instability
 - Patients who wish to participate in contact sports in school or Special Olympics
 - The natural history of atlantoaxial instability and subluxation remains poorly understood.
 - Whether only 1 set of cervical spine radiographs is necessary or whether these films need to be repeated is unclear.
 - Cervical spine radiographs may be unreliable in identifying all children at risk.
- Cervical spine computed tomography
 - Child with normal radiographs but abnormal neurologic examination results
- Echocardiography
 - To check for mitral valve prolapse in young adults
- Pelvic ultrasonography
 - Gynecologic examination by age 17 years
- Mammography
 - Baseline at age 35 years
 - Follow-up is based on the physical examination and family history.

TREATMENT APPROACH

- Early detection and correction of medical problems (preventive management)
 - The usual preventive interventions and anticipatory guidance given to other children and families
 - Additional evaluation and close monitoring of problems specific to children with DS
 - Growth: failure to thrive and growth retardation
 - Dental: malaligned teeth and periodontal disease
 - Ophthalmologic: refractive errors, strabismus, myopia, and cataracts
 - Otologic: chronicotitis media, and hearing loss
 - Respiratory: obstructive sleep apnea
 - Cardiac: congenital heart defects
 - Endocrine: hypothyroidism and diabetes mellitus
 - Gastrointestinal: constipation and congenital intestinal obstruction
 - Neurologic: delayed development, intellectual disability, seizures, and depression
 - Immune: immunologic disorders and leukemia

SPECIFIC TREATMENTS

Newborn to 1 month of age

- Provide a gentle and hopeful delivery of diagnosis to the family.
 - Avoid discussion over the telephone.
 - Inform both parents together.
 - Meet in a quiet and private place where the physician and parents will not be interrupted.
 - Provide current information to the family.
 - Be hopeful.
 - Provide name and telephone number of a local DS support group (National Down Syndrome Congress)
 - Discuss future expectations briefly.
 - Discuss potential medical problems.
 - Point out that many children who have DS are healthy and participate in most of the usual childhood activities.
 - Inform that the average life span of those who have DS is 55 years.
 - Discuss the plan to identify and manage medical problems.
 - Allow time for the parents to respond, voice concerns, raise questions, and express feelings:
 - Anger
 - Guilt
 - Sorrow
 - Provide written information about DS.
 - Parents find that having something to read after their discussion with the physician is useful.
 - Most information >5 years old should be considered outdated.
 - Suggest consultation with a geneticist.
 - Reinforces the discussion provided by the pediatrician
 - Provides information about additional resources, such as literature and support groups
 - Educates the family about prenatal detection and the risk of recurrence
 - Arrange for a follow-up meeting with the family.
 - Give time to begin adjusting to the new information and to formulate questions.
 - Offer to meet extended family members to answer questions.
- Adoption
 - Most families accept a child born with DS.
 - Some families have greater initial difficulty and require more extended counseling.
 - In rare cases, a family cannot accept a child with DS.
 - In this event, adoption should be discussed.

- In many instances, families are waiting to adopt children with DS.
 - Call the Down Syndrome Adoption Exchange (914/428-1236) for more information.
 - Oral motor problems
 - Mild feeding problems include weak sucking, fatigue during feeding, and uncoordinated breathing.
 - Usually resolve in 2–3 weeks
 - Measures parents can take to help simplify feeding
 - Make sure the child is fully awake when fed at night.
 - Clear mucus from the baby’s nose before feeding so that breathing will be easier.
 - Support the infant’s chin during feeding.
 - The primary care physician should monitor the weight and caloric intake carefully.
 - If feeding problems are particularly severe or do not resolve with these interventions, consider referral to an oral motor (swallowing) specialist.
 - Breastfeeding problems
 - Most infants who have DS can breastfeed successfully.
 - If breastfeeding appears to be going poorly:
 - Primary care physician should arrange a visit to review the infant’s weight gain and the mother’s breastfeeding technique.
 - For particularly severe problems:
 - Referral to a lactation specialist may help.
 - Bottle feeding may be needed.
 - Constipation
 - Stool softeners
 - If an infant has constipation despite adequate intake and does not respond to stool softeners:
 - Evaluation for Hirschsprung disease should be considered.
- Infants 1–12 months of age**
- The parents’ anxiety and questions decrease with time.
 - For the initial few months, they need to be able to depend on the primary care physician to be available.
 - Set aside a period each week, perhaps half a day, for consultation and family education.
 - Keep this time free of acute-care office visits.
 - Consider reliance on a nurse practitioner to help meet extra educational and health care needs.
 - Set up a medical record with special sections for:
 - Problems
 - Procedures (date, site, and result of all special medical procedures completed)
 - Consultants involved in the child’s care (with emergency telephone numbers)
 - An updated, 1-page medical summary to be used for emergency admissions and consultations
 - A flowchart of significant laboratory data and medications
 - Provide special check-out instructions for covering or on-call physicians.
 - Especially those outside the office and not familiar with the patient
- Discuss with the family:
 - Enrollment in an early education program
 - Supplemental Security Income (SSI) and other government programs that help families financially with the extra costs of a special needs child
- Tongue protrusion
 - Factors that produce tongue protrusion include a small oral cavity and mouth breathing.
 - Behavior management techniques can be used.
 - Oromotor exercises may alleviate tongue protrusion.
- Controversial therapies
 - Discuss whether the family is contemplating:
 - Tongue resection
 - Improvement in speech has not been observed.
 - Primary care physician should try to inform families about risks and benefits of any surgical procedures.
 - Megavitamin supplements
 - Preparations high in vitamins and minerals initially seemed to result in increased intelligence scores.
 - However, no studies to date have replicated these results.
 - Because side effects from megavitamin regimens have been reported, unproved megavitamin and mineral therapies should be avoided.
 - Routine nutritional screening should be performed at health assessment visits and vitamins prescribed when warranted by standard criteria.
- Children 1–5 years of age**
- Behavioral problems
 - Many children who have DS do not fit the stereotype of being placid or compliant.
 - Parents may not volunteer information about obstinacy or noncompliance.
 - When the child seems to have a behavioral disorder:
 - A thorough history should be obtained.
 - Parents should be asked about changes in the environment or their expectations.
 - A complete physical examination should be performed.
 - Laboratory tests should be obtained, if warranted, to identify medical problems that may lead to behavior disorders.

- A trial of behavior management should be initiated for mild problems.

■ Learning problems

- School learning problems require further evaluation.
 - They often come to the physician's attention when children with DS are placed in mainstream classes.
- Review the current individual educational program.
 - Ensure that appropriate developmental testing has been completed.
 - Parents should have had an opportunity to provide information in the individual educational program process.
- History should be reviewed thoroughly.
 - Ensure that the parents' and teachers' expectations are appropriate for the child's developmental age.
- Medical problems that can affect learning and behavior should be identified.

Children 5–13 years of age

■ Obesity

- Preventive approach:
 - Monitor the child's diet.
 - Promote regular exercise.
 - Screen yearly for hypothyroidism.

■ Hyperactivity

- Parents or teachers may bring up symptoms of hyperactivity.
 - Thoroughly assess to identify medical problems associated with inattention.
 - Behavior-management techniques and classroom adaptations should be tried before resorting to medications.

Adolescents 13–21 years of age

■ Physical, emotional, and educational needs in adolescents with DS require a special approach.

- During the annual health assessment visit, the primary care physician should discuss with the family the child's:
 - Health
 - Educational program
 - Behavioral problems
 - Prevocational experience and training

■ Sexuality

- Many adolescents who have DS receive some formal education about sexuality in school.
 - Primary care physicians should ensure that this education is complete and discuss this with the family.
- When a young woman who has DS becomes pregnant, the father of the woman's child is usually a close relative.
 - Families need to know about birth control options and routine procedures for safeguarding their adolescent.

- Families usually have many questions about a teenager's sexuality but often do not ask the primary care physician about them.

- Sexual interests of their children
- Level at which they experience sexual feelings
- How to deal with masturbation
- How to answer questions about wanting to give birth
- Management of menstrual hygiene

• Sterility

- Although young men who have DS are usually sterile, a small number of girls and women have given birth to children.
- Families may ask about sterilization procedures for both young men and young women.
- In most states, performing sterilization procedures is difficult because of the difficulty in obtaining consent.

■ Smoking and drug abuse

- Adolescents who have DS need education about smoking and drug abuse.
- If at all possible, they should:
 - Have well-balanced diets
 - Continue regular exercise
 - Be involved in appropriate social activities

■ Prevocational experiences

- When possible, adolescents with DS should also have opportunities for prevocational experiences, such as volunteer work that can provide adequate supervision.
- The school curriculum should make the transition to planning for a life vocation.
 - Psychoeducational testing is often helpful to determine the individual's aptitudes and job interests.

■ Behavioral problems

- Assess any changes or regression in self-care skills.
 - Family may report important information about withdrawal or loss of interest in recreational activities.
- Some emotional disorders are characterized by:
 - Excessive anger
 - Frustration
 - Aggressive behaviors
- Other signs of a possible disorder
 - Self-injurious behavior (hitting or biting themselves)
 - Crying spells
 - Refusal to participate in self-care activities
- When evaluating a patient who has a sudden increase in behavioral problems:
 - The primary care physician should look for underlying medical problems.

- Changes in vision or hearing may result in withdrawal or temper tantrums.
- Hypothyroidism can cause lethargy and lack of interest in activities.
- Alzheimer disease may (rarely) appear in adolescence.
- Psychological testing that includes an assessment of self-care skills should be performed.

■ Community living arrangements

- The primary care physician needs to discuss with the family a long-term plan for the adolescent's living arrangements.
- Most communities have a spectrum of community living facilities, for example:
 - Small, heavily supervised group homes
 - Apartments that have minimal supervision
- Families need to make living arrangements 2 or 3 years before they anticipate need.
 - Most community facilities will have waiting lists.

Young adults

- Primary care physicians often continue to monitor and treat adolescents into the early adult years.
 - Families are often attached to the primary care physician and ask about continuing care.
 - This discussion can center on aspects of preventive medical care for the young adult.
- Adults with DS require the same annual health assessment as any other adults.
 - Limited expressive speech may not allow accurate history.
 - Medical problems may be seen as behavioral problems.
- Immunizations should be reviewed and kept current.
 - Hepatitis B and pneumococcal vaccines should be considered for adults at special risk.
- Vocational training
 - Young adults should be enrolled in vocational training to enhance skills for either a community job or workshop placement.
 - The program should include some basic educational activities for continued improvement in skills.
- Community living arrangements
 - The primary care physician should ask about:
 - Family or community living arrangements
 - Future living arrangements if the adult with DS continues to live at home
 - Plans for guardianship and wills and trusts
 - Young adults should be guided to:
 - Voter registration
 - Selective Service System (men)

■ Health education

- Drug and alcohol abuse
- Smoking
- Sex

WHEN TO REFER

■ Newborn to 1 month of age

- All infants
 - Cardiology consultation
 - Genetics consultation
- Leukocoria/lens opacity
 - Ophthalmology assessment
- Transient myeloproliferative disease
 - Hematology consultation every 3 months
- Severe constipation
 - Pediatric gastroenterology evaluation
- Families who have serious difficulty adapting to their newborn
 - A family counselor may be needed.

■ Infants 1–12 months of age

- Severe constipation not responding to dietary control
 - Pediatric gastroenterology evaluation
- Chronic middle ear effusions
 - Consultation with an ear, nose, and throat specialist
- Ophthalmology consultation
 - At 6 months
- All infants should be referred to an early intervention program.

■ Children 1–5 years of age

- Infantile spasms
 - Immediate referral to a pediatric neurologist
- Neck pain, loss of bladder and bowel control, and gait disturbance
 - Immediate pediatric neurosurgery consultation
- Disruptive behavior or excessive short attention span
 - Evaluation by developmental or behavioral specialists
- Chronic middle ear effusions and symptoms of obstructive sleep apnea
 - Require a consultation with an ear, nose, and throat specialist
- Ophthalmology evaluation
 - Every 2 years from 12 months of age
- Behavior specialist
 - Severe behavioral problems
 - Persistent behavioral problems with no medical cause

■ Children 5–13 years of age

- Audiology evaluation
 - Annual
- Ophthalmology evaluation
 - Annual
- Symptoms of obstructive sleep apnea
 - Require a consultation with an ear, nose, and throat specialist.
- Normal cervical spine radiograph results but abnormal neurologic examination results
 - Referral to a neurosurgeon or orthopedic physician experienced with DS

■ Adolescents and young adults

- Gynecologic evaluation by age 17 years
 - Pelvic examination
 - Birth control options
 - Seek a specialist with experience in evaluating women with developmental disabilities.
- Sexual issues
 - Referral to community resources should be considered if the primary care physician's expertise or the school curriculum needs to be complemented.
- Neurologic evaluation
 - Teenagers who have lost skills with no obvious medical explanation
- Financial and custody issues
 - The Arc (formerly known as The Association for Retarded Citizens) has local branches around the country.
- Psychiatric evaluation
 - Recommended for all adolescents with severe behavioral disturbances
- Ophthalmologic evaluation
 - Annual
- Audiologic evaluation
 - Annual

FOLLOW-UP

Newborn to 1 month of age

- The primary care physician should arrange a visit with the parents and child 1–2 weeks after discharge.
 - This meeting provides time for further discussion with the family and for a follow-up medical assessment.
 - Karyotype results may not be available at discharge from the hospital.
 - Recurrence risk of DS in future pregnancies and prenatal diagnosis should be discussed when the karyotype is available.

Infants 1–12 months of age

- Psychosocial concerns—habilitation
 - Refer the parents to an infant education program.
 - Continue educating the family about DS, and review risk of DS in future pregnancies.

Children 1–5 years of age

- Eye examination every 2 years
- Hearing test every 6 months till age 3 years, annually thereafter
- Dental examination
 - Twice a year
 - Children with DS have higher risk of periodontal disease.
- Psychosocial concerns—habilitation
 - Discuss behavioral management and sibling adjustments.
 - Review:
 - The child's education program
 - Dietary habits and physical activity pattern
 - Risk of DS recurrence and prenatal diagnosis

Children 5–13 years of age

- Eye examination every year
- Hearing test every year
- Dental examination
 - Twice a year
 - Children with DS have higher risk of periodontal disease.
- Psychosocial concerns—habilitation
 - Review:
 - Dietary habits and physical activity pattern
 - The child's education program
 - Psychosexual development, menstrual hygiene, and fertility
 - Review risk of DS in future pregnancies
 - Discuss:
 - Respite and long-term care plans, guardianship, and financial arrangements with the family
 - Age-appropriate social skills, self-help skills, and the development of a sense of responsibility
- If the child has normal neurologic examination and cervical radiographs are normal, he or she may participate in all sports.

Adolescents 13–21 years of age

- Eye examination every year
- Hearing test every year
- Dental examination
 - Twice a year
 - Children with DS have higher risk of periodontal disease.

- Psychosocial concerns—habilitation
 - Check to see whether the patient is obtaining vocational training.
 - Have the patient continue speech therapy.
- Family concerns
 - Ask about community living plans for the patient.
 - Discuss:
 - Enrolling the patient in Medicaid and SSI if eligible
 - Sexuality, including preventing pregnancy
 - Help the parents teach their child to avoid smoking and abusing drugs.
 - Facilitate transfer to adult medical care.

Young adults

- Cardiologic examination
- Eye examination every 2 years
- Hearing test every 2 years
- Dental examination
 - Twice a year
 - Children with DS have higher risk of periodontal disease.
- Cervical spine examination at age 30 years
- Psychosocial concerns—habilitation
 - Inquire about the patient's exercise and recreational activities.
 - Urge the patient and family to continue with vocational and adult education programs to allow better job placement.
 - When appropriate, check to see whether patient has registered to vote and (for young men) has registered with the Selective Service System.
- Family issues
 - Remind the family to update their estate planning and wills.
 - Evaluate the patient for community living if not already in this type of setting.
 - Check on patient's eligibility for Medicaid and SSI.

Atlantoaxial instability

- Excess mobility of the atlantoaxial joint without neurologic complications
- If atlantodontoid distance is >5 mm and neurologic examination results are normal:
 - Patient should be monitored yearly with repeated neurologic examinations.
 - Sports that place the child's neck in extreme extension (tumbling, gymnastics, diving) should be avoided.
- Careful monitoring during intubation for induction of anesthesia is needed if surgery is performed.

COMPLICATIONS

- Acquired hypothyroidism
 - 9–35% of individuals with DS
- Atlantoaxial instability
 - ~15% of children with DS
- Atlantoaxial subluxation
 - Backward movement of the odontoid process of the axis, compressing the spinal cord and resulting in the signs and symptoms of cord compression
 - Neck pain
 - Head tilt
 - Progressive weakness and loss of bladder or bowel control
 - Neurologic examination reveals:
 - Long-tract signs, such as increased deep-tendon reflexes in the lower extremities
 - Positive Babinski sign
 - Ankle clonus
 - Although rare, it is life threatening.
- Cardiac malformations
 - Increased incidence
- Cataracts
 - Absent red reflex
- Congenital hearing loss
 - 15% of children with DS
- Gastrointestinal problems
 - Celiac disease
 - Gastrointestinal malformations
 - Duodenal atresia
 - 2–15% of cases
- Infection
 - Increased susceptibility
- Leukemia
 - Increased incidence
- Mitral valve prolapse
 - Develops in ~50% of adults with DS
- Obesity
 - Increased risk in those with:
 - Greater hypotonia
 - Shorter stature
 - Preschool-age children
 - Adolescents
- Transient leukemia (transient myeloproliferative disease)
 - 10% of newborns with DS

PROGNOSIS

- Newborn to 12 months of age
 - The first year of life holds the highest probability of death for children with DS who have an additional anomaly.
 - ~78% survive with an additional anomaly.
 - 96% survive without an anomaly.
- Cardiac malformation
 - Survival of children with cardiac malformations has improved.
 - Only 8–9% mortality in children with DS and heart defects is now reported.
- Leukemia
 - As a cause of death, <10% of cases
 - Transient leukemia (transient myeloproliferative disease)
 - 10% of newborns with DS
 - Most infants with transient leukemia go into spontaneous remission and recover by 3 months of age.
 - 20% develop life-threatening complications.
 - Of those who recover, ~20% develop acute megakaryocytic leukemia (a type of acute myelogenous leukemia) in the first 4 years of life.
 - Cure rate for acute megakaryocytic leukemia is >80%.
- Children 1–5 years of age
 - >50% have serious medical disorders.
 - 2% of children with DS have Hirschsprung disease.
- Life expectancy
 - Average life expectancy in adults with DS has increased into the middle 50s.
 - Some are alive in their 60s.

PREVENTION

- Recent advances have improved noninvasive techniques for identifying fetuses with DS.
 - Regardless of maternal age, this screening should to be offered to all pregnant women.
- Screening using a combination of maternal age and multiple serum markers
 - α -Fetoprotein, unconjugated estriol, human chorionic gonadotropin, and dimeric inhibin A in the second trimester of pregnancy
 - Detects 75% of fetuses with DS
 - False-positive rate of 5%
- Screening during the first trimester at 10–14 weeks using:
 - Fetal nuchal translucency, maternal serum free β -human chorionic gonadotropin and pregnancy-associated plasma protein-A
 - Improves detection rate to 89%
 - False-positive rate of 5%
 - First-trimester screening may become the standard method of screening in the future.
- Risk of DS in subsequent pregnancies
 - For nondisjunction trisomy 21, ~1 in 100 for women <35 years
 - Age-related for older women
 - A higher recurrence risk may exist for the translocation types of DS if the mother has a balanced translocation.

Drowning and Near Drowning

DEFINITION

- Drowning is death caused by suffocation within 24 hours after submersion in a liquid medium.
 - It is an important cause of accidental death among children and adolescents.
- Near drowning is an event that a person has survived through resuscitative efforts.

EPIDEMIOLOGY

- Incidence
 - In the US, approximately 1400 drowning deaths occur each year in patients <19 years.
 - For every submersion injury resulting in death within 24 hours, 4 hospital admissions and 14 emergency department (ED) visits occur.
- Groups most at risk
 - Children <5 years
 - Boys age 5–19 years
- Age
 - Toddlers are more likely than older children to experience submersion injuries.
 - Older children and adolescents may experience submersion injuries during a diving accident.
 - Adolescent drowning incidents are often associated with drinking alcohol or using drugs.
- Bathtub submersion injuries
 - More common in children <1 year who are left in the care of an older sibling or who are without adult supervision
 - May be associated with scald burns from hot water or child abuse

ETIOLOGY

- Events in submersion injury
 - The child initially panics, then holds breath and loses consciousness.
 - The child may lose cough and gag reflexes, then aspirate large amounts of water.
 - This produces anoxia, resulting in decreased oxygen delivery to the tissues.
 - The heart rhythm becomes abnormal, with fibrillation and finally asystole.
 - The child's core temperature drops.
- The type of fluid aspirated affects circulatory volume and electrolyte balance.
 - Fresh water
 - Hypotonic
 - Rapidly absorbed across the alveoli
 - May result in increased blood volume, hemodilution, reduced serum electrolytes, and hemolysis

- Salt water produces:
 - Hemoconcentration
 - Decreased blood volume
 - Elevated serum electrolytes
- Most children aspirate <4 mL/kg of fluid.
- There is little clinical relevance to the type of water in which the child is submerged.

- Most patients who experience near drowning are intravascularly hypovolemic as a result of capillary leak from asphyxia.
 - Effects on the body may be on a single system or may be multisystem.
- In addition to hypovolemia, near drowning may cause serious injury.
 - Pulmonary injury with surfactant washout and aspiration of gastric contents or contaminated water contents
 - Central nervous system (CNS) injury resulting from anoxic or ischemic events
 - Myocardial injury
 - Renal impairment
 - Injury to the gut mucosa
 - Liver function abnormalities

RISK FACTORS

- Conditions predisposing children to submersion injuries
 - Underlying seizure disorders
 - Occult cardiomyopathy
 - Alterations in the conduction system

SIGNS AND SYMPTOMS

- Effects on lungs
 - Hypoxia and hypercarbia
 - Aspiration pneumonia or simple pulmonary edema that may progress to acute respiratory distress syndrome
 - The patient may have apnea or agonal respirations.
 - The patient may have difficulty with airway protection.
 - Understanding the mechanism enables the astute clinician to act to prevent further hypoxic or anoxic injury.
- Cardiovascular effects
 - Cardiovascular instability
 - Hypotensive shock
 - Metabolic acidosis
 - Pulmonary vascular resistance may be increased and further potentiate metabolic acidosis.
 - If cardiovascular instability continues, the clinician must consider sepsis or further myocardial dysfunction.

- CNS effects (ultimate complication)
 - Severity is determined by the duration of hypoxia and hypotension.
 - After loss of consciousness, blood flow to the CNS may be increased and result in:
 - Reperfusion injury
 - Marked decrease in cerebral blood flow
 - The patient may have severe CNS injury even after:
 - Restoration of cardiac output
 - Normalization of blood pressure
 - Adequate oxygenation
- Other systems
 - Gastrointestinal system
 - Rectal discharge of material sloughed from the intestinal mucosa mixed with blood is commonly associated with severe hypoxic-ischemic injury after perfusion to the gastrointestinal tract becomes severely reduced.
 - Followed by gut necrosis
 - Hematopoietic system (disseminated intravascular coagulation)
 - Hypoxic-ischemic injuries may result in:
 - Coagulopathy
 - Renal failure
 - Predisposition to infection

LABORATORY FINDINGS

- Periodic review of blood tests is important for changes in:
 - Hematocrit
 - Coagulation profile
 - Leukocyte count
- Review of liver and renal function studies helps ascertain whether other organs have been injured.

IMAGING

- Before transfer to a pediatric intensive care unit (PICU)
 - Radiographic studies to confirm:
 - Placement of the endotracheal tube
 - Placement of vascular access catheters
 - Contour of the lungs
- If indicated, the physician may order head computed tomography to evaluate the brain and to determine whether traumatic head injury has occurred.

TREATMENT APPROACH

- Approach after significant submersion injury involves at least 4 phases.
 - Initial lay person rescue at the scene
 - Emergency medical team or paramedic response

- Stabilization in the ED
- Care in the PICU

Initial rescue

- Identify the problem.
- Call 911.
- Remove the child from the water.
- Clear the airway and perform CPR until emergency medical team arrives.
 - Effective CPR at the scene is a major determinant of success.
 - Note the time that CPR was initiated.
 - If possible, note the duration of submersion and temperature of the water.

Emergency response

- At the scene, an effort should be made to resuscitate the child to restore cardiac output, oxygenation, and acid-base status.
 - Ignore the down time that the child may have had during this initial resuscitative phase.
 - Assessing patency of the airway is critical, as is clearing airway of any debris before attempting to ventilate the patient with either a bag-mask device or intubation in the field.
 - Try to protect:
 - Airway from aspiration of stomach contents
 - Lungs from aggressive positive pressure ventilation, which may produce overdistention of the lungs and possibly barotrauma.
- Once heart rate is established and adequate chest wall rise is observed, the child should be transported to the closest ED that deals with children.

Stabilization

- In the ED, the child should be in a room large enough to accommodate the many interventions required.
 - Careful examination
 - Further stabilization
 - Vascular access
 - Gastric decompression
 - Bladder catheterization
 - Appropriate respiratory support
- Vital signs, including temperature, should be assessed.
- The child's cardiorespiratory status should be monitored, including:
 - Continuous electrocardiographic monitoring
 - Recording of oxygen saturation
 - If possible, intermittent recording of blood pressure
- If the child is spontaneously moving and breathing, close observation and monitoring are required to ensure that response to the submersion injury is not delayed.

- Children may be discharged after 4–8 hours if they:
 - Are well saturated in room air
 - Have age-appropriate responses
 - Have a normal Glasgow Coma Score
- Children need to be admitted if they:
 - Require significant amounts of oxygen
 - Have abnormal sensorium
- Imaging studies may be required to make certain that internal organs are not adversely affected.
- Before transferring the child to the PICU:
 - His or her neurologic condition must be carefully determined.
 - The cervical spine must be cleared.
 - All lines and tubes must be stabilized to make certain that the child cannot dislodge them.
- Patients should be assessed to ensure that no pneumothorax or other evidence of air leak exists.

PICU

- Closely monitor:
 - All aspects of vital signs
 - Oxygen saturation
 - End-tidal carbon dioxide (if child is intubated)
- If the child is intubated, an arterial line should be positioned.
- If the child requires cardiovascular support with inotropes, a central venous catheter should be placed.
- Management is aimed at:
 - Restoring cardiac output
 - Minimizing brain injury
 - Preventing catastrophic complications
- Neurointensive care support is often required.
 - Aggressive management of intracranial hypertension (with osmotic agents, hypothermia, hyperventilation, steroids, or barbiturate-induced coma) have not proven to have much benefit.
 - Such interventions may increase risk for nosocomial infections, pulmonary insufficiency, and cardiac dysfunction.
- Efforts should be made to assess the degree of neurologic injury over the first 24–48 hours.
 - Electroencephalography may help identify electrical seizures.
 - Seizure activity should be treated quickly and aggressively.
 - Patients should receive sedation only if clinically indicated.
 - Severity of encephalopathy is the main determinant of outcome.

SPECIFIC TREATMENTS

Initial management

- If spontaneous respirations are present, the clinician should first administer oxygen.
- If the child cannot protect the airway, intubate with an endotracheal tube of appropriate size.
- Initial ventilatory settings
 - Require enough tidal volume (6–10 mL/kg) or inspiratory pressure to allow adequate rising of the chest wall.
 - Higher tidal volumes may be associated with lung injury.
 - Positive end-expiratory pressure (4–8 cm H₂O) must be used to help alveolar distention.
 - An age-appropriate respiratory rate and a fraction of inspired oxygen of 1.0 should be provided.
- The child should undergo chest radiography to assess degree of lung injury and to make certain that the endotracheal tube is correctly placed.
- Patients who were intubated in the field:
 - Need thorough evaluation in the ED before being extubated
 - At most institutions, patients:
 - Remain intubated and mechanically ventilated
 - Get transferred to the closest PICU
 - The stomach must be decompressed with a nasogastric tube.
 - A bladder catheter must be placed to measure urine output.
 - Appropriate vascular access lines must be inserted.
- Patients who were not intubated in the field but have poor oxygenation
 - Positive-pressure ventilation is indicated if signs indicate increased work of breathing or if there is a high oxygen requirement.
 - The child should then be intubated with an appropriately sized endotracheal tube.
 - The child should be placed on an appropriate ventilator setting for the underlying condition.
- To facilitate intubation, the physician may administer a muscle relaxant and an analgesic-amnesic agent.

Cardiovascular management

- Vascular volume should be restored with an isotonic solution (10–20 mL/kg).
- The patient should be warmed to prevent hypothermia, which is associated with abnormal cardiac rhythms.
- Treatment for reduced myocardial contractility
 - The patient may require inotropic support via a proximal port.
 - Dopamine
 - Epinephrine
 - Dobutamine

- A central venous catheter and arterial line should be inserted.
 - A double-lumen catheter should be used for central venous access.
 - A distal port should be used to transduce the central venous pressure (CVP).
- Lines may be inserted into 1 of several vessels.
 - Subclavian
 - Internal jugular
 - External jugular
 - Femoral
- The child will require continuous monitoring of vital signs and CVP.
 - CVP monitoring enables assessment of volume status, which helps guide fluid administration.
 - An arterial line enables continuous monitoring of the mean arterial pressure, which should be kept in the correct range for age.
 - If patient continues to struggle with high CVP and poor cardiac output, the clinician should consider placing a pulmonary artery catheter to measure the wedge pressure (a reflection of true CVP).
- Normalization of blood gases by various ventilatory strategies is preferred to hyperventilation.
- Support of cardiovascular system with inotropes as needed to maintain
 - Adequate blood pressure
 - Blood flow to vital organs

Other care

- Nutritional support is provided as:
 - Parenteral nutrition *or*
 - Enteral nutrition if the intestinal tract can tolerate feeds
- Minimization of stress ulcers in the gastric mucosa is vitally important.
 - Agents may be used to maintain a gastric pH >5.
- Antibiotics to treat suspected or proven infections
 - Victims are susceptible to bacterial infections due to aspiration of water.
 - Bacterial infections may result from complications of mechanical ventilation or vascular access attempts.
 - Initiating empiric antibiotic treatment may be reasonable.
- Unusual forms of ventilatory support
 - High-frequency ventilation for acute pulmonary injury
 - Inhaled nitric oxide for severe hypoxia-induced respiratory failure
 - Extracorporeal oxygenation
 - Used for rewarming
 - In theory, allows the lungs to rest and prevent barotraumas associated with high airway pressures

WHEN TO ADMIT

- Children with significant respiratory distress requiring oxygen
- Children with abnormal sensorium
- Children with abnormalities on coagulation, liver, and renal function studies

WHEN TO REFER

- All patients with near drowning should be referred to an ED (preferably a children's ED) for complete physical, laboratory, and imaging evaluation.

FOLLOW-UP

- The health care team should provide resources to the family as needed.
 - Support for sustaining the child in a long-term care facility
 - Support after a child's death
 - A palliative care team or another specialist may provide bereavement support for the family.

PROGNOSIS

- Most important for positive outcome is:
 - Return of normal neurologic function within 24–72 hours
 - Successful resuscitative measures at the scene
 - If the child is conscious on arrival at hospital, the chance of intact survival is excellent.
 - Pulmonary injury can be managed successfully with new approaches to mechanical ventilation.
- The worst prognosis is associated with continued need for resuscitation in the ED, despite age, duration of submersion, pH at the time of care, or body temperature.
- Other poor prognostic findings
 - Continuation of CPR beyond 25 minutes
 - Fixed, dilated pupils
 - Seizures
 - Flaccidity
 - Glasgow Coma Score <5
 - Decreased cerebral blood flow
- Cold-water submersions that produce severe hypothermia may influence outcome.
- Outcome after submersion injuries will be determined within the first 24–72 hours.
- If neurologic function has not recovered after 48–72 hours, the child is not likely to recover neurologic function.
 - This must be explained to the child's parents within 12–24 hours after the child's admission to PICU.

- A multidisciplinary meeting (neurologists, primary care physician, PICU nurses, and a social worker assigned to the case) should be held with the family to explain in detail the potential outcomes of prolonged coma.
 - The child may regain much, but not all, of previous neurologic function.
 - The child may experience less severe neurologic sequela.
 - The child may remain in a vegetative state or may experience brain death.
 - Parents need to make informed decisions about aggressive approaches to care.
 - Technology-based ongoing support
 - Long-term mechanical ventilation
 - Tracheostomy
 - Gastrostomy feeds
 - Fundoplication
 - Placement in a long-term or chronic care facility or nursing the child at home
 - Parents may wish to attempt extubation, thinking that if recovery of breathing without mechanical ventilation does not happen, the physician will reintubate.
 - Provides more time to come to a consensus about what to do next
 - If the medical team has established that the most likely outcome is severe encephalopathy or a persistent vegetative state, the parents may request extubation and natural death.
 - A do-not-resuscitate order on record ensures that no further heroic efforts will be undertaken to save the child.
- A fence should be erected to separate house from pool.
 - The fence should be ≥ 4 feet high around all 4 sides of the pool.
 - The fence should completely separate pool from the house and play area of the yard.
 - Gates should auto-close and auto-latch, with latches higher than children's reach.
 - Parents should consider a safety cover.
 - A power safety cover that meets the standards of the American Society for Testing and Materials adds to the protection of children but should not be used in place of a fence between house and pool.
 - Even fencing and a power safety cover will not prevent all drownings.
 - Keep rescue equipment (eg, a shepherd's hook, life preserver) and a telephone by the pool.
 - Remove all toys from the pool after use so children are not tempted to reach for them.
 - After children are done swimming, the pool should be secured so they cannot get back into it.
 - Do not let children use air-filled swimming aids.
 - They are not a substitute for approved life vests.
 - They can be dangerous.
 - Know CPR.
 - Anyone watching young children around a pool should learn CPR and be able to rescue a child if needed.
 - Parents should stay within an arm's length of child.
 - Teaching a child how to swim does not mean that he/she is safe in water.

PREVENTION

- Primary care physicians need to educate families during routine office visits about pool safety.
- Swimming pools
 - Should not be built until children in the household are >5 years
 - Parents should never leave children alone in or near the pool, even for a moment.

Drug Eruptions

DEFINITION

- Systemically administered drugs can cause almost any kind of rash.
- The types of skin reactions caused by drugs include:
 - Most common
 - Morbilliform (measles-like) eruptions
 - Urticaria
 - Erythema multiforme (EM)
 - An acute, self-limited eruption of symmetrical erythematous macules and papules that can evolve into target lesions
 - Best viewed as a separate entity from Stevens-Johnson syndrome (SJS) and toxic epidermal necrosis (TEN)
 - Most severe
 - SJS
 - The major form of EM
 - SJS and TEN, also known as *Lyell syndrome*, are 2 ends of a more severe process involving the acute onset of mucocutaneous necrosis.
 - SJS produces more focal skin necrosis than TEN, with ≥ 2 mucosal sites involved.
 - TEN
 - Extensive areas of epidermal necrosis and resulting denudation
 - Other
 - Erythema nodosum
 - Vasculitis
 - Photosensitivity reactions
 - Acneform eruptions
 - Alopecia
 - Blistering disorders
 - Fixed drug eruptions
 - Lichenoid reactions
- Drug rash with eosinophilia and systemic symptoms (DRESS), formerly known as *drug hypersensitivity syndrome*
 - Characterized by the clinical triad of fever, rash, and internal organ involvement (most commonly hepatitis, nephritis, pneumonitis, or myocarditis)

EPIDEMIOLOGY

- DRESS
 - The incidence of DRESS with anticonvulsants has been estimated at 1 in 10,000 exposures.

ETIOLOGY

Morbilliform eruptions

- Caused by a wide variety of agents, most commonly among recipients of:

- Aminopenicillins
 - 4.4–8.0 per 100
- Sulfonamides
 - 2.5–3.7 per 100
- Ampicillin
 - 3.3 per 100
- Semisynthetic penicillins
 - 2.9 per 100
- Blood
 - 2.2 per 100
- Cephalosporins
 - 2.1 per 100
- Erythromycin
 - 2.0 per 100
- Penicillin G
 - 1.6 per 100
- Allopurinol
 - 0.8 per 100
- Nonsteroidal antiinflammatory drugs (NSAIDs)
 - 0.3–0.69 per 100
- Barbiturates
 - 0.4 per 100
- Diazepam
 - 0.04 per 100

Urticaria

- Drug-induced hives can be mediated immunologically by either:
 - Immediate immunoglobulin (Ig) E reactions, usually within hours
 - More common than delayed reactions
 - Delayed immune complexes that result in serum sickness-like reactions after 7–10 days
- A precise cause is not usually found among patients with hives.

DRESS

- Associated with the use of:
 - Aromatic anticonvulsants (phenytoin, carbamazepine, phenobarbitone)
 - Sulfonamides
 - NSAIDs
 - Ranitidine
 - Calcium-channel blockers
 - Allopurinol
 - Thalidomide
- Cross-reactivity with structurally related drugs is common.

EM

- Most often occurs in association with recurrent herpes simplex virus (HSV) types I and II
 - ~50% of patients had an HSV lesion a few days to 2 weeks before EM
 - In the rest a cause generally cannot be identified.
- Circulating immune complexes have been detected in patients who have EM, consistent with the concept that the disorder is an immunologic reaction
- Other infectious agents that have been rarely implicated in EM include *Histoplasma capsulatum* virus, and possibly Epstein-Barr virus.

SJS and TEN

- Medications are the most common cause.
- Antibiotics (especially sulfonamides), anticonvulsants, and NSAIDs have been most commonly implicated.
- Infections, particularly with *Mycoplasma pneumoniae*, have also been implicated in SJS.

RISK FACTORS

- DRESS
 - First-degree relatives with this syndrome

SIGNS AND SYMPTOMS**Morbilliform eruptions**

- Onset is not usually immediate but begins within several days to 1 week after drug initiation.
- Itching is usually present, but it is not helpful as a diagnostic marker.
- Eruption is generalized and consists of brightly erythematous macules and papules that tend to be confluent over large areas.
- It usually starts proximally and proceeds distally.
 - Legs are typically the last to be involved and the last to clear.
 - Palms and soles are affected.
- Most drug eruptions are not accompanied by an elevation in body temperature.

Urticaria

- Hives appear as edematous plaques.
 - Often have pale or dusky centers and red borders
 - Frequently assume geographic shapes
 - Sometimes confluent
 - May be scattered, but are usually generalized
- By definition, an individual hive is transient, lasting <48 hours, although new hives may develop continuously.
- Itching is almost always present.
- Obstructed airway or urticaria with significant edema suggests anaphylaxis.

- Fever, lymphadenopathy, and arthralgia often accompany hives in serum sickness reactions, for which the 2 most common causes are:
 - Drugs, especially antibiotics
 - Viral hepatitis
- Hives are skin lesions that are recognized more easily than described.

DRESS

- Occurs within 8 weeks of initiating medication use
- Clinical manifestations include:
 - Fever early in the course
 - Diffuse macules
 - Papules or pustules that can progress to an exfoliative dermatitis mimicking SJS or TEN
 - Eosinophilia
 - Atypical lymphocytosis
- The severity of skin involvement does not correlate with the extent of internal organ involvement.

EM

- HSV lesions a few days to 2 weeks earlier
 - Occasionally preceded by a febrile prodrome
 - Characterized by a variety of lesions, including:
 - Erythematous plaques
 - Blisters
 - Targetoid lesions, sometimes confused with hives
 - Hives have only 2 zones of color: a central pale area surrounded by an erythematous halo.
 - The target lesion requires 3 zones: a central dark area or blister, surrounded by a pale zone, surrounded by a peripheral rim of erythema.
 - True target lesions are diagnostic for EM.
 - Seen more often on the palms and soles but may occur anywhere
 - Typically, EM is a strikingly symmetrical eruption, most frequently seen on the dorsal hands and forearms and often involving palms, neck, face, and trunk.
 - Lesions can be quite numerous, often exceeding 100.
 - Lesions may appear grouped on the elbows or knees.
 - Koebner phenomenon can be observed: after cutaneous trauma, target lesions may appear in the affected areas.
 - Mild, discrete oral erosions occur in more than half of patients but are usually few in number and can be relatively asymptomatic.
- SJS and TEN**
- SJS and TEN are usually preceded by a prodrome of up to 2 weeks of influenza-like symptoms followed by the abrupt onset of skin eruption.

- When these conditions are drug related, eruption typically begins 7–21 days after initiation of the causative drug.
- Eruption is initially macular or morbilliform, tender, dusky, and erythematous and widespread in distribution.
- Skin strips off easily with minor friction (positive Nikolsky sign).
- Lesions gradually coalesce, and flaccid bullae develop.
- Bullae easily rupture and detach, leaving necrotic sheets of epidermis with a moist, bright red base.
- Similar lesions are also typically seen on mucous membranes, usually involving >2 mucosal sites.
- Thick, hemorrhagic crusts may appear on the lips.
- When up to 10% of the body surface area is involved, the eruption is termed *SJS*.
- When >30% is involved, it is termed *TEN*.
- When 10–30% is involved, the eruption is termed *SJS-TEN* overlap.
- Constitutional symptoms occur.
 - Fever
 - Arthralgia
 - Malaise
 - Lymphadenopathy
 - Occasional symptoms of an upper respiratory infection
 - Rarely, hepatitis, nephritis, and myocarditis

DIFFERENTIAL DIAGNOSIS

- A general principle of dermatologic diagnosis is: For any rash, think of drugs.

Morbilliform eruptions

- Patients receiving >1 drug present a problem.
- The 2 variables to consider are:
 - The temporal relationship between the administration of the drug and the onset of the rash
 - The likelihood that a given medication can cause a drug eruption (see Etiology)
- Morbilliform eruptions have been reported in patients with Epstein-Barr virus infection taking amoxicillin; their pathogenesis remains to be elucidated.
- Major differential diagnosis for morbilliform eruption
 - Drug reaction
 - May be more erythematous and confluent, but not always
 - Presence of eosinophilia favors a drug-related cause.
 - Viral exanthem
 - Clinically indistinguishable from a drug eruption
 - Toxic erythema, eg, scarlet fever, staphylococcal-induced scarlatiniform eruptions, Kawasaki disease (possibly)

- Distinguishing features
 - Sandpaper-like roughened texture of the rash and mucous membrane involvement (scarlet fever and Kawasaki disease)
 - Fever
 - Focus of infection
 - Lymphadenopathy
- Postinflammatory desquamation from the skin of the hands and feet often follows the rash of toxic erythema, but this sign is not specific.
 - Drug eruptions and viral exanthems can involve hands and feet, particularly palms and soles in drug eruptions.

Urticaria

- Differential diagnosis of urticaria may be approached in 2 ways.
 - From the causes of hives per se
 - Usually the cause of hives cannot be determined; when found, it is usually drug-related.
 - Other causes include infection, physical stressors (eg, cold, pressure, sunlight), emotions, and foods.
 - From consideration of the cause of lesions sometimes mistaken as hives
 - Includes those seen in EM and juvenile idiopathic arthritis
 - In juvenile idiopathic arthritis, lesions are transient but differ in:
 - Size (only 2–3 mm)
 - Color (typically salmon)
 - Timing (usually appear with fever spikes)

EM

- Skin reactions most commonly considered in the differential diagnosis are:
 - Giant urticaria
 - Individual hives last <48 hours; the lesions in EM persist much longer.
 - Subacute cutaneous lupus erythematosus
 - Viral exanthems
 - Usually monomorphic and tend to be less red, more confluent, and more centrally distributed than EM
 - Vasculitis
 - Purpura is the distinguishing feature of vasculitic lesions.
 - Staphylococcal scalded-skin syndrome (SSSS)
 - Other blistering eruptions
- Recurrent EM caused by HSV can be mistaken for photosensitive disorders because it can be triggered by significant sun exposure.
 - Polymorphous light eruption
 - Juvenile spring eruption

SJS and TEN

- The skin in SSSS is diffusely red and tender and exhibits a Nikolsky sign.

DIAGNOSTIC APPROACH

- Morbilliform eruptions
 - Presumptive diagnosis is made based on clinical data.
- Urticaria
 - Drug history is the most important but also the most difficult to obtain, at least among outpatients.
 - Whenever a drug is suspected, persist in eliciting a medication history to be sure no drugs are invariably overlooked.
 - Many patients and their parents consider over-the-counter medications unimportant.
 - Ask about specific medications to help jog their memories.
 - NSAIDs cause hives in some and can aggravate them in others who have urticaria, regardless of its cause.
 - Aspirin can cause hives but is not widely used in children because of the risk of Reye syndrome.
- SJS and TEN
 - History of all medications should be elicited.

LABORATORY FINDINGS**Morbilliform eruptions**

- No laboratory test can identify the responsible drug and are not usually helpful.
- Peripheral blood eosinophilia is sometimes present and may heighten the suspicion for a drug reaction.

Urticaria

- May be accompanied by eosinophilia
- In afebrile patients, laboratory tests are rarely helpful in eliciting a cause and are of no help in implicating a specific drug.
- To evaluate for hepatitis, obtain liver function tests in patients who have hives and fever.

DRESS

- Abnormal liver function test results

EM

- Laboratory evaluation usually is not helpful, although leukocytosis can be seen.
- For herpes simplex disease, if vesicular lesion is still present:
 - Base can be scraped for HSV direct fluorescent antibody.
 - Fluid can be cultured for HSV or examined for multinucleated giant cells (Tzanck preparation).

SJS and TEN

- *M pneumoniae* infection can be confirmed further by:
 - Cold agglutinin
 - IgM antibodies to *Mycoplasma*

- Complete blood count may show leukocytosis.
- Urinalysis may show hematuria or proteinuria.

IMAGING

- SJS and TEN
 - Chest radiography is appropriate to screen for pulmonary involvement, including that caused by *M pneumoniae*.

DIAGNOSTIC PROCEDURES

- EM
 - When the diagnosis is in doubt, skin biopsy can exclude conditions that mimic EM.
 - Lupus erythematosus
 - Vasculitis
- SJS and TEN
 - Skin biopsy helps distinguish SSSS from SJS.
 - Histologically, the level of the blister is intraepidermal in SSSS.
 - In SJS and TEN, the blister is subepidermal.

TREATMENT APPROACH**Morbilliform eruptions**

- When an offending agent is identified, its use should be discontinued.
- If a patient is taking several drugs and causative agent cannot be identified:
 - The number of drugs administered should be reduced to an absolute minimum.
 - Whenever possible, any remaining possible offending agents should be changed to alternative agents.
- Drug eruption may clear even when use of the offending agent is continued; however, continued use of the drug is unwise if an alternative is available.

Urticaria

- Use of any suspected medication should be discontinued.

DRESS

- Immediate withdrawal of all suspected medications
- Supportive care of symptoms

EM

- No convincing evidence has been found that medical therapy favorably alters the course of EM.
- Treating a precipitating infection seems appropriate, even though no proof exists that it alters the course of the skin reaction.

SJS and TEN

- Use of any drug suspected of causing the reaction should be discontinued.
- Underlying infection should be treated.

- Supportive measures are vitally important.
 - Restore and maintain fluid and electrolyte balance.
 - Prevent secondary infection.
 - Relieve pain.

SPECIFIC TREATMENTS

Morbilliform eruptions

- Therapy is directed toward symptoms.
- Antihistamines are used most commonly for the pruritus.
- Topical agents are usually confined to moisturizers, which are most helpful during the desquamative phase of the reaction.
- Although topical steroids may be of some value in controlling pruritus, systemic steroids are rarely required.

Urticaria

- Symptoms are usually treated with antihistamines given on a regular, rather than an as-needed schedule.
 - Hydroxyzine is the preferred agent; give every 6 or 8 hours.

DRESS

- Systemic corticosteroids are generally used in more severe cases involving significant exfoliative dermatitis, pneumonitis, or hepatitis.

EM

- Acyclovir begun after the onset of EM has not proven to be effective.
- Treatment of symptoms also can be helpful.
 - Antihistamines may reduce the sensation of stinging and burning.
 - Antacid suspensions applied topically may alleviate oral ulcers.
- Children with frequently recurring EM caused by HSV may be good candidates for prophylactic acyclovir for 6–12 months.
- Systemic prednisone is sometimes used early in the course of patients who have severe EM.

SJS and TEN

- Erythromycin is recommended for *M pneumoniae* infections, although treatment may not alter the course of the skin disease.
- Supportive care
 - Patients with severe oral involvement may be unable to eat and drink.
 - When skin involvement is extensive, transcutaneous fluid loss increases and replacement volumes must be adjusted accordingly.
 - Fluid replacement poses a unique challenge for patients with SJS and TEN.
 - Surface area in patients with SJS and TEN may change, thus altering their fluid requirements.

- Fluid intake may need frequent adjustment to maintain constant urine output while avoiding fluid overload, which can lead to pulmonary edema, acute respiratory distress syndrome, and death.
- Some experts recommend inserting a nasogastric tube on admission to maximize oral intake and decrease the need for intravenous fluids or parenteral nutrition, thus decreasing risk of fluid overload if the course becomes complicated.
- Parenteral nutrition requires a central venous line, with attendant risks of sepsis and other line-associated complications.
- Local therapy with antiseptics and dressings may help prevent secondary infection.
 - Patients who have severe involvement may require treatments similar to those for burn patients.
 - Silver nitrate-impregnated dressings have been shown to be particularly helpful without causing further epidermal detachment on removal.
- Systemic analgesics are used for pain.
- Topical anesthetics may be used intraorally to provide temporary relief for patients who have painful mouth lesions.
 - “Magic swizzle,” containing 1 part each of diphenhydramine hydrochloride elixir, aluminum and magnesium hydroxide (Maalox), and viscous lidocaine 2%, is one agent.
 - Be aware of the potential for systemic effects from lidocaine when ordering this agent for young children.
- Use of systemic steroids is controversial.
 - They have been used frequently in SJS and TEN, but with mixed success.
 - One retrospective study found that children treated for SJS with systemic steroids required a longer hospital stay and had more complications (eg, infection, gastrointestinal bleeding) than untreated patients.
- Intravenous immunoglobulin may hasten the course of this disorder by blocking apoptosis of epidermal cells.
 - However, published reports have been mixed.
 - Well-controlled, prospective, multicenter studies are needed to confirm efficacy and safety and to determine optimal dosing guidelines.

WHEN TO ADMIT

- Admit patients with SJS and TEN.

WHEN TO REFER

- Recurrent EM
- Drug hypersensitivity reactions with multiorgan involvement
- Early diagnosis and management of SJS and TEN with referral to a tertiary-care center may:
 - Lessen morbidity and mortality
 - Improve the outcome

FOLLOW-UP**■ SJS and TEN**

- Early ophthalmic evaluation is warranted because of mucous membrane involvement.

COMPLICATIONS**Morbilliform eruptions**

- The complications of skin rashes are primarily cutaneous.
- When large areas of skin are inflamed, body heat increases and water is lost.
 - These changes might be a problem for patients who are seriously ill.
- Continuing use of an offending agent in the setting of a drug eruption can result in 2 types of consequences.
 - Cutaneous
 - Possible progressive worsening of the rash may result (rarely) in SJS or TEN.
 - Renal
 - Allergic interstitial nephritis is an uncommon development usually associated with penicillins and cephalosporins and only rarely with other drugs.

Urticaria

- In rare cases, can be accompanied by anaphylactic reactions

SJS and TEN

- Oral mucous membrane involvement can produce painful erosions, restricting intake and resulting in dehydration.
- Similar lesions in genital mucous membranes can cause dysuria and urinary retention.
- Internal organs are affected less often.
 - TEN can affect the respiratory system and may lead to:
 - Patchy pulmonary disease
 - Bronchiolitis obliterans
 - Respiratory failure
 - TEN can affect the gastrointestinal tract.
 - Esophageal involvement can lead to dysphasia, malnutrition, and strictures.
 - Involvement of the small intestine can lead to abdominal pain and diarrhea.
- Conjunctivitis can produce residual ophthalmic complications, including
 - Keratitis sicca
 - Corneal ulceration or scarring
 - Permanent visual impairment
 - Blindness

PROGNOSIS**Morbilliform eruptions**

- Eruptions gradually clear after the use of responsible agent is discontinued, usually 1–2 weeks.
- Eruption may worsen for several days after use of the offending drug has been stopped.

Urticaria

- Drug-induced hives usually clear within several days after use of the responsible medication is discontinued.

EM

- Patients with mild forms of EM usually recover uneventfully within 2–3 weeks.
- EM recurs in 10–20% of patients and is particularly common in patients with milder disease that is precipitated by recurrent HSV infection.

SJS and TEN

- Disease can last as long as 4–6 weeks in patients with severe involvement.
- Patients with these disorders may die because of extensive loss of skin integrity or complications from involvement of other organ systems.
 - Mortality rates of up to 30% have been reported.
 - A severity-of-illness score for TEN predicts a patient's risk of death according to the presence or absence of 7 risk factors
 - Age >40 years
 - Presence of cancer
 - Heart rate >120 beats/min
 - Extent of skin involvement >10% on admission
 - Blood urea nitrogen level >28 mg/dL
 - Serum glucose level >252 mg/dL
 - Serum bicarbonate level <20 mM

PREVENTION**Morbilliform eruption**

- If a responsible drug has been identified:
 - The patient should be advised about the allergy.
 - The medical record should be clearly labeled, even though not all of these reactions reflect true allergy.

Urticaria

- If a specific agent has been identified, the patient must be alerted to avoid that drug in the future.
- Most hives are IgE mediated and a repeat challenge with the responsible drug is more likely to result in an anaphylactic response than it would following a morbilliform eruption.

Drug Overdose

DEFINITION

- Drug overdose occurs when a child ingests or is given an amount of a substance that exceeds the recommended dose.

EPIDEMIOLOGY

- Prevalence
 - In 2004, the American Association of Poison Control Centers tabulated 2,473,570 case reports of human exposure to potentially toxic substances among the 292.2 million people they serve.
 - 51.6% were <6 years.
 - 39.1% were ≤2 years.
- Incidence
 - Annually, 1.4 million children ≤12 years are exposed to drugs that are potentially toxic.
 - In 2002, these exposures resulted in 29 deaths.
- Toxic exposure, by patient age
 - Pharmaceutical agents
 - <6 years: 504,725
 - 6–9 years: 168,053
 - Nonpharmaceutical agents (chemicals, plants, gases)
 - <6 years: 725,941
 - 6–19 years: 188,002
- Deaths, by patient age
 - <6 years: 25
 - Reflects unintentional ingestions
 - 6–12 years: 4
 - 13–19 years: 48
 - Reflects suicidal events

ETIOLOGY

- Most drug overdoses do not affect the upper airway (larynx, trachea) but interfere with air exchange by either depressing the central nervous system or paralyzing neuromuscular transmission.

RISK FACTORS

- The most common drug overdoses causing death are analgesics, antidepressants, and over-the-counter cough and cold preparations.
- For some compounds, therapeutic mistakes may play a significant role.
 - Many acetaminophen poisonings are caused by errors in 1 of the following:
 - Inappropriate dosing
 - Unintentional multiple overdosing
 - Ingestion of acetaminophen along with another hepatotoxic drug

- Administration of adult rather than pediatric preparations
- Concurrent administration of an over-the-counter fixed-dose combination product that also contains acetaminophen
- Supervision of medication administration by another child

SIGNS AND SYMPTOMS

- Vomiting
- Altered mental status (lethargic or aggressive)
- Pale looking or cyanotic
- Suppressed or labored breathing
- Sometimes, hypotension
- Constricted (opiates, phenothiazines) or dilated (anticholinergics, amphetamines) pupils

DIFFERENTIAL DIAGNOSIS

- Other conditions can mimic signs and symptoms of drug overdose.
- Head trauma is a consideration in patients who have alterations in sensorium.
 - Adolescents who have head trauma may have ingested ethanol.
 - Head injury with drug overdose in a child may indicate child abuse.
- Near-drowning victims may have ingested ethanol.
- Use of illicit drugs can alter mental status and should be considered.
- General urine toxicologic screens ordered in an emergency department will test for:
 - Tetrahydrocannabinol (marijuana)
 - Cocaine
 - Opioids
 - Benzodiazepines
 - Barbiturates
 - Phencyclidine
- Spontaneous intracranial hemorrhages in pediatric patients are rare.
 - Usually produce focal neurologic signs rather than global depression of consciousness
- Metabolic conditions, such as:
 - Diabetes mellitus
 - Hypoglycemia
 - Addisonian crisis
- Infections of the central nervous system, particularly viral encephalitis

- Most difficult is the patient who has a psychiatric illness and who may develop tremors, hallucinations, or hysterical paralysis.
 - Precise and rapid laboratory analyses are most important in ruling out drug ingestion.
 - If the patient is having a reaction to prescribed psychoactive medications, management is identical to that for overdose, with special attention to child's emotional needs.

DIAGNOSTIC APPROACH

- As much information as possible should be gathered immediately.
- The person or persons who brought the child to the hospital or office should be detained.
- If initial contact is by telephone:
 - The caller's name and telephone number should be obtained.
 - The caller should be instructed to proceed immediately with the child to the hospital.
- Obtaining the precise description of the ingested drug is important, including, if known:
 - Name
 - Dose
 - Pharmacy of origin
 - Prescription number
 - Parents should be instructed to bring the actual container when they come with the patient.
- An attempt should be made to determine the amount of drug ingested.
 - Determination is frequently impossible; if obtained, it is occasionally misleading.
 - Maximal exposure is assumed unless a precise tablet count or liquid amount is available.
- As always with an acute, life-threatening event, the patient's airway, breathing, and circulation should be promptly assessed.
- General homeostatic support
 - Thermal monitoring is an important aspect of management in drug overdose.
 - Centrally and peripherally induced hypothermia is a common problem.
 - Hyperthermia can occur with salicylate, atropine, or selective serotonin reuptake inhibitor poisoning.
 - Monitoring fluid and electrolyte homeostasis is important.
 - Amount of maintenance fluids required depends on changes in the vital and physical signs.
 - Central venous pressure and arterial pressure should be monitored to assess vascular volume and tone.
 - Respiratory function and oxygenation (with pulse oximetry) require monitoring.

- Intracranial pressure may need to be assessed to determine the need to treat cerebral edema.
- The need for peritoneal dialysis, hemodialysis, charcoal perfusion, or exchange transfusion to remove the ingested drug must be considered.

LABORATORY FINDINGS

- Assays must be available for:
 - Blood
 - Urine
 - Gastric contents for:
 - Barbiturates
 - Antidepressants
 - Phenytoin
 - Iron
 - Digoxin
 - Salicylate
 - Acetaminophen
 - Narcotics
 - Alcohol
 - Cocaine
 - Propoxyphene
- Rapid drug screens should be available and quantitative analyses should follow as quickly as possible.

IMAGING

- Flat-plate radiographic examination of the abdomen may be required to identify radiopaque tablets (eg, iron) or foreign bodies.
- Computed tomography of the head should be performed if intracranial hemorrhage is suspected after amphetamine or cocaine ingestion.
- Chest radiography is needed if narcotic-induced pulmonary edema or aspiration is suspected.

TREATMENT APPROACH

- Major considerations are:
 - Expertise of the physician in the management of drug overdose
 - Available hospital support facilities
 - It is best to decide early in the clinical course whether special facilities will be needed.
 - It is preferable to transfer a stable patient earlier than a critically ill child requiring mobile life support later.
- Frequent and open communication with the patient's family should be maintained.
 - Parents are in constant need of counseling, especially with regard to any feelings of guilt they may be experiencing.

- Adolescents with intentional drug overdoses often have complex psychosocial problems that typically require psychiatric consultation.
- Steps to treat the patient with a drug overdose
 - Stabilize the patient.
 - Identify the drug ingested and determine the amount ingested.
 - Contact the local poison control center for toxicology data and information regarding the signs and symptoms and clinical course.
 - The toll-free telephone for poison control centers in the US is 800/222-1222.
 - Use gastrointestinal decontamination (see Specific Treatments).
 - If a specific antidote exists, administer it.
 - All staff members must know the precise location of antidotes within the hospital.
 - Provide supportive care in an intensive or intermediate care unit as appropriate.
 - Meet social service needs as indicated (eg, drug ingestion by a toddler as a symptom of chaotic family structure or by an adolescent as a symptom of depression or as a suicidal gesture).
 - Provide counseling concerning the institution of poison-control measures in the home.

SPECIFIC TREATMENTS

Gastric decontamination

- Gastric decontamination procedures have undergone recent changes in recommendations.
- Before 2003, the AAP recommended that ipecac syrup be kept in the home to administer to children on the direction of a physician or poison control center.
 - This policy has been reversed because research has shown that ipecac:
 - Does not completely remove an ingested substance from the stomach
 - Has side effects of its own (including lethargy)
 - May be given inappropriately by caregivers
 - Does not improve health outcomes or reduce utilization of emergency services
- Gastric lavage may still be used on occasion in an emergency setting for patients who have ingested a near-lethal or lethal amount of a toxic agent within the prior 1–2 hours.
- Activated charcoal is now considered the best method of gastrointestinal decontamination.
- Gastrointestinal fluid obtained by any decontamination method should be saved for drug analysis.

- Activated charcoal
 - Dose: 1 g/kg, usually administered via nasogastric tube
 - Use of a cathartic remains controversial, with no firm evidence supporting this measure.
 - Among the few compounds that appear not to be adsorbed by the charcoal are acids, alkalis, and iron salts.
- For substances that are poorly adsorbed by charcoal, whole-bowel irrigation (with a polyethylene glycol–electrolyte solution [Colyte or Golytely])
 - Dose: 25 to 40 mL/kg/hour
 - May be especially helpful in treating for overdoses of increasing numbers of delayed-release drugs

Antidotes

- Specific antidotes exist for some drugs but, unfortunately, not for most (see table Common Antidotes).
- For those without antidotes
 - Intensive supportive care
 - Treatment of signs and symptoms as they develop (eg, hypotension and hypertension, thermal instability, cardiac arrhythmias)
- Acetaminophen
 - Diagnostic findings requiring treatment: history of ingestion and toxic serum level
 - Antidote: N-acetylcysteine
 - Dosage: 140 mg/kg PO, then 70 mg/kg every 4 hr PO \times 17
- Anticholinergics, antihistamines, atropine, phenothiazines, tricyclic antidepressants
 - Diagnostic findings requiring treatment: supraventricular tachycardia (hemodynamic compromise); unresponsive ventricular dysrhythmia, seizures, pronounced hallucinations or agitation
 - Antidote: physostigmine
 - Dosage: in children, 0.5 mg IV slowly (over 3 minutes) every 10 minutes as needed
- Benzodiazepines
 - Diagnostic findings requiring treatment: drowsiness, ataxia, hallucinations, confusion, agitation, respiratory depression, hypotension
 - Antidote: flumazenil
 - Dosage: 0.01 mg/kg IV every min \times 1–5 doses; maximum, 0.2 mg/dose
- Cholinergics
 - Diagnostic findings requiring treatment: cholinergic crisis—salivation, lacrimation, urination, defecation, convulsions, fasciculations
 - Antidote: atropine sulfate, physostigmine, insecticides
 - Dosage: 0.05 mg/kg/dose (usual dose 1–5 mg; test dose for child 0.01 mg/kg) every 4–6 hr IV or more frequently as needed

Common Antidotes^a

Drug	Diagnostic Findings Requiring Treatment	Antidote	Dosage
Acetaminophen	History of ingestion and toxic serum level	N-acetylcysteine	140 mg/kg/dose PO, then 70 mg/kg/dose every 4 hr PO × 17
<ul style="list-style-type: none"> • Anticholinergics • Antihistamines • Atropine • Phenothiazines • Tricyclic antidepressants 	<ul style="list-style-type: none"> – Supraventricular tachycardia (hemodynamic compromise) – Unresponsive ventricular dysrhythmia, seizures, pronounced hallucinations or agitation 	Physostigmine	Child: 0.5 mg IV slowly (over 3 min) every 10 min as needed
Benzodiazepines	Drowsiness, ataxia, hallucinations, confusion, agitation, respiratory depression, hypotension	Flumazenil	0.01 mg/kg IV every min × 1–5 doses; max 0.2 mg/dose
Cholinergics	Cholinergic crisis: salivation, lacrimation, urination, defecation, convulsions, fasciculations	<ul style="list-style-type: none"> – Atropine sulfate – Physostigmine – Insecticides 	0.05 mg/kg/dose (usual dose 1–5 mg; test dose for child 0.01 mg/kg) every 4–6 hr IV or more frequently as needed
Carbon monoxide	Headache, seizure, coma, dysrhythmias	Oxygen, hyperbaric oxygen	100% oxygen (half-life 40 min); consider hyperbaric chamber
Cyanide	Cyanosis, seizures, cardiopulmonary arrest, coma	Amyl nitrite	Inhale pearl every 60–120 sec
		Sodium nitrite (3%)	0.27 mL (8.7 mg)/kg (adult: 10 mL [300 mg]) IV slowly (Hb ≥10 g/dL)
		Sodium thiosulfate (25%)	1.35 mL (325 mg)/kg (adult: 12.5 g) IV slowly (Hb ≥10g/dL)
		Also consider hyperbaric chamber	
Ethylene glycol	Metabolic acidosis, urine calcium oxalate crystals	Fomepizole	15 mg/kg IV over 30 min
		Ethanol (100% absolute, 1 mL–790 mg)	1 mL/kg in 5% dextrose in water IV over 15 min, then 0.16 mL (125 mg)/kg/hr IV; maintain ethanol level of 100 mg/dL
Iron	Hypotension, shock, coma, serum iron >350 mg/dL (or greater than iron-binding capacity)	Deferoxamine	<ul style="list-style-type: none"> • Shock or coma: 15 mg/kg/hr IV for 8 hr • No shock or coma: 90 mg/kg/dose IM every 8 hr
<ul style="list-style-type: none"> • Phenothiazines • Chlorpromazine • Thioridazine 	Extrapyramidal dyskinesia, oculogyric crisis	Diphenhydramine (Benadryl®)	1–2 mg/kg/dose (max: 50 mg/dose) every 6 hr IV, PO
Methanol	Metabolic acidosis, blurred vision; level >20 mg/dL	Fomepizole	15 mg/kg IV over 30 min
		Ethanol (100% absolute)	1 mL/kg in 5% dextrose in water over 15 min, then 0.16 mL (125 mg)/kg/hr IV
<ul style="list-style-type: none"> • Methemoglobin • Nitrate • Nitrites • Sulfonamide 	Cyanosis, methemoglobin level 30%, dyspnea	Methylene blue (1% solution)	1–2 mg (0.1–0.2 mL)/kg/dose IV; repeat in 4 hr if necessary

Common Antidotes^a, continued

Drug	Diagnostic Findings Requiring Treatment	Antidote	Dosage
<ul style="list-style-type: none"> • Narcotics • Heroin • Codeine • Propoxyphene 	Respiratory depression, hypotension, coma	Naloxone (Narcan [®])	0.1 mg/kg up to 0.8 mg initially IV, if no response give 2 mg IV
<ul style="list-style-type: none"> • Organophosphates • Malathion • Parathion 	Cholinergic crisis: salivation, lacrimation, urination, defecation, convulsions, fasciculations	Atropine sulfate	0.05 mg/kg/dose (usual dose 1–5 mg; test dose for child 0.01 mg/kg) every 4–6 hr IV or more frequently as needed
		Pralidoxime	After atropine, 20–50 mg/kg/dose (max: 2000 mg) IV slowly (<50 mg/min) every 8 hr IV as needed × 3

Abbreviations: Hb, hemoglobin; IV, intravenously; PO, orally.

■ Carbon monoxide

- Diagnostic findings requiring treatment: headache, seizure, coma, dysrhythmias
- Antidote: oxygen, hyperbaric oxygen
- Dosage: 100% oxygen (half-life 40 minutes); consider hyperbaric chamber

■ Cyanide

- Diagnostic findings requiring treatment: cyanosis, seizures, cardiopulmonary arrest, coma
- Antidote
 - Amyl nitrite: inhale pearl every 60–120 seconds
 - Sodium nitrite (3%): 0.27 mL (8.7 mg)/kg (adult: 10mL [300 mg]) IV slowly (hemoglobin level ≥ 10 g/dL)
 - Sodium thiosulfate (25%): 1.35 mL (325 mg)/kg (adult: 12.5 g) IV slowly (hemoglobin level ≥ 10 g/dL)
 - Also consider hyperbaric chamber.

■ Ethylene glycol

- Diagnostic findings requiring treatment: metabolic acidosis, urine calcium oxalate crystals
- Antidote
 - Fomepizole: 15 mg/kg IV over 30 minutes
 - Ethanol (100% absolute, 1 mL–790 mg): 1 mL/kg in 5% dextrose in water IV over 15 minutes, then 0.16 mL (125 mg)/kg/hr IV; maintain ethanol level of 100 mg/dL

■ Iron

- Diagnostic findings requiring treatment: hypotension, shock, coma, serum iron level >350 mg/dL (or greater than iron-binding capacity)
- Antidote: deferoxamine
- Dosage
 - Shock or coma: 15 mg/kg/hour IV for 8 hours
 - No shock or coma: 90 mg/kg/dose IM every 8 hours

■ Phenothiazines, chlorpromazine, thioridazine

- Diagnostic findings requiring treatment: extrapyramidal dyskinesia, oculogyric crisis
- Antidote: diphenhydramine (Benadryl)
- Dosage: 1–2 mg/kg (maximum, 50 mg/dose) every 6 hours IV, PO

■ Methanol

- Diagnostic findings requiring treatment: metabolic acidosis, blurred vision; level >20 mg/dL
- Antidote
 - Fomepizole: 15 mg/kg IV over 30 minutes
 - Ethanol (100% absolute): 1 mL/kg in 5% dextrose in water over 15 minutes, then 0.16 mL (125 mg)/kg/hour IV
- Dosage: 1–2 mg/kg/dose (maximum, 50 mg/dose) every 6 hr IV, PO

■ Methemoglobin, nitrate, nitrites, sulfonamide

- Diagnostic findings requiring treatment: cyanosis, methemoglobin level $\geq 30\%$, dyspnea
- Antidote: methylene blue (1% solution)
- Dosage: 1–2 mg/kg/dose (maximum, 50 mg/dose) every 6 hours IV, PO

■ Narcotics: heroin, codeine, propoxyphene

- Diagnostic findings requiring treatment: respiratory depression, hypotension, coma
- Antidote: Naloxone (Narcan)
- Dosage: 0.1 mg/kg up to 0.8 mg initially IV; if no response, give 2 mg IV

■ Organophosphates: malathion, parathion

- Diagnostic findings requiring treatment: cholinergic crisis—salivation, lacrimation, urination, defecation, convulsions, fasciculations

- Antidote
 - Atropine sulfate: 0.05 mg/kg/dose (usual dose, 1–5 mg; test dose for child 0.01 mg/kg) every 4–6 hr IV or more frequently as needed
 - Pralidoxime: after atropine, 20–50 mg/kg/dose (maximum, 2000 mg) IV slowly (< 50 mg/min) every 8 hours IV as needed × 3

WHEN TO ADMIT

- Any patient strongly suspected of ingesting a toxic or lethal dose of any substance
- An unstable patient
- Any patient requiring gastrointestinal decontamination, intravenous therapy, hemoperfusion, or charcoal perfusion, even if clinically well
- A patient in an environment suggesting child abuse

WHEN TO REFER

- Ingestion of any substance unfamiliar to the primary care physician
- Any patient who may require a therapy unfamiliar to the primary care physician

COMPLICATIONS

- Many poisoned patients require ventilator therapy for such complications as:
 - Pneumothorax
 - Oxygen toxicity
 - Airway infections
 - Nosocomial infections, especially hypostatic pneumonia
 - Urinary tract infection (secondary to catheter placement)
 - Septicemia from vascular catheters
 - Thrombotic and embolic episodes (from vascular catheters)

- Permanent central nervous system damage sometimes follows periods of hypoxia or hypoglycemia, usually before therapy is instituted.
- Skin, mucous membrane, and deeper-tissue injuries often result from acids, substances containing lye, or corrosives.
- Specific compounds can cause permanent organ damage.
- Hazards of treatment for drug overdose include:
 - Overtreatment
 - Occurs when errors are made in assessing the amount of drug ingested
 - Wrong treatment
 - A nontoxic ingestion may be inappropriately treated with potentially toxic antidotes.
 - Mistakes may be made in identifying the drug ingested.
 - Insufficient period of observation
 - Failure to appreciate drug ingestion as an indication of child neglect or abuse
 - Should be particularly suspected in a child <12 months admitted with accidental ingestion or the child who has a history of repeated drug ingestions

PROGNOSIS

- Prognosis depends on the drug ingested, early identification, and treatment at facilities equipped with managing toxic ingestions.

PREVENTION

- Preventive measures, such as child-resistant bottle tops, are effective in eliminating acute, single-dose, unintentional exposures.

Dysmenorrhea

DEFINITION

- Dysmenorrhea (painful menstruation) is a syndrome characterized by
 - Varying degrees of crampy, lower abdominal pain
 - Nausea
 - Vomiting
 - Urinary frequency
 - Low back pain
 - Diarrhea
 - Fatigue
 - Thigh pain
 - Nervousness
 - Dizziness
 - Sweating
 - Headache
- Pain typically begins just after menses and lasts approximately 1–2 days.
 - Can also begin 1–2 days before onset of menses and last up to 4 days into menstruation
 - Cramps may be more severe among teenagers who smoke.

EPIDEMIOLOGY

- Prevalence
 - At least 40–60% of adolescent girls suffer some degree of discomfort during menstruation.
 - ~15% report severe symptoms.
 - 14% report frequently missing school as a result of menstrual symptoms.
- Age
 - Incidence increases with gynecologic age (as does the percentage of ovulatory cycles).
 - Up to 31% of girls report dysmenorrhea in their first year of menses vs 78% in their fifth year.

MECHANISM

- Increased amounts of prostaglandins E_2 and $F_{2\alpha}$ in the endometrium lead to:
 - Smooth-muscle contractions
 - Vomiting
 - Diarrhea
- Correlates with the clinical observation that women who have anovulatory cycles usually do not have dysmenorrhea
 - Adolescent girls typically develop dysmenorrhea 1–2 years after menarche, correlating with the onset of ovulatory cycles.
- The increase in prostaglandin synthesis may be related to changes in serum progesterone levels not seen in anovulatory women.

- Women experience dramatic response with use of prostaglandin synthetase inhibitors or oral contraceptive pills (OCPs), which inhibit ovulation.
- Increased levels of prostaglandin activity are associated with increased uterine tone and high-amplitude myometrial contractions that result in reduced uterine blood flow and onset of pain.

HISTORY

- Assessment of a teenager with dysmenorrhea should include:
 - Complete menstrual history
 - Timing of cramps or pain
 - Episodes of missed school or other activities
 - Ability to participate in social events
 - Presence of nausea, vomiting, diarrhea, dizziness, or other symptoms
 - Medications used, including doses
 - Factors that improve or worsen symptoms
 - Family history of dysmenorrhea or endometriosis
- Consider the possibility that the patient has another, unstated purpose in seeking care.
 - Reluctance to attend school
 - History of physical or sexual abuse
 - Significant psychosocial problems
 - Secretly sexually active and seeking to obtain OCPs for the purpose of contraception
- Causes of secondary dysmenorrhea
 - Can usually be excluded by careful history and physical examination
 - Underlying pathologic conditions should be anticipated when:
 - Pain begins after 20 years of age.
 - There is a history of surgery related to the genitourinary or gastrointestinal tract.
 - Pain is dull and constant rather than crampy.

PHYSICAL EXAM

- Physicians differ in their opinions regarding what examination is necessary to evaluate a patient with dysmenorrhea; in general:
 - For a nonsexually active teenager with mild to moderate menstrual cramps relieved by nonsteroidal antiinflammatory drugs (NSAIDs)
 - Only an external genital examination to rule out hymenal abnormalities is indicated.
 - If dysmenorrhea is unresponsive to NSAIDs:
 - Initiate OCPs for a few cycles without first performing a pelvic examination.

- For a sexually active teenager or for one who is having significant pain that is unresponsive to NSAIDs
 - A thorough pelvic examination is necessary.
 - If pelvic examination is not possible, rectoabdominal examination will provide some useful information about the presence of masses or adnexal tenderness.

DIFFERENTIAL DIAGNOSIS

Primary dysmenorrhea

- Most affected teenage girls have primary dysmenorrhea.
 - Not associated with pelvic or other pathologic conditions
- Secondary dysmenorrhea always should be considered when the patient is evaluated.

Secondary dysmenorrhea

- Endometriosis
 - Functional endometrial glands and stroma are located outside the normal anatomic location in the uterus
 - Therapy with NSAIDs and OCPs fails.
 - A family history of endometriosis can often be elicited.
 - Signs and symptoms
 - Pain may be acyclic rather than cyclic.
 - Menstrual bleeding may be irregular.
 - Gastrointestinal symptoms may be present.
 - May be associated with dyspareunia, tenesmus, and rectal pain
 - Most adolescents generally have normal examinations.
 - Endometriosis can be difficult to detect on clinical grounds alone.
 - Some studies of teenagers with chronic pelvic pain show that 25–38% of those undergoing laparoscopy have endometriosis.
 - In other studies, 52–73% of teenagers with chronic pelvic pain have evidence of endometrial implants.
 - May be difficult to manage
 - Increases risk for infertility
- Pelvic inflammatory disease (PID)
 - Can cause dysmenorrhea acutely
 - Women often develop chronic pelvic pain as a consequence.
 - Even with assurances of confidentiality, some young women may still not admit to sexual activity.
 - Clinicians must maintain a high index of suspicion if historical and physical examination findings suggest PID.
 - A pelvic examination that reveals cervical motion tenderness, adnexal tenderness, or masses strongly suggests PID.
 - Should be treated according to standard antibiotic regimens (see Sexually Transmitted Infections)

- Follow-up is critical; once infected, young women are at risk for:
 - Further episodes of PID
 - Chronic pelvic pain
 - Ectopic pregnancy
 - Infertility

■ Outflow tract obstruction

- Teenagers with a history of genital tract surgery, including abortions, may have outflow tract obstruction.
- A variety of müllerian anomalies with incomplete obstruction of the outflow tract also produce dysmenorrhea.
- Depending on the type of obstruction, a pelvic mass may be palpable.
- Outflow obstruction is possible (eg, a uterus with a blind horn) if:
 - The cervical os is stenotic.
 - The cervix or uterus feels atretic or abnormally shaped.

■ Endometrial polyps or fibroids

- Rare in women <20 years
- Should be anticipated if menstrual bleeding is:
 - Heavy
 - Prolonged
 - Associated with the passage of clots
- Unclear whether these entities alone cause dysmenorrhea

LABORATORY EVALUATION

- If sexually active, evaluate for:
 - Sexually transmitted infections
 - Pregnancy

IMAGING

- Pelvic ultrasonography
 - May be useful in defining uterine and vaginal abnormalities associated with obstruction
 - Not helpful in the detection of pelvic or abdominal adhesions or endometriosis

DIAGNOSTIC PROCEDURES

- Confirmation of endometriosis requires laparoscopy.
 - Should be performed by a gynecologist experienced in evaluating adolescents because the lesions of endometriosis in adolescents may differ from the typical lesions seen in adults

TREATMENT APPROACH

- Treatment of primary dysmenorrhea is likely to include drug therapy.
- Valuable opportunity to teach the patient about her body
 - The patient may not understand fully the physiologic mechanisms of menstruation.
 - The patient may have inaccurate beliefs passed on from mother to daughter.

SPECIFIC TREATMENT

Primary dysmenorrhea

- NSAIDs
 - Teenagers who have very mild discomfort benefit from almost any analgesic.
 - Prostaglandin synthetase inhibitors in the form of NSAIDs are the treatment of choice for most young women with dysmenorrhea.
 - Dosage and timing vary from patient to patient.
 - Establishing prior use of specific medications as well as doses is important, given that most patients use them suboptimally.
 - In 1 study, 57% of adolescents used medications less often than the maximal daily frequency.
 - Advising patients of the range of correct doses is important.
 - Most effective if started at the first sign of menstrual bleeding
 - Women who experience significant nausea with menses may benefit from starting treatment at the earliest symptom of menses, even before bleeding occurs.
 - Some need medication only for part or all of the first day of menstruation; others require medication for ≥ 4 days.
 - Ibuprofen (200–800 mg every 6–8 hours) and naproxen sodium (550 mg immediately and then 275 mg every 6–8 hours) are highly effective.
 - Mefenamic acid blocks the effect of prostaglandin at the end-organ level and inhibits its production.
 - Can be used in an initial dose of 500 mg, followed by 250 mg every 6 hours
 - Note that there is a black box warning.
 - Response to different NSAIDs varies.
 - If the patient does not respond to a particular NSAID (eg, ibuprofen), another (eg, naproxen sodium) should be tried
 - Between 70% and 80% of girls will respond to NSAID therapy.
- OCPs
 - OCPs used in the same way as for contraception usually provide relief.
 - OCPs work by suppressing ovulation and decreasing endometrial prostaglandin production.
 - Patients should be told that 2–3 cycles may elapse before maximal effect.
 - If the patient is sexually active, OCPs can be continued on a routine basis.
 - For the nonsexually active teenager, therapy can be reassessed at 6- to 12-month intervals.
 - After 3 cycles, adolescent patients using OCPs with 20 μg of ethinyl estradiol and 100 mg of levonorgestrel experienced significant relief of dysmenorrhea compared with those using placebo.
- Other hormonal contraceptives
 - In a study of adolescent girls using a contraceptive patch, dysmenorrhea:
 - Decreased in 39%
 - Increased in 11%
 - Resulted in no change in 50%
 - Depot medroxyprogesterone acetate (DMPA)
 - Used to prevent ovulation and menstrual flow when OCPs are not tolerated or estrogen is contraindicated
 - Extended oral contraceptive regimen in which OCPs are taken for up to 12 consecutive weeks, followed by 1 hormone-free week
 - DMPA and extended OCP regimens:
 - Decrease dysmenorrhea
 - Decrease the frequency of menses
- Other treatments
 - Some authorities remain skeptical of alternative treatments, and efficacy is unproved.
 - Other experts recommend:
 - Heat
 - Pelvic exercise
 - General exercise
 - Biofeedback
 - Relaxation therapy
 - Massage
 - Vitamin E
 - Various herbal remedies
 - Magnesium has been shown to be beneficial in some studies.
 - Patient should be encouraged to:
 - Exercise
 - Eat a well-balanced diet

- Decrease stress
- Decrease caffeine consumption
- Stop smoking if applicable

WHEN TO REFER

- The clinician feels uncomfortable prescribing OCPs for the treatment of primary dysmenorrhea.
- The patient does not respond to NSAIDs and OCPs.
- The clinical presentation or course suggests that the patient has secondary rather than primary dysmenorrhea.
- The patient is sexually active and the clinician feels uncomfortable performing a pelvic examination.

WHEN TO ADMIT

- With PID, some clinicians recommend hospitalization of adolescents for treatment.
- Others recommend hospitalization under some but not all circumstances (see Sexually Transmitted Infections).

FOLLOW-UP

- Reevaluate after 2–3 menstrual cycles to determine the effectiveness of the treatment.
-

Dysphagia

DEFINITION

- Dysphagia is defined as difficulty with swallowing.
 - Derives from the Greek *dys* (difficulty) and *phagia* (to eat)
 - It is not synonymous with *odynophagia*, which refers to painful swallowing.

EPIDEMIOLOGY

- Prevalence
 - Minor feeding problems are reported in 25–35% of normal young children
 - Major feeding disorders observed in 40–70% of:
 - Infants born prematurely
 - Children with chronic medical problems

MECHANISM

- Normal development of swallowing
 - Sucking reflex
 - Present as early as 18 weeks' gestation
 - Initially disorganized
 - Organized and efficient for feeding by 34–36 weeks' gestation.
 - For the infant born at term, the suck reflex is mature and efficient for liquid feedings.
 - Early infancy
 - Development of a more rapid suck rate and higher suck pressure
 - Tongue movements are differentiated and become more coordinated, preparing the infant for pureed food by 5–6 months of age.
 - Later infancy
 - Sensory experience with food increases.
 - Oral motor skills expand to handle more textured food.
 - Gag reflex decreases to allow swallowing of an increasing amount of food with more texture.
 - By age 2 years
 - Chewing and tongue movements become more proficient.
- Normal phases of swallowing
 - Oral
 - Food is mixed with saliva and chewed if needed.
 - A single bolus of food is collected between the roof of the mouth and tongue.
 - The bolus is propelled to the posterior of the tongue and then to the pharynx.
 - In infants and young children, the suckling swallow allows liquid to fall from mouth into the pharynx.
 - Pharyngeal
 - Reflexive swallow stimulated by the presence of food on the posterior tongue.

- The soft palate rises to keep food out of the nasal passage.
- The larynx moves up and forward, closing the glottis.
- The vocal cords come together.
- The epiglottis closes over the airway.
- Respirations cease.
- Food is propelled further by contraction of the pharyngeal muscles and relaxation of the upper esophageal sphincter.
- Esophageal
 - Esophageal peristalsis moves the food down the esophagus into the stomach through the relaxed lower esophageal sphincter.
 - Lower esophageal sphincter then returns to the closed tonic state to prevent regurgitation of gastric contents.

HISTORY

- Emphasis should be placed on:
 - Birth history
 - Neurodevelopmental history
 - Medical comorbid conditions
 - Detailed feeding history
 - Current diet
 - Texture
 - Route of administration
 - Meal duration
 - Specific food aversions
 - Age at which oral feeding commenced
 - Exposure to taste and textures during sensitive periods
 - Aversive experiences
 - Method of delivering tube feeds
 - Prolonged tube feeding in infancy or childhood can lead to long-term feeding difficulties.
- General symptoms
 - Feeding difficulties
 - Food refusal
 - Failure to thrive
 - Sensation of food stuck in the throat or chest
- Additional symptoms
 - Drooling
 - Difficulty initiating swallowing
 - Change in dietary habits
 - Aversion to certain food textures
 - Unexplained weight loss
 - Change in voice
 - Recurrent coughing
 - Noisy breathing during feeding

■ Symptoms of specific dysphagias

- Oral phase
 - Failure to initiate or maintain sucking
 - Prolonged feeding time
 - Drooling
- Oral hypersensitivity
 - Exaggerated gag reflex
 - Difficulty making the transition to textured foods
 - Sensitivity to touch in and around mouth
- Oral hyposensitivity
 - Retaining food in the mouth
 - Increased drooling
- Pharyngeal phase
 - Coughing
 - Choking
 - Noisy breathing during feeding
 - Nasopharyngeal reflux
- Esophageal phase
 - Spitting up or vomiting
 - Irritability or arching during feeding
 - Preference for liquid food
 - Sensation of food stuck in the throat

PHYSICAL EXAM

- Document any orofacial malformation.
 - Mechanical or obstructive factors generally result in dysphagia for solids.
 - Micrognathia and glossoptosis seen in Pierre Robin sequence may cause feeding difficulty.
 - Cleft lip and palate, including submucous cleft, are important causes of dysphagia.
 - Choanal stenosis may cause difficulty feeding in newborns because of obligate nasal breathing.
- Neurologic examination
 - Assess muscle tone and strength.
 - Evaluate cranial nerve function.
 - Dysphagia for liquids is more pronounced in patients with neurologic disorders.
- Clinical feeding evaluation
 - Performed by an experienced occupational therapist or speech pathologist
 - Includes assessment of:
 - Posture
 - Positioning
 - Oral structure and function
 - Patient motivation
 - Interaction between the infant and feeder

- A variety of foods, positions, and adaptive utensils may be used during the examination.

DIFFERENTIAL DIAGNOSIS

Utility of specific symptoms

- Specific symptoms observed during feeding can help identify the underlying disorder.
 - Gagging, coughing, or emesis
 - Structural or neurologic disorder
 - Repeated swallowing after feeding, fussiness, crying, regurgitation, or nausea
 - Gastroesophageal reflux disease
 - Requires further investigation

Oropharyngeal dysphagia

- Oropharyngeal dysphagia should be considered in young children with:
 - Recurrent aspiration
 - Unexplained respiratory symptoms
 - Coughing
 - Chronic congestion
 - Recurrent choking
 - Acute life-threatening events
 - Recurrent pneumonia
 - Chronic lung disease

Causes of dysphagia

- Prematurity
 - Birth weight <10th percentile for gestational age is a risk factor for dysphagia and feeding difficulties.
- Congenital abnormalities of the nasal and oral cavity
 - Cleft lip or palate
 - Choanal atresia or stenosis
 - Craniofacial anomalies
 - Apert syndrome
 - Crouzon syndrome
 - Möbius sequence
 - Pierre Robin sequence
 - Treacher Collins syndrome
 - Congenital nasal masses
 - Dermoids
 - Encephaloceles
- Congenital anomalies of the larynx, trachea, and esophagus
 - Laryngomalacia
 - Laryngeal clefts
 - Laryngeal stenosis and webs
 - Vocal cord paralysis
 - Tracheoesophageal fistula

- Esophageal atresia
- Esophageal duplication
- Vascular rings
 - Double aortic arch
 - Right aortic arch with left ligamentum from a descending aorta
 - Innominate artery tracheal compression
- Infection
 - Acute pharyngitis or tonsillitis
 - Peritonsillar and retropharyngeal abscesses
 - Epiglottitis
 - Esophagitis (cytomegalovirus, herpesvirus, *Candida albicans*)
- Inflammatory causes
 - Esophagitis secondary to gastroesophageal reflux disease
 - Eosinophilic esophagitis
 - Should be considered in the differential diagnosis of children with unexplained:
 - Oral aversion
 - Feeding difficulties
 - Poor weight gain
- Neurologic or neuromuscular disorders
 - Hypoxic-ischemic encephalopathy
 - Head trauma
 - Cerebral palsy
 - Congenital malformations
 - Arnold-Chiari malformation
 - Absent corpus callosum
 - Degenerative diseases of white and gray matter
 - Brainstem tumors
 - Syringomyelia
 - Infantile spinal muscular atrophy (Werdnig-Hoffmann disease)
 - Diseases of the neuromuscular junction
 - Myasthenia gravis
 - Guillain-Barré syndrome
 - Botulism
 - Muscle disorders
 - Congenital myopathies
 - Mitochondrial diseases
 - Glycogen storage diseases
 - Congenital muscular dystrophy
 - Myotonic dystrophy
- Trauma
 - External trauma
 - Intubation injury
 - Caustic ingestion

- Neoplasms
 - Hemangioma
 - Lymphangioma

- Miscellaneous
 - Foreign body aspiration
 - Achalasia (esophageal motor dysfunction)
 - Epidermolysis bullosa

LABORATORY EVALUATION

- Complete blood count
 - Useful as a screening test for infectious or inflammatory conditions
- Serum protein and albumin
 - Useful for nutritional assessment
- Chromosomal karyotyping, metabolic analysis, specific DNA tests
 - May be required for a specific diagnosis as directed by physical and neurologic examination

IMAGING

- Chest radiography
 - Suspected pneumonia or chronic lung disease
- Magnified airway radiography
 - Infants or children with recurrent stridor or upper airway obstruction
- Computed tomography or magnetic resonance imaging of the brain
 - May be especially helpful in patients with suspected central nervous system injury or structural abnormalities
- Upper gastrointestinal barium study
 - Assess anatomic or structural abnormalities
 - Strictures
 - Fistulae
 - Masses
 - Intestinal rotational anomalies
 - Usually more sensitive than endoscopy in the evaluation of suspected:
 - Achalasia
 - Vascular rings, which appear as a persistent indentation of the esophagus
- Videofluorographic swallowing study (VFSS)
 - Gold standard for assessment of the oral and pharyngeal stages of swallowing
 - Also known as the *modified barium study*
 - Conducted jointly by a radiologist and a speech pathologist or occupational therapist
 - The child drinks or eats foods mixed with barium while radiographic images are observed and recorded.

- Provides evidence of all categories of oropharyngeal swallowing dysfunction:
 - Inability or excessive delay in initiation of pharyngeal swallowing
 - Aspiration of food
 - Nasopharyngeal regurgitation
 - Residue of food in the pharyngeal cavity after swallowing
- Allows for testing of the efficacy of compensatory:
 - Dietary modifications
 - Postures
 - Swallowing maneuvers

DIAGNOSTIC PROCEDURES

■ Fiberoptic endoscopic evaluation of swallowing (FEES)

- Permits observation of the pharyngeal phase of swallowing
 - Laryngeal penetration
 - Aspiration
- A fiberoptic endoscope is introduced into the nose and advanced into the laryngopharyngeal area
 - Swallowing assessment is performed with liquids and a variety of textures, if developmentally appropriate.
 - Typically, dye is added to the food to provide better visualization and to determine residual pooling of food versus saliva.
- Combined with laryngopharyngeal sensory testing:
 - Has shown that patients with a higher laryngopharyngeal sensory threshold are more likely to experience laryngeal penetration and aspiration during a feeding assessment.
 - Ability to initiate airway closure with stimulation demonstrates airway protection.
 - FEES and sensory testing may be particularly valuable for the evaluation of swallowing safety in children who refuse to ingest adequate amounts of barium to perform VFSS.

