Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of the information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in the publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at (800) 638-3030 or fax orders to (301) 223-2320. International customers should call (301) 223-2300.

CONTENTS

SECTION 4:
SURGICAL CRITICAL CARE

SECTION 5:
SPECIAL TOPICS

We are firmly committed to the tridisciplinary specialty—acute care surgery, which encompasses trauma, critical care, and emergency general surgery. This comprehensive textbook represents innumerable hours of dedication and sacrifice by us and the editors of this new edition along with the many accomplished contributors, who are recognized leaders in their respective areas of interest. The full spectrum of acute care surgery is expertly addressed in the 64 chapters included in this book, with each chapter highlighting cutting-edge advances in the field and underscoring state-of-the-art management paradigms.

In an effort to create the most definitive reference on acute care surgery, we have emphasized an evidence-based approach for all content included. Also, notable controversies are discussed in detail often accompanied by data-driven resolution.

Perhaps the most pivotal point in the process was the working retreat that we had in a makeshift conference room where we essentially had a marathon and critically reviewed each chapter for accuracy, relevance, and style. This process continued on an almost weekly basis until a consensus of high-level satisfaction was achieved for each chapter. Without hesitation or trepidation, we are dedicating this book to all the authors, whose tireless efforts contributed to the success of *Acute Care Surgery*. In addition, we graciously thank our family and friends for allowing us to spend some of our "free time" diligently working on this important project.

ACUTE CARE SURGERY: INTRODUCTION

Acute care surgery (ACS), an evolving tridisciplinary specialty, addresses the concern highlighted by Dr. William Steward Halsted when he stated that "…every important hospital should have on its resident staff of surgeons at least one who is well trained and able to deal with any emergency."[1] The evolution of ACS did not occur *de novo*. On the contrary, several forces created an optimal environment for its birth and development, including a precipitous decline in the surgical workforce that would be involved in the management of such emergencies, along with the well-documented short supply of specialty support in the acute care setting. A survey conducted by the American College of Emergency Physicians in 2005 showed that nearly three-quarters of emergency department medical directors believe they have inadequate on-call specialty coverage. In that same survey, orthopedic, plastic, and neurologic surgeons, as well as otolaryngologists and hand surgeons, were reported as being in short supply. A fact sheet entitled "The Future of Emergency Care," produced by the Institute of Medicine of the National Academies in 2006, corroborated these findings. Although some controversy still exists regarding scope of practice and the essential requirements for this specialty, ACS is a new and unique discipline. The label "acute care surgeon" has been erroneously applied to the "surgical hospitalists" and the "emergency general surgeons." However, the true definition of "acute care surgery" embodies three specialty components—trauma surgery, emergency general surgery, and surgical critical care (Figure 1).

As a result, the general principles of ACS are derived from these three specialties. The overarching principle, which transcends each of these three components, is early and expedient medical/surgical intervention. Whether managing a patient with perforated duodenal ulcer or enterotomies secondary to a gunshot wound to the abdomen, early diagnosis and expedient intervention make up the cornerstone of optimal management. There is no disharmony between the well-established tenets of trauma management and the general principles of ACS. While adhering to the basic priorities (airway, breathing, circulation, etc.) underscored in the primary survey is always prudent, such an emphasis needs to be tailored on a case-by-case basis in nontrauma surgical emergencies so that timely intervention is not delayed. For example, little attention has to be directed to the disability assessment, included in the primary survey, for a young patient who presents with a presumptive diagnosis of acute appendicitis and an obvious surgical abdomen. The same would be the case for many other nontrauma surgical emergencies. Because of the disparate disease entities and unique patient populations that can lead to surgical emergencies, it is unlikely and, perhaps, unnecessary that an all-encompassing management paradigm, such as Advanced Trauma Life Support (ATLS)[2], which is arguably the most accepted and successful practice guideline in American (and international) medicine—is actually needed. However, general principles of optimal management are, indeed, applicable even among special populations of patients with potential surgical emergencies. Such general principles are embedded in the thrust of surgical education that continually underscores the important role of surgical judgment and prioritization of patient management.

As articulated in a well-written commentary in a recent edition of the *New Yorker*, old age is the new demography.[3] The general principles of "acute care surgery" must adapt to this and other vulnerable populations. Between 2010 and 2050, there will be a substantial increase in the elderly population (Figure 2).[4] With the preexisting conditions, or comorbidities, increasing with age, the finding by Schloss[5] that the elderly require twice the time and effort of the general surgeon is even more relevant for the elderly patient in the acute care setting.

In addition, there are age-related physiologic changes that must be considered when managing the patients. Figure 3 represents a plausible treatment algorithm for this special population.

The accepted general principles of ACS management must be malleable enough that appropriate adjustments can be made for such age-related physiologic changes for this unique cohort of patients. Limited physiologic reserves should also be expected in the management of another vulnerable population—pediatric patients. For example, it is even more imperative to ensure environmental control (prevention of hypothermia) in management of the child in the acute care setting. Also, the health care provider team must be fully cognizant of the fact that hemodynamic instability is often a *late* finding in the pediatric patient population.

In addition to an aging population, each decade in the United States the population also increases by 25 million. With being an established trend toward specialization and a heavy emphasis on the elective practice, expert surgical management in the acute care setting needs to be both cultivated and fortified if optimal patient care is to be ensured for the injured and critically ill surgical patients. While a multifaceted approach will be needed to address this challenge, the establishment of the specialty, acute care surgery, is a major step in the right direction.

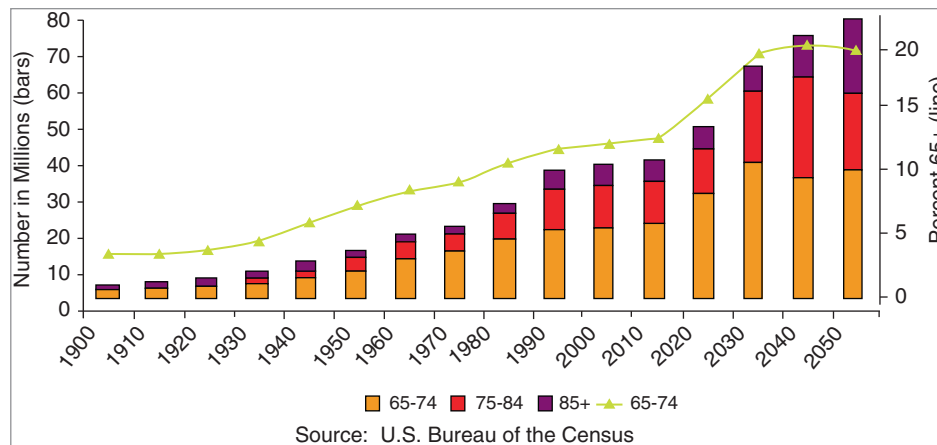
FIGURE 1. Acute care surgery: a tri-disciplinary specialty.


FIGURE 2. Growth of US population over age 65, 1900 to 2050, by age group.
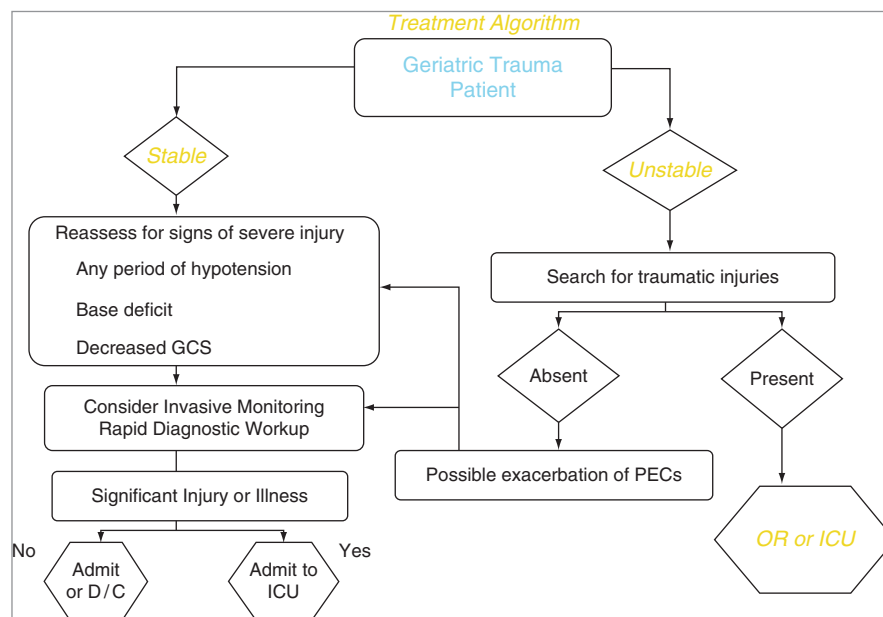

FIGURE 3. Geriatric trauma patient treatment algorithm.

CHAPTER 1 ■ ACUTE CARE SURGERY: GENERAL PRINCIPLES

L.D. BRITT

ACUTE CARE SURGERY-GENERAL PRINCIPLES

Expedient assessment/intervention is the paramount axiom of acute care surgery management. This in no way undermines or devalues the merits of comprehensive assessments. On the contrary, prioritization of management—in an attempt to quickly address disease and injury that can rapidly result in severe morbidity and mortality—has always been the cornerstone of all aspects of medicine. Emergency operative intervention, precluding a comprehensive assessment and preoperative clearance, is indicated in some circumstances. In such case, the complete evaluation is done after stabilization of the patient. While the importance of preoperative clearance cannot be over emphasized, it often cannot (and should not) be implemented in the acute care setting for a risk benefit analysis of delaying surgical intervention would be unfavorable and detrimental to the health status of the patient. However, when appropriate, a systematic approach to preoperative clearance should be done.

The general principles of acute care surgery, in the nontrauma setting, must be applicable in the following areas of emergency general surgery and surgical critical care: (1) inflammation, (2) perforation, (3) obstruction, (4) bleeding, (5) ischemia, (6) necrosis, (7) hypoxia, and (8) infection.

CORE MANAGEMENT PRINCIPLES

In the nontrauma setting, the core management principles (the four Es) in acute care surgery are the following:

- Expeditious initial assessment
- End point–guided resuscitation
- Early intervention and definitive management (if possible)
- Essential physiologic monitoring

Expeditious Initial Assessment

Each of the presentations highlighted in Table 1.1 is time sensitive and, therefore, often necessitates a rapid, methodical, and accurate evaluation process. When applicable, this would entail obtaining a relevant history from the patient and possible family members or health providers caring for the patient. In addition, the patient should, initially, undergo a focused physical examination, which can be expanded to a full and complete exam, if emergency intervention does not preclude such an assessment. Integrated in the assessment and resuscitative phase should be the acquisition of the important laboratory values and any required imaging

studies necessary to provide quality surgical care. Because of the broad spectrum of presentations in acute care surgery, there is some variability in the diagnostic/treatment paradigms although the core management principles remain the same. For example, the otherwise healthy young male patient who presents with relatively acute onset of right lower-quadrant pain (preceded by periumbilical pain), anorexia, and a fever is likely to have acute appendicitis. If physical exam confirms right lower-quadrant tenderness with localized peritoneal signs and no other remarkable abnormal findings, the patient should have ongoing resuscitation, antibiotics, and operative intervention for suspected acute appendicitis. While some physicians may advocate obtaining a CT scan, it is not essential in this setting. Also, if a patient presents toxic with diffuse peritonitis and has associated comorbidities suggestive of secondary peritonitis (e.g., perforated duodenal ulcer), he/she should be considered for surgery. Any patient with an acute surgical abdomen should not have intervention delayed by unnecessary imaging studies. However, the elderly patient, who has multiple comorbidities, presenting with an insidious onset of left lower-quadrant pain and tenderness elevated on abdominal palpation in this area will likely have diverticulitis. Radiologic imaging, specifically computed tomography (CT), would be essential in the diagnostic workup, disease classification, and management of this patient. A CT scan that demonstrates a contained pericolonic abscess secondary to a perforated inflamed diverticulum (Hinchey II classification) would dictate the need for CT scan–directed percutaneous drainage of the abscess and nonoperative management.

The importance of preoperative laboratory assessment cannot be overstated. Such an evaluation is needed to help determine if there are associated medical conditions that could adversely impact the postoperative course of a patient. However, in the acute care surgical setting, optimal preoperative evaluation, including imaging and laboratory studies, often cannot be accomplished (Algorithm. 1.1).

End Point–guided Resuscitation

Optimal resuscitation is imperative in the management of any patient in the acute care setting. It is a dynamic process that requires a continued assessment process to ensure that the targeted end points of resuscitation are achieved. The debate continues, however, over the optimal end points of resuscitation in trauma patients. Urine output, lactate levels, base deficit, gastric intramucosal pH, and direct determination of oxygen delivery and consumption are all proposed markers for end points of resuscitation. Irrespective of the end point chosen, the overarching goal in the resuscitation of patients is correction of inadequate organ perfusion and tissue oxygenation.

TABLE 1.1

BROAD SPECTRUM OF ACUTE CARE SURGERY (NONTRAUMA)—EMERGENCY GENERAL SURGERY AND SURGICAL CRITICAL CARE

■ INFLAMMATION	■ PERFORATION	■ OBSTRUCTION

e.g., appendicitis, diverticulitis, cholecystitis, cholangitis, pancreatitis, gastritis, gastric and duodenal ulcer disease	e.g., **hollow visceral rupture;**
	    esophageal
	    gastric
	    duodenal
	    small and large bowel
	    appendiceal
		e.g., **Airway**
		    aspiration
		    foreign body
		Esophagus
		    stricture
		    foreign body
		Intestine
		    mechanical obstruction of small bowl or large bowel (adhesions, intussusception, volvolus)
		    adynamic ileus
		Biliary
		    bile duct obstruction (intra-and extra-luminal
		    biliary pancreatitis

■ ACUTE BLEEDING	■ ISCHEMIA	■ NECROSIS

e.g., stress gastritis, esophageal and gastric variceal bleeding, gastric/duodenal ulcer disease, diverticulosis, hemorrhoidal bleeding, spontaneous splenic/hepatic rupture, vascular aneurysmal rupture, iatrogenic	e.g., **mesenteric ischemia**
	    non-occlusive
	    embolic
	    thrombotic
	compartment syndrome
	    extremity
	    abdominal
	    thoracic
		e.g., necrotizing fasciitis, gas gangrene, decubitus ulcers, and other open wounds

■ HYPOXEMIA	■ INFECTION	■ MULTIPLE ORGAN FAILURE
e.g., aspiration, pneumonia, acute lung injury, acute respiratory distress syndrome, pulmonary embolus	e.g., superficial and deep seated soft tissue abscesses, bacteremia, catheter sepsis, solid organ abscesses, suppurative cholangitis, septic shock	e.g., combined pulmonary, renal, and cardiovascular system failure (portends poor prognosis)

Inability to achieve adequate organ perfusion and tissue oxygenation can result in anaerobic metabolism with the development of acidosis and an associated oxygen debt. Scalea et al. reported that inadequate tissue perfusion can exist even when the conventional end points (e.g., blood pressure, heart rate, and urine output) of resuscitation are normal.[1]

Early Intervention and Definitive Management, If Possible

In the acute care setting, irrespective of the specific illness/injury encountered, early and often definitive intervention is the essential component of management. Specific treatment paradigms differ depending on the specific disease entity and its unique presentation (Algorithms. 1.2-1.6).

GENERAL PRINCIPLES—TRAUMA SETTING

Prior to focusing on the specific anatomical region where there is an obvious traumatic injury, an initial assessment of the entire patient is imperative.

The concept of initial assessment includes the following components: (1) rapid primary survey, (2) resuscitation, (3) detailed secondary survey (evaluation), and (4) reevaluation. Such an assessment is the cornerstone of the Advanced Trauma Life Support (ATLS) program. Integrated into primary and secondary surveys are specific adjuncts. Such adjuncts include the application of electrocardiographic monitoring and the utilization of other monitoring modalities such as arterial blood gas determination, pulse oximetry, the measurement of ventilatory rate and blood pressure, insertion of urinary or gastric catheters, and incorporation of necessary x-rays and other diagnostic studies, when applicable, such as focused abdominal sonography for trauma (FAST) exam, other diagnostic studies (plain radiography of the spine/chest/pelvis and CT), and diagnostic peritoneal lavage (DPL). Determination of the right diagnostic study depends on the mechanism of injury and the hemodynamic status of the patient.

The focus of the primary survey is to both identify and expeditiously address immediate life-threatening injuries. Only after the primary survey is completed (including the initiation of resuscitation) and hemodynamic stability is addressed should the secondary survey be conducted, which entails a head-to-toe (and back to front) physical examination, along with a more detailed history.

PRIMARY SURVEY

Only the emergency care disciplines of medicine have a two-tier approach to their initial assessment of the patient, with primary and secondary surveys as integral components. As highlighted above, the primary survey is designed to quickly detect life-threatening injuries. Therefore, a

universal approach has been established with the following prioritization:

- Airway maintenance (with protection of the cervical spine)
- Breathing (ventilation)
- Circulation (including hemorrhage control)
- Disability (neurologic status)
- Exposure/environmental control

Such a systematic and methodical approach (better known as the ABCDEs of the initial assessment) greatly assists the surgical/medical team in the timely management of those injuries that could result in a poor outcome.

A. Airway assessment/management (along with cervical spine protection)

Because loss of a secure airway could be lethal within 4 minutes, airway assessment/management always has the highest priority during the primary survey of the initial assessment of any injured patient, irrespective of the mechanism of injury or the anatomical wound. The chin lift and jaw thrust maneuvers are occasionally helpful in attempting to secure a patient airway. However, in the trauma setting, the airway management of choice is often translaryngeal, endotracheal intubation. If this cannot be achieved due to an upper airway obstruction or some technical difficulty, a surgical airway (needle or surgical

ALGORITHM 1.2 Acute cholecystitis.

cricothyroidotomy) should be the alternative approach. No other management can take precedence over appropriate airway control. Until adequate and sustained oxygenation can be documented, administration of 100% oxygen is required.

B. Breathing (ventilation assessment)

An airway can be adequately established and optimal ventilation still not be achieved. For example, such is the case with an associated tension pneumothorax (other examples include a tension hemothorax, open pneumothorax, or a large flail chest wall segment). Worsening oxygenation and an adverse outcome would ensue unless such problems are expeditiously addressed. Therefore, assessment of breathing is imperative, even when there is an established and secure airway. A patient airway but poor gas exchange will still result in a poor outcome. Tachypnea, absent breath sounds, percussion hyperresonance, distended neck veins, and tracheal deviation are all consistent with inadequate gas exchange. Decompression of the pleural space with a needle/chest tube insertion should be the initial intervention for a pneumo-/hemothorax. A

large flail chest, with underlying pulmonary contusion, will likely require endotracheal intubation and positive pressure ventilation.

C. Circulation assessment (adequacy of perfusion management)

The most important initial step in determining adequacy of circulatory perfusion is to quickly identify and control any active source of bleeding, along with restoration of the patient's blood volume with crystalloid fluid resuscitation and blood products, if required. Decreased levels of consciousness, pale skin color, slow (or nonexistent) capillary refill, cool body temperature, tachycardia, or diminished urinary output are suggestive of inadequate tissue perfusion. Optimal resuscitation requires the insertion of two large-bore intravenous lines and infusion of crystalloid fluids (warmed). Adult patients who are severely compromised will require a fluid bolus (2 L of Ringer's lactate or saline solution). Children should receive a 20 mL/kg fluid bolus. Blood and blood products are administered as required. Along with the initiation of fluid resuscitation, emphasis needs to remain on identification of the source of active bleeding and stopping the hemorrhage. For a patient in hemorrhagic shock, the source of blood loss will be an open wound with profuse bleeding, or within the thoracic or abdominal cavity, or from an associated pelvic fracture with venous or arterial injuries. Disposition (operating room, angiography suite, etc.) of the patient depends on the site of bleeding. For example, a FAST assessment that documents substantial blood loss in the abdominal cavity in a patient who is hemodynamically labile dictates an emergency celiotomy. However, if the expedited diagnostic workup of a hemodynamically unstable patient who has sustained blunt trauma demonstrates no blood loss in the abdomen or chest, then the source of hemorrhage could be from a pelvic injury that would likely necessitate angiography/embolization if external stabilization (e.g., a commercial wrap or binder) of the pelvic fracture fails to stop the bleeding. Profuse bleeding from open wounds can usually be addressed by application of direct pressure or, occasionally, ligation of torn arteries that can easily be identified and isolated.

D. Disability assessment/management

Only a baseline neurologic examination is required when performing the primary survey to determine neurologic function deterioration that might necessitate surgical intervention. It is inappropriate to attempt a detailed neurologic examination initially. Such a comprehensive examination should be done during the secondary survey. This baseline neurologic assessment could be the determination of the Glasgow Coma Scale (GCS), with an emphasis on the best motor or verbal response, and eye opening. An alternative approach for a rapid neurologic evaluation would be the assessment of the pupillary size and reaction, along with establishing the patient's level of consciousness (alert, responds to visual stimuli, responds only to painful stimuli or unresponsive to all stimuli). The caveat that must be highlighted is that neurologic deterioration can occur rapidly and a patient with a devastating injury can have a lucid interval (e.g., epidural hematoma). Because the leading causes of secondary brain injury are hypoxia and hypotension, adequate cerebral oxygenation and perfusion are essential in the management of a patient with neurologic injury.

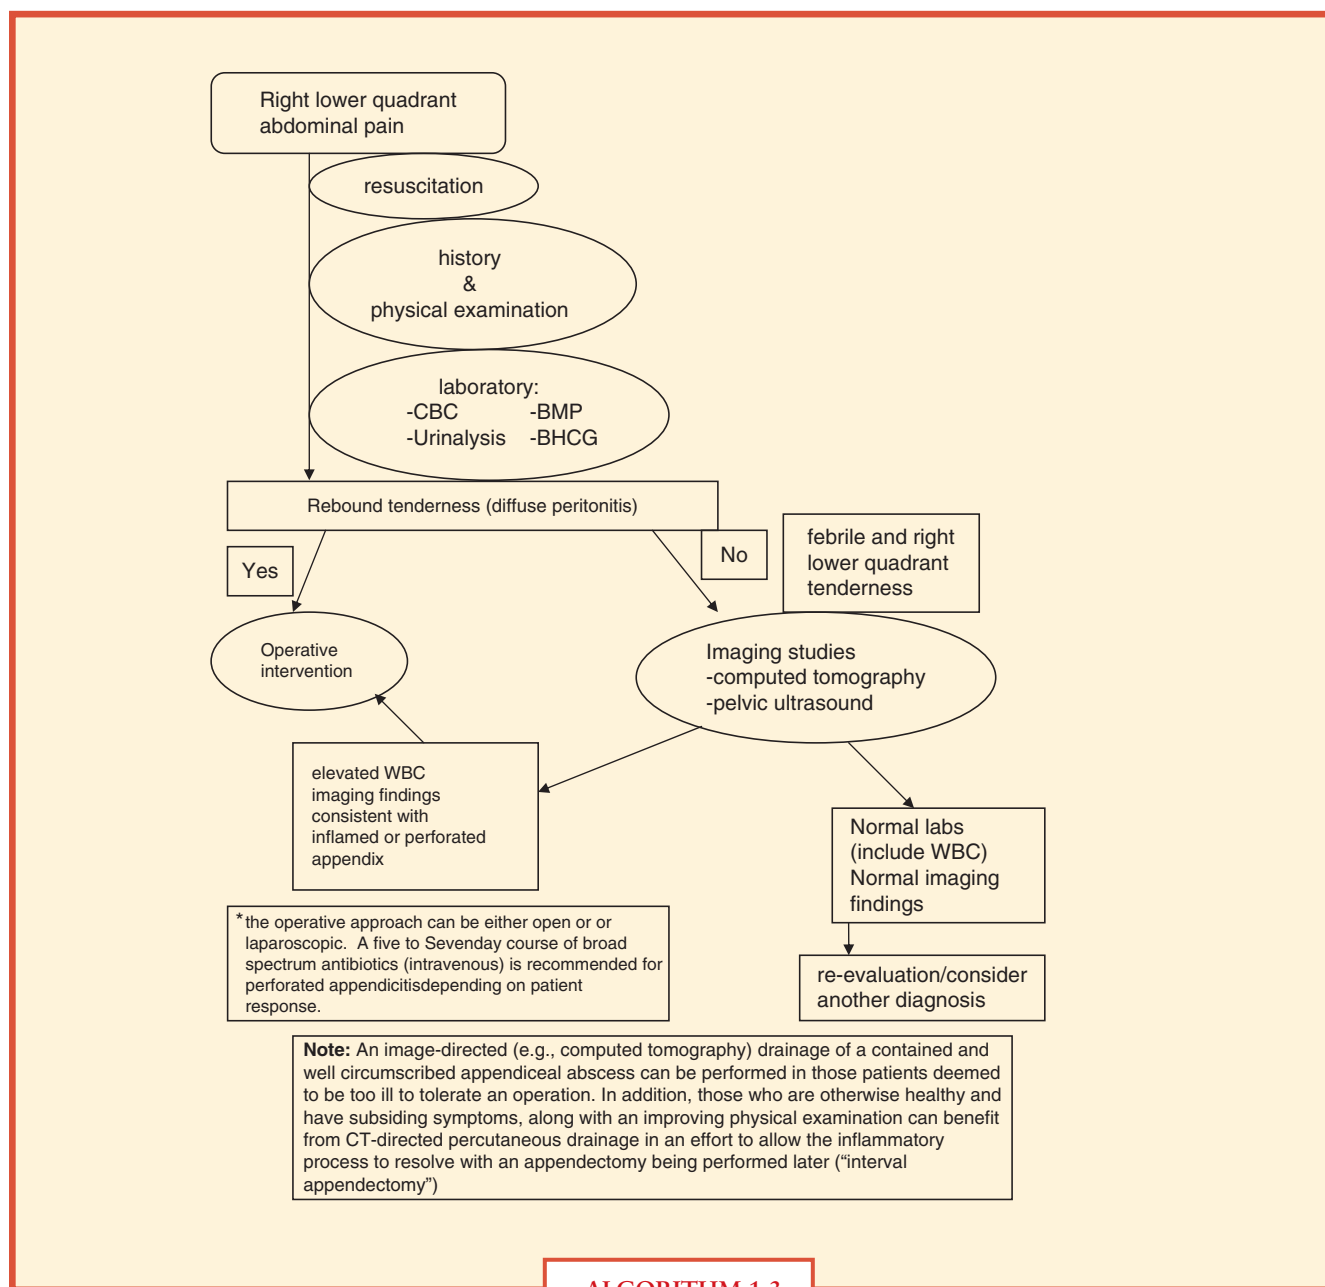
E. Exposure/environmental control

To perform a thorough examination, the patient must be completely undressed. This often requires cutting off the garments to safely expedite such exposure. However, care must be taken to keep the patient from becoming hypothermic. Adjusting the room temperature and infusing warmed intravenous fluids can help establish an optimal environment for the patient.

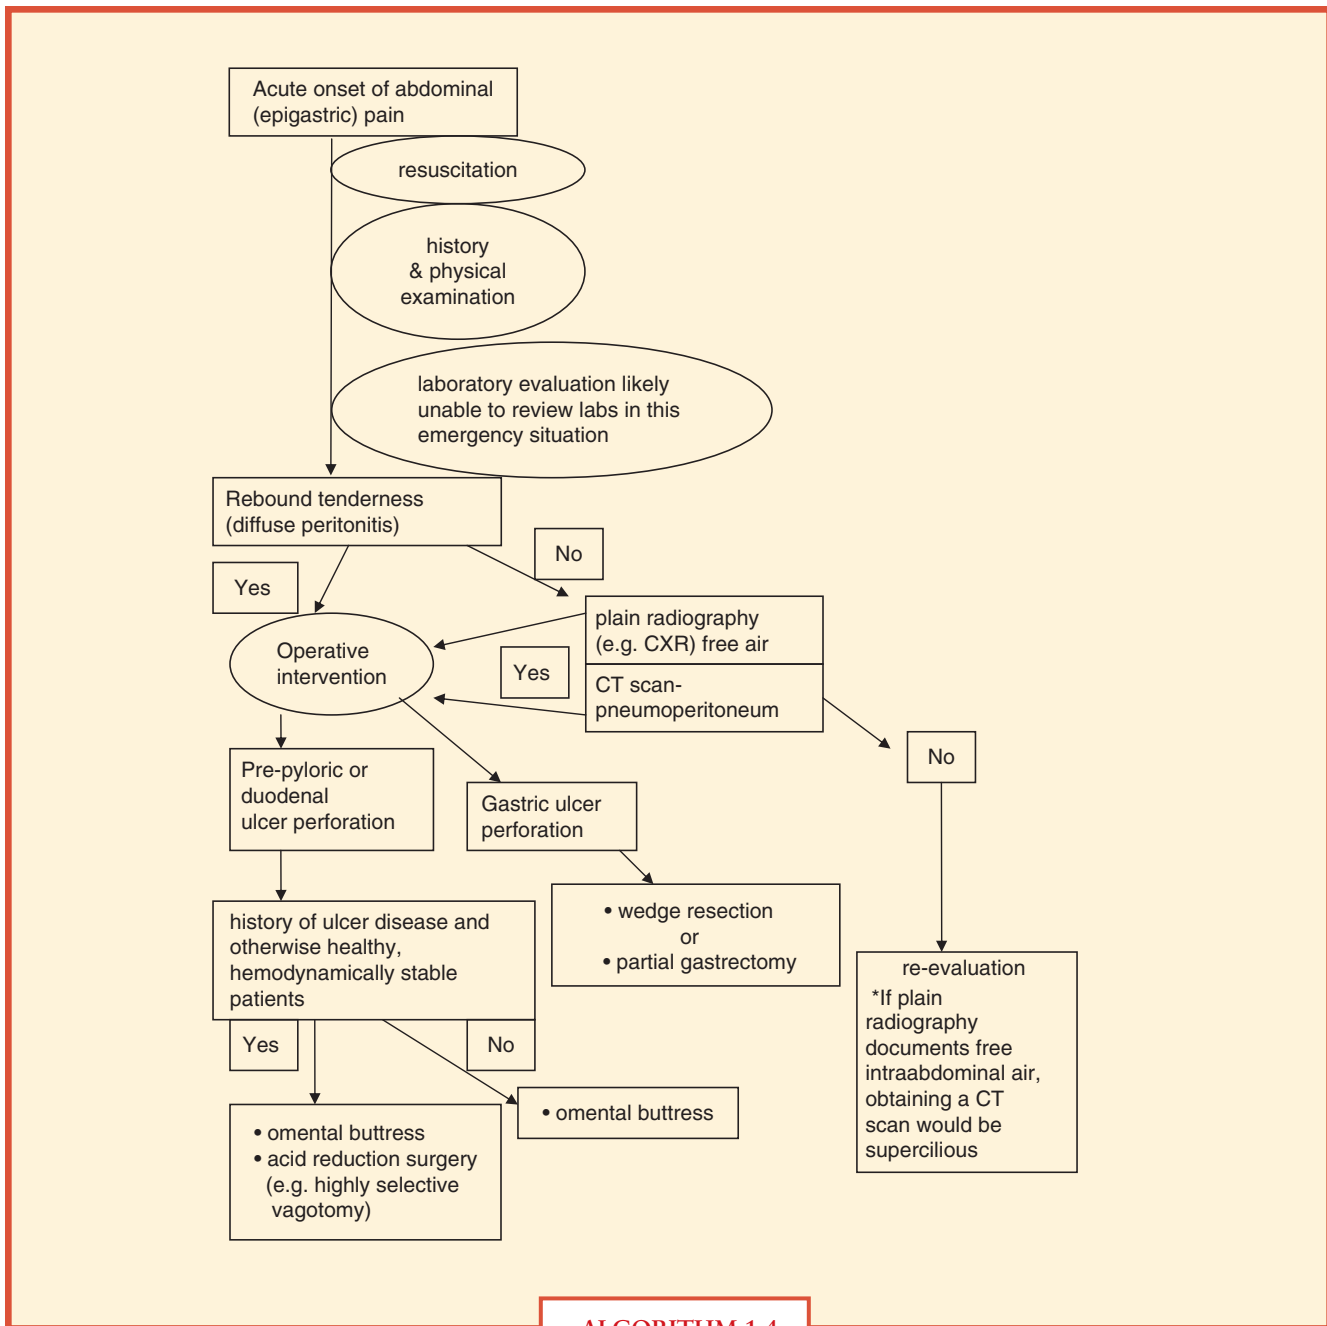
SECONDARY SURVEY

The secondary survey should not be started until the primary survey has been completed and resuscitation initiated, with some evidence of normalization of vital signs. It is imperative that this head-to-toe evaluation be performed in a detailed manner to detect less obvious or occult injuries. This is particularly important in the unevaluable (e.g., head injury or severely intoxicated) patient. The physical examination should include a detailed assessment of every anatomical region, including the following:

- Head
- Maxillofacial
- Neck (including cervical spine)
- Chest
- Abdomen
- Perineum (including the rectum and genital organs)
- Back (including the remaining spinal column)
- Extremities (musculoskeletal)

A full neurologic examination needs to be performed, along with an estimate of the GCS score if one was not done during the primary survey. The secondary survey and the utilization (when applicable) of the diagnostic adjuncts previously mentioned will allow detection of more occult or subtle injuries that could, if not found, produce significant morbidity and mortality. When possible, the secondary survey should include a history of the mechanism of injury, along with vital information regarding allergies, medications, past


ALGORITHM 1.3

ALGORITHM 1.3 Appendicitis


ALGORITHM 1.4

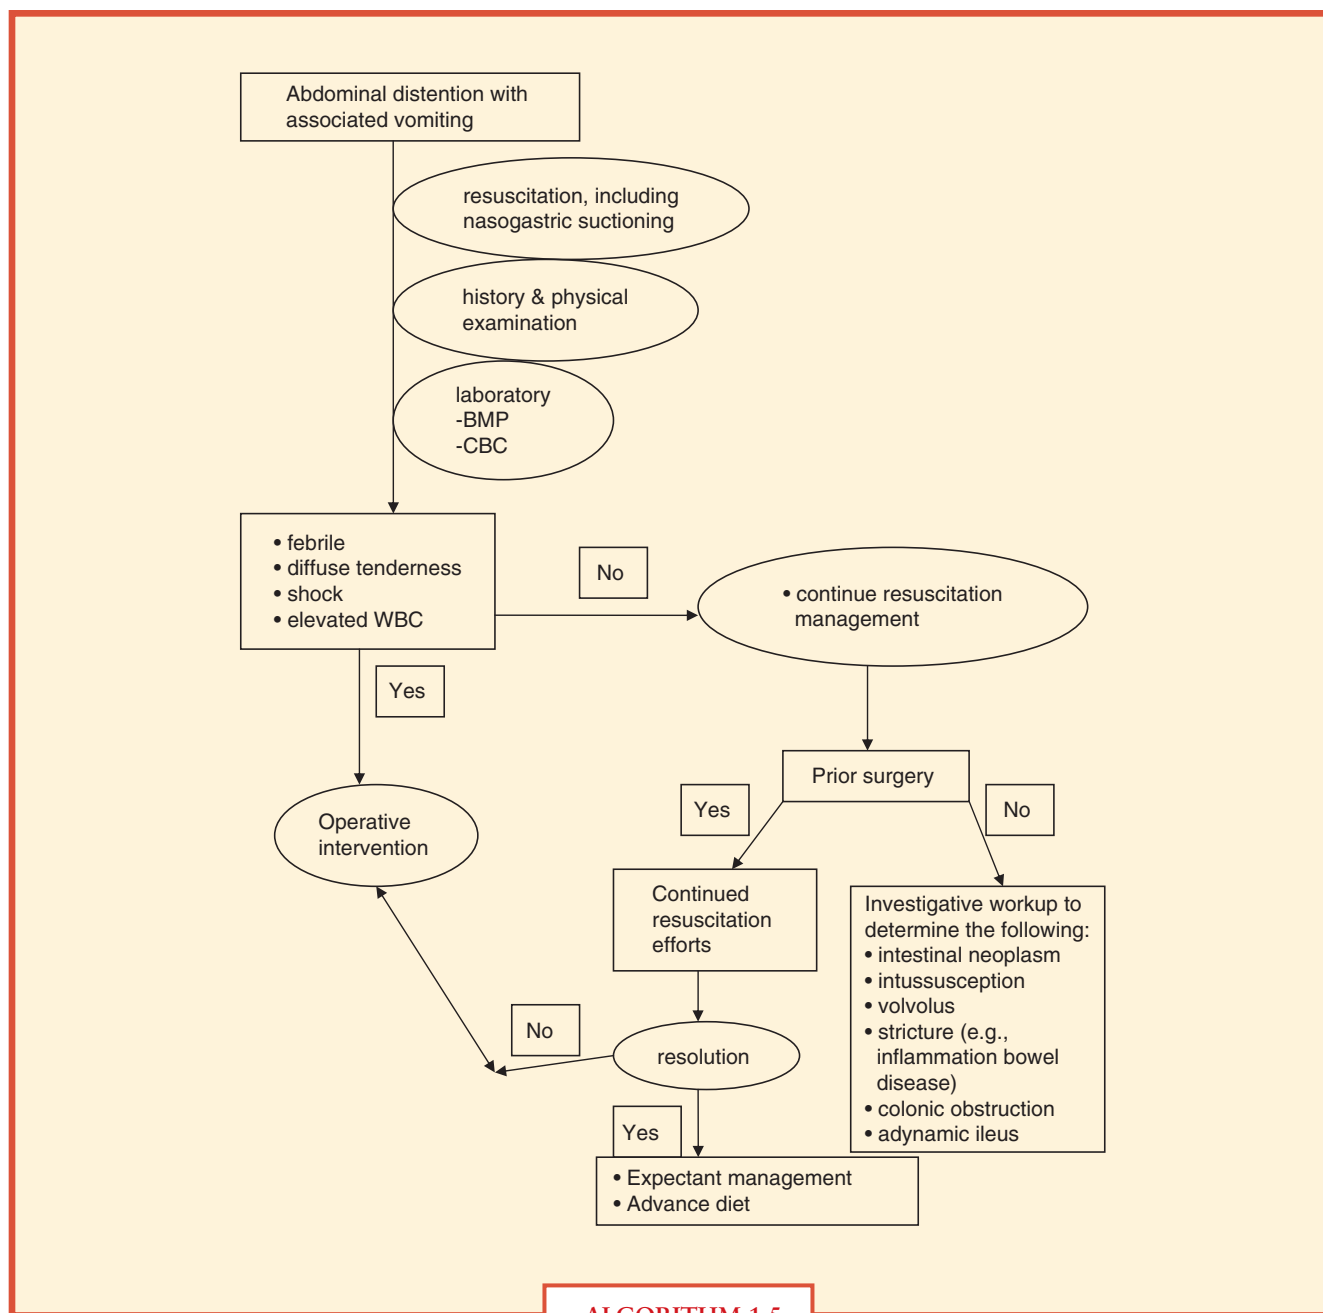
ALGORITHM 1.4 Perforated ulcer (duodenal and gastric).

illnesses, recent food intake, and pertinent events related to the injury.

It cannot be overemphasized that frequent reevaluation of the injured patient is critical to detect any deterioration in the patient status. This sometimes requires repeating both the primary and secondary surveys.

TOPOGRAPHY AND CLINICAL ANATOMY

The abdomen is often defined as a component of the torso that has as its superior boundary the left and right hemidiaphragm, which can ascend to the level of the nipples (4th intercostal

space) on the frontal aspect and to the tip of the scapula in the back. The inferior boundary of the abdomen is the pelvic floor. For clinical purposes, it is helpful to further divide the abdomen into four areas: (1) anterior abdomen (below the anterior costal margins to above the inguinal ligaments and anterior to the anterior axillary lines), (2) intrathoracic abdomen (from the nipple or the tips of the scapula to the inferior costal margins), (3) flank (inferior scapular tip to the iliac crest and between the posterior and anterior axillary lines), and (4) back (below the tips of the scapula to the iliac crest and between the posterior axillary lines). The majority of the digestive system and urinary tract, along with a substantial network of vasculature and nerves, are contained with the abdominal cavity. A viscera-rich region, the abdomen can often be the harbinger for occult injuries as a result of penetrating wounds, particularly


ALGORITHM 1.5

ALGORITHM 1.5 Small bowel obstruction.

in the unevaluable abdomen as the result of a patient's compromised sensorium.

Mechanism of Injury—Penetrating Trauma

In addition to the hemodynamic status of the patient, important variables in the decision making in the management of penetrating abdominal injuries are both the mechanism and location of injury (see "Physical Examination"). The kinetic energy generated by hand-driven weapons, such as knives and sharp objects, is substantially less than caused by firearms. Although not always evident, it is important to know the length and width of the wound along with the depth of penetration of the weapon or device that caused the stab injury. For example,

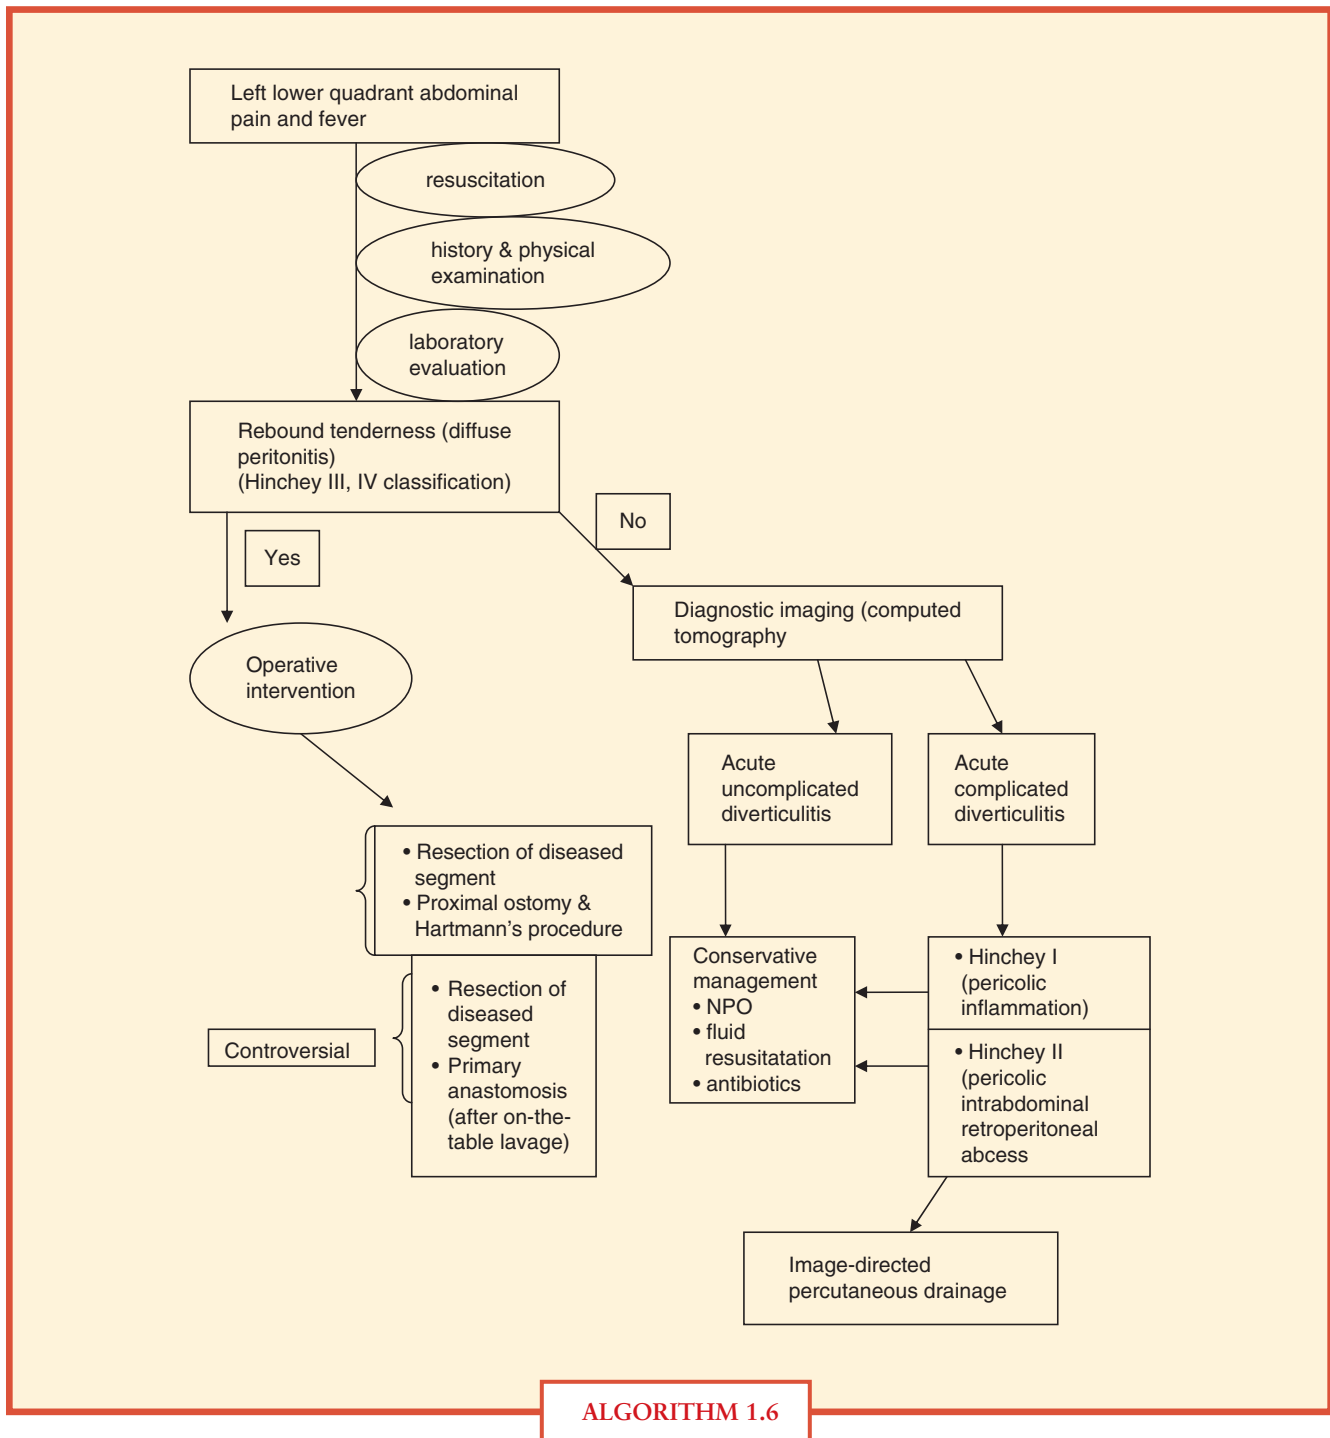
a stab injury usually results in a long, more shallow wound that does not penetrate the peritoneum. Local wound management is the primary focus for these injuries with no concern for any potential intra-abdominal injury.[2] Although there are some stab wounds that do not penetrate the peritoneal cavity, such cannot just be assumed without some formal determination or serial abdominal examinations to assess for worsening abdominal tenderness or the development of peritoneal signs.