■ Esophagoroduodenoscopy

- Confirms or establishes diagnosis of dysphagia of esophageal origin
 - When appropriate, used to implement therapy
- Endoscopic and histologic features are required for the diagnosis of eosinophilic esophagitis.
 - Normal appearance of the esophagus during endoscopy does not exclude histopathological esophagitis.
 - Subtle mucosal changes, such as erythema and pallor, may be observed in the absence of esophagitis.
 - During endoscopy, esophageal biopsy should be performed to detect microscopic esophagitis and to exclude causes of esophagitis other than gastroesophageal reflux.

- Particularly useful in evaluating suspected:

- Strictures
- Webs
- Mucosal inflammatory lesions
- Specific infections

■ Esophageal manometry

- Standard test for disorders of esophageal motility
- Especially useful in:
 - Establishing a diagnosis of achalasia
 - Detecting esophageal motor abnormalities associated with autoimmune diseases

■ Esophageal pH probe study

- Valid and reliable measure of acid reflux
 - Establishes the presence of abnormal acid reflux
 - Determines whether a temporal association exists between acid reflux and frequently occurring symptoms
 - Assesses the adequacy of therapy in patients who do not respond to treatment with acid suppression

■ Scintigraphy

- Useful in the evaluation of gastric emptying
- Can demonstrate episodes of aspiration detected during a 1-hour study or on images obtained up to 24 hours after the test feeding is administered
- Its role in diagnosing gastroesophageal reflux disease in infants and children is unclear.

■ Children with suspected neuromuscular disorders may need:

- Electromyography
- Nerve conduction studies
- Muscle biopsy

TREATMENT APPROACH

■ Goals

- Reduce aspiration
- Improve ability to eat and swallow
- Optimize nutritional status

■ Detect and treat:

- Surgically or endoscopically treatable structural abnormalities
- Inflammatory conditions
 - Reflux esophagitis
 - Eosinophilic esophagitis
- Infections
- Underlying systemic conditions

■ Management of associated disorders

- Associated disorders may also need to be specifically managed.

■ Management often involves a multidisciplinary approach.

SPECIFIC TREATMENT

Normalization of posture and tone

- Head and trunk control are crucial to the development of oral motor skills.
 - Children with neurologic abnormalities frequently have poor head control and poor trunk stability.
- As a basis for improved oral motor function, occupational and physical therapy can be used to improve:
 - Head control
 - Neck and trunk tone
 - Posture

Adaptation of food and feeding equipment

- Change the attributes of food and liquids.
 - Bolus volume
 - Consistency
 - Temperature
 - Taste
- Adjustments in feeding schedule
 - May be beneficial for children receiving continuous tube feeds with supplemental food orally
 - The feeds can be changed gradually to bolus feeds to stimulate the child's appetite.
- Rate of feeding
 - Should be paced to allow sufficient time to swallow before giving another bite
- Bottle or utensils
 - May be changed according to the child's needs

Oral motor therapy

- Focuses on improving the oral phase of feeding
- May include stimulation with:
 - Stroking
 - Stretching
 - Brushing
 - Icing
 - Tapping
 - Vibrating areas of the face and mouth

Nutritional support

- The child's nutritional needs must be met for adequate growth.
 - Supplemental feedings through a nasogastric tube or a percutaneous endoscopic gastrostomy may be necessary.
 - The presence of a feeding tube is not a contraindication to therapy.
 - Many children with feeding disorders have neurologic or anatomic abnormalities that cannot be corrected, making oral feeding difficult or unsafe

Synchronized neuromuscular electrical stimulation to cervical swallowing muscles (VitaStim therapy)

- Improves oral intake in adults
- Helps restore normal swallowing mechanism in adults
- Empirical data are lacking to support its use in children.

WHEN TO REFER

- Referral is warranted:
 - When symptoms are persistent
 - When the cause of dysphagia is unclear
 - On evidence of aspiration
- Referral to a pediatric dysphagia center, if available, provides the most complete method to establish a diagnosis and develop a management plan.
 - Members of the team vary from center to center and usually include a:
 - Gastroenterologist
 - Otolaryngologist
 - Physical medicine and rehabilitation specialist
 - Surgeon
 - Occupational therapist
 - Pediatric dietitian

WHEN TO ADMIT

- Severe feeding difficulties
- Malnutrition
- Failure to thrive
- Dehydration
- Aspiration

FOLLOW-UP

- Patients who are undergoing therapy for dysphagia should be monitored closely for appropriate weight gain.

COMPLICATIONS

- Undernutrition
- Failure to thrive

PREVENTION

- Early recognition, diagnosis, and intervention are necessary, especially in children born prematurely, those with anatomic abnormalities, and those with neuromuscular disorders.

Dyspnea

DEFINITION

- Dyspnea is the feeling of not being able to satisfy air hunger.
- It is a symptom and describes the sensation of breathlessness caused by an underlying disorder.

MECHANISM

- Dyspnea is most commonly seen with exercise because of the increased work of breathing necessary to keep up with increased metabolic demands.
- The sensation is probably transmitted from stretch receptors in the chest wall muscles to the central nervous system (CNS).
- The transmission is processed in the CNS, causing the individual to experience the sensation of dyspnea with exercise.
- In normal breathing, respiratory muscles work only during inspiration, and the diaphragm does most of the work.
 - The work of inspiration is the sum of the work necessary to overcome the elastic forces of the lung, the tissue viscosity of the lung and chest wall, and airway resistance.
 - When any of these factors is increased, the work of inspiration must increase.
 - The accessory muscles of inspiration (the sternocleidomastoid, anterior serratus, and external intercostal muscles) are recruited to accomplish this task.
 - Contraction of these muscles causes forceful expansion of the thorax, resulting in an unusually large negative intrathoracic pressure.
 - This negative pressure draws in the soft tissues of the chest wall and creates a classic sign of dyspnea: retractions.
 - Retractions may be seen in the suprasternal, infrasternal, intercostal, subcostal, and supraclavicular areas.
 - Alternatively, the rate of breathing is increased, resulting in the second classic sign of dyspnea: tachypnea.
- Little energy is expended during normal expiration.
 - Relaxation of the diaphragm, elastic recoil of the lungs and chest wall, and compression of the lungs by the intra-abdominal organs force air from the lungs.
 - In obstructive airway disease, the force generated by these processes may not be great enough to effect adequate expiration.
 - In a child with tachypnea, the elastic recoil may not be fast enough to allow adequate exhalation between breaths.
 - In either instance, accessory muscles of expiration are used.
 - Abdominal recti muscles contract and force the abdominal contents against the diaphragm to compress the lungs.
 - Internal intercostal muscles contract to pull the ribs downward and to create a positive intrathoracic pressure to force the air from the lungs.
 - Contractions of these muscles provide the most important expiratory sign of dyspnea.

- Although dyspnea is a respiratory symptom, it may be caused by primary disorders in other body systems.

HISTORY

- Obtain a complete description of the dyspnea.
 - Onset
 - Sudden, suggesting inhaled foreign body or lung collapse
 - Evolving over time, suggesting asthma or diabetic ketoacidosis
 - Duration
 - Frequency of attacks
 - Any identifiable trigger event
- Quantify the severity of the dyspnea.
 - Ask how daily activities are restricted by shortness of breath.
- Ask whether the dyspnea changes according to patient's position.
 - Dyspnea that is worse when the patient lies with the affected side down:
 - Suggests unilateral lung disease
 - Dyspnea that worsens when the patient is recumbent:
 - Suggests left ventricular failure, obstructive airway disease, or muscle weakness
 - Dyspnea in the upright position that is relieved by lying down:
 - Suggests intracardiac, vascular, or parenchymal lung shunts
- Ask about associated symptoms.
 - Cough
 - Wheezing
 - Sputum production
 - Pleuritic pain
- History (patient and family) of:
 - Allergies
 - Respiratory illness
 - Medications
 - Environmental exposure

PHYSICAL EXAM

- A complete physical examination is necessary, with special attention paid to the cardiac and respiratory systems.
- Observe for retractions in the following areas.
 - Suprasternal
 - Infrasternal
 - Intercostal
 - Subcostal
 - Supraclavicular

- Observe for tachypnea.
 - Measure the respiratory rate.
- Observe for nasal flaring and grunting.
- Observe the abdominal and intercostal muscles during expiration.
- Assess the ratio of inspiration to expiration.
 - In normal respiration, they are of equal length.
 - If inspiration and expiration are equally prolonged, a fixed obstruction may be present.
 - If inspiration is longer than expiration, extrathoracic obstruction may be present.
 - Inspiratory stridor is likely to be present in this setting.
 - If expiration is longer than inspiration, intrathoracic obstruction may be present.
 - If the large airways are involved, rhonchi are present.
 - If the small airways are involved, the patient will be wheezing.
- Observe for signs of chronic lung or heart disease.
 - Barrel chest
 - Clubbing
 - Cyanosis
 - Paradoxical pulse
- Palpate the chest.
 - Tactile fremitus can be a sign of pulmonary consolidation or pleural effusion.
- Percuss the chest.
 - Assess for effusions, consolidation, and abnormal diaphragmatic excursion.
- Auscultate the chest.
 - Listen for rales, rhonchi, and wheezing.
 - Assess for changes in whispered pectoriloquy and egophony.

DIFFERENTIAL DIAGNOSIS

Nonrespiratory causes of dyspnea

General

- Dyspnea is a respiratory symptom, but it may be caused by primary disorders in other body systems.
- The child's age is important.
 - Various disorders occur with different frequencies at different ages.

Exercise-induced dyspnea (EID)

- If EID is severe or occurs after only minimal exertion, further evaluation is warranted.
- Asthma is the most common cause.
- Other causes of EID

- Vocal cord dysfunction
- Exercise-induced laryngomalacia
- Exercise-induced hyperventilation
- Skeletal deformities (eg, scoliosis) that restrict the airway

Vascular pulmonary disease

- Characterized by a decrease in the size of the pulmonary vascular bed.
- Usually due to persistent pulmonary hypertension
- Can also be a result of:
 - Thromboembolic disease
 - Obliteration (vasculitis)
 - Destruction (emphysema)
- Cardiac findings in pulmonary edema
 - Accentuated P₂
 - Paradoxical splitting of the 2nd and 3rd heart sound
 - Pulmonary injection click
 - Right ventricular heave

Cardiac disease

- Congenital structural anomalies in the heart
- Pump failure (myocarditis or cardiomyopathy)
- Restrictive pericarditis
- Arrhythmia

Hematologic disease

- Severe anemia
 - Chronic or acute
 - Congenital or acquired
- Tissue hypoxia
- Dyspnea

Metabolic disease

- Disorders that increase the body's rate of metabolism and oxygen consumption (eg, hyperthyroidism or fever) can result in dyspnea.
- Disorders that increase production of hydrogen ion and carbon dioxide (eg, diabetic ketoacidosis or aspirin poisoning) can result in dyspnea-like breathing.
- Muscle enzyme deficiencies can result in increased acid production and decreased work tolerance.
- In chronic renal failure, the kidney cannot remove acid from the blood, resulting in dyspnea.

Obesity

- Dyspnea occurs because of increased metabolic requirements for a given amount of work.

Pregnancy

- Dyspnea is normal in pregnancy.
 - Rarely severe and rarely occurs at rest

- Dyspnea as a result of cardiac disease in pregnancy begins during the second half of pregnancy and is worst during the 7th month.

Intravenous drug use

- Heroin can cause bronchospasm.
- Heroin and other opioids can precipitate pulmonary edema.
- Infection in intravenous drug users
 - Community-acquired pneumonia is the most common.
 - Opportunistic pulmonary infections
 - Tuberculosis
 - Bacterial endocarditis
 - Talc granulomatosis

Psychogenic causes

- Stress or hysteria
 - Dyspnea does not improve with rest and may worsen.
 - The patient has chest pain.
 - The patient sighs frequently.
 - Paradoxical adduction of the vocal cords has been reported.

Causes of obstructive pulmonary disease

- Obstructive pulmonary disease is characterized by airway narrowing.

Newborns

- Choanal atresia or stenosis
- Dermoid cyst
- Encephalocele
- Nasolacrimal duct cyst
- Hemangioma
- Vocal cord paralysis
- Pierre Robin syndrome
- Ankyloglossia (tongue tie)
- Pertussis
- Tracheal stenosis (postintubation)

Infants

- Foreign body
- Vascular ring
- Tracheal web
- Bronchiolitis
- Asthma
- Cystic fibrosis
- Bronchomalacia
- Pyogenic thyroid
- Accessory thyroid

Children and adolescents

- Foreign body (airway or esophagus)
- Asthma

- Adenopathy
 - Lymphoma
 - Systemic lupus erythematosus
 - Tuberculosis
 - Sarcoidosis
- Croup
- Epiglottitis
- Retropharyngeal abscess
- Enlarged tonsils or adenoids
- Cystic fibrosis
- Anaphylaxis
- Tumors
 - Laryngeal
 - Vocal cord
 - Tracheal
 - Mediastinal
- Vocal cord polyp
- Laryngeal trauma
- Supraglottitis
- Diphtheria
- Bacterial tracheitis
- Ingestion of caustic substance
- Crack cocaine
- Trauma
- Environmental or occupational inhaled toxin exposure

Causes of restrictive pulmonary disease

Cardinal features of restrictive pulmonary disease

- Reduction in lung volume and pulmonary compliance
- Rapid, shallow respirations are usually present.

Newborns

- Hyaline membrane disease
- Hypoplastic lungs
- Pulmonary agenesis
- Eventration of the diaphragm
- Meconium aspiration
- Pneumonia (group B streptococci or gram-negative organisms)
- Diaphragmatic paralysis
- Osteogenesis imperfecta
- CNS depression
 - Hypoxia
 - Congenital
 - Maternal drugs
- Congenital myasthenia gravis
- Aspiration

- Pulmonary edema
- Septicemia
- Congenital heart disease

Infants

- Pneumonia
 - Bacterial
 - Viral
 - Aspiration
- Bronchopulmonary dysplasia
- Wilson-Mikity syndrome
- Hamman-Rich syndrome
- Pulmonary edema
- Infantile botulism
- Congenital lobar emphysema

Children and adolescents

- Skeletal
 - Kyphoscoliosis
 - Ankylosing spondylitis
 - Pectus excavatum
 - Crush chest injury
- Parenchymal
 - Pneumonia
 - Hypersensitivity pneumonitis
 - Systemic lupus erythematosus
 - Scleroderma
 - Fibrosis
 - Toxin inhalation
 - Granulomatous disease
 - Drugs (eg, antineoplastic agents, narcotics)
 - Carcinoma
 - Fat embolus
 - Pneumothorax
 - Pneumomediastinum
- Smoke inhalation
- Pulmonary infarction
- Pulmonary edema
 - Congestive heart failure
 - Sepsis
 - Intracranial disease
 - Croup
 - Epiglottitis
- Neuromuscular
 - Cord transection
 - Myasthenia gravis
 - Muscular dystrophy

- Multiple sclerosis
- Guillain-Barré syndrome
- Pickwickian syndrome
- Toxins

- Pleural effusion
 - Pneumonia
 - Cancer
 - Cardiac disease
 - Hepatic disease
 - Renal disease
 - Rheumatologic disease
- Hypoproteinemia
- Renal failure
- Tumor
- Pulmonary infarction

LABORATORY EVALUATION

- Most useful laboratory tests include:
 - Complete blood count
 - Peripheral blood smear
 - Arterial blood gas measurement
 - Normal with mild obstructive disease
 - Hypoxemia is the first abnormality seen in progressive disease, followed by hypocapnia, then hypercapnia.
 - Hypoexmia and hypocapnia in restrictive pulmonary disease
 - Vascular pulmonary disease shows reduced blood flow through the lungs, resulting in arterial hypoxemia and hypercapnia.
 - Hematologic disease may not show hypoxemia when assessed by arterial blood gas measurement.

IMAGING

- Chest radiograph in obstructive pulmonary disease
 - May reveal hyperinflation
- Chest radiograph in restrictive pulmonary disease
 - Decreased lung volume
 - Pleural thickening and effusions
 - Increased interstitial markings
 - Parenchymal consolidation
 - Skeletal deformities
 - Abnormal movement of the diaphragm
- Chest radiograph in pulmonary edema
 - Increased right ventricular size
 - Enlargement of the pulmonary artery
 - Alterations in pulmonary blood flow

DIAGNOSTIC PROCEDURES

- Use pulse oximetry as a quick, noninvasive means to measure arterial saturation.
- Pulmonary function tests may be useful but may not be immediately available for an acutely ill patient.
- Laryngoscopy, bronchoscopy, and esophagoscopy may be useful to identify a radiolucent foreign body.

TREATMENT APPROACH

- Severe dyspnea is a medical emergency.
 - If not treated promptly, the child may progress to respiratory failure and death.
- Dyspnea in chronic illness
 - There may be no satisfactory therapy for the underlying disease.
 - Relieving the dyspnea can still improve functional ability and quality of life.

SPECIFIC TREATMENT**Severe dyspnea**

- Assess the adequacy of the airway.
- Remove foreign bodies, if present.
- Treat bronchospasm with β -agonists.
- In the postemergent period, evaluate the efficacy of ventilation.
 - If the child cannot effect adequate ventilation, consider the need for mechanical ventilation.
- Assess the heart, peripheral circulation, intravascular volume status, and blood oxygen-carrying capacity.
 - Treat with vasopressors, fluids, blood transfusion, or diuretics, as appropriate.
- Administer oxygen until the cause of dyspnea is known.

Dyspnea in chronic illness

- Sedatives and narcotics can be used to reduce minute ventilation.
- Prostaglandin inhibitors and β -agonists may blunt the feeling of dyspnea without affecting ventilation.
- Theophylline may improve diaphragmatic contractility.
- Continuous supplemental oxygen reduces ventilatory drive.
- Exercise and proper nutrition can maintain or increase inspiratory muscle mass.

Psychogenic dyspnea

- Calm reassurance
- Occasionally, mild sedation
- Psychotherapy and hypnosis may be required to reduce stress and gain insight in to the cause of the dyspnea.

WHEN TO REFER

- Chronic pulmonary disease
- Congenital or acquired heart disease
- Metabolic disease
- Conditions requiring endoscopy or surgical procedures

WHEN TO ADMIT

- Respiratory failure
- Impending respiratory failure
- Hypoxia while breathing room air

PROGNOSIS

- Prognosis depends on the underlying cause.

Dysuria

DEFINITION

- Pain or burning associated with urination that stems from irritation of the bladder, the urethra, or both

MECHANISM

- Dysuria is a result of any condition that leads to inflammation, irritation, or obstruction of the urinary tract.
- Typically stems from a common disorder, such as:
 - Urinary tract infection (UTI)
 - Urethritis
 - Chemical irritation
 - Trauma

HISTORY

- A thorough history is essential.
- Dysuria is rarely the only symptom.
 - Ask about associated symptoms.
- Ask about family history of nephrolithiasis or other genitourinary problems.
- Nonspecific symptoms not related to the genitourinary system
 - Any of the following suggest a systemic inflammatory condition.
 - Conjunctival erythema
 - Oral lesions
 - Joint pain or swelling
 - Generalized rash
 - Recent fever indicates a systemic infectious condition.
- Specific symptoms related to the genitourinary system
 - Hematuria
 - Malodorous urine
 - Frequency
 - Urgency
 - Incontinence
 - Refusal to void
 - Ask about exposure to chemicals, such as:
 - Detergents
 - Perfumed soaps
 - Bubble baths
 - Medications
- History of voiding dysfunction
 - Delayed toilet training
 - Enuresis
 - Constipation
- Sexual history
 - Ask whether the patient is sexually active.
 - Ask about sexual trauma, masturbation, or abuse.

PHYSICAL EXAM

- Perform routine physical examination.
 - Presence or absence of fever may be indicative of the cause of dysuria.
 - Pyelonephritis: fever usually present and temperature $>38.5^{\circ}\text{C}$
 - Cystitis: only occasionally produces fever
 - Infectious, chemical, or traumatic urethritis: no febrile response
 - If there is a history of voiding dysfunction, observe the lower back for midline defects.
 - Evaluate the integrity of the lower motor neuron reflex arcs.
 - Check the neurologic integrity of the lower extremities.
 - Elicit the bulbocavernosal reflex.
- Physical examination of the genitourinary tract
 - Palpate the abdomen.
 - Costovertebral tenderness suggests pyelonephritis.
 - Suprapubic tenderness suggests cystitis.
 - Enlarged kidneys or bladder suggests urethral obstruction.
 - Examine the genital area and observe for:
 - Labial adhesions
 - Vesicles
 - Ulcerations
 - In girls, observe for urethral prolapse.
 - Reddened or dark circumferential protrusion of the mucosa from the urethral orifice
 - In boys, note whether the child is circumcised.
 - Note the size and location of the meatus.
 - Observe for vaginal discharge or urethral discharge.
 - Character of the discharge can help to identify the specific pathogen.
 - Cheesy discharge is found in candidal vaginitis.
 - Green discharge is associated with gonorrhea.

DIFFERENTIAL DIAGNOSIS

UTI

- Most common cause of dysuria
- Patient may report suprapubic pain.
- Fever, if present, is usually low grade.
- Children <5 years with their first UTI should be evaluated for congenital anatomic abnormalities.
- Pyelonephritis is suggested by the presence of systemic features.
 - Fever
 - Chills
 - Vomiting

- Flank pain
- Costovertebral angle tenderness

Urethritis

- May result from:
 - Infection
 - Trauma
 - Allergy
 - Foreign body
- Urethral discharge or blood spots on the underwear may be present.
- Infectious urethritis in children is uncommon.
 - May occur in sexually active adolescents
 - May occur in children who have been sexually abused by an infected adult
 - *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are the most common pathogens.
 - Vesicles or genital ulcers may be present in cases of herpes simplex virus infection.

Irritants and trauma

- Local irritants may produce mild erythema.
 - Bubble baths
 - Detergents
 - Perfumed soaps
- Trauma may cause dysuria.
 - Sexual abuse
 - Voluntary sexual activity
 - Masturbation

Vulvovaginitis

- Erythema and inflammation of the vaginal mucosa
- Vaginal discharge is present.
 - Varies from scant whitish to green
 - Foul smelling
- Causes include poor hygiene, allergy, or infection.
 - Pathogens include group A *Streptococcus* and *Shigella*.
 - Vulvar bleeding may be present.
 - *Candida albicans*
 - Usually occurs after recent antibiotic use, in patients with diabetes, and in patients who wear diapers.
 - Pruritus usually present.

Dysfunctional voiding

- Dyscoordination between the bladder and bladder outlet that results in inefficient bladder emptying
- Neuropathic disorders
 - Spina bifida
 - Transverse myelitis
 - Spinal cord trauma

- Nonneuropathic disorders
 - Functional problems with micturition
- Patients may experience:
 - Incontinence
 - UTIs
 - Constipation

Less common causes of dysuria

- Pelvic inflammatory disease (in sexually active adolescent girls)
 - Fever
 - Abdominal pain
 - Pelvic discomfort
- Balanitis and balanoposthitis
 - Inflammatory lesions of the glans penis or glans penis and prepuce
 - Most common in uncircumcised young boys
 - Infection results from smegma trapped beneath the foreskin.
 - May be a result of trauma or poor hygiene
- Pinworms
 - Caused by *Enterobius vermicularis* parasite
 - Anal pruritus is the symptom, but young children may incorrectly describe this as dysuria.
- Labial adhesions in prepubertal girls may cause:
 - Dysuria
 - Postvoid dribbling
 - UTIs
 - Easy to visualize on inspection
- Urethral strictures
 - Acquired
 - Result of urethral instrumentation, trauma, or inflammation
 - Congenital
 - Symptoms include retention, dysuria, or a weak urinary stream.
- Meatal stenosis (circumcised boys)
 - Typically an upward, deflected, difficult-to-aim urinary stream
 - May be accompanied by:
 - Dysuria
 - Urgency
 - Frequency
 - Prolonged urination

- Urethral prolapse
 - Occurs primarily in black girls
 - Presenting age is 4 years.
 - Vaginal bleeding is the most common symptom.

- Hypercalciuria
 - Patients report:
 - Urinary frequency
 - Hematuria
 - Recurrent UTIs
 - Dysuria

Systemic causes

- Stevens-Johnson syndrome
- Behçet syndrome
- Reiter syndrome
- Varicella

LABORATORY EVALUATION

- Perform a urethral smear and urine culture if urethritis is suspected.
- If vaginal discharge is present, examine sample for:
 - pH
 - Wet preparation
 - Potassium hydroxide
 - Gram stain
 - Culture

IMAGING

- Retrograde urethrography or cystoscopy can confirm a diagnosis of urethral strictures.

TREATMENT APPROACH

- The overall goal is to identify the cause of dysuria and treat appropriately.

SPECIFIC TREATMENT

- Cystitis and UTI—see Urinary Tract Infections
- Suspected sexual abuse
- Antibiotic treatment of vaginitis—see Vaginal Discharge
- Dysfunctional voiding due to neurologic conditions—see Anuria and Oliguria
- Pelvic inflammatory disease and sexually transmitted infections—see Sexually Transmitted Infections
- Labial adhesions
- Balanitis and balanoposthitis
 - Warm soaks
 - Appropriate antibiotic therapy
- Meatal stenosis
 - Refer to a pediatric urologist.
 - Surgical meatomy is the recommended treatment.
- Urethral prolapse
 - Medical treatment
 - Sitz baths
 - Antibiotics
 - Estrogen cream
 - Surgery is recommended if medical treatment fails.

WHEN TO REFER

- Voiding dysfunction
- Nephrolithiasis
- Girls <5 years with a UTI for the first time
- Boys of any age with a UTI
- Genitourinary tract anomalies

WHEN TO ADMIT

- Systemic inflammatory or infectious cause of dysuria
- Suspicion of sexual abuse

Edema

DEFINITION

- Edema is the accumulation of fluid in the interstitial tissues.
 - Results from disruption of forces that control normal fluid movement out of and into capillaries
 - May result from many different disease states
 - Diagnosis of the underlying cause is generally apparent, but it may be subtle.
 - Intervention may initially need to be supportive.
 - Once a patient is stable, efforts to treat the underlying cause of the edema should be pursued.
 - Services of a specialist may be required.

MECHANISM

- Fluid distribution between the intravascular compartment and the interstitial compartment results from the interplay of:
 - Oncotic pressure
 - Hydrostatic pressure
 - Capillary membrane permeability
 - Disruption of these forces can result in edema.
 - Sodium concentration is usually the ultimate controller of this fluid movement.
- An increase in capillary membrane permeability is often the result of cytokines released from inflammation.
 - Infections and burns tend to cause localized edema.
 - An allergic reaction may cause more generalized edema.
 - Hereditary angioedema can cause localized edema of the gastrointestinal tract and larynx.
 - Trauma causes local edema.
- A decrease in the capillary oncotic pressure can be caused by decreased levels of protein (usually from albumin in the blood).
 - Decreased synthesis of albumin occurs
 - In patients with cirrhosis
 - As a result of malnutrition or intestinal malabsorption
- Protein loss by the kidneys in nephrotic syndrome may also contribute to edema.
 - Albumin levels <2 mg/dL are usually associated with generalized edema.
 - The mechanism of edema formation with decreased oncotic pressure results in extravasation of fluid into the interstitium.
 - It also results in poor kidney perfusion.
 - Activates renin-aldosterone secretion and results in:
 - Increased sodium reabsorption
 - Fluid retention
 - Increased capillary hydrostatic pressure
 - All of which compounds the formation of edema.

- Systemic venous hypertension can be the result of:
 - Heart failure
 - Constrictive pericarditis
 - Cardiomyopathy
 - Tricuspid valvular disease
 - Cirrhosis
 - All of these conditions increase the capillary hydrostatic pressure and result in edema from increased extravasation of fluid into the interstitium.
 - Left-ventricular heart failure results in pulmonary edema.
 - Right-ventricular heart failure results in venous congestion, hepatomegaly, and peripheral edema.
- Localized edema may result from
 - Increased venous pressure with deep-vein thrombosis
 - Compression of the inferior vena cava or iliac vein by a tumor
 - Increased venous pressure raises the capillary hydrostatic pressure.
- All of the conditions below lead to increased plasma volume through a similar mechanism:
 - Renal disease
 - Glomerulonephritis
 - Nephrotic syndrome
 - Renal failure
 - Heart failure
 - Liver disease
 - Cirrhosis
 - Increased sodium reabsorption in the kidney leads to increased water reabsorption and increased plasma volume.
 - Activation of the renin-angiotensin-aldosterone system
 - Sympathetic nervous stimulation can also result in increased sodium reabsorption in the kidney.
- Increased interstitial hydrostatic pressure, although rare, may result from lymphatic obstruction.
 - By a tumor or large lymph nodes
 - From damage to the lymphatic system by radiation or surgery
 - From parasitic infections such as filariasis

HISTORY

- A detailed history must be obtained to discover the cause of the edema.
- The time course of the edema—whether its onset is recent or chronic—is particularly important.
 - If chronic, then the parents and child may report:
 - Weight gain
 - Tight clothing
 - Snug-fitting shoes
 - Parents may have attributed findings to normal growth.

- History of a recent illness, such as pharyngitis, is important for the diagnosis of glomerulonephritis.
- Other systemic complaints may be present, which may indicate the presence of heart failure and pulmonary edema.
 - Shortness of breath
 - Tachypnea
 - Cough
- Ascites, a form of localized edema, is seen with liver failure or cirrhosis and with some congenital liver malformations.
- The child's nutritional status should be assessed.
 - Malnutrition may result in hypoalbuminemia, which can result in edema.

PHYSICAL EXAM

- Edema may be generalized or localized.
 - If localized, edema is very apparent when it affects an extremity.
 - Deep-vein thrombosis
 - Cellulitis
 - Burn
 - Edema may be more occult.
 - Pulmonary edema from left-ventricular heart failure
 - Ascites from liver disease
 - Generalized edema may include scrotal or labial edema.
 - Findings related to generalized edema may depend on whether the patient has been lying down (sacral edema) or standing (feet and lower legs).
 - Chronic edema may result in bedsores.
- Physical examination should begin with close observation of the vital signs.
 - Tachypnea may indicate pulmonary edema.
 - Increased blood pressure may be present in glomerulonephritis and renal failure.
 - Fever and localized edema may be present with cellulitis.
 - Periorbital edema is generally found with nephrotic syndrome and glomerulonephritis.
 - Crackles or rales may indicate the presence of pulmonary edema.
 - A gallop may indicate heart failure.
 - With ascites, the following may be present:
 - Abdominal distention
 - Shifting dullness
 - A fluid wave
 - A distinction may be made between pitting and nonpitting edema.
 - *Nonpitting edema* is often the result of lymphedema.
 - *Pitting edema* is the result of increased membrane permeability, increased hydrostatic pressure, or decreased oncotic pressure.

DIFFERENTIAL DIAGNOSIS

- Renal causes of edema
 - Nephrotic syndrome
 - The presence of proteinuria with low serum albumin is highly suggestive of nephrotic syndrome.
 - Glomerulonephritis
 - Assess for the presence of:
 - Red cell casts
 - Hematuria
 - Cola-colored urine
 - C3 levels may be needed to help distinguish between the types of glomerulonephritis.
 - For nephrotic syndrome, levels of C3, C4, or antinuclear antibody can help exclude lupus or membranoproliferative glomerulonephritis.
 - Bilateral hydronephrosis in an infant boy with edema may be the result of posterior urethral valves.
 - Congenital renal anomalies may produce ultrasound results of small or malformed kidneys and clinical findings of renal failure.
 - Children with undiagnosed reflux nephropathy may have severe hydronephrosis and renal failure.
- Cardiovascular causes of edema
 - Congestive heart failure
 - Deep-vein thrombosis
 - Embolic disease
 - Vasculitis
 - Constrictive pericarditis
- Hematologic causes of edema
 - Severe anemia can result in edema, especially in a newborn.
 - Edema can be the result of:
 - Hemolysis from ABO blood type or Rh incompatibility
 - Glucose-6-phosphate dehydrogenase deficiency
- Endocrine or metabolic causes of edema
 - Thyroid disease
 - Starvation
 - Hereditary angioedema
- Gastrointestinal causes of edema
 - Cirrhosis
 - Protein-losing enteritis
 - Cystic fibrosis
 - Celiac disease
 - Enteritis
 - Lymphangiectasis
 - Lymphatic abnormalities
 - Milk protein allergy
 - Inflammatory bowel disease

- Hypoalbuminemia without proteinuria suggests:
 - Synthesis defect found with chronic liver disease.
 - A protein-losing enteropathy.
- Prothrombin time is a good marker of the liver's ability to synthesize protein.
 - Should be assessed when hypoalbuminemia is present without proteinuria.
- Liver function tests may also provide helpful information.
 - Analysis of stool α 1-antitrypsin will help diagnose protein-losing enteropathy.
- Venous thrombosis
 - If venous thrombosis is suspected, then coagulation studies should be conducted.
 - Especially if no predisposing factor, such as an indwelling catheter is present.
 - A Doppler ultrasound examination should be performed to assess the blood flow in the area that may be affected by the thrombosis.
- Enteropathy
 - The presence of increased fat in fecal matter strongly suggests intestinal malabsorption.
 - Determining which intestinal disorder may be the cause of the hypoalbuminemia requires further testing and consultation with a gastroenterologist.
 - Cystic fibrosis
 - Inflammatory bowel disease
 - Milk protein allergy
 - Enterokinase deficiency
 - Celiac disease
 - Intestinal lymphangiectasia

LABORATORY EVALUATION

- Initial testing may include:
 - Urinalysis
 - Complete blood count
 - Electrolytes with blood urea nitrogen and creatinine
 - Liver function tests (liver enzymes as well as serum albumin, prothrombin time and partial thromboplastin time)
 - Testing for fecal fat is appropriate if intestinal malabsorption is suspected.
 - α 1-antitrypsin may be helpful for diagnosing protein-losing enteropathy.
 - With angioedema levels of C1 esterase inhibitor are low.
 - Whether hereditary or acquired
 - When serum albumin is normal, depending on the clinical circumstance, thyroid function tests may be required.

IMAGING

- When serum albumin level is normal, depending on the clinical circumstance, chest x-ray may be required.
- Renal and abdominal ultrasound examination may be appropriate.
 - Bilateral hydronephrosis is usually demonstrated on a renal ultrasound.

DIAGNOSTIC PROCEDURES

- When serum albumin is normal, depending on the clinical circumstance, electrocardiogram may be required.

TREATMENT APPROACH

- Initial management involves determining whether the patient should be admitted to the hospital.
 - Many causes of edema require admission, including:
 - Presence of respiratory distress that results from airway swelling as in angioneurotic edema
 - Heart failure with pulmonary edema
 - Previously undiagnosed renal failure
 - Acute glomerulonephritis
 - Nephrotic syndrome
 - Oliguria from renal failure or poor renal perfusion
 - Previously unrecognized cirrhosis
 - Respiratory distress resulting from the ascites
 - Localized edema that results from venous thrombosis or lymphatic obstruction
 - Admission is needed to assess and treat the underlying cause.
- Ongoing management depends on the underlying cause of the edema.

SPECIFIC TREATMENT

General

- Most patients with renal disease benefit from a low-sodium diet.
- Fluid restriction may help, but should be used cautiously on an individual-patient basis in consultation with a nephrologist.
- Diuretics may be needed but should be used cautiously.
- If plasma volume is decreased, then fluid expansion with colloid followed by diuretics may be necessary.

Anemia

- Severe anemia may need to be treated with transfusion.
 - A hematologist should be consulted if the cause of the anemia is not readily apparent.

Ascites

- A low-sodium diet is generally helpful.
- Diuretics may be beneficial, especially spironolactone.
- When possible, treating the underlying cause of the ascites is critical.

Heart failure

- Treating heart failure may require inotropic medications.
 - Digoxin
 - Dobutamine
 - Angiotensin-converting enzyme inhibitor may help with afterload reduction.
 - If congenital heart disease is the cause of heart failure, surgical repair of the underlying structural lesion is the ultimate treatment.

Venous thrombosis

- When venous thrombosis is present, anticoagulation therapy may be indicated.
 - Consultation with a hematologist and possibly a vascular surgeon may be necessary.
 - In the absence of an obvious predisposing factor, investigation for an underlying coagulopathy is appropriate.

Enteropathy

- For patients with enteropathy, treatment depends on the cause.
 - A gastroenterologist should be consulted.

Hypothyroidism

- Generally, myxedema is found with hypothyroidism.
 - Responds to treatment with thyroid hormone replacement

WHEN TO REFER

- Many disorders that cause edema may require the assistance of a specialist.
- A referral to a specialist should be considered if evidence exists of
 - Liver disease (ie, ascites)
 - Renal disease (glomerulonephritis, nephritic syndrome)

- Anemia
- Protein depleting enteropathy or increased fecal fat with malabsorption with secondary hypoalbuminemia
- Heart failure

WHEN TO ADMIT

- Many of the causes of edema are serious medical problems that require admission.
 - This approach may initially be for support.
 - Once a diagnosis is established and the patient is stable, further treatment usually continues on an outpatient basis with assistance of a specialist.
- Any of the following may require admission:
 - Respiratory distress
 - Heart failure
 - Renal failure
 - Acute glomerulonephritis or nephrotic syndrome
 - Oliguria from renal failure should result in emergent admission.
 - Edema caused by previously unrecognized cirrhosis
 - Localized edema that results from venous thrombosis or lymphatic obstruction
 - Anemia severe enough to require a transfusion

PROGNOSIS

- Prognosis depends on the underlying cause and the appropriateness of treatment.

Encopresis

DEFINITION

- Soiling
 - Voluntary or involuntary passage of feces into the clothing
- Retentive encopresis
 - Leakage of fecal material involuntarily from an impaction
- Nonretentive encopresis
 - Passage of normal bowel movement into underwear rather than the toilet

EPIDEMIOLOGY

- Prevalence
 - ~2% of children in kindergarten and first grade are affected.
- Sex
 - Boy-to-girl ratio is 3:1.

ETIOLOGY

- Organic basis for retentive encopresis in <5% of cases
 - Constipating medication
 - Constipating diet
 - Chronic anal fissure
 - Perianal cellulitis
 - Hypothyroidism
 - Anal or rectal stenosis
 - Pelvic mass
 - Hirschsprung disease
- Most children who hold back stool do so:
 - In an attempt to avoid the pain associated with passage
 - Because they are enmeshed in a control issue with a parent
- Approximately 10–20% of children with encopresis are not constipated.
 - Preschoolers often resist bowel training deliberately.
 - School-aged children postpone bowel movements (BMs).
 - They do not want to leave some enjoyable activity (eg, video games).
 - They do not want to use public toilets (eg, school bathrooms).

SIGNS AND SYMPTOMS

- Patient or parent reports:
 - Constipating medication
 - Constipating diet
- Findings on physical examination
 - Chronic anal fissure
 - Perianal cellulitis
 - Delayed linear growth
 - Indicates hypothyroidism

- Mass on rectal examination
 - Dilated rectum packed with stool (often 6–10 cm across)
 - Impacted stool usually has the consistency of wet clay.
- Rectal ampulla empty, rectum tight
 - Hirschsprung disease
- Retentive encopresis
 - Palpable abdominal mass
 - Usually involves only the rectosigmoid area but may extend throughout the colon
 - Midline, suprapubic, irregular, and moveable
 - Can be missed if the rectus abdominis muscles are not relaxed
 - Protuberant abdomen may be caused by backup of gas and stool
 - Fecal matter protruding from the anal opening
- Nonretentive encopresis
 - Normal abdominal examination
 - Rectal vault contains:
 - Stool of normal caliber
 - Nothing, if the child has evacuated recently

DIFFERENTIAL DIAGNOSIS

- Retentive encopresis
 - Symptoms of constipation
 - Soiling many times per day
 - Small stools
 - Loose stools
 - Need for laxatives, suppositories, or enemas
 - Abdominal mass present
 - Abdominal distention
 - The anal canal may be full
 - Rectum packed with stool
 - Periodic pain or crying with BMs
 - Blood on the toilet tissue
 - Passage of a huge BM that clogs the toilet
 - Posturing that suggests deliberate holding back
- Nonretentive encopresis
 - No constipation
 - Soiling once per day
 - Stool of normal size
 - Stool of normal consistency
 - No need for laxatives, suppositories, or enemas
 - No abdominal mass
 - No abdominal distention
 - Empty anal canal
 - Normal rectum

DIAGNOSTIC APPROACH

- Thorough history to distinguish between retentive and nonretentive encopresis
- Review diet.
 - Milk products
 - Fruit juice
 - Fiber
- Question child's use of the toilet.
 - How many times per day?
 - Is sitting spontaneous or prompted by parents or teachers?
- If the stool pattern is unknown, the parent should be sent home with a soiling diary to complete for the child.

LABORATORY FINDINGS

- Urinalysis
 - For nitrite and pyuria
 - To screen for urinary tract infection, especially if associated with enuresis
- Culture for group A *Streptococcus* if abnormal perianal erythema is present
- Thyroid function tests if warranted

IMAGING

- Plain film, postvoiding, supine abdominal radiography
 - Needed to determine whether the patient is impacted (eg, abdominal fullness but empty rectum)
 - For a sexually abused child who might be emotionally traumatized by a rectal examination
 - If child refuses rectal examination
- Radiologic findings
 - Grossly dilated rectum
 - Granular stool
 - Increased stool in the transverse and descending colon
- Barium enema
 - Only if Hirschsprung disease is strongly suspected
 - For children with repeated treatment failures, to reassure the family (and physician) that some rare diagnosis has not been overlooked

DIAGNOSTIC PROCEDURES

- Rectosigmoid manometric study
 - In suspected Hirschsprung disease

CLASSIFICATION

- Soiling
- Retentive encopresis
- Nonretentive encopresis

TREATMENT APPROACH

- Retentive and nonretentive encopresis must be addressed separately.
- Retentive encopresis
 - Hyperphosphate enemas (1 daily for 2 or 3 days) to remove impaction
 - Mineral oil, polyethylene glycol, or lactulose for 3 months to keep the stools soft
 - Senna laxatives if stool softeners are ineffective
 - Sitting on the toilet for 10 minutes after meals
 - Nonconstipating high-fiber diet
 - Such foods as popcorn, grains, fruits, and vegetables
 - Limited consumption of milk products
 - ~10% of children with impactions are drinking great amounts of milk (>32 oz per day).
 - Milk intake can be limited to 16 oz per day in children >1 year.
 - Fluid requirements for these children can be met with fruit juices.
 - Pear, peach, and prune juices have high sorbitol content that can increase the frequency of stools.
- Nonretentive encopresis
 - Medications are not needed.
 - Stop all reminders, lectures, or punishments.
 - Give incentives for BMs into the toilet.
 - For soiling, insist on immediate cleanup.
 - Refer treatment failures.

SPECIFIC TREATMENTS

Retentive encopresis

Disimpaction

- The traditional approach is daily sodium phosphate enema for 2 or 3 days.
 - Excessive doses of phosphate enemas can cause tetany, dehydration, or death.
 - If the child refuses an enema, administer high-dose mineral oil or polyethylene glycol (Miralax) orally for ~4 days.
- These approaches may be combined, starting with mineral oil or polyethylene glycol orally and followed by enemas on day 3.
- Occasionally, enemas must be administered in the office or clinic.

Stool softeners

- First line of therapy for constipation
- Appropriate for long-term treatment
- Administered orally
- Begun as soon as the impaction is eliminated

- Goal is the passage of 1 or 2 normal-sized BMs per day.

- Continued for 3 months

- It takes 3 months for bowel diameter and tone to return to normal.

- Mineral oil

- 1–2 mL/kg twice daily
- Adolescents: 60 mL/dose (max 8 oz/day)
- Contraindicated in children who:
 - Have gastroesophageal reflux or vomiting
 - Are not yet walking
- Emulsified derivatives of mineral oil taste better but are more expensive.

- Lactulose

- 0.5–1.0 mL/kg twice daily
- Adolescents: 15 mL twice daily (max 3 oz/day)

- Polyethylene glycol (Miralax)

- 0.5 g/kg/day
- Adolescents: 17 g/day

- Milk of magnesia

- 1–2 mL/kg/dose
- Adolescents: 30–60 mL

Stimulant laxatives

- Recommended if stool softeners are not effective

- Usually needed for children who deliberately hold back BMs or for those who have developed megarectum and megacolon (see table Medications for Constipation)

- Treatment failure and recurrence usually are due to undermedicating.

- Increase dose if child is not having a normal-sized BM daily.
- Some children temporarily require doses that exceed the standard dose recommended by textbooks and the package insert.
- Children can be tapered off laxatives successfully, even after 6 months.
- Continue medications until the child has gone ≥ 1 month without any soiling.
- Taper medications gradually over 1–2 months.

- Senokot (senna)

- <5 years: 1–2 tsp syrup/day
- ≥ 5 years: 2–3 tsp syrup
- Adolescents: 1 tbsp/day (max 2.5 tbsps or 8 tablets)

- Fletcher's Castoria

- <5 years: 1–2 tsp/day
- ≥ 5 years: 2–3 tsp
- Adolescents: 2 tbsps max

- Ex-Lax (senna)

- >5 years: 1 square/day
- Adolescents: 2 squares

- Dulcolax, 5-mg tablet

- >5 years: 5 mg/day
- >12 years: 10 mg (2 tablets)
- Adolescents: 4 tablets max

- Rectal suppositories

- Glycerin suppository
 - 1 or 2 suppositories
- Dulcolax, 10-mg suppository
 - >2 years: 1 suppository

- Enema for disimpaction

- Mineral oil enema
 - 1–2 oz/20 lb of body weight/day
 - Adolescents: 4 oz
- Sodium phosphate enema (Fleet)
 - 1 oz/20 lb of body weight/day
 - Adolescents: 4 oz (max 8 oz)

Oral disimpaction

- Mineral oil

- 1 oz per year of age/day
- Max dose: 8 oz/day

- Polyethylene glycol (Miralax)

- 0.5 g/kg 3 times daily
- Max 25 g, or 1.5 capful 3 times daily

Toilet habits

- The child must sit on the toilet for ≥ 10 minutes once a day with a timer.

- The gastrocolic reflex takes effect 20–30 minutes after a meal (especially breakfast).
- Should be used to advantage
- Any treatment that neglects this opportunistic timing will fail.

- Children who have been impacted for many months have no urge to defecate.

- The defecation urge may not return until the rectum is kept empty for 1–2 weeks.
- Child should be instructed to flex the hips to open the rectum, to use a footstool for leverage, and to apply some pressure to the abdomen while pushing down.
- If they have no BM for 24 hours, then these children need to sit on the toilet more often and longer each time.
- Soiling (leakage) requires:
 - Sitting on the toilet
 - Cleanup

Medications for Constipation

Medication		Dosage	Comments
Stool Softeners	Mineral oil	<ul style="list-style-type: none"> • 1–2 mL/kg per dose twice daily • Adolescents: 60 mL/dose (max 8 oz/day) 	<ul style="list-style-type: none"> • Do not use in children who have gastroesophageal reflux or vomiting or who are not yet walking. • Emulsified types (Petrogalar, plain Agoral, Kondremul) taste better.
	Lactulose	<ul style="list-style-type: none"> • 0.5–1.0 mL/kg per dose twice daily • Adolescents: 15 mL twice daily (max 3 oz/day) 	This is a prescription item.
	Polyethylene glycol (Miralax)	<ul style="list-style-type: none"> • 0.5 g/kg per day • Adolescents: 17 g/day 	This is a prescription item.
	Milk of Magnesia	<ul style="list-style-type: none"> • 1–2 mL/kg per dose • Adolescents: 30–60 mL 	1 Milk of Magnesia tablet = 2.5 mL liquid.
Stimulant laxatives	Senokot (senna)	<ul style="list-style-type: none"> • <5 yr: 1–2 tsp syrup/day • >5 yr: 2–3 tsp syrup/day • Adolescents: 1 tbsp/day (max 2.5 tbsp or 8 tablets) 	1 tablet = 3 mL granules = 5 mL syrup.
	Fletcher's Castoria	<ul style="list-style-type: none"> • <5 yr: 1–2 tsp/day • >5 yr: 2–3 tsp/day • Adolescents: 2 tbsp max 	—
	Ex-Lax (senna)	<ul style="list-style-type: none"> • >5 years: 1 square/day • Adolescents: 2 squares 	Chewable squares
	Dulcolax, 5-mg tablet	<ul style="list-style-type: none"> • >5 yr: 5 mg/day • >12 yr: 10 mg (2 tablets)/day • Adolescents: 4 tablets max 	Liquid form not available
Rectal suppositories	Glycerin suppository	1 or 2 suppositories	
	Dulcolax suppository, 10 mg	>2 yr: 1 suppository	
Enema for disimpaction	Mineral oil enema	<ul style="list-style-type: none"> • 1–2 oz/20 lb of weight daily • Adolescents: 4 oz 	Squeeze-bottle size: 4.5 oz
	Sodium phosphate enema (Fleet)	<ul style="list-style-type: none"> • 1 oz/20 lb of weight/day • Adolescents: 4 oz (max 8 oz) 	Squeeze-bottle size: 2.25 oz children, 4.5 oz adult

	Polyethylene glycol (Miralax)	<ul style="list-style-type: none"> • 0.5 gm/kg per dose 3 times daily • Max 25 g or 1.5 caps 3 times daily 	—

- Preschoolers and toddlers:

- May refuse to sit on the toilet
- May hold back stools when forced to sit on the toilet
- The goal is to produce a BM daily.
 - Pediatricians and parents need to lower their expectations.
 - The child can be told that the “poop wants to come out every day and it needs your help.”
 - Going in the diaper is fine.
 - The child is not put back in diapers full-time.
 - The diaper is made available when child needs to release a stool.
 - This approach prevents the child from bladder control regression.

Nonretentive encopresis

- Stool softeners, laxatives, and enemas are not needed.
- For children who simply postpone BMs:
 - Admonition “to find a toilet whenever you feel rectal pressure” or “don’t make your body wait” usually removes the symptom.
- Stop all reminders, lectures, or punishments.
 - Parents should be reassured that nothing more can be taught to their child.
 - To eliminate the control issue, the parents should be told to let the child decide when the need exists to go to the bathroom.
 - Reminders, inquiries, and lectures are a form of pressure, and pressure does not work.
 - Parents should not threaten punishment.
 - Many young children try to hold back all BMs to avoid punishment for soiling.
 - Parents should be told about the importance of not punishing their child for soiling.
 - Child should be reassured that soiling will no longer incur punishment.
- Give incentives for BMs into the toilet.
 - Immediate positive feedback, such as praise, a hug, or a sticker/stars on a chart
 - Major incentives may be offered to achieve breakthrough with some children who have never had a BM into a potty chair or toilet.
- Soiling should not be ignored.
 - Immediate cleanup
 - Parents should help the child change clothes.
 - Changing should be a neutral, timely interaction.

- Most children with nonretentive encopresis are resistant to toilet training.
- If initial behavioral methods above are not helpful, more intensive psychological or family interventions are needed.

WHEN TO ADMIT

- Hospitalization rarely is needed for children with constipation.
- For severe impactions involving the entire colon, possible hospitalization for polyethylene glycol-electrolyte solution by nasogastric tube for 8–24 hours

WHEN TO REFER

- Refer to a mental health professional in the following situations:
 - Nonretentive encopresis unresponsive to pediatric management
 - Child >5 years who refuses to sit on the toilet
 - Child who refuses to take medications
 - Child >8 years with nonretentive encopresis
 - Child with nonretentive encopresis who deliberately passes BMs on family possessions or at school (overt anger)
 - Child who is depressed
 - Severely disturbed parent-child relationship

FOLLOW-UP

- Follow up ~1 week into treatment.
 - >30% still will be impacted.
 - Some children need enemas in the office.
- If a child still is impacted at the follow-up examination, a more detailed explanation of the disimpaction process is necessary.
- Repeat abdominal examination even if patients report that the child is having normal BMs and no soiling.
 - Children who have an impaction can keep themselves clean temporarily by making a superhuman effort at control and sitting on the toilet several times a day.

COMPLICATIONS

- Secondary emotional problems
 - Shame
 - Constant fear of exposure
 - Many children with encopresis are scapegoated at home, teased by peers, and ostracized at school.

PROGNOSIS

- 99% of children who have mainly pain-related impaction are cured by pediatric management.
- ~70% of children who have psychogenic impaction are successfully treated by the pediatrician.
 - The remainder need to work with a mental health professional
- Nonretentive encopresis
 - Good results if the problem is recent
 - Poor results if the problem is long-standing (>5 years)
- In mildly resistant children, primary care management can achieve a 90–95% cure rate.
- Children who have severe resistance need early referral.

PREVENTION

- Back-up plans for preventing relapses
 - Increased dose of stool softener or laxative if >48 hours without a normal-size BM
- Child is at risk for recurrent impaction if soiling occurs more than twice over a few days.
 - Double dose of laxative, a suppository, or an enema
 - Merely mentioning an enema sometimes results in the child sitting on the toilet and producing a BM.
 - For older children who are cooperative about sitting on the toilet, sitting there for 10 minutes out of every hour will usually relieve an early impaction.
 - The family should be made to realize that soiling always means that the rectum is full and the impaction is returning.
- Primary care interventions may fail due to:
 - Rectal hyposensitivity acquired from prolonged stretching of the rectum
 - Inability to relax the external anal sphincter caused by voluntary attempts to prevent stool leakage or pain
 - Both of these conditions usually recede once stool impaction is permanently resolved with more aggressive interventions.

Enterovirus Infections

DEFINITION

- Enteroviruses are *Picornaviridae*, small RNA viruses.
- Traditionally classified into 3 groups:
 - Polioviruses
 - Coxsackieviruses
 - Enteric cytopathogenic human orphan viruses (echoviruses)
- Classification is based on disease produced in humans and animals.
- Modern molecular genetic analysis has allowed a better understanding of the relationships among the various enterovirus serotypes.
 - The current taxonomy divides the enteroviruses into 4 species: human enterovirus A, B, C, and D (see table Classification of Enteroviruses).
 - Except for those reclassified as nonenteroviral, individual serotypes have retained their traditional names.
 - Newly identified enteroviruses are designated by number, starting with EV68 up to the most recently identified EV101.

EPIDEMIOLOGY

- Prevalence
 - In the US, ~15 million cases of symptomatic enterovirus infections occur every year.
 - ≥90% of infections are clinically silent.
 - Reinfection is common.
 - Nonpolio enteroviruses are the major cause of hospitalization in febrile infants <3 months of age.
 - Resulted in hospitalization in 2% of infants in the first month of life
 - Accounted for 82% of admissions for suspected sepsis

- Paralytic disease with wild-type poliovirus has been eradicated in the Western Hemisphere.
 - No cases have occurred in the US since 1979.
 - Outbreaks continue in parts of South Asia and Africa.
- Enteroviruses and parechoviruses are the most commonly identified viral infections in neonates, with mortality as high as 10%.
- The economic impact of enteroviral aseptic meningitis is estimated to be >\$1.5 billion annually.
- Host
 - Age correlates inversely with the severity of clinical disease.
 - An individual becomes immune to an increasing number of serotypes over several seasons.
 - Neonates may develop fatal sepsis rapidly.
 - Most older children and adults have mild or no symptoms.
 - Some enteroviral syndromes are severe at any age.
 - Poliomyelitis
 - Acute hemorrhagic conjunctivitis
 - Myocarditis
 - In childhood, boys seem to suffer more infections and more diseases than girls.
 - Individuals with humoral immunodeficiencies may have chronic, debilitating infection.
 - Except for poliovirus, enteroviral infection does not seem to pose a particular threat to individuals who have cancer or AIDS.
 - Recipients of bone marrow transplants may experience severe or prolonged infection.

Classification of Enteroviruses^{a,b}

Traditional Taxonomy	Current Taxonomy
Polioviruses • PV1–3	Human enterovirus A (HEV-A) • CAV2–8, 10, 12, 14, 16; EV71, 76, 89–91
Coxsackie A viruses • CAV1–22, 24	Human enterovirus B (HEV-B) • CAV9; CBV1–6; E1–7, 9, 11–21, 24–27, 29–33; EV69, 73–75, 77–78, 79–88, 100–101
Coxsackie B viruses • CBV1–6	Human enterovirus C (HEV-C) • CAV1, 11, 13, 17, 19–22, 24; PV1–3
Echoviruses • E1–7, 9, 11–21, 24–27, 29–33	Human enterovirus D (HEV-D) • EV68, 70
Numbered enteroviruses • EV68–71	

^a Enterovirus 79–101, which are not yet included in the International Committee on Taxonomy of Viruses classification, are shown in italics. The gaps in numbering result from changes in classification.

^b From: Khetsuriani N, LaMonte-Fowlkes A, Oberste MS, et al, Centers for Disease Control and Prevention. Enterovirus surveillance—United States, 1970–2005. *MMWR*. 2006;55(No 55-8):1–20.

- Virus
 - Most enteroviral syndromes are not serotype specific.
 - Several different types may produce the same clinical disease.
 - A single serotype may produce varying clinical syndromes in different seasons and communities, or even in different individuals infected at the same time and place.
 - The common pattern is endemic infection caused by several concurrently circulating enterovirus types.
 - The predominant serotypes may vary yearly, by locality, and within the same year.
 - The pattern of clinical syndromes changes over the enterovirus season.
 - Pandemic illness is unusual but not unknown.
- Environment
 - Enterovirus infections are seasonal, although sporadic cases are noted in all seasons.
 - Occur from June through October in the northern hemisphere
 - In tropical regions, infection is noted throughout the year, with increased incidence during rainy periods.
 - Crowding, poor sanitation, and low socioeconomic conditions increase incidence of infection.
- Subsequently, a major viremia results in viral dissemination to secondary organs.
 - Skin
 - Heart
 - Liver
 - Pancreas
 - Adrenal glands
 - Central nervous system
- This phase is often recognized clinically as a nonspecific febrile illness.
 - In poliomyelitis, it is the phase of minor illness.
 - In a very small percentage of cases, viral replication continues, producing clinical syndromes of enterovirus infection, such as poliomyelitis, herpangina, or pleurodynia.

Nonspecific febrile illness

- Can be caused by any of the enteroviruses
- Lasts ≥ 7 days
- Increases in late summer and early fall
- A child may have several episodes of enterovirus-induced febrile illness within the same season.
- Most frequent presenting symptoms
 - Fever
 - Irritability
 - Lethargy
 - Myalgia
 - Malaise
 - Poor feeding
 - Diarrhea, vomiting, sore throat, or upper respiratory tract symptoms may be present but are not severe.
 - Concomitant aseptic meningitis in infants is common and is not predicted by clinical symptoms.
 - The illness occasionally takes a biphasic course.
 - Relapse of fever associated with irritability within 1 or 2 days sometimes results in a second hospital admission for the same illness.

ETIOLOGY

- Enterovirus infection is initiated by viral replication in the lymphoid tissues of the oropharynx and intestines (days 1–3).
- Virions spread to the reticuloendothelial system at 3–5 days.
- The reason why serotypes have a tropism for certain tissues, such as poliovirus for the neurons of the brain and spinal cord, is unknown.

SIGNS AND SYMPTOMS

Natural history

- >90% of enterovirus infections are not apparent.
- When symptoms do occur, a variety of host factors and viral factors determine the clinical disease.
 - Nearly all protean syndromes associated with enteroviruses have been noted with numerous serotypes.
 - Certain diseases are associated more frequently with specific serotypes, eg, coxsackievirus A16 is the likely etiologic agent of an outbreak of hand-foot-mouth disease.
 - In the US, 15 serotypes accounted for almost 85% of all enterovirus identification reports over 1970 to 2005.
- Patient is symptom free for 1–3 days after infection.
 - A minor viremia follows.
 - The patient is contagious at 3–5 days.
 - Symptoms of disease are not yet apparent.
 - In subclinical infection, the process is halted at this point by host defenses.
- Respiratory tract disease
 - Nonexudative pharyngitis with or without lymphadenopathy is common.
 - Major cause of summertime sore throat
 - May be the initial manifestation of more severe disease that appears after an apparent recovery period of 1–3 days
 - Other respiratory syndromes are less common and are generally mild.
 - Bronchitis
 - Croup
 - Pneumonia

Enanthem and exanthem diseases

- Hand-foot-mouth syndrome
 - Toddlers
 - School-age children
- Hallmark signs
 - Relatively painless vesicles on a red base
 - Buccal mucosa
 - Tongue
 - Hands
 - Feet
- May spread to extremities and buttocks
- Patients usually have a low-grade fever and a sore throat.
 - Recovery within 1 week

Gastrointestinal disease

- Enteric disease is not a prominent clinical syndrome.
- Gastrointestinal symptoms are occasionally seen, but almost always with other signs of systemic enterovirus infection.
 - Nausea
 - Vomiting
 - Abdominal pain
 - Constipation
 - Diarrhea
 - Peritonitis
- Hepatitis or pancreatitis is usually part of a generalized enterovirus syndrome.

Acute hemorrhagic conjunctivitis

- Epidemic disease
- Marked by sudden onset of:
 - Severe eye pain
 - Photophobia
 - Tearing
 - Subconjunctival hemorrhage
 - Swelling
- Lasts 7–10 days
- Most often observed in middle-age individuals
 - Epidemics in schools have been noted.
- Neurologic sequelae may be seen in adults.
- Clinical improvement may take several months.

Aseptic meningitis

- Enterovirus infection is the major cause in countries that immunize against mumps.

- Most cases are sporadic, but epidemic aseptic meningitis does occur.
 - Usually associated with person-to-person spread
 - Summer camps
 - Playgrounds
 - Child care centers
- Typically occurs in school-age children
- Symptoms
 - Headache
 - Nuchal rigidity
 - Fever
 - Photophobia
 - Pharyngitis
 - Rash
 - Meningismus may be subtle or absent in up to 50% of patients.
- Infants often have nonspecific symptoms.
 - Fever or febrile seizures
 - Poor feeding
 - Cough or congestion
 - Diarrhea
 - Rash
- Course is usually mild.
 - Adults and older children may have headache severe enough to require narcotic analgesia.
 - Most patients recover within 2 weeks, but relapses may occur.
 - Early information suggested that as many as 10% of survivors of aseptic meningitis that occurred before 3 months of age suffered long-term neurologic sequelae, eg, speech and language delays.
 - Recent prospective outcome studies dispute this claim.
 - Older children recover completely.

Paralytic disease

- All cases of poliovirus infection acquired in the US since the 1990s were associated with vaccine-derived poliovirus strains and occurred in:
 - Young adults
 - Immunodeficient individuals
 - Unimmunized individuals
- Live polio vaccine has not been used in the US since 2000.
 - Any case of vaccine-derived or wild-type poliovirus infection is likely to have been imported and should be reported immediately to public health authorities.

Perinatal infection

- Enterovirus infection in neonates may occur as any of the syndromes seen in older children.
- Premature infants and newborns born without specific passively acquired maternal antibody may have a fulminant, rapidly fatal disease.
 - Begins as a syndrome of lethargy and poor feeding, with or without fever, indistinguishable from early bacterial sepsis
 - Progression is swift.
 - Multiorgan involvement
 - Hepatitis
 - Pancreatitis
 - Coagulopathy
 - Myocarditis
 - Encephalitis
- The virus in neonates is most often transmitted from mother to infant at or near the time of delivery.
 - Nursery outbreaks with fatal cases have been reported.
- Myocarditis and pericarditis occur, with a high mortality rate as part of the generalized disease of newborns.
 - <50% of older children and adults who have myocarditis die; severe sequelae have been reported.
- Orchitis and parotitis occasionally occur in association with coxsackievirus B infection and are differentiated from mumps only by laboratory studies.

Unusual enterovirus syndromes

- Encephalitis often occurs in severely ill neonates.
- Chronic meningoencephalitis in patients with hypogammaglobulinemia
- Dancing eyes-dancing feet (opsoclonus-myoclonus) syndrome

DIFFERENTIAL DIAGNOSIS

- Herpangina
 - Commonly diagnosed in a young child
 - Fever
 - Sore throat
 - Pain on swallowing
 - Enanthem may be noted early; it is soon succeeded by small vesicles or tiny white papules and then by ulcers.
 - Tonsils
 - Pharynx
 - Soft palate
 - Herpangina is differentiated from herpes simplex stomatitis by:
 - Milder fever
 - Primarily posterior oropharyngeal involvement
 - Epidemic seasonal occurrence

- Epidemic pleurodynia or Bornholm disease
 - Coxsackievirus B serotypes
 - Fever
 - Severe pain in the intercostal and abdominal muscles occurs in spasms lasting minutes to hours.
 - Succeeding episodes are milder than the first and may occur days or months later.
 - Rarely, symptoms are severe enough to prompt exploratory laparotomy.
- A variety of exanthems may be the sole or major manifestation of enterovirus infection.
 - Classic macular blanching
 - Rubella-like rash
 - Boston exanthem
 - Begins on the face and trunk and spreads to the extremities
 - Distinguished from rubella by lack of posterior auricular and suboccipital adenopathy
 - Unusual enterovirus rashes may be maculopapular, vesicular, roseola-like, urticarial, or petechial.
 - When such exanthems occur in conjunction with other enterovirus syndromes, such as aseptic meningitis, illness may be mistaken for a more serious disease, such as meningococcal meningitis.
- Meningitis-like illness
 - Diagnostic dilemmas are common.
 - Lyme meningitis occurs in a similar age group and during the same season as enteroviral meningitis and can usually be distinguished by symptoms not seen in enteroviral disease.
 - Presence of cranial neuropathy
 - Papilledema
 - Erythema migrans
 - West Nile virus infection in children is clinically indistinguishable from enteroviral meningitis.
 - Differential diagnosis depends entirely on virologic evaluation.
- Paralytic disease
 - Asymmetrical weakness, paralysis, or both, without sensory loss, differentiates enteroviral paralysis from Guillain-Barré syndrome.
 - Guillain-Barré syndrome is a life-threatening disease, usually involving paralysis of primary and accessory respiratory muscles or inflammation of the bulbar respiratory center.
 - Recovery of muscle function may continue for several months.
 - Infection with other enterovirus serotypes may also result in paralysis.

- Nonpolio enterovirus and West Nile virus associated paralysis are more common than classic poliovirus-associated disease.
 - Postpolio syndrome is seen decades after the initial infection.
 - A syndrome of progressive weakness and fatigue
 - Occurs in long-term survivors of paralytic poliomyelitis
 - Previously affected muscles are denervated as overburdened motor neurons eventually wear out.
 - Long-term outcome is unknown.
 - Most patients have only modest decline in function even >50 years after infection.
 - Associated fatigue may adversely affect the quality of life.
 - Parechovirus infection
 - Enteroviruses 22 and 23 have been reclassified as HPeV1 and HPeV2.
 - They share many clinical and epidemiologic features with the enteroviruses.
 - Disease appears in an endemic pattern.
 - Summer-fall seasonality
 - Most infections are reported in very young children.
 - Necrotizing enterocolitis
 - Nursery outbreaks
 - Neonatal sepsis syndrome
 - Febrile seizures
 - Paralysis
 - Rash
 - Respiratory illness
 - Death may occur in up to 10% of patients with recognized HPeV1 infection.
 - Asymptomatic disease is common.
 - >95% of adults show serologic immunity.
- probably explained by such incidental enterovirus identification.
- Classic enterovirus disease during a known epidemic season is interpreted more easily.
 - Isolating an enterovirus from the stool of an infant who has fever and cerebrospinal fluid (CSF) pleocytosis in the summer, without any other pathogen isolated, is presumptive evidence of enteroviral meningitis.
 - Nonpermissive sites are those from which virus is identified only during periods of disease, eg, blood, spinal fluid, skin vesicle.
 - Shedding of virus in these sites is usually brief.
 - Finding an enterovirus in a nonpermissive site is strong evidence that the virus is related to the concurrent clinical illness.
 - Almost all enterovirus serotypes can produce any enterovirus syndrome.
 - No disease is associated uniquely with any enterovirus serotype.
 - An enterovirus usually does not need to be identified beyond its actual presence.
 - Enterovirus presence from a nonpermissive site is sufficient to diagnose the origin of the illness.
 - In rare cases, both enteroviral and bacterial pathogens may be present in blood or spinal fluid.
 - Symptoms associated with the bacterial agent are more severe than those with the viral agent and dictate clinical management.
 - Virus isolation
 - Enteroviruses are isolated readily in cell cultures.
 - A positive culture can be noted as early as 18 hours.
 - Culture typically requires 2–5 days.
 - Suckling mouse inoculation is the only available method of isolating most coxsackievirus A serotypes.
 - It is expensive and difficult to obtain.
 - Viruses may be isolated from:
 - Throat swabs
 - Feces
 - CSF
 - Blood or serum
 - Skin vesicles
 - Tissue obtained at autopsy
 - Specimens from several sites increase diagnostic yield.
 - Predicting the pathologic stage of infection and, thus, the most likely source of the virus, is not always possible.

LABORATORY FINDINGS

- When obtaining specimens, understand the concept of permissive versus nonpermissive sites.
 - Permissive sites may harbor enteroviruses and may persist for weeks to months after infection, eg, nasopharynx, feces.
 - Identification of an enterovirus from a permissive site may be completely unrelated to the illness under investigation.
 - Vague, nonspecific symptoms or highly unusual or rare syndromes may be completely unrelated to enterovirus shed in the gastrointestinal tract.
 - Many disease associations with enteroviruses are

■ Aseptic meningitis

- Cerebrospinal fluid (CSF) analysis shows moderate pleocytosis with a predominance of lymphocytes, normal glucose levels, and slightly increased protein levels.
 - Predominant polymorphonuclear cell type
 - Cell counts >1000 cells/mm³
 - The percentage of mononuclear cells tends to increase over time.
 - In some children, the polymorphonuclear predominance persists for several days.
- In 20–50% of cases of proven aseptic meningitis in infants < 30 days of age, pleocytosis is minimal or absent.
- Other laboratory studies on CSF, such as C-reactive protein level or leukocyte aggregation, show too broad an overlap to distinguish reliably from bacterial meningitis.
- Results of rapid virus identification techniques may reduce empirical use of antibiotics and the length of hospitalization.

SPECIFIC TREATMENTS

- Intravenous immunoglobulin has been successful in eradicating chronic enterovirus infections in some patients with immunodeficiency diseases.
- Neonates with severe disseminated disease have been treated with infusions of intravenous immunoglobulin up to 1 g/kg and of specific serotype high antibody titer maternal plasma, with no discernible benefit.
- Pleconaril is a novel oral antiviral drug.
 - Active against picornaviruses, including enteroviruses
 - In clinical trials, infants, older children, and adults who have enterovirus-associated aseptic meningitis treated with pleconaril had a shorter illness and returned to normal activity sooner.
 - Older children reported a marked decrease in headache apparent as early as 24 hours after the initiation of treatment.
 - Pleconaril is available for compassionate use.
 - Effective in stopping replication of virus in immunodeficient individuals
 - Well tolerated
 - Few or no side effects are attributed to the drug.
 - Clinical enterovirus isolates resistant to pleconaril have not been detected.

WHEN TO ADMIT

- Neonates and infants <90 days with suspected enteroviral syndromes in whom systemic bacterial disease is not yet ruled out
- Disease significant enough to require subspecialty expertise, especially cardiac, immunologic, or neurologic disease
- Any enteroviral syndrome that has a rapidly progressive or atypical course
- Older children who have aseptic meningitis who require symptomatic treatment for severe headache or dehydration

WHEN TO REFER

- Neonates with any evidence of disseminated or rapidly progressive enterovirus-like infection
- Immunocompromised individuals who have chronic enterovirus-like syndromes
- Normal hosts who have atypical progression of enteroviral disease, especially those with neurologic or cardiac involvement

COMPLICATIONS

- Poliovirus infections lead to permanent paralysis of muscles innervated by affected neurons.
- Aseptic meningitis may lead to neurologic sequelae, such as speech and language delay.
- Enteroviral infections in neonates may be fatal.

PROGNOSIS

- Prognosis in neonates with enteroviral infection without passive immunity from mother is poor.

PREVENTION

- Attenuated live or killed poliovirus vaccines are the only preventive enterovirus preparations currently available.
 - Enhanced-potency inactivated poliovirus vaccine is the only choice for routine immunization in the US.
- In the prevaccine years, 0.2 mL/kg of pooled immune serum globulin given intramuscularly prevented or ameliorated poliovirus infection and might be indicated:
 - In nursery epidemics
 - For infants of mothers who develop a probable enterovirus disease within a few days of delivery

Enuresis

DEFINITION

- Urinary incontinence occurring when a child:
 - Is at least 5 years old *and*
 - Urinates in bed or on clothes
 - At least twice per week
 - For at least 3 consecutive months
- Variations
 - Diurnal
 - Nocturnal
 - Monosymptomatic nocturnal enuresis (MNE): no daytime symptoms to suggest lower urinary tract disorders
 - Polysymptomatic: associated with additional symptoms
 - Urgency
 - Frequency
 - Dribbling
 - Daytime enuresis
 - Primary
 - Children who have never had a period of sustained dryness
 - Secondary
 - Children who have been dry in the past
 - At least 6 months with nocturnal enuresis
 - At least 3 months with diurnal enuresis

EPIDEMIOLOGY

- Prevalence
 - Nocturnal
 - ~20% of children at 5 years of age
 - 6%–10% by age 7
 - 1%–3% persisting into late teens
 - Diurnal
 - 10% of 5-year-olds at least once every 2 weeks
 - Primary
 - Twice as common as secondary enuresis
- Sex
 - Nocturnal
 - 2–3 times more common in boys than in girls
 - Diurnal
 - More likely in girls than in boys
- Age
 - By 5 years of age, 24-hour/day bladder control should be achieved.
 - Children who are mentally disabled should reach a mental age of 4 years before they are considered enuretic.

ETIOLOGY

- Monosymptomatic nocturnal enuresis (MNE)
 - Relative nocturnal polyuria that exceeds the child's bladder capacity
 - In children with enuresis, bladder capacity has been found to be smaller at night compared with normal controls.
 - In some children with MNE, secretion of antidiuretic hormone is decreased at night, resulting in increased urine production.
 - Some children with MNE are more difficult to arouse from sleep than normal controls or children with primary nocturnal enuresis.
- Diurnal enuresis
 - Anatomic abnormalities
 - Urethral obstruction
 - Congenital (posterior urethral valves)
 - Acquired (foreign body)
 - Ectopic ureter in girls
 - Lesions involving the spinal cord
 - Vaginal reflux of urine
 - Girls who do not open the labia during voiding develop leakage of urine on standing.
 - Holding urine
 - Common in preschoolers and older children at school

RISK FACTORS

- Nocturnal enuresis
 - Family history
 - Strong hereditary component
 - Concordance rate of 19%–36% for dizygotic and 46%–68% for monozygotic twins
 - Sleep disorders
 - Obstructive sleep apnea (33%)
 - Resolves in 61% and decreases in 23% within 9 months after tonsillectomy and adenoidectomy
 - Nocturnal hypercalciuria
 - Aquaporin-2 dysfunction
 - Developmental/psychological factors
 - Delayed speech
 - Delayed walking
 - Early toilet training
 - Poor self esteem
 - Chronic anxiety

- Diurnal enuresis
 - Urinary tract infection
 - Cystitis causes spontaneous detrusor contractions
 - More common in children who have abnormal genitourinary anatomy

SIGNS AND SYMPTOMS

History

- Determine nocturnal or diurnal enuresis
 - Does the wetting occur during the day, the night, or both?
 - How often does wetting occur and at what times?
 - How often does the child void during the day and during the night?
- Determine primary or secondary enuresis
 - What age did the wetting start?
 - Has the child ever been dry?
 - Has the child had any dry spells?
 - How long did dry spells last?
 - What has been done about the symptom before this evaluation?
- Social situation
 - How does the family handle wet nights?
 - Does the child wear pull ups or is a plastic sheet used?
 - Who is responsible for laundering sheets and clothing?
 - Do siblings tease the child?
 - Is the child punished for wetting?
 - Any recent traumatic events or changes in social situation?
- Fluid intake before bedtime
 - How much and when does the child drink after supper?
- Sleep habits
 - Is the child difficult to wake from sleep?
 - Are there any signs of obstructive sleep apnea (mouth breathing, snoring, and restless sleep)?
- Daytime symptoms
 - Urinary frequency (normal = 4–7 times per day)
 - Urgency
 - Dysuria
 - Dribbling between voids
 - Straining with voids
 - Constipation
- Medical history including a thorough perinatal history
 - Spina bifida or meningomyelocele
 - Delayed developmental motor milestones

- Spinal trauma
- Psychological issues
 - Attention deficit disorder
 - Depression
 - Conduct disorder
 - Feelings about the enuresis
 - Motivation for doing something about it
- History of enuresis in 1 or both parents

Physical examination

- Physical exam is often normal.
- Examination should be thorough with focus on signs that may indicate any of the causes of enuresis.
 - Abnormal vital signs and growth parameters may indicate chronic disease.
- Complete neurologic examination
 - Gait
 - Muscle tone and strength
 - Deep-tendon reflexes
 - Sensory abnormalities
- Spinal examination may reveal subtle signs of spinal dysraphism
 - Dimples
 - Hair tuft
 - Skin discoloration
- Abdominal examination
 - Distended bladder
 - Constipation
- Rectal examination
 - Fecal impaction
 - Decreased rectal tone
- Flank examination
 - Lower abdominal tenderness may indicate urinary tract infection.
- Genitourinary examination
 - Rash
 - Adhesions
 - Trauma
 - Foreign body
 - Vulvitis
 - Vaginitis

DIFFERENTIAL DIAGNOSIS

- Focuses on excluding underlying disorders:
 - Urinary tract infection
 - Renal masses or renal diseases
 - Neurologic disorders
 - Neurogenic bladder
 - Detrusor instability
 - Spinal cord conditions
 - Structural genitourinary tract defects
 - Ectopic ureter
 - Posterior urethral valves
 - Constipation
 - Endocrine disorders
 - Diabetes mellitus
 - Diabetes insipidus
 - Hypercalciuria
 - Sickle cell disease
 - Drugs
 - Caffeine
 - Methylxanthines
 - Sexual abuse

DIAGNOSTIC APPROACH

- Diagnosis depends on a thorough history and physical examination.
- Imaging is indicated
 - In the presence of daytime symptoms
 - If initial laboratory evaluation, physical examination are abnormal

LABORATORY FINDINGS

- Urinalysis
 - Useful in MNE
 - Renal pathologic abnormality
 - Proteinuria
 - Hematuria
 - Red blood cell casts
 - Diabetes mellitus
 - Glucosuria
 - Diabetes insipidus, psychogenic polydipsia
 - Low specific gravity
- Urine culture
 - Diagnostic for urinary tract infection

IMAGING

- Ultrasound
 - Prevoid and postvoid renal and bladder
- Voiding cystourethrogram, urodynamic studies if ultrasound result is abnormal
- Spine MRI
 - To rule out possible spinal dysraphism

CLASSIFICATION

- Diurnal
- Nocturnal
 - MNE: no daytime symptoms to suggest lower urinary tract disorders
 - Polysymptomatic: associated with additional symptoms
 - Urgency
 - Frequency
 - Dribbling
 - Daytime enuresis
- Primary
 - Children who have never had a period of sustained dryness
- Secondary
 - Children who have been dry in the past

TREATMENT APPROACH

- Treat any underlying cause(s).
- Consider treatment of MNE in children 6–8 years of age.
 - Conservative measures
 - Careful/detailed explanation to parents and child
 - Alarm therapy is most effective.
- Pharmacotherapy depends on underlying cause.

SPECIFIC TREATMENTS

General

- Treat any underlying organic causes.
- If both daytime and nighttime symptoms are present, daytime symptoms should be treated first.
- Good voiding hygiene and habits should be reinforced.
- Primary and secondary nocturnal enuresis are treated similarly.
- In children <8
 - Conservative measures
 - Pull-ups
 - Plastic-lined bed sheets

■ MNE

- Treatment should be considered in a child 6–8 years of age.
 - Provide careful and detailed explanation of the condition to both parents and child in language that is easily understood.
 - Expect relapses.
- The combination of a motivated child and a cooperative family is the best predictor of a positive outcome.
- Alarm therapy should be considered in most patients 8 or older

■ Nonpharmacologic therapy

■ Conservative measures to minimize nocturnal polyuria:

- Decrease fluid intake several hours before bedtime.
- Void before bed to minimize nocturnal bladder volume.
- Consider awakening the child to urinate before the parents go to bed.
- Encourage the child to void often during the day and take the time to empty the bladder completely.

■ Charts for positive reinforcement

- Children fill out a chart depicting wet and dry nights symbolically, such as stars or the sun for dry nights and a cloud for wet nights.

■ Enuresis alarm therapy

- In some families, alarms may increase parental annoyance and place the child at risk for physical or emotional abuse.
- Many children will not initially awaken with the alarm and need a parent to assist in awakening.
- Relapses occur and do not preclude future success.
- Despite the evidence supporting the efficacy of alarm therapy, it is prescribed to <5% of children

■ Dry bed training

- Effective, comprehensive program combining:
 - Enuresis alarms
 - Positive practices
 - Waking routines
 - Personal cleanliness routine after enuresis
 - Bladder training

■ Pharmacotherapy

■ Desmopressin (DDAVP)

- First-line treatment often together with alarm therapy for MNE
- Efficacy
 - Produces faster improvement (2–3 months) by itself than alarm therapy alone
 - Not as effective as alarms over long term
 - Up to 80% relapse rate when desmopressin is stopped
 - Thus, if used, should be done so in conjunction with alarms

- Side effects
 - Nausea
 - Vomiting
 - Abdominal pain
 - Headache
 - Facial flushing
 - Elevated blood pressure
 - Chest pain
 - Tachycardia
 - Hyponatremia from water intoxication

- If treatment is successful, a 1-week interruption every 3 months is recommended to see if enuresis has resolved.
- Some patients who do not respond to the usual dose of DDAVP may respond when the dose is doubled.
- If no response occurs to medication alone, alarm therapy should be considered.

■ Oxybutynin

- Useful in treating daytime enuresis caused by detrusor overactivity
 - May be of benefit to enuretic children with restricted bladder capacity caused by bladder overactivity
- Efficacy
 - Ineffective as a single agent for primary enuresis
 - Combined therapy with oxybutynin and desmopressin produces more rapid results for nocturnal enuresis than single therapy with either desmopressin or imipramine.
- Also used to treat:
 - Urge syndrome
 - Hinman syndrome
 - Neurogenic bladder
- Side effects
 - Nausea
 - Vomiting
 - Abdominal pain
 - Diarrhea
 - Constipation
 - Urinary retention
 - Dry mucous membranes
 - Blurred vision

■ Imipramine/tricyclic antidepressants

- Efficacy
 - Minimal effectiveness in treatment of MNE
 - Relapse is common.

- Side effects
 - Potential for lethal effects in the setting of accidental or intentional overdose
 - Clinicians must use caution in prescribing these agents.
 - Families must be aware of dangerous potential of overdose and need for safe storage and supervision.
 - Nausea
 - Vomiting
 - Constipation
 - Blurred vision
 - Urinary retention
 - Cardiac arrhythmias
 - Hypotension

WHEN TO REFER

- Abnormal urinalysis findings suggestive of a metabolic disorder
- Concerns of neurologic bladder dysfunction
- Failure to respond to appropriate therapy

- Presence of any structural urinary tract abnormalities on imaging studies
- History of:
 - Recurrent urinary tract infections
 - Significant constipation and encopresis

PROGNOSIS

- Nocturnal enuresis
 - Annual spontaneous resolution rate is approximately 15%.
 - With alarm therapy
 - Long-term cure rate of MNE with alarm therapy
 - 25% by 2 months
 - 50% by 3 months
 - 90% by 6 months
 - 47% remain dry long term after alarm therapy is stopped.
 - Alarm therapy is not only a management modality but also a cure.

Envenomations

DEFINITION

- *Venoms* are complex chemical mixtures designed either for defending or for hunting.
 - Various venom delivery systems exist.
 - Most systems consist of specially evolved exocrine gland mechanisms to make and store venom and a sophisticated delivery apparatus.
- *Stings* are delivered through a posterior structure (stinger) and are primarily defensive.
- *Bites* refer to injection through structures associated with the mouth that are primarily for handling prey.
- *Envenomation* is the injection of venom through a bite or sting.

EPIDEMIOLOGY

- Incidence
 - In 2005 the American Association of Poison Control Centers National Poison Database reported 2,547,394 exposures.
 - 82,151 (3.2%) were a result of a bite or sting.
 - Of the 1460 total deaths recorded in the database, 7 (0.5%) were from bites and stings, and none involved children.
- Prevalence
 - Bites and envenomations ranked number 10 in all age groups in the National Poison Database but did not make the top 20 in children <6 years.

Hymenoptera

- Prevalence
 - Systemic reactions occur in <5% of patients.
 - Large local cutaneous reactions occur in 2.3–18.6% of the general population.
 - Biphasic anaphylactic reactions, characterized by the return of symptoms 6–10 hours after initial symptoms resolve, occur in up to 20% of patients.
 - Death by honeybee or wasp envenomation is rare, especially in children.
 - IgE-mediated type 1 anaphylaxis, although uncommon, is usually responsible for related deaths.
 - Massive envenomation involving hundreds of stings may also result in death.
 - Hymenoptera envenomation is the second-leading cause of anaphylactic reactions, after penicillin.
 - It accounts for more deaths in the US than any other envenomation.
- Fire ants
 - Fire ant envenomations are becoming an increasingly important concern in the US.
 - Systemic allergic reactions occur in ≤16% of patients treated for fire ant stings.

- Serious reactions, including anaphylaxis, occur in ≤2%.
- The literature suggests a 20–30% annual attack rate in areas where imported fire ants are endemic.
- The highest sting rate (close to 50%) occurs in persons <20 years.

Arachnids

- Approximately 50 spider species are of medical importance.
 - Most are venomous and can cause serious injury.
 - Fatalities from spider bites are rare.
- Scorpion envenomation may be life threatening in children.
 - Systemic manifestations tend to be more common in children <10 years.

Snakes

- Envenomations by snakes in North America are overwhelmingly caused by indigenous Crotalinae, also called *pit vipers*.
 - ~20–25% of pit viper bites are dry, meaning they do not result in envenomation.
- Coral snakes constitute <1% of envenomations.
- Nonindigenous snakes in zoos or kept as exotic pets are responsible for a small percentage of envenomations.
- All sea snakes are venomous; none inhabit the coastal waters of North America.
- Most bites in the US occur in the Southwest.
- Body area
 - Most bites are inflicted on the upper extremity, including fingers, hand, and arm.
 - Less commonly affected sites are the leg, foot, and torso.
- Mortality
 - The number of deaths from snakebite in the US ranges from 0 to 14 per year.
 - Most snakebite deaths are associated with absence of medical care, errors in medical management, or presence of an underlying medical condition.
 - Children are at increased risk for serious sequelae because of their lower body mass and relatively high venom dose compared with adults.

ETIOLOGY

Hymenoptera

- In the US, Hymenoptera are responsible for most insect stings.
 - Family Apidae (honeybees)
 - Family Bombidae (bumblebees)
 - Superfamily Vespidae (paper wasps, white-faced hornets, yellow hornets, and yellow jackets)
 - Superfamily Formicidae (harvester ants and native and imported fire ants)

- All Hymenoptera possess a stinger located posteriorly.
- Reactions may be either a direct effect of the venom or an IgE-mediated allergic reaction.

Winged Hymenoptera

- The sting apparatus, or aculeus, of wasps (vespids) and honeybees resembles a stylet with 2 shafts that pulls the stinger deep into the flesh.
- Unlike the honeybee, the vespids sting stylet is less likely to remain in the victim.
- Honeybees die after stinging; because vespids can withdraw their stingers, they can sting multiple times.
- Venoms of the winged Hymenoptera contain many different protein components that account for the observed reactions.

Ants

- Fire ants bite the skin of their victims with their mandibles, then arch their bodies to inject venom through a lancet-shaped stinger located at the distal end of their abdomen.
 - If undisturbed, they will sting repeatedly in a circular pattern, using their mandibles as a pivot, injecting venom with each sting.
- Harvester ants also bite the skin with their mandibles and envenomate their victim through a sting.
 - Their venom contains a larger fraction of protein constituents than fire ant venom and is more similar to other Hymenoptera venoms.

Arachnids

- Class Arachnida includes 2 orders: Araneae (spiders) and Scorpionidae (scorpions).
- Envenomations can result in significant morbidity, but deaths are rare.

Spiders

- A diverse group with approximately 40,000 species worldwide
- In North America, spiders most commonly involved in human exposures are:
 - *Loxosceles* species (brown recluse spider, also known as the *violin spider* or *fiddleback spider*); 11 species in the US, usually the Southeast and Southwest
 - *Latrodectus* species (black widow spider)
 - Tarantulas

Scorpions

- *Centruroides exilicauda*, or the black scorpion, is the only medically relevant species of scorpion in the United States.
 - Found in Arizona and adjacent southwestern states
- Its venom is a potent neurotoxin that activates neuronal sodium channels and results in excessive firing of affected neurons, including both the adrenergic and parasympathetic systems.

Snakes

- Venomous snakes of North America can be divided into 2 families: Viperidae (subfamily Crotalinae) and Elapidae.
 - Crotalinae, also called *pit vipers*, includes rattlesnakes, water moccasins or cottonmouths, copperheads, pygmy rattlesnakes, and massasauga rattlesnakes.
 - Elapidae includes coral snakes, as well as nonindigenous cobras and mambas.

Crotaline snakes (pit vipers)

- Their highly mobile, retractable, hollow fangs function like a hypodermic needle.
 - Usually penetrate to subcutaneous tissue, whereas the fangs of larger snakes penetrate dermal or subcutaneous structures and deposit venom into the muscle
- Venom is generally absorbed through the lymphatic system.
- Crotaline venom is a complex mixture of biologically active proteins and peptides capable of damaging vascular endothelial cells.
 - This leads to increased permeability to plasma and erythrocytes into the extravascular space and ultimately can result in hypotension and shock.
 - Venom is spread throughout the body as a result of the action of hyaluronidase and its integrity-reducing effect on connective tissue.
- Pit viper venoms are designed to immobilize and digest prey; prominent effects include:
 - Direct tissue injury resulting from enzymatic degradation
 - Local inflammatory responses exaggerated by metalloproteinases
 - Increased intracellular calcium in skeletal muscle, resulting in prolonged contraction and necrosis
 - Increased permeability of erythrocyte membranes, changing their morphology and potentially causing hemolysis
 - Damage to mast cell membranes, causing histamine release
 - Isolated defibrination caused by coagulopathy following fibrinolysis and thrombin-like peptide actions
 - Thrombocytopenia resulting from platelet aggregation at sites of tissue injury and from a direct effect of venom on individual platelets, particularly from rattlesnake venom.
 - Neurotoxins are present in varying degrees, notably in the Mojave and timber rattlesnakes, and can produce weakness, paralysis, and myokymia.
- The notion that juvenile rattlesnakes are more dangerous than adult snakes is a misconception.

Coral snakes

- Coral snakes tend to be small, secretive, and mild-mannered unless provoked.
- Coral snakes lack facial pits, are diurnal, and have fixed fangs and nearly round pupils.

- Bites may produce superficial scratches or definite fang marks; retroverted teeth gnaw or chew on their prey, making coral snakes difficult to shake off.
- Local tissue injury is uncommon.
- Venom causes paresthesias and paralysis by inhibiting acetylcholine receptors at the neuronal synapse.

RISK FACTORS

- An amount of venom that would not harm an adult may be disastrous for a child.

Hymenoptera

- The risk of a systemic reaction appears to be increased:
 - In patients with a history of multiple stings
 - In patients who are stung within a few weeks of a previous sting
- In patients with a history of anaphylaxis, the risk of anaphylaxis with subsequent stings is 35–60%.
- Atopic patients do not appear to be at greater risk of systemic complications, but the severity of their symptoms may be greater.
- History of a large local reaction does not reliably predict progression to systemic complications.
 - Risk of subsequent anaphylaxis after a large local reaction is approximately 5–10%.
- Children are at high risk because of their failure to perceive the risk and inability to escape.