There is notable variability among the full spectrum of firearms in the civilian setting, with this arsenal including handguns, rifles, shotguns, and airguns. The kinetic energy, which correlates with the wounding potential, is dependant on mass and velocity ($KE = 1/2\ mv^2$). Therefore, the higher the velocity (v), the greater the wounding potential.[3] Because the barrel is longer in a rifle than a handgun, the bullet has more time to

accelerate, generating a much higher velocity. A high-velocity missile is propelled at 2,500-5,000 ft per second. Airguns usually fire pellets (e.g., BBs) and are associated with a lower velocity and wounding potential. Shotguns fire a cluster of metal pellets, called a shot. The pellets separate after leaving the barrel, with a rapidly decreasing velocity. At a distance, the wounding potential is diminished. However, at close range (<15 ft), because of the increase in aggregate mass, the tissue destruction is similar to a high-velocity missile injury.

Although each injury should be handled on an individual basis, there are general principles that will provide some guidance in the management of penetrating injuries based on mechanism of injury. With respect to stab wounds, approximately one-third of the wounds do not penetrate the peritoneum and only half of those that penetrate require operative intervention. The number of organs injured and the intra-abdominal sepsis complication rate are significantly less than wounds caused by gunshots.[4,5]

ALGORITHM 1.6

ALGORITHM 1.6 Diverticulitis


PHYSICAL EXAMINATION

A complete and thorough physical examination of the entire body is essential in the management of penetrating abdominal injury. There are some findings (Table 1.2) on physical examination that are absolute indications for operative intervention. The components of the physical exam should include careful inspection, palpation, and auscultation.

In addition to determination of the location, extent, and the number of wounds, inspection can sometimes determine the trajectory of the missile or other wounding agent and, consequently, guide management decisions. For example, a patient with a documented, superficial tangential gunshot wound (low-velocity), with no other remarkable physical findings, would likely be managed expectantly (observation). However, if a penetrating abdominal injury results in a patient presenting with an evisceration, exploratory laparotomy would be the management option of choice. Palpation will enable the examiner to elicit abdominal tenderness or frank peritoneal signs, along with detection of abdominal distention and rigidity. On occasion, missiles can be palpated lodged in the soft tissue. Unless in a controlled and sterile setting such as the operative theater, probing of a wound should be avoided. Auscultation is also an important component of the physical examination. It can detect diminished or absent bowel sounds that could be suggestive of evolving peritonitis. Also, auscultation could detect a trauma-induced bruit, suggestive of a vascular injury. The examiner must be keenly aware that there are situations in which the abdominal exam will be unreliable due to possible spinal cord injury or a patient's altered mental state.

DIAGNOSTIC STUDIES

Even with penetrating injuries, the abdomen is notorious for hiding its secrets—occult injuries. Access to an extensive diagnostic armamentarium is imperative in the optimal management of these injuries. Strongly advocated by some for abdominal stab wounds, local wound exploration has the advantage of allowing the patient to be discharged from the trauma bay or emergency department, if surgical exploration of the wound fails to demonstrate penetration of the posterior fascia and peritoneum. However, if the patient goes to the operating room for other injuries, the local wound exploration should be done in the surgical suite with better lighting and a more sterile environment. A positive finding during local wound exploration dictates a formal laparotomy or laparoscopy. However, even with local wound exploration as a guide, the nontherapeutic laparotomy rate can be high, given that only a third of the patients with stab wounds to the anterior abdomen require therapeutic laparotomy.[6,7] In the patient who has an evaluable abdomen, serial abdominal examinations would be an acceptable alterative to local wound exploration,

to determine the need for operative intervention (selective management). Local would exploration should only be done for stab wounds to the anterior abdomen. Such an approach is potentially too hazardous for thoracoabdominal penetrating injuries and back/flank wounds. Plain radiography (abdomen/pelvis/chest) can be pivotal in documenting the presence of missiles and other foreign bodies and determining the trajectory of the injury tract, particularly for wounds from firearms. Also, the presence of free air might be confirmed by plain radiography. Unless there is concern about a retained broken blade, there is little utility for plain radiography for stab injuries.[8] The DPL developed by David Root, in 1965, was a major advance in the care of the hemodynamically labile patient who sustained blunt trauma.[9] With the advent of FAST and rapid CT, DPL has limited utility. DPL has never had a broad appeal in the diagnostic evaluation of penetrating abdominal wounds. Although some have advocated its use with tangential wounds of the abdominal wall, the technique has failed to receive widespread support.[10] Its reliability in detecting clinically important injuries sustained as a result of penetrating abdominal injuries has been a prevailing concern.[11-13] The reported sensitivity and specificity of DPL for abdominal stab wounds are 59%-96% and 78%-98%, respectively.[14] Also, DPL is a poor diagnostic modality for detection of diaphragmatic and retroperitoneal injuries.

Diagnostic imaging has had the greatest impact in changing the face of trauma management with CT taking the lead in this area. Its ubiquitous presence in the management of blunt abdominal trauma is well established. However, it is becoming an important diagnostic study in the evaluation of penetrating abdominal injuries. In addition to its excellent sensitivity in detection of pneumoperitoneum, free fluid, and abdominal wall/peritoneal penetration, CT is helpful in identifying the tract of the penetrating agent. Hauser et al. recommended the use of "triple contrast" CT in the assessment of penetrating back and flank injuries.[15] CT scan evaluation is an essential diagnostic tool in the increasing advocacy for selective management of abdominal gunshot wounds, obviating the need for mandatory surgical exploration.[16] However, there still remain two major limitations of CT: detection of intestinal perforation and diaphragmatic injury.

Unless the injury is confined to the solid organ of the abdomen, such as the liver or spleen, the matrix of intestinal gas patterns makes detection of penetrating injuries difficult. Kristensen et al.[17] were one of the first teams to introduce the role of ultrasonic scanning as part of the diagnostic armamentarium in trauma management. Kimura and Otsuka[18] endorsed using ultrasonography in the emergency room for evaluation of hemoperitoneum. FAST does not have the same broad application in the evaluation of penetrating trauma as it does in blunt trauma assessment. Rozycki et al.[19] reported on the expanded role of ultrasonography as the "primary adjuvant modality" for the injured patient assessment. Rozycki also reported that FAST examination was the most accurate for detecting fluid within the pericardial sac. Such a finding would be confirmatory for a cardiac injury and possible cardiac tamponade, given a mechanism of injury that could result in an injury to the heart.

As a diagnostic modality, laparoscopy is not a new innovation. Other specialists have been utilizing this operative intervention for several decades. However, it was formally introduced as a possible diagnostic procedure of choice for specific torso wounds when Ivatury et al.[20] critically evaluated laparoscopy in penetrating abdominal trauma. Fabian et al.[21] also reported on the efficacy of diagnostic laparoscopy in a prospective analysis.

With no conventional diagnostic tool that can conclusively rule out a diaphragmatic laceration or rent, diagnostic laparoscopy becomes the study of choice for penetrating thoracoabdominal injuries, particularly left thoracoabdominal wounds

(Algorithm. 1.7). Laparoscopy can also be used to determine peritoneal entry from a tangential penetrating injury.

Penetrating Abdominal Injuries and the Hemodynamically Stable and Unstable Patient

As highlighted above, the management principles in patients who sustain penetrating abdominal injuries and remain hemodynamically stable depend on the mechanism and location of injury, along with the hemodynamic status of the patient. Irrespective of the patient's hemodynamic parameter, the Adult Trauma Life Support (ATLS) protocol should be strictly followed upon arrival of the patient to the trauma bay (Algorithms. 1.8-1.11).

Trauma Laparotomy The operative theater should be large enough to accommodate more than one surgical team, in the event the patient requires simultaneous procedures to be performed. In addition, the room should have the capability of maintaining room temperature as high as the lower 80's °F to avoid hypothermia. Also, a rapid transfusion device should be in the room to facilitate the delivery of large fluid volume and ensure that the fluid administration is appropriately warm.

Abdominal exploration for trauma has basically four imperatives: (1) hemorrhage control, (2) contamination control, (3) identification of the specific injury (ies), and (4) repair/reconstruction. The abdomen is prepared with a topical antimicrobial from sternal notch to bilateral midthighs and extending the prep laterally to the side of the operating room table followed by widely draping the patient. Such preparation allows expeditious entry into the thorax if needed and possible vascular access or harvesting. Exploration is initiated with a midline vertical incision that should extend from the xiphoid to the symphysis pubis to achieve optimal exposure.

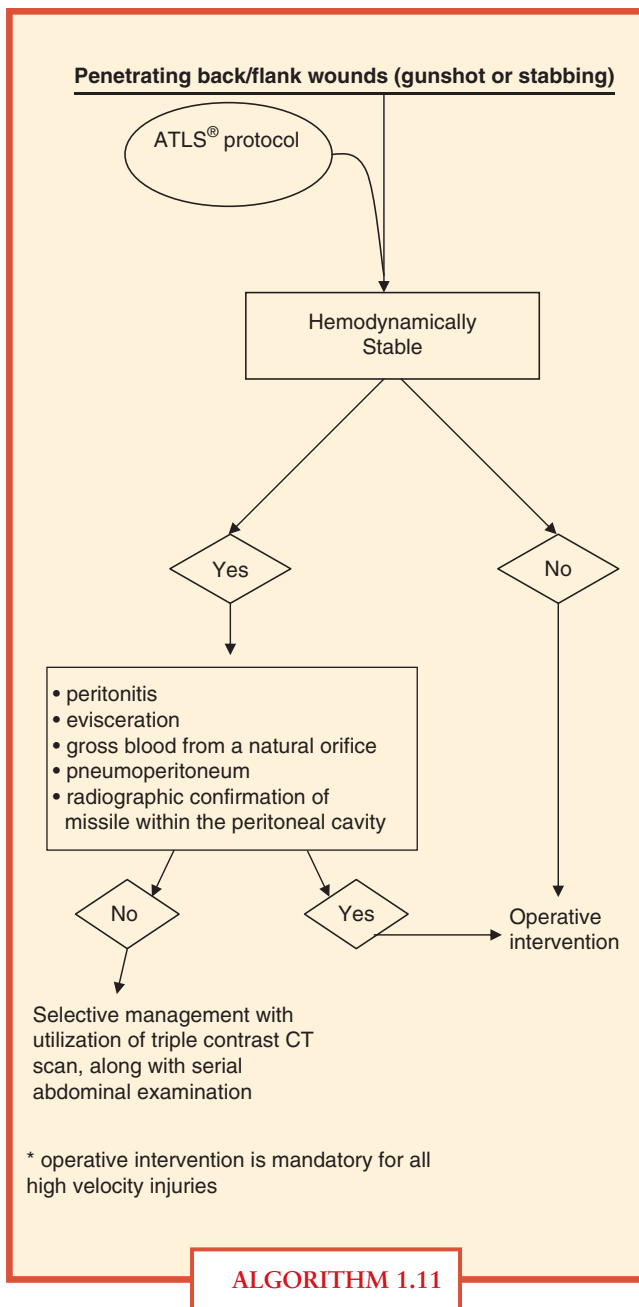
ALGORITHM 1.10

ALGORITHM 1.10 Management algorithm for penetrating abdominal injuries.

The first priority upon entering the abdomen is control of exsanguinating hemorrhage. Such control can usually be achieved by direct control of the lacerated site or obtaining proximal vascular control. After major hemorrhage is controlled, blood and blood clots are removed. Abdominal packs (radiologically labeled) are used to tamponade any bleeding and allow identification of any injury bleeding. The preferred approach to packing is to divide the falciform ligament and retract the anterior abdominal wall. This will allow manual placement of the packs above the liver. Abdominal packs should also be placed below the liver. This arrangement of the packs on the liver creates a compressive tamponade effect. After manually eviscerating the small bowel out of the cavity, packs should be placed on the remaining three quadrants, with care taken to avoid iatrogenic injury to the spleen. During the packing phase after ongoing hemorrhage has been controlled, the surgeon should communicate with the anesthesia team that

major hemorrhage has been controlled and that this would be an optimal time to establish a resuscitative advantage with fluid/blood/blood product administration.

The next priority is control or containment of gross contamination. This begins with the removal of the packs from each quadrant—one quadrant at a time. Packs should be removed from the quadrants that you least suspect to be the source for blood loss, followed by removal of the packs from the final quadrant; the one that you believe is the area of concern.

After control of major hemorrhage has been achieved, any evidence of gross contamination must be addressed immediately. Obvious leakage from intestinal injury can be initially controlled with clamps (e.g., Babcock clamp), staples, or sutures. The entire abdominal gastrointestinal tract needs to be inspected, including the mesenteric and antimesenteric border of the small and large bowel, along with the entire


ALGORITHM 1.11 Management algorithm for penetrating back/flank injury.

mesentery. Rents in the diaphragm should also be closed to prevent contamination of the thoracic cavity.

Further identification of all intra-abdominal injuries should be initiated. Depending on the mechanism of injury and the estimated trajectory of wounding agent, a thorough and meticulous abdominal exploration should be performed, including exploring the lesser sac to inspect the pancreas and the associated vasculature. In addition, mobilization of the C-loop of the duodenum (Kocher maneuver) might be required, along with medical rotation of the left or right colon for exposure of vital retroperitoneal structures.

The final component of a trauma laparotomy is definitive repair, if possible, of specific injuries. As will be highlighted later in the chapter, the status of the patient dictates whether each of the components of a trauma laparotomy can be achieved at the index operation. A staged celiotomy ("damage control"

laparotomy) might be necessary if the patient becomes acidotic, hypothermic, coaglopathic, or hemodynamically compromised.

GENERAL PRINCIPLES IN MANAGEMENT OF SPECIFIC INJURIES

Small Intestine

Isolated small bowel enterotomies can be closed primarily with nonabsorbable sutures for a one-layer closure. If the edges of the enterotomy appear nonviable, they should be gently debrided prior to primary closure. However, multiple contiguous small bowel holes or an intestinal injury on the mesenteric border with associate mesenteric hematoma will likely necessitate segmental resection and anastomosis of the remaining viable segments of the small bowel. The operative goal is always the reestablishment of intestinal continuity without substantial narrowing of the intestinal lumen, along with closure of any associated mesenteric defect. Application of noncrushing bowel claps can contain ongoing contamination while the repair is being performed. Although a hand-sewn or stapler-assisted anastomosis is operator dependant, trauma laparotomies are time-sensitive interventions and expeditious management is imperative.

Colon

The segment of injured bowel should be thoroughly inspected, particularly missile injuries that are most common, through and through enterotomies. This requires adequate mobilization of the colon to visualize the entire circumference of the bowel wall. Initially controversial, an enterotomy (right- or left-sided injuries) of the colon can be closed primarily, irrespective of contamination or transient shock state.[22] If the colon injury is so extensive that primary repair is not possible or would severely compromise the lumen, a segmental resection should be performed. Depending on the environmental setting, the remaining proximal segment can be anastomosed to the distal segment or a proximal ostomy and Hartmann's procedure can be performed. If the distal segment is long enough, a mucous fistula should be established. Documented rectal injuries, below the peritoneal reflection, should necessitate a diverting colostomy and presacral drainage (exiting from the perineum). Such drainage is, however, not universally endorsed.

Stomach/Duodenum

With respect to penetrating wounds of the stomach, the anterior and posterior aspects of the stomach need to be meticulously inspected for accompanying through-and-through injuries. Penetrating injuries of the stomach should be repaired primarily after debridement of nonviable edged. The primary repair can either be single layer with nonabsorbable suture or double layer closure with an absorbable suture (e.g., Vicryl) for the first layer and the second layer closed with nonabsorbable sutures (e.g., silk) Few penetrating injuries of the stomach or primary repairs of a through-and-through gastric injury would compromise the gastric lumen. Duodenal injuries can be repaired primarily in a one- or two-layered fashion if the penetration is less than half the circumference of the duodenum. However, for more complex duodenal injuries, an operative procedure is needed to divert gastric contents away from the injury site (where closure of the wound has been attempted). Pyloric exclusion with the establishment of a gastrojejunostomy is such a procedure.[23-25]

Pancreas

Superficial or tangential penetrating wounds of the pancreas, without injury to the main pancreatic duct, can be externally drained. However, a penetrating injury that transects the pancreas, including the main pancreatic duct, requires extirpation of the distal pancreas (distal pancreatectomy), particularly if the transection site is to the left of the superior mesenteric vessels. A more proximal penetrating pancreatic injury can generally be managed by wide drainage. If a proximal injury involves the main pancreatic duct, with associated complex duodenal injury (e.g., injury to the ampulla), pancreatoduodenectomy may be necessary. Thus, the indication for pancreatoduodenectomy is combined destructive injury to both the duodenum and pancreas; the operation in essence completes the procedure that the injury has functionally necessitated. Unfortunately, because of the rich vascular network surrounding the pancreas, penetrating pancreatic wounds can be lethal injuries.

Spleen

Most penetrating splenic injuries, particularly gunshot wounds, require splenectomy. To visualize the entire spleen, it should be mobilized to the midline by division of its ligamentous attachments. Superficial penetrating injuries of the spleen can sometimes be managed by either splenorrhaphy or application of a topical hemostatic agent. Splenorrhaphy can be by pledgeted repair or an omental buttress. However, complex repair of the spleen is not a prudent approach in the always time-sensitive trauma setting.

Gallbladder and Liver

Penetrating injuries to the gallbladder dictate the need for extirpation. There is no role for primary repair of a penetrating wound to the gallbladder.

Liver injuries are common in both blunt and penetrating trauma. The majority of injuries are superficial or minor and require no surgical repair. Simple application of pressure or a hemostatic agent or fibrin glue will constitute definitive management of the majority of these injuries. The argon beam coagulation, also a helpful adjunct, in superficial hepatic injuries with persistent oozing generates ionizing energy through an argon gas stream that causes rapid coagulation. The operative armamentarium for complex penetrating hepatic injuries is highlighted in Table 1.3.

Genitourinary System

Less than 10% of patients with penetrating abdominal wounds sustain genitourinary tract injury; the majority are renal. Penetrating injuries that result in a grade IV (cortical/calyceal injury and associated vascular injury with contained hemorrhage) or grade V (shattered kidney and vascular avulsion) invariably necessitate nephrectomy, particularly if there is a viable

contralateral kidney. Lacerations or more superficial wounds of the kidney might require renorrhaphy, with approximation of the disrupted capsule with pledgeted sutures or a prosthetic (mesh) wrap. Absorbable interrupted suture should be used and all repairs should be drained. The injury pattern may dictate the need for a partial nephrectomy. Ureteral injuries can be difficult to identify in penetrating wounds with an accompanying retroperitoneal hematoma. When possible, the ureter should be repaired primarily with interrupted absorbable suture over a double J stent. A complete transection of the ureter requires debridement of the nonviable edges, spatulation of the ends, and primary repair over a stent. All repair sites should be adequately drained. If the anastomosis cannot be performed in a tension-free fashion, a bladder flap (Boari) could be surgically constructed, with implantation of the proximal segment of the transected ureter into the flap. A psoas "hitch" might be required if there is any tension on the flap and the tunneled ureter.

Penetrating injury to the intraperitoneal bladder requires surgical repair. After confirmation that there is no involvement of the trigone, the bladder should be closed with a two-layer closure with absorbable suture (the second layer incorporates Lembert sutures to imbricate the first layer). Suprapubic drainage should only be done selectively; however, a Foley's catheter should be left in place.

Retroperitoneal Hematoma

The retroperitoneum, an organ-rich region, has several vital structures that can be injured when its boundaries are penetrated. It can be a major potential site for hemorrhage in patients sustaining either penetrating or blunt trauma due to the substantial vascularity along with bleeding that can occur from an associated solid organ wound (e.g., kidney). In the central region (Zone 1) of the retroperitoneum resides the abdominal aorta, celiac axis, and the superior mesenteric artery, vena cava, and proximal renal vasculature. The lateral retroperitoneum (Zone 2) encompasses the proximal genitourinary system and its vasculature. The pelvic retroperitoneum (Zone 3) contains the iliac arteries, veins, and their tributaries. In addition to the vasculature and the kidneys (plus ureters) highlighted above, the retroperitoneum contains the second, third, and fourth portion of the duodenum, along with the pancreas, the adrenals, and the intrapelvic portion of the colon and rectum. Table 1.4 underscores the management principles of trauma-related retroperitoneal hematomas. Ideally, proximal (and when applicable, distal) control needs to be achieved prior to exploration of a retroperitoneal hematoma. For retroperitoneal hematomas in Zone 1, irrespective of a penetrating or blunt mechanism, mandatory exploration is required. Also, retroperitoneal hematoma in any of the three zones requires exploration for all penetrating injuries. For Zone 2 retroperitoneal hematomas resulting from blunt trauma, all pulsatile or expanding hematomas should undergo exploration. Gross extravasation of urine also necessitates exploration. Zone 3 (pelvic retroperitoneum) hematomas should be explored only for penetrating injuries to determine if there is a specific intrapelvic colorectal, ureteral, or vascular injury. However, such an approach should not be taken for blunt trauma, for the injury would likely be venous and application of an external compression device would be the preferred intervention. An arterial injury could be addressed by arteriography/embolization.

Intra-abdominal Packing and "Damage Control" Strategy

"Damage control" strategy, popularized by Rotondo et al., is a staged celiotomy strategy that was initially made operationally visible by Mattox and Feliciano. Although this approach was not actually developed by them, Mattox and Feliciano certainly popularized the technique and made it acceptable for

TABLE 1.4

KIDNEY INJURY SCALE OF THE AAST

■ GRADE[a]	■ TYPE OF INJURY	■ INJURY DESCRIPTION	■ ICD-9[b]	■ AIS-90[c]
I	Contusion	Microscopic or gross hematuria, urologic studies normal	866.00 866.02	2
	Hematoma	Subcapsular, nonexpanding without parenchymal laceration	866.11	2
II	Hematoma	Nonexpanding perirenal hematoma confined to renal retroperitoneum	866.01	2
	Laceration	Parenchymal depth of renal cortex (>1.0 cm) without urinary extravasation	866.11	2
III	Laceration	Parenchymal depth of renal cortex (>1.0 cm) without collecting system rupture or urinary extravasation	866.02 866.12	3
IV	Laceration	Parenchymal laceration extending through the renal cortex, medulla, and collecting system	866.02	4
	Vascular	Main renal artery or vein injury with contained hemorrhage	866.12	4
V	Laceration	Completely shattered kidney	866.03	5
	Vascular	Avulsion of renal hilum, which devascularizes kidney	866.13	5

use in this country.[26-30] Irrespective of the name given to this strategy of surgically managing only immediate life-threatening injuries (along with intra-abdominal packing and rapid temporary closure of the abdominal cavity), the goal is the same—avoid the potential irreversibility of sustained acidosis, hypothermia, coagulopathy, and hemodynamic lability by delaying definitive operative management until the patient can be stabilized in the intensive care unit. Although "damage control" is most frequently used in association with severe hepatic wounds, other organ injuries, including vascular wounds, can necessitate this staged celiotomy approach with hepatic packing and a rapid, creative abdominal closure.

Mechanism of Injury—Blunt Trauma

The management paradigm of blunt abdominal has evolved over the last few decades. For example, the emphasis on the physical examination, plain x-radiography, laboratory findings, and DPL has shifted to greater reliance on CT and ultrasonography. Treatment for visceral injury has traditionally been operative but many forms of solid organ injury can now be managed nonoperatively or with minimally invasive and interventional radiology techniques. Management of the multiply injured trauma patient at level I trauma centers with state-of-the-art techniques has now conclusively shown significantly improved patient outcome and survival.[31]

CURRENT DIAGNOSTIC AND IMAGING TECHNIQUES

Focused Abdominal Sonography for Trauma

One of the most recent advances in the workup of the acutely injured patient is the use of bedside ultrasonography for detection of cardiac and intra-abdominal injury. Known as FAST, the technique's noninvasive nature allows the operator to perform an exam simultaneously during the initial resuscitation and stabilization of a multiply injured trauma patient. The technique may thereby provide evidence of significant hemorrhage early in the course of evaluation. An ultrasound probe is used to examine four key windows for fluid; the subxiphoid area permits visualization of the pericardium, the left subcostal area visualization of the splenorenal recess, right subcostal area visualization of Morison's pouch, and the suprapubic area visualization of the pelvic cul-de-sac (Fig. 1.1). The presence of fluid may indicate presence of cardiac tamponade, intra-abdominal hemorrhage, hollow viscus perforation, hemoperitoneum, or ascites. False-positive results secondary to preexisting ascites or false negatives due to operator error or body habitus are the main limitations. Scanning the suprapubic area with distension of the urinary bladder will enhance the sensitivity of the exam for the detection of pelvic fluid.

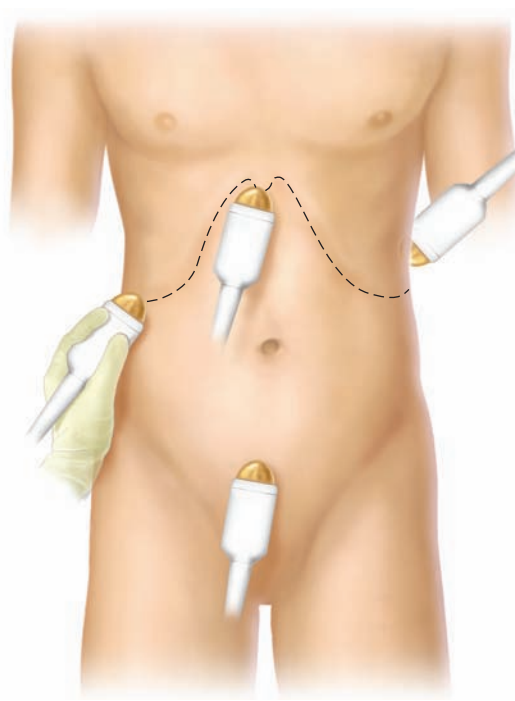
A threshold of at least 200 mL of fluid in the abdominal cavity is necessary for detection; intra-abdominal injuries must be associated with the presence of this much free fluid for a positive finding.[32] Reported sensitivities range between 73% and 88% and specificity between 98% and 100%.[33] Accuracy rates range from 96% to 98%. FAST is an inexpensive, rapid, portable, noninvasive technique that can be performed in serial fashion if patient stability changes.[34-36] Additionally, it obviates the risk of exposing pregnant females to radiation. Positive findings in stable patients can be further evaluated with CT or DPL while unstable patients with a positive finding may be taken to the operating room for emergent exploration. Workup of a patient with a reliable


FIGURE 1.1. Schematic showing sonographic windows for (1) subxiphoid, (2) left subcostal, (3) right subcostal and suprapubic areas. Distension of the urinary bladder either prior to Foley's catheter placement or by installation of 150-200 mL normal saline will enhance sensitivity. (Redrawn from Rozycki GS, Ochsner MG, Schmidt JA, et al. A prospective study of surgeon-performed ultrasound as the primary adjuvant modality for injured patient assessment. *J Trauma.* 1995;39:492-498; discussion 498-500.)

abdominal exam may be complete with a negative FAST in the absence of abdominal signs or symptoms. However, in the patient with significant mechanism of injury, we generally follow a negative FAST with CT of the chest and abdomen.

Computed Tomography

Technologic advances in CT have revolutionized the initial management of trauma patients over the past two decades. Multidetector scanners have dramatically improved resolution and accuracy of these imaging studies. Negative predictive values as high as 99.63% have been reported for patients sustaining major mechanisms of blunt trauma, allowing the use of CT as a reliable and noninvasive screening tool for screening patients with blunt abdominal trauma. In light of modern-day CT capabilities, prospective data have demonstrated that patients with an important mechanism and a benign abdomen can be released from the emergency department if a CT scan of the abdomen shows no evidence of visceral injury provided that there are no other reasons for hospitalization.[37]

CT reliably identifies injuries in solid organs such as the spleen, liver, and kidney because of their vascular anatomy, demonstrating disruption of normal architecture, associated free fluid, and the so-called vascular blush. Similar grading scales have been developed to allow for accurate classification and determination of management plan (Tables 1.3-1.5).[38,39]

Detection of bowel injury via CT in patients who are intoxicated, intubated, or have associated closed head injury or other distracting injuries can present a diagnostic challenge in the absence of a reliable abdominal exam. The incidence of blunt bowel injury varies from series to series but is generally

TABLE 1.5

[c]AIS, Abbreviated Injury Score.

reported in the 1%-5% range in all blunt trauma patients admitted to level 1 trauma centers.[40] A high index of suspicion is predicated on mechanism of injury and physical exam findings such as abdominal wall tattooing or seat belt sign. CT findings may be direct such as extravasation of oral contrast or pneumoperitoneum, or more commonly, indirect such as bowel wall thickening, stranding of the mesentery, or free fluid in the absence of solid organ injury. Indirect findings may be fairly nonspecific and secondary to bowel edema from resuscitation or preexisting ascites. Reproductive-age females may have a small amount of normal or "physiologic" pelvic fluid present, sometimes adding to the complexity of the evaluation. Patients on positive pressure ventilation or with substantial barotrauma may develop mediastinal or subcutaneous emphysema that can tract through the peritoneum or retroperitoneum and give the appearance of free air. Great care in the radiologic interpretation and close clinical correlation are necessary in such cases. The liberal use of DPL may prevent nontherapeutic laparotomy. Obviously, when significant doubt remains, abdominal exploration may be necessary to confirm an injury.