Winged Hymenoptera

- Yellow jacket wasps are common near exposed food and garbage.
- If disturbed, any wasp or bee will sting in self-defense.
- Eyes, mouth, and nostrils may be selectively targeted.

Fire ants

- Trespassing into their territory or disturbing a nest will incite aggressive, swarming behavior, often resulting in multiple stings.
- Ants do sometimes attack victims indoors, especially following heavy rains.

Arachnids

- Most spiders are not aggressive and only bite in self-defense when:
 - Humans invade their territory.
 - The spider becomes lost in such items as bedclothes.
- Tarantulas kept as pets pose a risk to the unsuspecting child.
- *Loxosceles* (brown recluse spider) bites are usually the result of accidental contact.
- Scorpion stings usually result from accidental contact with a scorpion trapped in linen or clothing or during outdoor play.

Snakes

- The typical snakebite victim is a young white adult male who is bitten while handling or playing with a snake.
- Alcohol consumption increases risk.
- Most bites are inflicted on an upper extremity, including fingers, hand, and arm.

SIGNS AND SYMPTOMS

Winged Hymenoptera

- Local
 - The nonallergic reaction is a direct result of envenomation through mast cell degranulation and the production of a wheal-and-flare response causing:
 - Erythema
 - Swelling
 - Pain
 - Itching
 - In conjunction with these reactions, some patients may experience:
 - Headache
 - Nausea
 - Malaise
 - Skin and soft-tissue necrosis in the weeks after a Hymenoptera sting have also been reported.
 - Corneal stings
 - May result in damage through toxic and immunologic reactions
 - Stingers retained in the eye may cause corneal edema with striate and toxic keratopathy.
 - Immunologic reactions can result in extensive inflammation, uveitis, and inflammatory glaucoma.
- Systemic
 - Common systemic manifestations include:
 - Urticaria
 - Angioedema
 - Wheezing
 - Shortness of breath
 - Stridor
 - Nausea
 - Vomiting
 - Diarrhea
 - Abdominal pain
 - Malaise
 - Dizziness
 - Anaphylaxis

- Dysphagia
- Dysarthria
- Hoarseness
- Weakness
- Confusion
- Effects on the hematologic system include:
 - Hemolysis with associated hemoglobinuria and hemoglobinemia
 - Thrombocytopenia
 - Disseminated intravascular coagulation
- Multiple stings from Africanized bees may cause:
 - Hemolysis
 - Thrombocytopenia
 - Rhabdomyolysis (skeletal and myocardial)
 - Acute tubular necrosis
- Systemic symptoms typically develop within 24 hours, although delayed onset (2–6 days) has been reported.

Fire ants

- Local
 - Stings tend to be multiple and cause immediate local burning and itching.
 - Soon after, the area becomes erythematous and raised.
 - This reaction usually subsides after 30–60 minutes.
 - The classic pathognomonic finding of small, sterile pustules developing 4–24 hours later is more common with stings of imported fire ants.
 - Pustules may occur in rings or lines consistent with fire ant stinging behavior.
 - Pustules usually resolve over 3–10 days.
 - Some patients develop a large local reaction similar to that of other Hymenoptera stings.
 - The initial wheal-and-flare reaction evolves into an erythematous, pruritic, warm, indurated area around the sting site.
 - Large local reactions may progress over 48 hours and may not subside for 7 days.
 - The pathophysiologic mechanism of large local reactions is not clear and may be confused with cellulitis.
- Systemic allergic reactions are similar to those associated with other insects and include:
 - Bronchospasm
 - Angioedema
 - Urticaria
 - Pruritus
 - Laryngeal edema
 - Hypotension

- Anaphylaxis
- Seizures
- Mononeuritis
- Guillain-Barré syndrome
- Serum sickness
- Nephritic syndrome
- Worsening of preexisting cardiopulmonary disease
- Direct systemic toxic effects of fire ant venom are not well understood.
- No deaths have been attributed to date to fire ant venom.

Harvester ants

- Unlike imported fire ants, harvester ants do not leave characteristic skin lesions.
- Their sting resembles that of other insects and may be associated with allergic reactions.

Loxosceles (brown recluse spider)

- Local, cutaneous
 - The bite itself does not cause much discomfort and may go unnoticed.
 - A minor stinging or burning sensation may be felt at the site.
 - Erythema, pruritus, pain, and edema typically develop within 2–8 hours.
 - Symptoms may be followed in the next 24–48 hours by a blue-gray halo surrounding the erythematous center.
 - Vesicles or bullae containing serous or hemorrhagic fluid soon follow.
 - Local ischemia and necrosis result in formation of a black eschar within 7–10 days of the bite.
 - This necrotic area may expand slowly for weeks, especially in fatty areas that have delicate blood supplies such as the abdomen, buttocks, and thighs.
 - The eschar is shed after 2–5 weeks, and an ulcer remains that may take weeks to months to heal.
- Systemic manifestations of the bite are less common.
 - The most common symptoms are:
 - Fever
 - Chills
 - Malaise
 - Symptoms usually occur within 24 hours of the bite and also may include
 - Nausea
 - Vomiting
 - Diarrhea
 - Arthralgia
 - Urticaria or maculopapular rash

- Hemolytic anemia
- Disseminated intravascular coagulation
- Jaundice
- Renal failure
- Transverse myelitis
- Seizures
- Shock

***Latrodectus* (black widow spider)**

■ Local

- A bite may go unnoticed or may be experienced as a pinprick or burning sensation.
- 2 small puncture lesions may be visible.
- Within 30 minutes, pain develops at the site and in the regional lymph nodes.
- Central pallor at the bite site with surrounding erythema has been described.
- Inflammatory response is mild.
- An unusual reaction may include compartment syndrome, which may improve after antivenin administration.

■ Systemic

- The onset of systemic symptoms is frequently sudden, with crampy, skeletal muscle pains in the legs, abdomen, back, and chest and associated autonomic dysfunction.
- The most frequent systemic signs and symptoms are:
 - Generalized abdominal pain or back pain
 - Local or extremity pain
 - Hypertension
 - Diaphoresis
 - Isolated abdominal or chest pains
 - Nausea
 - Vomiting
 - Tachycardia
 - Restlessness
 - Salivation
 - Bronchorrhea
 - Priapism
 - Urinary retention
 - Periorbital edema
 - Tremor
 - Convulsions
 - Muscle symptoms
 - Target-shaped skin lesions
 - Irritability
 - Agitation

- Abdominal rigidity may mimic peritoneal irritation.
- Respiratory paralysis, heart failure, and myocarditis have been reported.
- Patients who do not receive antivenin may experience protracted symptoms that may last for several days to 1 week, including:
 - Fatigue
 - Weakness
 - Paresthesias
 - Generalized aches
 - Diaphoresis
 - Headache
 - Sleeplessness
 - Excessive sweating
 - Impotence
 - Mental status changes
 - Transient hemiparesis

Tarantulas

- Most bites are no more severe than a bee sting.
- Occasionally result in local erythema, swelling, and pain
- Nausea and vomiting may occur.
- Some genera (*Lasiadora*, *Grammostola*, *Acanthoscurria*, and *Brachypelma*) can release urticaria-producing hairs from their abdomen by rubbing their hind legs on the area.
 - Can result in local histamine release with mild pruritus
 - Itching can last for weeks.
 - Hairs may cause considerable itching and discomfort in eyes or airways.

Scorpions

- Not all stings result in clinical evidence of envenomation.
- Patients may have both adrenergic and cholinergic symptoms.
- Local
 - Pain at the sting site with or without paresthesias is common.
 - In mild envenomations, pain may be the only symptom and may account for such manifestations as unexplained crying in infants.
 - Local erythema and swelling may surround a small puncture wound, but the sting site is often unidentifiable.
 - Paresthesias and pruritus are frequent.
- Systemic
 - Manifestations can be dramatic and usually develop within 60 minutes of sting.
 - Tachycardia or bradycardia
 - Central nervous system dysfunction, a finding that is rare in adults

- Severe hypertension in one third to two thirds of the victims
 - Can be associated with acute hypertensive encephalopathy
 - May not respond to medical management
- Heart failure
- Acute lung injury
- Pulmonary edema
- Neurologic toxicity includes excessive cholinergic stimulation resulting in salivation, sweating, and vomiting.
- Profound sialorrhea
- Skeletal muscle findings include twitching or jerking of the extremities, which may be severe enough to be mistaken for seizure activity.
- Rhabdomyolysis
- Nystagmus
- Seizures and agitation

Crotaline snakes

- Local
 - Presence of ≥ 1 fang marks, typically with ragged edges that may be obscured as a result of trauma resulting from first-aid attempts
 - Pain in $>90\%$ of envenomations
 - Edema
 - Ecchymosis
 - Erythema develops 15 minutes to 4 hours after the bite.
 - Hemorrhagic toxins in pit viper venom may cause blood to ooze from the puncture sites, and hemorrhagic bullae may develop.
 - Muscle necrosis
 - Lymphangitis and lymphadenopathy with tender regional lymph nodes and warmth in the injured body part as a result of lymphatic spread of venom
- Systemic
 - Malaise
 - Weakness
 - Lightheadedness
 - Diaphoresis
 - Visual disturbances
 - Nausea
 - Vomiting
 - Syncope
 - Myokymia
 - Perioral paresthesias
 - Metallic or minty taste

- More severe systemic effects include:
 - Altered sensorium
 - Acute respiratory distress syndrome
 - Respiratory depression
 - Hemodynamic instability leading to circulatory collapse
 - Renal failure
- A consumptive coagulopathy is frequently present in serious envenomations and is characterized by:
 - Hemolysis
 - Unmeasurable international normalized ratio (INR) and activated partial thromboplastin time
 - Hypofibrinogenemia
 - The presence of fibrin degradation products
 - Thrombocytopenia ($<20,000$ cells/mm)
 - Generalized hemorrhage
- When combined with defibrination, venom-induced thrombocytopenia may appear as disseminated intravascular coagulation.
- Mojave rattlesnake venom may cause more neurotoxicity, specifically myokymia, than the venom of other rattlesnakes.

Coral snakes

- Local
 - Erythema and local pain are transient or absent.
 - Most patients have evident fang marks.
- Systemic
 - May be delayed for 12 hours
 - May appear suddenly
 - May include bulbar paralysis with:
 - Ptosis
 - Dysphagia
 - Dysarthria
 - Excessive salivation
 - Paresthesias
 - Euphoria or apprehension
 - Drowsiness
 - Dizziness
 - Weakness
 - Confusion
 - Nausea
 - Vomiting
 - Diaphoresis
 - Muscle tenderness or fasciculations
 - Tremors

- Altered sensorium
- Drowsiness
- Ophthalmoplegias that cause visual disturbances
- These manifestations may be followed by:
 - Seizures
 - Respiratory paralysis
 - Pulmonary hemorrhage
- It can be unclear which findings are the result of the venom itself and which are the result of hypoxia.
- Envenomation by other insects or reptiles
- Fat herniation with infarction
- Pressure sore
- Pyoderma gangrenosum
- Poison oak or ivy
- Cutaneous manifestation of gonorrhoea or herpes simplex
- Diabetic ulcer
- Purpura fulminans
- Erythema nodosum
- Erythema multiforme
- Stevens-Johnson syndrome
- Abusive or self-inflicted trauma

DIFFERENTIAL DIAGNOSIS

Hymenoptera

Flying Hymenoptera

- Differential diagnosis of the local reaction includes:
 - Other arthropod envenomations
 - Puncture wounds with reactive erythema or cellulitis
 - Simple cellulitis
- Differential diagnosis of systemic reactions include:
 - Any other cause of allergic reaction
 - Reactive airway disease
 - Infectious processes
- Other causes of stridor, wheezing, and allergic reaction should be considered if a sting site cannot be identified.
- A stinger may sometimes be found at the sting site, which usually indicates a honeybee sting or, in some cases, a yellow jacket sting.
- Most patients cannot reliably identify the insect that stung them.

Fire ants

- Large local reactions must be carefully examined to differentiate them from cellulitis.
- Absence of lymphadenopathy and lymphangitis supports the diagnosis of large localized reaction.

Arachnids

- Differential diagnosis includes:
 - Other arthropod bites
 - Skin infections
 - Injury caused by chemical and physical agents

Loxosceles (brown recluse spider)

- In the absence of a definitive history of spider bites, other diagnostic possibilities must be considered, such as:
 - Emboli
 - Thrombi
 - Focal vasculitis

- Cutaneous anthrax has been misdiagnosed as *Loxosceles* envenomation.
- Other species of spiders have been implicated in the cause of necrotic skin lesions similar to *Loxosceles*.
 - *Argiope* (orb weaver spider)
 - *Chiracanthium* (sac spider)
 - *Lycosa* (wolf spider)
 - *Phidippus* (jumping spider)
 - *Tegenaria agrestis* (hobo spider)
- The temptation to diagnose all necrotizing skin lesions as *Loxosceles* bites should be avoided.
- Positive identification of the spider is important not only for correct diagnosis but also to understand true clinical course of *Loxosceles* envenomation.

Latrodectus (black widow spider)

- Causes of acute abdominal pain should be part of the differential diagnosis.
- Close resemblance of the autonomic hyperactivity seen after black widow spider bites and those seen in organophosphate poisoning

Scorpions

- 2 factors make establishing the correct diagnosis difficult.
 - The sting site may not be identifiable
 - The child may not be able to communicate the history of a sting clearly.
- Some of the differential diagnostic possibilities are:
 - Seizure disorder
 - Intraabdominal process
 - Phenothiazine or cholinergic poisoning
 - Allergic reaction
- Asthma has been misdiagnosed in some children with wheezing and respiratory distress.

- Progression of symptoms is not predictable.
 - Progression to serious symptoms usually occurs in <5 hours, if at all.
 - Numbness, tingling, and pain may persist for 2 weeks.
 - Duration of symptoms has been found to be inversely related to the age of the patient.

Snakes

- The helpfulness of identifying the type of snake is controversial.
- The bite reflex in recently killed or decapitated snakes can remain intact, rendering them capable of biting even when they are dead.
- If medically necessary, a herpetologist from a zoo or aquarium may be able to help with positive identification.

LABORATORY FINDINGS

Hymenoptera

- No specific laboratory test is useful in the acute management of Hymenoptera stings.

Arachnids

- *Loxosceles* (brown recluse spider)
 - No current clinical laboratory study can confirm the presence of arachnid venom-related necrosis.
 - Several research tests, including enzyme-linked immunosorbent assay and passive hemagglutination inhibition test, have been studied but are not in clinical use.
 - Complete blood count, coagulation profile, electrolytes, and renal function should be monitored in systemic illness.
- *Latrodectus* (black widow spider)
 - No specific laboratory test helps establish a diagnosis.
 - Leukocytosis and hyperglycemia are common.
 - Creatine phosphokinase may be increased as a result of increased muscle activity.
 - Serum calcium levels are normal.
- Scorpions
 - No confirmatory laboratory test exists.
 - Leukocytosis, cerebrospinal fluid pleocytosis, and increased creatine phosphokinase have been reported.

Snakes

- Crotaline snakes (pit vipers)
 - Only of minor assistance to assess severity
 - May be useful in determining whether envenomation has occurred
 - Tests include:
 - Complete blood count with differential
 - Erythrocyte morphology (to assess for spherocytosis)

- INR and prothrombin time
- Plasma thromboplastin time
- Fibrinogen level
- Fibrin-split products
- Platelet count
- If these studies reveal any abnormalities, or if the patient has clinical symptoms, then envenomation must be assumed and the clinician should perform:
 - Analysis of electrolytes
 - Blood urea nitrogen
 - Blood type and cross-match
 - Urinalysis
- Coral snakes
 - Do not mandate routine laboratory screening
 - If respiratory insufficiency is suspected, obtain:
 - Transcutaneous pulse oximetry
 - Arterial blood gases

IMAGING

- Rarely indicated, except in the case of a scorpion sting, where echocardiography can reveal hypodynamic ventricular motion with decreased systolic performance

DIAGNOSTIC PROCEDURES

- Rarely indicated, except in the case of a scorpion sting, where electrocardiographic changes are common and include:
 - Ischemic electrocardiographic pattern
 - Nonspecific ST-T changes or ST elevation or depression consistent with myocardial infarction

TREATMENT APPROACH

- The primary care clinician must be aware of local venomous species and be able to recognize and treat the injuries caused by them.
- In North America, venomous species include:
 - Arthropods
 - Bees
 - Wasps
 - Hornets
 - Ants
 - Arachnids
 - Spiders
 - Scorpions
 - Snakes
 - Pit vipers
 - Coral snakes

SPECIFIC TREATMENTS

Winged Hymenoptera

■ Stinger removal

- Traditional teaching advocates stinger removal by scraping with a hard-edged object, such as a credit card, to prevent pressure on the venom sac.
- However, experimental data show that removal of the stinger with the fingers does not increase envenomation.
- Rapid removal of the stinger by any means is most effective in minimizing envenomation.
- Removal of bee stingers embedded for >1 minute will not reduce envenomation; most venom empties from detached honeybee stings within 10–20 seconds.

■ Nonallergic local reactions

- Nonallergic local reactions require symptomatic treatment, including:
 - Cool compresses (ice should not be placed directly on the skin)
 - Elevation
 - Local wound care
- No further evaluation is necessary.
- If local itching is bothersome
 - An oral histamine-1 (H₁) antagonist, such as diphenhydramine, may help.
- Local allergic reactions require similar care as nonallergic reactions.
- For very large cutaneous reactions
 - Prednisone (0.5–2 mg/kg/day given in 1–4 doses for 3–5 days) may be useful.

■ Acute management of corneal bee sting includes:

- Preventing secondary infection with broad-spectrum topical antibiotics
- Reducing inflammation with topical corticosteroids
- Treating anterior uveitis
- Early detection and treatment of inflammatory glaucoma
- Providing pain relief
- Surgical removal of the embedded stinger is controversial.
- Pulse corticosteroids may prevent permanent loss of vision.

■ Medications

- Mild systemic allergic reactions
 - Diphenhydramine or another H₁-antihistamine
 - Supportive care
 - Observation

- Severe systemic allergic reactions

– Epinephrine

- 0.01-mL/kg dose of 1:1000 aqueous epinephrine solution is injected subcutaneously.
- The original dose should not exceed 0.3 mL, but may be repeated in 15 minutes.
- Susceptible individuals should carry epinephrine self-administered kits when they go outdoors.
- After kit is used, medical help should be sought because the effect of the drug is short lasting.

– H₁-antagonists

– Corticosteroids

– Intensive supportive care

- Severe systemic reactions from direct toxic effects of massive envenomation require:

– Intensive supportive care

– Therapy similar to that for anaphylactic reactions

– Careful monitoring for:

- Rhabdomyolysis
- Thrombocytopenia
- Cardiac arrhythmias
- Renal failure
- Possible dialysis

Fire ants

■ Mild local reactions are treated conservatively with

- Cool compresses
- Oral antihistamines
- Wound care

■ Large local reactions may require oral antihistamines and systemic corticosteroids.

■ Systemic allergic reactions are treated similarly to those from any cause.

■ Epinephrine is the mainstay of therapy, coupled with:

- H₁-antagonists
- Systemic corticosteroids
- Vigorous supportive care as appropriate

Harvester ants

■ Treatment is the same as that for other Hymenoptera stings.

Loxosceles (*brown recluse spider*)

■ Management is controversial.

■ Serial observation, wound cleansing, cool compresses, splinting of the affected extremity, and tetanus prophylaxis are often-suggested measures.

■ Symptomatic relief with antipruritics and analgesics may be useful in some cases.

■ Different therapies have been proposed, including:

- Systemic corticosteroids
- Antibiotics
- Antihistamines
- Colchicine
- Dapsone
- Electric shock
- Hyperbaric oxygen
- Metronidazole
- Surgical excision
- Skin graft

■ Delay surgical repair of skin defects until necrotic demarcation is discrete and no further spread occurs, which takes about 8 weeks.

Latrodectus (black widow spider)

■ Most black widow spider bites require only:

- Cool compresses
- Elevation of the affected extremity
- Tetanus update (if needed)
- Analgesics

■ In more severe cases, suggested treatments include:

- Oxygen
- Cardiac monitoring
- Intravenous access

■ Muscle cramps may be relieved with opiates and muscle relaxants.

- The following have been used, with varying results:
 - Diazepam
 - Methocarbamol
 - Calcium gluconate (the efficacy of 10% calcium gluconate has been questioned)

■ Patients who do not receive antivenin will gradually improve over the next 12–48 hours.

- Some patients may experience protracted symptoms.

■ *Latrodectus* antivenin of equine origin neutralizes venom from all related species.

- Patients should be tested for horse serum hypersensitivity before administration to prevent death from anaphylaxis.
- Consider in cases of:
 - Severe envenomation with evidence of respiratory distress, marked hypertension, and cardiovascular compromise
 - Pregnancy
 - Protracted symptoms that do not respond to analgesic and muscle relaxants

- Response is usually dramatic after antivenin infusion.
- Administration of antivenin may decrease length of hospital stay and prevent lingering neurologic complications.

Tarantulas

- Local wound care and a tetanus update are all that is needed in most cases.
- Antihistamines and oral analgesics may be helpful.
- Adhesive tape or irrigation with saline solution may be used to remove the urticaria-producing hairs from the skin.

Scorpions

- There is no standard therapy.
- Treatment is primarily supportive, with the use of cold compresses and analgesics.
- Severe cases require aggressive supportive therapy.
- Antihypertensives have been used, including:
 - Calcium-channel blockers
 - Hydralazine
 - Prazosin
 - Captopril
- Afterload reducers are front-line therapeutic agents for hypertension, including:
 - Angiotensin-converting enzyme inhibitors
 - Calcium-channel blockers
 - Prazosin
- Concern about reflex tachycardia has led some clinicians to favor prazosin and captopril.
- The use of diuretics for pulmonary edema is controversial.
- Atropine may be used with caution if cholinergic symptoms become severe.
 - Atropine may improve hypersecretion, obviating the need for more aggressive therapy.
- Treatment should be guided by thorough hemodynamic monitoring.
- Benzodiazepines are generally administered for seizures and agitation.
- Corticosteroid therapy has been shown to be of no benefit.
- Currently, no scorpion antivenin is approved by the US Food and Drug Administration.
- Clinical trials are ongoing of an equine-derived antigen-binding fragment (Fab₂) antivenin.

Snakes

- First aid
 - Observe the approximate size and characteristics of the snake only if this can be done without danger of remaining within striking range.
 - Move the patient as little as possible.
 - Mark the victim's skin with a pen to indicate the area of swelling and the time and repeat every 15 minutes.

- Remove rings, watches, and constrictive clothing.
- Immobilize the affected limb by splinting as if for a fracture, keeping the limb below the level of the heart.
- Regardless of early symptoms, transport the victim to the nearest medical facility at a safe speed.
- Avoid use of:
 - Ice (tissue damage)
 - Aspirin (anticoagulation)
 - Alcohol or sedative drugs (vasodilation)
 - Stimulants, such as caffeine (acceleration of venom absorption)
- As soon as possible, start basic life support, including volume expansion and Trendelenburg position for patients with hypotension.
- Patients should be kept as calm as possible during transport because agitation hastens venom distribution.
- Controversial forms of first aid
 - Incision and suction should not be performed.
 - Constricting bands that impede blood or lymph flow should not be used.
 - Loose-fitting bands placed in an effort to reduce lymphatic flow have been advocated but have not been shown to be of clear benefit.
 - Although the routine use of an extractor device for field care is not advocated, patients with an extractor or suction device in place should not remove it until they arrive at a health care facility.
- In-hospital care
 - Medical history of known envenomations should include
 - Size and species of the snake
 - Circumstances of the bite (eg, through clothing, alcohol related)
 - Number of bites and body area affected
 - First-aid methods used
 - Time of bite and transport time
 - Previous snakebite history
 - Allergy to horse- or sheep-derived products (eg, drugs, food, animal products)
 - Tetanus immunization status
 - Coexisting medical conditions, with special attention paid to the cardiovascular, pulmonary, and neurologic systems, should be factored into clinical management.
 - Snakebites from exotic (nonindigenous) species, which usually occur in zoo employees or in those illegally keeping the snake as a house pet, should be part of the history-gathering process.
 - Clinical presentation and medical management of an exotic bite may differ from bites of North American poisonous snakes.
- Local therapy
 - Local wound care includes:
 - Gentle irrigation
 - Nonconstrictive immobilization
 - Elevation of the bitten extremity
 - Close observation
 - Circumferential measurements at several points along the affected limb should be performed at baseline and regularly repeated.
 - Intercompartmental pressures should only be measured when the patient's symptoms are consistent with compartment syndrome.
 - In cases of suspected compartment syndrome, clinical diagnosis requires objective evidence of increases in compartment pressure to >30 mm Hg.
 - Fasciotomy has not been shown to be beneficial; it may lengthen hospitalization and cause significant long-term morbidity.
 - Digital dermatomy may be indicated on clinical grounds.
- Use of antivenin
 - Crotaline polyvalent immune Fab (ovine) antivenin (CroFab)
 - CroFab has replaced the horse serum-based antivenin ACP as the drug of choice.
 - CroFab is a purified ovine polyvalent Fab immunoglobulin fragment product produced by immunizing sheep with venoms of 4 crotaline snakes.
 - Indicated in treatment of patients with minimal or moderate North American crotaline envenomation
 - Administer within 6 hours.
 - Delayed use of CroFab has been reported with successful correction of significant toxicity incurred after crotaline envenomation.
 - Antivenom use should proceed simultaneously with supportive therapy.
- Steps in using antivenin
 - Prepare to manage anaphylaxis.
 - Anaphylactic reaction to CroFab is uncommon but has been reported.
 - All patients receiving antivenin should be monitored, and 2 sites for intravenous access should be considered—1 for the antivenin and 1 for emergency drugs and fluids.
 - Intravenous epinephrine, diphenhydramine, and plasma expanders, as well as cardiorespiratory support, must be readily available.

- Test for sensitivity.
 - Skin testing is not needed for the administration of CroFab.
 - Pretreatment with epinephrine, H₁-receptor antagonists, and H₂-receptor antagonists, or corticosteroids is not routinely recommended unless the patient has a history of hypersensitivity.
- Start the infusion.
 - Dosing is based on estimated venom injected; no dose adjustment is required for children.
 - Each vial of CroFab is reconstituted with 10 mL of sterile water for injection.
 - After reconstitution, the entire dose (4–6 vials) is diluted in 250 mL of 0.9% sodium chloride and mixed by swirling gently.
 - Use reconstituted and diluted product within 4 hours.
 - Dose should be infused intravenously over 60 minutes with careful observation for allergic or anaphylactoid reactions.
- Repeat infusion.
 - If initial control is not achieved, the loading dose of 4–6 vials should be repeated until initial control of envenomation syndrome has been achieved.
 - After initial control has been achieved, giving additional 2-vial doses every 6 hours for 3 doses is recommended.
 - Additional doses may be necessary, as guided by clinical status and consultation with a clinician experienced in treating snakebite or a regional poison control center.
- CroFab is administered with the goal of achieving initial control, defined as the reversal or marked attenuation of all effects of venom.
 - This process encompasses 3 general areas.
 - Coagulation abnormalities
 - Systemic effects
 - Local effects (progression of swelling)
 - Volume depletion should be aggressively treated before initiating antivenin therapy because of the risk of rapid vasodilatation and third-space fluid loss associated with anaphylaxis.
 - Anaphylaxis associated with antivenin therapy should be treated in the standard manner.
- Antivenom use in copperhead bites
 - Envenomations by copperheads are not considered to be as serious as rattlesnake or cottonmouth bites.
 - Clinically significant local effects may occur, suggesting that these bites should be cautiously managed.
 - Copperhead victims treated with CroFab had marked improvement in local tissue effects, but clinical failures and recurrence of local effects also occurred.
- The use of CroFab in copperhead bites has been shown to halt local tissue effect.
 - More data are needed to define the role of CroFab for treatment of copperhead envenomation.
 - The suggested dosing of CroFab in copperhead envenomation is a single loading dose.
 - Additional maintenance doses after initial control did not reduce incidence of recurrent swelling in 1 study.
 - After administering the loading dose, monitor patient for progressive swelling, coagulopathy development, and systemic effects.
 - The need for additional antivenin should be evaluated on a case-by-case basis, and poison control center consultation is advised.
- Antivenom use in children
 - CroFab use in children 14 months to 13 years of age has been found to be safe and effective.
 - Children with crotaline envenomation may be more likely to experience serious effects as a result of the larger ratio of venom to serum volume.
 - Any child with a crotaline envenomation that meets the criteria for antivenin therapy should receive the same dosing regimen as adults.
 - Weight-based dosing is not appropriate for antivenin neutralization because the dose should reflect venom load, not patient size.
- Additional therapeutic measures
 - Pain control
 - Adequate pain control allows rehabilitation to begin as early as possible to prevent contractures.
 - Opioid analgesics should be used cautiously if the venom is known to have neurotoxicity (eg, Mojave rattlesnake).
 - Nonsteroidal antiinflammatory agents should be used with caution, especially in patients with evidence of coagulopathy.
 - Infection control
 - Infection is rare in the absence of severe necrosis.
 - Good wound care is usually sufficient to prevent secondary infection.
 - Antibiotic prophylaxis is not currently suggested.
 - Corticosteroids
 - They should not be routinely administered to snakebite victims.
 - They are efficacious in patients who develop serum sickness after antivenin administration.
 - Tetanus prophylaxis
 - *Clostridium tetani* are not part of the mouth flora of snakes.
 - Updating the patient's tetanus immunization is the only necessary intervention.

Coral snakes

- First aid
 - Do not use cryotherapy, incision and suction (including the Sawyer extractor), or constricting bands.
 - Australian pressure mobilization technique has been used.
 - Wrapping the entire bitten extremity with a crepe bandage, elastic bandage, or article of clothing as tightly as possible, then splinting it
- Use of antivenin
 - Antivenom effective against Eastern and Texas coral snake venom is used if a patient has definitely been bitten or if any signs or symptoms develop.
 - Guidelines are based on the judgment that risks of intravenous hyperimmune horse serum are offset by potential prevention of respiratory paralysis if therapy is not immediately administered.
 - Skin testing is of little benefit in making therapeutic decisions.
 - 3–5 vials of antivenin are mixed in 250–500 mL of normal saline, and 1–2 mL is given intravenously over 3–5 minutes.
 - The medical team must be prepared for anaphylaxis and have necessary drugs and equipment at bedside.
 - If the patient does not show any signs of an allergic reaction, then the remainder of the solution is infused slowly as tolerated.
 - An additional 3–5 vials of antivenin-saline mixture may be infused if signs and symptoms do not abate.
 - >10 vials of antivenin are rarely required for coral snake envenomations.
- Additional therapeutic measures
 - Prophylaxis for infection and tetanus as for pit viper bites is not indicated.
 - Additional measures may become necessary if aspiration pneumonia develops.
 - Patients should be aware that muscular weakness may persist for 3–6 weeks.
- Supportive therapy
 - Elective intubation before impending respiratory paralysis tends to prevent aspiration pneumonia and should be performed if any signs of bulbar paralysis develop.
 - Patient should receive cardiac and pulse oximetry monitoring (if not intubated), and intravenous access should be established.

Nonindigenous snakes

- If a bite from an exotic species is suspected, the suggested approach includes:
 - Local wound care
 - Supportive care
 - Consultation with experts at a regional poison control center

WHEN TO ADMIT

- Hymenoptera
 - Severe systemic allergic reactions or severe systemic reactions caused by massive envenomation
- *Loxosceles* (brown recluse spider)
 - Secondary infection requiring intravenous antibiotics
 - Inability to provide adequate wound care at home
 - Severe systemic symptoms
- *Latrodectus* (black widow spider)
 - Severe systemic symptoms
 - After use of antivenin
- Tarantulas
 - Significant comorbidity
 - Inability to tolerate oral fluids
- Scorpions
 - Cardiac or neurological toxicity
 - Severe systemic signs or symptoms
- Pit vipers
 - Chance of envenomation
- Coral snakes
 - Chance of envenomation
 - All victims of potential coral snake envenomation should be admitted to an intensive care unit and monitored closely for a minimum of 12 hours.
 - Effects of envenomation may develop precipitously hours after a bite and are not easily reversed once they occur.
 - If the snake cannot be found, then victims of bites suspected to be from coral snakes should be admitted to the hospital for 12 hours of observation.

WHEN TO REFER

- Concerns about allergic reactions, mostly from insects, result in referrals to allergy and immunology specialists.
- Hymenoptera
 - Children who experience extracutaneous systemic reactions should be referred to an allergist for risk analysis and possible venom immunotherapy.
- Fire ants
 - Patients who have experienced severe allergic reactions to stings should be referred to an allergist or immunologist for venom immunotherapy assessment.
- *Loxosceles* (brown recluse spider)
 - Surgical intervention necessary for wound care
- *Latrodectus* (black widow spider)
 - Before administration of antivenin
- Tarantulas
 - Hairs in eyes that are not easily removed

- Scorpions
 - Considered use of antivenin
- Pit vipers
 - Considered use of antivenin
 - Surgical intervention necessary for wound care
- Coral snakes
 - Patients who experience full-thickness tissue damage may require referral to a surgeon.
 - Physical or occupational therapy may be needed to encourage joint mobilization of the affected extremity.
 - Anticipated need for airway control or intensive care unit monitoring

FOLLOW-UP

Hymenoptera

- Patients with systemic reactions who respond completely to therapy in the emergency department should be observed for 6–8 hours after the sting for a possible delayed anaphylactic episode.
- Patients with severe symptoms, including airway, cardiovascular, or pulmonary compromise, or persistent symptoms should receive a short course of corticosteroids.
- At the time of discharge after a systemic reaction, all patients should be given a prescription for a self-administered epinephrine kit.
 - Patient or caretaker should be instructed in its proper use before discharge from the emergency department.
 - They should be encouraged to wear a Medic Alert bracelet indicating allergy to insect stings.
- Patients should be taught how to prevent further stings.
- The perception that children generally outgrow Hymenoptera sting allergies is not always true.

Snakes

- After pit viper envenomation, all patients should be observed in the emergency department for a minimum of 8 hours.
 - Patients who remain asymptomatic and whose coagulation study results are normal may be discharged with instructions to return if symptoms develop.
 - Symptomatic patients and all patients treated with antivenin should be admitted to the intensive care unit.
- Preservation of joint mobility and muscle strength is a goal after pit viper envenomation.
 - Pain control may be needed in the weeks after discharge.
 - If the patient received antivenin, then serum sickness should be discussed.
 - The patient should be taught how to monitor for this syndrome.

COMPLICATIONS

Winged Hymenoptera

- Severe neuroophthalmic complications include:
 - Optic neuritis
 - Loss of vision
 - Cataracts
- Respiratory and cardiovascular complications are observed more often in adults than children.
- In rare cases, serum sickness, vasculitis, encephalopathy, neuritis, and renal disease with or without rhabdomyolysis have been observed.
- Renal failure or death may occur when 20–200 wasp stings or 150–1000 or more honeybee stings have been inflicted.

Fire ants

- Secondary bacterial infections from excoriation and open erosions are not uncommon after fire ant stings.
 - These infections are usually minor and localized.
- Sepsis may result from superinfected lesions.

Snakes

- Shock
 - Patients may have a marked decrease in intravascular volume as a result of:
 - Hemorrhage
 - Third-space fluid loss
 - Vomiting
 - Diaphoresis
 - Crystalloid replacement should begin immediately in envenomated patients.
 - In the case of hypotension caused by extravascular fluid shifts or hemorrhage, antivenin therapy should be considered.
- Fluid and electrolyte abnormalities
 - May be caused by extensive third-space fluid loss
 - Electrolyte and urine output monitoring with fluid and electrolyte replacement with crystalloid is essential.
- Hematologic complications
 - Treatment of thrombocytopenia and anemia (caused by hemolysis) may require multiple transfusions.
 - Transfusions of fresh-frozen plasma and cryoprecipitate may be required in severely envenomated patients.
 - Therapy with blood products is rarely effective in the absence of antivenin therapy.
 - Treatment with coagulation factors may worsen coagulopathy by adding more substrate for unneutralized venom, thus increasing the levels of degradation products, which are also anticoagulants.

- Thrombocytopenia often corrects with antivenin therapy alone, and clotting factor levels rarely improve when blood products are provided without antivenin.
- Disseminated intravascular coagulopathy caused by snake-bite does not respond to heparin; antivenin is the treatment of choice.
- Recurrence phenomena
 - Worsening status caused by return of venom effect after it has been successfully abated with antivenin
 - *Local recurrence* is return of swelling after initial control is achieved.
 - *Coagulopathic recurrence* is return of thrombocytopenia or hypofibrinogenemia after initial control is achieved.
 - All CroFab recipients should be reevaluated at least once during the 5 days after antivenin treatment.
 - The decision to administer additional antivenin in patients who develop delayed coagulopathy must be made on a case-by-case basis.
 - An isolated hematologic abnormality after envenomation poses a low risk for significant bleeding.
 - *Multicompartment coagulopathies* (critically abnormal INR, activated partial thromboplastin time, fibrinogen, platelets) may represent a risk for bleeding and may warrant additional antivenin consideration.
 - Conservative management for this scenario may be adequate; clinicians should consult with someone experienced in treating crotaline envenomations or with a regional poison control center.
- Serum sickness
 - Delayed reactions to antivenin are thought to be the result of serum sickness–like reactions attributable to immune complexes due to an immune response against antivenin proteins.
 - May occur 7–21 days after completion of treatment
 - Few patients require hospitalization.
 - Oral corticosteroids (prednisone) should be prescribed at the first signs (usually urticaria and pruritus) and should be continued for 24 hours after all symptoms have subsided and then tapered over 72 hours.
 - If necessary, diphenhydramine or hydroxyzine may be added to control pruritus.

PREVENTION

Hymenoptera

- Do not disturb nests or hives—have someone else remove them.
- Do not wear perfume, cologne, scented sunscreens, or hairspray when outdoors.
- Use footwear when outside.
- Avoid garbage sites, orchards, fields of clover, and flowerbeds.
- Be extra careful when gardening, and cover the hands and body.
- For patients receiving immunotherapy, avoid trips outdoors if medical help is not readily available or until maintenance immunotherapy is established.
- Install screens on windows and doors to prevent insects from entering the home.

Spiders

- Prevention is mostly focused on caution in areas inhabited by spiders.
- A clean house greatly decreases the risk of spider bite.
- Wear long-sleeved shirts and gloves when outside gardening or long pants tucked into socks when hiking.
- Insect repellents that contain meta-*N,N*-diethyltoluamide (DEET) or picaridin offer some protection.

Snakes

- Children should not approach, disturb, play with, capture, or kill any snake.
- Snakes frequently can be found under rocks, boulders, fallen trees, fences, rubbish piles, and boats that have been left on shore for several hours; in tall grass and heavy underbrush; or sunning themselves on logs, boulders, trees, walls, or cliffs.
- The striking distance of a snake is roughly half its length.
- The striking reflex remains intact for up to 1 hour after the snake has died.
- Rattlesnakes are nocturnal feeders and are active after dark.
 - Never gather firewood after dark.
 - Camp should be set up on open ground.
 - Camp should not be set up near wood, rubbish piles, swampy areas, or the entrance of a cave.
- Once someone is bitten, everyone present should get away from the snake as quickly as possible.
 - The benefit of identifying the snake is small compared with the risk of additional bites.

Epistaxis

DEFINITION

- Defined as acute bleeding from the nostril, nasal cavity, or nasopharynx
 - Relatively common and usually self-limited occurrence in childhood
 - Can be extremely distressing to children and parents when profuse or recurrent
 - Can at times be a sign of a more serious condition
- Anterior epistaxis
 - Accounts for >90% of epistaxis in children
 - Almost all the blood exits anteriorly through the nares.
 - Much easier to visualize and control than posterior bleeding
- Posterior epistaxis
 - Most of the blood flows into the nasopharynx and mouth, making the degree of bleeding difficult to assess.
 - Bleeding generally much more profuse than anterior bleeding
 - More likely than anterior bleeding to lead to hemodynamic instability

EPIDEMIOLOGY

- Incidence
 - 5–14% of Americans have a nosebleed each year.
 - Approximately 10% of those affected seek care from a physician.
- Prevalence
 - In a study of the epidemiology of epistaxis in US emergency departments (EDs) from 1992–2001:
 - Approximately 1 in 200 of all ED visits were for epistaxis.
 - Peaks were found in children <10 years and in older adults age 70–79 years.
 - 83% of cases were from atraumatic causes.
 - A higher proportion of visits occurred during the winter months.
 - Likelihood of experiencing ≥ 1 nosebleed during childhood
 - ~30% of children from birth to age 5 years
 - 56% of children age 6–10 years
 - 64% of children age 11–15 years
- Sex
 - More common in boys than in girls
- Age
 - Bimodal distribution, with peaks in children <10 years and in adults >50 years
 - Rare under age 2 years
 - Peaks between age 3 and 8 years
 - Infrequent after puberty

MECHANISM

- Blood supply to the nose originates in both the internal and the external carotid arteries.
- Nosebleeds are usually classified as anterior or posterior on the basis of the location of the vessels that are the source of the bleeding (see Definition).
- Anterior epistaxis
 - Kiesselbach plexus is primary source.
 - Made up of anastomoses of vessels in the anterior 2–3 cm of the nasal septum, just 0.5 cm from the tip of the nose
 - Also known as *Little area*
 - Rich vasculature under thin mucosa
 - Area most exposed to trauma and dry air
- Posterior epistaxis
 - Woodruff plexus, specifically the sphenopalatine, is the primary source.
 - Convergence of the sphenopalatine, posterior nasal, and ascending pharyngeal arteries, located over the posterior middle turbinate

HISTORY

- Evaluation should begin with a careful history and physical examination.
- Note season and associated environmental conditions.
- History of nose picking or blunt trauma
- Unilaterality
 - May suggest a local anatomic cause
- Unilateral foul-smelling discharge in a young child
 - May indicate a retained foreign body
 - One-half of children treated in an ED for intranasal foreign body admitted placing the object in the nose; therefore, young children should be questioned.
- Unilateral progressive obstruction
 - Suggests a mass
- Presence and character of any associated rhinorrhea
 - Clear, watery rhinorrhea with associated sneezing suggests allergic rhinitis .
 - Mucosal discharge with cough suggests upper respiratory infection.
- Degree of chronicity
 - May suggest an inherited systemic cause
- History of petechiae or easy bruising or other mucosal bleeding (eg, menorrhagia, postsurgical)
 - May point to a bleeding disorder
- Associated fever or pallor
 - May suggest leukemia

- History of medication use
 - Particularly aspirin or nonsteroidal antiinflammatory drugs (NSAIDs)
- Family history of bleeding symptoms or diagnosed disorder
 - Useful in identifying children with a bleeding diathesis
- Migraine headaches
 - A recent study showed a significant association between migraine headaches and recurrent epistaxis, suggesting a common pathogenesis.

PHYSICAL EXAM

- Blood pressure and pulse if the history suggests significant acute or chronic blood loss
- Careful examination of the nose
 - Attempt to identify the source of any active bleeding.
 - Note any discharge, obstructing mass, or foreign body.
- The neck should be examined for the presence of a mass.
- The skin should be checked for petechiae or unusual location or number of ecchymoses.
- If the child is ill, perform a full examination, including a search for lymphadenopathy and hepatosplenomegaly.

DIFFERENTIAL DIAGNOSIS

Local causes

- >1 factor often plays a role in the bleeding.
 - Trauma from nose picking or rubbing
 - Accounts for most cases in children, particularly in association with inflammation from infection or allergy
 - Blunt external trauma
 - Generally acute and self-limiting
 - Should prompt evaluation for fractures of the facial bones and an anterior septal hematoma
 - Trauma from a foreign body
 - Occasional cause in toddlers
 - Often results in unilateral bleeding accompanied by foul-smelling or bloody discharge
 - Upper respiratory infection and allergic rhinitis
 - Resultant rhinorrhea leads to digital manipulation or forceful sneezing and nose blowing.
 - Vascular congestion and mucosal irritation promote easy injury to the blood vessels of the anterior septum.
 - Association in children of positive allergy skin tests and recurrent epistaxis
 - Low environmental humidity, especially in winter months
 - Deviated nasal septum
 - Can contribute to recurrent epistaxis by causing a change in normal airflow, leading to mucosal drying and irritation

- Intranasal drugs (steroids, cocaine)
- Neoplasms
 - Uncommon in children but should be considered in certain circumstances
 - Polyps in children are usually associated with cystic fibrosis.
 - Juvenile nasopharyngeal angiofibroma
 - Benign vascular tumor originating in the lateral nasopharynx
 - Occurs only in male adolescents because of its hormonal sensitivity
 - Recurrent epistaxis is the most frequent presenting symptom.
 - Unilateral progressive obstruction or discharge are clues to the diagnosis.
 - Rhabdomyosarcoma of the nasal cavity or nasopharynx
 - A rare malignant cause of severe episodic epistaxis
 - May be associated with signs of eustachian tube dysfunction, such as unilateral middle ear effusion
 - Nasal hemangioma
 - Rare
 - Should be considered in infants
 - Nasopharyngeal carcinoma
 - Extremely uncommon but serious disease in children
 - Epistaxis is the presenting symptom in approximately 50% of children.
 - Nearly always accompanied by a neck mass or neck pain

Systemic causes

- Should be considered whenever nosebleeds are recurrent or persistent in the absence of any obvious local cause
- Epistaxis scoring system (see table Epistaxis Scoring System)
 - Frequency, duration, amount, age at onset, and bilateral epistaxis have been used to determine which patients should be evaluated for an underlying bleeding disorder.
- Hematologic disorders (congenital or acquired)
 - Platelet disorders
 - Coagulation defects
 - Thrombocytopenia
 - Almost always accompanied by petechiae or ecchymoses
 - Idiopathic thrombocytopenic purpura
 - Most common cause of isolated thrombocytopenia in otherwise healthy children
 - Presents as acute mucosal hemorrhage, often epistaxis, in approximately 30% of patients
 - Bleeding is rarely severe.

Epistaxis Scoring System^a

Component		Score ^b
Frequency	5–15/yr	0
	16–25/yr	1
	>25/yr	2
Duration	<5 min	0
	5–10 min	1
	>10 min	2
Amount^c	<15 mL	0
	15–30 mL	1
	>30 mL	2
Epistaxis history and age^d	33%	0
	33–67%	1
	>67%	2
Site	Unilateral	0
	Bilateral	2

^aFrom: Katsanis E, Luke K, Hsu E, et al. Prevalence and significance of mild bleeding disorders in children with recurrent epistaxis. *J Pediatr*. 1988;113(1):73–76. Copyright © Elsevier 1988.

^bMild=0–6; severe=7–10

^cEstimate of average blood loss per episode, based on fractions or multiples of teaspoons, tablespoons, or cups.

^dProportion of the child's life that nosebleeds have been recurrent (>5/yr).

- Can be an adverse reaction to a variety of medications, including anticonvulsants, such as carbamazepine and chemotherapeutic agents
- Leukemia
 - Epistaxis is rarely the first symptom.
 - Should be considered in an ill-appearing child with epistaxis, especially with fever, pallor, lymphadenopathy, or hepatosplenomegaly
- Platelet dysfunction from aspirin or NSAIDs can predispose the individual to epistaxis.
- Bernard-Soulier syndrome
 - Disorder of platelet aggregation
 - Occasional diagnosis in children evaluated for isolated epistaxis

- Primary coagulation defects
 - May result in persistent and long-standing epistaxis
 - Positive family history is often present.
 - Up to one-third of children with isolated recurrent epistaxis have a diagnosable coagulopathy.
 - Von Willebrand disease (VWD)
 - The most commonly identified inherited coagulopathy
 - 60% of patients with VWD have recurrent epistaxis.
 - Other mucosal bleeding (eg, menorrhagia or post-surgical or postdental extraction) is also a common symptom in older children and adolescents.
 - Hemophilia
 - Much less common
 - In mild cases, may cause isolated epistaxis (factor VII, VIII, IX, or XI deficiency)
- Acquired coagulopathies
 - Unlike adults, rare cause of epistaxis in children
 - Include various liver diseases (eg, chronic active hepatitis) with consequent depletion of clotting factors
 - An acquired form of VWD has been described in children receiving valproic acid.
- Vascular abnormalities
 - Osler-Weber-Rendu disease (hereditary hemorrhagic telangiectasia)
 - Autosomal-dominant disorder of the blood vessel walls
 - Characterized by the progressive development of cutaneous and mucosal telangiectasias
 - >90% of affected patients have recurrent and progressively worsening epistaxis.
 - Present at a mean age of 12 years
 - Gastrointestinal bleeding and pulmonary arteriovenous malformations occasionally also occur in childhood.
- Primary isolated hypertension
 - Has not been clearly associated with epistaxis in children, except in the context of renal failure

LABORATORY EVALUATION

- The need for and extent of laboratory testing should be guided by history and physical examination.
- Frequent and prolonged episodes may warrant ruling out anemia caused by blood loss.
- Complete blood count
 - Always indicated in the presence of petechiae or unusual ecchymoses to rule out thrombocytopenia
 - Will help rule out leukemia in an ill child with pallor, fever, lymphadenopathy, or hepatosplenomegaly

- Prothrombin time and partial thromboplastin time
 - Useful as initial screening tests for VWD
 - Results may be within the normal range in some patients with VWD.
 - Further evaluation with von Willebrand factor studies may be necessary.

IMAGING

- Rarely indicated
- Plain films can rule out associated fracture of the facial bones in the setting of blunt trauma.
- Computed tomography should be considered if a mass is thought to be present.

DIAGNOSTIC PROCEDURES

- Identifying the source of posterior bleeding must be done by an otolaryngologist using a flexible fiberoptic nasopharyngoscope.
 - Sedation may be required for younger patients.
 - Endoscopic visualization may also reveal such causes as foreign bodies, tumors, or sinusitis.
 - In older, more cooperative patients, a rigid endoscope may be used.
- Cauterization of a posterior bleeding site can be performed under general anesthesia.
 - Posterior packing can be done with gauze or even urinary catheter balloons.
 - Other types of packing include premade nasal tampons or balloons.

TREATMENT APPROACH

- Management can be divided into 3 general phases.
 - Initial first aid measures
 - Often performed at home
 - Should also be the first line of treatment on presentation to the physician
 - Parents should be educated about the home management of an acute nosebleed.
 - Acute management of persistent bleeding
 - May be initiated by a pediatrician in an office or ED
 - May have to be continued by an otolaryngologist if initial measures are unsuccessful
 - May involve medical or surgical intervention
 - Long-term preventive treatment of recurrent epistaxis
 - Including evaluation and treatment of underlying causes
- Once acute episode of epistaxis has resolved:
 - Look for predisposing factors or causes.
 - Implement respective preventive strategies or specific management.

- If allergic rhinitis is a factor:
 - Appropriate testing and medical management are indicated.
 - Treat with inhaled topical nasal steroids.
- For sinusitis, oral antibiotics are prescribed.

■ Management of recurrent nosebleeds

- Common challenge for physicians
- No consensus on the frequency or severity of episodes that warrant medical intervention
- Common interventions for less severe cases include:
 - Cautery with silver nitrate
 - Antibiotic nasal creams
 - Nasal saline spray
 - Coating of the interior nose with ointments, such as petroleum jelly
- Less frequently advocated topical agents include:
 - Oxymetazoline
 - Desmopressin
 - Antifibrinolytics
 - Fibrin sealants (most recently)
- More invasive measures rarely indicated in children:
 - Arterial embolization for refractory bleeding
 - Arterial ligation for recurrent epistaxis
- A recent Cochrane review of the literature on interventions for recurrent idiopathic epistaxis in children (<16 years) exposed the lack of evidence for current treatments.
 - No single treatment (neomycin-chlorhexidine antiseptic cream, silver nitrate cautery, petroleum jelly) was found to be superior to another or to no treatment.
 - No serious adverse effects were experienced.
 - Silver nitrate cauterization caused pain in children despite topical anesthesia.
 - High-quality studies are needed to ascertain which, if any, of these remedies are most effective.

SPECIFIC TREATMENT

First aid measures

Direct pressure

- Many health care providers and patients are unaware of the proper spot for applying direct pressure to the nose to stop a nosebleed.
 - Vast majority of bleeding episodes originate anteriorly, in the Little area.
 - Apply pressure to the alar nasi using the first and second fingers.
 - Pressure should be held by pinching the nostrils without interruption for 5–10 minutes.

- The child should sit up with the head bent forward slightly.
 - Minimizes blood dripping posteriorly and being swallowed, which can cause nausea and hematemesis
- Some providers suggest placement of ice packs on the forehead, bridge of the nose, nape of the neck, or upper lip to promote vasoconstriction.
 - Only theory supports this practice.

First aid in the health care setting

- Initial treatment measures should occur simultaneously with assessment and history taking.
- Basic equipment should be readied.
 - Examination
 - Flashlight *or*
 - Otoscope with speculum *or*
 - Headlight and nasal speculum suction
 - Vasoconstriction
 - Oxymetazoline *or*
 - Phenylephrine *or*
 - Epinephrine (1:1000)
 - Topical anesthesia
 - 4% lidocaine *or*
 - 3–5% cocaine ethyl chloride solution
 - Hemostasis
 - Silver nitrate sticks
 - Vaseline strip gauze
 - Oxycellulose sponges *or*
 - Gelatin sponges *or*
 - Nasal tampons
 - Additional items
 - Antibiotic ointment or cream
 - Cotton pledgets, gauze
 - Gown, gloves, mask
- Most anterior nosebleeds in children will stop after basic first aid.
- If bleeding persists, then additional measures are available.
 - As in any acute situation, an initial ABCD assessment should be made.
 - Evaluation for major hemorrhage includes evaluating for tachycardia, hypotension, and orthostasis.
- Attempt to locate the source of bleeding.
 - Bleeding has often stopped by the time medical attention is sought.
 - The child should be asked to blow out all clots.
 - If this is not possible, blood in the nose can be suctioned out.

- To try to visualize the source of bleeding, use:
 - A flashlight, while applying gentle upward pressure to the nasal tip *or*
 - An otoscope with speculum *or*
 - A headlight and nasal speculum
- Inspect the anterior septum first.
- Anterior bleeding on the septum, or lateral wall, should be evident by:
 - Active bleeding
 - Clots
 - Crusts
 - Ulcerations
 - Prominent blood vessels
- If an anterior source is not found and posterior bleeding is suspected, an otolaryngologist should be consulted immediately.
 - Posterior bleeding is usually profuse and difficult to stop.

Topical vasoconstrictors

- Use if anterior bleeding has not ceased with application of pressure alone.
- Oxymetazoline, phenylephrine, or epinephrine (1:1000) can be applied with a cotton pledget to:
 - Shrink the nasal mucosa to improve visualization
 - Possibly slow down or stop the bleeding
- Pressure, again by pinching, should be applied for another 5–10 minutes.

Chemical cauterization

- Next step to attempt to stop persistent hemorrhage
 - Local anesthesia with 4% lidocaine should be administered with a cotton pledget for 5 minutes to reduce the discomfort of cauterization.
 - Insert and open a nasal speculum.
 - Using adequate lighting, apply silver nitrate on applicator sticks to the bleeding point.
 - Can be rolled over the site for several seconds
 - May have to be repeated several times to achieve hemostasis
 - Silver nitrate does not work well in pools of blood; therefore, suction may be necessary to keep the area dry.
 - A gray eschar will form at the cautery site.
 - Remove excess silver nitrate with cotton or gauze to minimize dispersion by nasal secretions and resulting injury to intact mucosa.
 - Caution should be used to avoid cauterizing too large or too deep an area or both sides of the septum.
 - Can lead to septal perforation

- After cauterization
 - Prescribe antibiotic cream or ointment to apply to the area twice a day for 5 days to prevent crusting and infection.
 - Hydration with saline or ointment should continue until healing is complete (approximately 1–3 weeks).
 - Nasal trauma and forceful nose blowing should be avoided.
- Otolaryngologists may use electrocautery as another hemostatic measure.
 - Cannot be performed with topical anesthesia alone

Nasal packing

- Nasal packing may be required if anterior bleeding persists despite direct pressure or nasal cautery.
 - Packing is uncomfortable, requires subsequent removal (usually after 2–3 days), and can cause additional mucosal injury.
 - All types of packing and sponges should be impregnated or coated with antibiotic ointment to prevent toxic shock syndrome, a reported complication of anterior and posterior nasal packing.
- Petroleum jelly gauze
 - Layered into the anterior nose
 - Provides a tight pack
- Oxycellulose or gelatin sponges
 - Absorbable and do not require later extraction
 - Do not apply a great deal of pressure to the bleeding site but are usually adequate for most nosebleeds
- Commercially available nasal tampons made of a dehydrated polyvinyl polymer sponge:
 - Are inserted dry and then expand with blood or added saline partially to fill the nasal cavity
 - Come in many sizes and can be cut to fit a child's nasal cavity
 - Must be removed, usually after 3–5 days, and have a tendency to adhere to the nasal lining
- Prophylactic antibiotics
 - No clear evidence exists to prove that they reduce the incidence of serious infection.
 - Studies have shown that they reduce gram-negative bacterial growth.
 - Common practice is to prescribe them for any patient with nasal packing.
 - May also help prevent sinusitis that can result from stasis of nasal secretions when packing is in place
 - Recommended antibiotics include:
 - First-generation cephalosporins *or*
 - Penicillins with activity against penicillinase-producing organisms

WHEN TO REFER

- Ear, nose, and throat
 - Urgent referral
 - Profuse, uncontrollable bleeding
 - Inability to locate source of bleeding
 - Posterior bleeding
 - Assistance with anterior packing
 - Recurrence of bleeding after initial ED measures
 - Nonurgent referral
 - Removal of anterior packing
 - Recurrent epistaxis
 - Evaluation for structural lesions (ie, granulomas, tumors, polyps)
 - Treatment of specific lesions
- Hematology
 - Abnormal coagulation laboratory profile
 - Severe, persistent, or recurrent bleeding
 - Bleeding from >1 site, based on history or physical examination
 - Bleeding that required blood transfusion or iron therapy
 - Family history of coagulopathy

WHEN TO ADMIT

- Airway compromise or hemodynamic instability on presentation

FOLLOW-UP

- Posterior nasal packing in place
 - Must be monitored in an intensive care unit for airway obstruction and respiratory compromise

PREVENTION

- In a dry environment
 - Normal saline nasal spray to humidify the nasal cavity
 - Spray should be used 4–5 times a day.
 - Home humidifier
 - Increased moisture:
 - Helps prevent the accumulation of crusts, which are often the impetus for nose picking
 - Keeps scabs soft, allowing them to stay in place longer, promoting healing of underlying mucosal injury
- Local trauma should be minimized.
 - Discourage nose picking, forceful rubbing, or blowing of the nose.
 - Trim fingernails.

Esophageal Caustic Injury

DEFINITION

- Caustic injury of the esophagus is a major, but preventable, pediatric health concern.
- Injuries continue despite federal legislation mandating preventive packaging and labeling, injury-prevention programs, and laws restricting potency and availability of caustic substances.

EPIDEMIOLOGY

- Prevalence
 - 20% of caustic ingestions result in esophageal injury.
 - In 2003 cleaning substances were the second most frequent substance involved in pediatric exposures (9.7% of the total).
- Age
 - 39% of exposures occur in children <3 years.
 - 52% occur in those <6 years.
- Sex
 - Among victims <13 years, most caustic injuries occur in boys.
 - This sex association is reversed during adolescence, when intentional suicide attempts are more prevalent.

ETIOLOGY

- Many household agents can cause caustic exposures.
- Acids and alkalis both can induce pylorospasm, resulting in pooling of the agent in the gastric antrum and extensive damage to this area.

Acids

- Hydrochloric acid
 - Swimming pool cleaners
 - Toilet bowl cleaner
 - Metal cleaner
- Hydrofluoric acid
 - Rust remover
- Sulfuric acid
 - Automotive batteries
 - Drain cleaners
- Acids have rapid esophageal transit and previously were thought to cause more damage to the stomach or intestine.
- Recent studies have revealed that acids cause extensive esophageal injury as well.
- Acids cause coagulation necrosis, resulting in superficial eschar formation, which may limit penetration into deeper tissues.

Alkalis

- Ammonia
 - Toilet bowl cleaners
 - Hair dyes
 - Floor strippers
 - Glass cleaners
- Sodium hydroxide
 - Anhydrous Benedict's reagent tablets
 - Detergents
 - Laundry powders
 - Paint removers
 - Drain cleaners
 - Button batteries
 - Oven cleaner
- Sodium borates, carbonates, and phosphates
 - Detergents
 - Electric dishwasher detergents
 - Liquid laundry detergents and dishwasher solutions usually cause mild esophageal injury that heals without complication.
 - Water softeners
- Sodium hypochlorite
 - Bleaches
 - Household bleaches rarely have been associated with severe esophageal injury because of their low concentration of sodium hypochlorite.
 - Household cleaners
 - Mildew remover
- Solid alkalis, such as anhydrous Benedict's reagent tablets and batteries, tend to lodge and cause focal burns and perforations at point of impaction.
- Strong alkalis cause liquefaction necrosis.
 - This allows penetration of the corrosive agent transmurally through esophagus and into adjacent mediastinal tissues.
 - Heat production and small-vessel thrombosis resulting from the reaction compound initial damage.
- Ensuing inflammatory reaction can result in:
 - Gangrene
 - Perforation
 - Mediastinitis
 - Fibrosis
 - Severe contracture of the esophagus
- Lye is the lay term for the alkaline agent found in most cleaning substances.
 - Liquid lye is the most common cause of esophageal caustic injury and associated with the greatest morbidity.

- Lye is odorless, tasteless, and viscous, which facilitates ingestion by children and suicidal teens and adults.
- High viscosity retards transit through the esophagus.
 - Tissue injury is rapid in the first few minutes, but lye can continue causing further injury for hours.
- Lesions caused by lye injury occur in 3 phases.
 - Acute necrotic phase
 - Usually lasts 24–96 hours after ingestion
 - An intense inflammatory reaction surrounds nonviable tissue.
 - Ulceration and granulation phase
 - Begins 3–5 days after injury
 - Superficial necrotic tissue sloughs and is replaced by an ulcerated and inflamed granulation bed.
 - Healing tissue lacks collagen deposition and has very little tensile strength.
 - Although perforation can occur at any point during the first 2 weeks after injury, during this phase (10–12 days) the esophagus is most vulnerable.
 - Scarring and cicatrization phase
 - Begins during the third week after injury
 - Wound contracture may lead to stricture formation and alteration of lower esophageal sphincter pressure, leading to gastroesophageal reflux.

SIGNS AND SYMPTOMS

- No single symptom, sign, or combination has been found to predict accurately the degree of esophageal injury after corrosive ingestion.
- Symptoms
 - Searing or burning pain of mouth and lips
 - Drooling or hypersalivation
 - Difficulty with swallowing
- Absence of pain does not exclude significant injury.
- Epiglottic or vocal cord edema may result in:
 - Stridor
 - Dysphonia
 - Aphonia
- Substernal or back pain usually results from esophageal disruption and mediastinitis.
- Acute epigastric pain may indicate gastric perforation.
- Presence of fever is strongly correlated with significant injury.
- Absence of oral burns does not exclude an esophageal burn injury.
 - 20–45% of patients with esophageal burns have no evidence of oral burns.

- Oropharyngeal damage does not reliably indicate esophageal involvement.
 - 70% of persons with oropharyngeal injuries do not have esophageal lesions.
- Bleeding can result from mucosal sloughing, with persistent ooze from the exposed submucosa or muscularis.
 - Life-threatening hematemesis from development of an aorto-esophageal fistula is rare.

DIFFERENTIAL DIAGNOSIS

- Every attempt should be made to identify the agent ingested.
 - In the case of young children, parents are usually aware of the offending agent and often bring the container to the emergency department.
 - With suicidal intent, the caustic agent may be unknown.

IMAGING

- Chest radiography may identify:
 - Concomitant aspiration
 - Subcutaneous cervical emphysema
 - Pneumomediastinum, corroborating perforation
- Circumferential burns limit full visualization.
 - Contrast radiography with water-soluble medium followed by thin barium may be required for identification of grade III injuries (see Figure 29 on page F11).

DIAGNOSTIC PROCEDURES

- Laryngoscopy
 - After the patient is stabilized, the airway and gastrointestinal tract are inspected.
 - Initial examination should include laryngoscopy.
 - Evidence of a supraglottic or epiglottic burn indicates a risk for airway obstruction and requires endotracheal intubation.
- Endoscopy
 - Once upper airway integrity is confirmed, endoscopy should be performed to establish extent of injury.
 - Done even in the absence of oropharyngeal burns
 - >50% of victims of caustic ingestion have no evidence of damage to the gastrointestinal tract.
 - Many have extensive esophageal damage in the absence of oropharyngeal lesions.
 - Presence of a third-degree burn to the hypopharynx precludes advancement of the endoscope beyond that level.
 - Flexible esophagoscopy is preferred to minimize risk of iatrogenic perforation.
 - Most endoscopists will advance the scope only to the level at which maximal injury is encountered.
 - Others advocate full examination of stomach and, if possible, duodenum.

- Endoscopy allows examination of superficial mucosa only, making it difficult to differentiate between grade IIb and III lesions.

CLASSIFICATION

- The degree of injury can be graded similarly to that of thermal skin burns and holds similar prognostic implications.
 - Grade 0: normal
 - Grade I: mucosal hyperemia and edema
 - Grade IIa: mucosal hemorrhage, exudate, superficial ulceration, sloughing, and pseudomembrane formation
 - Grade IIb: same as IIa, plus deep discrete or circumferential ulcerations
 - Grade IIIa: deep ulcerations and necrosis, massive hemorrhage, obliteration of the lumen, charring, and perforation
 - Grade IIIb: extensive necrosis

TREATMENT APPROACH

- Therapy depends on the grade assigned at endoscopy.
 - No injury or grade I injuries
 - Usually admitted and observed for 24–48 hours
 - More severe injuries
 - Admitted to pediatric intensive care unit for monitoring and management
- Emergency management
 - Close attention to the ABCs (airway, breathing, and circulation)
 - Stridor or aphonia indicate laryngoepiglottic injury and may require urgent orotracheal intubation for airway protection.
 - Occasionally, severe laryngeal destruction necessitates emergency cricothyroidotomy or tracheostomy.
 - Adequate vascular access to allow for correction of hypovolemia or hypotension
 - Nasogastric tube placement is not recommended routinely because it may be associated with subsequent stricture formation.
 - Initial orders include:
 - Nothing by mouth
 - Proper fluid resuscitation
 - Nutritional support through total parenteral nutrition
 - Pain management
- Antimicrobial therapy
 - After disruption of the mucosal barrier by caustic ingestion, bacterial translocation and secondary bacterial invasion are likely.

- Rationale for early institution of prophylactic antibiotic therapy
 - However, controlled trials do not support antibiotic use.
 - Most experts no longer advocate empirical antibiotic therapy.

- Vigilance for mediastinitis or systemic infection must be maintained.
- Reserve appropriate antimicrobials for any evidence of local or systemic infection.
- Nutrition
 - Parenteral nutrition for patients with grade II and III injuries
 - Oral feedings are withheld until dysphagia of initial phase has regressed and no evidence exists of clinical or radiographic deterioration.
- Proton pump inhibitors should be prescribed.
 - Loss of lower esophageal sphincter tone occurs secondary to corrosive esophageal injury.
 - Acid reflux can exacerbate underlying injury and accelerate stricture formation.
- Use of corticosteroids to limit fibrosis after caustic injury has debatable efficacy.
 - Most studies demonstrate lack of proven benefit.
 - Potential side effects argue against routine use.
- Gastric lavage and emetics should be avoided, because of:
 - Risk of reexposing esophagus to ingested corrosive agent
 - Threat of aspiration
 - Possibility of propagation of injury beyond level of the pylorus
- Any attempt to neutralize an ingested caustic agent poses additional danger, because resultant exothermic reaction frequently exacerbates the primary burn injury.
- Activated charcoal is not recommended, is ineffective, and obscures endoscopic visualization.
- Placement of a nasogastric tube should be deferred because of risk of esophageal perforation.

SPECIFIC TREATMENTS

Surgical management

- Surgical management is required for:
 - Severe corrosive injuries
 - Intractable esophageal strictures
- Surgical options include:
 - Bypass with placement of an esophageal substitute
 - Resection
 - Both bypass and resection
 - Esophagoplasty (see Figure 30 on page F11)

- Decisions regarding surgical management are based on:
 - Age
 - General health
 - Severity and extent of stricture
 - Risk of long-term complications
 - Early surgical intervention is vital and can be life saving.
 - Bypass with complete esophageal resection is the preferred approach, because
 - The retained proximal esophagus may distend, forming a mucocele or abscess.
 - The distal esophagus may develop reflux esophagitis, ulceration, and hemorrhage.
 - The retained esophagus is at increased risk for malignant transformation.
 - Resection is not without risk.
 - Extensive dissection necessary to remove damaged esophagus can result in significant morbidity.
 - Accepted procedures to replace injured esophagus include:
 - Colonic interposition
 - Gastric advancement
 - Gastric tube esophagoplasty
 - Jejunum interposition
 - Esophagoplasty with a colonic patch over less extensive but persistent strictures has been used to manage focal strictures.
 - Full and immediate resection of devitalized tissue is necessary to prevent expansion of corrosive injury.
 - Delay in diagnosis of esophageal perforation can be fatal; a high index of suspicion in grade II and III injuries must be maintained.
 - Immediate surgery is required for:
 - Peritonitis
 - Pneumoperitoneum
 - Clinical deterioration, evidenced by refractory acidosis, neurologic decline, or coagulopathy
 - Complete surgical exposure of the foregut—esophagus, stomach, and duodenum—is necessary to assess extent of the damage and allow resection.
 - Full-thickness injury to stomach or duodenum invariably predicts severe esophageal injury.
 - An indication for complete esophagogastrectomy
 - Full-thickness circumferential injury to esophagus carries a 20% mortality rate, mandating surgical resection.
- Esophageal dilation**
- Conservative management, including later esophageal dilation, may be considered for short segments of full-thickness esophageal mucosal damage.
 - If any question persists after initial exploration, then a second-look operation (often within 24 hours) is required.
 - Primary treatment with esophageal dilation offers a satisfactory outcome for most otherwise healthy children with grade IIa injuries.
 - Repeated dilation rarely is successful for the most severe corrosive strictures; early surgical resection is associated with a better outcome.
 - Because risk of perforation is highest in the first weeks after injury, most experts advocate waiting 6 weeks before initiating dilation.
 - Dilation can be accomplished by 2 methods.
 - Pulsion dilation
 - Graded bougies are passed over endoscopically or radiographically placed guide wires.
 - This technique is difficult with tortuous or complicated strictures and warrants fluoroscopic guidance.
 - Radial dilation
 - Uses endoscopically or radiographically controlled balloon dilation
 - The goal is dilation of the stricture to 18 mm, the diameter required for normal swallowing.
 - Typically performed every other week
 - ≥ 3 dilations usually are required.
 - Esophageal rupture is a potentially fatal complication of dilation and warrants immediate surgical repair.
 - Incidence is 17–32%.
 - Serial dilations are complicated by dysphagia between treatments, which may precipitate pulmonary aspiration.
 - An adequate lumen is usually attained within 6 months to 1 year, with progressively longer intervals between dilations.
 - Esophageal replacement should be considered if dilation is ineffective beyond 1 year.
- WHEN TO ADMIT**
- All patients with esophageal caustic injury should be hospitalized.
- WHEN TO REFER**
- All patients need referral to gastroenterologists and surgeons for evaluation of extent of damage and for management.
- FOLLOW-UP**
- Strictures after grade I and IIa injuries are rare, and follow-up contrast esophagography is unnecessary.
 - After grade IIb and III injuries, barium esophagography for early detection of stricture development is performed 2–4 weeks later.
 - Early stricture detection is important because less mature strictures are more responsive to dilation.
 - Long-term follow-up of children who have grade II and III burns is warranted, regardless of their symptoms.

- Esophagography and surveillance esophagoscopy should be performed annually or biannually.

COMPLICATIONS

- Long-term complications of corrosive ingestions include:
 - Stricture formation
 - Gastric outlet obstruction
 - Esophageal carcinoma
- Gastric outlet obstruction
 - Occurs in ~9% of corrosive ingestions
 - Is characterized by early satiety and weight loss
 - Can occur years after initial injury
 - Follows acid or alkaline ingestions with equal frequency
 - Is treated surgically
 - Balloon dilation of the pylorus, pyloroplasty, and Billroth I reconstruction are all effective.
 - Selection of operation depends on findings at laparotomy and surgeon preference.
- Esophageal carcinoma
 - Where native esophagus is retained, risk of postcorrosive esophageal carcinoma is estimated to be 1000- to 3000-fold higher than the incidence in the general population.
 - ≤3% of patients with esophageal carcinoma have a history of corrosive ingestion.
 - These squamous cell carcinomas usually originate in mid-esophagus.

- Because local dissemination occurs infrequently, the potential for curative resection is slightly improved over that for primary esophageal cancer.
- The interval between burn injury and development of carcinoma ranges from 10–70 years, with a mean of 50 years.

PROGNOSIS

- Long-term morbidity after corrosive esophageal ingestion correlates with the grade of injury.

PREVENTION

- Proposed interventions to prevent stricture formation have not demonstrated a proven benefit.
 - Esophageal dilation to prevent adhesion formation in the injured segment
 - Intraluminal stenting
 - Prolonged esophageal rest (maintenance of nothing-by-mouth status; total parenteral nutrition)
 - Multiple animal studies with a variety of agents (heparin, epidermal growth factor, caffeic acid phenethyl ester) have demonstrated varying degrees of success, but none of these agents have been studied in humans.

Extremity Pain

DEFINITION

- Extremity (limb) pain is pain present in ≥ 1 of the arms or legs.

EPIDEMIOLOGY

- Incidence
 - Up to 16% of school-age children report at least 1 episode of activity-limiting extremity pain annually.
- Prevalence
 - Between 6% and 7% of pediatric office visits are related to extremity pain.

MECHANISM

- The mechanism for extremity pain depends on its etiology.

HISTORY

- Description of pain: OLD CAR
 - **O**nset/precipitating event (eg, trauma, only at night)
 - Trauma accompanied by an audible pop or snap suggests a dislocation, sprain, or fracture.
 - **L**ocation/distribution of pain (eg, specific joints)
 - Referred pain is common in children; thus, the location of pain may be deceiving.
 - Joint pain may refer to the bones and joints adjacent to the presenting symptom.
 - Hip pathology may present as knee pain (eg, as in slipped capital femoral epiphysis [SCFE]).
 - Spine pathology may present as lower-extremity pain or gait disturbance.
 - Migrating extremity pain is less likely to occur after trauma and is more typical of systemic illness.
 - Multiple joint involvement may also suggest reactive arthritides or rheumatologic conditions, such as lupus and juvenile idiopathic arthritis.
 - Pain in a nonanatomic distribution or that disturbs unpleasant but not pleasant activities may suggest a functional disorder.
 - **D**uration (eg, continuous, variable, specific time of the day only, frequency)
 - **C**haracter or quality (eg, aching, cramping, deep, burning, tingling, numbness, with stiffness)
 - Muscular pain may be described as aching or cramping.
 - Bone pain is often described as deep.
 - Nerve pain may present as burning, tingling, or numbness.
 - Stiffness, especially with clinical evidence of arthritis not associated with trauma, should prompt concern about a rheumatologic process.
 - **A**ssociated factors that relieve or worsen
 - Pain that is worse with sleep or rest and improves with activity may suggest a rheumatologic process.
 - Types of activities that may affect the pain
 - **R**adiating/pattern of pain
- Medical history/review of systems
 - When considering overuse injuries, may assess for repetitive motions, handedness
 - Signs of systemic illness (eg, fever, recent weight loss, sweating, rashes, gastrointestinal symptoms)
 - Signs of spinal disease (eg, retention or incontinence of urine or stool)
 - Recent infectious exposures, including hepatitis B, pharyngitis/strep throat, upper respiratory tract infection
 - Consider transient synovitis of the hip in children < 10 years
 - A history of exposure to viral illness might explain myalgia or arthralgia, eg, the prodrome of hepatitis B can cause significant arthralgia.
 - Recent travel or potential infectious exposures (eg, home-processed meats)
 - History of autoimmune disease, or congenital/acquired asplenia
 - Family history of autoimmune diseases, hemoglobinopathies, human leukocyte antigen B27 (HLA-type B27), joint hypermobility, fibromyalgia
 - A sickle cell pain crisis must always be considered in a child of African or Mediterranean origin with a painful extremity.
 - HLA-B27 is associated with Reiter syndrome, psoriatic arthritis, inflammatory bowel disease, and ankylosing spondylitis and may be associated with enthesitis-related arthritis (inflammation at attachments of tendons/ligaments/fascia to bone).
 - Recent medication use
 - A serum sickness-like illness, particularly associated with cefaclor
 - Even a short course of systemic steroids can cause aseptic necrosis of the hip or demineralization of bone.
 - Immunizations, particularly for rubella, may cause joint or extremity pain.
- Growth patterns/growth spurt
- As indicated, consider a full HEADSSS assessment or at a minimum the following:
 - Home situation
 - Educational status
 - Activities (specific activities and changes in activities), exercise patterns
 - Sexual history

PHYSICAL EXAM

■ Vital signs

- Evaluate temperature.
- Evaluate blood pressure and heart rate.
 - These may be elevated with clinically significant pain, or with endocrine abnormalities.
 - An elevated resting heart rate may be associated with rheumatic fever.
- Plot previous growth data (especially height, weight, and body mass index).
 - SCFE is more likely in an overweight adolescent.

■ Physical examination

- Conduct a general, if brief, physical examination, even if the history points to extremity pain from minor local trauma.
- Examine the extremities, especially proximal and distal to the site of the symptom (given the possibility of referred pain), assessing for:
 - Skin color and temperature
 - Color change associated with extremity pain may indicate:
 - Redness—inflammation
 - Intense red with streaking—infection
 - Darkened—bruising or gangrene
 - Pallor—anemia, or systemic illness
 - Vascular status, by palpating pulses and determining distal capillary refill time
 - Muscle strength and distribution pattern (eg, proximal vs distal weakness)
 - Isolated distal weakness is likely to be of neurologic origin, whereas proximal weakness is most likely from muscle disease.
 - Soft-tissue swelling
 - Presence of skeletal deformities
 - Tenderness to palpation
 - Joint disruption or effusions
 - Joint laxity or hyperextensibility
- Examine the other extremities and joints.
 - Comparing with the opposing limb may be useful when assessing swelling, muscle bulk and tone, and joint mobility.
 - Symmetry of skin folds and limb lengths can be helpful.
 - Examining other limbs may reveal a broader extent of involvement.
 - Observing use of the affected limb (when the patient is unaware) may suggest involvement versus a functional process.

- If lower extremities are involved, observe and classify gait.
- Nail pitting may be consistent with psoriasis.
- Examine for organomegaly.
- Assess for rashes.
 - Vasculitic rash on extensor surfaces of knuckles, knees, and elbows: Consider dermatomyositis.
 - Palpable purpura: Consider Henoch-Schönlein purpura.
 - Photosensitive rash: Consider systemic lupus erythematosus, dermatomyositis, and parvovirus infection.
- Pain out of proportion to examination may suggest necrosis or leukemia.

DIFFERENTIAL DIAGNOSIS

■ Most visits to a primary care pediatrician for extremity pain involve pain caused by:

- Minor trauma
- Overuse syndromes
- Normal skeletal growth variants

■ Limb pain may be related to primary processes related to infection, nutritional derangements, neoplasms, or specific orthopedic disorders.

- Also may be related to systemic illnesses or to psychosocial issues

■ The challenge is to determine when the pain is significant without exposing the child to excessive diagnostic studies, so that referrals can be made in a timely manner.

■ The differential diagnosis of extremity pain is extremely broad.

■ Most limb pain is benign, requires no intervention, and is self-limited.

■ Mild trauma that leads to a fracture may suggest previous underlying bone pathology.

■ Consider physical abuse if clinical findings and/or imaging are not consistent with history.

Orthopedic

■ Trauma

- Fracture
 - Myohematoma
 - Myositis ossificans
 - Osteoporosis
 - Pathologic fracture/osteogenesis imperfecta
- Sprain: a physical disruption of a ligament
 - Less common in children than in adults
 - Consider fractures when physical examination reveals point tenderness or pain on stretching the ligament.
- Physical abuse

- Overuse injury
 - Chondromalacia patella (patellofemoral syndrome)
 - Little League elbow: painful inflammation of the epicondyles related to repetitive throwing, potentially with diminished range of joint motion
 - Fragments of bone splintered into the joint may cause the joint to catch or lock.
 - Shin splints
 - Occurs most commonly at the beginning of a training season and is exacerbated by running and jumping
 - Although the pain occurs initially after activity, it may occur during or before activity as the syndrome progresses.
 - Tenderness may be felt over the posteromedial aspect of the tibia, proximal portion of the posterior tibia, or anterior tibia.
 - Stress fractures
 - Localized, gradually increasing, and persistent extremity pain that worsens with weight bearing, exercise, and activity but diminishes with rest
 - Rare in children <12 years of age and most commonly affect the second metatarsal, proximal tibia, or fibula
- Osteochondroses: irregular mineralization of bone resulting from necrosis followed by regeneration of bone tissue
 - Freiberg disease
 - Köhler disease
 - Legg-Calve-Perthes disease
 - Osgood-Schlatter disease
 - Osteochondritis dissecans
 - Sever disease
- Nerve and/or vascular compression syndromes
 - Carpal tunnel syndrome
 - Cervical nerve root entrapment
 - Compartment syndrome
 - Popliteal artery entrapment syndrome
 - Associated with vascular calf pain that radiates to the foot, which begins with activity, sometimes more with walking than with running
 - Consider if normal pedal pulses are lost with simultaneous knee extension and foot plantar flexion.
 - Thoracic outlet syndrome
- Radial head subluxation (nursemaid's elbow)
 - A common injury in toddlers, following sudden, forceful traction of the hand or forearm
 - Often, the child refuses to use the extremity; if verbal, he or she usually localizes the pain to the elbow or occasionally to the wrist.
 - Holds the arm with the elbow flexed, the forearm close to the chest, and the hand in pronation
- SCFE
 - Caused by dislocation of the head of the femur from its neck and shaft at the level of the upper epiphyseal plate
 - Characteristic pain occurs in the affected hip or the medial aspect of the ipsilateral knee.
 - If displacement is sudden, pain is usually severe and associated, with inability to bear weight.
 - Gradual displacement is associated with slowly increasing, dull pain.
 - Examination may reveal diminished abduction and internal rotation of the hip.
 - Typically affects obese children or adolescents
- Anatomic variants (eg, inflexible flat feet, tarsal coalition)
- Growing pains
 - Intermittent, deep extremity pains that affect the lower more often than the upper extremities
 - Pain is nearly always bilateral, lasts <2 hours, and is worse at night, resolving completely in the morning; it rarely involves joints.
 - Onset is described at 3–5 or 8–12 years of age (not most frequently during periods of rapid growth).
 - Most growing pains resolve in 12–24 months, although they may persist into adolescence.
 - The diagnosis is significant for its lack of associated physical signs.
 - Abnormal findings should prompt a search for another cause.
- Infectious/post-infectious
 - Septic arthritis
 - Osteomyelitis
 - A local infection of bone, usually involving 1 of the long bones; incidence is highest in children 3–12 years of age.
 - Infection often occurs by hematogenous seeding, or by direct inoculation after local trauma.
 - Osteomyelitis can produce extremity pain alone or with signs of a systemic infectious disease—fever, irritability, and septic appearance.
 - Most commonly due to *Staphylococcus aureus*
 - In puncture wounds to the foot, consider *Pseudomonas aeruginosa*, especially if injury is through a tennis shoe.
 - Cellulitis/abscess
 - Transient (toxic) synovitis
 - A self-limited inflammation of the hip joint, most commonly in children <10 years of age
 - The cause is unknown, but the condition often occurs within 2 weeks of upper respiratory infection.
 - Typically, the child refuses to walk because of apparent pain in the hip, with hip held in flexion, abduction, and external rotation.

- Diskitis, spinal epidural abscess
- Pyogenic or viral myositis
- Meningococcal disease
- Immunization reaction (especially rubella)
- Tuberculosis
- Arthralgia or myalgia associated with streptococcal or viral infection
- Sexually transmitted infection (gonorrhea, syphilis [periostitis])
- Enteric disease (includes trichinosis)
- Histoplasmosis
- Lyme disease

Rheumatologic/immune-mediated

- Dermatomyositis
 - Muscle pain
 - Proximal weakness associated with a vasculitic rash on the extensor surfaces of knuckles, knees, and elbows (Gottron papules)
- Familial Mediterranean fever
- Henoch-Schönlein purpura
 - Palpable purpura and extremity pain
- Hypermobility syndrome/mixed connective-tissue disease
 - Generalized joint laxity and hyperextensibility differentiates benign hypermobility syndrome from a focal ligament injury.
 - Joint laxity allows chronic hyperextension, which can cause pain, typically in weight-bearing joints, that is often worse in the evening.
 - Dancing, gymnastics, and other joint-impacting activities may exacerbate arthralgia.
- Inflammatory bowel disease
- Juvenile idiopathic arthritis
- Kawasaki disease
- Polyarteritis nodosa
- Rheumatic fever
- Reactive arthritis
- Scleroderma
- Serum sickness
- Systemic lupus erythematosus

Genetic/nutrition

- Sickle cell anemia, thalassemia
- Hemophilia
- Hypercholesterolemia
- Hypervitaminosis A
- Vitamin deficiencies (vitamin C, scurvy; vitamin D, rickets)

- Gout
- Enzyme deficiencies (carnitine palmityltransferase deficiency, Fabry disease, McArdle syndrome, phosphofructokinase deficiency)
- Mucopolidosis
- Mucopolysaccharidosis

Neoplasm

- The possibility of a tumor is a common parental concern.
- While rare, neoplasms can cause limb pain.
- The differential diagnosis includes leukemia, benign (osteoblastoma, osteoid osteoma) and malignant neoplasms (eg, sarcomas [chondrosarcoma, Ewing sarcoma, fibrosarcoma, osteogenic sarcoma, rhabdomyosarcoma, synovial cell sarcoma], lymphomas, neuroblastomas, bone tumors, soft-tissue tumors, and spinal cord tumors).
- Osteoid osteoma is a benign prostaglandin-secreting bone tumor that occurs most often in adolescents.
 - Pain, the presenting symptom, is initially dull and increases in intensity to deep and boring (piercing).
 - More intense at night and with weight bearing
 - Usually involves a femur, tibia, or lumbar vertebral body
- Systemic neoplasms in which extremity pain occurs include leukemia and metastatic neuroblastoma.
 - In children with acute lymphocytic leukemia:
 - One-third have bone pain at the time of diagnosis; in one-fourth, joint or bone pain is a significant presenting symptom.
 - Examination may reveal strikingly little to account for the degree of pain.
- Primary malignant bone tumors may cause severe unilateral pain, with swelling and tenderness at the tumor site.
- Metastatic bone tumor may present as extremity pain.
 - Pain is characterized as unrelenting; increasing pain that worsens at night or with rest; and not relieved by analgesics, heat, or massage.
 - Systemic signs may accompany the pain (eg, weight loss, pallor, lymphadenopathy, hepatosplenomegaly, fever).

Other systemic illnesses

- Caffey disease
- Fibromyalgia
- Guillain-Barré syndrome
- Histiocytosis X
- Hypercortisolism
- Hyperparathyroidism
- Hypothyroidism
- Sarcoidosis

Psychosocial

- Behavior disorders
- Psychogenic pain
- Reflex neurovascular dystrophy
- School phobia

LABORATORY EVALUATION

- Laboratory studies are unnecessary for most extremity pain.
- Consider screening tests if there is suspicion of systemic or infectious process, pain persists longer than anticipated, and history and examination do not lead to a definitive diagnosis.
- Screening tests may include:
 - Complete blood count
 - Complete blood count may reveal anemia or may suggest active infectious process.
 - White blood cell (WBC) count and sedimentation rate are often elevated in osteomyelitis.
 - Transient synovitis may cause a slight elevation in the WBC count and the sedimentation rate.
 - With leukemia, the WBC count may vary, with immature WBCs present; or thrombocytopenia may be present.
 - Erythrocyte sedimentation rate and/or C-reactive protein
 - Elevated erythrocyte sedimentation rate raises suspicion of an infectious, inflammatory (or occasionally, neoplastic) disorder.
 - Effectiveness of osteomyelitis treatment can be monitored by a serial sedimentation rate and/or C-reactive protein level.
 - A C-reactive protein <1 mg/dL has been shown to have an 87% negative predictive value for septic arthritis.
- Additional testing may be performed as guided by clinical suspicion, including:
 - Blood cultures
 - If septic arthritis is suspected, synovial fluid analysis and cultures

IMAGING

- When no clear history of trauma is revealed, when symptoms persist, when associated systemic symptoms are present, or with clinical suspicion, imaging may be obtained.
- Radiographs can help to identify:
 - Fractures, acute and/or pathologic
 - Traumatic injury that would ordinarily cause a sprain in an adult is more likely to cause a greenstick or buckle fracture in a child, so a lower threshold for obtaining posttraumatic radiographs in children may therefore be justified.

- Orthopedic conditions, including SCFE
- Bony tumors
- Some metabolic defects
- In Legg-Calve-Perthes disease, radiographs may be normal or show only joint capsule swelling, although subsequent radiographs may show areas of bone resorption, irregular widening of the epiphysis, and dense new bone formation.
- In leukemia, studies of the extremities may show lucent leukemic lines in the subepiphyseal area.
- In osteogenic sarcoma, radiographs may reveal a tumor in the metaphysis.
 - Presence of both radiolucent and radiopaque areas
 - Characteristic sunburst results from extension of calcification into the overlying soft tissue
 - Periosteal elevation may be present, but it is not diagnostic of the disease.
- Bone scans
 - Are a suggested part of the evaluation for a limping child <5 years of age with a nonfocal examination (per the American Academy of Radiology)
 - Should be considered when a stress fracture, osteomyelitis, or cancer is suspected
 - In rare cases of osteomyelitis, a reduction in perfusion caused by pressure from the exudative process may result in a false-negative scan.
 - In Legg-Calve-Perthes disease, the scan may demonstrate diminished blood flow to the femoral head compared with the contralateral hip.
- Magnetic resonance imaging is being used as a replacement for bone scans in the diagnosis of osteomyelitis.
 - ≥2 weeks may be required for radiographic evidence of osteomyelitis to develop.
 - A bone scan is usually, but not always, diagnostic.
 - The combined use of T1, T2, and short-tau inversion-recovery images effectively rules out osteomyelitis with a negative predictive value approaching 100%.
 - Magnetic resonance imaging offers the additional advantages of imaging of soft-tissue and joint disease.

DIAGNOSTIC PROCEDURES

- Diagnostic procedures (eg, biopsies) may be obtained as guided by clinical suspicion.

TREATMENT APPROACH

- Treatment is aimed at the underlying disease entity.
- With chronic extremity pain, serial examinations over the course of weeks may aid in establishing a diagnosis.

SPECIFIC TREATMENT

- Treatment is highly dependent on clinical presentation and diagnosis.
 - Growing pains
 - Treatment involves heat, massage, and analgesics.
 - Little League elbow
 - Treatment consists of resting the arm by avoiding the repetitive movement, and a change in pitching technique may reduce recurrences.
 - Shin splints
 - Treatment of shin splints involves rest, application of ice, and antiinflammatory drugs.
 - For runners, training on a softer surface or with better-quality running shoes may help.
 - Sprains
 - Grade I sprains can be treated with icing and wrapping to minimize swelling.
 - Early range of motion exercises should be encouraged, with a gradual return to activity.
 - The recurrence of pain indicates too rapid a return to a given level of activity.
 - Grade II sprains and grade III sprains should generally be referred to an orthopedist for immobilization.
 - Stress fractures
 - Treatment consists mostly of rest and treatment with nonsteroidal antiinflammatory agents.
 - Casting or splinting is occasionally necessary.
 - Radial head subluxation (nursemaid's elbow)
 - The practitioner can reduce the subluxation by using 1 hand to supinate the patient's forearm quickly while simultaneously exerting traction on the forearm and using the thumb of the other hand to create pressure over the patient's radial head.
 - This maneuver is completed by placing the elbow through full extension and flexion while maintaining pressure over the radial head.