The role of oral contrast in the evaluation of the acutely injured patient has recently come under question. Little time is usually available in the emergent setting to permit adequate opacification of the small bowel. Patients are further at risk for aspiration of the contrast media and administration often requires placement of a nasogastric tube. Reports have shown that elimination of oral contrast media does not lead to an increased incident of missed bowel injury.[41,42] Many centers have now safely eliminated the use of oral contrast media from their routine trauma protocols, expediting management and ease of patient care. Resuscitation edema may cause a hazy

appearance around the head of the pancreas and duodenal c-loop, raising the question of a pancreatic or duodenal injury. Further clarification in this situation can be obtained via repeat CT scan with the administration of oral contrast and the injection of 300-500-mL bolus of air down the nasogastric tube may make pneumoperitoneum obvious.

CT may also be of importance in identification in patients with arterial hemorrhage related to pelvic fracture. CT may demonstrate an arterial blush or large hematoma in the vicinity of a pelvic fracture, indicating the need for pelvic arteriography or pelvic external fixation. A "CT cystogram" may also be helpful and eliminate redundancy of x-ray evaluation. The Foley's catheter is clamped after placement in the trauma bay. Real-time interpretation as the CT is performed by the evaluating physician, which may dictate further delayed images or a formal three-view (anterior/posterior, lateral, and post void views) cystogram.

SPECIFIC ORGAN INJURY

The Spleen

The spleen is the most commonly injured intra-abdominal organ followed by the liver and small bowel in blunt trauma patients. The spleen's location in the left upper quadrant lends susceptibility to injury from broken ribs, deceleration, and blunt percussion forces. Clinically, patients with splenic injury may present with hypotension, left upper-quadrant pain or tenderness to palpation or diffuse peritonitis from extravasated blood. Referred pain to the left shoulder on deep inspiration, in face of splenic hematoma, is known as Kehr's sign.

NONOPERATIVE MANAGEMENT

Most series indicate that 60%-80% of patients presenting with blunt splenic injury can be managed nonoperatively at level I or II trauma centers.[43] Facilities without the resources and experience of a bonafide trauma team may not safely meet the demands of nonoperative management and should consider patient transfer.[44] Patients selected for nonoperative management must have stable vital signs, be free of peritoneal signs or other concern for hollow viscus injury, and have no evidence of free extravasation of IV contrast from the splenic parenchyma.

Considerable debate remains regarding risk factors for failure of nonoperative management. Higher American Association for the Surgery of Trauma (AAST) splenic injury grade, age >55 years, moderate to large hemoperitoneum, subcapsular hematoma, and portal hypertension have all been suggested to increase the risk of failure. Early reports in the evolution of nonoperative management regarding ASST grade did not demonstrate higher failure rates for higher grade injury. More recent reports using high-resolution multidetector CT scanners allow better assessment of injury grade. The data from these studies show that patients with injury grades III-V to be at increased risk for nonoperative failure.[45-47] Age continues to be controversial subject matter in the literature, with numerous reports claiming that age >55 years *is* or *is not* a risk factor for failure.[48,49] Documentation of a moderate or large hemoperitoneum is suggestive of a major injury and should be considered an important factor in individual patient assessment.

Patients with splenic subcapsular hematoma or history of portal hypertension are specific subgroups of patients who deserve special consideration. Patients with subcapsular hematoma in our experience tend to ooze from the raw parenchymal surface and further disrupt the capsule, leading to more raw surface area to bleed. These patients are at increased risk for delayed rupture 6-8 days following injury and may already be discharged from the hospital if they have isolated injury. Furthermore, splenic embolization is not an effective treatment of this condition because it usually necessitates coiling of the main splenic artery, which can lead to substantial pain and abscess formation. History of portal hypertension or cirrhosis, while not an absolute contraindication to nonoperative management, certainly should raise concerns. The general risks of laparotomy in a Childs B or C cirrhotic need to be carefully weighed against the risk of ensuing and worsening coagulopathy. This scenario may, indeed, call for main splenic artery embolization. None of these risk factors alone should dictate the decision to proceed immediately to operative intervention. Nonoperative management does reduce hospital length of stay and transfusion requirement; however, the morbidity of splenectomy should remain low in any surgeon's hands. Overall, the patient's condition including comorbidities, coagulopathy, and other problems (such as traumatic brain injury, aortic injury, and suspicion for concomitant hollow viscus injury) factor into the decision-making process. No one undergoing nonoperative management should ever succumb to splenic hemorrhage.

BLUNT SPLENIC INJURY—GENERAL PRINCIPLES OF MANAGEMENT

Approximately 20% of patients initially undergoing nonoperative management of blunt splenic injury require further intervention (Algorithm. 1.12). Failure has been associated with the presence of a contrast blush in up to two-thirds of these patients.[50] The presence of a contained contrast blush within the parenchyma of the spleen represents pseudoaneurysm formation of a branch of the splenic artery. Angioembolization is now commonly used to selectively occlude the arterial branches containing these injuries.[51] Implementation of this salvage technique at centers that routinely screen for the presence of pseudoaneurysm has increased the success of nonoperative management to 90% or greater. Pseudoaneurysm formation has been observed in even grade I and II injuries and may not be present on the initial imaging.[52] Therefore, follow-up CT scan is recommended on all patients with splenic trauma within 24-48 hours after injury. If these images show stable injuries without pseudoaneurysm formation, expectant management may ensue.

Long-term data are unavailable concerning the risk of outpatient or delayed rupture, but the incidence is low and has been reported to be about 1.4%.[53] The average date to readmission for delayed splenectomy after discharge was 8 days in this study. Lower grade (I and II) injuries tend to heal more quickly and most injuries are healed by 5-6 weeks.[54] However, approximately 20% of blunt splenic injuries will not show complete healing and may be at risk for pseudocyst formation. CT should be repeated in 6 weeks for grade I and II injuries and 10–12 weeks in grades III-V before reinstating patients to normal activity.

Splenectomy

Patients requiring urgent or emergent intervention for splenic hemorrhage may develop hypothermia, coagulopathy, and visceral edema. The most expeditious and safest course of action under these conditions is removal of the spleen. The general assumption of abdominal exploration for trauma is that there are known and, possibly, unknown injuries. The operative approach is via a midline vertical incision that allows the best exposure and facilitates temporary abdominal closure should visceral edema or damage control measures be necessary. Standard operating procedure is similar to that previously highlighted in the section, "Management of Penetrating Abdominal Trauma."

With respect to performing a splenectomy, a self-retaining (Buckwalter, Thompson, Rochard, etc.) retractor is used to expose the left upper quadrant. The spleen is retracted medially with some downward compression and the posterior attachments can be taken with the cautery. Once these attachments are freed, the spleen can be mobilized medially for optimal exposure. The assistant stands on the left side of the table and supports the spleen while the surgeon ligates short gastric and hilar vessels. Being careful to avoid the tail of the pancreas, a large clip, placed on the specimen side of the splenic hilum, will reduce back-bleeding and expedite the procedure. Once the spleen has been removed, the splenic fossa is inspected for further bleeding with a rolled laparotomy pad.

Splenorrhaphy

Hemodynamically stable patients found to have small to moderate amounts of parenchymal hemorrhage at laparotomy may be candidates for splenic preservation. The spleen is mobilized into the wound using the same technique as for splenectomy. The injury to the spleen is assessed and decision is made whether to resect a portion if the parenchymal injury extends into the hilum or if arterial bleeding is coming from within the splenic laceration itself. If the decision is made to resect the upper or lower pole, the parenchyma is divided with the cautery and the associated hilar vessels are taken with clamps and ties. Any arterial bleeding from the parenchyma is controlled with suture ligature and the cautery is used to control oozing from the parenchyma. A tongue of omentum is then sutured into the laceration or to the raw surface of the remaining spleen in the

ALGORITHM 1.12

ALGORITHM 1.12 Blunt splenic injury—general principles of management.

case of resection. Approximately 50% of the spleen is required to preserve adequate phagocytic and immunologic function. If this cannot be achieved, a splenectomy is probably the best option, with appropriate postsplenectomy immunization.[55,56]

THE LIVER

The liver is susceptible to the same blunt force mechanisms as the spleen, making it the second most frequently injured intra-abdominal organ. Similar to the spleen, nonoperative management of blunt liver injury has reduced transfusion requirements, hospital length of stay, and mortality.[57-60] Angiographic embolization of arterial injury has also reduced the morbidity and mortality of liver trauma. Complications of nonoperative management such as biloma and liver abscess can usually be managed with minimally invasive techniques as well. What is imperative in the management scheme is to know when to take the patient immediately to the operating room for active hemorrhage versus attempting nonoperative management with angioembolization. The liver is obviously not as expendable an organ as the spleen, and there is no substitute for an in-depth knowledge and experience handling hepatic injuries.

Nonoperative Management

Similar to the experience with blunt splenic trauma, routine use of CT has revolutionized the management of blunt hepatic trauma. The most recent data show that 70%-85% of all patients presenting with blunt liver injury can be managed nonoperatively.[61,62] Patients must be hemodynamically stable, free of peritoneal signs or other evidence of bowel injury, and have absence of contrast extravasation. Worsening grade of injury makes nonoperative management less likely but injury grade alone should *not* dictate the decision to intervene.[63,64] Patients should have stable systolic blood pressure >90 mm Hg with a heart rate <100 bpm after controlling other possible sources of extraabdominal blood loss, such as orthopedic and soft tissue injuries. Failure from subsequent liver hemorrhage occurs in 0.4%-5% of patients and failure due to missed injury of other intra-abdominal organs, such as the kidney, spleen, pancreas and bowel, occurs in 0.5%-15% of patients.[65] The results of these data are summarized in Table 1.6. It is difficult to tell the specific cause of immediate surgery in the earlier reports because laparotomy for *all* causes, such as associated splenic hemorrhage, was included.

Angiographic embolization is a useful adjunct in the management of blunt hepatic trauma both in nonoperative patients and those who have undergone damage control laparotomy in a number of small series.[66-70] Intravenous contrast extravasation from the liver parenchyma into the peritoneal cavity and contrast contained within the parenchyma of the liver associated with a large amount of intraperitoneal blood on initial CT scan are emergent situations mandating angiographic embolization or surgery.[71] If bleeding appears to originate from the retrohepatic vena cava or hepatic veins and it is ongoing, emergent exploration is the only option because arterial embolization is ineffective in these scenarios. Patients with labile blood pressure and parenchymal injury may be better served with emergent exploration depending on the time necessary to assemble the angiography team. However, if angiography is readily available, favorable results have been obtained transporting patients to the angiography suite with ongoing resuscitation for arterial bleeding.[72] Patients requiring significant resuscitation during a successful embolization procedure may still be at risk for abdominal compartment syndrome and should have bladder pressures monitored.[73]

Patients with contrast extravasation contained within the liver parenchyma without significant associated hemoperitoneum are less worrisome but should probably undergo arteriogram for further assessment. A perceived contrast blush on CT scan is associated with bleeding identified at angiography in 60% of patients.

Operative Management

Bleeding from minor liver injuries (grades I and II) usually stops spontaneously and surgical intervention is rarely required.[74] Occasionally, patients may require exploration for other injuries after abdominal trauma in the presence of minor liver trauma. Nonbleeding liver injuries should be left alone. In the face of coagulopathy or hypothermia, minor hepatic injuries may present with persistent oozing. In such cases, topical hemostatic agents, with or without perihepatic packing, may be all that is necessary to stop the bleeding if the patient is being adequately resuscitated.

Major liver injuries (grades III-V) are more likely to bleed and require surgical intervention. Because grade IV and V liver injuries can present formidable technical challenges even in the hands of the most capable individuals, a variety of surgical techniques have been developed for their management.

Large liver wounds should be quickly inspected to get some idea about the degree of hemorrhage and packed initially. Anesthesia should be notified about anticipated blood loss and blood availability checked. Vital signs and resuscitation status should be reviewed. Bleeding should be contained with packing and direct pressure until anesthesia has had time to "catch up." Remaining focused and well organized, as well replenishing intravascular volume is invaluable in the management of any trauma patient.

The most direct approach at this point is to remove the packing and visually inspect for bleeding vessels, which can be individually ligated. Debridement of devitalized tissue using finger fracture technique will expose additional bleeding vessels, which may have retracted into the surrounding parenchyma. If bleeding prevents adequate visualization of the surgical field, the next step should be vascular control of the portal triad (e.g., Pringle's maneuver). This maneuver is easiest to perform for the person standing on the left of the patient. This individual places the fingers of the left hand into the foramen of Winslow and he/she uses the thumb to palpate for the cord of tissue running into the caudal surface of the liver. Once this structure is suspected, its identity can generally be confirmed by appreciating the pulse in the hepatic artery. A hole is then created in the hepatoduodenal ligament using blunt finger dissection. A noncrushing vascular clamp or a half-inch Penrose's drain or vessel loop can be double-looped around the porta and cinched down with a Kelly clamp. We prefer the latter technique because it seems to be less obtrusive to further manipulation of the liver and may be less traumatic to the structures of the porta hepatis.

TABLE 1.6

FAILURE RATES FOR NONOPERATIVE MANAGEMENT OF LIVER TRAUMA

■ STUDY (YEAR)	■ NUMBER OF PATIENTS	■ IMMEDIATE SURGERY (%)	■ OVERALL FAILURE RATE (%)	■ LIVER FAILURE RATE (%)	■ OTHER FAILURE RATE (%)
Meredith (1994)	116	48	3	3	0
Croce (1995)	136	18	11	5	6
Pacther (1996)	404	53	1.2	0.7	0.5
Malhotra (2000)	661	15	7	3	4
Velmahos (2003)	78	29[a]	15	0	15
Christmas (2005)	561	32[b]	1.8	0.4	1.4

Other Failure refers failure due to injuries from other intra-abdominal organs such as the spleen, kidney, pancreas, or bowel.
[a]15% for liver bleeding.
[b]13% for liver bleeding.

If a Pringle's maneuver does not adequately decrease liver bleeding, then concern for hepatic vein or retrohepatic caval injury should be entertained. Obtaining adequate exposure in deep liver wounds or in juxtahepatic caval injuries is of utmost importance. The falciform ligament is taken off the diaphragm posteriorly to the bare area. The right and left triangular ligaments are dissected with the cautery, along extension to the corresponding coronary ligaments. Further dissection of the coronary ligaments to the bare area will allow full mobilization of the liver into the surgical field. Careful dissection of the bare area will allow access to the suprahepatic inferior vena cava. If the plane in the bare area is difficult to develop, a transverse incision in the diaphragm here will gain access to the pericardium and intrapericardial control of the inferior vena cava can be achieved. Total hepatic isolation can be achieved with a Pringle's maneuver and vascular control of the infrahepatic, suprarenal inferior vena cava, and the suprahepatic intra-abdominal or intrapericardial inferior vena cava. The physiologic stress of this technique may not be well tolerated in patients with severe shock and clamp times <20-30 minutes should be maintained.

INTESTINE

A missed intestinal injury may have devastating consequences. Therefore, the basic principle in the management of hollow viscus injuries is operative intervention. In general, the surgical management is straightforward: debridement of any devitalized tissue and primary closure of a simple enterotomy. However, for more destructive injuries, segmental resection and primary anastomosis (or stomal formation) will likely be required.

Knowledge of the AAST organ injury grading scale is helpful in describing wounds of the bowel[75] (Tables 1.7 and 1.8). Grade I injury is contusion or partial thickness laceration of the bowel wall without perforation. Grade II injury is a full-thickness wound involving <50% of the bowel wall circumference.