- Normal use of the extremity usually returns within 30 minutes.
- SCFE
 - Management involves surgical placement of a pin through the femoral head and the epiphysis to prevent further slippage.
- Osteochondroses
- Osteoid osteoma
 - Surgical excision is curative.
- Transient synovitis
 - Treatment consists of bed rest, usually for <4 days.

WHEN TO REFER

- When a surgical procedure or subspecialist is required for definitive treatment (eg, operative repair of fracture, ligament tear, Ewing sarcoma)
- When a surgical procedure or subspecialist required for diagnostic evaluation (eg, septic arthritis, juvenile idiopathic arthritis, systemic lupus erythematosus)
- When extremity pain occurs in the context of likely systemic illness (eg, Fabry disease, Crohn disease)
- Consider ophthalmology and rheumatology consultation if limb pain occurs in conjunction with uveitis, photophobia, eye injection, or eye pain.

WHEN TO ADMIT

- If a child cannot ambulate, and outpatient or emergency department screening does not confirm a diagnosis
- High clinical suspicion for septic arthritis

COMPLICATIONS

- SCFE
 - Avascular necrosis of the femoral head is a common complication, even with early recognition and treatment.
- Transient synovitis
 - In rare instances, avascular necrosis of the femoral head may be a late complication.

Facial Dysmorphism

DEFINITION

- Congenital malformations are clinically significant abnormalities of form or function that result from localized intrinsic defects in morphogenesis that occur in embryonic or early fetal life.
 - These include clefting of the lip or palate; congenital heart disease, such as tetralogy of Fallot; and multicystic kidney disease.
 - They may result from an unknown cause but increasingly can be traced to mutations in single developmental genes.
 - Malformations usually require surgical intervention.
- Deformations differ from malformations in that they arise as a result of environmental forces acting on normal primordial tissue.
 - For example: A fetus in a uterus where a large fibroid is present may have limited space for normal range of motion for limbs.
 - Limitation of limb motion leads to congenital contractures, arthrogryposis multiplex congenita.
 - Deformations occur later than malformations, usually after the first trimester, and often resolve with minimal therapy.
- A malformation (such as a cleft lip) or a deformation (such as clubfoot deformity) may occur in isolation or as part of a malformation sequence, a syndrome, or an association.
 - When a single malformation causes secondary effects on other structures later in development, a malformation sequence results.
 - In clinical genetics, a syndrome is defined as a group of malformations that occur together and are caused by a clearly identifiable causative agent.
 - Associations have no single underlying cause that explains a recognizable pattern of anomalies that occur together.

EPIDEMIOLOGY

- Prevalence
 - 2–5% of newborns are found during the neonatal period to have ≥ 1 congenital malformations.
 - 7–8% at 1 year of age, because some malformations (eg, congenital heart disease) may remain clinically silent during the newborn period.
 - In approximately 50% of children with congenital malformations, only a single malformation is identifiable.
 - Multiple malformations are present in the other 50%.
- Causes of multiple malformation syndromes
 - ~7.5% result from single gene mutations.
 - ~6% result from a chromosomal abnormality.
 - ~6% result from teratogens.
 - >50% result from unknown factors.

MECHANISM

- A malformation sequence occurs when a single malformation causes another to develop: for example, the Pierre Robin malformation sequence.
 - Primary malformation, failure of the growth of the mandible during the first weeks of gestation, results in micrognathia (small jaw).
 - Insufficient jaw size forces the normal tongue into an unusual position.
 - The abnormally placed tongue blocks fusion of the palatal shelves that normally come together in the midline, producing a U-shaped cleft of the palate.
 - After delivery, the normal-sized tongue in the abnormal oral cavity can lead to airway obstruction and obstructive apnea, a potentially life-threatening complication.
- Syndromes may be caused by a single gene mutation: for example, Marfan syndrome.
 - A mutation in the *FBN1* gene on chromosome 15 leads to abnormally formed fibrillin, resulting in a characteristic set of abnormalities of the skeletal, cardiovascular, and ophthalmologic systems.
- Syndromes may result from chromosomal abnormality: for example, Down syndrome.
 - An extra copy of chromosome 21 leads to craniofacial dysmorphic features, developmental disabilities, cardiac anomalies, and other abnormalities.
- Syndromes can be caused by a teratogenic agent.
 - A drug, chemical, or environmental toxin that causes damage to the developing embryo or fetus; for example, valproic acid, an anticonvulsant that when used during the first trimester of pregnancy leads to:
 - Spina bifida
 - A characteristic facial appearance
 - Limb defects
 - Other anomalies
- A syndrome can result from unknown factors: for example, Russel-Silver syndrome.
 - Intrauterine growth restriction with failure to thrive, skeletal asymmetry, small and incurved fifth fingers, and learning disabilities.
 - A small number of patients have maternal uniparental disomy of chromosome 7, but 90% of patients have no identifiable cause.
- An association is a group of unconnected anomalies that regularly occur together: for instance, the VACTERL association (vertebral anomalies, anal atresia, cardiac defects, tracheoesophageal fistula, renal anomalies, and limb anomalies)
 - A group of malformations that occur more commonly together than might be expected by chance

- No single unifying cause has ever been identified to explain this condition.
- As the cause of an association becomes known, the disorder moves into the category of syndrome.

HISTORY

- Establishing a standardized routine is helpful for the evaluation of the child with dysmorphic features.
 - This routine should include taking the history, including a 3-generational family history, and performing a careful physical examination.
 - Following these steps, specific diagnostic laboratory tests can be ordered to confirm a diagnosis.
- Health care providers should be sensitive about the terminology used to describe the infant.
 - The physician should describe the abnormal features as clearly and concisely as possible.
- In taking the history, the following questions about the pregnancy should be asked:
 - *What was the birth weight?*
 - A lower-than-expected birth weight can be associated with a chromosome anomaly or exposure to a teratogen.
 - Babies who are large for gestational age may have diabetic mothers or an overgrowth syndrome, eg, Beckwith-Wiedemann syndrome.
 - Infants who are accurate for gestational age may have a single gene mutation; a multifactorial condition; or, most likely, no genetic disease at all.
 - *Was the baby full term, or pre- or postmature?*
 - Especially important when evaluating an older child with developmental disabilities
 - Postmaturity is associated with some chromosome anomalies, eg, trisomy 18 and anencephaly.
 - *Was the baby born by vaginal or cesarean delivery? If the latter, what was the indication?*
 - Caesarean delivery may be performed because of fetal distress, a risk factor for developmental disability caused by oxygen deprivation.
 - Babies born from breech presentation are approximately 4 times more likely to have congenital malformations.
 - *How old were the parents at the time of the child's delivery?*
 - Advanced maternal age is associated with an increased risk of nondisjunction leading to trisomies, eg, Down syndrome (trisomy 21).
 - Advanced paternal age may be associated with an increased risk of a new mutation leading to an autosomal-dominant trait, eg, achondroplasia.

- *Did the pregnancy have complications? Does the mother have underlying medical problems? Does she take any medications? Did she smoke cigarettes, drink alcohol, or take any drugs?*
 - Exposure of the embryo to teratogens, medications, or environmental agents known to cause birth defects is a significant cause of congenital malformations.
- *When did the mother feel quickening? Were fetal movements active?*
 - Quickening, which normally occurs between 16 and 20 weeks' gestation, is delayed in hypotonic fetuses, who also have less vigorous movements during fetal life.
 - Persistent hiccups in an infant found to have neonatal seizures suggests prenatal onset of the condition.
- *Was the amount of amniotic fluid normal?*
 - An increased amount of amniotic fluid is associated with intestinal obstruction or a central nervous system anomaly leading to poor swallowing.
 - Decreased fluid may point to a renal or urinary tract abnormality leading to failure to produce urine or chronic amniotic fluid leak.
- A 3-generation pedigree should be constructed, searching for similar and dissimilar abnormalities in first- and second-degree relatives.
 - A history of pregnancy or neonatal losses should be documented.

PHYSICAL EXAM

- In the process of evaluating the child with dysmorphic features, the physical examination is the most important element.
 - Whenever possible, the patient should be examined using a standardized approach.

Growth

- The height (length), weight, and head circumference should be carefully measured and plotted on appropriate growth curves.
- Growth appropriate for age may be consistent with:
 - A single gene disorder
 - A multifactorially inherited condition
 - Most commonly to no genetic disease
- Small size or growth restriction may be secondary to:
 - Chromosomal abnormality
 - Skeletal dysplasia such as achondroplasia
 - Exposure to toxic or teratogenic agents
- Larger-than-expected size suggests an overgrowth syndrome.
 - If in the newborn period, suggests maternal diabetes

- Proportions
 - Do limbs look appropriate for the head and trunk?
 - Short limbs imply presence of a short-limbed bone dysplasia, such as achondroplasia.
 - Trunk and head that are too small for the extremities may suggest a disorder affecting the vertebrae.

Craniofacial features

- Careful examination of the craniofacies is crucial for the diagnosis of many congenital malformation syndromes.
 - In assessing the face, the following should be systematically observed.

Head shape

- In newborns, the examiner may need to allow a few days for the deformation from molding to resolve.
- The head should be described using the following terms:
 - *Normocephaly*: a normal head shape.
 - *Dolichocephaly* or *scaphocephaly*: a long, thin head.
 - *Brachycephaly*: a head that is narrow in the anteroposterior diameter and broad laterally.
 - *Plagiocephaly*: a head that is asymmetric or lopsided.

Facial features

- A dysmorphic face may be appropriate given the family's physiognomy, or it may indicate a particular syndrome.
- Smith's Recognizable Patterns of Human Malformation aids identification and helps determine whether a particular condition is genetically based.
- Examples of causes of genetic facial malformation
 - Cause: Chromosomal
 - Down syndrome (trisomy 21)
 - Facial dysmorphism: midface hypoplasia, upward obliquity of palpebral fissures, epicanthal folds, flat nasal bridge, anteversion of nares
 - Cause: Autosomal dominant
 - Treacher Collins syndrome
 - Facial dysmorphism: dysplastic ears, maxillary hypoplasia
 - Cause: Autosomal recessive
 - Hurler syndrome
 - Facial dysmorphism: corneal clouding, coarse facies
 - Cause: Teratogenic: intrauterine infection
 - Congenital rubella
 - Facial dysmorphism: cataracts
 - Cause: Drug induced
 - Fetal alcohol syndrome
 - Facial dysmorphism: smooth philtrum, small eyes

- In evaluating the face, the examiner should first note the symmetry; facial asymmetry may be due to:
 - Deformation related to intrauterine or extrauterine positioning
 - Malformation of 1 side of the face: eg, hemifacial microsomia (Goldenhar syndrome or facio-auriculo-vertebral syndrome)
- Evaluate the 4 regions of the face separately.

Forehead

- Extends from the anterior hairline to the eyebrows.
 - Overt prominence: achondroplasia
 - Deficiency: sloping appearance, which occurs in children with primary microcephaly

Midface

- Encompasses the region from the eyebrows to the upper lip and laterally from the outer canthus of each eye to the outer commissure of the lips
- Hypoplasia of the midface is a common component of many syndromes, including Down syndrome and fetal alcohol syndrome.
- In evaluating the midface, carefully measure and plot measurements on appropriate growth curves for:
 - The distance between the eyes: inner and outer canthal distances
 - Pupils: interpupil distance
 - Eyes that are too close together may confirm an impression of hypotelorism, a defect in midline brain formation (holoprosencephaly).
 - Eyes that are too far apart—hypertelorism—are suggestive of such syndromes as Opitz syndrome (ocular hypertelorism, tracheal and esophageal anomalies, and hypospadias).
 - Length of the palpebral fissure
 - Short in fetal alcohol syndrome
 - Excessively long in Kabuki syndrome (short stature, mental retardation, long palpebral fissures with eversion of lateral portion of lower lid)
 - Other features of the eyes
 - The obliquity (slant) of the palpebral fissures may be upward, as in Down syndrome, or downward, as in Treacher Collins syndrome.
 - Epicanthal folds, flaps of skin covering the inner canthus of the eye that are usually associated with flattening of the nasal bridge, may indicate Down syndrome or fetal alcohol syndrome.

- Features of the nose
 - Nasal bridge can be flattened, as in Down syndrome, or prominent, as in velocardiofacial syndrome.
 - Nares may be oriented normally or tipped back (anteversion)
 - Body of the nose may be normal or deficient

Malar region

- Extends on either side from the upper portion of the ear to the midface.
- Ears should be checked for:
 - Size: measured and plotted on growth charts that record length for age
 - Shape: noting abnormal folding or flattening of the helices
 - Position: low set if the top of the ear is below a line drawn from the outer canthus to the occiput
 - May be low set because they are small or microtic or because of a malformation of the mandibular region
 - Orientation: posterior rotation is present when ear appears turned toward the rear of the head.

Mandibular region

- The mandible extends from lower ear to lower ear and includes the lower lip and jaw.
- In most newborns, the chin is often retruded, slightly set back behind the vertical line extending from the forehead to the philtrum.
- If the mandible itself is small, it is described as micrognathic (Pierre Robin malformation sequence).
- An unusually prominent mandible is described as prognathic.

Neck

- Webbing, a feature common in Turner and Noonan syndromes
- Shortening, occasionally seen in:
 - Some skeletal dysplasias
 - Conditions in which anomalies of the cervical spine occur (Klippel-Feil syndrome)
- The position of posterior hairline
- Size of the thyroid gland

Trunk

- Chest should be examined for shape.
 - A shieldlike chest is found in Noonan and Turner syndromes.
- Symmetry
 - Hypoplasia of the pectoralis major and minor muscles, leading to asymmetry (Poland malformation sequence)
- A pectus deformity of the chest, either pectus excavatum or pectus carinatum, is usually an isolated finding.
 - Also a cardinal feature of Marfan syndrome

- Scoliosis is usually an isolated feature
 - Often seen in Marfan syndrome and in several other disorders

Extremities

- Anomalies of the extremities are common in many congenital malformation syndromes.
- All joints should be examined for range of motion.
- The presence of single or multiple joint contractures suggests either:
 - Neuromuscular dysfunction, as in the case of some forms of muscular dystrophy, *or*
 - External deforming forces that limited motion of the joint in utero
- Radioulnar synostosis, an inability to pronate or supinate the elbow occurs in:
 - Fetal alcohol syndrome
 - In some X chromosome aneuploidy syndromes, such as 48,XXXX and 48,XXXY syndromes
- The hands should be examined.
 - Polydactyly: the presence of extra digits
 - Can occur in isolation as an autosomal-dominant trait in up to 1% of all newborns
 - Can occur as part of a malformation syndrome, such as trisomy 13
 - Oligodactyly: a deficiency in the number of digits
 - Seen in Fanconi syndrome (growth retardation, aplastic anemia, development of leukemia or lymphoma and associated heart, renal, and limb defects including radial aplasia and thumb malformation or aplasia)
 - Generally part of a more severe limb reduction defect or secondary to intrauterine amputation that may occur with amniotic band disruption sequence
 - Syndactyly, a joining of ≥ 2 digits, is common to several syndromes.
 - Dermatoglyphics are important to note, especially the palmar crease pattern.
 - A transverse palmar crease, indicative of hypotonia during early fetal life (~50% of children with Down syndrome and 10% of individuals in the general population)
 - A characteristic palmar crease pattern is seen in fetal alcohol syndrome.

Genitalia

- Genitalia should be examined for abnormalities in structure.
- In male infants, if the penis appears short, it should be measured and plotted on an appropriate growth chart.
- Ambiguous genitalia can be associated with endocrinologic disorders, such as:
 - Congenital adrenal hyperplasia (female infants have masculinized external genitalia, but male genitals may be unaffected)

- Chromosomal disorders, such as Turner syndrome mosaicism
- Part of a multiple malformation disorder, such as Smith-Lemli-Opitz syndrome
- Hypospadias (occurs in 1 in 300 male newborns) is a common congenital malformation that often occurs as an isolated defect.
 - If it is associated with other anomalies, the possibility of a syndrome is strong.

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis comprises conditions that feature some or all of the clues.
- Once this list has been assembled, a series of laboratory and imaging tests can be performed to move toward a definitive diagnosis.
- In the majority of cases, no specific diagnosis is immediately evident.
 - Some constellations of findings are rare, and finding a match may prove difficult.
 - In many cases, all laboratory tests are normal, and confirmation relies on subjective findings.
- Clinical geneticists have attempted to resolve this difficulty by developing scoring systems.
 - Cross-referenced tables of anomalies that help in developing a differential diagnosis
 - Computerized diagnostic programs
- An accurate diagnosis is important for 3 reasons:
 - It offers the family an explanation of why their child was born with congenital anomalies.
 - This may help allay feelings of guilt, given that parents frequently believe that they are responsible for their child's problem.
 - The natural history of many disorders is well described, and a diagnosis allows:
 - Anticipation of medical problems associated with a particular syndrome and performance of appropriate screening
 - Reassurance that other medical problems are no more likely to occur than they might with children who do not have the diagnosis
 - It permits accurate recurrence risk for future progeny.
 - Genetic counseling
 - Future prenatal diagnostic testing
- The diagnosis enables the clinician to provide the family with:
 - Educational materials
 - The chance to meet other families who have children with the same condition

- The Internet has become an important source for information.
 - Care should be exercised, because information on the Internet is not always subject to editorial control.
 - Some information may be inaccurate or inappropriate.
 - Physicians should try to screen sites before encouraging a family to seek information.
 - 2 good Web sites are:
 - National Organization for Rare Disorders (www.rarediseases.org)
 - A clearinghouse for information about rare diseases and their support groups
 - Genetests (www.genetests.org)
 - Provides information on available clinical and research testing for many diseases

LABORATORY EVALUATION

- Chromosome analysis (karyotype), either metaphase or prophase (high resolution), should be routinely ordered for children with:
 - Multiple congenital anomalies
 - Involvement of 1 major organ system and ≥ 2 dysmorphic features
 - Presence of mental retardation
- Chromosome analysis will identify conditions caused by:
 - Too much chromosomal material, such as trisomies
 - Too little chromosomal material, such as monosomies
- Fluorescent in situ hybridization (FISH) uses DNA technology to identify specific regions of the genome that are missing or duplicated.
 - FISH uses a DNA probe that is complementary to a specific region of the genome.
 - After a fluorescent marker is attached to this probe, it is incubated with chromosomal DNA from the patient.
 - FISH is requested when a syndrome with a known chromosomal defect is suspected, such as:
 - Velocardiofacial syndrome: deletion of 22q11.2
 - Prader-Willi syndrome: deletion of 15q11.2
 - Angelman syndrome: deletion of 15q11.2
 - Beckwith-Wiedemann syndrome: duplication of 11p15.2
- In a growing number of disorders, direct DNA analysis can be performed to identify specific mutations known to cause disease.
 - Uses Web-based resources for the most recent information, because the list of these disorders increases every day
 - Genetests (www.genetests.org), which is updated frequently, provides information about availability of testing for specific conditions.
 - Identifies laboratories performing these tests

IMAGING

- Radiologic imaging plays an important role in the evaluation of children with dysmorphic features.
- Individuals found to have multiple external malformations should have a thorough evaluation to detect internal malformations.
- Testing might include ultrasonographic evaluation of:
 - Head
 - Abdomen (possible anomalies in the kidney, bladder, liver and spleen)
- 3-dimensionally reconstructed computed tomography of the head is indicated in craniosynostosis.
- Skeletal radiographs should be obtained if concern exists about a possible skeletal dysplasia.
- Magnetic resonance imaging may be indicated in children with:
 - Neurologic abnormalities
 - Spinal defect

DIAGNOSTIC PROCEDURES

- The presence of a heart murmur should trigger cardiology consultation.
 - Electrocardiography and echocardiography may be indicated.

TREATMENT APPROACH

- The pediatric health care provider seeing a patient who has dysmorphic facial features must decide whether the patient or family will benefit from a thorough evaluation or referral.
 - The most important task initially is to determine whether features are:
 - Consistent with the individual's genetic background
 - An abnormal phenotype
 - Following systematic diagnosis, the physician should convey the implications to appropriate family members.
 - Including genetic counseling

WHEN TO REFER

- A dysmorphologist should assist with diagnosis and meet with the family in person to explain the condition and all of its ramifications.
- A sufficient amount of time should be allotted for this meeting, because families may have many questions.
 - Each should be answered in a thoughtful and considerate way.
- It is helpful to include social support professionals as participants in these meetings.
 - Genetic counselors, social workers, and psychologists can be helpful in assisting the family in accepting the news and moving on with the next phase of their lives.

Failure to Thrive

DEFINITION

- Abnormal pattern of weight gain in children <2 years
 - Growth pattern irreconcilable with a predetermined standard for age
 - Weight consistently <80% of the median for age
 - Weight on >1 occasion falling below the 3rd percentile for age
 - Weight that has fallen across 2 major percentiles on the National Center for Health Statistics standard growth charts
- Social Security Administration definition
 - A drop in weight to below the 3rd percentile
 - In children <2 years, drop in weight to <75% of the median weight-for-height or age
- When acute malnutrition results in decreased weight-for-age, the condition is referred to as *wasting*.
- If caloric deprivation is prolonged, then it will eventually affect the child's linear growth as well, at which point the child is said to be *stunted*.
- Abnormalities in linear growth not accompanied by wasting (the child who has short stature alone) are not failure to thrive.

MECHANISM

- Infants and children grow in the presence of adequate amounts of 4 fundamental constituents.
 - Oxygen: deprivation at the tissue level will result in poor weight gain.
 - Congestive heart failure
 - Chronic lung disease
 - Anemia
 - Substrate: inadequate calories, protein, or micronutrients
 - Environmental deprivation
 - Malabsorption
 - Inability to metabolize them at the tissue level
 - Hormones: deficiencies can result in failure to thrive
 - Growth hormone
 - Insulin-like growth factors
 - Glucocorticoids
 - Thyroid hormone
 - Other regulators of growth
 - Love
 - Infants or children severely deprived of affection often will not grow despite what appears to be normal caloric intake.

- In the past, patients who had inadequate weight gain have been classified as a minority whose difficulty stems from a readily identifiable organic cause and a majority whose problem resides in a residual nonorganic category.
 - Other researchers have emphasized the overlapping nature of these distinctions and have suggested a third, or mixed, category of failure to thrive.
 - More recent approaches have tended to depart from the organic-nonorganic dichotomy in recognition of the somewhat arbitrary nature of this distinction.
- Energy
 - The largest share of energy consumed, approximately 55–60%, is devoted to maintaining a basal metabolic rate.
 - 5–10% of energy is lost in urine and stool.
 - 5% is accounted for by specific dynamic action.
 - 15% is used for normal physical activity above basal metabolic functions.
 - 15% is directed toward growth.
 - To support all these functions, infants need approximately 100–110 kcal/kg/day.
 - An imbalance between energy needs and energy supplies can arise either from increases in the former or deficiencies in the latter.
- Parenting difficulties may prevent the infant from receiving sufficient calories.
 - Unfamiliarity with proper preparation of infant formula or appropriate breastfeeding techniques
 - Psychosocial dysfunction
 - Maternal depression
 - Frank abuse or neglect
 - Economic deprivation
 - Unsound parental beliefs regarding nutrition
 - Subtle central nervous system abnormalities in the child that make them difficult feeders
- Food refusal in children
 - May begin even in infancy
 - Can result from many causes
 - Pain (from reflux esophagitis)
 - Psychosocial adjustment disorders from emotional deprivation
 - Anorexia from chronic infection or intoxication
 - Structural abnormalities resulting in dysphagia
- Inability to ingest nutrients properly
 - Structural malformations of the naso- or oropharynx
 - Cleft palate
 - Choanal atresia
 - Treacher Collins syndrome

- Muscular weakness
- Cerebral palsy or other central nervous system abnormalities
- Diseases that give rise to excessive dyspnea
- Vomiting
 - May impede growth through caloric deprivation
 - May be caused by
 - Structural abnormalities of the gastrointestinal tract
 - Increased intracranial pressure from any source
 - Chronic acidosis
 - Rumination
 - Gastroesophageal reflux
- The principal organ of nutrient absorption is the small bowel.
 - Malabsorption may result from:
 - Gross structural abnormalities
 - Inflammatory conditions
 - Infectious agents
 - Disorders of organs that elaborate enzymes essential for digestion

HISTORY

- Prompt evaluation of infants and children who do not gain weight as expected is important.
- The physician should begin by asking the parent or parents, guardian or guardians, or principal caregiver or caregivers how they think the baby is doing and what they believe the problem to be.
- Every evaluation of an infant or child who is not gaining weight must begin with a thorough history.
 - Gestational age at birth
 - Any unusual complications of the labor and delivery
 - Presence of malformations or other obvious deformities
- Knowledge of a parent's frame of mind may propel further evaluation toward or away from difficulty in parent-child interaction, including child neglect.
- Feeding history
 - Is the baby bottle-fed or breastfed?
 - How often does the child breastfeed, and for how long?
 - Does the mother feel as though the child is sucking well?
 - Does the baby appear satiated after feeding?
 - If bottle-fed, how is the formula prepared and by whom?
 - How many ounces will the baby take in a 24-hour period?
 - Does the infant wet 6–8 diapers a day?
 - For older children, when were solids introduced?
 - Does the parent find the child to be a picky eater or difficult to interest in food?
 - Does the child drink excessive amounts of juice during the day, substituting for more calorically rich nutrients?
- What are meal times like at home?
 - Where does the child eat, and with whom?
 - Are distractions, such as television, game boys, or video games, present during meals?
- Is food being used for discipline or in battles over control?
- A 24-hour dietary recall of a typical day often can help quantify the caloric intake of the patient.
 - If this information proves difficult to elicit, the parents can be sent home with a nutritional diary to fill out prospectively and bring in at the next visit.
- A home visit provides an opportunity to observe the family interaction around feeding in the context in which it normally occurs.
- Vomiting or spitting up
 - Frequency
 - Volume
 - Presence of blood or bile in the emesis
 - Gastric outlet obstructions (pyloric stenosis, antral web) often result in the generation of significant propulsive forces leading to projectile vomiting.
 - Gastroesophageal reflux often results in less dramatic patterns of regurgitation.
 - An obstruction distal to the ligament of Treitz will generally produce bilious vomiting.
 - In infants, this symptom may indicate the presence of a malrotation and midgut volvulus.
- Pattern and frequency of stooling
 - Liquid stools may indicate a small-bowel pathologic condition.
 - Bulky, foul-smelling stools may result from fat malabsorption.
 - Mucus or blood in the stools may indicate an inflammatory condition.
- Additional information should be obtained about the medical history, beginning with the parents' attitudes regarding their decision to have a baby and what their experience with the pregnancy was like.
 - Did the mother gain a reasonable amount of weight?
 - Did she experience any illnesses during her pregnancy?
 - Hypertension or preeclampsia will result in an infant who is small for gestational age.
 - Gestational diabetes may produce an infant with macrosomia who fails to gain weight because of postnatal cardiac complications.
 - Ask about specific toxic exposures in utero.
 - Tobacco use may result in a small baby, but he or she rapidly catches up in weight with peers.
 - Marijuana and alcohol use exert an influence on growth that may be sustained throughout childhood.

- Family history
 - Growth patterns of siblings
 - Occurrence of fetal loss or infant deaths
 - Presence in the family of immune deficiencies, neurologic disorders, or metabolic derangements
 - Any unexplained growth deficiencies in close relatives
 - Recent comprehensive longitudinal studies from England emphasize the extent to which mean parental height and parity overwhelm the influence of traditional markers of socioeconomic deprivation on infant weight gain, such as parental education or occupational status.
- Social history
 - Availability of social supports for the parents
 - Economic or legal circumstances that threaten the stability of the family
 - Nature of the relationship between the parents
 - Presence of affective disorders in the primary caregiver
 - Recent disruptive events in the family's life
- Finally, look for unrealistic expectations regarding feeding patterns, dietary fads, or infant behavior.

PHYSICAL EXAM

- Initial examination begins with observation of how the child relates to the parent or parents and the examiner.
 - Does the child appear listless, easily distractible, or irritable?
 - Can the child be engaged to make eye contact or to play with an age-appropriate toy?
- Repeated anthropometric measurements over time constitute the most important component of the physical evaluation of children who are not gaining weight.
 - Assemble all data available from previous anthropometric measurements of the patient, including weight, height, and head circumference.
 - Premature infants must have their measurements corrected for gestational age
 - Until 18 months of age for head circumference
 - Until 24 months of age for weight
 - Until 40 months of age for height
- The child should be completely undressed, and notations should be made of:
 - Any evidence of wasting
 - Presence and distribution of normal subcutaneous body fat
 - Muscle mass and tone
 - Any dysmorphic features
- Particular attention should be paid to organ systems that may reflect evidence of malnutrition.
 - Mucous membranes, hair, nails, and skin
 - Abnormalities may indicate vitamin, protein, fat, and micronutrient deficiencies.
 - Head, eyes, ears, nose, and throat
 - Open fontanelles may indicate hypothyroidism.
 - Craniotables are seen in nutritional rickets.
 - Blurred disk margins of increased intracranial pressure are seen in chronic emesis.
 - Submucosal cleft of the hard palate is seen in infant who feeds poorly
- Thyroid
 - Palpated gently
 - Auscultated for evidence of hyperthyroidism
- Lungs and heart
 - Observation, palpation, and particularly auscultation may reveal wheezing, rales, or heart murmurs suggestive of the presence of chronic conditions.
 - These conditions often result in energy expenditures that can outstrip the supply of nutrients available to an infant.
 - Examine the digits for clubbing in the older children.
- Abdominal examination
 - To rule out organomegaly associated with tumor, infection, or storage disease
 - Intestinal distention can be associated with carbohydrate malabsorption.
- Neurologic examination being watchful for
 - Disorders of mentation
 - Cranial nerve abnormalities
 - Generalized weakness
 - Spasticity

DIFFERENTIAL DIAGNOSIS

- Conditions that increase energy needs
 - Chronic heart disease (congenital or acquired)
 - Chronic lung disease (bronchopulmonary dysplasia, cystic fibrosis, pulmonary lymphangiectasis)
 - Chronic anemia (hemaglobinopathies, enzyme deficiencies, membrane abnormalities)
 - Chronic infection (urinary tract infections, respiratory infections, tuberculosis)
 - Endocrine abnormalities (hyperthyroidism)
 - Malignancy (neuroblastoma, ganglioneuroma)
- Conditions that compromise the efficiency of energy utilization
 - Chronic infection
 - Chronic renal disease

- Hepatic insufficiency
- Inborn errors of metabolism
- Hormonal abnormalities
- Certain genetic syndromes
- Deficiencies of various micronutrients, including iron, zinc, and carnitine
- Conditions leading to deficiency in energy supply
 - Calories withheld
 - In utero conditions
 - Formula preparation mistakes
 - Breastfeeding difficulties
 - Parent-child psychosocial dysfunction
 - Maternal depression
 - Intentional abuse or neglect
 - Poverty
 - Unsound parental beliefs regarding nutrition
 - Difficult feeders
 - Calories not properly ingested or digested
 - Anorexia (reflux esophagitis, emotional deprivation, chronic infection, dysphagia)
 - Structural abnormalities of the oro- or nasopharynx (cleft palate, choanal atresia, Treacher Collins syndrome, Pierre Robin syndrome, laryngeal web)
 - Structural abnormalities of the gastrointestinal tract (stenosis or atresia of the esophagus or duodenum, tracheoesophageal fistula, vascular ring, strictures, achalasia, malrotation, antral web, pyloric stenosis)
 - Neuromuscular disorders (cerebral palsy, hydrocephalus, myopathies)
 - Conditions leading to excessive dyspnea (congestive heart failure, chronic lung disease)
 - Vomiting and rumination
 - Malabsorption
 - Small bowel (celiac disease, inflammatory bowel disease, disaccharide malabsorption, intestinal lymphangiectasia, jejunal atresia, duplication cysts, chronic parasitic infections)
 - Pancreas (cystic fibrosis, Shwachman-Diamond syndrome, chronic pancreatitis)
 - Liver (cirrhosis, intrahepatic cholestatic syndromes, biliary atresia)

LABORATORY EVALUATION

- If the cause of the failure to thrive is not made clear by history and physical examination, laboratory investigation is unlikely to reveal it.
- In cases in which psychosocial features predominate, most laboratory tests may be unnecessary.

- If the cause of a child's failure to gain weight adequately remains uncertain after careful history and physical examination, a limited number of screening studies may be considered:
 - Complete blood count
 - Blood pH
 - Serum electrolytes
 - Blood urea nitrogen and creatinine
 - Urinalysis and urine culture
 - Stool examination
 - Reducing substances
 - pH
 - Occult blood
 - Ova and parasites
- More extensive testing should be done only when historical or physical examination evidence indicates a specific diagnosis.

TREATMENT APPROACH

- The therapeutic approach to a child failing to gain weight adequately must be tailored to individual needs of the family and the child.
- Therapy should be directed toward the underlying disease or condition where a specific diagnosis has been identified.
- When disturbance in the parent-child interaction is recognized as the cause of the patient's inability to gain weight, the family should be approached nonjudgmentally.
- The severity of the child's condition should dictate the initial approach to treatment.

SPECIFIC TREATMENT

Mild to moderate failure to thrive

- Goals
 - Nutritional rehabilitation
 - Parental education
 - Behavioral intervention
- Infants and children exhibiting mild degrees of malnutrition (>80% of ideal body weight for age)
 - May be managed as outpatients
 - May be managed by primary care physician, with consultation from a nutritionist
 - Occasional consultation may be provided by subspecialist colleagues.
- Patients who have evidence of more severe caloric deprivation require involvement of a multidisciplinary team
 - Primary care physician
 - Nutritionist
 - Mental health or behavioral therapist
 - Social worker

- Hospitalization may be necessary for a subset of these patients whose malnutrition is combined with or results from another significant medical condition.
 - Home visitation using professionals may be a successful intervention in select circumstances.
 - Child protective services must be alerted about any child thought to be the victim of neglect.
 - Refeeding regimen
 - ~10–15% of calories from protein
 - 50–60% from carbohydrate
 - 30–40% from fat
 - Attempts to overfeed malnourished infants at the outset of therapy should be avoided.
 - They may exhibit some degree of anorexia initially.
 - Refeeding that is too vigorous may induce malabsorption and diarrhea.
 - A typical 3-phase regimen:
 - Phase 1
 - Day 1: begin with provision of 100% of daily age-adjusted energy and protein requirements based on the child's weight.
 - If this phase is well tolerated, proceed to Phase 2.
 - Phase 2
 - Intake is increased to provide adequate nutrition to achieve catch-up growth.
 - (Age-adjusted energy requirements [kcal/kg/day]) × (ratio of the child's ideal body weight for height)/(the child's actual body weight at presentation) = reasonable estimate of the nutritional requirements for this stage
 - The same calculation can be made for protein requirements.
 - Energy and protein requirements for these phases of infant refeeding usually can be accomplished with the use of a routine infant formula modified to increase its caloric density.
 - Mixing 13 oz of concentrated formula with 10 oz of water rather than 13 oz of water will create a formula that is 24 cal/oz.
 - Alternatively, carbohydrates in the form of glucose polymers or fat in the form of medium-chain triglycerides adds calories while avoiding complications of overhydration.
 - For older children, available caloric supplements will include a wide variety of solid foods.
 - Phase 3: consolidation phase of nutritional rehabilitation
 - A varied diet is offered ad libitum.
 - The child gradually approaches ideal body weight.
 - Multivitamin and iron supplementation should be part of every refeeding regimen for undernourished children.
 - Initiation of nutritional rehabilitation is an ideal time to educate parents and to address family interactions, psychological vulnerabilities, social needs.
 - Emphasis should be placed on appropriate nutritional information.
 - Concrete suggestions should be offered about how to structure mealtime at home.
 - Minimize distractions.
 - Provide a relaxed social environment that encourages good eating habits.
 - For families in need, access to community resources must be facilitated.
 - Special Supplemental Nutrition Program for Women, Infants, and Children (WIC)
 - Food stamps
 - Pediatricians should be prepared to advocate vigorously for patients in need of supplemental nutrition or special infant formulas when families experience difficulties in obtaining these products.
- Severe failure to thrive**
- Children who are <60% of ideal body weight for height should be hospitalized.
 - The nutritional rehabilitation
 - Will be more prolonged
 - May entail a period of tube feedings in addition to oral supplements
 - In cases in which the gastrointestinal tract is temporarily inaccessible, parenteral feedings with central venous access may be necessary.
- WHEN TO REFER**
- If a diagnosis is made of a chronic disease pertaining to an organ subspecialty discipline such as cardiac, pulmonary, renal, gastrointestinal, or endocrine
 - If the psychosocial family dynamic indicates a need for psychiatric intervention for either or both parents
 - If nutritional rehabilitation warrants the attention of a nutritionist
- WHEN TO ADMIT**
- Any child with a weight <60% of ideal body weight should be hospitalized.
 - Care should be provided by a multidisciplinary team.
 - Nutritionists
 - Social workers
 - Pediatricians
 - Pediatric subspecialists, when appropriate

- Other children who should be hospitalized include
 - Any child who, despite aggressive outpatient management, continues to fail to gain weight at an acceptable rate
 - Any child who presents with signs of marasmus or severe protein malnutrition (kwashiorkor)

FOLLOW-UP

- Poor weight gain in infancy should be followed up assiduously.
- Initial weekly visits for infants may be necessary to reassure the parents and practitioner that the therapy undertaken is having the desired effects.
- Children <6 months, when provided with adequate calories, begin to gain weight in a few days.
- Older children may take longer than their younger counterparts before sustained weight gain is established.
- Ongoing developmental, behavioral, and social evaluations must be incorporated into any plan for follow-up.
 - Children who gain weight poorly often have abnormalities in these areas.
 - The lingering effects of calorie, protein, and micronutrient deprivation may manifest as developmental and behavioral abnormalities.
 - Such results are particularly likely in children whose mothers exhibit affective disorders.

COMPLICATIONS

- Most children who fail to gain weight adequately suffer from malnutrition and are therefore at risk for its attendant consequences.

PROGNOSIS

- Caution must be used when predicting outcomes for children who have abnormal weight gain patterns in infancy and childhood.
- A variety of conditions may give rise to this clinical picture.
 - High-quality data on which reasonable predictions might be sustained are lacking.
 - One systematic review of 13 long-term longitudinal studies concluded that growth and neurocognitive outcomes probably do not differ substantially between children with failure to thrive and their unaffected peers.
 - In an extensive review of the literature, the Agency for Healthcare Research and Quality concluded that children with failure to thrive in infancy are likely to suffer immunologic, behavioral, cognitive, and psychomotor developmental deficits that persist despite interventions.
- Such disparate findings suggest that most children in the mild failure to thrive category will
 - Experience brisk nutritional rehabilitation
 - Do well with adequate follow-up
- More severely affected children may require more prolonged or repetitive interventions.
 - Type of intervention depends on the underlying cause
 - These children may suffer residual cognitive, behavioral, and educational consequences.
- All children who exhibit faltering weight gain during infancy and childhood absolutely must receive early comprehensive evaluation and prompt treatment.

Family Screening and Assessments

BACKGROUND

- Because primary care providers develop ongoing relationships with families, they are uniquely poised to discuss and screen for a variety of family stresses that may negatively affect children.
- Family screening and assessment involves identifying parents who face challenges in meeting their child's needs, such as:
 - Depression
 - Smoking
 - Poverty
 - Addiction
 - Violence

Maternal depression

- Prevalence
 - Of the 4 million births annually, depression affects 500,000 women.
 - The most common complication of childbearing
 - 12–42% of maternal depressive symptoms are seen in pediatric primary care settings.
 - Socioeconomic
 - Maternal depressive symptoms are ubiquitous in all social and economic groups.
 - Postpartum blues (mildest)
 - Approximately 70% of women
 - Postpartum depression (moderate)
 - Approximately 15% of women
 - Postpartum psychosis (severe)
 - 1–2 of every 1000 births
 - Women at highest risk
 - Personal or family history of depression
 - Previous episode of postpartum depression
 - Low income
 - Low level of education
 - Poor maternal health status
 - Other stressful life events
 - Etiology
 - Probably involves a complex interaction of biochemical, interpersonal, and social factors
 - Disease spectrum
 - Postpartum blues
 - Lasts ~10 days
 - Typically does not interfere with a woman's ability to function
 - Postpartum depression
 - More persistent and debilitating than postpartum blues
 - May develop insidiously over the initial 3 postpartum months or occur more acutely
 - Can interfere with a mother's ability to care for herself or her child
 - Lasts an average of 7 months if left untreated
 - Postpartum psychosis
 - Occurs within the initial 2 weeks of delivery
 - Psychiatric emergency requiring immediate action because of risk of suicide, infanticide
 - Characterized by major disturbances in thinking and behavior, hallucinations, and delusions
 - Maternal depression
 - Term often used to describe chronic or acutely depressed women with dependent children (may include postpartum)
 - Well described in the American Psychiatric Association *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition
 - Signs and symptoms are clinically indistinguishable from those of major depression that occurs in women at other times.
 - Women experience recurrence and relapses.
- Maternal depression: effects on children
 - Infant behaviors in maternal depression
 - Limited play and exploratory behaviors
 - Less responsive to facial expressions
 - More emotionally labile (ie, fussy)
 - Increased drowsiness
 - Less sociable with strangers
 - Difficulties with emotion regulation
 - Maternal-child interactions in maternal depression
 - Decreased reciprocity in interaction of the infant
 - Decreased enjoyment of the infant by mother
 - Lack of patience to soothe the infant
 - Less active interactions with the infant
 - Children's mental and emotional health after maternal depression
 - Hyperactivity
 - Defiance and disrespect
 - Higher rates of depression
 - Increased substance abuse in adolescent years
 - Children's cognitive development with maternal depression
 - Delayed cognitive development
 - Lower scores on the McCarthy Scale of Children's Abilities in infants
 - Poor school performance in later years
 - Preventive health and parenting practices among women with depression
 - Shorter duration of breastfeeding
 - Less play and reading

- Less use of safety items (eg, outlet covers)
- Higher use of acute health services
- Lower rate of up-to-date immunizations
- Fewer optimal parenting practices (eg, reading, playing)

Parental smoking

- Prevalence
 - 43% of children age 2 months to 11 years live in homes with ≥ 1 smoker.
 - 60% of children 3–11 years of age are exposed to environmental tobacco smoke (ETS) (~22 million children).
- Health risks to children
 - Lower respiratory infections
 - Middle ear effusions
 - Asthma exacerbations
 - Sudden infant death syndrome
 - Increased risk of cancer as adults
 - Lymphoma
 - Leukemia

Intimate partner violence

- Prevalence
 - As many as 2 million women will experience intimate partner violence each year.
 - >3 million children witness interparental violence.
 - Children in this setting are at risk for:
 - Developmental delay
 - Sleep disorders
 - School failure
 - Oppositional defiant disorder
 - Depression
 - Abuse

GOALS

- Prevent adverse outcomes
- Maximize each child's potential
 - Family well-being is critically important in achieving these goals.
 - Identify parents in need of psychosocial services.
 - Partner with parents.
 - Offer information and resources.
 - Use strategies that incorporate theories of behavioral health counseling.
 - The 5As (Ask, Advise, Assess, Assist, Arrange) are readily transportable to other family issues.

GENERAL APPROACH

- A large body of evidence supports family psychological screening.
 - The quality of the child's environment, especially the quality of caregiving relationships, influences:
 - Development of young children
 - Children's long-term outcomes
- How can pediatric providers include family psychosocial screening into pediatric primary care?
 - Barriers to discussing family stresses include lack of:
 - Time
 - Education
 - Resources
 - Barriers may be community specific, and some may be more difficult to rectify than others.
- Maternal depression: rationale for screening
 - Screening for maternal depression is necessary when viewed in the context of the effects on children.
 - Pediatricians are reluctant to discuss maternal mental health in the course of routine pediatric primary care.
 - Pediatricians recognize only 25% of mothers with depressive symptoms.
 - Mothers at risk for depression may not seek health care from their own primary care physician.
 - However, they see their child's pediatrician many times during the postpartum period and beyond.
 - Every well-child visit presents the opportunity to ask a mother if she is feeling overwhelmed, stressed, anxious, or depressed.
 - Simple steps can be taken that may open windows of communication that will encourage a mother to discuss her feelings.
 - Mothers will be open to help if:
 - A consistent, trusting relationship exists
 - Concerns about maternal emotional needs become an expected component of each pediatric visit
 - Treating maternal depression can:
 - Have a positive effect on both mothers and their children
 - Reduce psychiatric conditions in children
- Parental smoking: rationale for screening
 - The consequences of exposure to tobacco smoke on children pose immediate health risks and long-term health concerns.
 - Smoking is a highly addictive behavior, but treatment is effective.

- Exposure to secondhand smoke primarily comes from parental tobacco use.
 - Despite recommendations from Bright Futures, pediatricians infrequently assess and advise parents to quit smoking.
 - Pediatricians can address children’s exposure to ETS by asking a few simple questions.
- The AAP issued a policy statement with strong recommendations for pediatricians to:
 - Inform parents about the health hazards of passive smoking
 - Provide guidance on smoking cessation during primary care visits
- Pediatricians should familiarize themselves with treatment options that are available to:
 - Help their adolescent patients who smoke
 - Assist the parents of their youngest patients
- Intimate partner violence: rationale for screening
 - AAP policy statement
 - Pediatricians are in a position to recognize abused women in pediatric settings.
 - Intervening is an active form of child abuse prevention.
 - Barriers to screening
 - Asking mothers about intimate partner violence during a pediatric visit is often difficult, especially when older children are present.
 - Pediatricians may be unprepared to raise questions with mothers.
 - However, this area of inquiry is critical and has been recommended by numerous advisory boards.
- Note the mother-child interaction.
 - Helps to assess attachment and bonding
 - This assessment is the most rudimentary but is already an inherent component of a primary care visit.
- Ask specific questions:
 - “How are you feeling about being a mother?”
 - “How is your energy level?”
 - “Have you had any periods of sadness? Feeling blue? Crying?”
 - “Are you feeling overly worried about your infant?”
 - “How have you been eating? Sleeping?”
 - “Do you have any worries about your overall mood?”
- Ask about resources mothers have to assist them.
 - Family members
 - Child care
 - Financial assistance
- Ask about other stressors that may have a negative impact on children.
 - Marital problems
 - Substance abuse
 - Housing instability
- Ask about history of depression.
 - Be specific
 - Ask about suicidal ideation.
 - Make appropriate emergency referrals as needed.
- Listen.
 - Mothers will talk about their concerns if they believe you are listening without judging them.

SPECIFIC INTERVENTIONS

Maternal depression

- Screening strategies
 - Signs and symptoms of maternal depression
 - Sadness or low mood
 - Feeling down
 - Feeling worthless
 - Loss of interest or pleasure (anhedonia)
 - Anxiety
 - Guilt
 - Loss of energy
 - Anger
 - Increased or decreased sleep
 - Increased or decreased appetite
 - Delusions or paranoia
 - Thoughts of death (their own or their child’s)
 - Suicidal ideation
- Screening tools
 - Edinburgh Postnatal Depression Scale (EPDS)
 - 10-item, 5-minute questionnaire
 - Easy to use
 - Can be scored immediately
 - Sensitivity: 93–100%
 - Specificity: 83–90%
 - EPDS instructions
 - The mother is asked to indicate 1 of 4 possible responses that comes the closest to how she has been feeling in the previous 7 days.
 - All 10 items must be completed.
 - Care should be taken to avoid the possibility of the mother discussing her answers with others.
 - The mother should complete the scale herself, unless she has limited English or has difficulty with reading.

- Sample EPDS question:
 - Given that you have recently had a baby, we would like to know how you are feeling. Please check the box next to the answer that comes closest to how you have felt IN THE PAST 7 DAYS, not just how you feel today.
 - Example: I have felt happy:
 - Yes, all the time
 - Yes, most of the time
 - No, not very often
 - Not at all
 - Checking box 2 would mean: “I have felt happy most of the time” during the past week. Please complete the following questions in the same way.
 - Patient Health Questionnaire-2
 - 2 questions
 - Answers on a scale of 0–3
 - 0 = Not at all
 - 1 = Several days
 - 2 = More than one-half the days
 - 3 = Nearly every day
 - Score of 3 or more points is considered a positive score.
 - Over the past 2 weeks, how often have you been bothered by any of the following problems?
 - Little interest or pleasure in doing things
 - Feeling down, depressed, or hopeless
 - US Preventive Task Force
 - 2 questions are asked of the mother at every primary care visit.
 - Yes to either question is considered a positive score.
 - During the past 2 weeks, have you ever felt down, depressed, or hopeless?
 - During the past 2 weeks, have you felt little interest or pleasure in doing things?
 - Center for Epidemiologic Studies Depression scale
 - Beck Depression Inventory
 - Patient Health Questionnaire-9
- Using results that reveal depression**
- Assure the mother that:
 - She is not alone.
 - Many mothers experience similar feelings.
 - Depression is treatable.
 - Support is available if they need it.
 - You are a partner that can help.
 - Encourage her to:
 - Get the help she might need
 - Be the best mother she can be

- Offer to:
 - Help her meet other mothers
 - Provide information about community, print, and online resources
 - Speak to the mother’s primary care provider
 - Initiate a referral to a mental health professional, support group, or other therapeutic agency
 - Speak with other family members who might be supportive to the mother
- Intervene if:
 - The mother shows severe impairment, psychosis, or suicidal ideation by initiating an emergency behavioral evaluation by a specialist
 - The child is at any imminent physical risk, strongly consider contacting child protective services
- Be prepared to:
 - Maintain communication with a mother who initially denies her symptoms and is unwilling to seek further treatment
 - Develop a strong therapeutic alliance and close follow-up
 - These strategies can help encourage mothers to address depressive symptoms
 - Schedule frequent office visits to follow up with the mother and her child or children

Parental smoking

- Screening tools for ETS
 - 3-item validated measure of ETS exposure
 - Does the child’s mother smoke?
 - Do others smoke?
 - Do others smoke inside?
 - Alternative 5-item screen
 - Does “_____’s” mother currently smoke?
 - In the home?
 - Does “_____’s” father currently smoke?
 - In the home?
 - Is your child exposed to cigarette smoke on a regular basis (any exposure at least 1 time a week) from anyone other than the parents (eg, stepparents, day care providers, grandparents, siblings, friends)

Intimate partner violence

- Screening tools
 - During every pediatric visit, pediatricians can ask mothers a few simple questions, such as:
 - “We all have disagreements at home. What happens when you and your partner disagree?”
 - “Does shouting, pushing, or shoving occur?”
 - “Does anyone get hurt?”

- “Has your partner ever threatened to hurt you or your children?”
- “Do you ever feel afraid of your partner?”
- “Has anyone forced you to have sex in the last few years?”
- The American Medical Association has suggested 3 questions.
 - Are you in a relationship now or have you ever been in a relationship in which you have been harmed or felt afraid of your partner?
 - Has your partner ever hurt any of your children?
 - Are you afraid of your current partner?
- HITS (hurt, insulted, threatened with harm, screamed at)
 - How often does your partner:
 - Physically hurt you?
 - Insult or talk down to you?
 - Threaten you with harm?
 - Scream or curse at you?
- Answers
 - 1 = Never
 - 2 = Rarely
 - 3 = Sometimes
 - 4 = Fairly often
 - 5 = Frequently
- Scoring: A total score >10 is considered positive for partner violence.
- Partner Violence Screen
 - Have you been hit, kicked, punched, or otherwise hurt by someone within the past year? If so, by whom?
 - Do you feel safe in your current relationship?
 - Is there a partner from a previous relationship who is making you feel unsafe?
 - Scoring: A “yes” response on any question is considered positive for partner violence.

Fatigue and Weakness

DEFINITION

- *Fatigue* and *weakness* are terms that are difficult to define and often used interchangeably.
 - Ubiquitous symptoms that may or may not be related to medical diagnoses
 - Used commonly in medical and colloquial language
 - Any acute illness or trauma may be accompanied by fatigue.
 - Usually, only prolonged fatigue is noteworthy.
- Adolescents and children often use other terms to describe perceptions of somatic weakness and fatigue.
- Fatigue involves:
 - Extreme and unusual tiredness
 - Decreased physical performance
 - Excessive need for rest
 - Often is accompanied by feelings of:
 - Sleepiness
 - Weariness
 - Irritability
 - Lassitude
 - Boredom
 - Decreased efficiency
- *Weakness* refers to diminished body or muscle strength.
 - True weakness can be identified only by demonstration of abnormal neurologic or muscular function based on:
 - History
 - Physical examination
 - Laboratory studies
- The term *chronic infectious mononucleosis* and *chronic fatigue syndrome* have become popular with both physicians and the media.
 - Attention has led to:
 - Misuse of these terms
 - Mild mass hysteria among young adults and adolescents, convinced they have one of these disorders

EPIDEMIOLOGY

- Age
 - Adolescents are most likely to experience fatigue, lassitude, lack of energy, or mild depression.
- Seasonality
 - Most common in spring among adolescents

MECHANISM

- Fatigue
 - Most commonly associated with recurrent or chronic infection in children

- May be a normal result of any physical or mental work in which energy expenditure exceeds restorative processes
- Temporary fatigue that follows intense exercise involves several complex mechanisms, including:
 - Increased central inhibition mediated by group III and IV muscle afferents
 - Decrease in muscle spindle facilitation and suboptimal cortical output
- At the level of the muscle cell, fatigue results from a reduction in adenosine triphosphate caused by:
 - High utilization rates
 - Depletion of glycogen
- Normal fatigue follows:
 - Such activities as cramming for examinations
 - Lack of food
 - Sleep deprivation
- The degree of fatigue, even when prolonged, is usually appropriate for the amount of physical or mental exertion expended.
- Fatigue may be a pathological state with an organic or psychological foundation.
 - Lassitude associated with somatic illness often has definable physical or laboratory abnormalities.
 - Fatigue has also been shown to have a strong correlation with:
 - Depression
 - Anxiety disorder
- Weakness
 - True weakness in a child is a cause for concern.
 - Results from a derangement of neuromuscular function
 - Cerebral hemispheres
 - Cerebellum
 - Spinal cord
 - Anterior horn cells
 - Peripheral nerves
 - Myoneuronal junction
 - Muscle

HISTORY

- Goals
 - Rule out underlying medical illness.
 - Return the child to a state of well-being.
 - Relieve parental concerns.
- Critical evaluation of history, physical examination, and laboratory tests should enable quick determination of organic causes for fatigue.
- Points to consider
 - Adequate time and concern are needed to evaluate history.

- Symptoms of chronic fatigue cannot be dismissed casually over the telephone or with a quick office visit.
 - The problem may seem insignificant, but either the child or parents are worried about the fatigue.
 - Family members may disagree about the significance of the symptoms.
 - Patients who come to the primary care physician complaining of fatigue often have emotionally based problems.
 - A careful history, with information from both child and parents (taken separately when appropriate), often helps narrow the differential diagnosis.
 - Discrepancies between the child's and the parents' observations become evident.
 - Emotional stress or some disruption in the patient's life is often part of the history.
 - In most cases, a diagnosis of emotionally related fatigue emerges on the basis of the history alone.
 - Information derived from a long-standing physician-patient relationship helps reduce tensions during the evaluation.
 - **Fatigue**
 - Young children infrequently complain of feeling fatigued.
 - Before adolescence, most children cannot verbalize a feeling of fatigue.
 - Even with chronic organic diseases, most children do not express fatigue verbally.
 - Younger children occasionally express a sense of lassitude and fatigue on questioning.
 - Fatigue is usually exhibited in terms of a child's physical activity and performance in school, sports, and other organized activities.
 - The problem may be manifested by trouble running or keeping up in gym class, clumsiness, or lack of agility.
 - Concerned parents usually report that the child appears fatigued.
 - "He has no energy."
 - "She lies around all the time."
 - "She seems bored and droopy."
 - "He's sleeping a lot of the time."
 - "She has no pep."
 - "He drags around."
 - "I can't get her to do a thing."
 - The younger the child, the more likely that the expressed or observed fatigue has a pathological basis.
 - Chronic fatigue is common among adolescents.
 - Even minor illnesses often precipitate prolonged fatigue in adolescents.
 - Parents often perceive their adolescent children to be fatigued, even when the adolescents do not agree.
- **PHYSICAL EXAM**
 - Thorough physical examination may be the only assessment necessary.
 - In all age groups
 - Search for sites of chronic latent infection
 - Adenopathy
 - Cervical adenopathy can be a clue to the diagnosis of infectious mononucleosis
 - Enlargement or tenderness of the liver and spleen
 - Abdominal masses
 - Prolonged fever, however low grade, must always be viewed as significant and may suggest:
 - Infection
 - Inflammatory disease
 - Cancer
 - Palpate for an enlarged or tender thyroid gland.
 - Look for mild scleral icterus and petechiae.
 - Examine for pallor from:
 - Anemia
 - Hypothyroidism
 - Examine the oropharynx for hyperpigmentation of gums and buccal mucosa (Addison disease).
 - Assess plotted height and weight.
 - Failure to progress along expected growth parameters may indicate an underlying systemic process.
 - Chronic cardiac disorder
 - Pulmonary disorder
 - Gastrointestinal disorder
 - Renal disorder
 - Poor growth velocity and obesity may indicate underlying endocrinopathy.
 - Hypothyroidism
 - Cushing syndrome
 - In adolescents with unexplained fatigue, poor weight gain may be a manifestation of inflammatory bowel disease.
 - A young child's affect and appearance are most revealing.
 - Adolescents may be more difficult to evaluate and may:
 - Be slovenly
 - Be uncommunicative
 - Be depressed
 - Be unwilling to express their feelings
 - Appear physically ill

DIFFERENTIAL DIAGNOSIS

Fatigue

Infants

- The term fatigue is rarely pertinent in this age group.
- Parents sometimes report that the infant tires easily during feedings or seems droopy.
- Infants with cyanotic or congestive heart disease:
 - Often appear to tire easily
 - Sweat excessively with feedings
- Other serious conditions, including severe anemia and hypothyroidism, may present as listlessness.

Children

- Recurrent or chronic infection is the most common cause.
- Otitis media, sinusitis, and tonsillitis of a recurrent and smoldering nature
 - Often overlooked for systemic effects
 - Fatigue may be prominent.
- Upper respiratory tract allergies
 - Often mistakenly considered insignificant
 - May cause impressive fatigue, irritability, and mild depression
- Toxoplasmosis and cytomegalovirus infections
 - May mimic mononucleosis
 - Produce significant fatigue, but with only minimal cervical adenopathy and fever
 - Fluorescent antibody test positive for toxoplasmosis or cytomegalovirus with negative results of a heterophil antibody test confirms the diagnosis.
- Hepatitis and other viral infections
 - Child may be anicteric (or only slightly icteric), with little or no hepatic tenderness or enlargement.
 - Other common viral infections, especially during convalescence, can cause prolonged fatigue accompanied by depression.
- Endocrine disorders
 - Only hypothyroidism is likely to be associated with fatigue.
 - A child with hypothyroidism whose growth rate has decreased may exhibit increasing fatigue and lassitude, at first subtle, as the only symptoms.
 - Thyrotoxicosis is uncommon in young children but occasionally produces isolated fatigue in adolescents.
- Diabetes mellitus
 - Any metabolic disorder can cause fatigue, but only diabetes mellitus occurs with enough frequency to merit consideration.
 - Fatigue almost always accompanies an initial or uncontrolled diabetic state.

■ Inflammatory diseases

- Rheumatoid arthritis and other rheumatoid-like disorders, such as Lyme arthritis
- Significant fatigue out of proportion to the child's musculoskeletal symptoms

■ Pulmonary disease

- Cyanotic heart disease
- Chronic advanced pulmonary disease, as with cystic fibrosis
- Underlying disease is usually readily evident before fatigue becomes severe.
- Severe fatigue may be caused by a previously undiagnosed hypoxic disorder.

■ Anemia

- Often thought to be cause of fatigue, but generally not the case
- Symptoms are usually not seen in children until the hemoglobin level decreases to 6 or 7 g/dL.
 - If erythrocyte counts decrease gradually, even lower hemoglobin levels may ensue without clinically evident symptoms.
 - Younger children especially seem to tolerate markedly low hemoglobin levels with no symptoms.
- Irritability and attention problems may be present.

■ Cancer

- Leukemia or lymphoma occasionally develops insidiously, with fatigue as the major symptom.

■ Emotional disorders

- Most children experience brief, transient periods of lassitude or fatigue that are usually self-limited.
- Unexplained chronic fatigue is often found to be emotionally related.
- Before adolescence, the complaint usually stems from the parents' concern about a child's reduced activity level.
- A younger child will be noted to:
 - Prefer sedentary activities
 - "Lie around the house a lot"
 - Appear tired
 - Lack energy
 - Shrink from social contacts
- Observed traits may have been long-standing.
 - A comment from grandparents or a teacher may arouse parental anxiety and precipitate a visit to the primary care physician.
 - The family usually suspects that the child has a serious organic disease.
 - Further evaluation usually reveals that the child is performing very satisfactorily but not up to the family's excessive expectations.

- The child may be withdrawing because of:
 - Failure to compete with an exceptional sibling
 - Real or imagined failure in school
- A child may feel a lack of well-being because of parental discord.
- Lack of parental involvement with a child may lead to lassitude and boredom.
- Stress and anxiety in children often result in either hyperactivity or withdrawal.
 - The more common withdrawal reaction may express itself as chronic fatigue.
 - Protracted and severe periods of withdrawal are more likely to be caused by a pathological process.
- In some children, chronic fatigue may be a sign of true psychiatric depression.

Adolescents

- Chronic fatigue is encountered most frequently in adolescents.
- Even minor illnesses often precipitate prolonged fatigue in adolescents.
- Normal swings of mood and energy are usually of more concern to parents and teachers than to the patient.
 - However, some adolescents initiate visits to their primary care physician because they feel fatigue.
- Infectious illnesses
 - Infectious mononucleosis
 - Most adults and many infants and children have been infected with the Epstein-Barr virus (EBV).
 - Clinical manifestations in proved cases are extremely variable.
 - Some patients remain symptom free.
 - Symptoms usually resolve in several weeks, but the occasional patient may have an atypical or more prolonged course.
 - The leukocyte count may be normal.
 - Lymphocytosis with atypical lymphocytes will most likely be present.
 - The heterophil antibody screening test (mono test) is diagnostic in most circumstances.
 - Initial clinical findings either persist or are intermittent over months or, in rare cases, years and typically include chronic fatigue.
 - Patients should not be labeled with a diagnosis of chronic infectious mononucleosis syndrome or chronic EBV infection, which used to be and still is a quick fix diagnosis for patients who are chronically fatigued.
 - *Mycoplasma pneumoniae*
 - Often low grade and without fever; produces progressive fatigue
- Hepatitis
- Cytomegalovirus infection
- Toxoplasmosis
- Addison disease
 - Unexplained fatigue and associated weakness
 - Anorexia
 - Nausea
 - Vomiting
 - Weight loss
- Alcoholism and drug abuse
 - Possible cause of chronic fatigue that should not be overlooked in this age group
- Emotional disorders
 - Fatigue
 - Lassitude
 - Lack of energy
 - Mild depression
 - May be sleep deprived, have unhealthy eating habits
 - Hypochondriacal symptoms
 - Possible fever, usually caused by infection (eg, infectious mononucleosis, influenza)
 - Emotional reaction may be precipitated by a physical illness, particularly infection
 - Usually seen during periods of greatest stress
 - May collapse with fatigue after intense and exuberant activity, eg, schoolwork, extracurricular activity, sports, social events
 - Burnout and fatigue are common in overachieving high school and college students.
- Chronic fatigue syndrome (CFS)
 - Initially attributed to infection with EBV
 - Symptoms include:
 - Persistent or relapsing severe fatigue
 - Fever
 - Headache
 - Sore throat
 - Tender lymphadenitis
 - Nausea or vomiting
 - Myalgia
 - Arthralgia
 - Abdominal pain
 - Neurocognitive symptoms, such as:
 - Inability to concentrate
 - Sleep disturbances
 - Episodic confusion

- Memory problems
- Depression
- Anxiety
- Irritability
- Neurocognitive symptoms are the most difficult to evaluate because of individual differences in emotional perception.
- Extensive laboratory evaluations usually produce normal results.
- Centers for Disease Control and Prevention (CDC) criteria for the case definition of CFS (based mainly on observations in adults):
 - New onset of persistent or relapsing fatigue lasting ≥ 6 months
 - No prior history of such fatigue
 - Exclusion of other clinical conditions that might produce similar symptoms
 - In addition, symptoms must include ≥ 4 of the following:
 - Muscle pain
 - Tender lymphadenopathy
 - Headaches of new type, pattern, or severity
 - Arthralgia
 - Impaired memory or concentration
 - Pharyngitis
 - Low-grade fever
 - Postexertional malaise lasting >24 hours
 - Sleep disturbances
 - Individuals with >6 months of disabling fatigue but an insufficient number of symptoms to meet criteria have been labeled as having idiopathic chronic fatigue.
 - CDC criteria exclude most past or current psychiatric disorders but allow some comorbid psychiatric symptoms (eg, anxiety and nonmelancholic depression).
- Autoimmune disease
 - Children with autoimmune disease may initially have fatigue with little else.
 - Mild articular or periarticular inflammation may be missed on examination.
 - Children with the following conditions may have prolonged symptoms, including fatigue, without any physical findings.
 - Inflammatory bowel disease
 - Unexplained fatigue may continue for months as the only major symptom.
 - A loss of sense of well-being
 - Eventually accompanied by fever, abdominal symptoms, abnormal stools
 - Arthritis
 - Arthritis-like illness
 - Cancer (monocytic leukemia, in particular)

- Thyroid disease
 - Enlarged, tender thyroid gland and fatigue may indicate thyroiditis with emerging hypothyroidism.
 - Thyroid is often palpable and full in healthy adolescents.
 - Chronic fatigue from thyroid disease can usually be ruled out quickly with:
 - A thyroid-stimulating hormone test
 - A free thyroxine (free T_4) test
 - Some patients with hypothyroidism also demonstrate mild to moderate anemia.
 - Those who have active thyroiditis may have an elevated sedimentation rate.
- Anemia
 - The diagnosis of pure anemia requires a marked reduction of the hemoglobin level.
 - Erythrocyte indices and a reticulocyte count will characterize the anemia and its probable cause.
 - Anemia accompanied by thrombocytopenia suggests leukemia or aplastic anemia.

Weakness

Infants

- Infants with weakness are often described by parents as being “floppy.”
 - In the newborn period, some may assume a frog-leg position.
- Usually indicates hypotonia caused by a neuromuscular disorder.
- Chromosomal anomalies are among the more common causes of hypotonia in infants.
 - Down syndrome
 - Congenital hypothyroidism
 - Infantile form of spinal muscular atrophy (Werdnig-Hoffmann disease)
- Infant botulism
 - Caused by ingesting *Clostridium botulinum* spores in honey
 - Can cause floppy appearance accompanied by:
 - A weak cry caused by muscle weakness
 - Loss of head control
 - Lethargy
 - Inability to feed
 - Constipation

Older children and adolescents

- Myasthenia gravis and Guillain-Barré syndrome (postinfectious polyneuropathy)
 - Perhaps the 2 most common causes of weakness in this age group

- In myasthenia gravis, deep-tendon reflexes may be diminished but are rarely absent.
- Guillain-Barré syndrome is remarkable for bilateral, symmetrically absent tendon stretch reflexes.
- Other causes of weakness in the older child include:
 - Muscular dystrophies
 - The juvenile form of spinal muscular atrophy
 - Dermatomyositis
 - Polymyositis

LABORATORY EVALUATION

- Initial laboratory evaluation can include:
 - Complete blood count with erythrocyte indices
 - Thyroid and liver function tests
 - Throat culture
 - Stool examination for blood
 - Cold agglutinin test (simple screen for *Mycoplasma* infection)
 - Erythrocyte sedimentation rate (ESR)
 - The most valuable screening test for inflammatory diseases of all varieties
 - Normal sedimentation rate almost always rules out:
 - Autoimmune disease
 - Inflammatory bowel disease
 - Chronic smoldering infections
 - Disseminated cancer
 - Elevated ESR requires further investigation.
- Routine urinalysis
 - Almost always reveals diabetes
 - Most patients who have chronic renal failure have abnormal urinalyses, as well as significant anemia.
 - Confirm these diagnoses with:
 - Measurement of blood glucose in diabetes
 - Measurement of creatinine or blood urea nitrogen in renal disease
- Thyroid disease can usually be ruled out quickly with:
 - A thyroid-stimulating hormone test
 - A free T₄ test
- Infectious mononucleosis
 - Results of the heterophil antibody test may be negative in many young children and infants and ~10% of older children and adolescents with the disease.
 - Reliability of EBV antibody testing can confirm active infectious mononucleosis.

- EBV antibody titers can usually differentiate long-past infection from recent and active infection.
 - Eliminates EBV infection and infectious mononucleosis as causes for the fatigue
 - Permits a search for other likely neuropsychiatric causes

- Toxoplasmosis or cytomegalovirus can be confirmed by:
 - Positive results of a fluorescent antibody test
 - Negative results of a heterophil antibody test
- Adrenocorticotrophic hormone stimulation test
 - Definitive diagnostic test for Addison disease
 - Hyperkalemia, hyponatremia, and hypoglycemia are useful diagnostic features.
- Laboratory studies for muscle weakness may include:
 - Chromosomal studies
 - Muscle enzyme assays

IMAGING

- Radiography is rarely necessary and should be discouraged.

DIAGNOSTIC PROCEDURES

- The evaluation of a patient who has weakness may include:
 - Nerve conduction studies
 - Electromyography
 - Edrophonium (Tensilon) challenge
 - Muscle biopsy
 - Lumbar puncture

TREATMENT APPROACH

- Chronic fatigue, in the absence of other physical symptoms, is usually emotionally based.
- In most patients, further management requires meaningful communication among primary care physician, patient, and parents.
- Older children and adolescents benefit from personal, warm attention and a continuous relationship with one physician.

SPECIFIC TREATMENT

- In younger children, variability in performance and behavior of healthy children must be put into perspective.
- Appropriate parental expectations must be emphasized.
- Conversation after the physical examination, with appropriate give and take, should:
 - Reassure children or adolescents about basic health
 - Reiterate common and normal occurrence of fatigue
 - Examine daily routine and stresses
 - Suggest modifications of lifestyle and approach to life's situations

- If emotional fatigue is thought to exist:
 - The patient (especially adolescents) must accept that organic diseases have been ruled out.
 - The patient must be made aware of emotional basis for the fatigue.
 - Reasons for any psychiatric referral must be made clear.

WHEN TO REFER

- Attempting to establish the probable cause of the fatigue is the primary care physician's responsibility.
- Referral to a specialist is appropriate with:
 - Hypotonia in infants
 - Unexplained weight loss
 - Suspected major affective disorder, eg, depression
 - Suspected cancer

WHEN TO ADMIT

- Severe depression or suicidal ideation
- Need for evaluation of neuromuscular disorders, including:
 - Werdnig-Hoffmann disease
 - Guillain-Barré syndrome
 - Myasthenia gravis

PROGNOSIS

- CFS
 - Although few longitudinal data are available, the prognosis for adolescents with CFS is better than that for adults.
 - Symptoms may persist for months or several years, but most adolescents with CFS have a good outcome.
 - Complete recovery in approximately 50%

Fever

DEFINITION

- General definition: an increase in body temperature
- More accurately described as a homeostatic response under control of thermoregulation
 - Distinct from hyperthermia: an increase in body temperature from conditions that overwhelm normal thermoregulation
- Normal core body temperature measured rectally ranges from 97°F to 100°F (36.1°C–37.8°C).
 - May be as low as 95.5°F (35.3°C) or as high as 101°F (38.3°C)
- “Normal” temperature of 98.6°F (37°C) was derived from an 1868 study of >1 million axillary temperatures taken in adults.
 - This value may have no relevance for children, not only because adults were studied but also because axillary and rectal (core) temperatures correlate poorly.
 - Young children appear to have higher core body temperatures than adults, with temperatures slightly higher than 37.8°C occurring frequently in those <2 years.
- Upper limits of the normal range for a rectal temperature
 - 100.4°F (38.0°C) for infants <1 month
 - 100.6°F (38.1°C) in 1-month-olds
 - 100.8°F (38.2°C) in 2-month-olds
- The lowest body temperatures occur between 2AM and 6AM, and the highest occur between 5PM and 7PM.
- A consensus panel has recommended the lower limit of fever be defined as a rectal temperature of 38°C (100.4°F).

EPIDEMIOLOGY

- Newborns
 - Temperature >98.6°F (37°C) occurs in 1% of all newborns.
 - 10% of these children have a bacterial infection.
 - Fever during the first 4 days of life has been associated with a high incidence of bacterial disease.
 - Neonates up to 28 days of age with fever have a significant risk of a bacterial infection (approximately 12% in some studies).
- Infants
 - 5–8% of children in the 3- to 36-month-old age group with undifferentiated febrile illness have a urinary tract infection (UTI).
 - Female infants with temperatures above 39°C (102.2°F) have a UTI incidence of 16–17%.
 - Uncircumcised boys in the first 12 months of life have an 8- to 9-fold higher rate of UTI than circumcised boys.
- Types of bacterial infection
 - Except for neonates <28 days, the rate of serious bacterial infections in febrile patients is lower if they are infected with influenza and respiratory syncytial virus.

- UTI and occult bacteremias are the most common types of infection.
- Pneumococcal infection is uncommon; group B *Streptococcus*, *Escherichia coli*, and other enteric pathogens are more usual.
- With group B *Streptococcus* infection, the risk of accompanying meningitis is as high as 39%.
- Since the introduction of pneumococcal vaccine, the disease has decreased 60–80% in children <24 months.
 - Because occult pneumococcal bacteremia and other pneumococcal infections previously made up most of the serious bacterial infections in young children with high fever (>102°F [>39°C]), use of this vaccine has greatly decreased the incidence of serious bacterial infections in children at greatest risk.
 - Given the marked decrease in pneumococcal and *Haemophilus influenzae* type b (Hib) serious bacterial infections, the likelihood of a serious bacterial infection in infants and toddlers with high fever (>102°F [>39°C]) has been reduced.

HISTORY

- Because many evaluations of the febrile child take place over the telephone, the clinician must take a pertinent history, including:
 - Patient age (the younger the child, the more thorough the evaluation)
 - Associated signs and symptoms
 - Exposure to illness in family or community
 - History of recent immunizations
 - History of any recurrent infections (eg, urinary tract infections, streptococcal infections, otitis media)
 - Duration and height of the fever
 - Low-grade fever present for many days (signifying chronic or benign illness) usually does not need to be evaluated as urgently as a temperature of 106°F (41°C) present for a few hours (indicating potentially serious infectious disease).
 - Time of year
 - Winter: respiratory syncytial and influenza virus infections
 - Spring and fall: parainfluenza virus infections (the most common cause of croup)
 - Summer: enterovirus infections

PHYSICAL EXAM

Findings on general physical examination

- Pronounced hypermetabolic state
- Flushed cheeks
- Unusual glitter in the eyes

- Sleepiness and lethargy or exceptional alertness and excited demeanor (particularly 5- to 10-year-olds)
- Pulse increased by about 10–15 beats per 1°C of fever
- Increased respiratory rate
- Hot and dry skin (“burning up with fever”)
 - Distal extremities may be cold and pale (vasoconstricted), obscuring an extremely high core body temperature.
- Shivering or sweating (mechanisms by which the body increases or decreases temperature).
 - Excessive sweating may cause dehydration, particularly with poor fluid intake.
- Dry mouth and lips from rapid mouth breathing and dehydration
- Febrile seizure may occur if irritability of the central nervous system increases.

Small infant

- Signs and symptoms may be less obvious.
- Shivering does not occur in the first few months of life.
- Diaphoresis is less frequent than in the older child.
- Irritability, pallor, and anorexia may be the only suggestions of illness; carefully measure temperature if the parent mentions these signs.

Examine the following:

- Respiratory tract
- Tympanic membranes
 - Otitis media
- Pharynx
 - Pharyngitis
- Nose
 - Discharge of sinusitis or viral upper respiratory tract infection
- Lungs
 - Evidence of pneumonia or bronchiolitis
- Eyes
 - Conjunctivitis as a clue to adenovirus, influenza, or respiratory syncytial virus infection, conjunctivitis-otitis syndrome, or Kawasaki disease
- Skin
 - Typical viral exanthems (rubella, roseola, or chickenpox)
 - Erythema marginatum (rheumatic fever)
 - Rose spots (typhoid fever)
- Lymph nodes
 - Generalized lymphadenopathy
 - Viral illnesses (eg, infectious mononucleosis, hepatitis, or cytomegalovirus infection)
 - Leukemia or lymphoma

- Localized enlargement
 - Skin infection
 - Tumor
- Isolated cervical lymphadenopathy
 - Tuberculosis
 - Cat-scratch disease (*Bartonella* infection)
- Musculoskeletal system
 - Localized bone tenderness (osteomyelitis)
 - Restricted range of motion in a warm joint (arthritis)
- Heart
 - Carditis of rheumatic fever
 - Infective endocarditis
- Spine
 - Diskitis
 - Costovertebral angle tenderness should prompt examination of the urine for evidence of UTI.

Factitious fever

- Pulse that is not correlated with the increase in temperature
- Inability to document fever when temperature is measured rectally
- Absence of sweating during defervescence

DIFFERENTIAL DIAGNOSIS

General

- Differentiate fever from hyperthermia, an increased body temperature resulting from conditions that overwhelm the normal process of thermoregulation.
 - Dehydration
 - Excessive muscle activity
 - Heat exposure
- Conditions associated with fever
 - Infection
 - If pulse rate is less than expected for the degree of fever, consider typhoid fever, tularemia, mycoplasma infection, or factitious fever.
 - Autoimmune disease
 - Neoplastic disease
 - Metabolic disease (eg, hyperthyroidism)
 - Chronic inflammatory disease
 - Hematologic disease (eg, sickle cell disease, transfusion reaction)
 - Drug fever and immunization reaction
 - Poisoning (eg, aspirin, atropine)
 - Central nervous system abnormalities
 - Factitious fever

- Although any disease in these categories may cause fever at any age, some diseases are more likely to occur at some ages than at others.

Viral infections

- Use findings of viral infections and their course to distinguish them from bacterial diseases.
- Viral infections tend to be less serious than bacterial infections.
 - Enterovirus
 - Influenza virus
 - Parainfluenza virus
 - Respiratory syncytial virus
 - Adenovirus
 - Rhinovirus
 - Rotavirus

Bacterial infections

- More aggressive and more serious outcomes compared with viral infections
- May be especially devastating in younger children with immature immune systems
- Infection that remains localized in the older child may in the infant and toddler disseminate rapidly to:
 - Blood (bacteremia)
 - Lungs (pneumonia)
 - Meninges (meningitis)
 - Bones (osteomyelitis)
 - Joints (arthritis)

Distinguishing bacterial from viral infections

- In younger children:
 - Difficult to recognize bacterial infection because children cannot verbalize complaints
 - Physical signs and symptoms are more subtle and easily missed.
 - Serious bacterial disease is especially difficult to diagnose in children with no obvious focus of infection.
- Efforts to improve the ability to diagnose a serious bacterial infection focus on 3 areas.
 - History and physical examination
 - Neither height of fever nor degree of toxicity is a reliable predictor by itself of bacteremia or serious bacterial infection.
 - Laboratory data
 - Response to antipyretics
 - The most unhelpful criterion in distinguishing serious bacterial infection from more benign viral infection
 - Children with a serious infection respond to antipyretics no differently from those whose illness is less significant.

- Rochester criteria, a combination of clinical and laboratory criteria to identify infants at low risk for a bacterial infection
 - The infant appears generally well.
 - The infant has been previously healthy.
 - Born at term (≥ 37 weeks' gestation)
 - Did not receive perinatal antimicrobial therapy
 - Was not treated for unexplained hyperbilirubinemia
 - Had not received and was not receiving antimicrobial agents
 - Had not been previously hospitalized
 - Was not hospitalized longer than the mother
 - No evidence of skin, soft tissue, bone, joint, or ear infection
 - Laboratory values
 - Peripheral blood leukocyte count $5.0\text{--}15.0 \times 10^9$ cells/L ($5000\text{--}15,000/\text{mm}^3$)
 - Absolute band form count $\leq 1.5 \times 10^9$ cells/L (≤ 1500 cells/ mm^3)
 - ≤ 10 leukocytes per high-power field ($\times 40$) on microscopic examination of a spun urine sediment
 - ≤ 5 leukocytes per high-power field ($\times 40$) on microscopic examination of a stool smear (only for infants with diarrhea)

Seizure

- Most dramatic manifestation of fever in a child
- Generalized tonic or tonic-clonic seizure, usually lasting < 15 minutes and occurring within 24 hours of the onset of fever, may begin without warning.
- Most parents are not aware that fever was present.
- The primary care physician may be called immediately after the seizure has occurred or after transport to the emergency department.
 - The child is likely to be postictal and have a rectal temperature of $102^\circ\text{F}\text{--}104^\circ\text{F}$ ($39^\circ\text{C}\text{--}40^\circ\text{C}$).
 - Seizure may be the first sign of meningitis or encephalitis.

Psychosocial factors

- A visit or telephone call for minimal fever and little evidence of disease should prompt thorough assessment of the psychosocial factors that may be contributing to parental concern.
- Answers to the following questions and others may clarify the situation.
 - Is the main concern about something else—a hidden agenda?
 - What knowledge about fever and disease does the caregiver have?
 - Has the caregiver had a previous traumatic experience with disease resulting in excessive anxiety?
 - Might the patient be a vulnerable child?

- Is this family dysfunctional, in which minor illness either cannot be dealt with or is used as a means to meet other needs?

Factitious fever

- Infrequent but well-described entity
- Children as young as 8 years have been known to increase the thermometer reading artificially by rubbing the mercury thermometer bulb on the sheets or by exposing it to warm liquids.

LABORATORY EVALUATION

- In newborns (≤ 4 days old) with fever, a full workup is indicated.
 - Complete blood count
 - Differential count
 - Urine analysis
 - Cultures of blood, urine, and cerebrospinal fluid (CSF)
- In an older infant who appears nontoxic and is at low risk for bacterial infection
 - CSF and blood culture may be avoided if:
 - Good observation and follow-up can be made within 24 hours.
 - Antibiotics are not administered.
 - If antibiotics are to be administered, then full workup, including blood and CSF cultures, should always be performed.
- For children who do not appear toxic:
 - Consider obtaining a leukocyte count.
 - If the count is $>15,000$ leukocytes/ mm^3 , consider blood culture.
 - Obtaining a leukocyte count and blood culture at the same time is easiest, with the blood sent for culture only if the leukocyte count warrants doing so.
 - Procalcitonin and C-reactive protein blood levels might have better sensitivity and specificity than leukocyte count in predicting serious bacterial infection, but studies vary widely with respect to the best cut-off levels.
- Given the current lower incidence of pneumococcal disease, avoiding blood tests altogether might be more cost-effective and reasonable if the child:
 - Has received ≥ 3 doses of the Hib and pneumococcal vaccines
 - Does not appear toxic
 - Has no obvious focus of infection
 - Has reliable health care providers and excellent follow-up capabilities
- Urine culture
 - For febrile boys <6 months of age (<12 months if uncircumcised)
 - Girls <12 –24 months

Rapid diagnostic viral testing

- Available for influenza A and B, respiratory syncytial virus, and enterovirus
- Sensitivity and specificity vary, but a positive result may help decrease the number of other tests that need to be performed to rule out bacterial infection.

IMAGING

- Chest radiography
 - Generally necessary only if clinical symptoms or signs suggest pneumonia (eg, cough, tachypnea, dyspnea, rales, decreased breath sounds, dullness to percussion)
 - At least 1 study has suggested that as many as 20% of children with a temperature of $\geq 102.2^\circ\text{F}$ (39°C) and a leukocyte count $>20,000$ cells/ mm^3 have pneumonia on the chest radiograph, even in the absence of respiratory symptoms and signs.

DIAGNOSTIC PROCEDURES

- Lumbar puncture
 - The younger the child is, the more difficult it is to diagnose meningitis clinically (eg, meningismus, Kernig sign, Brudzinski sign).
 - Children <12 months: strongly consider lumbar puncture since clinical signs of meningitis may be absent
 - Children 12–18 months of age: Consider lumbar puncture.
 - Children >18 months: Lumbar puncture is not routinely warranted except in the presence of signs and symptoms suggestive of meningitis or other intracranial infection.
 - Antibiotic treatment can mask meningitis; consider lumbar puncture in a child with a febrile seizure who has received antibiotics.
 - Reexamination after a convulsive episode may help determine whether examination of the CSF is needed.

WHEN TO REFER

- Patients with prolonged fever may be referred to rheumatologists.

WHEN TO ADMIT

- If the child appears toxic (eg, lethargic or irritable, noninteractive, poor perfusion)
 - Consider hospitalization *and*
 - Further diagnostic tests to assess for serious bacterial infection

Fever of Unknown Origin

DEFINITION

- Fever of unknown origin (FUO) is defined as ≥ 2 weeks of daily rectal temperature $>38.3^{\circ}\text{C}$ (101°F) with cause not determined by simple diagnostic tests, including:
 - Complete history
 - Thorough physical examination
- Some experts say that 1 of the 2 weeks of fever should be documented in the hospital.

MECHANISM

- Most cases of FUO eventually are found to be caused by common pediatric illnesses that are either self-limited or treatable.
 - Infectious illness accounts for 40–60% of FUO in children.
 - Although most infections that exhibit as FUO are an atypical or incomplete manifestation of a common infectious disease, several other types of infections should be considered.
 - Autoimmune disease accounts for 7–20% of cases.
 - Cancer is a much less common cause of FUO in children (1.5–6%) than in adults (7–16%).
- Children <6 years are most likely to have FUO resulting from an infection.
- Autoimmune diseases start to become more common after 6 years of age.
 - However, infection remains the most frequent cause of FUO.

HISTORY

- Careful documentation of fever is necessary before diagnosing FUO.
 - “Day of fever” is defined as a 24-hour period in which a temperature $>38.3^{\circ}\text{C}$ (101°F) occurs at least once.
 - Thorough explanation of the range of normal core body temperature for age, with its diurnal variation, may help to exclude patients who are not truly febrile but who instead have a high normal body temperature.
 - Physician should instruct parents in the technique of taking a rectal temperature.
 - Circumstances that may affect body temperature must be recorded.
 - All medications taken
 - Activities in which the child has participated
 - Environmental temperature
- Information must be obtained regarding:
 - Travel
 - Patient residence if outside the US
 - Animal exposure

- Frequency of exposure to other persons who have common febrile illnesses
- Previous illness
- Hospitalizations
- Medications
- Family history of disease
- Race and ethnicity
- Precise course of the exhibiting symptoms
- Meticulous documentation of dates is especially important.
 - Family should record on a calendar the daily time and degree of the fever, along with associated symptoms.
 - For children >11 – 12 years of age, a separate interview should be conducted alone with the child to:
 - Obtain the child’s perspective on the illness
 - Elicit information about subjects difficult to discuss in presence of parents
 - School
 - Peer relationships
 - Family functioning
 - Sexual identity and activity
- Some inflammatory diseases have recognizable fever patterns (eg, double quotidian fever of systemic juvenile idiopathic arthritis).
 - Fever patterns (ie, remittent, intermittent, sustained) rarely are diagnostic of a specific disease.
 - Determine whether even 1 or 2 days of normal temperature are interspersed between days of fever.
 - Child may have a series of rapidly sequenced brief febrile illnesses, masquerading as a single febrile illness.
- Careful documentation of fever should also help exclude pseudo-FUO, characterized by:
 - Absence of documented, persistent fever
 - Lack of objective, abnormal physical findings
 - History of significant or near-fatal illness
 - Parental fear of malignant or crippling disease
 - Frequent environmental exposure to illness
 - Absence of persistent weight loss
 - Normal erythrocyte sedimentation rate (ESR) and platelet count
 - Many missed school days because of subjective morning symptoms
 - Excessive amount of school missed, given the general degree of illness described
 - School absence for symptoms that are conspicuously absent during the rest of the day: fatigue, abdominal pain, and headache in the morning

- Discordance of fever and pulse rate
- Medical or paramedical family background
- ≥ 1 of the following:
 - Mild self-limited diseases
 - Behavioral problems
 - Parents who have misconceptions concerning health and disease
- Families under stress
- Child without a true fever if body temperature is measured accurately and consistently
 - Sometimes this must be done under hospital supervision.

■ Periodic fever syndromes

- Some children have shorter-than-normal episodes of fevers that recur in a regular (periodic) fashion with predictable symptoms.
- Many of these periodic fevers are now known to be genetically based and can be diagnosed by sophisticated genetic testing.

PHYSICAL EXAM

- A full physical examination must be performed.
 - Rectal temperature
 - Respiratory rate
 - Heart rate
 - Blood pressure
- A discrepancy between heart rate and temperature suggests factitious fever.
- A thorough examination of the respiratory tract is indicated.
 - Inspection of the pharynx for hyperemia and exudate
 - Transillumination of the sinuses for sinusitis
 - Search for purulent nasal discharge
 - Auscultation of the chest for localized wheezing
- Inspection of the tympanic membranes for chronic otitis media
- In the older child, examination of the teeth to exclude dental caries and periodontal disease
- A new cardiac murmur may be a clue to rheumatic fever or infective endocarditis.
- Lymphadenopathy, especially if generalized, may suggest a viral infection.
 - Infectious mononucleosis
 - Cytomegalovirus
 - Toxoplasmosis
 - HIV
- Joints must be examined meticulously for:
 - Swelling
 - Restricted range of motion
 - Tenderness

■ Skin rashes may suggest:

- Viral disease
- Autoimmune disease, such as juvenile idiopathic arthritis
- Absence of sweating and presence of a smooth tongue are consistent with familial dysautonomia.
 - Rare genetic disorder of thermoregulation
- Imperative tests
 - Rectal examination in the older child
 - Pararectal lymphadenopathy may suggest a pelvic infection.
 - Stool guaiac test
 - Positive result may be consistent with inflammatory bowel disease.

DIFFERENTIAL DIAGNOSIS

Bacterial infectious diseases

- Bacterial endocarditis
- Bartonellosis (caused by *Bartonella henselae*)
 - Usually exhibits as classic cat-scratch disease
 - May also appear as atypical cat-scratch disease, producing prolonged fever and hepatosplenic abscesses, lymphadenopathy, or central nervous system disease
 - When exposure to kittens and cats can be documented, serologic testing for *Bartonella* should be obtained.
 - If positive, abdominal ultrasonography should be considered.
- Brucellosis
- Chlamydia
 - Lymphogranuloma venereum
 - Psittacosis
- Leptospirosis
- Liver abscess
- Mastoiditis (chronic)
- Osteomyelitis
 - Particularly of the axial skeleton (intervertebral disk space and vertebral body infections) and the pelvis
- Pelvic abscess
- Perinephric abscess
- Pyelonephritis
- Salmonellosis
- Sinusitis
- Subdiaphragmatic abscess
- Tuberculosis
- Tularemia

Viral infectious diseases

- Cytomegalovirus
- Epstein-Barr virus (infectious mononucleosis) is the most common infectious cause of FUO.
- Hepatitis viruses
- HIV and AIDS
 - Assess the child thoroughly for characteristic physical signs and symptoms, as well as known risk factors for HIV.
 - Parental intravenous drug abuse
 - Parental sexual contact with individuals who may be HIV positive
 - HIV-positive mother
 - Hemophilia requiring transfusion of blood products
 - Fever is not usually the sole manifestation of HIV infection.
 - HIV infection should be strongly considered and the appropriate laboratory tests performed if fever has been present for >2 months and is associated with ≥ 1 of the following:
 - Failure to thrive or weight loss >10% from baseline
 - Hepatomegaly
 - Splenomegaly
 - Generalized lymphadenopathy (lymph nodes measuring ≥ 0.5 cm in ≥ 2 sites, with bilateral site involvement counting as 1 site)
 - Parotitis
 - Persistent or recurrent diarrhea
- Rickettsial diseases
 - Q fever
 - Rocky Mountain spotted fever

Fungal infectious diseases

- Blastomycosis (nonpulmonary)
- Histoplasmosis (disseminated)

Parasitic infectious diseases

- Malaria
- Toxoplasmosis
- Visceral larva migrans
- Visceral leishmaniasis

Autoimmune diseases

- Systemic juvenile idiopathic arthritis
 - Fever is almost always associated with this illness.
 - Often precedes the joint manifestations by weeks or months
 - The typical double quotidian fever (2 fever spikes in 24 hours with a normal temperature in between) is a helpful clue to this diagnosis.

- Polyarteritis nodosa
- Systemic lupus erythematosus
- Chronic regional enteritis
 - More common among children >6 years

Cancer

- Diagnosis that provokes the most anxiety
- Malignancies that may present with FUO in children include:
 - Leukemia (the most common malignancy in children)
 - Solid tumors, such as lymphoma, neuroblastoma, hypernephroma, and hepatoma
 - Hodgkin disease
- The reason for fever in these diseases is unclear.
 - May be related to endogenous pyrogen and other cytokines produced by the neoplastic cells

Periodic fever syndromes

- Recurrent fevers that do not satisfy the classic definition of FUO
 - Associated with a well-defined constellation of symptoms each time
- PFAPA (periodic fever, aphthous stomatitis, pharyngitis, and cervical adenopathy) is the most common.
 - Nonhereditary autoinflammatory syndrome
 - Onset before the age of 3 years
 - Associated with a sudden fever to 39°C–40°C (102°F–104°F) lasting 3–5 days
 - Anorexia
 - Mild oral ulcerations with pharyngitis, cervical lymphadenopathy, an increased leukocyte count, and an increased ESR
 - This constellation of symptoms recurs every 3–6 weeks.
 - A single dose of corticosteroids may quickly resolve the symptoms of individual episodes.
- Other periodic fever syndromes include:
 - Cyclic neutropenia
 - Familial Mediterranean fever
 - Hyperimmunoglobulinemia D and periodic fever syndrome
 - Tumor necrosis factor receptor-associated periodic syndrome
- Periodic fever syndromes are found in various populations around the world and are associated with known genetic mutations.
 - The primary care physician should know the patient's race, ethnicity, and country of origin.
 - These factors may provide clues about a specific periodic fever syndrome.

Miscellaneous causes

- Central diabetes insipidus
- Drug fever
- Ectodermal dysplasia
- Familial dysautonomia
- Granulomatous colitis
- Infantile cortical hyperostosis
- Münchausen by proxy syndrome
- Nephrogenic diabetes insipidus
- Pancreatitis
- Pseudofever
- Sarcoidosis
- Serum sickness
- Thyrotoxicosis
- Ulcerative colitis

LABORATORY EVALUATION

- If history and physical examination disclose no specific findings and growth is normal, only simple diagnostic tests are indicated.
- Routine blood counts and urinalysis
 - Have not been shown to be particularly useful; however, elimination from the workup is not advocated.
- A purified protein derivative tuberculin skin test should be given to detect tuberculosis.
 - Anergy may occur in active tuberculous infection.
- Blood, urine, and throat cultures
 - Negative cultures exclude infections of these areas.
- Erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) level, and albumin/globulin ratio
 - Most useful laboratory tests
 - Higher probability of serious disease exists, particularly an autoimmune vascular disease or cancer; pursue further evaluation if:
 - ESR is >30 mm/h *or*
 - CRP level is elevated *or*
 - Albumin/globulin ratio is inverted
- The remainder of the evaluation should be individualized based on historical and clinical findings.
- Because infectious causes are the most common, specific serologic tests may be useful.
 - Hepatitis A and B
 - Epstein-Barr virus infection (infectious mononucleosis)
 - Bartonellosis
 - Toxoplasmosis
 - Cytomegalovirus

- Bone marrow examination
 - Occasionally helps in diagnosis of:
 - Tuberculosis
 - Leukemia
 - Metastatic cancer
 - Fungal infections
 - Should be considered only in children with:
 - Clinical or laboratory suggestion of cancer *or*
 - Immunocompromise
- If ESR, CRP level, and albumin/globulin ratio are normal and no signs and symptoms are present that are specific to a particular disease, little can be gained from any of the previously mentioned tests.
- If the child is not deteriorating visibly, a period of observation may be necessary until new findings appear that can give more direction to the investigation.
- It is likely that the parents and patient will be anxious about an undiagnosable problem.
 - The physician must be ready to provide all family members with a clear explanation of the evaluative process, any normal results, and reassurance.

IMAGING

- Radiologic studies may be appropriate in certain individuals but should not be done routinely.
 - Sinuses
 - Gastrointestinal tract
 - Chest
- Radioactive gallium scan
 - To detect occult abscesses and infections
 - Less useful in children than in adults
- Total-body computed tomography
 - May help find tumors
- Abdominal ultrasonography
 - If the abdomen is of primary concern

DIAGNOSTIC PROCEDURES

- Bone marrow aspiration may need to be done to rule out cancer and to culture the bone marrow for bacterial and fungal organisms.

TREATMENT APPROACH

- Fever without a discernible cause is always difficult for clinicians because fever suggests disease.
 - Inability to identify the cause of fever can undermine the physician's credibility and can affect rapport with patients.
 - The longer fever persists, the more concern is raised by the parents.

■ Intensive examination of all of the following is the physician's responsibility and first stage of managing the patient.

- History
- Physical examination
- Particular social environment in which the child and family live

WHEN TO REFER

■ Referrals to the following may occasionally be necessary for additional assistance in determining diagnosis.

- Pediatric infectious disease specialists
- Rheumatologists
- Specialized diagnosticians
- Any combination of these professionals

WHEN TO ADMIT

■ Need for hospitalization depends on:

- Amount of parental anxiety
- Necessity to document fever
- Need to perform diagnostic tests that cannot be done on an outpatient basis

FOLLOW-UP

■ The health care professional must continue to assess these children frequently to:

- Detect new findings early
- Maintain the confidence of the family while the fever continues

PROGNOSIS

■ Children with FUO generally do well, even though fever may last for weeks or months.

Foot and Leg Problems

DEFINITION

■ Terms used to describe leg and foot disorders

- *Abduction*: deviation away from the midline of the body
- *Adduction*: deviation toward the midline of the body
- *Calcaneus*: foot dorsiflexed, placing the heel below the level of the toes
- *Cavus*: medial longitudinal arch of the foot elevated
- *Equinus*: foot plantar flexed, placing the toes below the level of the heel
- *Pes*: the foot
- *Planus*: medial longitudinal arch of the foot flattened
- *Talipes*: congenital deformities of the foot that, if untreated, result in walking on the ankle (talus)
- *Torsion*: excessive or abnormal twisting along the long axis
 - *Internal torsion*: excessive or abnormal inward twisting
 - *External torsion*: excessive or abnormal outward twisting
- *Varus*: medial or inward deviation of 1 segment of an extremity relative to the proximal (previous) segment
- *Valgus*: lateral or outward deviation of 1 segment of an extremity relative to the proximal (previous) segment
- *Version*: physiologic or normal twisting along the long axis
 - *Inversion*: physiologic or normal twist inward
 - *Eversion*: physiologic or normal twist outward
 - *Anteversio*n: physiologic or normal twist forward
 - *Retroversion*: physiologic or normal twist backward
- *Pronation*: outward rolling of the foot with eversion of the heel and abduction of the forefoot (*flexible foot, relaxed foot, fatfoot, flatfoot, pes planus*)

EPIDEMIOLOGY

- Clubfoot: both forms (*talipes equinovarus* and *talipes calcaneovalgus*)
 - 1 of every 200 live births
 - Bilateral in 50% of cases
 - Affect boys almost twice as often as girls
 - Incidence in siblings if one has clubfoot is 3–4%.
 - If 1 parent and a child have clubfoot, then subsequent children have a 25% chance of having clubfoot.
- Curly toe
 - Curly toe is quite common in infancy and childhood.
- Polydactyly
 - Common
- Accessory tarsonavicular
 - Fairly common; probably occurs in 1% of the population
 - Bilateral in 50% of patients

- Forefoot adductive deformities (*talipes varus, metatarsus varus, and metatarsus adductus*)
 - Combined incidence of these 3 deformities is ~1 per 100 live births (the most frequent musculoskeletal congenital malformation).
 - Metatarsus adductus: the most common
 - Talipes varus: the least common
- Femoral anteversion occurs twice as frequently in girls as in boys.

MECHANISM

- Hallux valgus
 - Many factors cause the problem.
 - Foot structure (which may or may not be hereditary)
 - Narrow stylized shoes that crimp toes
 - Hammertoe
 - In infants, usually hereditary
 - In the older child, usually results from faulty shoe wear
 - Clubfoot
 - Usually idiopathic
 - Claw toe
 - Usually occurs in conjunction with a cavus foot, in neuromuscular diseases
 - Charcot-Marie-Tooth disease
 - Myelomeningocele
 - Extra toe
 - Usually, family history
 - Syndactyly (webbed toes)
 - May exist as an isolated finding or as part of a more extensive syndrome of congenital anomalies
 - Family history often found
 - Metatarsus adductus
 - Crowded intrauterine environment
 - Uterine fibroids
 - Bicornate uterus
 - Multiple gestation
 - Oligohydramnios
 - Toe-walking
 - Commonly associated with cerebral palsy if persists beyond 2 years of age
 - Also caused by congenitally short tendocalcaneus
- ## HISTORY
- Pronation (flatfoot)
 - Most infants have flexible flatfeet.
 - Transient, with resolution by 2.5 years of age in 97%

- Family history of pronation may be found in children with flatfoot that persists beyond the usual time of physiologic resolution.
- Symptoms are uncommon but may occur.
 - Aching of the feet and legs
 - Muscle cramps in the calves at night
 - Easy fatigability
 - Reluctance to participate in strenuous activity
- Tarsal coalitions
 - May be found in other family members who are asymptomatic but have no hindfoot motion
- Pes cavus
 - Seen in:
 - Muscular dystrophy
 - Peripheral neuropathies
 - Disease of the spinal cord, brainstem, and cerebral cortex
 - Conditions producing it as a late manifestation
 - Cerebral palsy
 - Meningomyelocele
 - Poliomyelitis
 - Charcot-Marie-Tooth disease
 - Friedreich ataxia
 - Family history should be sought because many conditions producing this deformity are inherited.
- Bowed legs/knock-knees
 - History of uterine crowding during fetal development can be associated with extreme cases.
 - Prior trauma
 - Abnormalities
 - Endocrine
 - Metabolic
 - Bone
- Femoral anteversion
 - In utero and postnatal positioning of the legs and hips

PHYSICAL EXAM

- If a pathologic deformity of the legs or feet is diagnosed, the clinician should look for other congenital anomalies, especially those involving the skeletal system.

Forefoot adductive deformities

- Talipes varus
 - The entire foot is inverted and the forefoot is adducted.
- Metatarsus varus
 - The forefoot is inverted and adducted while the hind foot and heel are in the normal position.
 - The great toe is widely separated from the second toe.
 - The lateral border of the foot is convex.

- Metatarsus adductus
 - The only finding is adduction of the metatarsals at the tarsometatarsal joints.
 - The forefoot is adducted but not inverted.
 - Severity may be graded by the heel bisector method (line bisecting the heel that falls between the second and third toes).
 - Mild if line falls through third toe
 - Moderate if between the third and the fourth toes
 - Severe if between the fourth and fifth toes
 - Flexibility of the forefoot should be assessed.
 - With a flexible foot, the second toe can be easily brought in line with or past the heel bisector.

Clubfoot

- The leg and its appended foot are turned to resemble a club.
 - Plantar flexion (equinus) of the ankle
 - Adduction (varus) of the heel (hindfoot)
 - High arch (cavus) at the midfoot
- 2 varieties
 - Talipes equinovarus (more severe)
 - The heel and forefoot are inverted.
 - The forefoot is adducted.
 - The entire foot is plantar flexed.
 - Talipes calcaneovalgus
 - Eversion of the heel and forefoot
 - Abduction of the forefoot
 - Dorsiflexion of the entire foot
- Associated neurologic, muscular, or other skeletal anomalies should be sought.
 - Neuromuscular clubfoot is associated with arthrogryposis, meningomyelocele, and congenital constriction band syndrome.

Toe deformities and their presentations

- Hallux valgus
 - The great toe is deviated laterally to overlap the second toe.
 - The first metatarsal bone is deviated medially.
 - Prominence on the medial aspect of the metatarsophalangeal (MTP) joint
 - Bursa forms from the constant irritation and inflammation, forming a painful bunion.
 - May see some degree of pronation (flatfoot)
- Hammertoe
 - Occurs at the proximal interphalangeal joint
- Mallet toe
 - Occurs at the distal interphalangeal joint

- Claw toe
 - Involves all joints of the toe—hyperextension of the MTP joints and flexion at both the proximal interphalangeal and distal interphalangeal joints
- Curly toe
 - The fourth or fifth toe is usually flexed downward and twisted underneath the adjacent toe.
- Syndactyly
 - Interconnection between ≥ 2 toes can vary from thin skin to a bony attachment.
 - Growth differential between the involved toes tends not to be significant.
- Bunionette (tailor bunion)
 - Bunionette occurring at the fifth MTP joint
 - Bursa over the lateral aspect of the fifth MTP joint is prominent, inflamed, and painful.
- Associated neurologic, muscular, or other skeletal anomalies should be sought.
 - Neuromuscular clubfoot is associated with arthrogryposis, meningomyelocele, and congenital constriction band syndrome.

Pronation (flatfoot)

- The Achilles tendon curves inward.
- The medial longitudinal arch of the foot, observed without weight bearing, disappears on standing.
- Look for associated conditions, such as:
 - Obesity
 - Neuromuscular disorders
 - Structural abnormalities above the ankle
- In newborns, bony prominences on the medial and plantar aspects of the foot, with limited plantar flexion and forefoot inversion, indicate vertical talus and accessory tarsonavicular.

Tarsal coalitions

- Usually detected in late childhood or adolescence
- A fibrous/cartilaginous bar connecting the hindfoot bones becomes ossified, producing pain with walking and an inability to invert the foot.
- The foot is held in a pronated position, with eversion of the forefoot.
- Peroneal tendons stand out prominently when attempts are made to invert the foot.
- Calcaneonavicular coalition tends to develop between 9 and 13 years of age.
- Talocalcaneal coalition develops at 13–16 years of age.

Pes cavus

- Weakness or paralysis of the intrinsic muscles of the foot and its dorsiflexors
- Leads to deformity over time; usually seen in late childhood or adulthood

- A high-arched foot characterizes the deformity.
- Takes 1 of 2 forms
 - *Cavovarus*, in which the calcaneus is inverted with tightness of the heel cord
 - *Calcaneocavus*, in which a high arch with normal heel alignment is present

Bowed legs (genu varum)/knock-knees (genu valgum)

- From birth until 18 months, some bowing is normal.
- Continued growth results in a knock-knee pattern of 10–15 degrees, which assumes prominence by age 3–4 years.
- Persists until later childhood or early adolescence, when balancing and straightening occur spontaneously (normal).
- Marked degrees of these conditions require investigation to rule out underlying disease that can result in permanent deformity.

In-toeing (pigeon toe)

- If the child's patellae are rotated inward (kissing knees) while walking, the underlying problem is above the knee.
- If the patellae face straight forward, the underlying problem is below the knee.
- Excessive in-toeing is likely to be caused by benign conditions representing variations of normal development from excessive rotations of the femur, the tibia, or both.
- In-toeing does not usually cause pain or interfere with development or stability of gait.
- Best position to assess rotation of the lower extremities:
 - Child in the prone position
 - Hips fully extended
 - Knees flexed to 90 degrees
 - To measure hip rotation, the lower leg is used as a pointer and the legs are rotated through the axis of the hip joint.
 - Until 1–2 years of age, clinical measurement of hip rotation is limited by the physiological tightness of the hip joint capsule.
 - After 18–24 months, measurement of hip rotation is a close approximation of bony femoral rotation, averaging 50 degrees of internal rotation and 40 degrees of external rotation.

Out-toeing (slew foot)

- To assess tibial rotation: measure the thigh-foot angle, the axis of the foot relative to the axis of the thigh.
 - Normal angle ranges from 0–30 degrees of external rotation; an internal thigh-foot angle indicates internal tibial torsion.
 - By age 2 years, children typically walk with feet turned out relative to the line of progression.
 - Thigh-foot angle of 10–15 degrees is normal in older children.

Femoral anteversion

- Produces kissing knees, in-toeing, and clumsy gait.
 - With the patella in neutral position, the greater trochanter of the femur lies posterior to the lateral, longitudinal midhigh line.
 - External rotation is decreased.
 - Internal rotation of the hip in extension is increased (normally 35–45 degrees for both).
 - External rotation of the hip in flexion is normal.

Femoral retroversion

- Findings are the opposite of those found in anteversion of the femoral neck.

DIFFERENTIAL DIAGNOSIS**■ Pronation**

- Foot flattening includes vertical talus, accessory tarsonavicular, and fusion of ≥ 1 of the tarsal bones (tarsal coalition).
 - Accessory tarsonavicular
 - A normal anatomic variant
 - A secondary center of ossification forms in the medial portion of the tarsonavicular at the attachment of the posterior tibialis tendon.
 - Ossification becomes more prominent or symptomatic during adolescence.
 - Can have repetitive sprains of the fibrous attachment of the ossicle to the navicular
 - Tarsal coalitions
 - Not usually detected until late childhood or adolescence, when they produce pain with walking and inability to invert the foot
 - 2 types have been identified.
 - Calcaneonavicular coalition, which involves the calcaneus and the navicular bones
 - Talocalcaneal coalition, in which is the calcaneus is coalesced to the talus
- Toe-walking
 - May be habitual (idiopathic toe-walking)
 - Cerebral palsy associated with toe-walking that persists beyond 2 years of age.
 - Congenitally short tendocalcaneus causes persistent toe-walking even though the child can toe-heel and heel-toe walk; the condition disappears at 6–8 years of age.
- In-toeing is generally caused by benign conditions.
 - Protective or compensatory shifting of body weight in pronation and knock-knee, both normal developmental stages
 - Most common cause of in-toeing
 - Corrects itself in time

- Developmental bowing
 - Self-correcting
 - May lead to temporary in-toeing
- Internal tibial torsion
- Femoral anteversion
- Metatarsus adductus
- Talipes equinovarus and metatarsus varus
- Spasticity of the internal rotator muscles of the hip (seen in cerebral palsy)
- Anterior maldirection of the acetabulum

■ Out-toeing is seen with:

- Calcaneovalgus
- Pes planovalgus
- Flaccid paralysis of the internal rotator muscles of the hip
- Posterior maldirection of the acetabulum
- External tibial torsion

■ Tibial torsion

- Pathologic degrees of internal/external tibial torsion due to:
 - Deformities of the feet, ankles, knees, and hips *or*
 - Improperly applied casts, braces, or Denis Browne splints

■ Genu varum (bowed legs)

- When extreme or unilateral, may result from:
 - Rickets
 - Dyschondroplasia
 - Osteogenesis imperfecta
 - Osteochondritis
 - Blount disease (tibia vara)
 - Injury to the medial proximal epiphysis of the tibia

■ Genu valgum (knock-knees)

- Often associated with pronation
- More apt to be marked in overweight children
- Injury to the lateral proximal tibial epiphysis can cause unilateral genu valgum.
- Underlying generalized diseases of the bone can cause marked bilateral genu valgum.

IMAGING**■ Clubfoot**

- Radiographic examination is required at the time of diagnosis and periodically during treatment.
 - Delineates the pathologic finding
 - Guides management

■ Metatarsus adductus

- In babies with limited forefoot flexibility, radiographic examination is necessary to rule out talipes varus and metatarsus varus.

- In the primary care physician's office, placing the child in a standing position on a copy machine and taking a photocopy of the soles of the feet is an easy way to assess the heel bisector position.
- Allows for tracking of the progression or improvement of the condition over time.
- Pronation
 - Flexible flatfoot (pes planus) does not require any imaging in most cases.
 - Radiograph may be necessary if:
 - Pronation persists beyond 2.5 years of age.
 - Symptoms are present.
 - Flexibility is limited.
 - Planovalgus is suspected.
- Pes cavus
 - Radiographic examination may be necessary, especially if surgical management is under consideration.
- Genu varum (bowed legs), when extreme or unilateral, requires roentgenographic examination to exclude:
 - Rickets
 - Dyschondroplasia
 - Osteogenesis imperfecta
 - Osteochondritis
 - Blount disease (tibia vara)
 - Injury to the medial proximal epiphysis of the tibia
- In-toeing and out-toeing rarely require imaging studies.

TREATMENT APPROACH

- Most problems require no treatment or are managed easily without consultations.
- A few require services of an orthopedist.

SPECIFIC TREATMENT

Talipes varus and metatarsus varus

- Fixed deformities of the foot that require early treatment
- Serial casting
 - Abduction stretching exercises and out-flare last shoes may be used as an adjunct to cast treatment but should not be relied on as the only therapy.
 - Long-leg splints on both legs

Metatarsus adductus

- Requires no treatment because resolves spontaneously, usually within the first year

Hallux valgus

- Patients should wear shoes with plenty of toe room and no heels.

- If flatfoot is present, a shoe insert to correct the foot pronation may help prevent progression of the disease.
- In more severe cases, surgical correction may be needed.

Hammertoe

- Most cases are mild, cause no pain, and can be left alone.
- The child should have roomy shoes that allow the toes to stretch.
- In more severe cases, at an older age, surgical correction may be needed.

Mallet toe

- Most cases are mild and need no treatment.
- If a corn develops over the deformity, shaving and padding will help.
- In more severe cases, surgical correction can be performed.

Curly toe

- If the condition is severe and causes irritation with shoe wear, surgical transfer of the toe flexor may correct the problem.

Extra toe

- If the extra toe is not causing problems with walking and shoe wear, no treatment is needed.
- Can be ablated by suture ligation
- If an extra little or big toe and sticks out prominently, difficulty with shoe wear is common.
 - In these cases, surgical excision will remove the problem.
 - Typically performed after 9–12 months of age

Bunionette

- If padding does not help relieve the discomfort of a bunionette, surgical correction is needed.

Clubfoot

- Treatment is with casting immediately on initial diagnosis.
- 2–4 months of manipulation and casting are usually required.
- Recurrence is common after correction by manipulation alone, and prolonged casting is usually required.
 - Recurrence is most common in the first 2–3 years but may still happen up to age 5–7 years.
- Surgical correction (tenotomies, muscle transplants, and arthrodeses) may be required in severe cases.
 - When conservative management fails *or*
 - Because of recurrence when the child is older
- Recurrence is much less likely after surgical correction.
- Early initiation of therapy will:
 - Increase success rate of manipulative or conservative management
 - Decrease the need for surgical intervention

Pronation

- Usually disappears before 2.5 years of age and requires no treatment
- If pronation persists, treatment is not necessary unless symptoms occur.
- Corrective shoes with a long medial counter and a Thomas heel
- Support to the medial longitudinal arch with a flexible felt, rubber, or leather pad placed beneath the inner sole may help.
- Wedges that are 1/8- to 3/16-inch thick applied to the medial aspect of the heel and the lateral aspect of the sole are sometimes helpful.
- Steel arch supports placed in the shoe rarely are required.
- If neuromuscular disorders (eg, tight heel cords) are present, then heel cord-stretching exercises may reduce discomfort.
- Pes planovalgus
 - Orthopedic shoes
 - Surgical correction is required only for accessory tarso-navicular or tarsal coalition if symptoms cannot be relieved through conservative means (~10% of cases)
 - Usually performed in adulthood

Vertical talus

- Usually requires surgical correction early in infancy

Toe-walking

- The only treatment required for either idiopathic or habitual toe-walking is reassurance.
- If it persists beyond 2 years of age, a dorsiflexion-assist ankle-foot orthosis may be of benefit.

Bowed legs/knock-knees

- Simple observation and reassurance are all that are required, because the condition spontaneously corrects 99% of the time.
- When identified, the underlying causes of extreme varus or valgum deformities must be effectively treated to improve angulation.
- Treatment of severe bowing or knocking of the knees caused by underlying disease is determined by the nature of the condition and may include:
 - Wedge osteotomy
 - Epiphyseal stapling

In-toeing/out-toeing

- Most children will simply outgrow their variant.
- Tibial torsion
 - If a child trips on his or her feet and falls frequently, or if parents are unduly concerned about in-toeing, use:
 - Passive stretching exercises (externally rotating the foot at the ankle)

- Corrective shoes
 - Thomas heel
 - Longitudinal arch pad
 - Inner heel
 - Outsole wedges
 - Application of torque heels
- Denis Browne splints should not be used without orthopedic consultation, as they may create abnormal stress on the hip joint.
- In extreme cases, orthopedic treatment
 - Use of a bivalve lower-trunk and leg cast during sleeping hours
 - Rarely, derotation osteotomy of the middle or lower femoral shaft
- Femoral anteversion (in-toeing)
 - A simple measure if parents are concerned is to have the child learn to sit in the tailor, modified lotus, or Indian-style sitting position.
 - Use of Denis Browne splints is contraindicated.
 - Corrective shoes are of no value.

WHEN TO REFER

- Toe anomalies
 - Referral to a podiatrist or orthopedist may be indicated if:
 - The anomaly leads to pain or uncomfortable shoe wear or ambulation.
 - These symptoms do not respond to conservative management.
- Clubfoot
 - Immediate referral to an orthopedist should be made on diagnosis.
- Metatarsus varus
 - Forefoot has limited flexibility.
 - Condition appears to be progressing or is not improving with growth.
- Pronation
 - Limited flexibility or a suspicion of planovalgus
 - Persistence of pronation beyond 2.5 years of age
 - Symptoms are present that are not relieved through conservative management
- Pes cavus
 - Always refer for evaluation by a neurologist, physiatrist, or orthopedist, individually or in collaboration.
- Toe-walking
 - If it persists beyond 2 years of age
 - If the child has an abnormal neurologic history or examination

- Bowed legs and knock-knees
 - Severe, asymmetric, or unilateral genu varum or genu valgus
 - Condition that does not follow the expected physiologic progression with growth
- In-toeing and out-toeing
 - If in-toeing is severe
 - Unsteady gait (especially while running) that causes stumbling
 - Condition that does not follow the expected physiologic progression with growth
- Tibial torsion
 - Extreme rotation (especially when associated with difficulty walking or running)
 - Significant asymmetry
 - Sudden proximal tibial deviation
 - Condition that does not follow the typical pattern of improvement with growth
- Femoral anteversion
 - Extreme rotation (especially when associated with difficulty walking or running)
 - Significant asymmetry
 - If the condition does not follow the typical pattern of improvement of growth by 7 years of age

FOLLOW-UP

- Many foot and leg problems are benign and resolve with time.
 - Close follow-up and monitoring for the resolution of condition is necessary.
 - If the condition does not resolve at the expected time, a referral to a specialist should be made.

PROGNOSIS

- Many common foot and leg problems are benign and resolve with time.

PREVENTION

- The foot takes the shape of the shoe, not vice versa.
 - Improperly fitted or manufactured shoes may be the primary cause of acquired foot deformities and problems.
 - Shoes that do not fit properly can deform an otherwise normal foot, resulting in hammertoe, hallux valgus, bunions, corns and, ultimately, the need for surgery.

- Determining the proper fitting for shoes involves no great science.
 - The foot widens while standing and throughout the day, so measurements should:
 - Be made later in the day
 - Be made with the child standing
 - Should apply only to the time the shoes are newly acquired
 - Both feet should be measured, and shoes should be fitted to the larger foot.
 - The counter should hug the heel snugly.
 - Length should allow a fingerbreadth (0.5 inch) between the tip of the great toe and the toe box.
 - The foot should fit snugly into the widest part of the shoe.
 - Width should not crowd the ball of the foot and should allow the toes to extend without wrinkling the upper.
 - While still in the store, the parents should have the child walk in the shoes to ensure comfort.
 - Shoes should not be expected to stretch to fit; if shoes do not fit, then they should not be purchased.
- Shoes in good condition can be handed down from 1 child to another.
- The frequency with which shoes should be changed depends on the:
 - Rate of growth of the feet
 - Quality of the shoes
 - Degree of their use
 - Parents can usually tell when shoes become too small (or rather, when feet become too large) without professional advice.
 - The toes will be felt to press against the toe box.
 - Getting the shoes on or having the child keep them on will be increasingly difficult.
- Lightweight cotton, nylon, or wool socks that adjust to the length and width of the foot for foot comfort

Foreign Bodies of the Ear, Nose, Airway, and Esophagus

DEFINITION

- Foreign bodies of the ear, nose, respiratory, and digestive tracts are a common problem among children, particularly those <5 years.
- Children are at risk as soon as the pincer grasp is achieved around 9 months of age.

EPIDEMIOLOGY

- Prevalence
 - In 1998 foreign-body aspiration and asphyxiation was the fourth leading cause of accidental death in the home among children <5 years.
 - As of 2006 foreign body aspiration and asphyxiation accounted for ~9% of all home accidental deaths of children <5 years.
 - The incidence declines rapidly among those ≥5 years.
 - National Safety Council data from 2005 to 2006 report choking deaths in 133 per 100,000 population in children from birth to 4 years.
 - Increased parental awareness of the risks of leaving small objects within the reach of young children.
 - Consumer education has been important in diminishing this hazard.
 - Development of life-saving techniques (Heimlich maneuver) that can be performed by people who are not health care workers account for a higher survival rate.

ETIOLOGY

Ear and auditory canal

- Foreign bodies of the ear and external auditory canal can include:
 - Food
 - Insects
 - Toys
 - Buttons
 - Crayon pieces
 - Pencil erasers
 - Button-shaped batteries
- Accidental entry of a foreign object through external auditory canal
 - The child or a companion can insert the object during play.
 - Insects can fly or crawl into the ear canal.
- Children who have chronic external otitis or itching may be more likely than healthy children to place objects in their ear canal.
- Earrings can become embedded in the auricle when a chronic infection of the pierced site is followed by overgrowth of granulation tissue.
 - Use of the spring-loaded piercing gun has resulted in numerous cases of embedded earrings.

Nose

- Foreign bodies in the nose fall into 2 categories.
 - Soft
 - Tissue paper
 - Eraser material
 - Clay
 - Hard
 - Bead
 - Pebble
 - Candy
- A foreign object may enter the nose accidentally while the child is attempting to sniff or smell it.
- Chronic rhinitis is the most common underlying factor in children placing objects in the nose.
- Frequency of foreign bodies in the nose increases during the summer and Christmas, when toy sales increase.

Airway

- Infants in particular will place almost anything they can handle into their mouth.
 - A startle may cause inadvertent ingestion or aspiration.
- Lack of complete dentition and lack of attention to chewing may allow large food particles to enter the posterior pharynx.
- Other contributors to foreign body ingestion
 - Incomplete development of mouth and tongue coordination
 - Neuromuscular mechanism for swallowing in young children
- A positive association exists between the occurrence of upper respiratory tract infections and foreign body aspiration.
 - A cold interrupts a smooth breathing-swallowing pattern and leads to an increase in aspiration.
 - More common among younger children, but some estimates indicate that 23% occurred in children >5 years
- Complete airway obstruction is generally caused by globular foods and objects.
 - Hot dogs
 - Nuts
 - Candies
 - Grapes
 - Toys
 - Latex balloons
- Impaction may take place in 3 segments of the airway.
 - Larynx
 - A review found 11 of 91 cases of a foreign body lodged in the larynx.
 - Of these, 5 died and 3 had anoxic encephalopathy.
 - Trachea
 - Bronchial tree

Esophagus

- More than one-half of foreign bodies in children involve the esophagus.
 - Coins, food, marbles, buttons, pins, tacks, jewelry, and batteries are a few of the numerous foreign bodies children have ingested.
 - Coins are the most common foreign body in the esophagus in children <10 years in the US.
 - Fish bones are the most common in children ≥10 years.
 - The esophagus has 4 physiologic areas of narrowing.
 - Cricopharyngeal sphincter
 - Aortic arch
 - Region of the left main bronchus
 - Gastroesophageal sphincter
 - These correspond to the 4 most common sites of foreign body obstruction.
 - The cricopharyngeus is the most common.
 - Arch of the aortic region is the most dangerous.
 - If the foreign body is lodged at the lower border of the cricopharyngeus muscle, it will be visualized at the level of the clavicles on the chest radiograph.

RISK FACTORS

- Children at risk
 - Those with developmental delays
 - Children who have undergone esophageal surgery
 - Children with a damaged esophagus from prior caustic ingestions

SIGNS AND SYMPTOMS

Foreign bodies in the ear

- Most common among children between 2 and 4 years of age
- Eliciting a history of placing an object in the ear canal is difficult.
 - Most children are reluctant to admit to this activity.
 - If insertion is not witnessed, the foreign body may go undetected for an extended period.
- Findings depend on:
 - Depth of the foreign object within the external auditory canal
 - Nature and composition of the object
 - Duration in the canal
- Children may complain of or the following may be observed.
 - Ear pain
 - Discomfort
 - Bleeding
 - Discharge

- Odor
- Aural fullness
- Hearing loss
- Nausea
- Vomiting
- Coughing
- Tearing
- Dizziness
- Inert substances, such as plastic, that are not obstructing the canal and are not abutting the tympanic membrane may not cause symptoms.
- Insects tend to incite local irritation.
 - Discomfort
 - Erythema
 - Drainage
- Food may cause local inflammation.
 - Often leads to local pain and itching
- Objects that touch the tympanic membrane cause pain, particularly with movement of the drum or swallowing.
- If the entire canal is obstructed, hearing will likely be decreased.
- Button-size alkaline batteries may leak battery alkali and cause a severe local tissue reaction or destruction.
 - Pain, swelling, or discharge may be seen.
 - Expedient management prevents serious injury to the canal, tympanic membrane, or middle ear.
- When the history indicates a small foreign body that cannot be seen, it may be lodged anteriorly in the tympanic sulcus.
 - Instillation of water to fill the medial half of the external canal may act as a concave lens and allow visualization of the tympanic sulcus.
- Microscopic evaluation will aid in visualization if a patient has a small, narrow, or swollen external ear canal.

Foreign bodies in the nose

- Children will usually not admit to placing foreign bodies in the nose.
- Most common symptom is unilateral nasal discharge that may be foul smelling.
 - Unilateral nasal discharge in a young child should be considered evidence of a foreign body until proved otherwise.
- Epistaxis may be the presenting symptom.
- Anterior nasal cavities should be examined with a nasal speculum and suction.
 - Powerful illumination is important.
- When an alkaline disk battery is lodged in the nose, symptoms may be acute.

■ Tissue damage can occur through 3 mechanisms.

- Electrical burn
- Liquefaction necrosis (from sodium hydroxide)
- Pressure necrosis

Foreign bodies in the airway

■ When an object is aspirated, it initially produces:

- Choking
- Gagging
- Coughing
- Wheezing

■ This may be followed by an asymptomatic interval during which little evidence remains to suggest the presence of a foreign body.

■ Depending on the site of the foreign body in the airway, a patient may exhibit a spectrum of findings from an almost complete lack of symptoms to signs of complete airway obstruction.

■ High index of suspicion and knowledge of possible presentation scenarios are the best insurance against missed or delayed diagnoses.

■ Laryngeal foreign bodies

- Most likely to produce acute and dramatic presentation
- Large objects that completely obstruct the airway cause:
 - Stridor
 - High-pitched wheezing
 - Cough
 - Dysphonia
 - Aponia
 - Cyanosis
- Small objects that obstruct partially but allow adequate air exchange produce:
 - Cough
 - Stridor
 - Hoarseness
 - Pain or discomfort

■ Tracheal foreign bodies

- Usually associated with cough, some degree of stridor, or wheezing
- May produce an audible slap as the object moves from the carina to the glottis with respiration

■ Bronchial foreign bodies

- Usually cause wheezing or coughing if they are partly obstructing
- Are often misdiagnosed as asthma
- With complete obstruction of a bronchus, initial asymptomatic period is followed by a postobstructive pneumonitis or bronchiectasis.

- Sharp objects, such as pins or tacks, may cause pain or hemoptysis.

Foreign bodies of the esophagus

■ Highest incidence in children 14 months to 6 years

■ History of foreign body ingestion is often not obtained.

■ Most foreign bodies pass through the esophagus undetected.

■ Swallowed or aspirated object can cause a respiratory emergency, no symptom at all, or anything in between.

■ Objects that do not pass freely initially stimulate the larynx and cause gagging and coughing.

■ Subsequent symptoms depend on size, composition, and nature of the foreign body.

■ In young children, the following symptoms are common.

- Poor feeding
- Refusal to eat or drink
- Increased salivation

■ When the esophagus is completely or almost completely obstructed

- Choking
- Vomiting

■ Duration of obstruction can affect clinical presentation.

- Longer time, increased tissue reaction and local inflammation
- In the later stages
 - Pain on swallowing
 - Airway compromise
 - Fever
 - Leukocytosis

DIFFERENTIAL DIAGNOSIS

■ Differential diagnosis of foreign bodies in the nose includes:

- Suppurative rhinitis
- Adenoiditis
- Sinusitis
- Nasal or nasopharyngeal tumors
- Nasal polyps also may cause unilateral nasal discharge.
- In a young child, cystic fibrosis must be ruled out.

IMAGING

■ Foreign bodies in the nose

- Radiography may be helpful if the object is radiopaque or has become calcified.
- Incidental finding of a nasal foreign body on a routine dental radiograph examination has been reported.
- In a review of children who had nasal foreign bodies, 28 of 71 (39%) radiographs demonstrated a foreign body.

- US toy manufacturers are required by law to make toy parts radiopaque.
 - Those manufactured outside the US do not have to conform to this regulation.
- Foreign bodies of the airway
 - For objects suspected of being lodged in the laryngeal inlet, high-kilovolt anteroposterior and lateral radiographs of the upper trachea or esophageal inlet should be obtained if the patient's condition permits.
 - Bronchial foreign bodies may be suggested by a dynamic radiographic study.
 - Inspiratory-expiratory films
 - Lateral decubitus films
 - Videofluoroscopy
 - These studies can demonstrate air-trapping in the affected lung.
- Foreign bodies of the esophagus
 - Posteroanterior and lateral chest radiographs, in addition to neck radiographs, are diagnostic if the object is radiopaque.
 - If the foreign body is a coin, it will be oriented in a transverse position because the opening of the esophagus is widest in a transverse position.
 - Contrast studies can be used when a foreign body that does not show on routine radiographs is strongly suspected.

DIAGNOSTIC PROCEDURES

- Direct visualization of the foreign body by endoscopy may be necessary when the foreign body is not visualized by different imaging techniques.

TREATMENT APPROACH

- The severity of the problems caused by the presence of a foreign body depends on site, composition, and duration of time in the body.
- Removal of a foreign body is not usually an emergency except:
 - If the airway is compromised
 - If the object is a battery
- Removal should be attempted only if the following are available.
 - Appropriate sedation or anesthesia
 - Proper instrumentation and illumination
 - Skilled practitioner
 - Attempts to remove the foreign body without these may aggravate the problem and jeopardize the child's well-being.

SPECIFIC TREATMENTS

Foreign bodies in the ear

- Nonurgent situations
 - Nonreactive foreign bodies that do not occlude the external canal completely or impinge on the tympanic membrane do not present an emergency.
- Aural foreign bodies may be removed by:
 - Irrigation
 - Gentle irrigation may be used on nonabsorbable substances.
 - Ensure that the tympanic membrane can be visualized.
 - Make sure it is intact and that there is no evidence of inflammation of the external canal.
 - 18-gauge catheter attached to a 10- to 20-mL syringe
 - The pressure generated is well below the pressure required to burst a tympanic membrane.
 - Flow of fluid should be directed around the retained object.
 - Allow backpressure to force the object out of the canal.
 - Fluids should be warmed to avoid irritation of the labyrinths.
 - Food tends to swell when water is applied, making removal difficult.
 - Suction
 - Frazier tip suction
 - Instrumentation
 - Choice of instrument will depend on the shape and composition of the object.
 - Alligator forceps
 - Right-angle hook
 - Pass instrument beyond the object, hook it from behind, and pull it out gently.
- Urgent situations
 - In older children who are cooperative
 - Local anesthetic injected with a small-gauge needle into the skin lining the external canal may allow complete removal of the foreign body and subsequent examination.
 - In younger children or for those who are uncooperative:
 - General anesthesia may be necessary.
 - This is preferable to traumatic removal if the child cannot cooperate or cannot be restrained adequately.
 - Remove the foreign body immediately when:
 - The tympanic membrane cannot be visualized
 - Evidence exists of inflammation or injury to the external canal

- Expeditious removal is particularly important with an alkaline battery.
 - Tympanic membrane perforations have been reported within only 8 hours of entry.
 - Magnets may be helpful for removing metallic objects, such as batteries or metal beads.

■ Insects

- Kill before removal.
 - Instill water, mineral oil, or topical lidocaine into the external canal.
 - Extract the insect with suction or alligator forceps.

Foreign bodies of the nose

- Remove as quickly as possible, particularly in the case of an alkaline battery.
 - Can cause severe local inflammation, with tissue damage occurring within 1 hour of placement
 - Saline irrigation should be avoided as it can cause further tissue damage.
- Young children are averse to nasal instrumentation, and removing a nasal foreign body requires cooperation or restraint.
 - Sedation or general anesthesia may be needed.
 - Topical application of a vasoconstrictor agent (eg, oxymetazoline, phenylephrine) in conjunction with removal of secretions by a small suction tip aids visualization, particularly when the object is lodged in the middle or posterior nasal cavity.
- An endoscope is recommended for visualization.
- Most items can be removed with a grasping instrument, eg, straight forcep, mosquito clamp.
 - If foreign body is firm and flat or has an edge, then it may be removed by using a nasal bayonet or Hartmann or alligator forceps.
 - A wire loop may be placed beyond a spherical object, which is then removed by pulling loop forward.
- Other methods include suction, irrigation, and adhesives.
 - Soft, friable objects can usually be removed with a Frazier tip suction device.
 - A Fogarty or a small Foley catheter may be used for removal.
 - Place the catheter beyond the foreign body into the posterior portion of the nasal cavity or nasopharynx.
 - Inflate with 2–3 mL of saline solution.
 - Draw the catheter gently forward and out of the nose, expelling the object.
 - Foreign object may be dislodged by pushing it posteriorly into the nasopharynx, which may lead to aspiration of the object.

- Nebulized adrenaline together with nose blowing has been reported to expel nasal foreign bodies successfully.
 - Using pepper to induce a sneeze while the uninjured nostril is occluded or blowing in the child's mouth while the contralateral nostril is held shut is not suggested.
- Ambu-bag insufflation of the mouth with the patient in Trendelenburg position has been described.

■ After removal, local inflammation exhibited by bloody or purulent oozing may be controlled with:

- Saline nose drops
 - Sterile water should be used in place of saline if the foreign object removed was an alkaline battery.
- Antibacterial ointment, eg, bacitracin, mupirocin

■ A foreign body that has remained in the nose for a long time may become calcified and form a rhinolith.

- Removal is often difficult and bloody.

Foreign bodies of the airway

- Foreign bodies that completely obstruct the laryngeal inlet create a life-threatening emergency.
 - They should be expelled immediately by using the Heimlich maneuver (abdominal thrusts).
 - For infants <1 year, the AAP recommends 5 back blows in the head-down position followed by 5 chest thrusts in the supine position, in place of the Heimlich maneuver.
 - Blind finger sweeps are dangerous and should be avoided.
 - If the foreign body cannot be expelled, a large-bore needle or angiocatheter (14 gauge) should be inserted into the cricothyroid space to allow ventilation until the patient can be taken to the operating room.
 - Alternatively, emergency tracheotomy may be necessary.
- Partly obstructing laryngeal foreign bodies should be treated in a manner that prevents total obstruction of the airway.
 - Back blows and abdominal thrusts should not be used in these cases.
- Tracheal and bronchial foreign bodies should be removed by a physician specifically trained for the task.
 - Procedure requires controlled endoscopic removal in the operating room.
 - It is not usually an emergency, and adequate preparations can be made.

Foreign bodies of the esophagus

- Usually does not require emergency intervention
- Endoscopic removal under anesthesia by a trained expert remains the method of choice.
- Remove the object as soon as possible after proper evaluation and preparation.
 - If the child has eaten recently, allow an appropriate period pass before general anesthesia is administered.

- If the foreign body is corrosive, such as an alkaline button battery, it should be removed as soon as possible to prevent severe inflammation and potential perforation of the esophageal wall.
- Rigid esophagoscopy
 - Optical forceps are passed through the central channel for retrieval of the foreign body.
 - Allows for direct visualization of the esophagus, mucosa, and foreign body
- Flexible endoscopy
 - Once the scope is passed, a variety of flexible graspers, forceps, baskets, and magnets can be passed through the instrument channel for retrieval.
 - Nonendoscopic techniques are not recommended.
 - Using catheters to remove the foreign body can lead to aspiration, airway obstruction, and death.

WHEN TO ADMIT

- Foreign bodies in the airway
 - If prolonged or difficult instrumentation of the airway occurred during removal of the foreign body
 - If postoperative edema develops
- Foreign bodies in the esophagus
 - If the object is sharp and irretrievable by endoscope

WHEN TO REFER

- If airway compromise exists
- Anytime a battery is involved
- If the child cannot be restrained adequately
- If an object cannot be removed
 - Ear
 - If the tympanic membrane cannot be visualized or perforation is suspected
 - If the object is touching the tympanic membrane
 - If the object is spherical or in the canal for >24 hours
 - If hearing loss, nystagmus, vertigo, central nervous system deficits, or deep-seated infection exists
 - Nose
 - If a rhinolith has formed
 - Airway
 - For tracheal and bronchial foreign bodies
 - Esophagus
 - For endoscopic removal if perforation is suspected

FOLLOW-UP

- Foreign bodies of the ear
 - Postextraction care
 - After any foreign body is removed, the external canal and tympanic membrane should be thoroughly inspected.

- If the external auditory canal appears infected or irritated
 - Topical antibiotic otic drops with steroids may be instilled.
 - The affected ear should be protected from water until it has healed completely.

COMPLICATIONS

Foreign bodies of the ear

- Complications can be caused by:
 - The foreign body
 - Traumatic removal
- Laceration or inflammation of the external canal
 - Usually not serious
 - Resolves with instillation of liquid analgesics and antibiotics
- Perforations of the tympanic membrane
 - Carefully inspect to ensure that a flap of the membrane has not folded into the middle ear, leading to a permanent perforation or a cholesteatoma.
 - The middle ear space can become contaminated, and otitis media can develop.

Foreign bodies of the nose

- Complications include:
 - Epistaxis
 - Local infection
 - Inflammation
 - Nasal septal perforation
- Occasionally a scar band, or synechia, may form between the turbinate and septum.
 - Prevent synechia by placing a splint made of Gelfilm or Silastic over the raw, exposed area.
- Obstruction of a sinus ostium by a foreign object may lead to the development of sinusitis.
 - Typically causes pain and tenderness over the affected sinus
 - Clouding and an air-fluid level will be observed on the radiograph.
 - Treatment includes oral antibiotics and nasal decongestant drops.
- Aspiration can be prevented in most cases by prompt and skilled removal.

Foreign bodies of the airway

- Abdominal and chest thrusts may damage intraabdominal contents (eg, liver, spleen) and ribs.
 - Should be used only in cases of complete airway obstruction that would otherwise cause certain death
- Conversion of a partial airway obstruction to a complete obstruction can be prevented by having skilled personnel retrieve the foreign body.

- Pneumonia was the most common complication in 127 cases of foreign body aspiration.
- A bronchial foreign body that remains in place for an extended period may cause air trapping and irreversible bronchiectatic changes distal to the obstruction.
- Prolonged or difficult instrumentation of the airway during removal of a foreign body can lead to laryngeal edema or injury, with obstructive symptoms.
 - May require a period of intubation after surgery
 - Postoperative edema can sometimes be prevented by using steroids during and after surgery.

Foreign bodies of the esophagus

- Perforation of the esophagus can result from:
 - Endoscopic retrieval procedure
 - By the foreign body itself
- Endoscopic removal is particularly dangerous with objects lodged at the level of the aortic arch.

- If an esophageal tear is suspected, a radiographic gastrograffin swallow study will usually confirm or negate the suspicion.
- Retropharyngeal abscess has been reported as the most frequent complication of a sharp esophageal foreign body.
- Foreign bodies that have been in the esophagus for long periods can cause a stricture to develop.
 - A contrast study, computed tomography, or esophagoscopy should be performed to aid in the diagnosis.

PREVENTION

- During anticipatory guidance, parents and caregivers should be instructed not to:
 - Leave small objects or inappropriate food where a young child can reach them
 - Give small objects or inappropriate food to a young infant

Fractures and Dislocations

DEFINITION

- A fracture is a break or crack in a bone.
 - Direct fracture: at the site of injury
 - Indirect fracture: at a site different from the applied force
 - Closed fracture: no break in the skin
 - Open fracture: bone fragment is exposed to air.
 - Comminuted fracture: bone has ≥ 3 fragments.
 - Impacted fracture: bone ends are compressed into each other.
- Salter-Harris classification system
 - Describes injury to the growth plate
 - Fractures that do not cause any direct injury to the growth plate (eg, chip fractures) are not usually included in the Salter-Harris classification system.
 - Type I fracture
 - The epiphysis is separated from the metaphysis without a true break in the bone.
 - Type II fracture
 - The most common growth plate fracture
 - A fragment of metaphyseal bone separates from the epiphysis.
 - Type III fracture
 - Partial growth plate injury through the epiphysis
 - Type IV fracture
 - Extends across the growth plate, injuring both the epiphysis and the metaphysis
 - Type V fracture
 - Growth plate is compressed.
- Dislocation
 - Malposition of bone ends that normally appose each other within a joint

EPIDEMIOLOGY

- Fractures
 - Fractured clavicle
 - Most common fracture in children
 - Incidence can be as high as 3.5% in babies delivered vaginally.
 - Growth plate injuries
 - ~15% of all childhood fractures
- Dislocations
 - In children, far less common than fractures
 - A child's ligaments are quite strong compared with an adult's.
 - With an injury, it is more likely that bone will break or growth plate will separate than that ligament will tear.
 - Developmental dysplasia of the hip (DDH)
 - Formerly known as *congenital hip dislocation*

- The femoral head has a tendency to dislocate in as many as 5 of every 1000 infants.
- 6–8 times more common in girls than in boys
- Nursemaid's elbow
 - Common dislocation in pediatrics
 - Usually occurs in children between 1 and 4 years of age

ETIOLOGY

- Stress fractures
 - Result from recurrent trauma to a bone
- Pathologic fractures
 - Can occur without trauma or with minor trauma
- Toddler's fracture
 - Torsion of the foot creates a spiral break in the tibia.
- DDH
 - May be related to left occiput anterior fetal position, which puts pressure on the left hip to dislocate
 - Genetic predisposition
 - Theories suggest that female fetuses are more sensitive to maternal hormones that can induce ligamentous laxity of the hip.
- Nursemaid's elbow
 - Pulling or yanking a child's arm, often by a parent or caretaker
 - Annular ligament of the radial head becomes entrapped in the radiohumeral joint

RISK FACTORS

- Stress fracture
 - Athletic activity
 - Long-distance running is associated with long-bone fractures.
- Pathologic fracture
 - Conditions resulting in weakened bone
 - Osteogenesis imperfecta
 - Tumor
- Fractured clavicle
 - Difficult vaginal delivery
- DDH
 - Positive family history of hip dislocation
 - Breech delivery
 - Cesarean section

SIGNS AND SYMPTOMS

History

- Whenever a fracture or dislocation is suspected, an accurate history is essential.

- Historical details may provide clues about the mechanism of injury.
 - Where any pain is located
 - How, where, and when the injury occurred
 - A fall off of a skateboard or scooter increases suspicion for a forearm fracture.
- Does the parent or child report any loss of function in the affected limb?
 - Does the history show acute or recurrent trauma?

Physical examination

- Key to revealing signs of serious trauma and secondary sites of injury
 - Includes vital signs and neurovascular assessment
- Pulses
 - Should be normal
 - Absence of pulses signifies a serious injury requiring immediate medical attention.
- Sensation
 - Should be intact
 - Absence of sensation signifies a serious injury requiring immediate medical attention.
- Movement
 - Should be present even if limited by discomfort
 - Absence of movement signifies a serious injury requiring immediate medical attention.
- The examiner should look carefully for:
 - Any unnatural or deformed position of joints or limbs
 - Pain on palpation or attempted movement
 - Swelling and discoloration
 - Crepitus, which can sometimes be elicited at a fracture site
 - Any of the above findings should alert the clinician to order imaging studies.
- Clinical appearance of fractures
 - Closed fracture
 - Hidden fracture causes slight pain and swelling but no obvious bone deformity.
 - Radiographs are necessary to confirm diagnosis.
 - Open, or compound, fracture
 - Patient is at risk for infection and injury to adjacent nerves and blood vessels.
 - Immediate medical attention is necessary.

Fractured clavicle

- Can occur at any time during childhood as a result of trauma
 - Diagnosis is often made after the fact, when a callus at the fracture site is noted at a well-baby visit.
- Physical findings
 - Decreased arm motion on the affected side

- Crepitus
- Swelling at the fracture site
- Imaging may be needed to confirm diagnosis.

DDH

- 3 times more common on the left than the right side
- Bilateral in approximately 20% of cases
 - Children <1 year should be examined for hip dislocation at every routine visit with the appropriate tests.
 - Ortolani test (not usually positive beyond 3 or 4 months)
 - With the baby laying supine, the hips and knees are flexed and the knees brought together.
 - The examiner then places a hand on each of the baby's knees, with each middle finger over the greater trochanter and each thumb over the medial thigh.
 - With gentle abduction of the knees, the dislocated femoral head will slip back into the acetabulum with an audible or palpable *clunk*.
 - This motion pushes a dislocated hip back into the hip socket.
 - Notably, a hip *click* (without a *clunk* and without any movement of the femoral head) does not indicate hip dislocation.
 - Barlow test (not usually positive beyond 3 or 4 months)
 - The reverse of the Ortolani test
 - The femoral head can be felt slipping out of the acetabulum when the knees are brought back together.
 - This motion pushes a dislocatable hip out of the hip socket.
 - Telescoping sign
 - The examiner may feel unusual laxity of the hip by pushing up and down on the thigh when hips are flexed and adducted.
 - Older infants should be examined for:
 - Limited hip abduction
 - Asymmetry of the thigh skin folds
 - Limp when cruising or walking
 - Leg length discrepancy
- Galeazzi sign to determine leg-length discrepancy
 - With the infant lying supine, the examiner flexes the infant's thighs and brings the knees together.
 - If one knee is higher than the other, the Galeazzi sign is positive and the possibility of a dislocated hip exists.

Nursemaid's elbow

- Transient subluxation of the proximal radial head
- The child refuses to move the arm and keeps it flexed and pronated.
- History (yanking or pulling of the arm by another person) and characteristic posture of the child's arm confirm the diagnosis.

Child abuse

- Fractures and dislocations are commonly suggestive of child abuse.
- Child abuse may be suspected when:
 - Unexplained injury occurs.
 - Inconsistency exists between history and physical findings.
 - Delay between time of injury and time that medical attention is sought is unusually long.
 - Multiple bruises are noted on physical examination.

Toddler's fracture

- Spiral fracture of the tibia in a child <6 years of age
- Trauma to the leg often is minor or unwitnessed; therefore, no history of trauma may be found.
- If the cause of the fracture is unexplained, child abuse may be a consideration.
- Symptoms may be minimal.
 - The child may be brought for medical attention only because of reluctance to bear weight on the affected leg.
 - Physical examination is significant for tenderness over the affected area of the tibia.
 - The examiner should have a high index of suspicion in a child who has a limp or fails to bear weight.

Injury to growth plate

- Growth or epiphyseal plate injuries occur only in childhood.
- They must be treated with care to protect a bone's growth potential.
- Type I fractures
 - Radiographs are often normal.
 - Therefore, diagnosis is based on the clinical picture: tenderness over the area of the growth plate.

DIAGNOSTIC APPROACH

- Careful history to elicit precipitating event
- Physical examination to reveal signs of trauma and secondary injury
- Radiography to detect subtle fractures and to exclude dislocation
- Infants and children should be assessed for DDH annually.
- Pediatric care practitioners are morally and legally responsible for detecting child abuse and reporting all suspected cases.

IMAGING

- Radiography
 - A mainstay in the diagnosis of fractures and dislocations
 - Confirms diagnosis of closed fracture
 - 2 angles are used to delineate subtle fractures.
 - Including the joint above and below the injury can be helpful in excluding dislocation.

- In many cases, a film of the unaffected side for a comparison view is needed.
- Breaks in the bone may be described by their radiographic appearance as:
 - Transverse
 - Oblique
 - Spiral
- Stress fractures are often missed on radiographs.
- Torus or buckle fracture
 - Most commonly occurs after injury to the forearm
 - The radiograph shows a wrinkled appearing break of the distal radius.
- DDH
 - A radiograph in infants >4–6 months of age will confirm or rule out a dysplastic hip.
- Nursemaid's elbow
 - Imaging is unnecessary.
- Child abuse
 - If abuse is suspected, a radiographic bone survey should be performed in younger children.
 - Silent fractures, or multiple fractures in varying stages of healing, may be seen.
- Toddler's fracture
 - Anteroposterior and lateral radiographs of the tibia-fibula confirm the diagnosis.
 - Fracture is sometimes not evident on a radiograph for a few days.
 - Physician should not hesitate to repeat films in a child who has an unexplained limp that does not resolve spontaneously.
- Computed tomography
 - Can be useful when injury to the growth plate is a concern
- Magnetic resonance imaging
 - May be indicated to confirm torus or buckle fracture
- Radionuclide bone scan
 - May be indicated to confirm torus or buckle fracture
- Ultrasonography
 - May be needed to confirm:
 - Fractured clavicle
 - DDH

TREATMENT APPROACH

- Fractures and dislocations should be splinted and immobilized immediately.
 - Most pediatric fractures respond to closed reduction by an orthopedist.
 - Even some compound fractures can be managed nonoperatively.

- Close pediatric and orthopedic follow-up are important.
- If the growth plate is affected:
 - Open reduction in the operating room is performed.

SPECIFIC TREATMENTS

Fractured clavicle

- If the condition is asymptomatic:
 - No treatment is needed.
- If the fracture causes pain or reduced arm movement:
 - Immobilization of the arm on the affected side for 2–3 weeks
 - In older children, splinting for 3–4 weeks in a simple sling is required.
 - Figure-of-8 bandages are cumbersome and work no better than a sling.
- Most of the fracture's healing and realignment are spontaneous.

DDH

- Treatment requires referral to an orthopedist for a harness or casting.
 - Treatment is more straightforward the earlier the diagnosis is made.
- Infants <6 months of age
 - A Pavlik harness is worn for up to 5 months.
- Infants ≥6 months of age, and infants in whom the harness was not successful
 - Casting
 - Possibly surgery

Nursemaid's elbow

- Treatment is easily performed by the pediatrician.
 - Rapid, forceful supination of the forearm while pressure is placed over the proximal radial head, followed by extension then flexion of the elbow
- Symptoms usually resolve within 30 minutes.
- The condition is sometimes recurrent.
 - Great care must be taken when holding hands with the affected child, lest the child suddenly tries to pull away.

Child abuse

- When child abuse is suspected, the child should be hospitalized for protection and for appropriate evaluation and orthopedic care.
- Child protective services and social services should be involved.

Toddler's fracture

- Immobilization in a cast for 3–4 weeks.

Long-bone fractures

- Often corrected with overriding of broken ends to prevent length discrepancies with the uninjured side

Growth plate injuries

- The growth plate must be protected when treating children's fractures.
 - A growth plate injury can result in the loss of growth potential.
- Type I fracture
 - Immobilization by cast for approximately 3 weeks
- Type II fracture
 - Closed reduction of the fracture is usually possible; with proper casting, growth is not disturbed.
- Type III fracture
 - Open repair of the fracture in the operating room is indicated to align articular surfaces and preserve joint function.
- Type IV fracture
 - The fracture must be perfectly realigned to protect growth potential.

WHEN TO ADMIT

- Whenever child abuse is suspected or if the patient is not medically stable (ie, multiple injuries)

WHEN TO REFER

- All fractures and dislocations not easily managed in a primary care setting
- In most cases, consultation with an orthopedic specialist is necessary.

FOLLOW-UP

- A child in a cast should be comfortable.
- The child needs reevaluation and possibly requires recasting if:
 - Pain is persistent *or*
 - Color changes or sensory changes occur to the casted extremity.

PROGNOSIS

- Fractures heal more quickly in children than in adults.
 - Remodeling that occurs in the healing of pediatric fractures often corrects residual bony deformities.
- Accelerated growth rate of bony fragments during healing (overgrowth) occurs in pediatric long-bone fractures.
- Type I and II fractures
 - Growth is usually not disturbed.
- Type V fracture
 - Prognosis for preserving growth is poor because of a crush injury to the growth plate.

Gastroesophageal Reflux Disease

DEFINITION

- Gastroesophageal reflux (GER) is the passage of gastric contents into the esophagus.
 - Most episodes are brief and unaccompanied by symptoms.
- Gastroesophageal reflux disease (GERD) is symptoms or complications resulting from exposure of the esophagus, the oropharynx, or the airway to gastric refluxate (acid, food, bile).
 - *Regurgitation* occurs when gastric contents enter into the oropharynx.
 - *Vomiting* refers to gastric contents exiting through the mouth.
 - *Rumination* is regurgitation with subsequent reswallowing of the gastric contents.

EPIDEMIOLOGY

- GER
 - Age
 - Infants <1 year frequently have GER.
 - 50% of infants <3 months have recurrent regurgitation and other GER symptoms.
 - 67% of healthy infants 4 months of age have these symptoms; the peak prevalence is between 4 and 6 months of age.
 - The prevalence of GER decreases to 5% among infants 10–12 months of age.
 - By 1 year of age, most infants have stopped having symptoms of GER.
- Barrett syndrome, often called *Barrett esophagus*, is a metaplasia of lining of lower esophagus from squamous epithelium to columnar epithelium that is acquired as a result of long-standing esophagitis.
 - The incidence of Barrett esophagus in children is rare and <1 per 1000 in children undergoing endoscopy.

ETIOLOGY

- The causes of GERD are multifactorial and depend on anatomy, motility, and physiologic factors.
- Anatomy
 - In an infant, the normal obtuse angle of His does not occlude the hiatus when the stomach is distended postprandially and may result in regurgitation.
 - Abnormalities such as malrotation, annular pancreas, or antral web may also result in symptoms of GERD.
- Motility
 - Impaired esophageal motility associated with repair of esophageal atresia or tracheoesophageal fistula or delayed gastric emptying may result in prolonged acid exposure in the esophagus and eventual complications of GERD.

- Impaired buffering of acid in the esophagus by saliva may lead to esophagitis in children with cystic fibrosis or adults with autoimmune disease.
- Lower esophageal sphincter (LES) pressure is an important antireflux barrier.
 - Possibly because of the other factors, LES pressure by itself correlates poorly with GER.
- Physiologic factors
 - In both children and adults, the most common cause of reflux is inappropriate transient LES relaxation with inhibition of esophageal peristalsis.
 - Transient LES relaxations typically occur up to 5 times in the immediate postprandial hour with episodic movement of gastric contents into the distal esophagus.
 - These relaxations are vagally mediated, brief in duration, and probably play a normal role in eliminating gas from the stomach.
 - When the refluxate enters the esophagus, it is buffered by saliva and cleared by normal esophageal peristalsis.
 - In patients with GERD, these relaxations last longer, from 5–35 seconds.
 - During this period, a combination of LES hypotonia and inhibited esophageal peristalsis prolong the contact time of the gastric contents with the esophageal mucosa and contribute to tissue injury.
 - Inappropriate LES relaxation and delayed gastric emptying has been shown to occur in 28–50% of children with GERD.
- Conditions associated with GERD
 - Asthma and chronic cough are associated with GERD.
 - Vagal afferents innervate both the esophagus and the bronchi and acid stimulation of receptors in the esophagus may induce reflex bronchoconstriction.
 - Bronchoconstriction and laryngospasm
 - May be caused by microaspiration of gastric contents into the trachea
 - Increased airway responsiveness in asthmatic patients
 - Esophageal acid exposure per se, even though it has a minimal effect on pulmonary function, is a contributor.
 - No convincing temporal relationship exists between esophageal acidification and apnea or bradycardia in unselected patients.

RISK FACTORS

- GERD occurs in infants who have irritability associated with feeding or food refusal.
- Infants who have symptoms for >90 days are at increased risk of having symptoms of GERD 9–11 years later.
- The significance of heartburn at age 10 years and whether it predisposes one to complications of GERD later in life is not known.

- Factors in increased risk and severity of GER
 - Increasing intraabdominal pressure (crying in infants, coughing, obesity)
 - Gastric acid secretion
 - Consumption of:
 - Large meals
 - Fatty foods
 - Caffeinated beverages
 - Candy
 - Certain medications (theophylline, morphine, calcium-channel blockers)

SIGNS AND SYMPTOMS

- Symptoms of GER depend on the age of the patient.
- Clinical manifestations change with age and the development of language.
 - Infants may express discomfort from acid reflux by crying, refusing to eat, or failing to thrive.
 - Older children may mention abdominal pain but will not localize the pain to the epigastrium or retrosternal areas.
 - Adolescents are more likely to report heartburn symptoms similar to those reported by adults.
 - Extraesophageal symptoms, such as pneumonia, cough, hoarse voice, or dental disease, may occur at any age.

Symptoms of GER

■ Gastrointestinal

- Nausea
- Vomiting
- Regurgitation
- Irritability during and after feedings
- Refusal to feed
- Failure to thrive
- Heartburn
- Dysphagia
- Odynophagia
- Hematemesis
- Melena
- Eructation
- Anorexia

■ Respiratory

- Chronic cough
- Reactive airway disease
- Recurrent pneumonia
- Stridor
- Chest pain

- Apnea
- Hoarseness of voice
- Choking
- Gagging

■ Neurobehavioral

- Apnea or apparent life-threatening event (ALTE)
- Seizure-like events
- Sandifer syndrome
- Rumination

History in the child with suspected GER/GERD

- Little is known about the natural history of children and adolescents with symptoms of GER/GERD.
- The following information should be obtained.
 - Feeding history
 - Amount and frequency (overfeeding)
 - Preparation of formula
 - Source of dietary protein
 - Position and burping
 - Behavior during feedings (choking, gagging, coughing, arching, discomfort, feeding refusal)
 - Pattern of vomiting
 - Frequency and amount
 - Painful
 - Forceful
 - Hematemesis
 - Association with fever, lethargy, diarrhea
 - Medical history
 - Prematurity
 - Growth and development (mental retardation, cerebral palsy, developmental delay)
 - Surgery
 - Hospitalizations
 - Newborn screen (galactosemia, maple sugar urine disease, congenital heart disease)
 - Recurrent illness (croup or stridor, pneumonia, wheeze, hoarseness, excessive fussiness or crying, hiccups)
 - Apnea
 - Inadequate weight gain
 - Psychosocial history
 - Stress
 - Family history
 - Significant illness
 - Gastrointestinal disorders (familial pattern to obstructive disorders, celiac disease)
 - Other (metabolic, energy)

- Growth chart
 - Length, weight
 - Head circumference
- Warning signs
 - Bilious vomiting
 - Gastrointestinal bleeding: hematemesis, hematochezia
 - Forceful vomiting
 - Onset of vomiting after 6 months of life
 - Failure to thrive
 - Diarrhea
 - Constipation
 - Fever
 - Lethargy
 - Hepatosplenomegaly
 - Bulging fontanelle
 - Macrocephaly, microcephaly
 - Seizures
 - Abdominal tenderness, distention
 - Genetic disorders (eg, trisomy 21)
 - Other chronic disorders (eg, HIV)

DIFFERENTIAL DIAGNOSIS

Conditions similar to GER

- A variety of conditions have clinical features that resemble GER, including:
 - Eosinophilic esophagitis
 - Food allergy
 - Achalasia
 - Cyclic vomiting syndrome
 - Pill esophagitis
 - Infectious esophagitis
 - Rumination syndrome
- These conditions may be suspected on the basis of characteristic features, diagnostic testing, or a failure of symptoms to respond to standard medical therapy for acid reflux.

Specific conditions

Eosinophilic esophagitis

- Occurs in young children, teenagers, and adults
- Appears to be more common today than 25 years ago
- The majority of patients are male, and most have dysphagia or food impaction.
- Younger children may have symptoms suggestive of GERD such as abdominal pain or food refusal.
- Dysphagia or esophageal food impaction is more commonly noted in older children.

- Partial or complete unresponsiveness to acid-suppression therapy suggests that GERD is not a contributing factor.
- A personal or family history of allergic disease is found in 75% of cases.
- The diagnosis is suspected when white exudate, circular rings, or linear furrowing is seen during upper endoscopy.
- Establishing diagnosis depends on finding >15–20 eosinophils per high-power field on an esophageal mucosal biopsy.

Food allergy

- Milk protein and other food allergies in young infants may mimic symptoms of GER, but they usually resolve with dietary restriction or time.
- A challenge with the suspected allergen may reproduce the symptoms but is usually not necessary for managing the patient.
- Eczema, skin rash, wheezing, concomitant diarrhea, or blood in the stool should alert the clinician to the possibility of allergy.

Achalasia

- A motor disorder characterized by lack of peristalsis in the distal two-thirds of the esophagus, an elevated resting pressure in the distal esophagus, and failure of the LES to relax
- Results in functional obstruction in the lower esophagus and accumulation of food in the esophagus
- Children may have weight loss; regurgitation of undigested food; halitosis; cough, especially when supine; or pneumonia.
- The most common feature on chest radiograph is absence of air in the stomach and an air-fluid level in the esophagus.
- Widening of the mediastinum may be seen in long-standing disease.
- Esophageal manometry is often diagnostic and demonstrates:
 - Aperistalsis in the distal two-thirds of the esophagus
 - Elevated resting LES
 - Failure or incomplete relaxation of the LES
- In young children with achalasia, sphincter relaxation and occasional peristalsis may be present.
- Barium esophagography often reveals a symmetrical narrowing in distal esophagus with the appearance of a bird beak.

Cyclic vomiting syndrome

- A functional gastrointestinal disorder characterized by:
 - Bouts of intractable nausea
 - Vomiting lasting for hours
 - Lethargy and pallor
 - Periods of complete symptom relief
- These episodes are intense in severity, but unlike in GER, the patient is completely asymptomatic between episodes.
- A bout may be triggered spontaneously, by stress, or by menstruation.
- No diagnostic test or identifiable neurologic, metabolic, or other gastrointestinal disease exists to explain the condition.

■ Differential diagnosis of vomiting

- Gastrointestinal obstruction
 - Pyloric stenosis
 - Malrotation with intermittent volvulus
 - Intermittent intussusception
 - Intestinal duplication
 - Hirschsprung disease
 - Antral or duodenal web
 - Foreign body
 - Incarcerated hernia
- Gastrointestinal disorders
 - Achalasia
 - Gastroparesis
 - Gastroenteritis
 - Peptic ulcer disease
 - GER
 - Eosinophilic esophagitis, gastroenteritis
 - Food allergy or intolerance
 - Inflammatory bowel disease
 - Pancreatitis
 - Appendicitis
- Neurologic disorders
 - Hydrocephalus
 - Subdural hematoma
 - Intracranial hemorrhage
 - Mass lesion
- Infection
- Sepsis
- Meningitis
- Urinary tract infection
- Pneumonia
- Otitis media
- Hepatitis
- Metabolic or endocrine disorders
 - Galactosemia
 - Hereditary fructose intolerance
 - Urea cycle defects
 - Amino and organic acidemias
 - Congenital adrenal hyperplasia
 - Maple syrup urine disease
- Renal disorders
 - Obstructive uropathy
 - Renal insufficiency

■ Toxic agents

- Lead
- Iron
- Vitamin A or D
- Medications (eg, ipecac, digoxin, theophylline)

■ Cardiac disorders

- Congestive heart failure

Pill esophagitis

- Occurs when a pill is lodged in the esophagus
- Usually causes acute onset of severe midchest or substernal pain and dysphagia
- Minocycline, ibuprofen, iron, and potassium hydroxide are the usual suspects.
- Condition is suspected based on history; endoscopy may not be necessary if symptoms improve with acid-suppression therapy or sucralfate.

Infectious esophagitis

- Most infectious causes of esophagitis present with odynophagia and not dysphagia.
- Herpes simplex virus; cytomegalovirus; and fungal infection, such as candidiasis, may occur in both immunocompetent and immunocompromised hosts.
- Upper endoscopy is beneficial in making the diagnosis both by histopathologic features and by culture.

Rumination syndrome

- Characterized by regurgitation of food into the mouth with subsequent reswallowing of the material
- This syndrome was typically thought to occur in neurologically compromised children but is now recognized as occurring in otherwise healthy children and adolescents.
- Repeated masticatory movements, swallowing air, and tensing abdominal musculature help distinguish rumination from effortless GER.

IMAGING

■ Scintigraphy

- Oral intake of radiolabeled technetium followed by scan of esophagus, stomach, and the lungs to detect radiolabeled colloid that has been refluxed or aspirated
- Gastric emptying time may be calculated for potential therapeutic intervention.
- Techniques of performing this test are not standardized, and age-specific normative data are not available.
 - Their role in evaluating GERD in children is unclear at this time.
 - Determining gastric emptying may contribute to management.

- Upper gastrointestinal radiography (barium swallow)
 - Primary role is to rule out anatomic causes of GERD such as malrotation, annular pancreas, and antral web.
 - When compared with esophageal pH, upper gastrointestinal radiography:
 - Is neither sensitive nor specific for GER (31–86% and 21–83%, respectively)
 - Does not reliably determine the presence or absence of GER

DIAGNOSTIC PROCEDURES

- Esophageal pH monitoring
 - Frequency and duration of acid reflux episodes occurring over 20 hours recorded with:
 - Transnasally placed probe
 - Bravo pH probe clipped to the wall of the distal esophagus that transmits to a recorder using radiofrequency signals
 - Percentage of total time the esophageal pH is <4.0 (called the *reflux index*) is considered the most valid measure of reflux.
 - A reflux index $\geq 12\%$ in infants <1 year and $\geq 6\%$ in children >1 year is considered abnormal.
 - Not all patients with GER test positive on this study, but 95% of children with esophagitis (gross and microscopic) have an abnormal reflux index.
 - Only 50% of patients with a positive pH study have esophagitis, and the severity of esophagitis does not correlate with the reflux index.
 - Daily variation in severity raises questions about the diagnostic utility of pH probe testing for a condition that is diagnosed by clinical criteria.
 - Proximal esophageal and pharyngeal pH monitoring have not been proven useful in predicting which patients are at risk for upper airway complications.
 - Esophageal pH monitoring is not necessary to establish a diagnosis of GER.
 - It may be beneficial to relate acid reflux with cough, apnea, bradycardia, or other extraesophageal symptoms or to determine efficacy of therapy when symptoms persist.
 - The volume of acid needed to cause extraesophageal symptoms may be very small, and changes in pH may not be detected by pH probe monitoring.
 - The technique is limited because it detects only acid reflux and will not detect nonacidic, postprandial reflux.
- Multiple intraluminal electrical impedance measurement
 - Measures changes in electrical resistance and conductance in the mucosa when a fluid bolus moves down the esophagus, indicating nonacid and acid reflux
 - The clinical value of this test is not yet determined, but preliminary studies suggest that children with pulmonary symptoms may have increased nonacid reflux.

- In conjunction with pH probe, monitoring study may be useful in evaluating patients who do not respond to acid-suppression therapy.

- Endoscopy and biopsy
 - Endoscopy allows direct visualization of esophageal mucosa to detect erosions, ulceration, and reflux-related complications, such as peptic stricture and Barrett esophagus.
 - Because endoscopy requires sedation and the diagnosis of GERD is established based on clinical evidence, indications for this test are based on suspicion of complications of GERD or the need to rule out other disorders.
 - Biopsies routinely obtained at endoscopy determine presence and severity of esophagitis and may help exclude such conditions as Crohn disease of the esophagus, eosinophilic esophagitis, and infection.

TREATMENT APPROACH

- Management of GER/GERD involves:
 - Lifestyle modifications
 - Acid suppression
 - Proton pump inhibitors
 - Surgical therapy
- Children at different ages may respond differently to specific interventions.
- Consideration of issues related to growth, development, and compliance are important in determining the best therapeutic intervention.

SPECIFIC TREATMENTS

Lifestyle changes in infants

- Often the first therapy that should be initiated to treat a child with GER or GERD
- Normalization of feeding volume and frequency is essential.
 - Some infants may be fed an excessive volume.
 - By simply reviewing feeding history and educating the family, GER may resolve.
- Thickening formula with rice cereal or purchasing a commercial formula that becomes denser in the stomach may decrease frequency and volume of regurgitation.
 - 1 tablespoon of rice cereal added to each ounce of formula decreases the number of vomiting episodes without reducing the reflux index.
 - Increasing the hole in the nipple may be necessary, avoiding increasing flow so much so that the infant cannot swallow the volume and begins to cough.
 - May lead to constipation, decreasing gastric emptying, and increasing GER

- Increases calories (~34 cal/oz with addition of 1 tbsp/oz), which may be beneficial for infant with slow or poor weight gain
 - As GER resolves, the infant may gain excessive weight.
- Closely monitor growth during treatment for GER in the first year of life.
- Intolerance of dietary proteins, such as cow's milk or soy, may lead to symptoms identical to those of GER.
 - Generally seen in formula-fed infants; less common in breastfed babies
 - Diagnostic tests are generally not helpful, but children with GER related to dietary protein often improve with a switch to another formula.
 - 1- to 2-week trial of hypoallergenic formula may answer the question about the role of nutrition in causing GER.
 - In a breastfed infant with GER, symptoms often resolve with time.
 - If intervention is required, some infants will improve if the mother eliminates cow's milk and beef from her diet.
 - Soy is more ubiquitous, and restricting cow's milk, beef, and soy is more limiting for a mother's diet.
- A change in position may decrease GER in infants
 - The prone position is optimal when the infant is awake.
 - Sleeping in the prone position has been recognized to be associated with a higher risk for sudden infant death syndrome (SIDS) compared with the supine position.
 - Based on the new AAP recommendations, the supine position is recommended during sleep for children <12 months
 - The reduced risk of SIDS outweighs the potential benefits of prone sleeping with respect to GERD.
 - In certain unusual situations, prone positioning during sleep may be considered when risk of death from complications of GERD outweighs potential increased risk of SIDS.
 - When the prone position is a recommendation in a given case, the family should understand the rationale and be advised to avoid using soft bedding that is known to be a suffocation risk.
 - Use of infant seats may increase frequency and severity of reflux.
 - No evidence has been found for decreasing regurgitation by elevating the head of the crib, but many families report improvement with this intervention.
 - As infants begin to move around in their cribs, maintaining their head higher than their feet may become a challenge.
 - For the thriving infant with GER, feeding and positioning are important interventions that may decrease severity of regurgitation and prevent the need for medical therapy.

Lifestyle changes in children and adolescents

- Evidence-based data in children and adolescents with GER are limited, but avoiding lying down after meals and elevating the head of the bed may decrease symptoms of GER.
- Older children should avoid caffeine, chocolate, and spicy foods that exacerbate reflux-related symptoms.
- Active or passive exposure to nicotine will exacerbate GER, and children with GER should be aware of the additional risks in cigarette smoking.
- Obesity is a known risk factor for complications of GER, and reducing body weight should be discussed with every relevant child and family.

Drug therapy

- Several categories of drugs are effective for the management of infants, children, and adolescents with GER/GERD.
 - Histamine-2 receptor antagonists (H₂RAs) and proton-pump inhibitors (PPIs) suppress acid production.
 - Antacids neutralize acid that has been produced.
 - Prokinetic agents enhance gastric emptying and some may increase LES pressure.
- Each class of drugs has a specific role.
 - Acid suppressants reduce exposure of the esophagus to acid gastric contents and promote healing of the esophageal mucosa.
 - Prokinetic agents have not been shown to be effective in clinical trials but in theory may decrease reflux volume by increasing LES pressure, reducing frequency of transient LES relaxations, and accelerating gastric emptying.
 - Empiric trials of medication are often used in adults to support a clinical diagnosis of GER.
 - While recommended by many experts in pediatric gastroenterology, it has not been validated in children.
- Antacids
 - Buffer gastric acid and decrease its corrosive effect on esophageal mucosa
 - May relieve symptoms of heartburn, improve esophagitis, and prevent acid-related respiratory symptoms
 - Intensive high-dose antacid therapy with magnesium and aluminum hydroxide was shown to be as effective as cimetidine for treatment of esophagitis in children.
 - However, aluminum-containing antacids may increase aluminum levels, potentially causing osteopenia, anemia, and neurotoxicity.
 - Antacids are generally used for short-term management of intermittent symptoms of GERD.
- H₂RAs
 - Exert their antisecretory effect by blocking the H₂ receptors on gastric parietal epithelial cells
 - Ranitidine, 1 month–16 years: 5–10 mg/kg/day in 2 divided doses

- Famotidine, 1 year–16 years: 1 mg/kg/day in 2 divided doses up to 40 mg twice a day
- Nizatidine, ≥ 12 years: 150 mg twice a day
- Cimetidine, ≥ 16 years: 800 mg twice a day or 400 mg 4 times a day
- All are approved by the US Food and Drug Administration (FDA) for use in children; no over-the-counter H₂RAs are labeled for pediatric use.
- Numerous randomized controlled studies in adults have documented efficacy of this class of medication in relieving reflux symptoms and healing esophagitis.
- 2 randomized placebo-controlled studies in children report on the efficacy of cimetidine and nizatidine at improving reflux symptoms and healing of esophagitis with the medication.
- Concern exists about development of tolerance or tachyphylaxis with H₂RAs.
- In adults, antisecretory potency of medications in this class decreases after 3 days compared with PPIs, suggesting benefit for long-term use may not be as good as that with other classes of medications.
- Nevertheless, based on case series and expert opinion, H₂RAs are considered to be efficacious and safe in infants and children with GER.
- PPIs
 - The most potent class of acid-suppressive medications
 - Block the final step of acid production by covalently binding and deactivating hydrogen-potassium-adenosine triphosphatase enzyme (pump) in the gastric parietal cell
 - PPIs require acid in the parietal cell canaliculus to be activated and are most effective when taken after a prolonged fast, such as 30 minutes before the first meal of the day
 - When required, an evening dose should be administered 30 minutes before the evening meal.
 - Concomitant administration of H₂RAs may, in theory, reduce the efficacy of PPI therapy by reducing available hydrogen ions needed to activate the PPI.
 - Pharmacokinetic parameters for PPIs in adolescents are similar to those reported in adults; however, children <12 years require doses ranging from 1.5 to 2 times the adult dose on a per-kilogram basis to achieve adequate acid suppression.
 - Dose adjustment is attributed to a higher metabolic capacity in children, particularly those 1–6 years of age.
 - Drugs that are FDA approved for children
 - Esomeprazole, 12–17 years: 20 mg or 40 mg by mouth daily (capsule, oral suspension intravenous solution)
 - Lansoprazole, 1–17 years
 - 1–11 years, ≤ 30 kg: 15 mg by mouth daily
 - 1–11 years, >30 kg: 30 mg by mouth daily
 - 12–17 years, nonerosive: 15 mg by mouth daily
 - 12–17 years, erosive: 30 mg by mouth daily
 - Omeprazole, 1–16 years
 - 2–16 years, <20 kg: 10 mg by mouth daily
 - 2–16 years, ≥ 20 kg: 20 mg by mouth daily
 - Capsule, oral suspension
- Not FDA approved for children:
 - Rabeprazole, 18 years (tablet)
 - Pantoprazole, 18 years (capsule, oral suspension, intravenous solution)
 - Zegerid
- Efficacy data in children are mainly from open-label trials and a few controlled trials.
- PPIs are most effective in decreasing symptoms of reflux and healing esophagitis in children and adolescents.
- The benefit of PPIs alone in the treatment of GERD in children with asthma has not been well studied, but studies suggest that this class of medication is effective and is an excellent choice for an empiric trial.
- Over 10 years of safety data are reported with continuous use of omeprazole in adults, but safety data in children are more limited.
 - A limited number of children receiving omeprazole have been monitored for >8 years, with good safety data, and the safety of lansoprazole in children appears to be similar.
- Prokinetic agents
 - Used in the treatment of GERD to accelerate gastric emptying.
 - Studies have not shown a decrease in acid reflux episodes, thereby raising questions that these drugs may not reduce transient LES relaxations that are the most important pathophysiologic mechanism of GER.
 - The only prokinetic agents that are available in the United States are metoclopramide and erythromycin.
 - Metoclopramide has limited efficacy in treating GER and has potentially serious side effects that limit its value in treating children with GER.
 - Dyskinesia and tardive dyskinesia that result from crossing the blood-brain barrier
 - Increased serum prolactin levels
 - Erythromycin is rarely used in children who have only GER unless they have significant delay in gastric emptying.

Surgery for GERD

- Surgical therapy is an option for children who remain symptomatic during long-term medical therapy or have side effects of medication.

- Life-threatening complications, such as aspiration, may lead to recommendation of a fundoplication, but the concern that aspiration may result from swallowing and not from reflux is always present.
- If esophageal clearance is impaired, aspiration related to pharyngeal dysfunction may worsen after fundoplication.
- The rationale for surgery to avoid long-term medical therapy has not been well studied in children.
 - ~30% of adults who undergo fundoplication continue to use acid-suppression therapy after surgery.
- Nissen fundoplication is the standard form of surgery
 - It involves wrapping the fundus of the stomach around the LES to reinforce the antireflux barrier.
- Several modifications to Nissen fundoplication have been added, including the newer laparoscopic approach.
 - Recent studies suggest that children who have laparoscopic fundoplication may have fewer complications but a higher rate of reoperation (14%) when compared with children having an open Nissen fundoplication (8%).

WHEN TO ADMIT

- Failure to thrive
- Aspiration pneumonia

WHEN TO REFER

- Failure of medical therapy
- Side effects of medical therapy
- Failure to thrive

FOLLOW-UP

- Infants with GER should be monitored for weight gain, complications of GER and side effects of medication.

COMPLICATIONS

General

- Symptoms
 - Recurrent vomiting
 - Weight loss or poor weight gain
 - Irritability in infants
 - Regurgitation
 - Heartburn or chest pain
 - Hematemesis
 - Dysphagia or feeding refusal
 - Apnea or ALTE
 - Wheezing or stridor
 - Hoarseness
 - Cough
 - Abnormal neck posturing (Sandifer syndrome)

- Findings
 - Esophagitis
 - Esophageal stricture
 - Barrett esophagus
 - Laryngitis
 - Recurrent pneumonia
 - Hypoproteinemia
 - Anemia

Esophageal complications

- Peptic strictures are a known complication of severe GERD, especially in patients with neurologic impairment or esophageal motility disorders.
- Children with peptic stricture usually have dysphagia but, depending on their age, they may refuse to eat solids.
- Impaction of food may be the initial presentation.
- Peptic strictures are readily seen by barium swallow and are usually located in the distal third of the esophagus.
- Endoscopy is essential to look for Barrett epithelium, the columnar esophageal epithelium seen in Barrett syndrome.
- High-dose acid-suppression therapy and balloon dilation may obviate the need for fundoplication.
- In adults, Barrett epithelium is reported to occur in up to one-half of those with stricture, but Barrett epithelium is relatively rare in children.
- Cases have been reported of children with Barrett epithelium-associated adenocarcinoma and with mid-esophageal strictures, but the prevalence in this population is not well known.
- Patients with Barrett esophagus require at least annual surveillance for dysplasia.
- Fundoplication may not reverse Barrett esophagus, and no consensus exists on optimal therapy.
- Gastrointestinal bleeding associated with hematemesis, melena, guaiac positive stools, or anemia can occur as a complication of GERD resulting from erosive esophagitis.
 - Primarily in children who are neurologically impaired

Respiratory complications

- Chronic cough, stridor, hoarseness
- Laryngopharyngeal reflux in infants
 - Feeding resistance or refusal, growth failure
 - Irritability
 - Abnormal crying
 - Sleeping problems
 - Apnea
 - Recurrent croup
 - Laryngomalacia
 - Excessive salivation

■ Laryngopharyngeal reflux in children

- Chronic cough
- Dysphonia
- Globus, sore throat
- Halitosis
- Nasal obstruction
- Rhinorrhea, headache
- Regurgitation, vomiting
- Abdominal pain
- Dysphagia

■ Characteristic laryngoscopic findings attributed to GERD include airway erythema, edema, nodularity, granuloma, and cobblestoning.

■ See table Differential Diagnosis of Hoarseness and Laryngeal Edema.

■ Therapy with a PPI is usually recommended because of its acid-suppression capacity, but high doses over a prolonged period are often required because relapse after stopping therapy is common.

■ Recurrent pneumonia

- GERD may cause aspiration pneumonia and chronic pulmonary fibrosis and may occur without esophagitis.
- Children with neurodevelopmental delay present a special diagnostic problem because oropharyngeal incoordination may result in aspiration without reflux.
- Performing fundoplication in such a child might potentially impair esophageal clearance and increase the risk of aspiration.
- A videofluoroscopic swallowing study or fiberendoscopic swallowing evaluation with neurosensory testing may help identify patients at risk for aspiration.

■ Asthma

- Several studies suggest that GERD may contribute to the severity of asthma.
- Although symptoms of reflux are common in children with asthma and a high proportion of children with persistent asthma have abnormal pH monitoring, the relationship between asthma and GERD remains a challenge.
- The prevalence rates of GERD-associated asthma are reported to be 25–75%.
- Approximately 50% of patients with persistent asthma who test positive for GERD by pH monitoring have no or minimal symptoms of GERD.
- In a clinical trial of asthmatic children age 5–10 years, children with normal pH monitoring were randomized to receive a PPI or no acid-suppression treatment.
- ~25% of asthmatic children with normal pH probe studies were able to decrease asthma medication, whereas children who were not treated with acid-suppression medication continued therapy at the same dose of asthma medication.
- Studies have shown improvement of asthma symptoms after medical therapies for GERD that included positional therapy, thickening of formula without medication, cisapride, and an H₂RA.
- Evidence is insufficient to establish optimal medical therapy for GER in children with asthma.
 - The best test to determine whether association between asthma and GERD exists is an empiric trial with a PPI given twice a day for =3 months.

■ Apnea or ALTE

- An episode occurring in an infant that requires intervention and is characterized by a combination of apnea, cyanosis, pallor, rubor, plethora, limpness, stiffness, choking, or gagging

Differential Diagnosis of Hoarseness and Laryngeal Edema^a

Signs, Symptoms, or Factors	Laryngopharyngeal Reflux ^b	Infection ^c	Rhinosinusitis (Postnasal Drip) ^d	Allergy ^e	Benign Vocal Fold Lesion ^f
Hoarseness	Fluctuates	Acute	Acute, chronic, or recurrent	Fluctuates	Constant
Throat pain	Common (with cough, clearing of throat)	Yes	Uncommon	No	From secondary muscle tension
Laryngeal findings	Edema, granuloma, erythema, pseudosulcus	Erythema, edema	Secretions (thick discolored), edema	Edema, clear secretions, bluish mucosa	Nodules, polyps, cysts, scars

^a Adapted from: Ford CN. Evaluation and management of laryngopharyngeal reflux. *JAMA*. 2005;294(12):1534–1540. Copyright © 2005 American Medical Association. All rights reserved.

^b Aggravating factors are cigarette smoke, obesity, diet, or lifestyle.

^c Aggravating factors are systemic infection, immunosuppression.

^d Aggravating factors are laryngopharyngeal reflux, allergy, cigarette smoke.

^e Aggravating factors are environment and season.

^f Aggravating factors are cigarette smoke, vocal trauma, laryngopharyngeal reflux.

- ALTEs may be caused by cardiac, central nervous system, and infectious diseases, as well as upper airway obstruction, central apnea, and GERD.
- Despite reports that GER can induce obstructive apnea, subsequent investigations in unselected patients with ALTE have not demonstrated a convincing temporal relationship between ALTE and acid reflux, apnea, or bradycardia.
- The most convincing relationship between GERD and obstructive or mixed apnea has been in infants in whom episodes occurred while the patient was awake, in the supine position, and within 1 hour of a feeding.
- No evidence indicates that clinical characteristics of an ALTE or a combined pH study with polysomnography might predict risk for further episodes or sudden death.
- No randomized studies have evaluated usefulness of esophageal pH study in infants with ALTE.
- The benefit of medical therapy of GERD to prevent subsequent ALTE is not known.
- Thickening feeds, prokinetic agents, and acid-suppression therapy are reasonable therapeutic options.
- Surgical therapy is unproven and should be considered only in infants with ALTE that is unresponsive to acid-suppression therapy known to be associated with GERD.

Other complications

■ Sandifer syndrome

- A rare complication of GERD usually seen in otherwise neurologically normal children.
- Characterized by stereotypical, repetitive stretching and arching movements thought to be related to esophageal pain
- These behaviors may be mistaken for atypical seizures or dystonia.