Grade III is a laceration comprising >50% of the bowel wall circumference without complete transection. Grades IV and V injuries represent complete transection of the bowel wall and transection with segmental tissue loss or devascularization of the mesentery, respectively. The terms destructive and nondestructive simplify the terminology; nondestructive wounds are those injuries that can be managed with debridement and primary suture enterorrhaphy and are comprised of grades I through III. Destructive wounds necessitate resection of an entire segment of the bowel due to loss of colonic integrity or devascularization of the mesentery and encompass grades IV and V.

The distinction between destructive and nondestructive wounds is important in terms of the prescribed management. Nondestructive wounds of the large or small bowel can generally be repaired without further consideration. Most small bowel and large destructive injuries should be resected and reconstituted unless "damage control" management is planned.[74,76-78]

LUNG AND CHEST WALL

The most common lung injury in blunt trauma is pulmonary contusion. These specific injuries are managed expectantly and supportively. Extensive injury will likely dictate the need for endotracheal intubation and the administration of positive pressure ventilation to optimize oxygenation. A thoracotomy will likely be required for left or right mainstem bronchial tears with associated major airleak. Other indications for early operative intervention include a massive hemothorax (1,500 mL or greater or blood initially evacuated from the pleural space upon insertion of a chest tube or >200 mL per hour of blood chest tube drainage for successive hours). Operative fixation or chest wall stabilization by plating fractured ribs has gained some popularity for multiple rib fractures or a flail chest.[79,80]

TABLE 1.7

AAST SMALL BOWEL INJURY SCALE

■ GRADE[a]	■ TYPE OF INJURY	■ DESCRIPTION OF INJURY	■ ICD-9[b]	■ AIS-90[c]
I	Hematoma	Contusion or hematoma without devascularization	863.20-863.31	2
	Laceration	Partial thickness, no perforation		2
II	Laceration	Laceration <50% of circumference	863.20-863.31	3
III	Laceration	Laceration ≥50% of circumference without transection		3
IV	Laceration	Transection of the small bowel	863.20-863.31	4
V	Laceration	Transection of the small bowel with segmental tissue loss	863.20-863.31	4
	Vascular	Devascularized segment		4

ACUTE CARE SURGERY— GENERAL PRINCIPLES: SUMMARY

As highlighted above, the core principle of acute care surgery is expeditious and effective medical/surgical management, with early diagnosis an essential element. Many of the general principles of trauma management are applicable in the nontrauma setting. However, each specific disease entity has its own unique diagnostic/management paradigm that is covered throughout the textbook. Depending on the regional geography, the disease (nontrauma) entities that are most commonly encountered by the acute care surgeon are outlined in Table 1.9.

The severity of the disease and the stage of presentation, along with the status of the patient (e.g., hemodynamic stability) will often dictate the specific course of management (operative vs. nonoperative approach).

TABLE 1.9

COMMONLY ENCOUNTERED DISEASE ENTITIES

Appendicitis
Intestinal obstruction
Diverticulitis and deep (cartilage) of tissue, abscesses
Necrotizing soft tissue infection
Biliary diseases
Pancreatitis
Gastrointestinal bleeding
Mesentery ischemia
Inflammatory intestinal disease
Perforated hollow viscus

CHAPTER 2 ■ TRAINING IN ACUTE CARE SURGERY

GREGORY J. JURKOVICH

Training in acute care surgery has been formalized in an advanced surgical training fellowship that is currently endorsed and sponsored by the American Association for the Surgery of Trauma (AAST).[1,2] The AAST is a professional surgical society that was founded in 1938 and has been the academic home for trauma surgeons in North America. The curriculum for acute care surgery fellowships is outlined below (Table 2.1), as well as detailed on the AAST Web site (http://www.aast.org/Library/AcuteCareSurgery/Default.aspx).

Fundamental to this training is an emphasis on the three main components of acute care surgery: trauma, surgical critical care, and emergency general surgery. Key structural components of the curriculum are that it is 2 years in length and includes within its content an Accreditation Council on Graduate Medical Education (ACGME)-approved surgical critical care residency, as well as advanced surgical training in trauma care and emergency general surgical care. Applicants must have finished an ACGME-approved general surgery residency. Throughout this chapter, the term "residency" means a formal training program approved by the Surgery Residency Review Committee (RRC) of the Accreditation Council for Graduate Medical Education. The term "fellowship" means a formal training program that is similar to ACGME-accredited residencies, but is *not an* ACGME-accredited program. Current examples of such "fellowships" include minimally invasive surgery, acute care surgery, transplantation, breast surgery, and others. Some fellowships are generally in newer or developing fields and are considering seeking formal ACGME accreditation in the future. Other fellowships (including some established ones) are less inclined to seek ACGME overnight due to the reimbursement restrictions on resident care mandated by federal funding sources and the increasingly stringent additional requirements (e.g., duty hour limitations).

The curriculum includes a dedicated minimum of 9 months of surgical critical care, as mandated by the ACGME for accredited surgical critical care residencies. In the majority of the programs, this results in having a 1-year surgical critical care fellowship, along with an additional year of clinical operative experience in trauma and emergency general surgery. Only a program with an ACGME-accredited surgical critical care residency can be eligible for AAST approval for an acute care surgery training program.

The remaining 12-15 months are focused on operative rotations in emergency and elective surgery, with the expectation that there will be at least 12 months of acute care surgical on-call experience, or a minimum of 52 nights of trauma and emergency general surgery call. The 12-15 months of operative rotations have as a foundation time spent on an active acute care surgical service. This is ideally supplemented by three specific rotations in thoracic, vascular, and hepatobiliary–pancreatic surgery, with the expectation that these rotations will provide supplemental and advanced exposure to surgical skills and patient care challenges that often are inadequate in core general surgery training. It is felt that these three specific areas of advanced specialty training are needed to fully prepare a surgeon for the clinical challenges of emergency trauma and nontrauma surgery.

While there is considerable flexibility allowed in these new training fellowships, it is suggested that there is time spent on trauma orthopedics and neurosurgical services, with additional elective time to be allocated to meet the needs of the trainee. The expectation is that trainees will be competent in the management of a wide spectrum of acute care surgical needs and have specific operative competency in the procedures listed in Table 2.2.

In summary, the clinical component of these fellowships includes the following key areas:

1. The program should supply the necessary volume and variety of trauma, critical care, and emergency general surgery to ensure adequate training of fellows.
2. Each fellow must have ample opportunity and responsibility for the care of patients with acute surgical problems, and the operative experience must be consistent with developing competency in technical skills and procedures required to provide acute surgical care.
3. Elective general surgery is an essential component of the training of acute care surgeons.
4. Emergency surgical call and trauma call are mandatory components of the training curriculum. Fellows will take a minimum of 52 trauma and emergency surgery night calls during the 2-year fellowship.
5. Elective operative experience in thoracic, vascular, and complex hepatobiliary and pancreatic procedures are strongly encouraged as a means of developing competency in the management of acute surgical emergencies in these anatomic regions.
6. Working knowledge of the diagnosis, management, and operative treatment of neurosurgical and orthopedic injuries is expected.
7. Experience with the use of interventional radiology techniques is encouraged.
8. Experience and competency with diagnostic upper and lower gastrointestinal (GI) endoscopy and bronchoscopy are encouraged.

As of early 2011, there were seven formally approved training sites, one pending approval, with another estimated 10-20 programs in various stages of considering submitting applications for approved training sites.

The history of how the AAST became the sponsoring organization and pushed the development of acute care surgery fellowships is worthy of comment. Trauma surgery as a unique academic surgical specialty had its roots in the urban county hospitals of the United States, although it has always been the specialty of military surgeons. Those spheres of influence overlapped at the end of the Vietnam War, with the lessons learned in that massive trauma resuscitation experience being applied to the civilian trauma centers that had begun to develop in the late 1960s.[3] Primarily due to the charismatic and academically focused leadership in Chicago (Freeark), Dallas (Shires), and San Francisco (Blaisdell), followed by regional trauma systems in Illinois (Boyd) and Maryland (Cowley) in the early 1970s, the urban county hospitals had by necessity become hospitals for the most critically injured blunt and penetrating trauma patients.[4] The American College of Surgeons (ACS) recognized this trend, and its inherent value in patient care, and began to advocate for trauma centers and trauma surgeons via the Committee on Trauma (ACS/COT). The publication of the

TABLE 2.1

ACUTE CARE SURGERY CURRICULUM

■ REQUIRED CLINICAL ROTATION	■ LENGTH
Surgical critical care including:	
• Trauma/surgical critical care, including other relevant critical care rotations	9-12 mo
• This portion of the fellowship must comply with ACGME requirements for a surgical critical care residency	
Emergency and elective surgery:	12-15 mo
Total	**24 mo**
■ SUGGESTED EMERGENCY AND ELECTIVE SURGERY ROTATIONS	■ LENGTH
• Trauma/emergency surgery (required)	2-3 mo
• Thoracic	2-3 mo
• Transplant/hepatobiliary/pancreatic	2-3 mo
• Vascular/interventional radiology	2-3 mo
• Orthopaedic surgery	1 mo
• Neurological surgery	1 mo
• Electives	1-3 mo
• Recommended: burn surgery and pediatric surgery	
• Additional: endoscopy, imaging, plastic surgery, etc.	
Total	**12 mo**

Notes to Curriculum Outline

It is a requirement that over the 2-y fellowship, trainees participate in acute care surgery call for no less than 12 mo. Fellows are required to take 52 night calls in trauma and emergency surgery during the 2-y fellowship.

1. Flexibility in the timing of these rotations and the structure of the 24-mo training should be utilized to optimize the training of the fellow.
2. Rational for out-of-system rotations for key portions of the training must be based on educational value to the fellow.
3. Acute care surgery fellowship sites must have RRC approval for surgical critical care residency.
4. Experience in elective surgery is an essential component of fellowship training.
5. An academic environment is mandatory, and fellows should be trained to teach others and conduct research in acute care surgery.

sentinel document "Optimal Hospital Resources for Care of the Seriously Injured" first occurred in 1976 and has spurred over 30 years of formalized trauma center and trauma system development in the United States that is the template for how regionalization of care can occur.

Those who pursued a trauma career during this period fondly remember the golden age of trauma surgery from the mid-1970s to the late 1980s.[5] Mentorship was a decisive factor. The trauma surgeon was regarded as the master technician (Blaisdell, Carrico, Davis, Freeark, Lucas, Ledgerwood, Mattox, Shires, Moore, Feliciano) who operated confidently and effectively in the neck, chest, abdomen, and pelvis and repaired any injured blood vessel. After exposure to the "trauma service," residents initially bent on a career in cardiac surgery or transplant surgery often changed direction because of exposure to these individuals during surgical training. This was a time of novel operative techniques and frequent trauma operations. The annual program of the AAST was replete with presentations on innovative operative techniques (hepatic tractotomy, splenorrhaphy, pyloric exclusion; cervical, thoracic, abdominal, and peripheral vascular reconstruction). As poignantly stated by Tom Cogbill in the editorial entitled "Eraritjaritjaka," "I had no thought of choosing surgery as a career until the third year surgery rotation at the Denver General Hospital. In less than a day I felt as if I had been thrown into a busy field hospital on the edge of some unknown battlefield. The Knife and Gun Club lived up to its reputation night after night. Each day was more exciting than the day before... I looked with great admiration upon... attending surgeons for their excellent decision making and technical skills."[6] Eraritjaritjaka is

an archaic poetic expression in Arunta, which means "full of desire for something that has been lost."

Indeed, by 1990, a number of critical events radically changed the scope of practice for trauma surgery, but perhaps none so subtly yet dramatically as the progressive reduction in operative procedures and marked increased responsibility for nonoperative care of the injured patient; these became synonymous with a disenfranchisement of the specialty as a viable surgical career. The advent of computed tomographic scanning ushered in nonoperative management of solid organ injuries that has become the rule rather than the exception. A successful national emphasis on injury prevention lessened the injuries from motor vehicle crashes, and the operative management for blunt torso trauma became infrequent. Penetrating trauma, at one time the most prevalent indication for thoracic, abdominal, and vascular operations in urban trauma centers, became much less common for reasons that are still debated in social science circles. The emergence of other surgical specialists (thoracic, vascular, otolaryngology) additionally diverted many injuries away from trauma surgery, and angioembolization and endovascular stenting further decreased operative intervention. A report by Richardson and Miller in 1992[6] verified this trend away from trauma surgery as a desirable field, noting that only 8% of graduating surgical residents were interested in trauma.

Concurrent with these events, surgical critical care emerged as a viable discipline with strong academic interests and challenging physiology, and trauma surgeons became absorbed in delivering comprehensive care for all injured patients, with some developing a primary interest and focus of practice in

TABLE 2.2

OPERATIVE MANAGEMENT PRINCIPLES AND TECHNICAL PROCEDURE REQUIREMENTS OF ACUTE CARE SURGERY FELLOWSHIP

■ AREA/PROCEDURE	■ ESSENTIAL	■ DESIRABLE
AIRWAY		
Cricothyroidotomy	×	
Nasal and oral endotracheal intubation including rapid sequence induction	×	
Tracheostomy, open and percutaneous	×	
HEAD/FACE		
Nasal packing (for complex facial fracture bleeding)	×	
ICP monitor		×
Lateral canthotomy		×
Ventriculostomy		×
NECK		
Exposure and definitive management of vascular and aerodigestive injuries	×	
Elective neck dissection		×
Parathyroidectomy		×
CHEST		
Advanced thoracoscopic techniques as they pertain to the described conditions	×	
Bronchoscopy: diagnostic and therapeutic for injury, infection, and foreign body removal	×	
Damage control techniques	×	
Definitive management of empyema: decortication (open and video-assisted thoracic surgery [VATS])	×	
Diaphragm injury, repair	×	
Exposure and definitive management of cardiac injury, pericardial tamponade	×	
Exposure and definitive management of esophageal injuries and perforations	×	
Exposure and definitive management of thoracic vascular injury	×	
Exposure and definitive management of tracheobronchial and lung injuries	×	
Pulmonary resections	×	
Spine exposure: thoracic and thoracoabdominal	×	
VATS for management of injury and infection	×	
Partial left heart bypass		×
Repair blunt thoracic aortic injury: open or endovascular		×
ABDOMEN AND PELVIS		
Abdominal wall reconstruction following resectional debridement for infection, ischemia	×	
Advanced laparoscopic techniques as they pertain to the described procedures	×	
Damage control techniques	×	
Exposure and definitive management of duodenal injury	×	
Exposure and definitive management of gastric, small intestine, and colon inflammation, bleeding, perforation, and obstructions.	×	
Exposure and definitive management of gastric, small intestine, and colon injuries	×	
Exposure and definitive management of major abdominal and pelvic vascular injury	×	
Gastrostomy (open and percutaneous) and jejunostomy	×	
Hepatic resections	×	
Management of abdominal compartment syndrome	×	
Management of all grades of liver injury	×

Inguinal hernia repair		×
Trauma management		×
Treatment of bowel obstruction		×
Ventral hernia repair		×

this largely nonoperative specialty. The new specialty of emergency medicine further compounded these changes, as these physicians sought to be the primary hospital-based responders to trauma and directors of trauma resuscitation and evaluation. In response, the ACS/COT promulgated guidelines for the physical presence of the trauma surgeon in the Emergency Department for initial evaluation of the injured patient and the intensive care unit to provide nonoperative supportive care, all in an effort to provide a continuity of care and surgical presence that support surgeon primacy in caring for the injured patient. While clearly well intended, the guidelines became regulations in many states and translated into frequent nocturnal excursions to the ED to oversee initial care of head injuries and multiple fractures, forcing onerous mandatory in-house call, with decreasing operative experience.