■ Additional extraesophageal complications

- Dental erosions, recurrent sinus disease, rhinopharyngitis, hoarse voice, and otitis media have been attributed to GERD.
- All of these disorders have multiple causes, including infectious agents, immunoregulatory defects, and anatomic abnormalities.
- Attributing the cause to GERD may oversimplify what should be a more thorough evaluation to look for other underlying causes.

Gastrointestinal Allergy

DEFINITION

- Food allergy is a common but often unsubstantiated diagnosis in pediatric practice.
- An adverse reaction to a food is any untoward reaction, regardless of its cause; it can be classified under 2 general categories.
 - Food allergy or hypersensitivity—an immunologic response
 - Food intolerance—a nonimmunologic response caused by:
 - Underlying congenital or acquired enzyme deficiency in which a specific dietary nutrient cannot be metabolized properly
 - Disaccharidase deficiency
 - Galactosemia
 - Hereditary fructose intolerance
 - Ingestion of a toxin in the food
 - *Staphylococcus*
 - Shellfish
 - Mushrooms
 - Ingestion of a pharmacologic agent
 - Metabisulfite in wine or salad may cause bronchospasm.
 - Wine and monosodium glutamate may cause headache.
 - Caffeine may cause arrhythmia.
- Gastrointestinal (GI) allergic manifestations can be classified as
 - Immunoglobulin (Ig) E-mediated
 - Immediate GI hypersensitivity and oral allergy syndrome
 - Mixed GI allergy syndromes (involving some IgE components and some non-IgE- or T-cell-mediated components)
 - Eosinophilic esophagitis
 - Eosinophilic gastroenteritis
 - Non-IgE-mediated or T-cell-mediated allergic GI disorders
 - Dietary protein enteropathy
 - Protein-induced enterocolitis
 - Proctitis
- In all of these conditions, response of the immune system to a specific protein leads to pathologic inflammatory changes in the GI tract.
- Eosinophilic (or allergic) GI disorders (EGIDs) are characterized by infiltration of the GI tract with eosinophils.
 - Multiple food sensitivities are often identified.
 - Disorders are also usually associated with other systemic allergies.
- EGIDs are subdivided into specific areas of the GI tract.
- There is new focus on EGIDs because of the explosion of research into eosinophilic esophagitis.

EPIDEMIOLOGY

- Cow's milk protein allergy (CMPA)
 - Prevalence
 - 2.5% of newborns have hypersensitivity to cow's milk in the first year of life.
 - Age
 - CMPA rarely develops after 1 year of age.
- Soy protein allergy
 - Prevalence
 - 30–50% of infants with CMPA may also be allergic to soy protein; however, soy protein allergy may occur without concomitant CMPA.
- EGID
 - Previously thought to be rare
 - Prevalence
 - Eosinophilic esophagitis (a subset): 4 in 10,000 persons
 - May be underestimated because all incidence studies are based on referrals
 - Increased incidence appears to result from a combination of a higher index of suspicion and a true increase in pediatric allergy.

ETIOLOGY

Food allergy

- The GI tract contains lymphoid tissue capable of mounting an immunologic response to prevent penetration of antigens across the epithelium.
 - Lymphocytes and plasma cells are present in Peyer patches and the lamina propria of the small and large intestine.
 - IgA-containing plasma cells account for only 2%.
- Aberrations in immunologic mechanisms that trigger GI allergic reactions are unknown.
- This immunologic response can elicit symptoms consistent with a GI disorder, such as
 - Diarrhea
 - Vomiting
 - Dysphagia
 - Constipation
 - GI blood loss
- Foods that account for 90% of allergic reactions in children are:
 - Cow's milk protein
 - β -Lactoglobulin, the main whey protein, appears to be the most antigenic component.
 - Some infants can be sensitive to casein or whey protein.
 - Eggs
 - Peanut
 - Soy

- Tree nuts
 - Fish
 - Wheat
- Food allergy can cause:
- Urticaria or angioedema
 - Anaphylaxis
 - Atopic dermatitis
 - Respiratory symptoms
 - GI disorder
- These allergies are much more common in infants than in older children because infants may be predisposed to protein allergy caused by
- Enzymatic immaturity
 - Increased gut permeability
 - Relatively low secretory IgA

EGID

- Causes of EGID include:
- Sensitization to aeroallergens
 - Autoimmune processes
 - Ingested food allergies
 - Predisposition as a result of severe reflux or cutaneous atopy
- Both IgE-dependent and IgE-independent mechanisms are believed to be involved in the pathogenesis of these conditions.
- An allergic basis for this disease in some patients is indicated by presence of:
- Peripheral eosinophilia
 - Systemic allergies
 - Elevated IgE levels
 - Therapeutic response to steroids

SIGNS AND SYMPTOMS

CMPA

- Systemic manifestations
- Anaphylaxis
 - Iron-deficiency anemia (caused by GI blood loss)
 - Atopic dermatitis, urticaria
 - Peripheral eosinophilia
 - Poor sleep
- Respiratory manifestations
- Rhinitis
 - Wheezing
 - Pulmonary hemosiderosis
 - Nasopharyngeal obstruction leading to cor pulmonale

- GI manifestations
- Vomiting or gastroesophageal reflux
 - Diarrhea, malabsorption, protein-losing enteropathy
 - Enterocolitis
 - Constipation
 - GI bleeding
 - Failure to thrive
- The GI manifestations depend on the site of predominant inflammation in the GI tract.
- Esophagitis causes recurrent vomiting and reflux.
 - Gastritis causes vomiting, irritability or pain, and occult GI bleeding.
 - Antral gastritis is a common finding, with increased eosinophils and inflammatory cells in the antrum.
 - Enteritis causes diarrhea, malabsorption, or protein-losing enteropathy.
 - Colitis causes rectal bleeding, with blood or mucus in the stool.
 - Some infants can exhibit severe enterocolitis.
 - A significant number of these infants experience straining or discomfort with stools.

Soy protein allergy

- The clinical features of soy protein allergy are similar to those of CMPA, including:
- Esophagitis
 - Gastritis
 - Enteritis
 - Colitis

Human milk allergy

- Breastfed infants may develop the same symptoms as those who are formula-fed.
- Allergic colitis
 - Most common symptom
 - Esophagitis
 - Gastritis
 - Enteritis
 - Significant irritability
 - Occult blood or obvious rectal bleeding
 - Commonly asymptomatic

EGID

- Disease manifestations of EGIDs depend on the depth of GI involvement.
- Mucosal disease (more common in children)
- Dysphagia and heartburn if limited to the esophagus
 - Vomiting if involving the stomach

- Protein-losing enteropathy, malabsorption, and diarrhea if involving the small bowel
- Bloody stools if involving the colon
- Muscular disease (or submucosal)
 - Prominent inflammation in the stomach antrum can lead to pyloric obstruction.
- Serosal disease
 - Causes eosinophilic ascites
 - Symptoms resemble those of peritonitis.
- Patients with eosinophilic esophagitis have variable manifestations that may include:
 - Feeding disorder
 - Abdominal pain
 - Vomiting
 - Symptoms mimicking gastroesophageal reflux in young children
 - May have normal pH probe studies and fail to respond to antireflux medications
 - Symptoms may include dysphagia for solids or food impaction in older children.
- Other EGIDs have symptoms that vary with the anatomic site of eosinophilia and the depth of eosinophilic infiltration.
 - Mucosal form
 - Nausea, vomiting, colicky abdominal pain, diarrhea
 - Occult blood loss, iron deficiency anemia
 - Protein losing enteropathy leading to hypoalbuminemia
 - Failure to thrive/grow
 - Muscular (transmural) form
 - Obstructive symptoms, mimicking pyloric stenosis or thickening of the gastric outlet
 - Serosal form
 - Eosinophilic ascites
 - Approximately 75% of affected patients have peripheral eosinophilia (with all 3 types)
- If the stomach is involved, patients may have evidence of delayed gastric emptying, including nausea and bloating or vomiting, a symptom suggestive of pyloric obstructive disease.

DIFFERENTIAL DIAGNOSIS

- CMPA
 - Other causes of rectal bleeding
 - Rectal bleeding or guaiac-positive stools are probably the most common symptoms in infants with formula sensitivity.
 - Allergy is the most common cause of rectal bleeding among infants <6 months of age.
 - Celiac disease
 - Differentiation is made by the absence of antiendomysial or anti-tissue transglutaminase antibodies in CMPA.

- EGIDs
 - Eosinophilia can be associated with:
 - Parasitic infestations
 - Nutritional deficiencies
 - Inflammatory bowel disease
 - Neoplasms

DIAGNOSTIC APPROACH

- In patients with specific food allergies, removing specific food allergens from the diet ameliorates symptoms.
 - Reintroduction of the allergen leads to recurrence of symptoms.
- CMPA and soy protein allergy are the most clearly defined allergies in infants.
- In patients with refractory reflux food allergy or formula sensitivity should always be considered because these 2 conditions may coexist.
- CMPA
 - GI symptoms predominate in many patients.
 - In others, anaphylaxis or pulmonary symptoms occur.
 - Infants with severe atopic dermatitis should also be evaluated for possible CMPA and other food allergy.
- EGID has no classic symptoms; it can go undetected for several years.
- Whether these entities are variants of a similar disease process or distinctly different conditions remains to be solved.
- The diagnosis of EGID is based on clinical features and laboratory findings; endoscopy is essential to confirm a diagnosis
 - Collaboration with a pediatric gastroenterologist is necessary.
 - A pediatric allergist can help direct specific testing for allergy.
- For eosinophilic esophagitis, diagnosis is based on:
 - Patient or family history of allergy
 - Evaluation to rule out reflux
 - Typical eosinophilic infiltration of the esophagus on the biopsy specimen
 - Allergy testing

LABORATORY FINDINGS

- In formula allergy, the infant may not have peripheral eosinophilia.
- IgE measurement and radioallergosorbent tests (RASTs) to detect IgE antibodies specific for milk and soy proteins
 - Usually negative, suggesting that the immunologic mechanism occurs by means of a non-IgE (T-cell-mediated) mechanism.
 - A significant number of these patients have a concomitant transient hypogammaglobulinemia or hypoalbuminemia caused by protein-losing enteropathy.

- Treatment of the milk or soy or other food allergy results in normalization of serum proteins.
- An elevated IgE level or positive RAST result with these foods at this age in most cases suggests long-term rather than self-limited sensitivity.

■ EGIDs

- Half of patients have peripheral blood eosinophilia, elevated IgE levels, and an atopic history.
- Hypereosinophilic syndromes are characterized by infiltration of many organs with eosinophils.
- All EGIDs share a common feature of eosinophils infiltrating the GI tract, without involvement of extra-intestinal organs.
- Eosinophilic esophagitis is the only EGID for which normal and abnormal eosinophil counts are established.
- Because the mechanism of allergic GI diseases is probably on a spectrum between immediate hypersensitivity and cell-mediated immunity, the value of any single test is variable.
 - Allergy testing can include skin prick tests, RASTs, and patch testing.
 - Peripheral eosinophilia occurs, and an elevated IgE level is a variable finding; absence does not rule out eosinophilic esophagitis or other eosinophilic gastroenteropathies.
- In other EGIDs
 - Laboratory studies may include hypoalbuminemia and low immunoglobulin levels caused by malabsorption and protein-losing enteropathy.
 - If the patient has long-term blood loss, laboratory studies may show iron-deficiency anemia.
- >20 eosinophils per high-power field on a rectal biopsy specimen is indicative of an allergic cause for colitis; however, any inflammatory lesion of the GI tract appears to attract eosinophils.
- In CMPA, duodenal biopsy specimens reveal patchy changes, ranging from normal mucosa to flat gut lesions.
- Although scattered eosinophils are normal throughout the rest of the GI tract, they are pathologic when seen in esophagus.
 - Esophageal eosinophilia in reflux is mild (<15–20 eosinophils per high-power field) and is usually limited to the distal esophagus.
 - In eosinophilic esophagitis, eosinophilia is severe (>20 eosinophils per high-power field) and can involve most of the length of the esophagus.
- If allergic gastroenteropathy involves the small bowel, the lesions are in a patchy distribution, ranging from areas of normal mucosa to a flat villus lesion.
 - Eosinophilic infiltration may be mild or marked.
 - Gastric abnormalities, found more commonly in the antrum, have been described as being consistent in the mucosal form of the disease.
 - The stomach shows evidence of gastritis, with destruction and regeneration of gastric glands and surface epithelium, and eosinophilic infiltration usually is marked.
- In endoscopy of eosinophilic esophagitis
 - Mucosa may appear normal on gross examination.
 - Suggestive findings are often apparent, especially the classic ringed or furrowed esophagus and white exudates (seen exclusively in eosinophilic esophagitis).
- Biopsy samples of eosinophilic esophagitis help quantify eosinophilic infiltration and inflammation if mucosal disease is present.
- In other EGIDs, findings may be confusing because there is no consensus on histopathologic criteria.
 - The small intestine can reveal both normal mucosa (with or without eosinophilic infiltration) and a flat villus lesion.
 - In the stomach, a gastric antral biopsy specimen is of diagnostic value in the mucosal form of the disease and is usually positive, revealing evidence of gastritis with marked eosinophilic infiltration.

IMAGING

■ Eosinophilic esophagitis

- X-ray studies, including esophagography, may show thickened folds or a narrowing of the esophagus.

■ Other EGIDs

- X-ray studies, including esophagography or upper GI tract study:
 - May show thickened folds caused by edema in the esophagus or stomach
 - May show gastric outlet obstruction
 - Small-bowel follow-through may show nodular small bowel.

DIAGNOSTIC PROCEDURES

■ Biopsy

- The hallmark of GI biopsy results is an increased eosinophil count.

TREATMENT APPROACH

- Treatment of food allergy includes primary prevention to prevent sensitization to proteins.
- See Prevention for the AAP recommendations.

SPECIFIC TREATMENTS

Infant formulas

- Once a specific protein allergy is suspected or diagnosed, the infant should initially be fed a hypoallergenic formula.
- The choice of formula depends on the formula used at the time of diagnosis.
- Nonstandard infant formulas
 - Soy protein with L-methionine
 - Bright Beginnings Soy, Good Start Supreme Soy, Isomil Advance, Enfamil Prosobee
 - Partially hydrolyzed whey may help reduce the risk of CMPA but should not be used as treatment of existing allergy symptoms.
 - Good Start Supreme
 - Partially hydrolyzed casein, partially hydrolyzed whey
 - Gentlease
 - Casein hydrolysate (hypoallergenic) if the patient is taking a milk-based or soy-based formula
 - Alimentum, Nutramigen, Pregestimil
 - Amino acid base
 - Neocate, Elecare
- A comparison of partial versus extensive hydrolysates appears in the table Soy vs Partial vs Extensive Hydrolysates vs L-Amino Acid Formulas.
- Allergy may last as little as 3–12 months; therefore, this period is one of trial and error as the patient is gradually retried on the previously proved allergen.
- Approximately 10–15% of infants given casein hydrolysate formula still have a persistent sensitivity, as evidenced by continual guaiac-positive stools or overt GI bleeding.
 - Many respond to the L-amino acid formulas, such as Neocate and Elecare.

- These formulas are expensive and should be used only when persistent sensitivity to all other formulas is well documented.
- Milk or milk products from animals other than cows have been used anecdotally, eg, sheep's or goat's milk.
 - Risk of possible cross-reactivity between cow's milk proteins and sheep's or goat's milk proteins
 - Goat's milk is folate deficient.

Human milk allergy

- Treatment in infants who are sensitive to mother's milk involves persuading mothers to avoid cow's milk products.
- Not all infants will respond to this measure.
 - Accidental maternal ingestion of milk proteins
 - Some other factor
- Preventing many breastfeeding mothers from eliminating foods from their diet, which can cause significant maternal weight loss, can sometimes become extremely difficult.
- Mothers should be told that most infants who show sensitivity to foods the mother is eating do not have severe disease and breastfeeding can be continued unless symptoms are significant.
- Mothers who exclude multiple foods from their diets should consider vitamin and calcium supplementation.
- Use of a hypoallergenic formula may be worth a trial to determine whether the infant's symptoms disappear.

EGID

- If foods test positive on a combination of tests for immediate or delayed hypersensitivity and food challenges, these foods should be eliminated from the diet.
- The most common foods implicated are, in order: milk, egg, soy, corn, and wheat.
 - Several foods may be found to cause symptoms.

Soy vs Partial vs Extensive Hydrolysates vs L-Amino Acid Formulas

Category	Soy	Partially Hydrolyzed ^a	Extensively Hydrolyzed ^b	L-Amino Acid
Decreases protein sensitization	No	Yes	Yes	Yes
Treatment for established CMPA	No	No	Yes	Yes
Type of formula	Routine	Routine	Specialty	Specialty
Cost	Comparable with standard cow's milk	Comparable with standard cow's milk formula	3 to 4 times more costly than standard	Even more expensive than extensively hydrolyzed formula
Palatability	Comparable with standard	Comparable with standard	Less than standard	Less than standard

Abbreviation: CMPA, cow's milk protein allergy.

^aPartially hydrolyzed whey.

^bExtensively hydrolyzed casein.

- Dietary elimination of these allergens may alleviate most symptoms.
 - Some patients require complete dietary elimination with an L-amino acid–based formula.
 - An advantage of dietary management is a good rate of cure.
 - Restrictive diets may be difficult for children and may create social and behavioral problems.
 - Exclusive reliance on specialized formulas can be very expensive.
- For patients who cannot follow a restrictive diet, corticosteroid therapy may be required intermittently.
 - Quickly improves symptoms and normalizes tissue on biopsy specimens.
 - Steroids cannot be used on a long-term basis, and esophageal eosinophils and symptoms can recur after discontinuing therapy.
 - Topical steroids, such as swallowed fluticasone propionate, improve symptoms and histologic findings.
 - Eradication of eosinophils in the esophagus is less consistent with topical therapy, and symptoms and baseline histologic values return on discontinuation.
 - Topical treatment is associated with esophageal candidiasis.
- Oral cromolyn sodium (Gastrochrome®) has not been proven helpful.
- Leukotriene receptor antagonists improve symptoms but do not change histologic values.
- Symptomatic strictures resulting in food impactions or severe dysphagia may require endoscopic dilatation.
- Pyloric obstructive disease may require surgery.
- If patients have other symptoms of allergy or atopy, these should be addressed as well.

WHEN TO ADMIT

- Anaphylaxis
- Severe malnutrition

WHEN TO REFER

- Poor weight gain
- Immediate GI response after particular food or foods
- Incomplete response to exclusion or elemental diet
- Multiple food allergies
- Multiple allergic symptoms
- Malabsorption or protein-losing enteropathy
- Gastroesophageal reflux disease recalcitrant to appropriate therapy

COMPLICATIONS

- CMPA
 - Profuse vomiting and or diarrhea can lead to shock, anemia, and methemoglobinemia.
 - Children with enterocolitis may be predisposed to a severe rare form of enterocolitis to solid-food antigens later in life.
 - They may develop severe reactions to food proteins considered to be of low allergenicity.

PROGNOSIS

- CMPA
 - Previously, physicians counseled families that infants with CMPA would outgrow it by 2 years of age.
 - Later studies revealed that allergy may persist in:
 - 72% at age 2 years
 - 44% at age 4 years
 - 32% at age 6 years
 - Other studies are less pessimistic.
 - 44% with persistent symptoms at 1 year
 - 33% at 2 years
 - 23% at 3 years
 - Patients who have longer persistence of symptoms have:
 - Symptoms later after initial introduction of milk
 - Higher frequency of allergic disease
 - Multiple food allergies
- EGID
 - Evidence indicates that EGIDs are lifelong conditions with remissions and exacerbations, often requiring careful dietary manipulation and intermittent steroid therapy.
 - Preliminary data suggest that younger adolescents go through a phase in which they are much better able to tolerate foods to which they were previously sensitive.
 - If the EGID produces significant malabsorption, osteoporosis may occur.
 - Natural history of eosinophilic esophagitis remains unclear.
 - Among adults with initial misdiagnoses of reflux, some develop strictures requiring dilation.
 - The esophagus can be friable, tearing with the mere passage of an endoscope.
 - Possible evolution to Barrett esophagus remains to be studied.

PREVENTION

- AAP 2008 Recommendations for Prevention of Allergy
 - Nutritional interventions are largely limited to infants at high risk of developing allergy (ie, infants with at least 1 first degree relative with allergic disease).

- There is “evidence” that compared to intact cow’s milk protein formula, exclusive breastfeeding for at least 4 months prevents or delays the occurrence of atopic dermatitis, cow’s milk allergy, and wheezing.
- There is “modest evidence” that atopic disease may be delayed or prevented by the use of extensively or partially hydrolyzed formulas compared with intact cow’s milk formula, particularly for atopic dermatitis.
- There is “little” or “no current convincing” evidence that the timing (delaying) of introduction of complementary foods beyond 4 to 6 months of age prevents the occurrence of atopic disease.
- There is “no convincing” evidence for the use of soy formula for allergy prevention.
- Current evidence does not support maternal dietary restrictions during pregnancy or lactation.

Gastrointestinal Hemorrhage

DEFINITION

- Bleeding at any point along the length of the gastrointestinal (GI) tract, from the mouth to the anus
- Bleeding may be arterial, venous, or both.

MECHANISM

- A large vascular supply to the GI tract accounts for an appreciable fraction of cardiac output, especially after eating meals.
- Most bleeding is slow and involves oozing from the mucosal surface.
- Acute GI bleeding
 - May occur with or without symptoms
 - Can originate in either the upper or the lower GI tract
 - Massive bleeding can result from lesions involving high-pressure arteries or a large, engorged venous plexus.
- Chronic GI bleeding
 - Usually slow and intermittent

HISTORY

- The physician must quickly assess severity to expedite appropriate resuscitative measures.
- The physician must consider the most likely causes.
 - Does the problem require immediate surgery?
 - Does the problem require medical evaluation and management?
- The workup is based on:
 - Patient's age and history
 - Patient's clinical appearance
 - Physician's familiarity with the patient
- A detailed history may help determine the location and duration of the bleeding.
- A family history of polyps, bleeding disorders, or GI diseases is important.
- Presence or absence of abdominal pain
 - If present: location, severity, and quality
- Associated systemic symptoms (eg, with hemolytic-uremic syndrome [HUS] or inflammatory bowel disease [IBD])
- Altered mental status or lethargy
- Suggestion of surgical etiology (eg, Meckel diverticulum, intussusception, volvulus)
- Color of the stool
- Description of emesis
 - Whether a change has occurred in either in the preceding days or weeks
- Vomiting that progresses from bile-stained to bloody
 - Intestinal obstruction (volvulus, intussusception, necrotizing enterocolitis [NEC])
 - Mallory-Weiss tears

- Bloody diarrhea
 - Infectious enteritis
 - Food allergy
 - IBD
 - May precede HUS
- Painless lower GI bleeding
 - If substantial
 - Meckel diverticulum
 - GI vascular anomalies
 - If less severe
 - Polyps
 - Lymphonodular hyperplasia
- Fever
 - Common in infectious or inflammatory disorders
- Arthritis and rash are seen with Henoch-Schönlein purpura (HSP).
- Neonatal history should focus on risk factors for NEC or varices.
 - Umbilical vein catheters
 - Liver disease
 - Birth asphyxia
- Sexual activity or abuse involving anal penetration should alert the clinician to anal and rectal trauma.

PHYSICAL EXAM

- A complete and systematic examination should be performed because clues to the diagnosis may be present in any organ system.
- General appearance and vital signs can be helpful in determining duration of bleeding.
 - Acute GI bleeding may occur with or without signs of shock, depending on the amount of blood loss.
 - Slow, chronic bleeding allows time for physiologic changes.
 - Compensatory tachycardia
 - Orthostasis
 - Decreased pulse pressure
 - Iron-deficiency anemia
 - Fatigue
 - Pallor
- The nose and mouth should be examined for bleeding lesions or burns.
- The abdomen, perineum, and rectum should be thoroughly examined.
 - Abdominal examination to assess:
 - Tenderness
 - Bowel sounds

- Masses
- Hepatosplenomegaly
- Signs of chronic liver disease
 - Telangiectasias
 - Jaundice
 - Hepatosplenomegaly
 - Prominent abdominal venous pattern
- Rectal examination, with special attention to the perianal region
 - Skin tags
 - Abscesses
 - Fissures
 - Bleeding points
 - Hemorrhoids (uncommon)
 - Character and color of stool
 - Occult blood on guaiac testing
 - Palpation for polyps and pelvic masses
- Digital rectal examination should follow in an attempt to discover:
 - Anal fissures
 - Rectal polyps
 - Hemorrhoids
- Sigmoidoscopy for children who have persistent rectal bleeding to identify polyps or mucosal lesions
 - Blood originating from above the reach of the sigmoidoscope indicates the need to proceed with other diagnostic studies.
- Skin
 - Eczema
 - Possible association with food allergy
 - Skin lesions, such as purpura and petechiae
 - Bleeding disorders
 - HSP
 - HUS

DIFFERENTIAL DIAGNOSIS

Newborns

- Usually appears as rectal bleeding or blood suctioned from the stomach during routine postnatal care
- In many instances, no lesion is readily discernible, and bleeding resolves spontaneously and permanently.
- Common causes of GI bleeding in the first 24 hours of life include:
 - Maternal blood swallowed during delivery
 - Local trauma after nasogastric suctioning

- Premature infants and newborns who have low Apgar scores are at increased risk for gastric ulcerations and erosions that can bleed.
 - These lesions rarely are primary.
 - Usually result from asphyxia associated with a difficult delivery, a cardiac lesion, or sepsis
- Hemorrhagic disease of the newborn
 - Inherited deficits of coagulation factors or delay in administration of postnatal vitamin K occasionally produces GI bleeding.
 - More commonly, these disorders show as diffuse bleeding from venipuncture sites.
- NEC usually manifests as lower GI bleeding with bilious vomiting, abdominal distention, and lethargy.
 - Symptoms usually occur after the first feeding but may be delayed for a few weeks.
 - Most common in premature infants
 - Occasionally occurs in stressed full-term infants
 - Up to 5% of neonates in intensive care units develop NEC.
 - Overall mortality may be as high as 30%.
 - Complications include sepsis and shock.
- Intrinsic structural lesions can cause lower GI bleeding.
 - Duplication
 - A tubular structure lined with normal GI mucosa adjacent to the true intestine can be present anywhere along the GI tract.
 - Can cause lower GI bleeding, either acute or chronic, along with abdominal distention and vomiting.
 - Unrepaired duplications may lead to obstruction, volvulus, or perforation.
 - Volvulus or malrotation
 - A volvulus or malrotation of the GI tract should be suspected in any infant who has abdominal pain, bilious vomiting, and melena.
 - Because these symptoms and signs are often unreliable, the diagnosis should be considered in any newborn who vomits and has guaiac-positive stools.
 - Vascular malformation
 - Must be considered in the evaluation for painless rectal bleeding
 - Hemangiomas
 - Other vascular lesions, such as hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber syndrome)
 - The most common form is the larger cavernous hemangioma.
 - Either polypoid or diffuse
 - Extends several centimeters through the submucosa of the small or large intestine

- The diffuse type usually involves the large bowel, specifically the rectum.
- Cutaneous vascular malformations are often present but may require scrupulous searching to detect.
- Can occur anywhere along the GI tract
- Produce slow or diffuse lower GI bleeding
- The bleeding is usually painless.
- The color of the blood in the stool varies, depending on the level of the lesion.
- Vascular malformations may be associated with cutaneous hemangiomas or cardiac defects.
- Milk protein allergy or soy protein allergy
 - Can begin as early as the first week of life
 - Exhibits as:
 - Severe diarrhea
 - Gross blood in the stool
 - Abdominal distention
 - Vomiting
 - Older infants may have occult lower GI bleeding and mucus in the stool.
 - The diagnosis is made by clinical response to withdrawal and rechallenge with the offending protein.
- Infectious enteritis
 - Rare in the newborn
 - May appear later in the first month of life
 - In very young infants, bacterial gastroenteritis, especially that caused by *Salmonella*, can cause bloody diarrhea with or without fever.
 - 8–13% of infants may have associated bacteremia.
- Anal fissure
 - Suggested by bright red blood streaks on the surface of the stool
 - Often associated with hard stools
 - The most common cause of rectal bleeding
 - Visual inspection of the anus usually confirms the diagnosis.

Infants and young children

Upper GI bleeding

- Upper GI bleeding in the young child usually is caused by mucosal lesions in the esophagus and the stomach.

Esophageal bleeding

- Often slow and occult (without hematemesis), manifesting with signs of anemia or guaiac-positive stools
 - Acid reflux
 - Newborns who have persistent or severe gastroesophageal reflux can develop esophagitis.
 - Viral infection, or fungal infection particularly with immunocompromise.

- Caustic ingestion severe enough to burn the esophageal mucosa can result in painful swallowing, drooling, oral burns, and hematemesis.
- Esophageal foreign body
 - As infants become more mobile and dexterous, they are at higher risk for foreign body and toxic ingestions.
 - Coins and small toys, when lodged in the esophagus, can cause drooling, vomiting, and chest pain.
 - Persistent or unrecognized esophageal foreign bodies
 - Lead to edema and erosion of the esophagus
 - May cause hematemesis
- Mallory-Weiss tear
 - A rent at the gastroesophageal junction that may result from forceful or prolonged vomiting
 - The emesis becomes streaked with bright-red blood and may develop into coffee-ground emesis if the tear persists.

Gastroesophageal varices

- Variceal bleeding ranges from slow, persistent oozing to acute massive hematemesis.
- Physical examination usually reveals signs of portal hypertension, such as enlarged liver or spleen, or both.
- Most cases result from the cavernous transformation of the extrahepatic portion of the portal vein, which has been associated with:
 - Umbilical vessel catheterization
 - Omphalitis
 - Neonatal conditions associated with hypoxia, prolonged jaundice, or sepsis

Gastritis

- Infectious
- Medications (eg, nonsteroidal antiinflammatory drugs, corticosteroids)

Lower GI bleeding

- The differential diagnosis is broad.
- Polyps
 - Juvenile polyps
 - Most common cause of lower GI bleeding in 3- to 7-year-old children
 - Typically located in the colon
 - Simple, solitary, benign hamartomatous lesions
 - May irritate the GI tract, causing intermittent, painless, bright-red rectal bleeding
 - Many of these polyps autoamputate if left alone and are passed with the stool.
 - Most polyps are located within 25 cm of the anus.

- They are easily identified by:
 - Digital examination
 - Air-contrast barium enema
 - Sigmoidoscopy
- Can be removed with snare electrocautery
- Adenomatous polyps
 - Adenomatous polyps are premalignant tumors.
 - May transform into cancer over an average of 10 years
 - May produce rectal bleeding as early as infancy
 - Managed differently from juvenile polyps
 - Associated with familial polyposis and Gardner syndrome
 - Juvenile polyposis coli (JPC) is suggested by the presence of 5–10 juvenile polyps; ≥ 10 polyps is considered diagnostic.
 - JPC occurs in approximately 10% of patients with colonic polyps.
 - Associated with anemia, right-colon polyps, and adenomas

Meckel diverticulum

- A remnant of the omphalomesenteric duct
- Found within 2 feet of the ileocecal valve
- Present in up to 2% of the population
- The acid secreted by ectopic gastric mucosa, which is usually present in diverticula that bleed, causes peptic ulceration of the ileal mucosa.
 - Typically occurs in children <3 years
 - Causes painless, maroon- or red-colored lower GI bleeding
 - Typically, the bleeding is severe enough to cause the hemoglobin level to decrease to approximately 8 g/dL.

Intussusception

- Telescoping of an intestinal segment
- Typically seen in children 6–24 months of age
- Often idiopathic
- Usually involves invagination of the distal ileum through the ileocecal valve into the colon
- Older children with intussusception and those with multiple recurrences may have pathologic lesions that serve as lead points (eg, Meckel diverticulum, polyp, tumor).
- Classic presentation begins with intermittent, severe, crampy abdominal pain, with vomiting shortly thereafter.
- As the intussusception progresses, lethargy or paradoxical irritability develops.
- Guaiac-positive stools
 - Seen as the bowel becomes ischemic
 - May progress to the passage of red bloody mucus, classically referred to as *currant jelly stools*

- Complications include:
 - Intestinal perforation
 - Peritonitis
 - Significant bleeding

Lymphonodular hyperplasia

- May cause painless, blood-streaked stools
- Usually seen in children <6 years
- May be associated with food allergy
- Diagnosis is made by endoscopic examination and histologic confirmation.

Infectious enterocolitis

- Symptoms range from mild diarrhea to fever, abdominal cramping, and watery or mucoid stools (or both forms) with or without blood.
- *Salmonella*, *Shigella*, *Yersinia*, and *Campylobacter* are the most common bacterial causes of bloody diarrhea.
- Pseudomembranous colitis, caused by *Clostridium difficile*, also causes fever, diarrhea, abdominal cramping, and bloody stools.
- The child often has a history of recent hospitalization and antimicrobial therapy.
- Onset of symptoms can be delayed for weeks.
- A variety of parasites, such as amoebae, can cause bloody diarrhea.

Systemic diseases

- HSP: purpura with arthritis, hematuria, abdominal cramping, and bloody stool
- HUS: prodrome of hemorrhagic colitis, followed by thrombocytopenia, hemolytic anemia, and renal disease
 - Most commonly caused by Shigatoxin-producing *Escherichia coli* O157:H7

Other causes

- Milk protein allergy, anal fissures, and congenital GI structural anomalies can also occur in this age group.

Older children and adolescents

- Nasopharyngeal bleeding
- Esophagitis
- Mallory-Weiss tear
- Gastroesophageal varices
- Gastritis
 - Infectious
 - Medications (eg, nonsteroidal antiinflammatory drugs, corticosteroids, tetracycline)
- Peptic ulcer disease
 - Can occur at any age, but more common in the older child and adolescent
 - Symptoms usually begin with epigastric or periumbilical pain accompanied by nausea.

- GI bleeding is evident in approximately 50% of children as either hematemesis or melena.
- *Helicobacter pylori*
 - Bacteria found in the gastric mucous layer or adherent to the epithelial lining of the stomach causally associated with ulcers
 - Infection is common worldwide.
 - In areas of high prevalence, most children are infected by 10 years of age.
 - Infected children usually are asymptomatic and only occasionally develop disease in childhood.

■ Duplication

■ Vascular malformation

■ Polyps

- Juvenile (see above)
- Adenomatous (see above)

■ Infectious enterocolitis (see above)

■ Inflammatory bowel disease

- May appear in the adolescent age group as episodes of bloody diarrhea, cramping, and tenesmus
- The course may be atypical in children, making the diagnosis difficult.
- The diagnosis is suggested by:
 - Growth failure
 - Weight loss
 - Anemia
 - Evidence of recurrent bouts of GI bleeding
- Abdominal pain, fever, and weight loss suggest inflammatory bowel disease.

■ Systemic diseases (HSP, HUS)

■ Vascular malformation (see above)

■ Meckel diverticulum

■ Hemorrhoids

■ Anal fissure

Cirrhosis and chronic liver disease

- Intrahepatic causes of cirrhosis, leading to portal hypertension, that may first show during childhood, include
 - Wilson disease (after 6 years of age)
 - α_1 -Antitrypsin deficiency
 - Biliary cirrhosis
 - Metabolic, infectious, or anatomic forms of chronic liver disease
- These chronic liver diseases also may be associated with coagulopathy and thrombocytopenia from the hypersplenism that usually accompanies them.
- If the cause of the portal hypertension is extrahepatic, bleeding may be tolerated remarkably well.

- In patients with cirrhotic liver disease, bleeding may lead to rapid hepatic decompensation.

False bleeding

- Red color in the stool often is assumed to be blood; however, many other substances cause change in stool color.
 - Foods that contain a high concentration of red pigments, such as tomatoes, cranberries, beets, and red fruit juices and gelatin (Jell-O)
 - Red-colored medications, such as acetaminophen and amoxicillin, can be passed in the stools, especially if diarrhea is present.
 - Spinach, licorice, iron, and bismuth (Pepto-Bismol) often lead to dark, black stools, which can be confused with true melena.
- In infants, *Serratia marcescens* can cause red diaper syndrome as a result of the formation of red pigment in soiled diapers stored for >1 day.

Nongastrointestinal sources of bleeding

Infants

- An infant may swallow maternal blood either during delivery or when breastfeeding if the mother has bleeding nipples.
 - The Apt-Downey test is helpful in differentiating maternal blood from infant blood.
 - 1 part of the bloody stool (or gastric aspirate) is mixed with 5 parts of water to lyse the erythrocytes.
 - After the mixture is centrifuged, 1 mL of 0.2 normal sodium hydroxide is added to the supernatant hemoglobin solution.
 - After 2 minutes, fetal hemoglobin, which resists the alkaline reduction, remains pink, whereas maternal hemoglobin turns yellow-brown.
 - Melena contains denatured hemoglobin and therefore cannot be used for the Apt-Downey test.
- Vaginal bleeding in a newborn with estrogen withdrawal may be mistaken for rectal bleeding.

Older children

- Swallowed blood usually is the result of nosebleeds or bleeding mouth lesions.
 - This nasopharyngeal bleeding can mimic hematemesis or melena.
- Pulmonary hemorrhage
 - Rare in children
 - May exhibit acutely as hematemesis
 - May exhibit more chronically as melena and anemia
- In the menstruating teenager, vaginal blood may affect the accuracy of stool guaiac testing.
- The possibility of blood being added to the stool by a caretaker suggests Munchausen syndrome by proxy.

LABORATORY EVALUATION

- Laboratory testing should focus on:
 - Determining the amount and duration of the bleeding
 - Assessing for coagulopathy
 - Evaluating for other laboratory abnormalities that may be associated with the underlying disease process
- Initial laboratory studies
 - Complete blood count with reticulocyte count
 - Hemoglobin determination can help assess the degree of blood loss.
 - Acute bleeding may not decrease the hemoglobin level until intravascular equilibration has taken place.
 - The leukocyte count may be elevated in infectious colitis.
 - Coagulation studies
 - Prothrombin time may be elevated as a sign of a bleeding disorder or as result of abnormalities in liver synthetic function.
 - Partial prothrombin time
 - Platelet count
 - Serum chemistries
 - To assess renal function
 - An elevated blood urea nitrogen level may result from increased intestinal absorption of blood with long-standing upper GI bleeding.
 - Liver function tests for suspected liver disease
 - Blood type and screen
 - If patient has significant bleeding or a low hemoglobin level and transfusion may be needed
 - Stool specimen
 - If bloody diarrhea is present
 - For culture, if appropriate
 - For ova and parasites, if appropriate
 - Stool guaiac
 - The most common test
 - Highly sensitive
 - Uses the peroxidase activity of hemoglobin to catalyze a color change on a test card or paper strip
 - Can identify even trace amounts of blood
 - Foods that have peroxidase activity may cause false-positive results if eaten within 3 days of testing.
 - Red meat
 - Liver
 - Processed meats
 - Raw fruits and vegetables, especially melon, turnip, radishes, and horseradish

- High vitamin C intake interferes with the peroxidase reaction and can cause false-negative results.
- Outdated guaiac cards and prolonged storage may affect the accuracy of the test.
- Stool guaiac cards are not accurate for testing emesis for the presence of blood because gastric acid can affect the reaction that causes the color change.
- Serologic tests
 - *H pylori* IgG antibodies
 - IBD serologies

IMAGING

- Imaging studies are needed in most children with GI bleeding:
 - To locate the source of the bleeding
 - To confirm a suspected diagnosis
- The type of study is chosen on the basis of:
 - The child's age
 - Clinical presentation
 - Possible diagnosis
- Radiography
 - Plain radiographic films:
 - Usually are nonspecific
 - Usually require additional imaging to confirm a diagnosis
 - 2-view (flat and upright) abdominal radiographs will reveal:
 - Signs of obstruction or calcifications
 - Air-fluid levels
 - Dilated bowel loops
 - Some specific radiographic findings include:
 - Pneumatosis intestinalis in NEC
 - Intestinal obstruction with absence of gas in the right colon in intussusception
 - In volvulus/malrotation, the radiograph may show loops of small bowel overriding the liver shadow, with paucity of air in the GI tract distal to the volvulus.
- Barium studies
 - For identification of:
 - Intestinal foreign bodies
 - Polyps
 - Lymphonodular hyperplasia
 - IBD
 - An upper GI series, barium enema, or both are sometimes needed to confirm the diagnosis of volvulus/malrotation.
 - Barium swallow has poor sensitivity in esophagitis.
 - Barium enema or upper GI series with small-bowel follow-through should be the last studies performed.
 - They make use of arteriography, isotope scans, and endoscopy impossible for several days thereafter.

- Confirmation of intussusception, followed by hydrostatic reduction with barium or air enema, is successful in approximately 70–80% of cases, even in those with symptoms for >24 hours.
- Ultrasonography
 - The use of screening ultrasonography has decreased unnecessary enemas for clinically suspected intussusception.
 - Diagnosis can be confirmed by identification of the layering of intestinal mucosa as a bulls-eye or coiled spring lesion.
- Color Doppler ultrasonography
 - Increasingly useful as a diagnostic aid in both intussusception and malrotation
 - Usefulness depends on the skill of the operator.
- Computed tomography
 - Occasionally helpful in defining related anatomic features if the child is hemodynamically stable and either cooperative or sedated
 - Midgut volvulus also may be diagnosed by computed tomography or ultrasonography.
 - Duodenal dilatation
 - Fixed midline bowel
 - Wrapping of the bowel and the superior mesenteric vein around the superior mesenteric artery (whirlpool sign)
- Angiography
 - For severe, life-threatening bleeding
 - Can be both diagnostic and therapeutic, depending on the ability to embolize the bleeding vessels
 - Limited sensitivity in detecting slow or past bleeding, so best performed when bleeding is active
 - Selective arteriography or digital subtraction angiography may aid in demonstrating vascular malformation.
- Arteriography
 - If the bleeding is not immediately life threatening
 - Can demonstrate bleeding that occurs at a rate ≥ 0.5 mL/min
- Radionuclide scanning
 - For children with persistent, active bleeding who are clinically stable
 - Often can identify the source of an acute, ongoing bleed by pinpointing accumulation of an isotope at the bleeding site
 - Sulfur-colloid isotopic study
 - More sensitive and less invasive than arteriography
 - Can demonstrate active bleeding at rates as low as 0.05–0.1 mL/min
 - Demonstrates active bleeding by using a tracer with a very short half-life
 - Isotope is extracted rapidly so that background radioactivity is low.
 - In small infants, a large uptake of the isotope by the liver may mask the right upper quadrant.
 - The bleeding site may be determined with technetium-99-pertechnetate-labeled red blood cells.
 - Labeled cells may remain in circulation for more than a day and allow repeated imaging to locate the site of intermittent bleeding.
 - An isotope-labeled red blood cell infusion has a lower contrast ratio but is better at detecting slower or intermittent bleeds than a sulfur-colloid isotopic scan.
 - A Meckel scan uses technetium-99 pertechnetate, which is secreted by ectopic gastric mucosa, to identify the diverticulum.
 - The test is fairly sensitive, but only during active bleeding.
 - A repeat scan is sometimes necessary.
 - If the rate of bleeding does not permit enough time to perform these studies, vasopressin or octreotide may be administered parenterally in an attempt to control the bleeding and to stabilize the patient.

DIAGNOSTIC PROCEDURES

- Upper GI fiberoptic endoscopy can establish diagnosis in 75%–90% of patients.
 - Is unlikely to achieve adequate visualization if bleeding is massive and cannot be controlled with saline lavage.
 - Gastric ulceration is diagnosed in newborns by radiography or upper GI endoscopy
- Gastroduodenoscopy to determine source and type of lesion present if bleeding ceases.
- Colonoscopy and biopsy usually confirm diagnosis of inflammatory bowel disease.
- Esophagoscopy and pH probe manometry are used to diagnose gastroesophageal reflux.
- *H pylori* infection is diagnosed by culture of biopsy specimens from the stomach and duodenum.

TREATMENT APPROACH

- The approach to acute massive GI bleeding must be the same as that in any other emergency.
 - Obtain the pertinent historical information.
 - Perform a brief but adequate examination.
 - Stabilize the patient clinically.
 - Arrive at a working diagnosis
 - Institute appropriate therapy or consultations.
- Massive upper GI bleeding may lead to vomiting, aspiration, and airway obstruction requiring stabilization of the airway with endotracheal intubation.

- Administration of oxygen is always indicated.
- Assess adequacy of circulation by evaluating:
 - Peripheral perfusion
 - Quality of pulses
 - Capillary refill time
- In children, the initial response to hypovolemic shock is tachycardia.
- In acute bleeding, adequate blood pressure can be maintained with blood loss of up to 30% without replacement.
- Prompt surgical intervention is required:
 - In vascular compromise of the intestine
 - When the rate of bleeding is excessive and uncontrollable by more conservative methods
- Conservative measures control most acute episodes of GI bleeding relatively easily.
 - Patients who eventually require surgical intervention can usually undergo surgery electively at a later time.

SPECIFIC TREATMENT

Emergency management

Immediate response

- Tachycardia and capillary refill time are essential in determining the nature of the resuscitation required.
- Skin turgor and the color of the mucous membranes should be noted.
- Place a large-bore intravenous catheter if there are signs of shock.
 - Orthostasis or frank hypotension
 - Tachycardia
 - Poorly perfused extremities
 - Pale mucous membranes
- If percutaneous venous access is not obtained within a few minutes, an intraosseous line should be placed.
 - 20 mL/kg of normal saline should be given rapidly to reexpand the vascular volume.
 - Fluid bolus may need to be repeated several times.
 - Additional fluid should be given as needed
 - With >30–40% acute blood loss, packed red blood cells should be given as soon as possible (see Shock).
- A nasogastric tube, preferably of the vented sump type, helps to:
 - Determine the source of bleeding
 - Estimate the volume of ongoing blood loss
- The nasogastric tube should be left in place and attached to:
 - Low-pressure continuous suction, if vented
 - Intermittent suction, if nonvented

- Nasogastric tube placement may aggravate bleeding in a patient with varices.
 - Even in this case, a nasogastric tube may be required to quantitate blood loss adequately.

Controlling bleeding and determining specific diagnosis

- If the nasogastric aspirate contains blood, or if the patient has hematemesis
 - Saline irrigation may be instituted through the nasogastric tube to decrease mucosal blood flow and stop profuse bleeding.
 - The efficacy of lavage in decreasing and controlling gastric bleeding has not been demonstrated conclusively.
 - It allows easier assessment of the rate of bleeding
 - It helps in removing clotted blood.
 - Use saline at room temperature, because irrigation with water can lead to hyponatremia and iced or cold fluid may cause hypothermia.
 - Withdraw after 3–5 minutes.
 - Aspirate returns that do not clear in 15 minutes:
 - Suggest continued GI bleeding
 - Should prompt additional evaluation
- Gastroduodenoscopy if bleeding ceases:
 - To demonstrate the bleeding source
 - To determine the type of lesion present
 - Upper GI fiberoptic endoscopy can establish the diagnosis in 75–90% of patients.
 - Adequate visualization is unlikely if the bleeding is massive and cannot be controlled with saline lavage.
- If the bleeding is not immediately life threatening:
 - Arteriography can demonstrate bleeding that occurs at a rate ≥ 0.5 mL/min.
 - Sulfur-colloid isotopic study, more sensitive and less invasive than arteriography, can demonstrate active bleeding at rates as low as 0.05–0.1 mL/min.
 - Injection with technetium-99-pertechnetate-labeled red blood cells that may remain in the circulation for more than a day and allow repeated imaging can be used to locate the site of intermittent bleeding.

Mucosal erosion or inflammation

- Antacid therapy, with or without concomitant use of a histamine 2-blocker
- For bleeding ulcers, intravenous therapy with a proton-pump inhibitor:
 - Reduces risk of rebleeding
 - Does not appear to influence overall mortality

Variceal bleeding

- The cause of the lesions must be determined for appropriate treatment of the underlying disease.
- In particular, liver or portal venous disease should be sought.
- Clotting factors and platelets should be replaced as indicated.
- Use of balloon tamponade with a Sengstaken-Blakemore tube is effective in controlling bleeding but has a high incidence of complications.
- Vasoactive drugs and endoscopy have replaced the Sengstaken-Blakemore tube in most cases.
 - Somatostatin and octreotide have been found to be effective in adults and in smaller studies in children.
 - Octreotide decreases splanchnic blood flow, thereby decreasing portal pressure.
 - Octreotide has less effect on systemic blood flow and is associated with fewer side effects than vasopressin.
 - Pediatric studies (with no control groups) have shown octreotide to be 50–63% effective in controlling acute variceal bleeding.
 - Initially, a 50-mcg bolus is infused, preferably through a central or intraosseous line, followed by an infusion of 50 mcg/hour for 5 days.
 - Endoscopy is the preferred intervention for variceal bleeding because it can provide both diagnosis and therapy.
 - Endoscopic injection sclerotherapy (EIS) uses an injection of a sclerosing solution into the varices.
 - Endoscopic variceal band ligation (EVL) uses elastic bands placed around the varices in the distal esophagus.
 - Endoscopy has been found to be 80–100% effective in controlling variceal bleeding.
 - In a randomized controlled trial in 49 children, EVL achieved variceal eradication faster than EIS, with a lower rebleeding rate and fewer complications.
 - Endoscopy should be performed by an experienced gastroenterologist, with general anesthesia and endotracheal intubation available, especially when performed on small children.
- Studies in adults and experience in pediatrics, although limited to date, suggest:
 - Octreotide as the initial treatment for bleeding varices
 - Followed by endoscopic therapy, either EVL or EIS
 - If bleeding continues despite vasoactive and endoscopic therapies, then balloon tamponade can be attempted.

***H pylori* infection**

- Treatment, when indicated, consists of:
 - A 7- to 14-day course of any of a variety of antibiotic regimens
 - A proton-pump inhibitor

Necrotizing enterocolitis

- Neonates remain hospitalized for bowel rest and intravenous antibiotics.
- Occasionally requires surgical intervention

Meckel diverticulum

- Treatment requires surgical excision.

Mallory-Weiss tear

- Although the bleeding is minor and usually resolves spontaneously, a histamine 2-blocker may be needed to prevent continued irritation by stomach acid.

Volvulus malrotation

- Immediate surgical repair is necessary.

WHEN TO REFER

- Upper GI bleeding
- Lower GI bleeding
 - Of moderate amount
 - Persistent or intermittent

WHEN TO ADMIT

- Any nontrivial upper GI bleeding
 - Active bleeding
 - Moderate amount of blood
 - Anemia
 - Abdominal pain
- Significant lower GI bleeding

Gastrointestinal Obstruction

DEFINITION

- Gastrointestinal obstruction (GIO) is relatively uncommon during infancy, childhood, and adolescence.
- Obstructions distal to the pylorus are potential surgical emergencies.
 - The younger the patient is, the more ominous the probable cause and the more urgent the required therapy.

ETIOLOGY

- The presence or absence of key symptoms and signs, along with patient age, are important clues to the cause of the obstruction (see table Clinical Findings for Pediatric Gastrointestinal Obstruction):

- Esophageal atresia
- Gastric obstruction
- Hypertrophic pyloric stenosis
- Duodenal obstruction
- Volvulus
- Jejunioileal atresia
- Intussusception
- Meconium ileus
- Meconium plug
- Congenital aganglionosis
- Obstipation of prematurity
- Incarcerated inguinal hernia
- Imperforate anus

SIGNS AND SYMPTOMS

- The symptoms and signs of a GIO (see table Clinical Findings for Pediatric Gastrointestinal Obstruction) vary but involve the following, either singly or in combination:
 - Vomiting (often bilious)
 - Abdominal pain
 - Abdominal distention
 - Change in bowel habits
 - Fever
 - Abdominal tenderness
 - Palpable abdominal mass

DIFFERENTIAL DIAGNOSIS

Vomiting

- Vomiting usually is *not* caused by GIO.
- Diseases in neonates or infants associated with nonbilious, nonprojectile vomiting include:
 - Gastroesophageal reflux (chalazia) or regurgitation in an infant
 - Benign and self-limited
 - Can be ruled out by 24-hour pH probe study or a nuclear medicine milk reflux scan

- Esophageal obstruction (atresia)
 - Neonate may have copious, frothy bubbles of mucus that cause rattling respirations, coughing, choking, and cyanosis.
 - Respiratory distress caused by tracheal aspiration of saliva retained in the upper esophagus or aspiration through the commonly associated tracheoesophageal fistula proximal or distal to the atresia can be associated with this anomaly.
 - Denoted by esophageal block encountered during attempts to pass an 8- or 10-French transoral soft catheter approximately 17 cm into the stomach
 - With pediatric gastric volvulus, 1 of the 2 most likely neonatal conditions in which a congenital or early-acquired esophageal obstruction is likely to be encountered
- Acute gastric volvulus
 - Often accompanied by severe pain, unlike esophageal atresia
 - Can be associated with signs of shock, chest pain, dysphagia, dyspepsia, and acute respiratory distress
- Complete or incomplete gastric antral web
 - Diagnosis often delayed, made in late infancy
 - Associated with failure to thrive
- Diseases associated with projectile, nonbilious vomiting of early infancy include:
 - Congenital hypertrophic pyloric stenosis
 - Semiurgent medical condition of dehydration and electrolyte disturbances
 - Typically a hyponatremic, hypochloremic, hypokalemic contraction metabolic alkalosis with a possible late paradoxical aciduria
 - Suspected hypertrophic pyloric stenosis in infants
 - Usually does not require an upper GI series to confirm
 - Classic symptoms of upper abdominal peristaltic waves and palpable, olive-sized mass in the mid- to right upper quadrant are diagnostic.
 - Experienced pediatrician or surgeon will be able to palpate the mass in approximately 80–90% of affected patients.
 - Diagnosis may be aided by physical findings of hypoplastic inferior labial frenulum or an abnormal mucosal reflectance of the oral mucosa.
 - Abdominal ultrasound can aid diagnosis where pyloric stenosis is suspected but not palpable.
 - Radiographic confirmation is unnecessary, costly, and potentially hazardous.
- Bilious vomiting in infants, usually nonprojectile, is more ominous and denotes GIO below the level of the ampulla of Vater.
 - Possible intestinal malrotation with a complicating midgut volvulus

Clinical Findings for Pediatric Gastrointestinal Obstruction

Cause	Findings						
	Vomiting	Pain	Stool Pattern	Distention	Bowel Sounds	Tenderness	Masses
Esophageal atresia	Nonbilious (saliva)	No	Normal meconium	No	Absent to normal	No	No
Gastric obstruction	Nonbilious (curdled formula)	Severe with gastric volvulus; none with antral web	Normal meconium	Epigastric	Absent to normal	Severe with volvulus	No
Hypertrophic pyloric stenosis	Nonbilious, projectile	No	Constipation (dehydration)	Epigastric	Hyperactive (epigastric)	No	Yes (olive-sized mass)
Duodenal obstruction	Bilious	Minimal	Small meconium stool	Epigastric	Absent to normal	No	No
Volvulus	Bilious	Severe	Hematochezia	Epigastric to generalized	Hyperactive	Yes (severe)	No
Jejunioileal atresia	Bilious	No	Small, hard, light-colored meconium stool	Generalized	Variable	No	No
Intussusception	Bilious	Yes (crampy)	Currant jelly stool	Generalized	Hyperactive	Yes	Yes (sausage shaped)
Meconium ileus	Bilious	No	Obstipation	Generalized	Variable	No	Yes (doughy beads)
Meconium plug	Bilious	No	Obstipation	Generalized	Variable	No	No
Congenital aganglionosis	Bilious	No	Obstipation, constipation, and intermittent diarrhea	Generalized	Hyperactive	No	Palpable stool
Obstipation of prematurity	Bilious	No	Obstipation	Generalized	Hyperactive	No	No
Incarcerated inguinal hernia	Bilious	Yes	Diarrhea or constipation	Generalized	Hyperactive	Yes	Inguinal or scrotal
Imperforate anus	Bilious	No	Obstipation	Generalized	Hyperactive	No	No

G

- Can produce GIO with ischemia and subsequent bowel necrosis within a few hours
- Requires immediate radiologic examination for diagnosis
- Premature infant who has an immature pyloric sphincter can have bilious regurgitation without obstruction, especially when it is associated with an ileus related to an underlying septic process.
- Clinical signs of peritonitis preclude radiologic study for diagnosis
- Immediate exploratory laparotomy is necessary.
- Upper gastrointestinal (GI) radiographic series is the diagnostic study of choice in less severely ill neonates, although diagnosis may be made by ultrasound.
- Other causes of bilious vomiting in the neonate and infant include:
 - Duodenal, jejunal, and ileal atresias
 - Duodenal stenosis caused by an annular pancreas or Ladd bands (colonic peritoneal bands crossing the duodenum) associated with malrotation

- Meconium ileus
- Colonic atresia
- Congenital aganglionosis of the colon (Hirschsprung disease)
- Imperforate anus
- Infant or older toddler who has bilious vomiting can have a GIO produced by:
 - Incarcerated hernia
 - Intussusception
 - Previously unrecognized malrotation with associated volvulus
- Bilious vomiting in an adolescent can be caused by:
 - Incarcerated hernia
 - Postoperative adhesion
 - Meconium ileus equivalent associated with cystic fibrosis
 - Acute inflammation (appendicitis and pelvic inflammatory disease)
 - Chronic inflammation (regional ileitis or ulcerative colitis)
 - At this age, malrotation is less likely.
- In less developed countries, obstruction may be caused by:
 - Masses of worms, especially *Ascaris lumbricoides*
 - Tuberculosis
- A significant number of all patients with persistent bilious emesis will have an underlying pathological abnormality requiring early diagnosis and definitive surgical treatment.
- Hematemesis
 - Small amounts of blood may be observed in the vomitus of infants who have congenital hypertrophic pyloric stenosis, caused by gastric irritation as a result of repeated emesis.
 - In rare cases, hematemesis with larger amounts of blood is associated with GIO:
 - Acute peptic ulcer resulting in obstruction in a newborn (uncommon)
 - In an older, chronically stressed infant or child (more common)
 - *Helicobacter pylori* is a potential cause of peptic ulcer disease in children, more so in developing countries.

Abdominal pain

- Abdominal pain, which may cause inconsolable crying or irritability in an infant, usually accompanies GIO.
 - Intussusception
 - The pain is likely to be crampy or intermittent.
 - Results in crying and flexion of the legs to the abdomen, interspersed with periods of decreased distress
 - In ~10% of children who have intussusception, lethargy is the only symptom.

- Complete or partial obstruction of the intestine
 - Produces acute intermittent abdominal pain, which becomes constant in a matter of hours
 - Caused by intestinal distention, peritoneal inflammation, or both
 - Bowel wall edema ensues, increasing the degree of obstruction and causing a progression of changes that place the intussuscepted intestine at further risk for ischemic damage.
- Malignancies in the intestinal tract are rare and usually do not produce intestinal obstruction.
 - Intestinal or mesenteric lymphomas may cause GIO in patients >4 years.
 - Commonly present as intussusception
 - An immunocompromised child who has a malignancy or AIDS may develop primary or secondary inflammatory lesions that lead to obstruction.

Stools

- Obstipation in a newborn
 - Delay of initial bowel movement in:
 - Premature infants
 - Infants who are small for gestational age
 - Infants of mothers with diabetes
 - Infants with mothers with problems of substance abuse (narcotics such as morphine)
 - Infants with complications of maternal drug therapy (eg, magnesium sulfate for toxemia)
 - Neonatal stress (hypoxemia or sepsis)
 - Atresias of the proximal portion of the intestinal tract usually do not cause obstipation, except for those involving the most distal terminal ileum.
 - However, meconium passed by these infants usually is sparse and lighter in color, and may be hard and dry.
- The differential diagnosis of newborn obstipation includes:
 - Congenital aganglionosis of the colon
 - Meconium ileus (with underlying cystic fibrosis)
 - Meconium plug syndrome (30% of these are associated with congenital aganglionosis of the colon or cystic fibrosis)
 - Small left colon syndrome
 - Colonic atresia
 - Imperforate anus
 - Rectal atresia (rare)
- Strictures produce obstipation or constipation in an older infant or child and may result from:
 - Neonatal necrotizing enterocolitis
 - Intestinal surgery

- Extrinsic compression of the GI tract caused by:
 - Congenital cysts
 - Intestinal duplication
 - Inflammatory masses
 - Malignancies
 - Particularly in neonates and infants, diarrhea or alternating diarrhea and constipation can be a sign of:
 - Functional GIO
 - Partial or intermittent GIO
 - Congenital colonic aganglionosis
 - Intussusception (frequently seen with hematochezia or melena)
 - Intermittent volvulus (frequently seen with hematochezia or melena)
 - Hematochezia, or grossly bloody stools, in association with GIO symptoms, indicates intestinal vascular compromise.
 - Most common in patients who have an intussusception or volvulus
 - So-called currant jelly stools of intussusception that result from the admixture of blood and mucus, or darker (mahogany to black), melena-type stools from a more proximal intestinal bleeding site
 - A sign of superficial mucosal sloughing
 - Also accompany full-thickness necrosis of the bowel wall
 - In infants without grossly bloody stools, occult blood is present in up to 75% of cases of intussusception.
 - Hemocult test should be performed in all infants with altered mental status.
- ### DIAGNOSTIC APPROACH
- The infant with a history of vomiting must be evaluated for signs of dehydration by examining:
 - Anterior fontanelle
 - Rate and intensity of distal pulses
 - Level of consciousness
 - Perfusion of the extremities
 - Condition of the mucous membranes
 - Abdominal auscultation should be performed before any other aspect of abdominal examination.
 - Listen to all the abdominal quadrants.
 - High-pitched, *tinkling* bowel sounds heard in rushes are diagnostic of a complete GIO.
 - Bowel sounds often are normal early, and become diminished or absent late in obstruction.
 - When GIO is suspected, physical examination of the abdomen includes:
 - Evaluation for distention (see table Clinical Findings for Pediatric Gastrointestinal Obstruction)
 - Likely to be prominent if obstruction is distal to the duodenum
 - Mild to moderate epigastric distention seen with obstruction caused by:
 - Antral web
 - Hypertrophic pyloric stenosis
 - Duodenal atresia that produces only mild to moderate epigastric distention
 - Distal intestinal atresia or other forms of lower GIO produce generalized distention.
 - Distention does not aid in the diagnosis of a potential underlying midgut volvulus.
 - Palpation
 - Mild tenderness or discomfort is expected if the abdomen is moderately to grossly distended.
 - Pressure applied to gas- or fluid-filled loops of bowel causes pain.
 - Marked tenderness clearly indicates an accompanying peritoneal inflammation.
 - Peritonitis in the setting of GIO
 - Indicates ischemia of the bowel wall with possible necrosis
 - Demands immediate surgical evaluation and treatment
 - Diagnostic radiologic studies that use contrast material are contraindicated.
 - Multiple doughy, compressible, mobile, nontender abdominal masses in a newborn who has GIO
 - Associated with meconium ileus
 - A tender, palpable, immobile mass most likely is cellulitis or abscess related to visceral perforation caused by:
 - Necrotizing enterocolitis in infants
 - Appendicitis in children or adolescents
 - Inflammatory bowel disease in children and adolescents
 - Nontender, mobile mass that produces GIO symptoms
 - Congenital intestinal duplication cysts
 - Mesenteric cysts
 - Sausage-like mass in the right upper quadrant with absence of bowel in the right lower quadrant
 - Pathognomonic of intussusception
 - Called the *Dance sign*
 - Rectal examination often can clarify the cause of GIO.
 - In infant suspected of having an incarcerated inguinal hernia:
 - Palpate the peritoneal side of the internal inguinal ring transanally and identify an exiting intraperitoneal structure.

- Diagnosis of any suspected colonic or distal GIO
 - Previously unsuspected perirectal or presacral pelvic masses (eg, hydrometrocolpos, appendiceal inflammatory mass, presacral teratoma)
- Abnormal stool (as in the patient who has meconium plug syndrome) or blood (associated with intussusception or inflammatory bowel disease)
- Rarely, intraluminal rectal mass, such as with a low-lying intussusception

LABORATORY FINDINGS

- To ensure readiness of patients for surgery
 - Urinalysis, with catheterization if necessary
 - Complete blood count
 - Blood chemistry studies

IMAGING

- Studies are dictated by the results of the history and physical examination.
- See the table Roentgenographic Findings for Common Causes of Gastrointestinal Obstruction for radiographic diagnostic studies required for a patient who has GIO.

Plain-film radiograph studies

- A plain-film radiograph of the abdomen should be obtained for all patients suspected of having GIO.
 - Presence of even a large number of air-filled loops does not eliminate the need for a contrast study.
 - In a patient with volvulus, contrast study may show a corkscrew appearance projecting forward, away from the posterior abdominal wall.
- Chest radiography can demonstrate the curling of a nasogastric tube or dilated pouch in esophageal atresia.
- In a newborn infant, air localized to the stomach and duodenum (double-bubble sign) is diagnostic of a duodenal obstruction.
 - If no distal intestinal intraluminal air is seen, then GIO usually is caused by an atresia.
 - If even a small amount of air is found distally, then malrotation with possible volvulus must be suspected.
- Calcifications visualized by an abdominal radiograph in a neonate with suspected GIO
 - Evidence of an intrauterine intestinal perforation (meconium peritonitis), which often is associated with intestinal atresia
 - Calcifications may:
 - Be small, single, or multiple
 - Be scattered throughout the entire peritoneal cavity
 - Outline the peritoneal cavity
 - Cystic fibrosis may be the underlying disease.

- Abdominal radiograph of GIO in association with suspected cystic fibrosis (meconium ileus)
 - Gas may be absent in the right iliac fossa because of a meconium cyst.
 - Peculiar hazy pattern described as a *ground glass* or *soap bubble* appearance
 - The pattern is caused by abnormal meconium mixed with air that is inspissated in the bowel lumen.
 - Occasionally, this hard, dense meconium, palpable as multiple abdominal masses, appears on a radiograph as a chain of radiolucencies, known as the *string of beads* sign.
 - Air-fluid levels are rare in meconium ileus.
- Blunt injury to the abdomen, either accidental or intentional, can result in early obstruction from bowel wall edema and from a hematoma in the infant or toddler.
 - A full-thickness bowel wall injury often produces late sequelae such as an intestinal leak with initially normal or equivocal examination resulting in delay in diagnosis.
 - Diagnosis requires a high index of suspicion and, often, thorough and repeated radiologic evaluations.

Upper GI and barium enema

- Use of an upper GI series or a barium enema is necessary to rule out a malrotation or nonrotation of the intestine.
 - Upper GI series can determine the relationship among the duodenum, the jejunum, and the ligament of Treitz.
 - Barium enema can ascertain cecal position.
 - Barium enema of an *unused*, small-caliber distal colon (microcolon) in a normal position makes diagnosis of intestinal atresia or meconium ileus more likely than acute volvulus.
- Meconium ileus and meconium plug syndrome are neonatal GIO conditions that can be diagnosed and frequently can be treated with a water-soluble contrast enema.
 - Procedure is appropriate in a neonate suspected of having meconium ileus, but no evidence of perforation, and who is well hydrated.
 - Inspissated meconium is localized to the distal ileum, and may be freed from the bowel wall for spontaneous expulsion.
 - Technique is limited in application and duration, with subsequent surgical therapy required in as many as 50%.
- Uncomplicated meconium plug syndrome, infrequently associated with cystic fibrosis but occasionally associated with congenital aganglionosis, also is diagnosed and treated successfully with a barium enema.
 - Unlike meconium ileus, the meconium in meconium plug is localized to the distal colon.
 - Contrast enema is contraindicated when there is
 - Evidence of intestinal vascular compromise
 - Evidence of perforation, such as peritonitis, free intraperitoneal air, or intraperitoneal calcification

Roentgenographic Findings for Common Causes of Pediatric Gastrointestinal Obstruction

Cause	Finding				
	Dilated Area	Air or Fluid Levels	Calcium Deposits	Noncalcium Opacities	Further Studies That May Be Indicated
Esophageal atresia	Esophagus and stomach	Yes (gastric)	No	No	Esophageal air instillation
Gastric obstruction	Stomach	Yes	No	No	Gastric barium instillation ^a
Hypertrophic pyloric stenosis	Stomach	Yes	No	No	Ultrasonography
Duodenal obstruction	Stomach, duodenum (double bubble)	Yes	No	No	None
Volvulus	Variable	Variable	No	No	Upper gastrointestinal series or barium enema
Jejunioileal atresia	Stomach and small intestine	Yes	Yes (with prenatal perforation)	No	Barium enema to rule out nonrotation
Intussusception	Stomach and small intestine	Variable	No	Yes (soft-tissue densities)	Ultrasonography, barium/air enema ^b , or both
Meconium ileus	Stomach and small intestine	No	Yes (meconium peritonitis)	Yes (ground-glass appearance)	Water-soluble contrast enema ^c
Meconium plug	Stomach to colon	Yes	No	No	Water-soluble contrast enema
Congenital aganglionosis	Stomach to colon	Yes	No	No	Barium enema
Obstipation of prematurity (short left colon syndrome)	Stomach to colon	Yes	No	No	Barium enema
Incarcerated inguinal hernia	Stomach and small intestine	Yes	No	No	None
Imperforate anus	Stomach to colon	Yes	No	No	Complete evaluation of genitourinary tract

^a Should be performed cautiously to avoid aspiration.

^b Should be performed cautiously to avoid bowel perforation.

^c May be therapeutic and diagnostic.

■ Colonic dysfunction of prematurity, or *small left colon syndrome* (SLCS)

- Produces a functional mechanical obstruction
- Related to:
 - Extreme prematurity
 - Maternal diabetes
 - Prenatal maternal medications for eclampsia (magnesium sulfate)
 - Hypothyroidism
 - Maternal narcotic use

- A diagnosis of exclusion, because its barium contrast appearance resembles Hirschsprung disease.

■ Older infants and toddlers suspected of having GIO produced by intussusception can be diagnosed and often treated successfully with a barium enema.

- The study is performed with a limited pressure (3 feet) barium column.
- Intussusception is slowly reduced by the hydrostatic pressure.
- Because of the potential hazard of a barium perforation, the study should always be performed by an experienced radiologist with a surgical team standing by.

- Procedure can be used in approximately 75% of patients, with successful reduction of the intussusception in 85% to 90%.
- Surgical reduction is required in cases that cannot be reduced radiologically.
- The patient always should be observed for 12–24 hours in the hospital after successful intussusception reduction.
- Air enema reduction of the intussusception recently has become available.
 - Air insufflation of the rectum and colon using an in-line pressure-limiting valve while maintaining fluoroscopic or sonographic observation
 - Advantages of this technique
 - Elimination of barium and threat of severe chemical peritonitis if perforation inadvertently occurs
 - Possibly an improved mechanical advantage by using air reduction

Ultrasound

- May provide prenatal diagnosis of GIO
 - In up to 40% of cases, GIO may be suggested by findings such as:
 - Polyhydramnios, inability to identify the stomach
 - Cystic abdominal lesions
 - Dilated loops of bowel
- Prenatal diagnosis of GIO (eg, atresia, volvulus) eliminates the need for emergent postnatal workup.
- Color Doppler ultrasound
 - May show a distorted relationship of the superior mesenteric vessels in a patient with volvulus
- Duplication cysts can occur anywhere in the GI tract but are most common in the ileum, followed by the stomach.
 - Ultrasound is the most useful imaging modality to diagnose enteric duplication cysts.
 - *Rim sign* refers to an echogenic inner rim of mucosa and hypoechoic outer rim of the muscle layer.
 - Peristalsis of the cyst wall and septations aid in diagnosis.
- In meconium peritonitis, sonography may show ascites with echogenic debris, abnormal cystic masses, and thickening and dilatation of the bowel wall.
- Diagnosis of suspected intussusception can be made effectively by ultrasound or CT.
 - Both tests are useful in a patient whose examination is unremarkable and whose history is equivocal.

DIAGNOSTIC PROCEDURES

- Hypertrophic pyloric stenosis
 - Barium study of the upper GI tract may show normal duodenal bulb with a proximal antral chamber between the web and the pylorus, known as the *double duodenal bulb appearance*.

- Esophagogastroduodenoscopy may help identify and potentially divide the web.
- If the web cannot be treated safely during endoscopy, then open gastric antroplasty is effective.

■ Hirschsprung disease

- Initial diagnosis is made based on clinical suspicion because it cannot be verified by noninvasive diagnostic procedures.
 - Barium enema or anorectal manometry reflecting an absent rectosphincteric reflex often is helpful in diagnosis of older children.
 - Either a rectal mucosal or full-thickness rectal wall biopsy specimen is required to confirm the diagnosis in infants.

TREATMENT APPROACH

- Gastric decompression to prevent continued bowel distention, vomiting, and possibly aspiration
- Intravenous fluid therapy
 - Required immediately to replace intraluminal and intraperitoneal fluid loss
 - Luminal losses are high in electrolyte content, requiring administration of higher-than-maintenance concentrations of sodium, chloride, and potassium.
 - Solutions such as lactated Ringer's solution are needed to provide appropriate replacement.
- Emergent or semi-urgent surgery
 - Required by almost all children with GIO
 - The child must be well prepared for anesthesia and the surgical procedure.
 - This requires correcting fluid and electrolyte, hematologic, and metabolic imbalances before surgery.
 - Such measures should begin before extensive diagnostic imaging studies are undertaken.
- Nonsurgical therapy for failure to pass meconium caused by
 - Hypothyroidism
 - Hypercalcemia
 - Hypokalemia
 - Sepsis
 - Congestive heart failure

SPECIFIC TREATMENTS

- The type of surgical procedure performed and the patient's postoperative course and prognosis depend on the type of lesion causing GIO.

Incarcerated inguinal hernia

- Important cause of GIO in children and adolescents
 - Reduction can be accomplished by
 - Sedation with a tranquilizer, with or without an added narcotic analgesic

- Keeping the patient supine in mild Trendelenburg position
- Applying an ice pack to the inguinal region
- Medications must be used cautiously to prevent excessive sedation, because vomiting and aspiration can occur.
- Should be reduced gently and repaired later, after GIO and local edema have subsided
- If reduced but left unrepaired, recurrent incarcerations are likely, with potential strangulation and necrosis of the bowel.

Colonic dysfunction of prematurity/ small left colon syndrome (SLCS)

- Surgically, a temporary colostomy is indicated only by
 - Failure to respond to careful, small-volume, saline enema therapy
 - Signs of peritonitis or intestinal perforation
- Prognosis for uncomplicated cases is excellent.

Esophageal obstruction

- Esophageal atresia with associated tracheoesophageal fistula
 - A relative emergency that requires either
 - Primary repair, *or*
 - Staged procedure with initial gastrostomy for gastric decompression and prevention of aspiration
 - Subsequent definitive repair, including division of the fistula and anastomosis of the esophageal ends, after treatment of existing underlying pneumonic process
 - Gastrostomy and definitive repair occasionally are performed simultaneously.
 - Esophageal repair is performed without gastrostomy in selected patients.
 - Complications of definitive procedure include esophageal leaks, infection, and strictures.
 - As many as 50% of cases have associated anomalies:
 - Cardiovascular system
 - Imperforate anus
 - Duodenal atresia
 - Intestinal malrotation
 - In uncomplicated atresia and tracheoesophageal fistula, morbidity is low and mortality is negligible.
 - Associated cardiovascular anomalies and low birth weight lead to a mortality rate as high as 70%.
 - Late complications of atresia and tracheoesophageal fistula include congenital hypertrophic pyloric stenosis and chronic gastroesophageal reflux with reactive airway symptoms.

Gastric obstructions

- Gastric volvulus
 - Usually an acute problem
 - Requires

- Immediate surgical gastropexy to prevent ischemia and necrosis
- Temporary gastrostomy tube for fixation and decompression
- If no gastric necrosis is found, then recovery usually is uneventful.
- Gastric necrosis with resulting peritonitis results in high morbidity and mortality.
- Gastric antral web
 - Difficult to diagnose and often requires repeated diagnostic studies, but is not a critical problem
 - Surgical therapy consists of simple incision of the web and performance of a modified pyloroplasty.
 - Few postoperative complications
- Hypertrophic pyloric stenosis
 - Surgical therapy after adequate correction of associated, potentially life-threatening dehydration and hypochloremic alkalosis
 - Procedure is a muscle-splitting pyloromyotomy, leaving the mucosa intact.
 - Can be performed laparoscopically or through a right upper quadrant or supraumbilical incision with similar operative times, complications, and costs
 - Acute complications are unusual.
 - Patient without sequelae resumes postoperative feedings within 8–24 hr, sometimes as early as in the recovery room.
 - Chronic complications such as stricture related to intra-operative mucosal perforations and adhesions are rare.

Duodenal obstructions

- Duodenal atresia, stenosis, and annular pancreas
 - Semiurgent problems, as long as they are not accompanied by volvulus
 - Volvulus demands immediate abdominal exploration.
 - Surgical therapy consists of bypassing obstructed area via
 - Duodenoduodenostomy
 - Duodenojejunostomy
 - Gastrojejunostomy
 - Moderate feeding problems necessitating longer hospitalization may be encountered, particularly with gastrojejunostomy.
 - Prognosis is good.
 - With associated congenital cardiac problems, mortality can be as high as 50%.
- As many as 10% of cases of duodenal atresia are associated with Down syndrome (trisomy 21).
- Growth and development of patients who have uncomplicated and isolated duodenal obstructions are normal.

- Duodenal and other intestinal duplication cysts are completely excised if possible.

- At the least, mucosal lining should be excised, since cysts are associated with a late malignant transformation.

Jejunal and ileal obstructions

- Jejunal and ileal atresia

- Semiurgent, unless associated with a volvulus
- Surgical treatment involves:
 - Excision of the atretic bowel
 - Primary anastomosis of the dilated proximal and the narrowed distal segments
 - When multiple atretic segments of bowel, or small-bowel atresias associated with absence of the superior mesenteric artery, are present, overall intestinal length (absorptive surface) may be greatly reduced.
- Total parenteral nutrition commonly is required after surgery.
- Overall survival and prognosis are good, unless the atresia is complicated by:
 - Cystic fibrosis
 - Remaining small intestine that is too short for adequate absorption

- Malrotation with a complicating volvulus

- The most critical diagnosis in any child suspected of having GIO
- Twisted bowel mesentery may lead to ischemia and bowel necrosis within 4–6 hr after the onset of symptoms.
- Untreated volvulus has a high acute mortality rate because of associated metabolic imbalance and sepsis.
- Successful surgical resection of the involved necrotic bowel is associated with high long-term morbidity.
- Entire embryonically derived midgut may have to be resected, leading to
 - Reduced intestinal absorption of nutrients
 - Short-gut syndrome

- Early diagnosis, rapid correction of fluid and electrolyte imbalances, and surgical reduction of mesenteric torsion with or without resection of potentially necrotic bowel are imperative.

- Proximal and distal segments of involved intestine that appear ischemic but may be viable should be retained.

- Creation of abdominal enterostomas in lieu of extensive initial intestinal resection
- Second-look operation performed in 24 hours

- Postoperative complications include:

- Marked fluid and electrolyte disturbances
- Local and systemic infections
- Malnutrition

- Long-term parenteral nutrition, dietary adjustments, and repeated surgical procedures should be expected.

- Survival with reasonable quality of life can be expected if remaining viable small bowel is ≥ 30 cm.

- Morbidity is lessened when ileocecal valve remains intact.

- Long-term hospitalization and prolonged nutritional support with total parenteral nutrition usually are required.

- Meconium ileus may respond to water-soluble contrast enemas (see Imaging).

- Evidence of accompanying intestinal perforation or failure of carefully managed water-soluble contrast enema necessitates surgical therapy.
- Cystic fibrosis, almost always an underlying disease, complicates postoperative respiratory and nutritional status.
- Administration of solutions such as N-acetyl-cysteine by means of an enterotomy usually cleanses the intestinal lumen.
- Associated atretic or necrotic intestinal segments are excised.
- Primary anastomoses are performed.
- Enterostomas are created for:
 - Postoperative lavage of massively impacted meconium
 - Instances in which viability of the remaining bowel segments is in question.
- A stoma may be needed to protect an anastomosis.
- A transabdominal T tube may be left intraluminally to allow decompression and irrigation.
- Appendix may be used as a conduit.

- Surgical survival is good.

- Morbidity is high; ultimate prognosis is related to severity of other manifestations of cystic fibrosis.

Colonic and rectal obstruction

- Intussusception that is uncomplicated by a lead point, eg, Meckel diverticulum, polyp, or malignancy

- Hydrostatic air reduction is successful in up to 90% of appropriately selected patients.
- Recurrences seen in 5–7%.
- Surgical intervention is required if evidence of compromised bowel is found, eg, in free perforation or peritoneal irritation, and in failures of air-hydrostatic reduction.
 - Successful reduction requires retrograde reflux of contrast media or air into the terminal ileum.
 - Most intussusceptions that are reduced intraoperatively do well postoperatively, with a low (2–5%) recurrence rate.
 - Bowel resection is required when:
 - Intraoperatively recognized pathological lead point is present
 - Ischemic complication is found

- Early diagnosis and treatment of intussusception reduces morbidity and mortality.
- Rectal atresia and imperforate anus require diagnosis, initial therapy, and colostomy within 24 hr.
 - Very low perineal lesions (anterior displaced anus and fourchette fistula) can be treated with initial dilatations only.
 - Definitive therapy is a pull-through procedure and anoplasty.
 - Performed when the infant is 2–3 months of age
 - If lesion is not associated with other congenital anomalies, then survival is good.
 - Clinician should look for other anomalies, particularly those of the genitourinary tract (rectovaginal and rectovesicular fistulas, lower urinary tract obstructions with megacystis, hydroureter, and hydronephrosis).
 - Future stool continence is related directly to severity of the deformity, which is influenced by degree of normal embryologic descent of the colon through the levator muscle.
 - Definitive surgery for high lesions, in which colon descent is limited to a position above the levator muscle, results in daytime stool continence in ~60% of patients.
 - Overall continence rate for high lesions is 10–20%.
 - Repair of low lesions, in which the colon has descended below levator muscle, results in continence rate of at least 80–90%.
- Congenital aganglionosis of the colon (Hirschsprung disease)
 - Colostomy using a segment of proximal ganglionic colon
 - 6 months to 1 year later, excision of affected aganglionic segment and anastomosis of normally innervated (ganglionic) bowel to the anus (the pull-through procedure).
 - Many patients respond preoperatively to regular rectal stimulation and irrigations to evacuate the colon.
 - This measure allows performance of a primary pull-through procedure during the immediate newborn period and up to several months of age and avoidance of a colostomy.
 - Infant morbidity and mortality rates are high when the disease is complicated by enterocolitis; however, patients who have no such complications usually do well, with good anal continence, growth, and development.

Minimally invasive surgery

- Many procedures can be performed laparoscopically:
 - Pyloromyotomy
 - Fundoplication
 - Endorectal pull-throughs
- Obstructions caused by the following processes can be successfully treated with minimally invasive laparoscopic techniques:
 - Adhesions
 - Inflammation (inflammatory bowel disease, appendicitis, and Meckel diverticulitis)
 - Intussusception
- Procedures such as pyloromyotomy may be performed with a modified open technique, with less expensive and equally acceptable cosmetic results.
- Use of the minimally invasive technique for the Ladd procedure may be less effective than original open procedure.
- As smaller-size instrumentation improves and surgeons gain more experience, the list of procedures that can be performed laparoscopically continues to grow.

Fetal surgery

- Due to the risk to the mother from invasive procedures, in utero treatment or newly developed endoscopic fetal procedures must be considered only when death of the fetus or newborn is certain without such intervention.
- Open or endoscopic fetal surgery is accepted for:
 - Congenital cystic adenomatoid malformation
 - Fetal sacrococcygeal teratoma
 - Congenital diaphragmatic hernia
 - Obstructive uropathy
- None of the prenatal GIO diagnoses or their causes pose an immediate threat to the fetus or the mother.
 - Overall combined mortality rate is <5%.
 - Benefits to the baby do not outweigh the risk to the mother; therefore, these lesions are not appropriate for prenatal interventional therapy.

WHEN TO ADMIT

- All cases of intestinal obstruction

WHEN TO REFER

- All patients with suspected and confirmed intestinal obstruction should be referred to pediatric surgery.

COMPLICATIONS

- Decreased blood supply to the intestines may occur in patients with conditions such as volvulus.
 - Delayed diagnosis of this compromise in blood supply may lead to necrosis of the intestines and intestinal perforation, resulting in peritonitis, sepsis, and severe metabolic derangements.
- Problems related to malabsorption, if large portion of small intestine has been resected.

PROGNOSIS

- Prognosis depends on the underlying condition, rapidity in diagnosis, and surgical intervention.
 - Hypertrophic pyloric stenosis has excellent prognosis as compared to small gut volvulus.

Genetic Metabolic Disease Recognition

DEFINITION

- Prompt diagnosis of genetic disease is important.
 - Therapeutic interventions are available for some conditions; early therapy may improve outcomes.
 - Genetic counseling informs parents about recurrence risk and reproductive options.
- >300 diseases caused by inborn errors of metabolism have been identified.
- The primary care physician can expect to see several patients who have these disorders.
 - Often the first clinician to evaluate
 - Familiarity with clinical presentations and knowledge of initial laboratory evaluation are important.
 - Formal diagnosis and treatment is usually done in consultation with a specialist.
- Disease is detected:
 - By population-wide screening of newborns
 - By testing following clinical manifestation of disease
- With advances in understanding cellular processes, some defects can now be recognized.
 - Transport proteins
 - Membrane proteins
 - Organelle assembly
 - Intracellular processing and trafficking
 - Other biological processes that result in biochemical disturbances with clinical expression

EPIDEMIOLOGY

- Prevalence
 - Inborn errors of metabolism individually are rare.
 - Collective incidence is approximately 1 in 1000 live births.
 - Metabolic disease will be origin of symptoms in:
 - ~1 in 5 sick, full-term newborns who have no risk factors for infection
 - 1 in 100 children who have a serious medical problem

MECHANISM

Classification of genetic metabolic disorders

- Many of the clinical examples provided below refer to groups of disorders and do not distinguish specific enzymatic defects.
- All disorders listed below are autosomal-recessive unless otherwise noted.
- Diagnostic suspicion of a metabolic disorder does not require comprehensive knowledge of the various biochemical pathways involved.
 - Typical clinical presentations, specific historical clues, and pertinent findings on clinical examination should lead to their consideration.

- Some laboratory tests routinely obtained in ill children can help determine the presence of metabolic disease.

Metabolites

- Amino acids
 - Amino acid catabolism
 - Phenylketonuria
 - Homocystinuria
 - Tyrosinemia type 1
 - Maple syrup urine disease (MSUD)
 - Nonketotic hyperglycinemia
- Urea cycle disorders
 - Ornithine transcarbamylase deficiency (X-linked)
 - Citrullinemia
 - Arginosuccinic aciduria
 - Carbamoylphosphate synthase deficiency
- Amino acid transport
 - Lysinuric protein intolerance
 - Cystinuria hyperornithinemia-hyperammonemia-homocitrullinuria syndrome
- Synthesis of creatine and neurotransmitters
 - Creatine deficiency disorders
 - Disorders of γ -aminobutyric acid metabolism and monoamine synthesis
- Organic acids
 - Organic acid metabolism
 - Propionic acidemia
 - Methylmalonic acidemia
 - Isovaleric acidemia
 - Glutaric acidemia type 1
 - Holocarboxylase synthetase deficiency
- Fatty acids
 - Fatty acid oxidation
 - Short-chain, medium-chain, and very long-chain acyl-coenzyme A (CoA) dehydrogenase deficiency
 - Long-chain 3-hydroxyacyl-CoA hydrogenase deficiency
 - Carnitine uptake defect
 - Carnitine palmitoyl transferase (CPT) deficiencies (CPT 1 and CPT 2)
 - Cholesterol synthesis
 - Mevalonic acidemia
 - Smith-Lemli-Opitz syndrome
 - Conradi-Hünemann-Happle syndrome (X-linked)
- Carbohydrates
 - Carbohydrate intolerances
 - Galactosemia
 - Hereditary fructose intolerance

- Glycogen breakdown (glycogen storage disorders [GSDs])
 - Hepatic forms
 - Glucose-6-phosphatase deficiency (GSD 1)
 - Debrancher enzyme deficiency (GSD 3)
 - Muscle form
 - Muscle glycogen phosphorylase deficiency (GSD 5)
 - Lysosomal form
 - Pompe disease (GSD 2)
- Glucose catabolism (glycolysis) and synthesis (gluconeogenesis)
 - Pyruvate dehydrogenase deficiency
 - Pyruvate carboxylase deficiency
 - Fructose diphosphatase deficiency
- Vitamins, minerals, and cofactors
 - Activation, transport, recycling
 - Biotinidase deficiency
 - Molybdenum cofactor deficiency
 - Biopterin, cobalamin, and copper disorders

Organelles

- Peroxisome
 - Peroxisome biogenesis
 - Zellweger syndrome
 - Neonatal adrenoleukodystrophy
 - Infantile Refsum disease
 - Rhizomelic chondrodysplasia punctata
 - Single peroxisome enzyme or protein deficiencies
 - X-linked adrenoleukodystrophy
 - Adult Refsum disease
 - Hyperoxaluria type 1
- Lysosome
 - Lysosomal storage disorders
 - Mucopolysaccharidoses (MPSs)
 - Hurler-Scheie syndrome (MPS 1)
 - Hunter syndrome (MPS 2, X-linked)
 - Sanfilippo syndrome (MPS 3A-D)
 - Sphingolipidoses
 - Tay-Sachs disease
 - Krabbe disease
 - Metachromatic leukodystrophy
 - Niemann-Pick, Gaucher, Fabry diseases (X-linked)
 - Lysosomal enzyme transport
 - Mucopolipidoses (MLs)
 - I-cell disease (ML 2, ML 3)

- Cystinosis
- Sialic acid storage disease
- Mitochondria
 - Respiratory chain complexes
 - Leigh syndrome
 - Multiple acyl-CoA dehydrogenase deficiency (glutaric acidemia type 2)
 - Mitochondrial encephalomyopathy, lactic acidosis, and stroke syndrome; mitochondrial encephalomyopathy and ragged red fibers; neuropathy, ataxia, and retinitis pigmentosa (mitochondrial DNA-encoded defects)
 - Endoplasmic reticulum, Golgi
 - Intracellular protein processing and trafficking
 - Glycosylation
 - Congenital disorders of glycosylation

HISTORY

Dietary history

- High protein intake precipitates such symptoms as vomiting, lethargy, and coma.
 - Disorders in which protein catabolism is defective
 - Amino acid disorders
 - Organic acid disorders
- An infant who vomits but improves on glucose feeding, and in whom vomiting recurs within a few days of reinstatement of milk feeding, might have a metabolic disease.
- History may reveal onset of illness on weaning from breast milk, which has lower protein content than commercial formulas, or association of illness with high-protein meals.
 - Older patients may avoid protein by limiting protein intake.
- Carbohydrate intolerances
 - Fructose (fruit juices) in hereditary fructose intolerance
 - Lactose (human or cow's milk) in galactosemia

Response to infection, fever, and fasting

- History of unusual lethargy during mild illness or intolerance of fasting is an important clue for diagnosing metabolic disease.
- Infections, fever, and fasting result in an overall catabolic state.
 - Under these conditions, disorders involving impaired glucose production and fatty acid catabolism are exacerbated.
 - Endogenous protein catabolism may precipitate expression of amino acid and organic acid disorders.
- GSD may present within first few months of life at the time when the interval between feedings is lengthened.
- Disorders of fatty acid oxidation classically occur during an episode of intercurrent illness with prolonged fasting.

- Immunizations, which may produce mild illness in normal children, can cause metabolic decompensation in children with inborn errors of metabolism.
 - Immunization should not be avoided in these children.
 - Patients with metabolic disorders should be monitored carefully after immunization.
 - Influenza vaccines are recommended yearly.

Adverse reactions to anesthesia and surgery

- General anesthesia, surgery, and other causes of stress to metabolic systems and can precipitate illness in patients with metabolic disease.
 - Patients with homocystinuria are prone to thromboembolism
 - On administration of high-osmolar contrast dyes
 - During surgery
 - Some patients with myopathy are at risk of malignant hyperthermia when halothane is administered.

Family history

- Complete family history for all patients with suspected metabolic disease is essential.
- Most of these disorders are inherited in autosomal-recessive fashion.
 - Factors that increase the likelihood of autosomal-recessive disease
 - Parental consanguinity
 - 2.5-fold increase in risk for autosomal-recessive disorders
 - Consanguinity is practiced in Asia; North Africa; Switzerland; the Middle East; and some parts of China, Japan, Europe, and the United States
 - Intermarriage in the US occurs within some cultural religious groups, including members of the Amish and Latter-Day Saints (Mormon) communities.
 - Similarly affected siblings
 - Early death of a sibling
 - Some autosomal-recessive metabolic disorders are found at higher frequency in certain ethnic groups.
- Consanguinity is less common in the US than in other countries.
 - However, increased immigration from Asia, Africa, and Europe necessitates increased awareness.
 - Negative family history does not exclude the possibility of a metabolic disorder.
- Similarly affected male relatives on maternal side is consistent with X-linked disorders.
- Disorders of mitochondrial genome show an exclusively maternal pattern of inheritance.

PHYSICAL EXAM

- Metabolic disease affects multiple organ systems and produces a variety of physical findings; however, some general themes exist.
 - With disorders that occur along with episodic illness, significant findings may be present or exacerbated only during the acute phase.
 - Neurologic abnormalities and vomiting predominate in episodic presentations.
 - Hepatomegaly, cardiomyopathy, and muscle weakness may also be present, as in disorders of fatty acid oxidation.
 - Tachypnea and hyperpnea are often overlooked as signs of metabolic acidosis or respiratory alkalosis.
 - Other disorders feature characteristic pattern of findings that develop over time.
 - Coarse facial features, corneal clouding, hepatosplenomegaly, macrocephaly, and skeletal changes suggest:
 - MPSs
 - Disorders of glycoprotein degradation
 - MLs
 - A constellation of alopecia, chronic dermatitis, ataxia, and seizures is seen with biotinidase deficiency.
 - Lens dislocation, long extremities, and vascular occlusion caused by thrombosis are found in homocystinuria.
 - Metabolic disease should be suspected when physical examination reveals abnormalities in >1 organ system.
- Pertinent clinical findings in genetic metabolic disorders
 - Neurologic
 - Encephalopathy
 - Stroke-like episode
 - Macrocephaly or microcephaly
 - Developmental delay
 - Ataxia
 - Choreoathetosis
 - Dystonia
 - Peripheral neuropathy
 - Hypotonia or hypertonia
 - Seizures
 - Myoclonus
 - Deafness
 - Brain malformation
 - Cerebral calcification
 - Ophthalmologic
 - Cataracts
 - Lens dislocation
 - Corneal opacity
 - Macular cherry-red spot

- Macular degeneration
- Retinal pigment change
- Optic atrophy
- Respiratory
 - Tachypnea
 - Hyperpnea
- Cardiovascular
 - Cardiomyopathy
 - Pericardial effusion
 - Rhythm disturbance
 - Thrombosis
 - Bleeding diathesis
 - Anemia
- Abdominal
 - Hepatomegaly
 - Cirrhosis
 - Jaundice
 - Splenomegaly
 - Nephrolithiasis
 - Renal Fanconi syndrome
 - Renal cyst
 - Pancreatitis
- Muscular
 - Hypertrophy
 - Myopathy
 - Myalgias
 - Recurrent myoglobinuria
- Skin
 - Eczematous rash
 - Ichthyosis
 - Photosensitivity
 - Angiokeratomas
 - Xanthomas
- Hair
 - Sparse
 - Brittle, dry, coarse
- Skeletal
 - Scoliosis
 - Kyphosis
 - Joint contractures
 - Dysostosis multiplex
 - Epiphyseal calcifications
- Other
 - Dymorphic features
 - Coarse facial features

DIFFERENTIAL DIAGNOSIS

- Many common pediatric illnesses produce similar signs and symptoms.
 - Unfortunately, metabolic disease is often not considered until other disorders are excluded.
 - Diagnostic delay is particularly common for metabolic disorders with nonacute presentation, especially when slow development is the major initial finding.
 - For best outcomes, metabolic disease should be included in the earliest differential diagnoses.

High-risk scenarios for consideration of metabolic disorders

- Acute illness in a previously normal newborn; consider:
 - Aminoacidopathies
 - Organic acidemias
 - Urea cycle defects
 - Galactosemia
- Neonatalseizure disorder; consider:
 - Pyridoxine-dependent seizures
 - Nonketotic hyperglycinemia
 - Sulfite oxidase deficiency
 - Zellweger syndrome
- Recurrent episodes of illness (lethargy, vomiting, ataxia, encephalopathy, stroke-like episodes, myopathy); consider:
 - Aminoacidopathies
 - Organic acidemias
 - Urea cycle defects
 - Defects in fatty acid metabolism
 - Disorders of carbohydrate metabolism
 - Mitochondrial disorders
- Acute life-threatening event; consider:
 - Fatty acid oxidation defects
- Neurologic regression; consider:
 - Lysosomal storage disorders
 - X-linked adrenoleukodystrophy
- Chronic, progressive symptoms (poor feeding, poor growth, slow development, neurologic and other organ system dysfunction); consider:
 - Aminoacidopathies
 - Organic acidemias
 - Disorders of carbohydrate metabolism
 - Mitochondrial and peroxisomal diseases
- Cardiomyopathy; consider:
 - Pompe disease
 - Mitochondrial disorders
 - Fatty acid oxidation defects
 - Congenital disorders of glycosylation

■ Hepatopathy, consider:

- Tyrosinemia type 1
- Galactosemia
- Mitochondrial disorders
- Bile acid defects

■ Maternal HELLP syndrome (hemolysis, elevated liver enzymes, low platelets); consider:

- Fatty acid oxidation disorders

Neonatal presentation

■ Sudden deterioration of a full-term normal neonate within first few days of life is a hallmark of metabolic disease.

- Many infants remain free of symptoms for the first 24 hours of life.
- When feeding begins, toxic metabolites accumulate, vomiting may occur, and the infant becomes increasingly lethargic.
- Symptoms that highlight progression of many severe illnesses in neonate with limited repertoire of responses
 - Neurologic abnormalities
 - Respiratory distress
 - Shock
- The differential diagnosis includes:
 - Sepsis
 - Congenital heart disease
 - Neurologic insults
 - Gastrointestinal obstruction
 - Metabolic disease
- Clinician should pay particular attention to possibility of metabolic disease:
 - When risk factors for infection are absent *or*
 - When the infant deteriorates despite antibiotic therapy

■ Documentation of infection, cardiomyopathy, or brain abnormalities does not exclude underlying metabolic disease.

- Serious infection occurs in metabolically debilitated patients (eg, untreated infants with galactosemia are at increased risk for *Escherichia coli* sepsis).
- Cardiomyopathies develop in several categories of metabolic disease, including disorders of fatty acid oxidation.
- Metabolic crisis may result in diffuse cerebral swelling and stroke.
- Seizure activity predominates in certain disorders; others are associated with developmental brain abnormalities.

■ Some disorders occur within the first 24 hours of life and affected infants may have associated dysmorphic features and congenital abnormalities.

- Peroxisomal defects
- Disorders of pyruvate metabolism

- Respiratory chain defects

- Hydrops is an unusual presentation of some lysosomal storage diseases.

■ The infant with a metabolic disorder may also present with less fulminant signs during the first few months of life.

- Poor feeding, recurrent vomiting, and generalized hypotonia
- Infants who have tyrosinemia type I experience liver dysfunction, and their status can deteriorate rapidly.

Late-onset presentation

■ In one-third of patients, disease does not become clinically apparent until childhood or even later.

■ Late-onset presentation is more variable than neonatal presentation and frequently involves precipitating factors, such as diet and illness.

■ Mutations in responsible genes may encode a protein with more residual activity; patients with neonatal presentations may have none.

■ Poor growth, developmental delay, or other underlying chronic abnormalities are often found.

- However, illness can also occur acutely in a previously well individual.
- Toddlers with medium-chain acyl-CoA dehydrogenase deficiency typically exhibit the condition acutely.

■ Some patients with urea cycle defects have late-onset presentations.

- May involve neurologic symptoms and include:
 - Encephalopathy
 - Psychiatric symptoms
 - Ataxia
 - Stroke-like episodes
- Recovery may be slow, with permanent or transient neurologic dysfunction.

• Nongenetic diagnoses usually considered include:

- Reye syndrome
- Ingestion of toxic substances
- Encephalitis

■ In children with recurrent vomiting, lethargy, and dehydration resembling viral illness, each episode is protracted.

- Improvement often requires parenteral fluids.
- Patients with methylmalonic acidemia, isovaleric acidemia, and MSUD can exhibit symptoms later on in this fashion.

■ Recurrent crises of fever, vomiting, and diarrhea associated with dysmorphic features are found in mevalonic aciduria.

■ Recurrence of similar episodes of illness is characteristic of metabolic disease.

■ Abdominal pain, vomiting, and evidence of pancreatitis (eg, increased serum amylase) occur in ~8% of patients with organic acidemia.

- Organic acidemias constitute a high proportion of otherwise unexplained pancreatitis in children.
- Postpartum coma may lead to the diagnosis of an underlying urea cycle defect.

Neuropsychological regression

- Characteristic feature of lysosomal storage disorders
 - Typically, the child demonstrates either normal or slow developmental progress, then fails to reach developmental milestones.
 - Progressive deterioration occurs at variable ages and rates.
 - Certain associated physical findings can narrow the differential diagnosis in this group.

Chronic, progressive symptoms

- Metabolic disease can affect any major organ system chronically and progressively without episodes of acute illness.

LABORATORY EVALUATION

- Routine laboratory investigation can provide useful diagnostic clues.
- In disorders that have episodic symptoms, laboratory values may be abnormal only at the time of acute illness.
- Partial treatment with intravenous fluids, transfusions, or dietary changes can mask abnormalities.
- Drug metabolites can result in false-positive findings.
- Diagnostic results are more likely to be obtained by testing for metabolic disease early in the course of illness.
 - Collect specimens early.
 - Urine, heparinized plasma, spinal fluid
 - Store specimens frozen.
 - Send them later for analysis, if warranted.
- Key laboratory abnormalities are metabolic acidosis; hypoglycemia, with or without ketosis; and hyperammonemia.
- Low uric acid levels often escape attention.
 - Consistently present in molybdenum cofactor deficiency and disorders of purine catabolism
 - May be the result of renal tubular defects
 - Leukopenia and thrombocytopenia have been found in patients with organic acidemias.
 - Patients who have methylmalonic acidemia develop evidence of renal dysfunction.

Initial blood and urine tests for suspected genetic metabolic disorders

- Blood
 - Blood gases, electrolytes: Metabolic acidosis, increased anion gap
 - Disease: Organic acidemias, MSUD, disorders of carbohydrate metabolism, mitochondrial defects
 - Blood gases, electrolytes: Respiratory alkalosis
 - Disease: Urea cycle defects

- Glucose: Low with ketosis
 - Disease: Disorders of carbohydrate metabolism, organic acidemias
- Glucose: Low without ketosis
 - Disease: Fatty acid oxidation defects
- Ammonia: High
 - Disease: Urea cycle defects, organic acidemias, fatty acid oxidation defects
- Lactate, pyruvate: High
 - Disease: Disorders of carbohydrate metabolism, respiratory chain defects
- Uric acid: High
 - Disease: Glycogen storage disorders, fatty acid oxidation defects, organic acidemias
- Uric acid: Low
 - Disease: Molybdenum cofactor deficiency
- Urea nitrogen: Low
 - Disease: Urea cycle disorders
- Liver transaminases: High
 - Disease: Tyrosinemia, galactosemia, hereditary fructose intolerance, fatty acid oxidation defects
- Phosphate: Low
 - Disease: Hereditary fructose intolerance, fructose 1,6 diphosphatase deficiency
- Creatine kinase: High
 - Disease: Fatty acid oxidation disorders, mitochondrial myopathies, muscular dystrophies
- Blood count: Neutropenia, thrombocytopenia
 - Disease: Organic acidemias
- Urine
 - Odor
 - Assess by opening a closed container left at room temperature for 3 hours.
 - Sweaty feet, musty, tomcat urine, maple syrup odor
 - Disease: Organic acidemias, aminoacidopathies
 - Ketones
 - Essential test whenever hypoglycemia is documented
 - Positive
 - Disease: Organic acidemias, MSUD, disorders of carbohydrate metabolism
 - Reducing substances
 - Requires urine glucose determination for interpretation
 - Positive with glucose, galactose, fructose
 - Disease: Galactosemia, hereditary fructose intolerance

Specific laboratory tests for genetic metabolic disorders

- Blood
 - Test: Quantitative plasma amino acids
 - Disease: Aminoacidopathies, organic acidemias, disorders of carbohydrate metabolism
 - Test: Carnitine levels (total, free, and esterified), acylcarnitine profile
 - Disease: Disorders of fatty acid metabolism
 - Test: Very long-chain fatty acids, plasmalogens, phytanic acid
 - Disease: Peroxisomal disorders (leukodystrophies)
- Urine
 - Test: Quantitative amino acids
 - Disease: Specific amino acid transport defects
 - Test: Organic acids
 - Disease: Organic acidemias
 - Test: Oligosaccharide thin-layer chromatography
 - Disease: Lysosomal disorders of glycoprotein degradation
 - Test: Screens (ferric chloride, dinitrophenylhydrazine, sulfite MPS spot)
 - Disease: Aminoacidopathies, organic acidemias, sulfite oxidase-deficiency MPSs (frequent false positives and false negatives)
- Cerebrospinal fluid
 - Test: Amino acids, glucose, neurotransmitters, lactate
 - Disease: Nonketotic hyperglycinemia (requires simultaneous plasma amino acids), disorders of neurotransmitters, mitochondrial disorders
- Blood, skin, or other tissue
 - Test: Enzyme assays
 - Disease: Lysosomal enzymes, definitive diagnosis of most metabolic disorders
- If the child dies before a definitive diagnosis is made:
 - A small piece of muscle and liver should be flash frozen and held at -80°C .
 - A skin sample to culture fibroblasts should be obtained by biopsy before death for enzyme studies.
 - Heparinized plasma and urine should be frozen for metabolic studies.
 - EDTA-anticoagulated blood should be obtained for DNA studies.

DIAGNOSTIC PROCEDURES

- Skin biopsy for fibroblast cultures for enzyme studies and liver biopsy

TREATMENT APPROACH

- Treatment of metabolic disease can be divided into 2 categories.
 - Short-term therapy
 - Long-term management
- Short-term therapy and long-term management should be provided in consultation with a physician skilled in treating metabolic diseases.
- Careful monitoring of laboratory parameters and clinical status is required.
 - Attention needs to be given to complications that may result from biochemical abnormalities and therapy.

Short-term therapy

- In treatment of episodes of metabolic decompensation (before or after diagnosis has been established), the ill child is approached as usual.
 - Particular attention paid to:
 - Respiratory status
 - Cardiovascular status
 - Fluid status
 - Neurologic status
 - Intake of all potentially offending compounds (protein, lactose, fructose) is stopped.
 - Further catabolism is inhibited by providing high caloric intake.
 - Caloric supplements should include at least 60 calories/kg per day from glucose to prevent proteolysis.
 - Generally conforms to hourly rate of D10 (with appropriate electrolytes) at twice maintenance or 8–10 mg/kg per min of glucose
 - Insulin, starting at a low dose, may be required to maintain euglycemia and promote anabolism.
 - Bicarbonate is useful in cases of severe acidosis.
 - If a vitamin-responsive disorder is suspected, a trial of vitamin cofactors can be instituted.
 - Hydroxocobalamin
 - Biotin
 - Thiamine
 - Riboflavin
 - Pyridoxine
 - Folate
 - Carnitine may be added in organic acidurias to promote excretion of toxic metabolites.
 - In disorders of fatty acid oxidation, carnitine should be used judiciously and only to restore normal levels of free carnitine.

- Patients with hyperammonemia—detoxify and remove ammonia with:
 - Intravenous phenylacetate
 - Sodium benzoate
 - Arginine
- Situations requiring prompt institution of hemodialysis
 - Progressive hyperammonemia unresponsive to medications
 - Comatose states that result from hyperammonemia or other toxic metabolites
- For patients with MSUD, acute crises are best managed with the use of nasogastric branched-chain amino acid–free synthetic feeds.

Long-term management

- Long-term therapy is disease specific and involves several strategies.
- To reduce the accumulation of toxic metabolites, intake of offending compounds is limited to the smallest amount needed for growth and development.
 - This approach often requires an artificial diet that includes special formulas and caloric supplementation.
 - Regular monitoring of amino acids and other laboratory values is required to optimize diet for each individual patient.
 - For some disorders, the offending compound is non-essential and can be eliminated entirely.
 - When the enzyme defect involves binding of a cofactor (usually a vitamin) or defective synthesis of the cofactor itself, therapy centers on dietary supplementation of the cofactor.
 - Other strategies include stimulation of alternative biochemical pathways to detoxify and remove the offending substance.
- Tyrosinemia type I
 - Treatment with nitisinone blocks formation of succinylacetoacetone, a toxic compound.
- Cystinosis
 - Administration of cysteamine, an aminothioliol, reduces lysosomal storage of cystine.
- In disorders accompanied by fasting intolerance
 - Treatment consists of frequent meals.
 - May require administration of complex carbohydrates, such as cornstarch, between meals to allow prolonged absorption of glucose and nocturnal nasogastric feeding.
- Other therapeutic approaches directly provide the missing product.
 - Congenital disorders of glycosylation
 - Mannose supplements
 - Smith-Lemli-Opitz syndrome
 - Cholesterol
- None of these interventions constitutes a cure, and most are only partially successful in alleviating clinical symptoms.
- Chaperone therapy (use of pharmacologic molecules to normalize or stabilize protein structure or function) to optimize residual enzymatic activities has been proposed.
- Liver and bone marrow transplantations have been performed in several disorders, with mixed results.
- Enzyme replacement therapies have been developed for some lysosomal storage disorders; others are in the pipeline.
- Gene therapies and in utero therapies continue to be explored.
- On a community level, daily care of patients can be extensive.
 - The team approach includes education of ancillary caretakers, school systems, and the public.
 - There are psychosocial and financial consequences to patient and family.

SPECIFIC TREATMENT

Screening for genetic metabolic disease

- Newborn screening can accelerate diagnosis.
 - Specimens must be analyzed quickly and abnormal results reported promptly.
 - A sine qua non of newborn screening is that the prognosis can be improved by prompt institution of therapy.
 - Accumulated experience with screening has demonstrated that the outcome is not always as good as anticipated.
 - For some disorders, a few infants may receive therapy unnecessarily.
- Certain disorders for which treatment is effective are asymptomatic until it is too late for effective intervention.
 - In phenylketonuria (PKU), nonspecific signs (eg, eczema) occasionally appear early in infancy.
 - However, by the time developmental delay is apparent, irreversible damage has occurred.
 - For other disorders, symptoms appear early, but diagnosis is often delayed.
 - Galactosemia
 - MSUD
 - Some cases of congenital hypothyroidism (CH)
- A few single-gene conditions occur only after exposure to environmental agents that are not harmful to most in the doses encountered.
 - Screening might result in treatment that ameliorates harmful effects or warns those at risk to avoid exposure.
 - <10% of people who develop cancer have inherited alleles at single loci that greatly increase susceptibility to malignant transformation.
 - Retinoblastoma and breast and colon cancer have been studied most thoroughly.
 - The benefits of screening the entire population for genetic susceptibilities remain to be established.

- Most single-gene disorders are not treatable, but persons at risk, as well as heterozygous carriers, can be detected by genetic tests (see Prevention).
- Primary health care clinicians will be increasingly involved with neonatal, carrier, and prenatal screening and presymptomatic testing for adult-onset disorders.
 - In some cases, the clinician will:
 - Inform patients about availability of tests
 - Counsel patients about having tests
 - Interpret meaning of test results for patients

False-positive and false-negative findings

- Few people being screened will be at risk of disease in themselves or their offspring.
- False-positive findings frequently occur more often than the condition of interest in the population being screened.
 - Immunoreactive trypsinogen (IRT) test used in a few states to screen newborns for cystic fibrosis (CF) yields >5 times as many false-positive as true-positive results.
 - Because blood phenylalanine concentration may exceed normal levels only minimally during the first few days of life in infants who have PKU, the cutoff for phenylalanine level (and other metabolites) must be set lower than the minimal phenylalanine concentration needed to establish a diagnosis of PKU.
- On average, by using current methods, >50 false-positive findings are identified for every confirmed case.
- When DNA tests are performed appropriately for single-gene disorders, false-positive results are seldom encountered.
 - For disorders in which a single-gene mutation increases risk of disease but is insufficient to cause it, positive DNA test results do not always mean that disease will occur.
- False-negative results are a problem with both DNA tests and more traditional tests.
 - In DNA tests, they occur when the test does not detect all the different mutations capable of causing disease.
- Early discharge of healthy newborns before 24 hours of age increases the number of infants who have false-negative and false-positive test results.
 - Infants with PKU have near-normal levels of phenylalanine in cord blood; adequate exposure to exogenous protein is required to develop a high phenylalanine level.
 - When quantitation of blood galactose is used to screen for galactosemia, infants with galactosemia must have consumed sufficient amounts of galactose-containing human milk or cow's milk formula to accumulate galactose.
 - ~10% of infants with CH will have normal thyroxine (T_4) levels when screened early.
 - Most also have normal thyroid-stimulating hormone (TSH) levels.
 - When TSH is used as the initial screening test (common in Europe but not in US), $\leq 25\%$ of infants discharged early may have increased levels.
- In screening for congenital adrenal hyperplasia (CAH), samples collected before 36 hours of age are much more likely to yield false-positive increases in 17-hydroxyprogesterone than are samples collected after 48 hours.
- The chance of misclassification is higher the earlier an infant is screened.
 - Most, but not all, infants who have disorders for which screening usually is provided will be detected when tested after 24 hours of age.
- It is difficult to guarantee that a screening test will be performed soon after discharge.
 - Therefore, no infant should be discharged, even if <24 hours, without first being screened.
- Raising the threshold value to reduce the number of false-positive results or lowering it to reduce the number of false-negative results for infants screened before 48 hours:
 - Increases, respectively, the number of false-negative and false-positive results
 - Use of a different value for infants screened early or late requires the laboratory to treat the 2 groups of infants separately.
 - The best solution to prevent these errors is not to discharge infants until they are at least 48 hours of age.
 - Some state newborn screening programs require a second screening test at 2 weeks of age.
- No clinician should ever assume that an infant with symptoms of a disorder for which screening was performed might not have that disorder.
- Screening tests can give erroneous results because of the presence of other substances that interfere with analysis.
 - Donor blood products from recent transfusion can affect DNA tests.
 - Certain antibiotics can interfere with the bacterial inhibition assays used in some newborn screening.
- In absence of rigorous quality-control programs, laboratory error is probably the most common cause of false-positive and false-negative newborn screening test results.
 - Misidentification of specimens
 - Failure to transmit results properly
 - Erroneous assays

Newborn screening

General

- In the US, newborn screening is mandated by each state.
 - For many years, most states screened only for PKU and hypothyroidism.
 - Now, the scope includes conditions for which the hope is that early recognition will ameliorate outcome.

- The National Newborn Screening and Genetics Resource Center maintains current information on states screening requirements.
- All states and the District of Columbia routinely screen newborns for:
 - PKU (1 in 14,000 live births)
 - CH (1 in 3300 live births)
 - Galactosemia (approximately 1 in 59,000 live births)
 - Sickle cell anemia (>1 in 400 live births of black infants)
- All states except Florida screen for other hemoglobinopathies.
- Other state screening
 - 46 states screen for MSUD (<1 in 100,000 live births).
 - 45 for homocystinuria (<1 in 100,000 live births)
 - 44 for biotinidase deficiency (~1 in 80,000 live births)
 - 48 for CAH (1 in 20,000 live births)
 - 46 for medium-chain acyl-CoA dehydrogenase deficiency (1 in 15,000 live births)
 - 24 for CF (1 in 3200 white live births)
- Physicians should document screening test results and any follow-up in the child's medical record.
- Practitioners should not place undue faith in a negative result.
 - Screening tests can be falsely negative.
 - Repeat or more definitive testing should be obtained for infants whose findings arouse suspicion.
 - Treatment should not be started on the basis of a single positive screening test result.
 - Consultation with someone experienced in evaluation of metabolic disorders should be initiated.
 - When treatment is indicated, response may vary.
- Some infants may escape screening.
 - The largest group is composed of infants born at home; they should be screened at their first visit for pediatric care.
 - Sick infants transferred from one hospital to another may be missed; if any doubt exists, the receiving hospital should rescreen the baby.

PKU

- Infants with PKU show few signs until they develop mental retardation.
 - PKU may not be appreciated until the second year of life.
 - Disease is irreversible.
- Screening early in infancy, followed by prompt administration of a diet low in phenylalanine, is the only way to improve outcome.
 - Intellectual performance correlates with age at which dietary treatment is started and with success of dietary control.
 - Studies to confirm positive test results should be performed quickly to permit initiation of a low-phenylalanine diet as soon as possible, no later than the third week of life.
- The AAP recommends that every infant in the US be screened before discharge from the nursery.
 - Infants initially screened before 24 hours of age should be rescreened before the third week of life.
 - Premature and sick infants should be screened by the seventh day of life.
- A few states recommend that all infants undergo a second screening between 2 and 4 weeks of age.
- Defects in the synthesis or regeneration of bipterin cofactors for the conversion of phenylalanine to tyrosine also result in positive screening test results and clinical disease.
 - In addition to the predominant phenylalanine hydroxylase deficiency
 - Dietary restriction of phenylalanine is insufficient to prevent mental deterioration and seizures in these infants.
 - Use of bipterin or neurotransmitter precursors offers some hope.
 - Infants with these disorders will be identified by neonatal screening for PKU.
 - They represent <3% of all infants with hyperphenylalaninemia.
 - Tests for these variant forms should be performed in any infant who persistently has high blood phenylalanine levels, even in the moderate range of 10–20 mg/dL, while on a normal diet.

CH

- Causes of CH are multiple and complex.
 - Transplacental passage of maternal antibodies that interfere with fetal thyroid development or thyroid function
 - Maternal antibodies can cause transient hypothyroidism.
 - Mothers receiving antithyroid medication (propylthiouracil) may have babies with transient hypothyroidism.
 - Genetic factors are suggested in families with >1 affected infant.
 - Such findings do not rule out environmental or maternally acquired causes.
 - For unknown reasons, girls are twice as likely as boys to have CH.
 - Birth prevalence is somewhat higher in Hispanic and Native American persons than in white or Asian persons, in whom it is higher than in black persons.
- Infants with the most profound deficiencies of T_4 , usually as a result of thyroid agenesis, are more likely to have neonatal symptoms.
 - Persistent jaundice, difficulty feeding, and lethargy are most frequent.
 - Even infants with agenesis may be asymptomatic when examined following an abnormal screening test result.
 - Placental transfer of T_4 and some fetal production of triiodothyronine in the brain may explain this circumstance.

- The 10% of infants with CH found by a second screening (in states that screen twice) are less often symptomatic and have lower increases of TSH.
- Even if newborn test results are negative, hypothyroidism may still develop in infancy or childhood.
- The incidence of CH detected by neonatal screening is higher than that detected by clinical diagnosis in the prescreening era, suggesting either:
 - That infants who have milder disease escaped diagnosis *or*
 - That some infants receiving a diagnosis today do not really have CH
 - Thus it is important to ensure that CH persists in equivocal cases.
- In most laboratories in the US, T_4 is measured on the screening specimen.
 - If low, then TSH is measured on the same specimen.
 - If TSH is high and findings are confirmed by another specimen, treatment with T_4 is initiated.
 - Most infants who persistently have low T_4 levels but normal TSH levels will prove on further study to have normal free T_4 concentrations and thyroid-binding globulin deficiency and do not require treatment.
 - A few infants with low T_4 and normal TSH levels have pituitary gland failure, which is encountered much less frequently than thyroid-binding globulin deficiency.
 - Occasionally, an infant with initial low T_4 and normal TSH levels will have a delayed increase in TSH level and symptoms of hypothyroidism.
 - TSH should be retested if symptoms appear.
- Motor and cognitive development of infants with CH at 7.5 years of age correlate with the age at which T_4 treatment is started.
 - Most infants who receive early treatment have IQ scores in the normal range.
 - Many are at the low end compared with matched controls (approximately a 5- to 10-point loss in IQ).
- Patients with CH have persistent deficits in visuospatial abilities, memory, and attention, correlated to severity of early hypothyroidism.

Sickle cell anemia

- States have added sickle cell disease to their newborn screening programs.
- Before screening, ~10% of infants in the US with sickle cell disease died by 10 years of age.
- Effectiveness of screening in reducing morbidity and mortality depends on:
 - Ensuring that infants detected by screening are referred to a continuing source of care to receive prophylactic penicillin
 - Parents learning how to manage situations that increase chance of sickle cell crises

- No specific treatment is available for sickle cell anemia.
- Tests used for screening
 - Hemoglobin electrophoresis, isoelectric focusing, high-performance liquid chromatography
 - Reveals hemoglobinopathies in addition to sickle cell anemia
 - Specific sickle cell anemia DNA testing
 - Does not identify other hemoglobinopathies
 - All forms of sickle cell testing identify infants with sickle cell trait who will remain healthy.
 - Parents of an infant with sickle cell trait may be at risk for having an infant who has sickle cell anemia if both partners are carriers of the sickle cell gene.
 - A screening program will have 40 times more carriers to notify than parents of infants who have sickle cell anemia.
 - The purpose of notifying parents is to offer testing to determine whether they are both carriers and at 25% risk of having affected offspring with each subsequent pregnancy.
 - An infant who has this trait and triggers the investigative process has nothing to gain from it.
 - In most couples that have an infant with the trait, only 1 partner is a carrier.
 - Parents should be informed that newborn screening might provide information about their future risks of having a child with a serious hemoglobinopathy.
 - They should be given the opportunity to request the results.
 - Thalassemias are not directly screened for in the US
 - Will be detected when general hemoglobin electrophoresis is performed

Galactosemia

- In contrast to PKU, serious manifestations of classic galactosemia occur soon after milk feedings are started.
 - Diagnosis can be, and often is, made clinically before screening test results are reported.
 - Prompt administration of a lactose-free diet in newborns will save the lives of patients with this disorder.
 - May not prevent mental retardation or other developmental problems, including a high incidence of ovarian failure
 - The age of starting the galactose-free diet is not significantly associated with the magnitude of problems (developmental delay, physical growth, or speech).
- It is uncertain whether infants whose galactosemia is found by screening would have developed symptoms had they not been started on a lactose-free diet.
 - Some infants discovered by screening have variant forms of galactosemia.
 - Residual amounts of galactosyl-1-phosphate uridylyltransferase (ie, enzyme that is absent in classic cases) are found.

- Infants with some of these variants have acute neonatal symptoms, generally milder than in classic cases.
- Some infants exhibit no symptoms.
 - It is unclear whether they are less likely to have long-term manifestations, such as developmental delay.
- Much remains to be learned about the pathogenesis of galactosemia and development of effective therapy.
 - The value of neonatal screening for galactosemia is questionable, although classic galactosemia will result in death if untreated.
- The principal goal is to ensure prompt intervention in individuals who have early onset of symptoms and whose lives are threatened.
 - These infants can be diagnosed clinically.

MSUD

- Infants with the classic form of MSUD usually show signs within 2 weeks of birth.
 - The course can be fulminant and rapidly fatal.
 - Early treatment can prevent or ameliorate acute symptoms.
 - Patients require a special diet low in branched-chain amino acids.
 - If the diet is started early, long-term outcome can be good.
 - One problem with routine screening is the inherent delay in obtaining results.
 - A specimen collected on day 2 may not be reported until day 10.
 - By that time, most infants with classic MSUD will be severely ill or dead.
 - Starting the special diet will usually save infants who are still alive at this point, but survivors often have mental retardation and neurologic problems.
 - Confirmation of MSUD in sick infants can sometimes be hastened by contacting the laboratory responsible for performing newborn screening.
 - In many instances, the laboratory will process the specimen more quickly when it receives a special request.
 - Infants known to be at risk because of a previously affected family member or North American Mennonite descent:
 - Should undergo definitive testing (quantitative plasma amino acids) on the second day of life
 - Immediately begin a special diet to ensure the best possible outcome
 - Lapse into coma is associated with a decrease of up to 40 IQ points.
 - The enzyme defect in MSUD is complex, and many different mutations have been characterized.
 - Exception: a North American Mennonite community, in which a single mutation accounts for a high prevalence of the condition
- Many patients are compound heterozygotes.
 - As a result of screening and immediate institution of the special diet, establishing the genotype-phenotype relationship has been difficult.
 - Some infants started on the diet may have forms of the disorder that would have appeared only later in infancy or childhood with:
 - Episodes of ataxia
 - Failure to thrive
 - Mild ketoacidosis, particularly after infection or high-protein ingestion

CAH

- In 21-hydroxylase deficiency and 11-hydroxylase deficiency, cortisol production is impaired.
 - 21-hydroxylase deficiency accounts for >90% of patients with CAH.
 - 11-hydroxylase deficiency accounts for ~5% of cases.
 - As a result of the deficiency, feedback inhibition of adrenocorticotrophic hormone is lacking.
 - Cortisol precursors, including those that have androgenic activity, are overproduced.
- In girls, ambiguous genitalia should permit clinical diagnosis in the neonatal period.
 - Because the diagnosis is not always made, screening might increase recognition of girls, permitting them to be raised as girls.
 - The diagnosis is much more difficult to establish in newborn boys.
- Approximately two-thirds of infants who have 21-hydroxylase deficiency lose salt.
 - They may experience severe dehydration and vascular collapse accompanied by hyponatremia during the first 3 weeks of life.
 - Unscreened boys who have salt-losing CAH receive a diagnosis at a median age of 26 days vs 12 days for screened boys.
- Boys who have simple virilizing CAH are detected only by screening.
- Several different mutations in the gene for 21-hydroxylase have been found.
 - The presence of salt losing depends on the particular mutation, but a complete genotype-phenotype correlation has not been established.

Biotinidase deficiency

- Biotin is a cofactor of several carboxylases.
- Availability through recycling is reduced in inherited deficiencies of biotinidase.

- Manifestations and age at onset of biotinidase deficiency vary, possibly because of differences in degree of enzyme deficiency and amount of biotin available to the infant.
 - Symptoms usually appear between 2 weeks and 3 years.
 - Ataxia
 - Alopecia
 - Hearing loss
 - Decreased vision
 - Optic atrophy
 - Seizures
 - Not yet known whether some infants who have the disorder remain free of symptoms
 - It is possible that not all infants discovered by screening will develop symptoms.
 - Infants found by screening have higher levels of residual biotinidase than those diagnosed clinically.
 - Treatment with supplemental biotin is simple and inexpensive.
 - Biotin reverses some symptoms after they appear.
 - Not always true for hearing and visual impairments and developmental delay
 - Unclear whether clinical diagnosis will always be made expeditiously
 - Infants treated as a result of screening have so far remained free of symptoms.

CF

- IRT is increased in the blood of most newborns with CF.
- 24 states currently perform this test.
 - Those that mandate 2 screenings use this method alone.
 - Other states follow IRT with second-tier DNA testing for common CF transmembrane conductance regulator mutations.
 - Some states screen only for the *F508* delmutation, which is present in 70% of CF alleles worldwide.
 - Other states require a broader panel, which is enriched for mutations seen in black and Hispanic persons.
 - Decreases the rate of false-positive findings identified by IRT screening alone
 - May miss up to 10% of patients with CF who do not carry a common mutation on either allele
- Neonates with CF and meconium ileus usually have false-negative results.
- The Centers for Disease Control and Prevention issued a report concluding that screening newborns for CF was justified.
 - Long-term nutritional outcome is improved in children identified by screening compared with those identified clinically.
 - Newborn screening may improve childhood survival.

- No treatment is yet available that prevents the clinical manifestations.

Homocystinuria

- Vitamin B₆-dependent forms of homocystinuria
 - Treated easily and effectively
 - Account for ~50% of cases
- Newborn screening will not detect all affected infants.
- The detection rate after the first week of life by tests that measure blood or urine homocystine will be higher than that of neonatal screening, which detects hypermethioninemia.
 - Hard to justify newborn screening by bacterial inhibition assay
 - Some experts have suggested lowering the blood methionine cutoff to 1 mg/dL to decrease the false-negative rate.
 - Argument has been obviated by institution of tandem mass spectrometry (MS/MS) for newborn screening.
 - Results are quantitative, and MS/MS is currently being used to some extent in all but 6 states.

Medium-chain acyl-CoA dehydrogenase deficiency

- Medium-chain acyl-CoA dehydrogenase deficiency has an incidence of 1 in 10,000 to 14,000 in the white population.
 - 25–50% initial decompensation fatality rate
 - Easily treated by:
 - Avoiding fasting and catabolism
 - Instituting carnitine supplementation and intravenous glucose early in course of intercurrent illness
- Unscreened infants are usually discovered at between 6 and 18 months of age after decreased caloric intake usually associated with intercurrent illness.
 - The child develops hypoketotic hypoglycemia, followed by hepatic encephalopathy and ultimately death if untreated.
 - The whole progression can occur during the 12 hours of nighttime sleep.
 - Accounted for small percentage of deaths caused by sudden infant death syndrome in the prescreening era

Glucose-6-phosphate dehydrogenase deficiency

- A significant number of different alleles result in this X-linked genetic susceptibility.
- The usual manifestations are hemolytic anemia accompanied by jaundice and hemoglobinuria.
- ~10% of black boys inherit the mild A form.
 - Except for some sulfur compounds (eg, sulfamethoxazole), drugs that trigger reactions are seldom used in the US (eg, primaquine).
 - Some individuals may develop hemolysis after heavy exposure to naphthalene (mothballs).

- In the more severe Mediterranean variant (only occasionally in the A variant), hemolytic anemia (favism) is encountered after ingestion of fava beans.
 - A staple in many Mediterranean diets
 - Initiation of a newborn screening program for glucose-6-phosphate dehydrogenase deficiency in Sardinia, together with more education about the deficiency, was associated with a marked decline in occurrence of favism and need for blood transfusions.
- A dried-blood spot filter paper assay has been developed.
 - Many experts are advocating for adding this condition to the newborn screening panel.
- Treatment is variably effective.
 - In some patients, it affords complete resolution of heart and muscle disease.
 - In others, it converts a fatal disorder to a severe chronic illness, resulting in numerous hospitalizations and slow deterioration.

α_1 -Antitrypsin (α_1 -AT) deficiency

- α_1 -AT deficiency is usually the result of inheriting Z alleles from both parents.
- Individuals with severe α_1 -AT are at increased risk of chronic obstructive pulmonary disease (COPD).
 - In population-based surveys, many people who have severe deficiency remain asymptomatic throughout life.
 - Smokers who have the deficiency are likely to encounter pulmonary problems between 20 and 40 years of age, ~15 years earlier than nonsmokers.
 - Not all nonsmokers who have α_1 -AT deficiency get COPD (accounts for ~1% of all COPD).
 - Presymptomatic screening might alert individuals who have α_1 -AT deficiency to the especially harmful consequences of smoking.
- Treatment of α_1 -AT-deficient adults with emphysema with human α_1 -AT increased serum and lung α_1 -AT levels but did not improve their pulmonary function.
 - Whether treatment would prevent COPD remains to be established.
- Screening of newborns or young children is of questionable value because adolescents who have α_1 -AT deficiency have normal pulmonary function.
- ~10% of infants who have α_1 -AT deficiency develop cholestasis.
 - 2–3% later develop cirrhosis.
 - No specific treatment or known means of preventing liver manifestations is available.
 - Human milk may be protective.
 - Newborn screening would not be expected to alter prognosis.
- α_1 -AT deficiency should be included in the differential diagnosis of persistent jaundice in young infants.
- Screening adolescents or young adults might be of benefit.

New techniques for newborn screening

General

- Enzyme replacement therapy has been developed to treat infant-onset Pompe disease.
 - For the best outcome, treatment should be initiated before 6 months of age.
- Cord blood stem cell transplantation can cure Krabbe disease if undertaken in the first month of life.
 - One state has already added this condition to its newborn screening panel.
- New tests are being developed to screen for severe combined immunodeficiency and adrenoleukodystrophy.
 - Much research and interest exists in this area.

MS/MS

- MS/MS can quantitate accurately multiple amino acids, organic acids, and metabolites of fatty acid oxidation from dried blood on filter paper.
- The advent of this technique has:
 - Broadened the scope of newborn screening
 - Dramatically decreased (by 2 orders of magnitude) some false-positive rates
 - Decreased the false-negative rates for homocystinuria
- MS/MS is used to screen for:
 - PKU
 - MSUD
 - Homocystinuria
 - Tyrosinemia
 - Citrullinemia, by detecting increased citrulline
 - Argininosuccinic acidemia, by detecting increased citrulline
- MS/MS cannot detect ornithine transcarbamylase or carbamoylphosphate synthetase deficiencies.
 - Cannot reliably detect a low citrulline level
- MS/MS can detect a broad array of organic acids and metabolites of fatty acid oxidation.
- For many disorders that can be identified by MS/MS, no fully effective treatment exists.
 - Early intervention may not affect outcome.
 - Undiagnosed infant deaths would decrease.
 - Availability of prenatal diagnosis in subsequent pregnancies for at-risk families would increase.
- The American College of Medical Genetics and March of Dimes concurred on a core panel of disorders and secondary target conditions that can be detected by MS/MS.

Genetic susceptibilities

- In a few genetic conditions, disease is likely to appear only in certain environments.
 - Screening of infants or young children provides warning that certain exposures will be harmful and should be avoided.
 - If harmful exposures occur, awareness of the genetic susceptibility might speed appropriate management.
 - In the US, no state currently screens newborns for such genetic susceptibilities.
 - May reflect a lack of confidence in the ability of the health care system or parents to ensure that the harmful exposures will be avoided
 - Screening workers or prospective employees for genetic susceptibilities to agents that may be encountered is of interest to some employers.

Carrier screening

- Carrier screening is undertaken for severe untreatable inherited disorders to provide persons identified as carriers with options for preventing conception or birth of affected children.
 - Tay-Sachs disease
 - Carrier screening has resulted in a significant decrease in disease in many Jewish communities.
 - Thalassaemia
 - Carrier screening in Sardinia and elsewhere in the Mediterranean Basin has lowered incidence.
 - Sickle cell anemia
 - Most American couples found by carrier screening to be at risk of having a child with sickle cell anemia decide not to terminate the pregnancy.
 - With nondirective counseling, they may not view the disorder as severe.
- School-based screening programs for sickle cell and Tay-Sachs disease carriers probably recruit a much higher proportion of the at-risk population than do community programs or office or clinic screening programs.
 - However, may lead to stigmatization of students identified as carriers
 - Unclear that adolescents identified as carriers will retain this information or act on it when they consider having children
- If prenatal diagnosis of a condition is available and abortion of an affected fetus is acceptable, then less reason exists to offer screening before pregnancy.
 - Couples might be screened before the woman becomes pregnant or early in pregnancy.

- Since 2001, the American College of Obstetricians and Gynecologists has recommended offering carrier testing for CF for all pregnant white women.
 - In 2005 it altered its recommended panel of 25 mutations.
 - Uptake of screening approached 25% of pregnancies in 2004.
- Screening young women to determine whether they are carriers of X-linked disorders is technically feasible with DNA analysis.
 - Fragile X syndrome
 - Hemophilia
 - Duchenne muscular dystrophy
 - Because of new mutations, not all births of infants with these disorders might potentially be avoided.
 - Such testing is not routinely offered at this time.

Prenatal screening

- Practitioners who provide care to young persons do not usually have primary responsibility for managing pregnancies.
 - However, they often will have prior contact with the mother and father.
 - Can contribute to the parents' understanding of the indications for screening in pregnancy
 - May also be contacted by obstetricians to assist in counseling or in anticipation of high-risk newborns
- Neural tube defects
- Folate supplementation of bread products was initiated in January 1998.
- Maternal serum screening of α -fetoprotein (AFP) between the 15th and 21st weeks of pregnancy
 - Maternal serum AFP test can detecting 90% of fetuses that have anencephaly and ~80% of those that have open spina bifida.
 - For every true-positive result, there will be ~30 false-positive results.
 - Normal maternal serum AFP concentration is highly dependent on gestational age.
 - In women with high maternal serum AFP, sonographic examination is needed to determine the accuracy of estimated gestational age.
 - If sonography confirms gestational age, amniotic fluid is obtained by amniocentesis.
 - If amniotic fluid AFP is high, the likelihood of an open neural tube defect is >90%.
 - Further assurance that a defect is present is obtained by performing acetylcholinesterase determinations and high-detail (level 2) ultrasonography.
 - Although high-level ultrasonography performed by expert sonographers detects most fetuses with open spina bifida, it should not replace AFP screening.

■ Down syndrome

- Prenatal diagnosis for Down syndrome is rapidly evolving.
 - Definitive testing requires chorionic villi sampling or amniocentesis.
 - Routinely offered to women >35 years of age
 - Costly and invasive
 - Biochemical marker screening tests are now available for:
 - Younger women
 - Women >35 years for whom risks of amniocentesis or chorionic villi sampling are unacceptable
 - Second-trimester triple screening detects approximately 60% of fetuses with Down syndrome.
 - Free β -human chorionic gonadotropin
 - Maternal serum AFP
 - Estriol
 - Addition of inhibin A to form quadruple screening increases sensitivity to ~70%, with a 5% false-negative rate.
- New first-trimester screening can detect 70% of fetuses with Down syndrome.
 - Includes testing for pregnancy-associated plasma protein A and free β -human chorionic gonadotropin
 - When coupled with first-trimester nuchal translucency testing by ultrasonography, sensitivity increases to 86%, with only a 5% false-negative rate.
 - Technically challenging and not yet widely available
 - Sequential screening can detect $\leq 95\%$ of affected pregnancies, with only an overall false-positive rate of 5%.
 - First-trimester screening, followed by second-trimester quadruple screening for persons not at high risk by first-trimester screening
- First-trimester screening for Down syndrome does not obviate the need for second-trimester screening for neural tube defects.

■ WHEN TO REFER

- All patients suspected of having genetic metabolic disease should be referred to a physician who has expertise in this area.

■ WHEN TO ADMIT

- All infants whose respiratory, cardiac, hematologic, and neurologic status is unstable
- Patients in coma
- Patients with metabolic acidosis or respiratory alkalosis
- Patients with hypoglycemia and also elevated ammonia level
- Patients with significant electrolyte abnormalities
- Patients with significantly abnormal liver enzymes and liver function tests

■ PREVENTION

- Carrier testing before pregnancy provides couples the option of preventing conception of children who will have severe, untreatable, inherited disorders by:
 - Adoption
 - Artificial insemination of donor sperm
 - Ovum donation or surrogacy in the case of X-linked disorders
- Carrier testing early in pregnancy by chorionic villi sampling or amniocentesis provides couples the option of preventing the birth of an affected child.
 - By selective abortion
- Prenatal cytogenetic and biochemical testing can avoid the birth of children who have aneuploidy or neural tube defects, respectively.

Giardiasis

DEFINITION

- Gastrointestinal (GI) symptoms of waterborne disease caused by *Giardia intestinalis* (also known as *Giardia lamblia* and *iardia duodenalis*), an extracellular parasite that has no intermediate development outside of the intestinal lumen

EPIDEMIOLOGY

- *G intestinalis* is holoendemic in the US.
 - One of the most commonly identified pathogens in waterborne diarrheal disease
- Geographic distribution
 - Prevalence high in:
 - Mountainous regions
 - Child care centers
 - Major metropolitan areas
 - Among campers
 - Among international tourists
- Age
 - Children <5 years most commonly affected in the US.
 - With intensive exposure to stool, as in child care centers caring for infants in diapers, giardiasis quickly may become hyperendemic.
- Seasonality
 - Infection rates peak in late summer and early fall.

ETIOLOGY

- Many large common-source outbreaks have been traced to contaminated drinking water.
 - Municipal drinking water supplies that have sewage contamination, defective or deficient filtration facilities, and reliance on chlorination as the principal method of water disinfection
 - Use of surface water for drinking in mountainous regions
 - Although zoonotic infections have been documented, recent molecular epidemiologic studies suggest it is rare.
- *G intestinalis* exists in 2 forms.
 - Motile, flagellated trophozoite that causes disease
 - Dormant cyst that transmits infection
- Because cysts may be shed in abundance in the stool, *G intestinalis* may be transmitted by the fecal-oral route.
 - Main route of spread in families, institutions, and child care centers
- Foodborne giardiasis has been reported.
 - Food probably contaminated during preparation

RISK FACTORS

- HIV infection
- Intensive exposure to stool

- Poor sanitation
- Poor hygiene

SIGNS AND SYMPTOMS

- Incubation period of giardiasis is 7–14 days.
- Most infected patients remain asymptomatic; however, they shed cysts in their feces and are infectious.
- Children are more likely than adults to have symptomatic disease.
- Principal GI symptoms last 7–10 days or longer.
 - Most common
 - Diarrhea
 - Abdominal cramps
 - Nausea
 - Less common
 - Vomiting
 - Malodorous stools
 - Flatulence
 - Bloating
 - Anorexia
 - Constipation
 - Because of the disaccharidase deficiency that accompanies severe infections, some patients report milk intolerance, which may last for weeks.
- Giardiasis must be considered in the differential diagnosis of failure to thrive since some patients, particularly children, develop:
 - Chronic diarrhea
 - Frank malabsorption
 - Weight loss
 - Malnutrition
 - Growth retardation
- Malabsorption leading to iron-deficiency anemia also has been reported.
- Constitutional symptoms are not prominent, but up to 25% of patients experience:
 - Fatigue
 - Headache
 - Low-grade fever
- Extra intestinal syndromes (rare)
 - Urticaria
 - Erythema multiforme
 - Arthralgia
- Because the colon and rectum are not involved, tenesmus should suggest another diagnosis.
- Blood almost never is found in the stool.
- Presence of mucus is unusual.

- Physical examination
 - Generally unremarkable unless secondary malnutrition has developed

DIFFERENTIAL DIAGNOSIS

- Sprue
- Food allergy
- Psychogenic abdominal pain
- A wide variety of GI disturbances

DIAGNOSTIC APPROACH

- Confirm GI symptoms.
- Order laboratory workup for detection of parasites in stool.

LABORATORY FINDINGS

- Heat-stable antigen-detection in stool or detection of parasites by fluorescence is used more commonly now than microscopic examination of stool.
 - Tests often combined for simultaneous detection of *Cryptosporidium* species
 - These tests compare well with standard microscopic procedures.
 - In most cases, more sensitive
 - Multiple samples may be needed for optimal detection.
- Serologic tests are valuable in epidemiologic studies.
 - Of little use diagnostically
- Other blood tests
 - Sedimentation rate is normal.
 - No eosinophilia is found because the parasite is noninvasive.
- Biochemical evidence of malabsorption may be found, including:
 - Disaccharidase deficiency
 - Abnormal absorption of D-xylose and fat
 - Deficiency of folic acid

IMAGING

- Upper GI x-rays may reveal:
 - Mild dilation of the small bowel
 - Edema of the mucosa
 - Segmentation of barium
 - Either increased or decreased transit times
 - However, these changes are nonspecific.

DIAGNOSTIC PROCEDURES

- Direct duodenal aspiration or EnteroTest
 - Analysis of duodenal contents provides the optimum yield in patients requiring additional measures to have the pathogen detected.

- Small-bowel biopsy
 - In rare patients with chronic symptoms in whom the diagnosis must be excluded
 - Several sections of the biopsy specimen stained may be needed.
 - *Giardia* organisms are detected more easily in Giemsa-stained mucosal impression smears than in stool samples.
 - Biochemical evidence of malabsorption may be found, including:
 - Disaccharidase deficiency
 - Abnormal absorption of D-xylose and fat
 - Deficiency of folic acid

TREATMENT APPROACH

- Treat with an antiparasitic agent when infection is recognized, even if the patient is asymptomatic.
 - Carriers of the parasite are potential transmitters of disease and may have subclinical malabsorption.
 - Physicians may elect not to treat asymptomatic patients if reexposure to *G intestinalis* seems unavoidable in some hyperendemic settings.

SPECIFIC TREATMENTS

Metronidazole

- Used widely in adults and children
 - Giardiasis is not an approved indication for metronidazole in the US.
- Acceptable cure rate
 - Well tolerated (except for the mild metallic aftertaste)
 - Can be formulated as a suspension
 - Low incidence of serious side effects
 - Alcohol ingestion, including in concurrent medications, should be avoided with metronidazole because of disulfiram-like reactions.

Tinidazole

- Tinidazole is an imidazole similar to metronidazole
 - Had been used extensively in a single-dose regimen outside of the US
- FDA-approved for the treatment of giardiasis
 - Including in children ≥ 3 years
- Can be formulated as a suspension

Furazolidone

- Efficacy of furazolidone in children has been as high as 92%.
 - Comparable if not superior to cure rates seen with alternative agents
- Pleasant taste
- Available in a pediatric suspension

- Side effects have been minimal in children.
 - Mild GI distress
 - Hypersensitivity reactions
 - Hemolysis in individuals who have glucose-6-phosphate dehydrogenase deficiency
 - Brown discoloration of urine
 - Disulfiram-like reactions
- Contraindicated with monoamine oxidase inhibitors

Nitazoxanide

- Nitazoxanide is a recently FDA-approved antiparasitic agent with specific indications for the treatment of cryptosporidiosis and giardiasis in children
- Cure rates in small, randomized trials are similar to those with standard agents for giardiasis.
- Side effect rates seem similar to those with placebo.
 - Yellow sclera noted rarely
 - Clears with discontinuation of the drug
- More costly than other agents

Albendazole

- Albendazole is reported to be as effective as metronidazole in a study of children 5–10 years of age
- Active against a broad range of intestinal parasites, including helminths

Paromomycin

- Paromomycin is a nonabsorbable aminoglycoside
- Has been used to treat giardiasis in pregnancy
 - Data regarding its efficacy are limited.

Quinacrine

- Quinacrine was previously commonly used as therapy.
- Not commercially available in the US but can be obtained if needed (www.medicalletter.com).

Drug resistance

- No well-documented evidence exists for actual drug resistance in *Giardia* on an individual clinical case level.
- In vitro sensitivity has shown variations but is assay- and inoculum-dependent.
- For cases of severe or recalcitrant infections, prolonged or combination therapy may be necessary.

PROGNOSIS

- Relapse is possible after any of the treatment regimens.
- Re-treatment with the same agent or an alternative drug is often successful.

PREVENTION

- Because giardiasis is so prevalent, total prevention of transmission is virtually impossible.
 - Good hand washing is essential to limit spread by the fecal-oral route.
 - Especially important when infants in diapers are affected
- When an outbreak is suspected in child care centers that have infants in diapers, the local health department should be contacted.
 - Epidemiologic investigation should be undertaken to identify and treat all symptomatic children, child care workers, and family members infected with *Giardia*.
- Prevention of waterborne giardiasis is contingent on adequate water purification, including filtration, sedimentation, and flocculation in addition to chlorination.
 - Tourists in endemic areas should avoid drinking tap water.
 - Campers should not rely on chlorination tablets, which are ineffective against *Giardia* cysts.
 - Boiling for ≥ 2 minutes, even at high altitudes, and filtration (pore size $\leq 1 \mu\text{m}$ or with a filter rated for cyst removal) are satisfactory means for preparing drinking water free of *G intestinalis*.

Gluten-Sensitive Enteropathy (Celiac Sprue)

DEFINITION

- Gluten-sensitive enteropathy (GSE) is a condition characterized by clinical features of malabsorption and pathologic changes in the jejunal mucosa.
 - Both improve when gluten is removed from the diet and recur when it is reintroduced.
- Also known as *celiac sprue*
- Second-most common cause of malabsorption in children (cystic fibrosis is the most common cause)

EPIDEMIOLOGY

- Race/ethnicity
 - Has been identified in most ethnicities, including European, Hispanic, Indian, Chinese, Sudanese, African-Caribbean, and Middle Eastern persons
 - Prevalence in US is 1 in 133 persons.
 - Worldwide prevalence estimated to be 1 in 266 persons.
- Age
 - Average age at diagnosis is <24 months.
 - The diagnosis occurs sooner in infants who are fed cereal at an early age.
 - Incidence declines markedly after age 2 years.
 - Diagnosing GSE in a teenager is even less common.

ETIOLOGY

- GSE affects the mucosa of the small intestine, sparing the submucosa, muscularis, and serosa.
 - Mucosal lesions of the small intestine vary in severity and extent.
 - Lesions in the jejunum are generally more severe than those in the ileum.
- In active GSE, surface epithelial-cell damage occurs.
 - Compensatory crypt hypertrophy occurs, resulting in villus flattening.
 - Surface epithelial cells become more cuboidal.
 - Many intraepithelial lymphocytes are noted, and the lamina propria shows a marked increase in plasma cells and lymphocytes.
- GSE is a genetic disease, although the mode of inheritance is unknown.
 - Incidence in first-degree relatives is between 1 in 18–22; for second-degree relatives, the incidence is 1 in 24–39.
 - The presence of *HLA-DQ2* or *-DQ8* is necessary to develop GSE.
 - The *HLA-DQ2* allele combination is found in 90–95% of patients with GSE (however, 20–30% of the normal population also has this combination).
 - Remaining 5–10% of patients are *HLA-DQ8* positive.

- 2 possible mechanisms explain the cause of GSE.
 - Lack of a specific dipeptidase results in accumulation of toxic gluten peptides that initiate an inflammatory response.
 - May be mediated through immunologic aberrations associated with genetically determined cell-surface markers
- Various immunologic abnormalities have been described.
 - Increased levels of serum immunoglobulin (Ig)A and lower levels of serum IgM
 - Intestinal mucosal immunoglobulin synthesis, notably IgA and IgM, is markedly increased in active GSE.
 - 50% of the increased IgA is associated with specific anti-gluten antibody.
 - In vitro duodenal mucosa and peripheral lymphocyte transformation in response to gluten has been described.

RISK FACTORS

- Diseases associated with increased incidence of GSE
 - Type 1 diabetes
 - IgA deficiency
 - Down syndrome
 - Turner syndrome
 - Williams syndrome
 - Autoimmune thyroiditis

SIGNS AND SYMPTOMS

- Symptoms of an advanced case of GSE
 - Irritability
 - Anorexia
 - Chronic diarrhea
 - Failure to thrive
 - A potbelly
 - Muscle wasting, especially of the buttocks and proximal limbs
- Other manifestations
 - Growth failure (without gastrointestinal symptoms)
 - Anemia
 - Iron deficiency
 - Folate deficiency
 - Vitamin-B₁₂ deficiency (rare)
 - Rickets, osteoporosis, bone pain, pathologic fractures
 - Bleeding disorders
 - Edema
 - Constipation
 - Vomiting
 - Recurrent abdominal pain
 - Rectal prolapse
 - Clubbing of the fingernails

■ Celiac crisis (life-threatening condition)

- Massive diarrhea
- Severe electrolyte imbalance
- Dehydration
- Shock

DIFFERENTIAL DIAGNOSIS

■ Common causes of flat villus lesions include:

- Food sensitivity
 - Cow's milk protein allergy
 - Soy protein allergy
 - Eosinophilic gastroenteritis
 - Infection: viruses (rotavirus), bacteria (*Escherichia coli*), parasites (*Giardia lamblia*), or fungi (*Candida albicans*)
 - Malnutrition (kwashiorkor, not marasmus)
 - Tropical sprue
 - Immunodeficiency disorders (most notably AIDS)
 - Familial enteropathy
 - Lymphoma
 - Crohn disease
 - Whipple disease
- A sweat test should be performed to exclude cystic fibrosis.
- Most common cause of malabsorption in childhood
 - May coexist with GSE

DIAGNOSTIC APPROACH

■ For definitive diagnosis of GSE, the clinician must see:

- Demonstration of clinical malabsorption and abnormal intestinal lesions
- Clinical and histologic response to gluten withdrawal
- Subsequent gluten challenge that may exacerbate clinical symptoms but that always produces abnormal intestinal histologic findings

■ Diagnosis must be made with certainty because:

- GSE means lifelong gluten restriction.
- Untreated patients have higher risk of gastrointestinal cancer in late adulthood.

LABORATORY FINDINGS

■ Serologic markers for diagnosis and screening

- Anti-tissue transglutaminase (tTG) antibodies
 - First step in screening
- IgA endomysial antibodies
 - Most specific
 - Used as a confirmatory test when findings of tTG antibody testing are equivocal

- Anti-gliadin antibodies

- Less specific and less sensitive than endomysial antibodies
- Not suggested for screening

- False-positive endomysial and tTG antibody tests are unusual.
- When IgA is low or absent, consider measuring serum tTG-IgG and endomysial antibody-IgG levels.
- 10–15% of patients with GSE may have negative markers.
 - Thus a negative serologic test result does not exclude diagnosis.

■ Genetic markers *HLA-DQ2* and *-DQ8*

- If negative, this excludes GSE.
- Markers are present in people without GSE.

■ Hematology and electrolytes

- Anemia
- Hypoprothrombinemia
- Abnormal serum albumin and globulin levels
- Electrolyte disturbances, especially hypokalemia
- Calcium, phosphorus, and alkaline phosphatase levels may be abnormal in patients with rickets.

IMAGING

■ Radiographic findings in GSE are nonspecific.

- May see distended small intestine and segmented barium on a small-bowel follow-through

DIAGNOSTIC PROCEDURES

■ Biopsy of the small intestine is the best way to diagnose GSE.

- Should be performed to confirm diagnosis when serologic markers are positive
- Are routinely obtained by fiberoptic endoscopy, permitting visualization of the duodenum
- Scalloping of the small intestinal valvulae of Kerckring has been described as pathognomonic for GSE.
 - In young infants, edema of the duodenal mucosa is more common.

■ Repeat biopsy and rechallenge

- Not necessary if a child >2 years old has become asymptomatic on a gluten-free diet.
- Children <2 years old should undergo another biopsy to demonstrate healing then undergo rechallenge and another biopsy.
 - The same approach is suggested in children with an indeterminate diagnosis.

TREATMENT APPROACH

- Treatment of GSE is a gluten-free diet (GFD).
 - Remove gluten from the diet, including wheat, rye, and barley.
 - Oats do not contain gluten but may be cross-contaminated with gluten during manufacturing.
 - A lactose-free diet is advocated during the initial 4–6 weeks to alleviate diarrhea.
 - Lactose may be gradually reintroduced, provided that there is no concurrent infection, severe electrolyte imbalance, dehydration, or celiac crisis.
 - Nutrition counseling by a qualified dietician is an important component of treatment.
- Replacement iron, folic acid, vitamin K, vitamin D, and calcium should be initiated when appropriate.
- Compliance with GFD can be tracked by assessing serologic markers.
 - An increase in tTG antibody will be observed if the patient is noncompliant.
 - Weeks may be required for symptoms to disappear completely; subjective improvement occurs within the first few days.

WHEN TO ADMIT

- Failure to thrive and intractable diarrhea
- Dehydration and electrolyte abnormalities
- Celiac crisis

WHEN TO REFER

- Referral to a gastroenterologist is based on
 - Clinical suspicion
 - Presence of positive serologic markers
 - First-degree relatives with GSE
 - Syndromic presentations
 - Existence of other autoimmune disorders

FOLLOW-UP

- After GFD, monitoring serum tTG or endomysial antibodies (or both) is the preferred method for children >2 years.

COMPLICATIONS

- Celiac crisis
 - Triggers include:
 - Severe malnutrition
 - An infectious process
 - Poor compliance with GFD
 - Bacterial overgrowth caused by dysmotility
 - Hypoproteinemia
 - Patient needs to be admitted to the intensive care unit for further stabilization of electrolytes and fluids.
 - Once fluids have stabilized, start parenteral nutrition with total gut rest.
 - Slowly, introduction of a GFD with oral supplementation of iron, folic acid, vitamin D, and calcium should be attempted.
 - These patients might require prolonged total parenteral nutrition.

PROGNOSIS

- GSE means lifelong gluten restriction.
- Untreated patients risk developing gastrointestinal cancer in late adulthood.
- Refractory GSE occurs in 7–30% of patients.
 - Patients resistant to a GFD require therapy with immunomodulators.

Headache

DEFINITION

- Headaches are classified as primary or secondary.
- Primary headaches are directly attributed to a neurologic basis and include:
 - Migraine
 - Tension-type headaches (TTHs)
 - Cluster headaches
 - Other primary neuralgias
- Secondary headaches are attributed to a specific nonneurologic cause.
 - Infectious
 - Vascular
 - Traumatic
 - Toxic
 - Including medications and overuse of medications
 - Mass lesion

EPIDEMIOLOGY

- Prevalence
 - Headaches, particularly migraine, are being increasingly recognized as a significant health problem for children and adolescents.
 - Up to 75% of children report having a significant headache by the time they are 15 years of age.
 - Up to 28% of adolescents have had a migraine.
 - 10.6% of children between 5 and 15 years of age had significant headaches consistent with migraine.
 - There is an increasing 1-year prevalence in children between the ages of 10 and 19 years.
- Age and sex
 - In a meta-analysis of pediatric headache:
 - 1.2–3.2% of children between 3 and 7 years of age had migraine, with a slight male predominance.
 - Incidence of migraine increased to 4–11% between 7 and 11 years of age, with equal male and female occurrence.
 - Incidence of migraine increased to 18–23% between 11 and 15 years of age, with female predominance.
 - In the 15- to 19-year-old range, using the International Classification of Headache Disorders I (ICHD-I) criteria:
 - 28% of these adolescents had migraine.
 - Female predominance
 - Migraine without aura was more common than migraine with aura.
 - Mixed headaches were seen in 6.3% of the patients, with some TTHs in addition to migraines.

- 81% of adolescents with migraine had a positive family history.
 - Nearly one-quarter of female adolescents reported a relationship between headaches and menstruation.
 - Status migrainosus was noted in 14.8% of girls and 4.7% of boys.

- TTHs have been less well studied than migraine.
 - Estimates of prevalence in children range from 1–73%.
- Impact of headaches
 - 1989 National Health Interview Survey found that within a 2-week period, 975,000 children had a migraine, resulting in 164,454 missed school days.

MECHANISM

- Migraine has a genetic component.
 - Studies have shown a degree of inheritance as high as 90% in first- or second-degree relatives.
- TTHs are generally considered mild recurrent headaches, previously called *muscle contraction headache*, *idiopathic headache*, and *tension headache*.

HISTORY

- The first step in evaluating a child with headache is to rule out secondary causes.
 - Detailed headache history
 - Length of time the child has had headaches
 - Severity
 - Quality
 - Location
 - Frequency
 - The effect on the child's quality of life and disability
 - Factors that exacerbate and relieve the headaches.
 - Any aura before headaches
 - Detailed review of systems
 - Medical history
 - A psychosocial and family history to identify stressors that may be contributory

PHYSICAL EXAM

- Conducting a physical examination is important, with an emphasis on the neurologic examination.
 - Include a thorough search for potential sources of secondary headache.
 - Increased intracranial pressure
 - Sinusitis
 - Dental disease
 - Abnormalities of the cervical spine
 - Temporomandibular joint disorders

DIFFERENTIAL DIAGNOSIS

- After the detailed history and medical examination, it should be possible to determine whether the patient has a primary or secondary headache.

Secondary headache causes

- Head or neck trauma
- Cranial or cervical vascular disorder
- Nonvascular intracranial disorder
 - High-pressure headaches
 - Low-pressure headaches
- Substance use/abuse or withdrawal
 - Includes medication overuse headaches
- Infection
 - Meningitis
 - Encephalitis
 - Brain abscess
- Disorders of homeostasis or facial pain extending from
 - Cranium
 - Neck
 - Eyes
 - Ears
 - Nose
 - Sinuses
 - Teeth
 - Mouth
- Psychiatric disorders

Primary headache disorders

- Migraine
 - Migraine without aura, previously called *common migraine* or *hemicrania simplex*
 - Recurrent headache disorder
 - Attacks last 4–72 hours.
 - Typical characteristics
 - Unilateral location
 - Pulsating quality
 - Moderate or severe intensity
 - Aggravation by routine physical activity
 - Association with nausea, photophobia, phonophobia
 - Migraine with aura
 - Aura consists of visual, sensory, or speech symptoms.
 - Gradual development
 - Duration ≤ 1 hour
 - Complete reversibility
 - In addition to the aura, the headache will have symptoms of migraine without aura.

- Childhood periodic syndromes
- Retinal migraine
- Complications of migraine
 - Chronic migraine
 - Frequent headaches (≥ 15 times per month for the previous 3 months)
 - Presence of migraine features
 - Cannot be attributed to a secondary cause
 - Status migrainosus
 - Probable migraine

- TTHs
 - Generally considered mild recurrent headaches
 - Many features are the opposite of those of migraine.
 - TTHs can be subdivided based on frequency.

- Infrequent, episodic

- Frequent, episodic

- Chronic

- The headaches themselves are usually described as:

- Mild and moderate in severity
- Diffuse in location
- Having a pressing quality
- No secondary causes are identified.

- Cluster headache

- Trigeminal autonomic cephalalgias

- Other primary headaches

IMAGING

- If abnormalities on the neurologic examination cannot be explained by medical history, then neuroimaging may be required to identify a medically or surgically treatable cause of the headaches.

TREATMENT APPROACH

- In patients with secondary headaches, the treatment goal is to address the underlying cause.
 - Headaches should resolve once the underlying cause is addressed.
- Treatment of primary headache disorders in children must be 3-fold.
 - Acute therapy
 - Preventive therapy
 - Biobehavioral therapy
- Clear goals of treatment must be discussed with the patient and parents.

SPECIFIC TREATMENT

Short-term therapy

- Short-term therapy is designed to ameliorate the episodic headache.
- The goal of this treatment is a quick return to normal activity without relapse.
- For headache in children, medications include:
 - Nonsteroidal antiinflammatory drugs (NSAIDs)
 - Ibuprofen, naproxen sodium
 - Ibuprofen has become a mainstay for the acute treatment of childhood headaches and migraines.
 - Good tolerability
 - Effective in clinical trials
 - Proper use of ibuprofen requires:
 - Identification by the child of onset of the headache
 - Initiation of rapid treatment
 - Proper dosing based on weight
 - Avoidance of overuse; limited to ≤ 3 times per week
 - Aspirin for older children
 - General pain relievers, eg, acetaminophen
- Most prescriptive nonspecific medications have either not been evaluated in children or have not been proven effective.
- Many prescriptive medications contain sedatives or narcotics that may treat the pain but do not allow the child to return to normal functioning.
- When NSAIDs are ineffective or not completely effective, migraine-specific therapy is often required.
- Triptans
 - Triptans are 5-HT_{1B-1D} agonist migraine-specific medications.
 - Currently, 7 triptans have been approved for use in the US in adults.
 - Not approved for use in childhood migraine
 - Several studies in children, however, have shown their effectiveness.
 - Sumatriptan, zolmitriptan, rizatriptan
 - Two treatment methods may be used when prescribing triptans: rescue therapy or stepwise treatment within an attack.
 - The child starts with an NSAID at an appropriate dose at the onset of the headache.
 - If this medication is not working, then a triptan is used as rescue therapy.
- The stratified care model requires the patient to determine the headache severity at the onset.
 - For a mild or moderate headache, the patient takes an NSAID.
 - For a severe headache, the patient takes a prescribed triptan.
 - In this way, patients stratify their headaches and the subsequent treatment.
 - This method has not been successful in children because they often have difficulty recognizing the headache severity at its onset.
- Dihydroergotamine (DHE)
 - Ergot alkaloids have a long history of usefulness in migraines.
 - Frequently used in the emergency management of childhood headaches
 - Limited reports have shown usefulness of intravenous DHE in an inpatient setting.
 - Breaks status migrainosus or prolonged migraines in children
 - The effect may be enhanced if patients are premedicated with dopamine antagonists.
- Dopamine antagonists (prochlorperazine, metoclopramide)
 - Initially used for nausea and vomiting effects of migraine headaches
 - The dopaminergic model of migraine was developed, and these medications have been reanalyzed for usefulness in short-term therapy of the headaches themselves.
 - Dopamine antagonists should be given intravenously.
 - Their utility is limited by extrapyramidal side effects.
 - It is suggested that prochlorperazine can be used to break an acute episode of status migrainosus.
 - Best given with rehydrating fluids in the emergency department setting

Prophylactic treatment

- The second component of effective headache treatment
- Should be instituted when the headache or migraine becomes frequent or disabling
- Goals
 - Minimize the effect of the headache
 - Reduce the number of headaches
- A clear diminishment in severity and headache features may be observed.
- Having $>2-3$ headaches per month typically warrants treatment.

- For all prophylactic medications, titrate doses slowly to an effective level.
 - Requires understanding by the patient and family that this may be a lengthy process (weeks, months)
 - Failure to respond may be due to:
 - Inadequate time of treatment
 - Inadequate dosing
- Prophylactic medications can be grouped into:
 - Antiepileptics
 - Only divalproate sodium and topiramate are currently approved for the prevention of migraines in adults; they are not approved for children.
 - Divalproate sodium
 - 15–20 mg/kg/day
 - Topiramate
 - 2–4 mg/kg/day
 - Taper up to this dose slowly, in quarter steps, over 8–10 weeks.
 - Gabapentin
 - Levetiracetam
 - Zonisamide
 - Antidepressants
 - The most widely used tricyclic antidepressant for headache prevention is amitriptyline.
 - Has been used for many decades for its antidepressive properties
 - First recognized in the 1970s as an effective migraine therapy
 - Most studies in children with amitriptyline have been open-label studies; there are no placebo-controlled studies.
 - Amitriptyline was found to be effective in 50–60% of children in a cross-over study comparing amitriptyline with propranolol and cyproheptadine.
 - In an open-label study, amitriptyline resulted in a perceived improvement in >80% of the children.
 - Titrate slowly to the full dose over 8–10 weeks to minimize side effects, particularly somnolence.
 - Nortriptyline has been used instead of amitriptyline.
 - Potential for increased arrhythmias
 - Regular electrocardiographic evaluation may be required if nortriptyline is chosen.
 - Serotonin selective reuptake inhibitors have been studied for the treatment of headaches in adults; it has not yet been studied in children.
 - Effectiveness is not as notable as that of tricyclic antidepressants.
 - Suggests that a more global decrease in neurotransmitter reuptake inhibition is needed to treat childhood headache disorders
- Antiserotonergic medications
- Cyproheptadine has long been used for preventing childhood headaches.
 - Antihistamine with antiserotonergic effects
 - May have some calcium channel–blocking properties
 - Tends to be well tolerated
 - Increased weight gain is the most significant side effect.
 - Because weight gain is substantial, use of this medication tends to be limited to younger children.
- Antihypertensive medications
- β -Blockers have a long history of use for preventing childhood headaches.
 - Propranolol was found to provide mixed responsiveness when used for childhood headaches.
 - Even with their long history, β -blockers have limited usefulness in children.
 - They cause a decrease in blood pressure.
 - There is a risk for exercise-induced asthma.
 - They can result in depressive effects.
- Calcium-channel blockers have been extensively studied in adults for headache prevention.
 - Flunarizine has been demonstrated to be an effective migraine preventive agent.
 - Available in Europe but not in the US.
 - Baseline headache frequency was significantly reduced in flunarizine-treated children.
 - These data cannot be extrapolated to other calcium-channel blockers.

Biobehavioral therapy

- Third component of effective headache treatment
- Essential for children to maintain a lifetime response to the treatment and management of their headaches
- Biobehavioral therapy can be divided into 3 components.
 - Treatment adherence
 - A clear understanding by the patient and parent about the importance of the treatment is essential.
 - Psychological or biobehavioral intervention may be useful in assisting with adherence by identifying roadblocks to the medical plan and helping to overcome these barriers.
 - Lifestyle management
 - In many instances, unhealthy lifestyle habits serve as a trigger for childhood headaches.
 - Inadequate nutrition
 - Skipping meals
 - Altered sleep patterns

- Maintaining healthy lifestyle habits includes:
 - Adequate fluid hydration, with limited use of caffeine
 - Regular exercise
 - Adequate nutrition through regular meals and a balanced diet
 - Adequate sleep
 - The patient and parents must understand that these objectives are lifetime goals that can control the effect of migraines and minimize the use of medication.
 - Lifestyle changes may result in an overall long-term improvement in quality of life and may reverse any progressive nature of the disease.
- Biofeedback-assisted relaxation therapy
 - May be a useful addition
 - For children, single-session biofeedback-assisted relaxation therapy has been demonstrated to be learned quickly and efficiently.
- Disability
 - Pediatric Migraine Disability Assessment (PedMIDAS) uses a patient-based disability scale.
- Quality of Life
 - Pediatric Quality of Life Inventory version 4.0 (PedsQL 4.0) uses both parent and child input.
 - Evaluates functioning in health, emotional, social, and school domains
 - Headaches have been found to substantially affect emotional development and school functioning.

WHEN TO REFER

- Headaches that do not respond routinely to acute treatment
- Headaches that are increasing in frequency, severity, or duration
- Headaches in which the features acutely change
- Side effects of medications that limit increasing the medication to an effective dose
- Psychological factors that interfere with management
- Disability that impairs functioning

WHEN TO ADMIT

- Admission or emergency department treatment should be considered when:
 - Home therapies are ineffective for acute treatment.
 - Headache has continued for >24 hours.
 - Headache pain becomes intolerable.

FOLLOW-UP

- Important to assess regularly the morbidity of headaches and effectiveness of treatment
- Regular measurement of both disability and quality of life are helpful in assessing treatment strategies and improvement in outcomes.

COMPLICATIONS

- Avoiding overuse of medication is critical in short-term therapy.
- Overuse can cause analgesic rebound headaches.
 - Transformed migraines
 - Chronic daily headaches
- Overuse of medication is characterized by inadequate treatment of headache.
 - Low-dose or delayed treatment
 - Increase in analgesic use over time, with decreased effectiveness
 - When rebound headaches are identified, a recovery period free of analgesic use is required.
- Allodynia
 - A painful or heightened sensation beyond the location of the headache
 - Once allodynia has been established, patients have decreased response to medication.
 - For these patients, stress the need for early treatment.

PROGNOSIS

- Primary headaches can have a significant effect on a child's life.

Head Injuries

DEFINITION

- *Traumatic brain injury* (TBI) is a leading cause of death and disability in the US.
- *Primary brain injury* refers to the neural injury caused by the traumatic insult itself and exhibits in the form of:
 - Contusions
 - Intracranial bleeding
 - Fractures
 - Diffuse axonal injuries
- *Secondary brain injury* refers to the subsequent injury to neural tissue after trauma has occurred.
- *Concussion* is any head injury associated with alteration in mental status.
- *Cerebral contusions* are bruises of the cerebral cortex that can occur as a result of:
 - Direct injury (coup injury)
 - Injury at the opposite point where the relatively mobile brain strikes the bone on the other side (contrecoup injury)
- *Growing fractures* occur as a result of leptomenigeal cyst formation and frequently require neurosurgical closure.
- *Diffuse axonal injury* refers to damage at the gray-white matter junction, seen after an acceleration-deceleration mechanism.

EPIDEMIOLOGY

- Incidence
 - 1.6 million head injuries occur every year.
 - 250,000 require hospitalization.
 - 60,000 deaths are caused by head injuries occur every year.
- Prevalence
 - 70,000–90,000 patients are left with permanent neurologic sequelae.
- Cost
 - \$100 billion per year
 - In 2000 injuries to children <14 years old were projected to have a total lifetime economic costs >\$50 billion in medical expenses and lost productivity.
- Age
 - Among children age 0–14 years, TBI results annually in:
 - ~2685 deaths
 - 37,000 hospitalizations
 - 435,000 emergency department (ED) visits
 - ~50% of patients hospitalized with head injury are <20 years of age.
 - >75% of trauma deaths in children are due to brain injury.
 - Skull fractures occur in approximately 2 per 1000 infants and 0.5 to 1 per 1000 older children and adolescents.
- Sex
 - Boys are injured twice as often as girls.

ETIOLOGY

- The brain is covered by 3 layers of meningeal tissue (pia mater, arachnoid mater, and dura mater), followed by the skull bones (calvarium) and scalp, which has a strong layer of tissue (galea aponeurotica).
- The brain does not adhere to the skull, but is able to move freely within it, cushioned by cerebrospinal fluid.
- Causes of primary brain injury vary with age.
 - In infants
 - Falls
 - Child abuse
 - In preschool and school-age children
 - Vehicular accidents
 - In adolescents
 - Sports injuries
 - Assault
 - For all ages
 - Falls are the most common cause of head trauma.
 - Vehicular accidents are the leading cause of serious injury.
 - In most cases, the child is a pedestrian.
- Secondary brain injury results from numerous causes, including:
 - Hypoxia
 - Hypoperfusion
 - Excitotoxic damage
 - Free radical damage
 - Metabolic derangements
- Damage caused by secondary brain injury can be more devastating than that from the primary insult itself.
- The most important cause for secondary brain injury is brain ischemia resulting from inadequate cerebral blood flow.
 - Adequate cerebral blood flow depends on the cerebral perfusion pressure, which is the difference between mean arterial pressure and intracranial pressure (ICP).
 - Normally the cerebral perfusion pressure fluctuates inside a narrow range, the result of cerebral autoregulation.
 - When this control mechanism is lost because of brain injury and secondary brain tissue damage, an increase in intracranial volume (mainly the result of intracranial hemorrhage or cerebral edema) will lead to a disproportionate increase in ICP.
 - This increase further accentuates neuronal damage by reducing cerebral blood flow.
 - An increase in ICP leads to cerebral herniation syndromes.
 - These syndromes are characterized by:
 - Worsening of sensorium
 - Pupillary changes

- The Cushing triad
 - Bradycardia
 - Irregular respirations
 - Hypertension

RISK FACTORS

- Most children hit by a vehicle are not supervised by an adult at the time of the accident.

SIGNS AND SYMPTOMS

History

- The possibility of child abuse must be kept in mind.
 - Suggested when the given history is not proportional to the severity of injury
 - For instance, children rarely experience a serious injury when they fall out of bed.
- Indicators of severe head trauma include:
 - Loss of consciousness
 - Seizures
 - Amnesia for the circumstances surrounding the injury
 - Focal neurologic deficits
- Vomiting and headache are common symptoms after head trauma.
 - If not persistent or severe, they are not suggestive of any specific pathologic finding.
- Persistent clouding of consciousness is the most reliable sign of a significant brain injury.
- The duration of posttraumatic amnesia, defined as an inability to generate new memories after head injury, correlates positively with the severity of the injury.

Physical examination

- A detailed neurologic evaluation should be performed only when adequacy of the airway, breathing, and circulation are ensured.
- Should begin with assessment of mental status and assignment of a Glasgow Coma Scale (GCS) score
- Neurologic examination begins with assessment of the cranial nerves.
- Particular attention needs to be given to:
 - Pupillary responses and symmetry
 - Funduscopic examination (to rule out papilledema or hemorrhage)
 - Retinal hemorrhage suggests child abuse.
 - Eye movements (to assess for dysconjugate gaze)
 - Asymmetries of facial sensation or movement
 - Tongue movement
 - Gag reflex

- As a sensory screening examination, symmetrical responses to pain in all 4 limbs should be determined.
- The motor examination should assess:
 - Symmetry of muscle tone and movement and of the deep-tendon reflexes and plantar responses
 - The alert, cooperative child's ability to manipulate small objects
 - The child's gait and station
- General physical examination should focus on:
 - Presence of injury to other body systems
 - Seeking evidence of physical neglect or abuse
- The GCS (see table Glasgow Coma Scale), or a modified GCS for children and infants, can be used to evaluate mental status, assess prognosis, and follow the patient's progress.
 - The scale is based on the patient's response in 3 areas.
 - Motor response
 - Verbal response
 - Eye-opening response
 - Severe head injury may be defined as that resulting in a GCS score <9.
 - Moderate head injury is associated with a score of 9 to 12.
 - A score of 13–15 indicates a mild head injury.
- Pontine and midbrain function may be assessed by examining oculovestibular reflexes.
 - In the unconscious patient, the head should be rotated briskly from side to side after confirming there is no cervical spine injury.
 - Normally, when the head moves to the right, the eyes move to the left, and vice versa.
 - Loss of these reflex eye movements in a comatose patient suggests an injury to the midbrain or pons.
 - If the tympanic membranes are intact, then ice water caloric responses should be elicited.
 - With the patient's head elevated to 30 degrees, 120 mL of ice water is infused alternately into each ear canal.
 - The eyes should turn toward the irrigated ear.
 - If they do not, then a brainstem injury is likely.
 - To assess pontine function, the quality and symmetry of the grimace evoked by painful stimulation of the face should be observed.
 - In patients who do not respond to this stimulation, or in those who do so minimally, corneal reflex should be tested.
 - Failure to react by blinking is consistent with pontine injury or deep coma.
- Medullary function is evaluated by assessing the patient's gag reflex and tongue movement.
 - Examination of the patient's craniospinal axis should be performed in concert with the neurologic assessment, assessing for signs of trauma.

Glasgow Coma Scale^{a,b}

Eye-Opening Response			
Score	>1 Year	<1 Year	
4	Spontaneous	Spontaneous	
3	To verbal command	To shout	
2	To pain	To pain	
1	None	None	
Motor Response			
Score	>1 Year	<1 Year	
6	Obeys commands	Displays spontaneous response	
5	Localizes pain	Localizes pain	
4	Withdraws from pain	Withdraws from pain	
3	Displays abnormal flexion to pain (decorticate rigidity)	Displays abnormal flexion to pain (decorticate rigidity)	
2	Displays abnormal extension to pain (decerebrate rigidity)	Displays abnormal extension to pain (decerebrate rigidity)	
1	None	None	
Verbal Response			
Score	>5 Years	2–5 Years	0–23 Months
5	Is oriented and converses	Uses appropriate words and phrases	Babbles, coos appropriately
4	Conversation is confused	Uses inappropriate words	Cries, but is consolable
3	Words are inappropriate	Cries or screams persistently to pain	Cries or screams persistently to pain
2	Sounds are incomprehensible	Grunts or moans to pain	Grunts or moans to pain
1	None	None	None

^a Modified from: Teasdale G, Jennett B. Assessment of coma and impaired consciousness: a practical scale. *Lancet*. 1974;304(7872):81–84. Copyright © Elsevier 1974.

^b Glasgow Coma Scale score equals sum of best eye opening, motor, and verbal responses. Range is 3–15. Usual definitions of severity of head injury: severe, ≤9; moderate, 9–12; mild, 13–15.

- Swelling and bony depression of the skull suggests an underlying fracture.
- Signs of basilar skull fracture include:
 - Ecchymoses behind the ear (the Battle sign)
 - Ecchymoses around the orbits (raccoon sign)
 - Cerebrospinal fluid rhinorrhea
 - Otorrhea
 - Hemotympanum
- Basilar fractures or scalp lacerations overlying fractures serve as portals of entry for bacteria into the subarachnoid space and may cause meningitis .
- Most concussion patients can be discharged home after a period of evaluation and observation.
- Thorough evaluation is important, and the physician should advise parents regarding the child's return to sports.
- Guidelines for assessment and management of concussion from the American Academy of Neurology are presented in table Classification of Concussion.
- Skull fractures
 - The most common bone to fracture is the parietal bone.
- Parenchymal injuries
 - Clinical manifestations vary, but patients often exhibit:
 - Alteration in consciousness
 - Focal seizures
 - Focal neurologic findings (eg, cortical blindness in cases of occipital lobe injury)

DIFFERENTIAL DIAGNOSIS

■ Concussion

- Mild head injury with a GCS score of 13–15 and no focal neurologic findings

Classification of Concussion^{a,b}

Grade	Definition	Management
1	<ul style="list-style-type: none"> • Transient confusion • No loss of consciousness, mental status abnormalities for <15 min 	<ul style="list-style-type: none"> • Return to sports activities same day only if all symptoms resolve within 15 min • If a second grade-1 concussion occurs, no sports activity until asymptomatic for 1 week
2	<ul style="list-style-type: none"> • Transient confusion • No loss of consciousness, mental status abnormalities for >15 min 	<ul style="list-style-type: none"> • No sports activity until asymptomatic for 1 week • If a grade-2 concussion occurs on the same day as a previous grade-1 concussion, no sports activity for 2 weeks
3	<ul style="list-style-type: none"> • Concussion involving any loss of consciousness 	<ul style="list-style-type: none"> • No sports activity until asymptomatic for 1 week if loss of consciousness was brief (seconds) • No sports activity until asymptomatic for 2 weeks if loss of consciousness was prolonged (minutes or longer) • Second grade-3 concussion <ul style="list-style-type: none"> – No sports activity until asymptomatic for 1 month • Any abnormality on CT or MRI <ul style="list-style-type: none"> – No sports activity for remainder of season – Patient should be discouraged from any future return to contact sports

Abbreviations: CT, computed tomography; MRI, magnetic resonance imaging.

^a Modified from: Quality Standards Subcommittee, American Academy of Neurology. Practice parameter: the management of concussion in sports (summary statement). *Neurology*. 1977;48:581–585.

^b Concussion symptoms: early (minutes and hours)—headache, dizziness or vertigo, lack of awareness of surroundings, nausea or vomiting. Late (days to weeks)—persistent low-grade headache, light-headedness, poor attention and concentration, memory dysfunction, easy fatigability, irritability and low frustration tolerance, intolerance to bright lights or difficulty focusing vision, intolerance of loud noises, sometimes ringing in the ears, anxiety or depressed mood, sleep disturbance.

■ Diffuse axonal injury

- Often seen after an acceleration-deceleration mechanism (whiplash injury)
- Damage is at the gray-white matter junction.
- Most children will experience changes in sensorium.
- Some studies have reported that 82% will develop coma.

■ Intracranial hematoma

- Hematomas can occur anywhere in the intracranial space.
- Differences between the 2 most common types—epidural and subdural—are described in table Differences Between Epidural and Subdural Hematomas.

IMAGING

■ Cervical spine films to rule out fracture or subluxation

- Most ED physicians do not obtain cervical spine radiographs if:
 - Mental status and neurologic examinations are normal.
 - No tenderness of the spine is present.
 - The child moves his or her head around without difficulty, especially if >5 years of age.
 - The younger the child is, the lower the threshold for obtaining cervical spine films.

■ Noncontrast computed tomography (CT) of the brain with bone windows

- CT is the imaging study of choice in acute trauma.
 - Easier to obtain than magnetic resonance imaging (MRI)
 - May not require sedation
- CT identifies the relationship between bone fragments and intracranial contents.
- CT reveals extraaxial fluid collections such as epidural and subdural hematomas.
- CT often detects parenchymal brain injury.
- Has supplanted the use of skull radiographs
- All high-risk head injury patients require cranial CT.

■ Disadvantages of CT

- Exposure to radiation
 - Lifetime attributable cancer mortality risk for a child after a typical head CT is estimated at 1 per 5000.
 - Cranial CT should be used selectively in the ED evaluation of children with minor blunt head trauma.
- Transport of the child away from supervision in the ED
- Potential need for pharmacologic sedation
- Additional health care costs
- Increased time for completing the ED evaluation

Differences Between Epidural and Subdural Hematomas

Characteristic	Epidural Hematoma	Subdural Hematoma
Mechanism	Direct trauma that leads to bleeding from middle meningeal artery or shearing of epidural veins	<ul style="list-style-type: none"> • Shaking (acceleration-deceleration) injury leading to tearing of bridging veins in the subdural space. • In young children, this may result from child abuse.
Clinical manifestations	<ul style="list-style-type: none"> • Lucid interval—symptom-free interval between time of injury and time of manifestation can be seen • Patients run the gamut from asymptomatic to those who exhibit focal seizures and coma 	<ul style="list-style-type: none"> • Lucid interval unlikely. • Many children have coma, seizures, or evidence of chronic changes (tense anterior fontanelle, macrocephaly).
Investigations	CT is diagnostic for a lenticular lesion with an overlying fracture	<ul style="list-style-type: none"> • CT reveals blood collection as a hyperdense crescentic collection along the cerebral hemisphere. • In cases of child abuse, hemorrhage of different ages can be seen with changes suggestive of hydrocephalus.
Management	Craniotomy with drainage of hematoma and repair of the ruptured blood vessel	Management will vary depending on extent of bleeding, and in some cases, ICP monitoring with expectant observation may be the only therapy; intracranial evacuation of blood clot may be the therapy of choice for some cases.
Prognosis	Excellent after initial insult is adequately treated	Poor, with high mortality and high morbidity (sequelae).

Abbreviations: CT, computed tomography; ICP, intracranial pressure.

- MRI may be useful in later assessments because it is more sensitive than CT at detecting intrinsic brain injuries, such as diffuse axonal injury.

TREATMENT APPROACH

Emergency care

- The basic ABCs of resuscitation (airway, breathing, and circulation) should be addressed first.
- Maintaining normal oxygenation is imperative.
 - Ischemia, increased ICP, and uncontrolled seizures may cause further brain injury.
 - Correction of anoxia and poor cerebral perfusion is more important than detection of an intracranial hematoma.
- Coexisting cervical spine injury should be assumed until proved otherwise.
 - The neck should not be moved until cervical spine films can rule out a fracture or dislocation, which may result in spinal cord trauma if movement occurs.
 - The preferred initial radiographs are cross-table lateral, anteroposterior, and odontoid views.
- In the severely injured patient, the airway requires intubation to ensure adequate ventilation to reduce the chance of developing increased ICP.
 - When possible, an anesthesiologist should perform the intubation.
 - Rapid sequence intubation is indicated for most patients with head injuries to ensure that they are comfortable and that intubation can be safely achieved.
 - This task is usually accomplished with a combination of:
 - Sedative to induce anesthesia (thiopental, etomidate, fentanyl, or midazolam)
 - Atropine to reduce secretions and prevent vagal reflexes
 - Neuromuscular blocking agent to produce paralysis (rocuronium or succinylcholine)
 - Close attention to blood pressure is necessary because sedatives may cause hypotension.
 - Cricoid pressure may be applied to reduce the risk of aspiration.
 - Prolonged hyperventilation is no longer suggested for patients with acute severe head injury.

SPECIFIC TREATMENTS

Secondary brain damage

- Once TBI has been detected and the patient resuscitated, subsequent management is directed at preventing secondary insults.

- The most important causes of secondary brain damage are:
 - Hypoxia
 - Systemic hypotension
 - Increased ICP (intracranial hypertension)
- Vital signs should be frequently assessed to ensure adequacy of circulation.
- Shock leads to further brain injury despite adequate airway management and oxygenation.
- Vigorous fluid therapy to restore adequate circulating blood volume and sufficient cerebral perfusion is essential.
- Isotonic solutions or blood products
 - Preferred because hypotonic solutions may promote movement of free water into damaged brain tissue, increasing the potential for cerebral edema
 - Some authorities argue for the use of hypertonic solutions in acute severe brain trauma, although this approach is not widely used.
- If the patient is in shock, then a source of bleeding should be sought.
- Patients rarely sequester sufficient blood volume in the head to produce shock
 - Notable exceptions: the infant with an expansible skull, the presence of a large subgaleal hematoma
- Additional measures directed at reducing secondary brain injury
 - Elevation of the patient's head 30 degrees
 - Maintenance of the head in a midline position to maximize venous outflow from the cranial vault
- ICP should be monitored and decreased if necessary.
 - Placement of an intracranial ventricular catheter is the most accurate and reliable method for monitoring ICP.
 - Intracranial hypertension is defined as an ICP of >20 mm Hg.
 - Cushing response (hypertension and bradycardia) implies increased ICP.
 - This response and unilateral pupillary dilation (a sign of impending catastrophic temporal lobe herniation) should prompt administration of mannitol.
 - Reduction of cerebral metabolism by initiating barbiturate coma may improve outcomes and should be considered when pediatric neurosurgeons and pediatric intensive care units are available.
 - The role of therapeutic hypothermia in the treatment of children with severe TBI is still unclear.
 - Corticosteroids do not improve outcome when used in acute-phase management of TBI.
- Antipyretics should be administered to reduce fever.
 - Hyperthermia may increase cerebral metabolic demands, further taxing delivery of nutrients to the injured brain.

- Seizures greatly increase metabolic demands of the brain and should be treated promptly with intravenous diazepam or lorazepam, followed by intravenous phenytoin.
- Intravenous phenytoin should be provided if the patient is pharmacologically paralyzed because it results in an inability to detect seizure activity.
- Intravenous phenytoin is advisable before transfer to another medical center.

Types of TBI

- Concussion
 - Most patients can be discharged home after a period of evaluation and observation.
 - Physician should advise parents regarding the child's return to sports (table Classification of Concussion).
- Skull fractures
 - Linear skull fractures often require no intervention.
 - Admit the child for a period of observation.
 - Depressed skull fractures are often associated with underlying brain abnormalities and may require surgical interventions.
 - Basilar skull fractures are often associated with cerebrospinal fluid leakage and cranial nerve damage.
 - Require pediatric neurosurgical intervention
 - Should be managed at tertiary-care pediatric trauma centers
- Diffuse axonal injury
 - Most patients will need hospitalization along with ICP monitoring in the intensive care unit.

Care of the less severely injured patient

- Intermediate-risk patients might be managed in 1 of 2 ways.
 - 4- to 5-hour period of observation and reevaluation
 - Head CT
- Low-risk patients may be observed in the ED or at home with reliable caretakers.
- Management of closed head trauma
 - In 1999, the AAP published guidelines for the management of closed head trauma in previously healthy children 2–20 years of age.
 - This consensus statement used historical features of loss of consciousness and presence of symptoms as an indication for CT of the head.
 - For children without a loss of consciousness, a complete history and a physical examination should be performed.
 - The caregiver should observe the patient for any deterioration in mental status.
 - For patients who have a history of a brief loss of consciousness, along with amnesia, headache, or vomiting at the time of evaluation, the prevalence of intracranial injury may be as high as 7%.

- Many of these brain injuries have little clinical consequence.
 - A minority of these children may require neurosurgical intervention.
 - In symptomatic children with a brief loss of consciousness, CT of the head may be useful.
 - With a brief loss of consciousness in an otherwise asymptomatic patient, observation for neurologic deterioration may be an acceptable alternative to head CT.
 - The following 5 clinical findings have been found to identify 99% of all children with TBI on CT and 100% of those who required neurosurgery.
 - Abnormal mental status
 - Clinical signs of skull fracture
 - Scalp hematoma
 - History of headache
 - Vomiting
 - A clinical decision rule excludes TBI in need of neurosurgical intervention (negative predictive value of 100%) when none of these 5 clinical variables is present.
 - Use of this rule will reduce unnecessary exposure to radiation from CT by 25%.
- Discharge home
- Patients with mild head injury can be discharged home with appropriate instructions so long as they:
 - Promptly recover their neurologic function
 - Are not suspected of being abused
 - Have reliable caregivers
 - Children with normal neurologic examinations and negative CT rarely have neurologic deterioration after discharge from the ED.
 - Parents are often instructed to observe the child carefully for at least 24 hours, periodically awakening the child from sleep.
 - Caregivers should return immediately to the ED if their child:
 - Cannot be awakened
 - Demonstrates decreasing mental status while awake
 - Develops seizures, focal weakness, increasing headache, progressive instability, or vomiting to the point of dehydration
 - Linear skull fractures do not require admission to the hospital if the child is asymptomatic; they do require close observation because of the significant force required to fracture the skull.
 - After hospital or ED discharge, office follow-up is suggested at 2 weeks.
 - Recovery can be reviewed and further anticipatory guidance provided to the family regarding relevant neurologic sequelae.
- Children <2 years who have diastatic fractures (fractures that involve normal suture lines) should be evaluated again in 6–8 weeks to check for a growing fracture .
- WHEN TO ADMIT**
- Persistent alteration in mental state
 - Focal neurologic deficits
 - Seizures
 - Persistent vomiting that precludes adequate hydration
 - Severe headache
 - Suspicion of abuse
 - Unreliable caregivers or observers at home
 - Any injury requiring neurosurgical intervention
 - CT indicating intracranial bleeding or brain injury
- Admission of the less severely injured patient**
- The decision to admit a child with mild to moderate head trauma must be individualized.
 - Controversy exists regarding the use of clinical signs and symptoms to identify children at risk for TBI after blunt trauma.
 - Guidelines have been proposed in the approach of children with blunt injury.
 - These children have been traditionally divided into 2 groups.
 - Age ≤ 2 years
 - A multidisciplinary panel suggested stratifying patients into risk categories based on clinical features (eg, history and physical examination, mechanism of injury, presence or absence of skull fracture).
 - Between 2 and 20 years of age
 - Patient characteristics
 - High-risk patients have any of the following.
 - Depressed mental status
 - Focal neurologic findings
 - Signs of depressed or basilar skull fracture
 - Seizure
 - Irritability
 - Acute skull fracture
 - Bulging fontanelle
 - >5 episodes of vomiting or vomiting for >6 hours
 - Loss of consciousness that lasts >1 minute
 - Intermediate-risk patients have any of the following characteristics.
 - Vomiting 3–4 times
 - Loss of consciousness that lasts for <1 minute
 - History of lethargy or irritability, now resolved
 - Caretakers concerned about current behavior
 - Higher force mechanism
 - Hematoma (especially large or nonfrontal in location)

- Unwitnessed trauma
- Fall onto a hard surface
- Vague or no history of trauma with evidence of trauma
- Nonacute skull fracture older than 24–48 hours
- Patients in this category might be managed in 1 of 2 ways.
 - 4- to 5-hour period of observation
 - Reevaluation or a head CT
- Low-risk patients have:
 - Low-energy mechanism (eg, a fall of <3 feet)
 - No signs or symptoms
 - >2 hours since the injury
 - As the patient's age increases, the risk decreases.

WHEN TO REFER

- Deteriorating mental status
- Coma or persistent alteration in mental status
- A GCS score <9
- Subdural, epidural, or intraparenchymal hematoma
- Focal abnormalities on neurologic examination
- Seizures after the first week or recurrent seizures
- Shock
- Signs of Cushing response (bradycardia and hypertension)
- Suspicion of child abuse (refer to appropriate local governmental agency)
- Cervical spine injury
- Basilar skull fracture
- Depressed skull fracture
- Increasingly severe headaches
- Facial laceration or suspicion of significant trauma at other locations

PROGNOSIS

- Children who experienced mild head trauma (GCS score of 13–15) are indistinguishable from their peers 1 year after their injuries.
 - Significant neurologic dysfunction may be seen immediately after the child's injury and may persist for as long as 8 weeks.
 - Symptoms include:
 - Irritability
 - Sleep disturbance
 - Clinging behavior
 - Hyperactivity
 - Headache

- Anticipatory guidance for parents regarding the transient nature of these symptoms in mild head injuries is important.
- Children who have moderate head injury (GCS score of 9–12) and severe head injury (a score of 3–8) may suffer from multiple physical, cognitive, and psychological disabilities.
 - Prognosis is generally more favorable for head-injured children than adults.
 - Children with an initial GCS score >6 have an 80% chance of achieving functional independence.
 - Intellectual recovery continues for as long as 2 years after head injury in children.
 - Long-term rehabilitative services are needed.
 - Formal psychological assessment for staging school reentry and for ongoing adjustment of the child's academic curriculum should be obtained.
- 5% of patients will experience seizures within the first week after their head injury.
 - Occurrence of these early-onset seizures does not accurately predict development of later posttraumatic epilepsy.
 - The risk of subsequently developing epilepsy is significantly increased if seizures are present beyond the first week after head injury, particularly with severe head trauma, intraparenchymal hematoma, or depressed skull fracture.
 - With these risk factors, approximately one-third of patients will develop posttraumatic epilepsy.
 - Electroencephalographic studies do not accurately predict subsequent development of epilepsy; use of prophylactic anticonvulsant medications does not appear to reduce risk.
 - Anticonvulsants are generally not used in mild brain injury but are indicated for children with severe brain injury to prevent increased ICP caused by seizures per se.

PREVENTION

- Education regarding prevention of head injury is essential.
 - Anticipatory guidance can dramatically reduce the morbidity and mortality that result from head injury and includes:
 - Appropriate supervision of children
 - High-risk activities
 - Protective equipment
 - Car seats for infants
 - Bicycle helmets for older children

Hearing Loss

DEFINITION

- Pediatricians must recognize the signs, symptoms, and risk factors for hearing loss and become aware of appropriate referral paths.
 - Pediatricians are usually the first health care practitioners approached by parents who have concerns about their child's hearing.
 - Parents become concerned about the child's hearing at ~6 months of age when the hearing loss is severe.
 - Milder degrees of hearing loss typically do not generate concern until the child reaches school age.
 - Patterns of hearing loss that are termed *mild* or *minimal* are far from benign and cause academic, communicative, social, and emotional difficulty for school-age children.

EPIDEMIOLOGY

- Advent of vaccines for rubella and meningitis
 - Virtually eliminated hearing loss caused by congenital rubella
 - Dramatically reduced hearing loss resulting from meningitis
- Prevalence
 - Severe to profound hearing loss is not as common as it once was.
 - The incidence of severe bilateral hearing loss in newborns is 1 per 1000.
 - Milder degrees of hearing loss are more prevalent.
 - The incidence of very mild or minimal losses approach 1 per 20.
 - In the neonatal intensive care unit, hearing loss is seen in ~20 to 40 per 1000 babies.
 - In the course of a typical practice a pediatrician will encounter approximately a dozen children with severe to profound hearing loss.
- Impact
 - ~35% of children with minimal hearing loss fail ≥ 1 grade in school, compared with an overall failure rate of ~3%.

MECHANISM

- Newborn hearing screening is widespread, however such screening programs are designed to identify moderate degrees of hearing loss and greater.
- A child who passed a hearing screening as a newborn may still have hearing loss.
- Hearing loss from otitis media is the most common type of loss encountered by pediatricians.

HISTORY

- Approximately 35–50% of children with hearing loss have no known risk factors.
- Complete history and observation accompanied by hearing screening are essential.

- Significant speech and language delays, because of their association with severe to profound hearing loss, provide a high level of suspicion.
- A history of any of the following should also prompt screening for hearing loss.
 - Behavioral problems
 - Social difficulties
 - Academic difficulties
- Parents' comments and potential explanations for mild-to-moderate hearing loss.
 - "He can hear me when he wants to hear me. Sometimes he just ignores me."
 - With mild hearing loss, little or no difficulty listening in quiet settings
 - More difficulty when background noise is present
 - "When I call her, she has to look around for me. She never seems to know where I am in the house."
 - With unilateral hearing loss, difficulty localizing a sound source
 - "When we are in crowds, I have to call his name several times before he responds."
 - Difficulty hearing in the presence of background noise
 - "My child is exhausted when she comes home from school."
 - Fatigue from the effort exerted to listen throughout the day
 - "His speech is very difficult to understand. I don't think it's his hearing, because he always responds when I call him."
 - Children with high-frequency hearing loss may have poor speech production.
 - They cannot hear high-frequency speech sounds (consonants).
 - They can hear low- and mid-frequency sounds.
 - "My child is doing poorly in school, but I know she understands the material because we go over her homework at night."
 - Difficulty hearing in school settings because of background noise
 - No hearing difficulty apparent when working at home in a one-on-one situation

DIFFERENTIAL DIAGNOSIS

- Most congenital hearing loss is hereditary.
 - However, a negative family history is common.
 - 80% of inherited hearing loss results from autosomal recessive transmission.
 - 18% results from autosomal dominant transmission.
 - Approximately 2% results from X-linked recessive transmission.
 - Children with dominantly inherited hearing loss may have families who demonstrate incomplete penetrance.

- Evidence of the gene expression can be highly variable.
- Most children with inherited hearing loss are nonsyndromic.
- Several syndromes are associated with sensory hearing loss.
 - Alport syndrome
 - Neurofibromatosis
 - Usher syndrome
 - Waardenburg syndrome
- Children with Down syndrome are at high risk for conductive hearing loss and have a higher-than-average risk for sensory loss.
- Infants in the neonatal intensive care unit are at increased risk for:
 - Neural conduction dysfunction
 - Auditory brainstem dysfunction
 - Auditory neuropathy/dyssynchrony
 - A recently identified disorder characterized by a unique constellation of behavioral and physiologic auditory test results
 - Ranges from normal hearing to profound hearing loss and poor speech perception
 - Children with family history of childhood hearing loss or with hyperbilirubinemia are at particular risk.
- Audiologic and medical monitoring of infants at risk are recommended.

DIAGNOSTIC PROCEDURES

- If an infant or child fails a hearing, speech, or language screening measure in the pediatrician's office, referral for a full audiologic evaluation is recommended.
- A recent study suggested that more than one-half of children who failed screenings in primary care practices did not receive rescreening or referral for further testing.
- Audiologists with pediatric experience can define degree of hearing loss.
 - Distinguish among conductive, sensory, and neural types of loss in children of all chronologic ages and developmental levels
- Evaluation of hearing in infants and young children consists of a combination of physiological and behavioral measures.
 - For infants <6 months, testing is typically limited to physiologic measures because behavioral responses are not yet reliable enough to define the extent of loss.
 - See Auditory Screening.

TREATMENT APPROACH

- Early identification of hearing loss is of little value without timely intervention.
- Many children have conductive and sensorineural hearing losses not amenable to medical treatment; they may benefit from amplification.

SPECIFIC TREATMENT

Hearing aids

- Traditional hearing aids are designed to:
 - Pick up sounds
 - Convert them to electrical signals
 - Amplify, filter, and convert signals back to acoustic signals for a receiver
 - In noisy settings, frequency-modulated systems can be used alone or in combination with hearing aids.
 - For instance, a microphone worn by a teacher to amplify only the teacher's voice while minimizing interfering background noise

Cochlear implants

- An alternative to traditional hearing aids
- The device is surgically implanted in the cochlea.
 - Electrodes stimulate the auditory nerve with electrical current.
- Cochlear implants do not restore normal hearing.
- Children vary markedly in the benefits they derive from the implant.
 - Most experience at least an awareness of sound.
 - Some reach a high level of speech recognition and can develop normal speech and language skills.

WHEN TO REFER

- Family history of permanent hearing loss
- Postnatal infections associated with sensorineural hearing loss (eg, meningitis)
- History of in utero infections
 - Syphilis
 - Toxoplasmosis
 - Rubella
 - Cytomegalovirus
 - Herpes
- Neonatal indicators associated with progressive or late-onset hearing loss
 - Hyperbilirubinemia requiring exchange transfusion
 - Persistent pulmonary hypertension of the newborn associated with mechanical ventilation
 - Use of extracorporeal membrane oxygenation
- Syndromes associated with hearing loss
 - Alport syndrome
 - Down syndrome
 - Neurofibromatosis
 - Usher syndrome
 - Waardenburg syndrome

- Neurodegenerative disorders
 - Charcot-Marie-Tooth disease
 - Friedreich ataxia
- Head trauma
- The child does not pass a hearing screen in the pediatrician's office.
- The patient or caregiver is concerned about hearing, speech, or language development.

FOLLOW-UP

- For infants with permanent hearing loss:
 - Communicate with the state's coordinator for early hearing detection and intervention to ensure that the child and family are enrolled in appropriate services.
 - Be sure that the child has received a thorough medical evaluation (including genetics consultation) to determine the cause of the hearing loss.

- There is a high incidence of vision problems in children with hearing loss.
 - Referral for ophthalmologic evaluation may be warranted.
- Approximately 30–40% of children with hearing loss have additional disabilities.
 - Periodic developmental screening and surveillance is an integral part of their management.

COMPLICATIONS

- Children with hearing loss are especially vulnerable to the effects of otitis media with effusion because additional hearing loss can negatively affect the audibility of speech through hearing aids.
- Closely monitor and manage children who have persistent otitis media with effusion.

Hearing Screening

BACKGROUND

- Hearing loss is the most common congenital abnormality in newborns.
- Routine screening for hearing loss is a justifiable procedure, based on its prevalence and potential for treatment.
 - 1 to 6 in 1000 babies without risk factors are born with hearing loss >40 dB.
 - ~13.3 per 1000 babies with high-risk factors are born with hearing loss >40 dB.
 - ~15% of all children in the US have a hearing loss with thresholds \geq 16 dB.
- Hearing loss may be progressive or acquired.
 - 20–30% of hearing loss up to age 18 is acquired or progressive.
 - 75% of children have \geq 1 episode of otitis media by their third birthday.
 - The principal cause of hearing loss in preschool children is otitis media.
 - Many conditions place children at risk for late-onset or progressive hearing loss.
 - Neurofibromatosis
 - Osteopetrosis
 - Usher syndrome
 - Other syndromes (Waardenburg, Alport, Pendred, Jervell, and Lange–Nielson)
 - Neurodegenerative disorders, eg, Hunter syndrome
 - Sensory motor neuropathies, eg, Friedreich ataxia and Charcot–Marie–Tooth syndrome
 - Postnatal infections associated with sensorineural hearing loss (confirmed bacterial and viral meningitis)
 - Head trauma, especially basal skull or temporal bone fracture requiring hospitalization
 - Chemotherapy
- Hearing loss may cause:
 - Speech and language delay
 - Difficulty in social and educational environments
- Profound consequences
 - ~37% of children with mild hearing loss will fail \geq 1 grade in school.
 - Late-identified children with bilateral permanent hearing loss leave school at age 18 with a sixth-grade reading level and a language-age equivalent of 12 years.

GOALS

General

- To identify children with moderate to severe hearing loss as early as possible to prevent detrimental effects on language and speech development

- Joint Committee on Infant Hearing–endorsed goals
 - Test children by 1 month of age.
 - Identify those with hearing loss by 3 months of age.
 - Treat hearing-impaired children by 6 months of age.
- All 50 states and the District of Columbia have mandatory universal newborn hearing screening programs to detect moderate to severe hearing loss.

Goals of screening, by age group

- Neonatal/early infancy
 - Primary goal is to identify congenital or in utero acquired hearing loss and to ensure speech development.
 - If risk factors for delayed-onset or progressive hearing loss are present, the child should receive audiologic monitoring every 6 months for the first 3 years.
 - All infants should receive ongoing surveillance of communicative development during well-child visits, beginning at 2 months of age.
 - Objective physiological measures used together
 - Otoacoustic emissions
 - Auditory brainstem response (ABR) measures
 - Best time frame: approximately 3–4 days after birth or before hospital discharge
 - The Joint Committee on Infant Hearing recommends different protocols for neonatal intensive care unit and well-baby nurseries.
 - Screening of neonatal intensive care unit babies admitted for >5 days should always include ABR testing.
 - Any baby readmitted within first month of life who has risk factors for hearing loss should have repeat hearing screening before discharge.
 - Despite the sensitivity of a 2-step screening protocol, some infants with hearing loss will still be missed.
 - Acquired or progressive hearing loss will be unidentified in the neonatal population.
 - The main factor for effectiveness of hearing screening is appropriate follow-up.
- Toddler and preschool (2–5 years)
 - The primary goal is detection of remediable otopathologic abnormalities, or of progressive or acquired hearing loss.
 - Screening assumes that the more severe sensorineural hearing losses will have been identified by 2 years.
 - The screening protocol includes identification of:
 - Otopathologic abnormalities (especially otitis media with effusion)
 - Mild conductive hearing loss
 - Sensorineural hearing impairment

- School age
 - Primary goal: identical to that of toddler-preschool period, with addition of the maintenance of educationally optimal hearing
 - Typically screened in school by trained professionals; referred to physician only if they fail screening
 - Children are screened:
 - On initial entry
 - Annually through third grade
 - In seventh and eleventh grades
 - As needed, requested, or mandated by regulation
 - At-risk children should be routinely monitored for hearing loss.
 - During this period, central auditory processing disorders become apparent.
 - Elicitation of parental/caregiver concern about child's hearing and speech/language development is key.

GENERAL APPROACH

- Early identification and intervention are critical for:
 - Overall communicative development
 - Cognitive development
 - Educational development
 - Emotional/behavioral development
- Early intervention methods include:
 - Audiologic management
 - Otologic treatment
 - Amplification
 - Parental counseling
 - Special education
- Infants: auditory screening using a physiologic measure should be completed no later than 1 month of age.
 - Infants who do not pass initial and subsequent screening should have audiologic and medical evaluations no later than 3 months of age.
 - Infants with confirmed permanent hearing loss should receive early intervention services as soon as possible, but no later than 6 months of age.
 - A simplified, single point of entry into the intervention system is optimal.
- The intervention should be family centered, with infant and family rights and privacy guaranteed.
 - Informed choice
 - Shared decision making
 - Parental consent
 - Families should have access to information about all intervention and treatment options and counseling regarding hearing loss.
- Immediate access to high-quality technology, including hearing aids, cochlear implants, and other assistive devices when appropriate.
- Continued assessment of communication development should be provided to all children with or without risk indicators for hearing loss.
- Appropriate interdisciplinary intervention programs:
 - Should be provided by professionals knowledgeable about childhood hearing loss
 - Should recognize and build on strengths, informed choices, traditions, and cultural beliefs of the families
- Information systems should be designed and implemented to interface with electronic health records.
- Routinely refer children who fail their hearing screenings to a licensed audiologist for appropriate follow-up and management.

SPECIFIC INTERVENTIONS

- Initial follow-up evaluation for infant or child who fails hearing screen or is at risk for acquired or progressive hearing loss
 - Comprehensive audiologic evaluation by licensed audiologist
 - ≥ 1 ABR test, as part of assessment of children < 3 years, before permanent hearing loss can be confirmed
 - If hearing loss or middle-ear dysfunction is confirmed, refer for otologic and medical consultation to:
 - Determine the cause of the hearing loss
 - Identify related physical conditions (present in 40%)
 - Provide recommendations for medical treatment and other referrals, if appropriate
- Comprehensive evaluations should include:
 - Complete patient and family history to identify risk factors
 - Tests to identify any anatomic malformations
 - Physical examination
 - Possible laboratory and radiologic tests
 - Monitoring of developmental milestones
 - Referral for genetic evaluation and counseling by medical geneticist
 - Referral to an ophthalmologist to test for visual acuity
 - Other specialty referrals, such as a speech and language evaluation, once etiology and developmental concerns have been identified
- Audiologic intervention depends on type and degree of hearing loss.
 - For conductive hearing loss, medical and surgical options are often available.
 - For atresia or similar anatomic condition that precludes medical or surgical treatment, bone-conduction or bone-anchored hearing aid, with fit by an audiologist

- For sensorineural hearing loss, amplification or assistive listening devices are typically recommended.
 - Children as young as 4 weeks may be fitted with hearing aids following appropriate physiological tests.
 - If diagnosed with permanent hearing loss, children should be fitted with hearing aids within 1 month.
- Cochlear implantation is often considered for severe to profound hearing loss in children as young as 12 months; criteria for use by age:
 - 12–24 months
 - Profound sensorineural hearing loss in both ears
 - Lack of progress in development of auditory skills with appropriate binaural hearing aids
 - High motivation and realistic expectations from the family
 - Other medical conditions, if present, do not interfere with implant procedure.
 - 25 months to 17 years 11 months
 - Severe to profound sensorineural hearing loss in both ears
 - Little or no benefit from hearing aids (speech scores $\leq 30\%$ in best-aided condition)
 - Lack of progress in development of auditory skills
 - High motivation and realistic expectations from family
 - No medical contraindications
- Speech and language assessment and therapy are essential to development and intelligible speech by entry into kindergarten.
- Financial concerns should not limit a child's access to intervention services.
 - The Individuals with Disabilities Education Act (IDEA) ensures that children who have hearing loss receive appropriate, family-centered, multidisciplinary intervention services at no charge from birth through the school years.
 - Options available to cover cost of amplification due to permanent hearing loss
 - Private insurance
 - Medicaid
 - Services provided by IDEA/school education resources

Heart Failure

DEFINITION

- Congestive heart failure (CHF) is an inability to perfuse the body tissues adequately.

EPIDEMIOLOGY

- Age
 - CHF can occur in infants or children of any age, but up to 90% of cases occur during the first year of life, most during the neonatal period.

ETIOLOGY

- For a particular left ventricular (LV) preload, cardiac output or stroke volume increases progressively from fetal to neonatal to adult stages of life.
- Mechanisms are not entirely clear, but properties of contractile proteins, ion channels, and cell surface receptors are expressed differently at each developmental stage.
- These changes in protein expression affect contractility of the LV myocardium at different developmental stages.
- Animal studies suggest that neonates operate closer to maximal inotropic potential than adults, and neonates may have less reserve to handle excess ventricular preload and are more likely than adults to experience episodes of CHF.
- The age at onset of heart failure (HF) in children, especially in infants, is important in determining cause.

SIGNS AND SYMPTOMS

- Feeding
 - Helps quantify nutritional intake and compare it with weight gain
 - Children with CHF often have greater nutritional needs because of increased metabolic demands.
 - Often require ≥ 150 kcal/kg daily to gain adequate weight
 - Frequently, infants with CHF do not feed vigorously and may feed only in short, interrupted periods.
 - For older children, CHF over long intervals results in malnutrition.
 - Weight is usually the initial anthropometric measurement to be affected, followed by height and then head circumference.
- Activity level
 - Children with CHF usually change their activity level, becoming less active or more irritable and anxious.
- Tachycardia
 - Children with CHF may have persistent sinus tachycardia, with heart rates far higher than the normal range for their age.
- Tachypnea
 - Higher respiratory rates during sleep are often found in children with CHF.

- Rales
 - Clinically evident rales are less likely to be found in infants and young children with CHF.
 - In a young child, rales may suggest active pulmonary disease.
- Jugular venous distention
 - Found in many older patients with HF, but not seen as frequently in infants and children, largely because observing their jugular veins is difficult
- Hepatomegaly
 - The liver is frequently enlarged in infants and children with CHF.
 - Measuring the total liver span by percussion is more useful than determining how far the liver edge extends below the right costal margin.
 - The left lobe of the liver is frequently enlarged in CHF, and thus a palpable liver edge that crosses the midline is suggestive of CHF.
- Third heart sound gallop
 - Frequently observed in children of all ages with CHF
 - An S_3 gallop may not indicate CHF in a neonate.
- Pulses and perfusion
 - Diminished strength of the peripheral pulses and perfusion are common signs.
 - Simultaneously palpating upper and lower extremity pulses may reveal differences in intensity or timing of the pulses, indicating:
 - Coarctation of the aorta
 - Interrupted aortic arch
 - Another lesion interfering with arterial blood flow
- Arrhythmias and sudden death
 - Arrhythmias can be both a cause and a result of HF in children and young adults.
 - Ventricular dysfunction resulting from dilated cardiomyopathy may be associated with high-grade ectopy.
 - This may increase the risk of death associated with HF.
 - Unexplained syncope or palpitations in children with HF or cardiomyopathy should prompt evaluation for arrhythmias.
 - Syncope may be an important predictor of sudden death in these children.

DIFFERENTIAL DIAGNOSIS

- The transition from fetal circulation to postnatal circulation requires precise steps, any of which may be compromised and lead to HF.

Prenatal period

- Infections, such as those caused by parvovirus, can lead to CHF with or without myocarditis.
- Abnormalities of heart rhythm

- Fetuses tolerate prolonged supraventricular tachycardia poorly, and the mother must often be treated with antiarrhythmic medications to control the condition in the fetus.
- Fetuses with chronic or severe CHF have a greater likelihood of developing hydrops fetalis and dying.

First day of life

- Persistent fetal circulation or persistent pulmonary hypertension is the leading cause of CHF.
 - Associated with meconium aspiration and neonatal acidosis
 - In persistent pulmonary hypertension, CHF may not be clinically apparent.
 - When recognized early, careful use of fluids, inotropes, and oxygen can be beneficial.
- Neonatal sepsis
 - Prolonged rupture of membranes, maternal infection, and associated findings are risk factors.
 - Usually accompanied by the classic signs or symptoms
 - Treating sepsis with antibiotics and judicious use of fluids in conjunction with anticongestive therapy is often effective.
- Hematologic or metabolic disorders
 - Hematocrit that is too high or too low is a risk for HF.
 - Polycythemia resulting in sludging and hyperviscosity, most common in infants of mothers with diabetes
 - Partial exchange transfusion will often lead to a rapid improvement in signs of HF.
- Severe anemia
 - Determining whether reduced erythrocyte count has an acute or a chronic cause is important.
 - Acute blood loss, as from abruptio placentae, can be managed with blood transfusion and by otherwise increasing intravascular fluid volume.
 - Chronic anemia, such as that caused by Rh sensitization, may produce low erythrocyte count and a low hematocrit.
 - Intravascular volume may be high, and transfusion may worsen HF.
 - Such patients may benefit from double-volume exchange transfusion.
- Metabolic causes of cardiomyopathy include hypoglycemia and hypocalcemia.
 - The neonatal myocardium uses glucose for energy metabolism, diminishing fat reserves.
 - A newborn with a low blood glucose level and signs or symptoms of CHF will often improve when the blood glucose level is normalized.
 - Hypocalcemia is another metabolic cause; normalization of calcium, a potent inotrope, can reduce signs or symptoms of CHF.
 - Hypoglycemia and hypocalcemia are often seen together in infants of mothers with diabetes.

- Rare congenital heart defects, such as absent pulmonary valve syndrome, free tricuspid orifice, or severe anomaly of the tricuspid valve associated with severe pulmonary stenosis
- Heart rate abnormalities
 - A newborn can tolerate supraventricular tachycardia of 250–300 beats/min for only 12–36 hours before developing signs and symptoms of CHF.
 - Sinus rhythm should be established immediately in symptomatic neonates with supraventricular tachycardia and CHF.
 - If vagal maneuvers or intravenous administration of adenosine do not result in normal sinus rhythm and a pacemaker is unavailable, then cardioversion should be attempted, followed by treatment with drugs.
 - Slow heart rates may lead to CHF.
 - Heart rates <60 beats/min result in symptomatic CHF.

Days 1–2 of life

- Obstructed total anomalous pulmonary venous return
 - Persistent or progressive tachypnea and hypoxia and
 - Chest radiographs showing a snowman or snowball pattern, with vessels radiating from a small cardiac silhouette
 - Echocardiography can confirm the diagnosis.
 - Early identification is essential because surgery is the only effective intervention.

Days 2–3 of life

- Ductus arteriosus–dependent lesions, including the following:
 - Right-sided obstructive lesions, such as pulmonary atresia, maximal tetralogy of Fallot, or tricuspid atresia
 - Transposition of the great arteries (the most common type of cyanotic heart disease)
 - Left-sided obstructive lesions, such as hypoplastic left-heart syndrome, critical aortic stenosis, or complex coarctation of the aorta
- CHF is less likely when any of these conditions is accompanied by a patent ductus arteriosus but may develop after the ductus arteriosus has closed, especially in cases of left-sided obstructive lesions.
- If diagnosed in time, these patients can often be stabilized by infusions of prostaglandin E₁ to maintain patency of the ductus arteriosus.

Days 3–7 of life

- Endocrine disorders, including congenital adrenal hypoplasia, hyperthyroidism
- Renal disorders, such as renal vein thrombus, renal artery stenosis, and hypertension or oliguria of any cause

Weeks 1–2 of life

- Complex coarctation of the aorta
- Similar lesions, such as an interrupted aortic arch, also may present at this age.

- Typically, ductus arteriosus closes by 3 days of life in children without these conditions.
- In complex coarctation of the aorta, the ductus remains open for up to 1 or 2 weeks.
- A child with coarctation of the aorta and CHF at 1–2 weeks of age may have no pulse differential between the upper and lower extremities if cardiac output is low.
- Any suspected complex coarctation or interrupted aortic arch should be investigated by echocardiography.
- When diagnosed early, the child can often be stabilized quickly with anticongestive therapy and prostaglandin E₁.

Months 1–2 of life

- Left-to-right shunt lesions
 - For example, ventricular septal defect where pulmonary artery resistance has decreased over the first few postnatal weeks, resulting in increased left-to-right shunting
 - Others include atrial-level shunts (eg, atrial septal defect); common atria; ventricular-level left-to-right shunts (eg, complete atrioventricular canal defects, ventricular septal defects, single ventricle); and great vessel-level shunts, such as patent ductus arteriosus.
 - The timing of presentation often suggests existence of a left-to-right shunt.
 - Whether CHF in this circumstance is easily treated is unclear.
 - In the past, hypertransfusion therapy to reduce shunting was found to be useful.
 - This therapy is not commonly used.

Months 6–12 of life

- Metabolic, genetic, infectious, and inflammatory cardiomyopathies
- Children with metabolic or genetic cardiomyopathy seem asymptomatic to the family for the first 6 months of life.
- Children may exhibit growth failure and hypotonia.
- Such disorders as glycogen storage diseases also present in this way.
- Infectious and inflammatory diseases, such as HIV, enterovirus infections, and Kawasaki disease, can cause myocarditis at this age.

Years 1–18 of life

- Most common in children with comorbid severe or chronic illnesses
- Beyond the first year of life, CHF is unusual.
- Older children with congenital heart disease, other than those who have had corrective surgery, rarely develop CHF.
- Leading indications for pediatric heart transplantations, which indicate a failure of the medical management of CHF, are congenital heart disease during the first year of life and cardiomyopathies thereafter.

DIAGNOSTIC APPROACH

- A thoroughly obtained clinical history often provides clues to the cause of CHF.
- Classification systems for adults are not particularly useful in infants and children because of:
 - Variation in normal respiratory rates
 - Different developmental stages, reflecting different exercise capabilities
 - Different causes for HF across age groups

Ross scoring system of HF in infants

- Volume per feeding (oz)
 - 0 points: >3.5
 - 1 point: 2.5–3.5
 - 2 points: <2.5
- Time per feeding (min)
 - 0 points: <40
 - 1 point: ≥40
- Respiratory rate (breaths/min)
 - 0 points: <50
 - 1 point: 50–60
 - 2 points: >60
- Respiratory pattern
 - 0 points: normal
 - 1 point: abnormal
- Peripheral perfusion
 - 0 points: normal
 - 1 point: decreased
- S₃ or diastolic rumble
 - 0 points: absent
 - 1 point: present
- Liver edge from costal margin, cm
 - 0 points: <2
 - 1 point: 2–3
 - 2 points: >3
- Totals
 - No CHF: 0–2 points
 - Mild CHF: 3–6 points
 - Moderate CHF: 7–9 points
 - Severe CHF: 10–12 points

Pediatric clinical HF score

- Diaphoresis
 - 0 points: head only
 - 1 point: head and body during exercise
 - 2 points: head and body at rest

- Tachypnea
 - 0 points: rare
 - 1 point: several times
 - 2 points: frequent
- Breathing
 - 0 points: normal
 - 1 point: retractions
 - 2 points: dyspnea
- Respiratory rate (breaths/min)
 - 0–1 year
 - 0 points: <50
 - 1 point: 50–60
 - 2 points: >60
 - 1–6 years
 - 0 points: <35
 - 1 point: 35–45
 - 2 points: >45
 - 7–10 years
 - 0 points: <25
 - 1 point: 25–35
 - 2 points: >35
 - 11–14 years
 - 0 points: <18
 - 1 point: 18–28
 - 2 points: >28
- Heart rate (beats/min)
 - 0–1 year
 - 0 points: <160
 - 1 point: 160–170
 - 2 points: >170
 - 1–6 years
 - 0 points: <105
 - 1 point: 105–115
 - 2 points: >115
 - 7–10 years
 - 0 points: <90
 - 1 point: 90–100
 - 2 points: >100
 - 11–14 years
 - 0 points: <80
 - 1 point: 80–90
 - 2 points: >90

- Liver edge from costal margin, cm
 - 0 points: <2
 - 1 point: 2–3
 - 2 points: >3

CLASSIFICATION

- The Ross classification of HF in infants has been validated to address pediatric differences from adult classification systems.
 - Class I: no limitations or symptoms
 - Class II
 - Mild tachypnea or diaphoresis with feeding in infants
 - Dyspnea on exertion in older children
 - No growth failure
 - Class III
 - Marked tachypnea or diaphoresis with feeding or exertion
 - Prolonged feeding times
 - Growth failure from CHF
 - Class IV: symptoms at rest, with tachypnea, retractions, grunting, or diaphoresis
- Proposed HF staging for infants and children by the International Society for Heart and Lung Transplantation
 - Modified from the American College of Cardiology/ American Heart Association guidelines and complementing the Ross classification system
 - Stage A: patients with increased risk of HF but normal cardiac function and no evidence of cardiac chamber volume overload
 - Examples: previous exposure to cardiotoxic agents, family history of heritable cardiomyopathy, univentricular heart, congenitally corrected transposition of the great arteries
 - Stage B: patients with abnormal cardiac morphology or cardiac function, with no symptoms of HF, past or present
 - Examples: aortic insufficiency with LV enlargement, history of anthracycline use with decreased LV systolic function
 - Stage C: patients with underlying structural or functional heart diseases and past or current symptoms of HF
 - Stage D: patients with end-stage HF requiring continuous infusion of inotropic agents, mechanical circulatory support, cardiac transplantation, or hospice care

TREATMENT APPROACH

- The 4 classes of drugs used most frequently in the management of CHF in children are:
 - Diuretics
 - Inotropes
 - Agents to reduce afterload
 - β -Adrenergic antagonists

- Each class targets a different pathophysiologic feature of CHF, and they are often used in combination.
- A pediatric cardiologist should direct the treatment of CHF in children.

SPECIFIC TREATMENTS

Current consensus recommendations for management of pediatric HF

- All recommendations presented are class I (conditions for which general agreement exists that a given therapy is useful and effective).
- Recommendation 1
 - The underlying cause of new-onset ventricular dysfunction (HF stages B, C, or D) should be evaluated thoroughly in all patients.
 - The evaluation may include metabolic and genetic evaluation in selected cases, as indicated by the available history and physical findings.
 - Invasive assessment, including myocardial biopsy, may be considered in selected cases.
 - In infants, particular care should be given to the exclusion of coronary artery anomalies and other anatomic causes.
- Recommendation 2
 - Screening of first-degree relatives should be considered in patients with new-onset ventricular dysfunction caused by dilated cardiomyopathy (HF stages B, C, or D).
- Recommendation 3
 - Patients with fluid retention associated with ventricular dysfunction (HF stage C) should be treated with diuretics to achieve a euvolemic state using clinical criteria of fluid status and cardiac output.
- Recommendation 4
 - Digoxin should be used in patients with ventricular dysfunction and symptoms of HF (HF stage C) to relieve symptoms. Lower doses of digoxin are preferred for this purpose.
- Recommendation 5
 - For the treatment of moderate or severe LV dysfunction with or without symptoms (HF stages B and C), angiotensin-converting enzyme (ACE) inhibitors should be routinely used unless a specific contraindication exists.
 - These medications should be started at low doses and titrated up to a maximal tolerated safe dose.
 - Uptitration may require a reduction in the dose of diuretics.
- Recommendation 6
 - In all cases of HF associated with structural heart disease (HF stages B, C, or D), surgical repair of significant lesions should be considered because the long-term outlook may be more favorable than with medical management alone.
- Recommendation 7
 - Clinical management of diastolic dysfunction should address symptoms and attempt to address the underlying cause of the diastolic dysfunction, if known.
 - This management should include a careful evaluation for pericardial disease and coronary insufficiency with attendant myocardial ischemia.
 - Systemic hypertension, if present, should be aggressively controlled.
- Recommendation 8
 - Fluid management to control symptoms remains a cornerstone in the management of symptomatic diastolic dysfunction (HF stage C).
 - Diuretics can help control symptoms but must be used cautiously because cardiac output depends on increased filling pressures.
 - Renal function should be followed closely, with care taken not to administer too much.
 - Sodium and fluid restriction may be helpful in controlling symptoms.
- Recommendation 9
 - Atrial arrhythmias are not infrequent in patients with diastolic dysfunction caused by atrial enlargement. However, atrial contribution to ventricular filling is particularly important for this group of patients (HF stages B and C).
 - Therefore, efforts should be made to maintain sinus rhythm by use of antiarrhythmic therapy and pacemakers.
- Recommendation 10
 - Patients with diastolic dysfunction refractory to optimal medical or surgical management should be evaluated for heart transplantation because such patients are at high risk for pulmonary hypertension and sudden death (HF stage C).
- Recommendation 11
 - Institution of mechanical cardiac support should be considered in patients without structural congenital heart disease, those who present with acute low cardiac output, or those who have intractable arrhythmias during a presumably temporary condition that is refractory to medical therapy (HF stage D), such as myocarditis, septic shock, or acute rejection after heart transplantation.
- Recommendation 12
 - Institution of mechanical cardiac support should be considered in patients with or without structural congenital heart disease and who have acute decompensation of end-stage HF, primarily as a bridge to heart transplantation (HF stage D).

■ Recommendation 13

- In patients with significant arrhythmias in the setting of HF associated with structural heart disease (HF stages B, C, or D), surgical repair of important uncorrected or residual defects should be considered because this is likely to be essential in achieving adequate rhythm control.

■ Recommendation 14

- In patients with significant arrhythmias in the setting of HF associated with structural heart disease (HF stages B, C, or D), improving or optimizing the medical treatment for HF and correcting aggravating factors, such as electrolyte abnormalities, should be considered because this is likely to be a key determinant of the successful control of arrhythmias.

■ Recommendation 15

- In patients with significant arrhythmias in the setting of HF associated with structural heart disease (HF stages B, C, or D), maintenance of atrioventricular synchrony is of great importance in optimizing hemodynamics, and management of intraatrial arrhythmias should be oriented toward restoration of sinus rhythm rather than toward ventricular rate control alone.

Pharmacotherapy

- Symptomatic LV dysfunction or CHF in children can be caused by many different pathophysiologic mechanisms.

- The basis for using these agents is extrapolated from adults, and generally they are used for the palliative relief of symptoms in children.

- Treatments directed at prevention or cure of CHF in children have not been evaluated.

■ Diuretics

- Increased preload is 1 common mechanism.
- Overall systolic performance of the ventricle is reduced.
- Preload reduction with diuretic therapy is often beneficial.

■ Inotropes

- Depressed contractility of unhealthy LV myocytes and inotropic support frequently bring early symptom relief.
- However, determining the cause of HF in a child becomes critical because many children with unexplained HF have mitochondrial defects that impair their ability to respond to inotropic support.
- Aggressive use of inotropic support in such patients may hasten their deaths.
- Digoxin, an inotrope administered orally or intravenously, will raise a child to a higher inotropic state and, in the process, lead to a reduction in preload.
- Frequently, digoxin is used in combination with a diuretic.
- Some studies suggest synergy between digoxin and diuretics that potentiates primary ventricular function and reduces preload more than either agent alone.

- Combination therapy can also reduce the chance of individual agent toxicity.
- β -Adrenergic agonists, such as dopamine and dobutamine, are also inotropic and are useful for treating children with HF, especially those in a decompensated state.
- Newer inotropic agents are being investigated.
 - Calcium-sensitizing agents, in particular, improve cardiac output with minimal increases in heart rate, a common side effect of β -adrenergic agonists.

■ Agents that reduce afterload

- LV afterload reduction in a child with symptomatic LV dysfunction will improve function and reduce symptoms.
- ACE inhibitors, such as captopril and enalapril, are used most frequently.
 - They are vasodilators, but they affect neurohormonal mechanisms.
 - In adults with asymptomatic LV dysfunction or CHF, ACE inhibitors have been associated with slowing progression from asymptomatic LV dysfunction to CHF and reducing mortality from HF.
 - These benefits are believed to be caused by combination of vasodilatory and neurohormonal activation.
 - The vasodilatory effects of ACE inhibitors will often move a child to a more favorable preload state and reduce afterload, thus improving LV contractility.

■ β -Adrenergic antagonists

- β -Adrenergic antagonists reverse adrenergically mediated intrinsic myocardial dysfunction and remodeling.
- Atenolol and carvedilol
- In adults with CHF, β -antagonists improve symptoms, ventricular function, and survival.
- Small studies suggest that β -antagonists improve ventricular function in children with CHF.
- These agents have not yet been used extensively, and further evaluation of this class of drugs is under way.

■ Newer agents for management of CHF

- Angiotensin-receptor blockers
- Endothelin-receptor antagonists
- Phosphodiesterase inhibitors
- Aldosterone antagonists
- Calcium-sensitizing agents
- Tumor necrosis factor inhibitors
- Neural endopeptidase inhibitors
- Vasopressin antagonists

Arrhythmias

- Arrhythmias are a major cause of morbidity and mortality in children with HF, especially in the later stages of disease.

- Short-term treatment with intravenous antiarrhythmic agents and cardioversion or defibrillation should be considered for all children with hemodynamic instability.
- Long-term suppressive therapy or radiofrequency surgical ablation therapy may be required for long-term management of recurring arrhythmias.
- In adults with HF and arrhythmias, implantable cardiac defibrillators have greatly improved survival.
- These devices have not been used extensively in young children, and only a few small studies have assessed their use.
- However, technologic advances suggest the potential for decreased complications and infections; thus, they hold promise for use in younger children.

Nutritional management

- A systematic approach to overcoming failure to thrive has been suggested, starting with dietary intervention.
 - Counseling and educating patient and parents to optimize feeding to increase mean caloric intake and weight
- The high energy cost of eating might prevent a child from consuming larger quantities of food; fortified formula and breast milk have improved weight gain.
 - Monitor the patient closely, because high-energy formula can induce thermogenesis and increase metabolic inefficiency.
 - Breastfeeding is less stressful than bottle feeding for infants with congenital heart disease.
- Gastrostomy placement and parenteral feeding may be important considerations in severely malnourished infants, in part because they do not incur the energy costs of feeding.
- Mortality and morbidity associated with cardiac surgery increase in underweight infants.
- Conversely, some findings show that energy expenditures decrease and return to normal after surgery.
- Therefore, if an infant fails to thrive after all aggressive feeding and nutrition measures have been tried, surgery may be advisable even if the infant is not at an ideal weight.
- Other nutritional considerations
 - Managing electrolyte abnormalities that may occur from diuretic use
 - Balancing fluid intake with fluid overload in children with HF

Surgery

- Children with cardiomyopathy or HF after repair of a congenital cardiac defect may be candidates for heart transplantation.
- Aggressive pretransplantation evaluation is required, given the potential for long-term complications.
- Newer surgical techniques for congenital cardiac defects include techniques to correct failed procedures or revise older, less effective surgical procedures.
- As children with congenital heart disease live longer, revision procedures in young adulthood may become important in long-term management.
- For children at risk of sudden death from arrhythmias, implantable cardioverter defibrillators may be considered, although not well studied or used extensively in children.
- Difficulties include large size of the device and leads, difficult surgical access due to previous cardiac surgeries, and difficulties with programming devices as a result of inconsistent rate patterns.

WHEN TO ADMIT

- All pediatric patients with HF must be admitted for evaluation and management and monitoring of the progress.

WHEN TO REFER

- All pediatric patients with HF must be managed in consultation with pediatric cardiologists.

FOLLOW-UP

- All pediatric patients with HF must be closely monitored for growth and development.

PROGNOSIS

- Prognosis depends on the underlying cardiac cause leading to HF as well as on early and appropriate management.

PREVENTION

- All patients with congenital heart disease, with or without repair, must be monitored closely for symptoms.
 - Educate patients and parents on the early identification of HF symptoms.

Heart Murmurs

DEFINITION

- A heart murmur results from turbulent blood flow.

EPIDEMIOLOGY

- Heart murmur is a common finding during the physical examination of children.
- Few children have structural cardiac disease.

MECHANISM

Cardiac cycle and associated heart sounds

- When determining the significance of a heart murmur, the pediatric primary care physician needs to understand:
 - Events of the cardiac cycle
 - Associated heart sounds
- Heart sounds as auscultated during physical examination are directly related to the hemodynamic events of systole and diastole.
- The first heart sound (S1) is related to the closure of the mitral and tricuspid valves at the very end of diastole.
 - The ventricles are completely filled.
 - The ventricles then undergo a period of isovolumic contraction.
 - The aortic and pulmonary valves begin opening.
 - Rapid systolic ejection phase begins.
 - This phase is followed by a phase of reduced ejection later in systole.
- The second heart sound (S2) is created by closure of the aortic and pulmonary valves at the very end of systole.
 - Physiologic splitting of S2 is particularly important in the diagnosis of cardiac disease.
 - The first component of S2 is created by closure of the aortic valve (A2).
 - The second component of S2 is created by closure of the pulmonary valve (P2).
 - During inspiration, P2 occurs after A2, generating an audibly split S2 (A2-P2).
 - During exhalation, closure of the aortic and pulmonary valves is nearly coincident, creating a single S2.
 - Splitting of S2 can be difficult to hear in infants or children with accelerated heart rates.
 - Normal splitting pattern helps distinguish an abnormality from normalcy.
 - Wide splitting of S2 is associated with prolonged ejection from the right ventricle, as occurs with such conditions as an atrial septal defect (ASD), in which S2 is widely split and fixed.
 - A narrowly split S2 is associated with pulmonary hypertension, in which closure of P2 is early, or aortic stenosis, when closure of A2 is delayed.
 - Failure of S2 to split at all can be the result of simultaneous closure of the aortic and pulmonary valves during all phases of the respiratory cycle.
 - This is found with conditions that result in high pulmonary artery pressure.
 - A single S2 can also be associated with certain congenital cardiac anomalies, such as:
 - Truncus arteriosus
 - Tetralogy of Fallot
 - Cardiac surgical palliations
 - Bidirectional Glenn shunt
 - Fontan completion
- Third and fourth heart sounds may also be heard during physical examination.
 - The third heart sound (S3) is heard early in diastole, during the initial phase of passive rapid ventricular filling.
 - It is a low-frequency sound that can be best heard at the left lower sternal border or at the apex.
 - An apical S3 can frequently be heard in normal children, as well as in competitive athletes.
- The fourth heart sound (S4) is always pathologic.
 - S4 is also a low-frequency sound, but is heard late in diastole, just before S1.
 - It results from rapid filling of the ventricle caused by atrial contraction.
 - An S4 gallop is associated with decreased ventricular compliance (as is seen in cardiomyopathy) and congestive heart failure.
 - Auscultation of an S4 gallop warrants immediate evaluation by a pediatric cardiologist.
- Clicks may be audible during the cardiac cycle.
 - Ejection clicks are heard in systole.
 - The timing of the click in the cardiac cycle helps elucidate the cause.
 - An early systolic click, heard just after S1, is associated with:
 - Semilunar valve stenosis (aortic stenosis or pulmonary stenosis)
 - Dilation of the great arteries (the aorta or pulmonary artery)
 - Aortic valve clicks, best heard at the apex or right upper sternal border, do not vary in intensity with respiration.
 - Pulmonary valve clicks increase in intensity with exhalation and are best heard along the left sternal border.
 - A midsystolic apical click is heard with mitral valve prolapse and may be accompanied by a late systolic murmur.

Cardiac anatomy

- The physician must understand the anatomy of the heart and its position in the chest.
 - Location of the heart murmur on the chest wall serves as an important tool in deciding whether the murmur is innocent or abnormal.
-

HISTORY

- A complete and accurate history is the most important aspect of evaluating a cardiac murmur in children.
- Certain aspects of the patient's history may raise or lower the index of suspicion regarding the cause of a heart murmur.
- History should include the patient's chief symptoms and:
 - Medical history
 - Birth history
 - Family history
- Patient history
 - Poor weight gain
 - Difficulty feeding
 - Frequent respiratory difficulties
 - Respiratory distress
 - Cyanosis
 - Exercise intolerance
 - Chest pain with exercise
 - Unexplained syncope (especially syncope resulting in injury)
 - Concurrent syndromic disorder or genetic disease
 - Concurrent metabolic disorder or storage disease
 - Sick cell anemia or blood dyscrasias resulting in anemia
 - History of cardiotoxic chemotherapy
 - Concurrent HIV disease
 - Hypertension
- Birth history
 - Maternal diabetes
 - Maternal TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex) infections during pregnancy
 - Multiple gestation pregnancy
 - In vitro fertilization pregnancy
 - Maternal drug use (either legal or illicit), known teratogens
 - Abnormal amniocentesis
 - Abnormal fetal ultrasonogram
 - Maternal history of congenital heart disease
- Family history
 - Congenital heart disease
 - Sudden cardiac death
 - Unexplained death in young people
 - Cardiac disease in the young
 - Stroke or myocardial infarction in men <55 years or women <65 years
 - Seizure disorders
 - Congenital deafness

PHYSICAL EXAM

Patient evaluation

- Evaluation of a cardiac murmur involves more than auscultation of the heart.
- Complete physical examination is needed to put the murmur in perspective.
- Pertinent aspects of physical examination include:
 - Vital signs
 - Temperature, heart rate, respiratory rate, length/height, weight
 - Blood pressures in the right arm, left arm, leg
 - Pulse oximetry on room air (right hand and either foot if infant)
 - General
 - Cyanosis, pallor, dysmorphic features, overall distress
 - Breathing pattern: retractions, grunting, nasal flaring
 - Head and neck
 - Jugular venous distention
 - Thyromegaly, thyroid nodules
 - Chest
 - Chest wall deformity, asymmetry, surgical scars
 - Lung aeration
 - Rales, rhonchi, wheezes, stridor
 - Cardiac
 - Inspection
 - Palpation
 - Auscultation
 - Abdominal
 - Liver span
 - Tenderness
 - Distention, ascites
 - Extremities
 - Perfusion: capillary refill, temperature, quality of pulses
 - Clubbing, cyanosis, edema
 - Arachnodactyly, joint laxity (Marfan syndrome)
 - Increased arm span/upper to lower body ratio (Marfan syndrome)

Cardiac evaluation

- Includes:
 - Inspection
 - Palpation
 - Auscultation
- Inspection
 - Begin with:
 - General appearance
 - Nutritional status

- Genetic abnormalities
- Color
- Comfort
- Then inspect the chest wall for abnormalities, including:
 - Deformities, such as pectus excavatum
 - Asymmetry
 - Surgical scars
- **Palpation**
 - Begin with the extremities.
 - Evaluation of overall perfusion includes assessment of:
 - Pulses
 - Capillary refill
 - Temperature of extremities
 - The precordium is then palpated to detect the point of maximal impulse (PMI) of the left and right ventricles and to detect thrills.
 - PMI for the left ventricle is palpated in the left fourth or fifth intercostal space in the midclavicular line.
 - PMI for the right ventricle is appreciated in the fourth to fifth intercostal space along the left lower sternal border.
 - Displacement of the PMI suggests an underlying abnormality.
 - Thrills can be palpated:
 - In the suprasternal notch (suggesting aortic valve disease or coarctation of the aorta)
 - Along left upper sternal border (suggesting pulmonary valve disease)
 - Along right upper sternal border (suggesting aortic valve disease)
 - Along left lower sternal border, in association with ventricular septal defects (VSDs)
- **Auscultation**
 - A systematic approach to auscultation of the heart ensures that each major anatomic area of the heart is heard in systole and diastole.
 - The major areas of auscultation on the precordium
 - Apex
 - Left lower sternal border
 - Left mid or upper sternal border
 - Right upper sternal border
 - These areas correspond to each atrioventricular and semilunar valve, as well as the outflow tracts of the right and left ventricles.
 - The clinician should also auscultate:
 - Left and right infraclavicular areas
 - Axillae
 - Back
 - Auscultation for a continuous sound (bruit) should be performed over the liver and fontanelle.
 - A bruit suggests an arteriovenous malformation.
 - The patient should be examined in the following positions.
 - Supine
 - Sitting
 - Left lateral decubitus
 - Other postural maneuvers that may be useful:
 - Squatting
 - Standing
 - While performing a Valsalva maneuver
 - Auscultation includes an assessment of S1 and S2, including the nature of the splitting of S2.
 - Consideration of any S3 and S4, murmurs, clicks, and rubs completes the auscultation.
- **Evaluation of heart murmur**
 - Random fluctuations in velocity and pressure during blood flow results in vibration of the surrounding tissue, which is auscultated as a murmur.
 - A complete description of a heart murmur includes:
 - Intensity
 - Timing
 - Location
 - Radiation
 - Quality
- **Intensity**
 - Graded on a scale of I to VI for murmurs in systole
 - Grade I: Barely audible
 - Grade II: Soft, but easily audible
 - Grade III: Moderately loud without a thrill
 - Grade IV: Moderately loud with a thrill
 - Grade V: Loud with a thrill, heard with stethoscope barely on the chest
 - Grade VI: Loud with a thrill, heard with stethoscope off the chest
 - Some cardiologists use a scale of I to IV for murmurs in diastole.
 - Grade I: Barely audible
 - Grade II: Soft, but immediately heard
 - Grade III: Easily heard
 - Grade IV: Very loud
 - The intensity of a murmur does not necessarily reflect the severity of abnormality.
 - A small VSD may have a very loud murmur.
 - Critical aortic stenosis may have a very soft murmur if cardiac output is low.

Timing

- The point in the cardiac cycle at which the murmur is heard
- Murmurs are described as being:
 - Systolic
 - Diastolic
 - Continuous
- Systolic murmurs occur during anatomic systole, the time beginning with atrioventricular valve closure (S1) and ending with semilunar valve closure (S2).
- Systolic murmurs are further divided into:
 - Ejection (crescendo-decrescendo) murmurs
 - Begin shortly after S1, peak in intensity
 - End at or before S2
 - May be innocent or abnormal
 - Most innocent murmurs are grade I to III systolic ejection murmurs.
 - Abnormal murmurs result from:
 - Obstructed blood flow across a semilunar valve (aortic or pulmonary stenosis)
 - Excessive volume crossing a normal semilunar valve (ASD)
 - Abnormal murmurs may be of any grade of intensity.
 - Holosystolic (pansystolic, S1 coincident) murmurs
 - Start with S1
 - Continue to S2 at the same level of intensity
 - Sometimes obscure S2 during auscultation
 - Result from movement of blood from a higher-pressure chamber to a lower-pressure chamber, such as with a VSD or mitral regurgitation
 - Late systolic murmurs
 - Associated with mitral valve prolapse and resultant mitral regurgitation
 - Classically preceded by a midsystolic click
- Diastolic murmurs occur during anatomic diastole.
 - The time beginning with semilunar valve closure (S2) and ending with atrioventricular valve closure (S1)
 - Diastolic murmurs are divided into early, mid, and late diastolic murmurs.
 - All are abnormal by definition.
 - Early diastolic murmurs begin immediately after S2 and are decrescendo in nature, becoming less audible as the ventricle fills.
 - Aortic insufficiency and pulmonary insufficiency are heard in early diastole.
 - Mid-diastolic murmurs occur clearly after S2 during the rapid filling phase of the ventricle.
 - Mitral stenosis and tricuspid stenosis murmurs are heard in mid-diastole.
 - Late diastolic (presystolic) murmurs occur near the end of diastole during the phase of atrial contraction.
 - Severe mitral stenosis or tricuspid stenosis murmurs increase in late diastole.
- Continuous murmurs
 - Begin in systole
 - Continue throughout systole
 - End some time during diastole
 - Vascular in origin
 - Caused by:
 - Aortopulmonary (eg, patent ductus arteriosus)
 - Arteriovenous (eg, arteriovenous fistula)
 - Connections
 - Turbulent flow in arteries (eg, coarctation of the aorta)
 - Turbulent flow in veins (eg, venous hum)
 - These murmurs are abnormal, except for the innocent venous hum (see table Common Innocent Murmurs).
 - Continuous murmurs sound fairly uniform until they soften in late diastole.
 - They result from such lesions as:
 - A patent ductus arteriosus
 - An arteriovenous malformation
 - A surgical shunt
 - A to-and-fro murmur describes an ejection murmur heard in systole, coupled to a decrescendo murmur early in diastole.
 - To-and-fro murmurs are not true continuous murmurs.
 - Combined aortic stenosis and aortic insufficiency or pulmonary stenosis and pulmonary insufficiency produce to-and-fro murmurs.

Location and radiation

- Refer to the area where the murmur is best heard and where it radiates
- Useful in differential diagnosis

Quality

- Refers to the pitch and nature of a murmur
- Pitch is generally described as either high or low.
 - High-pitched murmurs occur when the pressure differential involved is large.
 - Aortic insufficiency is a high-pitched murmur.
 - Low-pitched murmurs occur when a lower pressure differential is involved.
 - Pulmonary insufficiency causes a low-pitched murmur.
- Systolic murmurs are described as ejection, regurgitant, harsh, blowing, musical, or vibratory.
- Diastolic murmurs are described as blowing, rumbling, crescendo, or decrescendo.

Common Innocent Murmurs

Murmur	Intensity	Timing	Location	Quality
Still	I–III or VI	Early-mid systolic	LM-LLSB or apex	Vibratory, musical
Pulmonary	I–III or VI	Early-mid systolic	LUSB	Low-pitched, ejection flow
Venous hum	I–III or VI	Continuous	Right or left infra- or supraclavicular	Low-pitched, disappears with head turn, supine position, jugular compression

Abbreviations: LM-LLSB, left mid to left lower sternal border; LUSB, left upper sternal border.

DIFFERENTIAL DIAGNOSIS

- The challenge for the primary care physician lies in distinguishing innocent murmurs from those that indicate a cardiac abnormality.
- Location helps narrow the differential diagnosis of the murmur.
- Radiation of the murmur can also aid in forming the differential diagnosis.
 - Murmurs that radiate to the neck tend to be of aortic or left ventricular outflow tract origin.
 - A murmur heard best at the left upper sternal border with radiation to the axillae and back is more likely to be pulmonary in origin.
- Postural maneuvers are useful in distinguishing among different types of murmurs.
 - Innocent murmurs tend to become louder when the patient moves from an upright to a supine position.
 - Placing the patient in the left lateral decubitus position increases the murmur of mitral stenosis.
 - Valsalva maneuver, by decreasing venous return:
 - Makes the murmur of aortic stenosis softer
 - Makes the murmur of hypertrophic obstructive cardiomyopathy louder
 - Decreases the murmurs associated with a VSD and mitral regurgitation
 - Can nearly eliminate innocent still murmurs (see table Common Innocent Murmurs)
 - Squatting increases venous return and makes the murmur of hypertrophic obstructive cardiomyopathy softer.
 - Standing up after squatting can accentuate the murmur or click of mitral valve prolapse by moving the murmur and click closer to the S1.
 - Turning the head can eliminate the innocent continuous murmur of a venous hum.

LABORATORY EVALUATION

- Patients with cyanotic heart diseases are polycythemic, with very high hemoglobin level and hematocrit.

IMAGING

- Chest radiograph may be done to determine the size of heart, the status of pulmonary vasculature, and evidence of congestive cardiac failure.

DIAGNOSTIC PROCEDURES

- Electrocardiography and echocardiography are usually done to define the lesion of organic heart disease that is causing the murmur.

TREATMENT APPROACH

- It is important to differentiate innocent murmur from abnormal murmur.
 - Once innocent murmur is established, reassurance is the mainstay of management.

SPECIFIC TREATMENT

- The specific management of cardiac murmur depends on the underlying cardiac lesion.

WHEN TO REFER

- Patient, maternal, or family history that raises the index of suspicion for heart disease
- All diastolic murmurs require referral to a pediatric cardiologist.
- Continuous murmurs, except venous hum
- All systolic murmurs grade IV or higher
- All systolic murmurs not clearly fitting the pattern of innocent murmur
- A thrill is an abnormal finding and warrants referral to a pediatric cardiologist.
- Cyanosis, clubbing
- Higher blood pressure in 1 or both arms than in a leg
- Congestive heart failure—rales, respiratory distress, hepatomegaly, edema
- Abnormal electrocardiogram
- Symptoms that suggest reactive airway disease that do not improve with appropriate medical therapy

Hematuria

DEFINITION

- Urine that contains blood or erythrocytes
- Microscopic
 - >5 erythrocytes per high-power field seen on microscopy of centrifuged urine
- Macroscopic (or gross)
 - Red or brown (cola-colored) urine with erythrocytes seen on microscopy

EPIDEMIOLOGY

- Prevalence
 - The rate of macroscopic hematuria in children presenting to a pediatric emergency department was 1.3 per 1000 visits in 1 study.
 - Studies of routine screenings for microscopic hematuria suggest rates of up to 32 per 1000 girls and 14 per 1000 boys.
- Thin basement membrane nephropathy (one of the common causes of microscopic hematuria)
 - Prevalence
 - Estimated at 1–10% of the population
 - Sex
 - More common in females than in males
 - Age
 - Has been diagnosed in children as young as 1 year

MECHANISM

- Infection of the upper or lower urinary tract is the most common cause of hematuria overall.
- Macroscopic hematuria may originate from any component of the genitourinary tract; possible causes include:
 - Infection
 - Glomerular, interstitial, and tubular diseases
 - Bleeding from trauma, stones, or coagulopathy
- Microscopic hematuria may be caused by:
 - Infection
 - Nephrolithiasis (hypercalciuria)
 - Glomerulonephritis
- The most common causes of asymptomatic isolated microscopic hematuria are:
 - Thin basement membrane nephropathy (TBMN)
 - Idiopathic hypercalciuria
 - Immunoglobulin A (IgA) nephropathy
 - Sickle cell disease or trait
- The most common glomerulonephritis is postinfectious.
 - Prodromal infection 1–6 weeks before the onset of hematuria
 - Often a streptococcal skin or throat infection

- Viral infections, such as:
 - Varicella
 - Cytomegalovirus
 - Epstein-Barr virus
 - Hepatitis B virus and hepatitis C virus
- Parasitic infections, such as toxoplasmosis
- Other causes of acute postinfectious glomerulonephritis include:
 - Ventriculoperitoneal shunt infections (shunt nephritis)
 - Acute or subacute endocarditis
- Henoch-Schönlein purpura
 - Can produce glomerulonephritis with hematuria

HISTORY

- Hematuria may manifest as:
 - Dramatic change in the color of a child's urine
 - Blood on a diaper or underwear
 - Finding on urinalysis
 - Routine screening urinalysis is recommended by the AAP at 5 years of age and again at 11–21 years of age.
- Hematuria of glomerular origin:
 - Presents with tea- or cola-colored urine
 - Is marked by the presence of erythrocyte casts
 - Is typically painless

Macroscopic hematuria

- Obtain a detailed description of the urine (see Figure 31 on page F12).
 - Renal or glomerular causes of hematuria result in tea- or cola-colored urine.
 - Hematuria of lower tract origin causes red or pink urine.
 - Highly turbid urine may indicate the presence of cells.
 - Suggests glomerular disease or infection
- Blood clots suggest urinary tract bleeding.
 - Timing of the bleeding may be helpful.
 - If bleeding occurs only with the onset of micturition, the source of the bleeding is likely to be in the lower tract.
- Laboratory and radiologic evaluation is dictated by associated signs and symptoms from a detailed history and physical examination.
 - Important historical elements include associated urinary symptoms, such as:
 - Dysuria
 - Frequency
 - Urgency
 - Enuresis
 - A decrease in urine output should prompt particular concern and rapid evaluation and treatment.

- A review of systems should include associated symptoms.
 - Abdominal pain or colic
 - Upper respiratory infection symptoms
 - Swelling of extremities
 - Blurry vision or headaches suggestive of hypertension
- Ask patient or parents about:
 - Prior episodes of hematuria
 - Preceding infections
 - Documented group A streptococcal throat infection
 - History of sore throat or skin infection
 - History of trauma
 - Other illnesses, such as the presence of sickle cell trait or sickle cell disease
- Systemic illnesses may be suggested by history of:
 - Fever
 - Malaise
 - Weight loss
 - Alopecia
 - Rash
 - Joint pains, such as may be seen in rheumatologic disease
- Important points of family history include:
 - Other family members with hematuria or kidney or rheumatologic disease
 - Any history of deafness, which may occur with Alport syndrome

Microscopic hematuria

- Figure 32 on page F12 shows a proposed algorithm for the evaluation of microscopic hematuria.
- Recent history of throat or skin infections
- Family history of hematuria, deafness, or kidney disease

PHYSICAL EXAM

- Growth parameters
- Measurement of blood pressure
- Evaluation of abdominal or costovertebral angle tenderness
- Search for evidence of local trauma to the genitourinary tract.
- Inspection and palpation for periorbital, genital, or extremity edema

DIFFERENTIAL DIAGNOSIS

- Macroscopic hematuria:
 - Is a common sign of glomerular and urologic disease
 - Rarely is a cause of anemia
- Blood on a diaper or underwear
 - Most commonly occurs with trauma to or manipulation of the genital area

- In boys, localized irritation of the meatus is the most frequent cause.
- Responds to treatment with petroleum jelly and reassurance to the parent without further evaluation
- Other causes include:
 - Sexual abuse
 - Urinary tract infection with *Serratia marcescens*
- Hematuria in association with edema and hypertension suggests glomerulonephritis.
- Hematuria arising from the urinary tract is usually red-pink, with or without clots.
- TBMN
 - Also known as *thin basement membrane disease*, *hereditary hematuria*, *benign familial hematuria*, or *benign hereditary nephritis*
 - One of the most common causes of persistent microhematuria
 - 5–22% of affected individuals will have an episode of macroscopic hematuria associated with an infection or exercise.
 - Persistent microhematuria distinguishes TBMN from other acute renal causes of hematuria, such as postinfectious glomerulonephritis.
 - Characterized by:
 - Painless microscopic hematuria with minimal proteinuria
 - Normal renal function
 - Renal biopsy reveals uniform thinning of the glomerular basement membrane.
 - Transmitted in an autosomal dominant fashion.
 - Diagnosis is suggested by:
 - Family history of microscopic hematuria without symptomatic renal disease
 - Asymptomatic parent testing positive for hematuria TBMN
 - No evidence has been found to support treatment of TBMN, which is typically nonprogressive.
 - Affected children should be monitored for hypertension, proteinuria, and renal insufficiency.
 - May point to the diagnosis of:
 - IgA nephropathy
 - Alport syndrome
 - Nephrolithiasis
 - Glomerulonephritis
 - Each has been reported in association with TBMN.
- Hypercalciuria
 - A common cause of microscopic hematuria
 - Defined as:
 - Urine calcium-to-creatinine ratio >0.21

- >4 mg/kg per day of excreted calcium on a 24-hour urine collection
- Children with hematuria and underlying hypercalciuria are at risk for nephrolithiasis.
 - The risk appears to be greater:
 - In older children
 - In children with macroscopic rather than microscopic hematuria
 - When there is a family history of stone formation
- Henoch-Schönlein purpura
 - Common systemic vasculitis in children
 - Usually associated with:
 - Crampy abdominal pain
 - Arthralgia
 - Palpable purpura
 - Can produce glomerulonephritis with hematuria

LABORATORY EVALUATION

- Most children with isolated microscopic hematuria do not have a serious or treatable cause for the hematuria and do not require an extensive workup.
- Begin with urinalysis with microscopic examination of fresh-spun urine sample to confirm the presence of erythrocytes.
 - Dysmorphic erythrocytes and erythrocyte casts are pathognomonic of hematuria of glomerular origin.
- Urine dipstick positive for blood and <5 erythrocytes found on microscopy
 - The diagnosis is hemoglobinuria or myoglobinuria rather than hematuria.
- Several drugs and foods can discolor urine to give it the appearance of hematuria (urinalysis will be negative for blood).
 - Rifampin
 - Ibuprofen
 - Nitrofurantoin
 - Beets
 - Blackberries
- Nephrolithiasis may be suggested by the presence in urine of:
 - Calcium
 - Uric acid
 - Cystine crystals
- Infectious causes of hematuria are indicated by:
 - Leukocyte casts
 - Leukocyte esterase
 - Nitrate positivity on urine dipstick
- Further evaluation is determined by the most likely cause of the blood in the urine.

- If microscopy is not immediately available, a reasonable panel of tests would include:
 - Serum electrolytes
 - Blood urea nitrogen
 - Creatinine
 - Calcium and phosphorus
 - Liver function tests
 - Antinuclear antibody test
 - Complement studies (C3, C4, and total complement)
 - Complete blood count with differential
 - Streptozyme (deoxyribonuclease B) and streptolysin O antibody titers
- Patients with a history of sore throat should undergo:
 - Throat culture
 - Rapid testing for group A β -hemolytic streptococci
- Urine culture should be performed on:
 - All patients with urinary symptoms
 - Infants with unexplained fever or sepsis
- Proteinuria on urinalysis should be further evaluated with a morning void for protein-to-creatinine ratio.
- Asymptomatic, normotensive child with isolated microhematuria
 - Repeating urinalysis ≥ 1 times before further evaluation often is prudent.
- Persistent microhematuria may represent an early presentation of a progressive glomerular disease, such as:
 - IgA nephropathy
 - Alport syndrome
- Periodic urinalysis should be done to monitor for the development of significant proteinuria.

IMAGING

- Every child with macroscopic hematuria should have renal ultrasonography to rule out:
 - Nephrolithiasis
 - Tumor
 - Urologic abnormalities
 - Cystic disease
 - Obstructive uropathy
 - Parenchymal renal disease

DIAGNOSTIC PROCEDURES

- Renal biopsy may be performed for:
 - Family history of hematuria
 - History or laboratory evaluation suggestive of rheumatologic disease, such as systemic lupus erythematosus

- Renal biopsy is absolutely indicated in cases of hematuria with:
 - Nephrotic syndrome
 - Recurrent hematuria
 - Azotemia
 - Renal insufficiency

TREATMENT APPROACH

- Management of glomerular disease depends on the cause of the glomerulonephritis.
- Poststreptococcal glomerulonephritis
 - Low C3 levels and elevated streptolysin O antibody titers are characteristic.
 - Typically self-limited
 - Good prognosis for long-term renal function
- Microhematuria without any other signs and symptoms:
 - Often is benign
 - Resolves spontaneously in many cases (transient hematuria)
- School-aged children with microscopic hematuria may be observed for ≥ 2 years before more extensive testing is undertaken.
- Patients with glomerulonephritis need to be monitored for hypertension and, if present, need to be treated with antihypertensive medications.

SPECIFIC TREATMENT

- Treat urinary tract infections with an appropriate antimicrobial regimen
- Skin or throat streptococcal infections should be treated with penicillin.

WHEN TO REFER

- Hematuria associated with pain
- Persistent microscopic hematuria with:
 - Associated proteinuria
 - Hypertension
 - Hearing loss
 - Family history of renal disease or deafness
- Glomerulonephritis
 - Some types require management by a nephrologist.
- Urologic evaluation, which may include direct visualization by cystoscopy, may be required for:
 - Trauma
 - Tumors
 - Cystic disease
 - Congenital obstruction

- Hemorrhagic cystitis
- Lower urinary tract bleeding
- Nephrolithiasis

- Children with nephrolithiasis benefit from both nephrologic and urologic evaluation.
- A family history of deafness or kidney disease and the presence of hypertension, proteinuria, or edema
- Significant proteinuria
- Occurrence of macroscopic hematuria

WHEN TO ADMIT

- Admission for intravenous hydration may be required for:
 - Patients with sickle cell disease or sickle cell trait and macroscopic hematuria from papillary necrosis
- Severe abdominal pain or flank pain
- Congestive heart failure or fluid overload indicative of oliguria or anuria
- Hypertension
- Renal insufficiency
- Anasarca (generalized edema)
- Oliguria
- Decreased urine output
- Azotemia
- Acute hypertension
 - Requires aggressive management with:
 - Fluid and salt restriction
 - Antihypertensive medications
- Further evaluation of glomerular hematuria may be continued as an outpatient or inpatient.

FOLLOW-UP

- Monitor growth (height).
- Monitor patients for hypertension.
- Hematuria should be monitored by periodic urine analysis.
- Kidney function (serum blood urea nitrogen, creatinine) may need to be monitored as appropriate.

COMPLICATIONS

- Some renal disorders associated with hematuria may lead to:
 - Hypertension
 - Progressive kidney disease leading to renal failure

PROGNOSIS

- Proteinuria is a more important prognostic finding than macroscopic hematuria.
- Proteinuria and hypertension are poor prognostic indicators.

Hemoglobinopathies and Sickle Cell Disease

DEFINITION

- The normal hemoglobins (Hb) are Hb A (96% of the total content), Hb F (1%), and Hb A₂ (3%).
- Hemoglobin synthesis is directed by controlling genes that are switched on and off at certain stages of human life, resulting in different globin-chain synthesis at different times.
- Inherited Hb disorders due to single-gene defects
 - Thalassemias: structurally normal but decreased amounts of globin chains
 - α -Thalassemias
 - β -Thalassemias
 - Structural Hb abnormalities: abnormal globin chains
 - Sickling disorders
 - Sickle cell trait
 - Benign carrier state
 - Rare structural hemoglobinopathies

EPIDEMIOLOGY

- Inherited Hb disorders comprise most common single-gene defects in humans.
- In the US and other developed countries, hemoglobinopathies remain a concern, particularly among certain ethnic groups.
- Incidence
 - Approximately 400,000 births per year of infants with serious hemoglobinopathies
- Prevalence
 - Worldwide frequency of carrier state estimated at 270 million
 - Prevalence is increasing worldwide.
 - Sickle cell trait
 - Varies from 6.7–10.1% in blacks
 - β -Thalassemia prevalence
 - Mediterranean region
 - Africa
 - Middle East
 - Indian subcontinent
 - Burma
 - Southeast Asia (including the Malay Peninsula)
 - Southern China
 - Indonesia
- α -Thalassemia retardation (ATR)
 - Occurs in racial groups in which α -thalassemia is otherwise rare
- Hb Bart disease accounts for 90% of all hydrops fetalis in Southeast Asia.
- Hb E is common in Southeast Asia and in certain areas of the Indian subcontinent.

ETIOLOGY

- Thalassemias are caused by mutations in the globin gene cluster, resulting in a genetic decrease in globin chain synthesis.
 - In theory, as many types of thalassemias exist as types of globin chains.
 - Practically, the most clinically relevant thalassemias are α - and β -thalassemia.
 - α -Thalassemia
 - Characterized by decreased α -chain synthesis
 - The most common defect is deletional, although nondeletional defects have been described.
 - The a gene is duplicated, and 2 α -globin genes per haploid genome are present.
 - See Classification for types of α -thalassemias.
 - ATR
 - The pattern of inheritance is different from that seen in α -thalassemia.
 - Occurs in association with a deletion on chromosome 16 (ATR-16) and in association with the ATR-X syndrome, which results from mutations of the *XH2* gene, located on the long arm of the X chromosome (Xq13.3)
 - β -Thalassemia
 - Caused by a decrease in production of β -globin chains as a result of mutations in the β -globin gene
 - Mutations cause variable impairments of globin synthesis.
 - More severe forms result from homozygosity or compound heterozygosity for the mutant β -globin allele.
 - Result in thalassemia major or thalassemia intermedia
- Structural hemoglobinopathies
 - Usually result from a point mutation in the α - or β -globin gene that causes a functional abnormality, effects of which depend on where the missense mutation occurs
 - Sickling disorders
 - Sickling disorders depend on gene interactions.
 - SS (known as sickle cell anemia)
 - Homozygosity for the mutant Hb S
 - Results in no normal β alleles and no Hb A
 - SC
 - Double heterozygosity for 2 β -chain mutants (Hb S and Hb C)
 - Results in no normal β alleles and no Hb A
 - Sickle β -thalassemia
 - Double heterozygosity for Hb S and β -thalassemia

- One β gene directs the synthesis of Hb S, and the other is either:
 - Completely suppressed, and patient has no Hb A (S β^+ -thalassemia) *or*
 - Incompletely suppressed, and patient produces a small amount of Hb A (S β^+ -thalassemia)
- Hb A₂ is increased.
- SO Arab and SD
 - Double heterozygosity for Hb S and Hb O or D, respectively
- Rare structural hemoglobinopathies (prototypes)
 - Hb Zurich
 - Unstable hemoglobin: usually results from amino acid substitutions near the heme pocket
 - Hb Bethesda
 - Hemoglobin with high oxygen affinity: amino acid substitution near the α_1 - β_2 interface
 - Hb Kansas
 - Hemoglobin with low oxygen affinity: amino acid substitution near the α_1 - β_2 interface
 - Hb M
 - Amino acid substitution near the heme pocket, close to the site of the iron molecule
 - Hb C, D, and E
 - Structural variant hemoglobins synthesized at a lower rate than normal β chains
 - Heterozygous Hb C (AC) results in mild target cells but no anemia.
 - Homozygous C (CC) produces mild hemolytic anemia, marked red blood cell (RBC) morphologic changes (target cells, hemoglobin crystals, and microspherocytes), and mild splenomegaly.
 - Heterozygous E (AE) causes mild thalassemic phenotype with mild microcytosis and hypochromia.
 - Homozygous E (EE) results in moderate thalassemic phenotype, with hypochromia, microcytosis, and mild anemia.
 - Combined E- and β -thalassemia inheritance results in a transfusion-dependent thalassemic phenotype.
- Hb Bart disease
 - Severe anemia
- ATR-X syndrome: α -thalassemia seen in nontropical populations
 - Severe intellectual disability
 - Minor facial anomalies
 - Genital anomalies
 - Mild form of Hb H disease
- β -Thalassemia
 - Clinical presentation is variable.
 - Thalassemia major
 - Symptoms at approximately 6 months with anemia that can be severe and symptomatic
 - Growth failure
 - Cardiac dysfunction
 - Pallor
 - Jaundice
 - Hepatosplenomegaly
 - The patient's body becomes loaded with iron, even when transfusions are sparingly provided.
 - Liver effects (leading to cirrhosis)
 - Pituitary effects (leading to hypogonadism and growth failure)
 - Heart effects (leading to arrhythmia and cardiomyopathy)
 - Bone effects (leading to pathologic fractures)
 - Thalassemia intermedia
 - Patients exhibit symptoms later in life.
 - Anemia is well compensated.
 - May be exacerbated by infection, folate deficiency, or increasing hypersplenism
- Sickling disorders
 - Pallor
 - Jaundice
 - Increased fatigue
 - Gallstones
 - Poor growth
 - Aplastic crises occur:
 - After viral infections
 - In situations in which transient marrow suppression results in a life-threatening decrease in hemoglobin
 - Episodic, variable, and unpredictable musculoskeletal pain
 - Disabling if frequent and severe
 - Usually uncomplicated and not life threatening
 - Acute bone pain or infarction
 - Common at all ages

SIGNS AND SYMPTOMS

■ α -Thalassemia

- Silent carrier
 - No anemia
- α -Thalassemia-1
 - Mild anemia
- Hb H disease
 - Moderate anemia

- Dactylitis (foot and hand swelling) is classic early childhood symptom.
- Splenic sequestration crisis may occur.
 - Sudden pooling of blood in the spleen with hypovolemic shock
 - Life-threatening and recurrent syndrome of early childhood
- Strokes, although uncommon, are a recurrent and serious problem.
- Variety of cerebrovascular catastrophes, such as hemorrhage and thrombosis, can occur.
- Acute chest syndrome is common.
 - Pulmonary infarction or pneumonia (or both)
- Large volumes of dilute urine even in young children
 - Need copious fluid intake to avoid dehydration
- Hematuria
- Priapism
- Trophic leg ulcers
- Blindness
- Sickle cell trait
 - Most people have no clinical symptoms.
 - Can cause hematuria and a loss of urine-concentration capacity
 - Symptoms from intravascular sickling have been reported with:
 - Strenuous exercise at high altitudes
 - Flying at high altitudes in unpressurized aircraft
- High oxygen–affinity hemoglobins
 - High arterial oxygen saturation
 - Markedly left-shifted oxygen-dissociation curve
 - Presence of familial erythrocytosis (polycythemia)
- Hb M
 - History of cyanosis since birth, with a normal oxygen saturation
- Low oxygen–affinity hemoglobins
 - Right-shifted oxygen-dissociation curve

DIAGNOSTIC APPROACH

- Prenatal diagnosis
 - Specific tests, such as:
 - Globin chain synthesis ratios
 - DNA analysis by sampling of fetal blood or chorionic villus
 - Restriction fragment polymorphism
- α -Thalassemias
 - Confirmation of decreased α chains by globin-chain synthesis measured in reticulocytes
 - Expensive and hard to do

- Sickling disorders
 - Clinical history and physical findings are the first steps to diagnosis.

LABORATORY FINDINGS

Thalassemias

- α -Thalassemias
 - Routine complete blood count shows hypochromia (mean cell Hb <27 pg).
 - Microcytosis (mean cell volume <80 fL)
 - Mild anemia with normal Hb A₂
 - Abnormal Hb tetramers are demonstrated by:
 - Presence of RBC inclusions on cresyl blue stain
 - Hemoglobin electrophoresis
 - Rapid movement (faster than Hb A)
 - Require special attention during electrophoresis testing
 - Hb Bart (γ -tetramers) are found in the first few weeks of life, and Hb H can be found in older patients.
 - Silent carrier: normal RBC count
 - Hb H disease: fragmented cells with hypochromia and microcytosis
- β -Thalassemia: thalassemia major
 - RBCs may be destroyed within the marrow, leading to ineffective erythropoiesis.
 - Hallmark of β -thalassemia
 - Decreased hemoglobin content per cell
 - Hypochromia
 - Microcytosis

Structural hemoglobinopathies

- Sickling disorders
 - Morphologic sickling can be assessed by blood smears.
 - Presence of Hb S is evaluated by the solubility test.
 - Inexpensive and sensitive to the carrier state
 - Hemoglobin electrophoresis confirms the exact phenotype.
- Unstable hemoglobins
 - Hemolytic anemia
 - Detection of Heinz bodies by staining and heat precipitation test
 - Hemoglobin electrophoresis is not always useful because of the tendency of hemoglobin to rapidly denature.
- High oxygen–affinity hemoglobins
 - High RBC mass
- Low oxygen–affinity hemoglobins
 - Hemoglobin level and RBC mass are normal.
- Hb M
 - Brown discoloration of freshly drawn blood
 - Does not change with aeration

- Spectrophotometry confirms presence of methemoglobin.
- Electrophoresis demonstrates abnormal hemoglobin.

DIAGNOSTIC PROCEDURES

- Hemoglobin electrophoresis may be diagnostic in many hemoglobinopathies and thalassemias.

CLASSIFICATION

- Classification of a thalassemias, by phenotype (number of a genes; genotype)
 - Normal (4; $\alpha\alpha/\alpha\alpha$)
 - Silent carrier (3; $-\alpha/\alpha\alpha$)
 - 2-gene deletion (α -thalassemia-1) (2; $--/\alpha\alpha$ or $-\alpha/-\alpha$)
 - Hb H disease (1; $---/\alpha$)
 - Hb Bart disease (hydrops fetalis) (0; $---/---$)

TREATMENT APPROACH

- Blood transfusion
 - Continues to be the mainstay of care of patients with hemoglobinopathies
 - Transfusion safety is an important consideration, particularly prevention of transfusion-transmitted infections.
 - Donors should be screened for hepatitis B and C, HIV, syphilis, and malaria.
 - Donor screening may sometimes be ineffective.
 - Insensitive tests
 - Expired kits and reagents
 - Improper procedures
- Iron chelation
 - Deferrioxamine
 - Daily 8-hour subcutaneous infusion via small portable pumps
 - Well tolerated and extremely effective
 - Oral deferasirox
 - Similar efficacy as deferrioxamine in preclinical trials, and much less cumbersome for patients
 - Starting dose is 20 mg/kg once daily as a dispersion in water or orange or apple juice.
 - Highest recommended dose is 30 mg/kg per day.
 - Toxicities
 - Increase over baseline of creatinine and proteinuria
 - Pediatric patients with sickle cell disease have low creatinine concentration.
 - Increases of 30% over baseline should prompt dose decreases for such patients.
 - Chemical hepatitis or aminotransferase elevation over baseline
 - Usually respond to dose decreases to 10 mg/kg per day

- Treatment effectiveness is measured by monitoring serum ferritin level.
 - Although not the most accurate measure of total body iron stores
 - Levels <2500 mg/dL are associated with improved cardiac disease-free survival.
 - Chelation should be interrupted for serum ferritin levels ≤ 500 ng/mL because of increased drug toxicity at low ferritin levels.
 - Magnetic susceptometry provides a noninvasive method for measuring hepatic iron stores.
 - This test is available in only a few centers worldwide.

■ Stem cell transplantation

- Improved techniques that use human leukocyte antigen (HLA)-matched sibling donors may result in cures for the hemoglobinopathies.
- Interest exists in nonmyeloablative or reduced-intensity myeloablative stem cell transplantation.
 - Has reduced morbidity but leads to a chimerism in the recipient
 - This procedure is still investigational.

■ Advances in genomics and other technologies

- Have promise to improve treatment of patients with hemoglobinopathies

SPECIFIC TREATMENTS

β -Thalassemia

■ Blood transfusions are provided to:

- Correct anemia
- Suppress erythropoiesis
- Prevent growth failure
- Inhibit increased gastrointestinal absorption of iron

■ Splenectomy

- Usually performed if transfusion requirements increase because of hypersplenism

■ Folic acid supplementation

- May be considered to meet its increased requirement

■ Iron chelation

■ Hematopoietic stem cell transplantation

- May be performed when chronic transfusions and chelation are not possible
 - If successful, reverses need for transfusions or chelation therapy
 - Carries risk of serious adverse effects
 - Graft failure
 - Rejection
 - Graft-versus-host disease
 - Death

- Does not reverse preexisting and established growth failure, endocrinopathies, and gonadal dysfunction
- Must also consider availability of supportive care after transplantation
- Using either related or unrelated HLA-matched donors results in excellent outcomes in low-risk patients without extensive organ damage.

Structural hemoglobinopathies

Sickling disorders

- Give symptomatic and supportive care of complications.
 - Treat pain episodes with analgesics (often narcotics) and local heat packs.
 - Ensure adequate hydration.
 - Adjust acid-base balance.
 - Prevent hypoxia.
 - Avoid exposure to cold.