A further destructive consequence was the practice of divorcing elective procedures from trauma surgery. While the stated rationale was that the trauma surgeon was preoccupied

with ED and SICU responsibilities, it often was the case that the trauma surgeons were prohibited from having an elective practice by either hospital administrators or private practice community surgeons who not only did not want to do trauma care but also did not want the trauma surgeons, who were paid by the hospital, to compete for their referrals. The net result was that trauma surgery—once a predominantly operative service—became a largely nonoperative field with disproportionate demands on lifestyle. Esposito et al convincingly articulated that trauma surgery was in the midst of an identity crisis, a feeling that was not lost on competing emergency physicians, some of whom felt they should be assuming the lead in trauma care.[7,8]

These forces combined with other social, demographic, and economic pressures to develop a crisis in trauma care. New graduates in all medical specialties were congregating to "controllable lifestyle" specialty practices; there was increasing unavailability of surgeons committed to the injured patient; the high economic pressures on hospitals to pay "on-call" surgeons of every conceivable specialty of what some would consider to be outrageous or at least disproportionate pay for simply being available, while the trauma surgeons provided the bulk of clinical care. While a disruptive lifestyle, extended work hours, poor reimbursement, risk of blood-borne infections, and medicolegal risk are to a degree shared by all surgical disciplines, the unique challenge confronting trauma surgeons was the shrinking scope of operative practice. The unique challenge confronting societal health care was the increasing cost of medical care, the unavailability of surgeons willing to provide emergency call, and the decreased availability of general surgeons well versed and comfortable with the management of all types of surgical emergencies, including trauma.[9,10]

Recognizing these challenges and the changing face of general surgery, the trauma community developed an active response to patient and provider needs. Representative members of the AAST, Eastern Association for the Surgery of Trauma, Western Trauma Association, and American College of Surgeons Committee on Trauma (ACS/COT) met in August of 2002 to consider the future of trauma surgery in light of the changing demographics and economics of trauma care. That initial meeting was cochaired by David Hoyt, MD, president of the AAST, and Wayne Meredith, MD, chairman of the ACS Committee on Trauma. The AAST was assigned primary responsibility for developing a plan of action, and Dr. Hoyt appointed Gregory J. Jurkovich, MD, chairman of an ad hoc committee, to accomplish just that. This became a standing committee of the AAST in the fall of 2006 and has subsequently been chaired by Dr. Grace Rozycki (2008-2010) and John Fildes (2010-2014). Further details of the history behind the organization of this committee and its workings to develop the acute care surgery training fellowship are referenced.[1,2]

The primary recommendation of this committee was that the AAST should take a leadership role in defining, developing, and promoting a new postgraduate training fellowship. It was believed this fellowship should be built on a foundation of "general surgery," meaning it would follow core general surgery training, currently a 5-year ACGME residency in the United States. The primary purpose of this new training fellowship would be to define and train a surgeon with expertise in trauma, critical care, and emergency general surgery. It was expected that this broad training would allow for great flexibility in local practice patterns, including encouraging an elective practice in general surgery if desired. This training paradigm, and the fellowships and specialty practice patterns it has spawned, have come to be known as acute care surgery.

The details of this 2-year fellowship have been described already. Extensive exposure and direct care of the injured patient are the bedrock of this fellowship, combined with surgical critical care and emergency general surgery. Academic

activities are expected of these trainees, and a core curriculum including operative experience has been mandated. Finally, a measurement of knowledge (multiple choice test) in trauma and general surgical emergencies has been developed.

It is clear this fellowship is in its infancy. However, in a recent survey of program directors of ACGME-approved surgical critical care programs, of which there are 95 programs offering 189 residency positions, 57% responded that they are considering incorporating an acute care surgery fellowship training paradigm.[11] In 2005, the American Board of Surgery initially established advisory councils for trauma, burns, and surgical critical care along with gastrointestinal surgery, surgical oncology, and transplant surgery. These advisory councils were in addition to component boards in pediatric surgery and vascular surgery.[12] In 2010, the Trauma, Burns, and Surgical Critical Care Advisory Council was made a component board, with ongoing discussions on the pathway to board-certification status for acute care surgery training. Programs are advertising acute care surgery positions, hospitals are recruiting to acute care surgery positions, other medical specialties are talking about acute care surgery, and importantly, medical students and residents are asking questions about a career in acute care surgery. Indeed, the dilemma of limited or restricted elective operative prerogative for trauma surgeons has been most conspicuous in university hospitals where general surgery has become maximally fragmented, compounded by the existence of financially powerful cardiothoracic, vascular, transplant, and interventional radiology services. Many of these academic centers have embraced at least part of the true acute care surgery practice concept, incorporating "emergency general surgery" into the trauma service with or without a critical care practice as a solution to the lack of availability of a "general surgeon."[13-17] And while many criticisms have been leveled at the concept and development of this training paradigm, it has gained traction because it is fulfilling a need.

This is the practice paradigm that most "trauma surgeons" identify with as we enter the 2nd decade of the 21st century. In reality, while the name is new, the practice paradigm of acute care surgery is not. Academic urban county hospitals, now often called "safety net hospitals," have always employed this model to ensure optimal care of the injured patient, convinced that emergent torso trauma surgery and elective general surgery are inseparable.[4,13] Moreover, this has always been the scope of practice for rural trauma surgeons.[18-20] Acute care surgery training is likely to become one of the pathways of specialization following core general surgery training and the one that best develops broadly trained general surgeons who will embrace the challenges of surgical emergencies and critical care.

CHAPTER 3 ■ PATHOPHYSIOLOGY OF ACUTE ILLNESS AND INJURY

TIMOTHY R. BILLIAR AND MARCUS K. HOFFMAN

In the setting of an acute surgical illness, the patient's body responds to stresses resulting from tissues in distress and often from microbial invasion. This results in profound changes in the function of most organs and systems. Most of these changes are adaptive. The range and extent of the responses depend on not only the type of insult but also host factors (see Table 3.1). When excessive, the responses designed to allow the host to adapt can become dysregulated or excessive and hence maladaptive. Timely intervention can limit the untoward consequences. However, an appreciation of both the adaptive and maladaptive response can assist with care decisions that can impact patient outcomes.

Systemic responses are secondary to a combination of factors including neurohormonal responses, release of bioactive molecules from damaged or injured tissues, or infectious organisms or elaborated products. The extent to which tissue damage and invasive infection contribute to the host response can vary considerably by the type of insult. For example, in cholangitis, minimal tissue damage occurs but bacteremia can be substantial. Likewise with gastrointestinal ulceration, a small area of tissue necrosis can result in diffuse peritonitis and sepsis if there is free perforation.

As local disease processes become more extensive, a systemic response ensues. Patients may exhibit tachycardia, tachypnea or carbon dioxide retention, or temperature elevation above 38°C or below 36°C. Complete blood counts may reveal leukocytosis of 12K white blood cells/mm³ (WBC) or higher, depression below 4K, or bandemia. Having at least two of the aforementioned physiologic changes or laboratory values defines a patient as having systemic inflammatory response syndrome (SIRS) and, in the setting of infection, defines a patient as having sepsis. However, in the clinical setting, a patient is usually referred to as being "septic" when he or she has sepsis and some form of organ dysfunction, such as altered mental status or oliguria. Patients have progressed to septic shock when they develop hypotension resistant to fluid boluses.

Along the spectrum of localized inflammation to septic shock, the surgeon must determine how well a patient is compensating and how much physiologic reserve the patient has remaining. A systematic approach to evaluating patients in acute care surgery allows for an appropriate global evaluation of the patient. Several scoring systems have been developed to estimate the physiologic status of the patient. Among the most predictive is the Acute Physiology and Chronic Health Evaluation II (APACHE II) classification system (see Fig. 3.1). Although not often calculated acutely, this classification system assesses parameters of organ and system function that should be part of the evaluation of acutely ill surgical patients.

CARDIOVASCULAR

Patients with coronary artery disease, congestive heart failure, or severe valvular problems will not tolerate drastic hemodynamic changes seen in severe systemic inflammation. With coronary artery disease, atherosclerosis prevents demand-driven vasodilation that can result in ischemia and myocardial

damage in the setting of sustained tachycardia as seen with SIRS. Aside from a history of previous myocardial infarction, coronary artery bypass grafting or percutaneous coronary interventions, coronary disease should be suspected in any patient with diabetes mellitus, smoking history, hyperlipidemia, and peripheral vascular disease.

Congestive heart failure and valvular disease do not drastically change the management of patients presenting with acute surgical issues but may necessitate more invasive hemodynamic monitoring as ongoing resuscitation occurs. Resuscitation should not be limited due to these comorbidities as aggressive resuscitation will likely correct disturbances in low cardiac output. Consideration must be given to heart rate control as tachycardia can lead to inefficient cardiac contractility, pulmonary edema, and hypotension. The development of atrial fibrillation in a patient with or without a cardiac history should cue the surgeon into the fact that the heart is irritated in the current physiologic state.

In a compensated state, the cardiovascular system will maintain a sinus rhythm and an acceptable blood pressure. In states of intravascular depletion, vascular resistance will increase via increased vessel tone to maintain a mean arterial pressure for perfusion of vital organs. This attempt at compensation is seen as a narrowed pulse pressure, as the diastolic pressure is elevated from increased vascular tone and the systolic pressure drops from decreased preload. For maintenance of cardiac output with decreased preload and resultant decreased stroke volume, the heart rate will increase.

Decompensated states of the cardiovascular system can be either obvious or arbitrary. Obvious states are the development of new nonsinus rhythms (e.g., atrial fibrillation) and the occurrence of myocardial ischemia or acute coronary syndromes. Arbitrary decompensated states lie along the same spectrum of compensated states, but occur further along, such as when a patient has a sinus tachycardia in the 160 bpm range or when mean arterial pressure drops below 55 mm Hg.

Therapeutic interventions begin with the insertion of an arterial line for continuous blood pressure monitoring, frequently followed by central venous catheterization if there is any doubt about the volume status of a patient. Pulmonary artery or Swan-Ganz catheters may be placed if large hemodynamic changes are expected in the setting of known severe aortic or mitral valve dysfunction or if the etiology of hypotension and cardiac dysfunction is unknown. Resuscitation begins with isotonic crystalloid fluids and may need to be supplemented with vasopressors depending on the degree of volume depletion (prolonged vomiting or lack of oral intake), presence of septic response (high cardiac output, peripheral vasodilation, high mixed venous oxygen saturations), and patient parameters such as high central venous pressure in the presence of low mean arterial pressure.

PULMONARY

Relevant respiratory history includes both previous and current smoking, known diagnosis of chronic obstructive pulmonary disease (COPD), pulmonary medications

TABLE 3.1

PATIENT FACTORS ASSOCIATED WITH INCREASED MORTALITY

■ DISEASE/INTERVENTION	
Necrotizing soft tissue Infectionsinfections	Age > 60, DM, acute renal failure,
Emergent colorectal surgery	Age
Perforated peptic ulcer	Age, number of comorbidities, NSAIDs or corticosteroid use
Upper GI bleed	Age, CHF, hepatic failure, malignancy, IBD, renal disease, DM, CAD, corticosteroid use
Appendectomy	Age, ASA Class IV or V, complete dependence functional status, insulin-controlled DM, COPD, chronic corticosteroid use, current pneumonia, history of bleeding disorder
Cholecystectomy	Age > 60, ASA Class III–V

DM, diabetes mellitus; NSAIDs, nonsteroidal anti-inflammatory drugs; GI, gastrointestinal; CAD, coronary artery disease; COPD, chronic obstructive pulmonary disease; IBD, inflammatory bowel disease; CHF, congestive heart failure; ASA, American Society of Anesthesiologists.

including inhalers or prednisone, or shortness of breath with activity. Patients with COPD may decompensate and develop hypoxemia or hypercapnia and carbon dioxide narcosis. For patients with appreciable pulmonary comorbidities, patients and their families should be aware that mechanical ventilation could be required for days to weeks while the patient's respiratory status is optimized for extubation following surgery. Septic patients may develop acute respiratory distress syndrome and require low tidal volume ventilation and early tracheostomy.

THE APACHE II SEVERITY OF DISEASE CLASSIFICATION SYSTEM

B AGE POINTS:
Assign points to age as follows:

AGE(yrs)	Points
≤44	0
45-54	2
55-64	3
65-74	5
≥75	6

C CHRONIC HEALTH POINTS:
If the patient has a history of severe organ system insufficiency or is immuno copromised assign points as follows:
a. for nonoperative or emergency poscoprative patien– 5 points
   or
b. for efective postoperative patients – 2 points

DEFINITIONS
Organ Insuficiency or immune-compromised state must have been evident prior to this hospital admission and conform to the following critenis.

LIVER Biopsy prowen crihisic and documented portal hypertension, spidoses of past upper GI bleeding as Inbuted to portal hypertension, or prior episodes of hepatic failure/encephalopathy/coma

CAROIOVASCULAR : New York Heart Association Class IV
RESPIRATORY: Chronic restrictive, obstructive, or vascular disease resulting in severe exercise restriction, i.e. unable to climb stairs or perform household dulies; or documented chronic hypoxia, hypercapnia, secondary polycythemia, severe pulmonary hypertension (> 40 mm/Hg), or respirato dependency.

RENAL : Receiving crhonic cialysis.

IMMUND COMPROMISED : The patient has received theraphy that suppresses resistance to infection, e.g. immumnosuppression, chemotherapy, radiation, long term of recent high dose streoids, or has a disease that is sufficiently advanced to suppress resistance to infection, e.g., Iruhemia, lymphomia, AIDS.

FIGURE 3.1. The APACHE II severity of disease classification system. (From Knaus WA, Draper EA, Wagner DP, et al. APACHE II: a severity of disease classification system. *Crit Care Med*. 1985;13:818-829.)

In most situations in acute care surgery, the lungs do not sustain a direct insult with the exception of possible aspiration pneumonitis during episodes of emesis. Instead, pulmonary dysfunction occurs as the result of systemic response to infection or hemorrhagic shock. The lungs appear to be especially sensitive to the "mediator storm" that occurs in the setting of SIRS. In states of metabolic acidosis via lactate, diabetic keto-acidosis, etc., the patient will become tachypneic to develop a compensatory respiratory alkalosis.

Respiratory decompensation and failure becomes imminent when patients show signs of accessory muscle use, head bobbing, or nostril flaring. First-line interventions of supplemental oxygen via nasal cannula or face mask should occur immediately. Chest radiograph and auscultation should also be performed to look for other causes of respiratory difficulty that could be corrected, such as wheezing and bronchospasm responsive to bronchodilators or large pleural effusions causing respiratory compromise. The next step in the majority of cases is intubation and mechanical ventilation.

RENAL

Renal failure is frequently seen with other comorbidities, especially diabetes and coronary artery disease, and should prompt further medical history interrogation. Urinary catheter placement and monitoring of urine output should occur early in patients with systemic illness. Basic metabolic panels should be reviewed and compared with previous values. Elevation in blood urea nitrogen (BUN) or creatinine can be indicative of intravascular volume depletion, which can occur due to a number of factors including decreased oral intake, increased vascular permeability, and peripheral vasodilation depending on the level of systemic inflammation occurring. Hyponatremia is of significance as it is commonly seen in necrotizing soft tissue infections.

Determination of the function of the renal system is difficult to perform. Gold standards involve measurements of inulin clearance. Creatinine is used as a surrogate marker, and various formulas have been created based on studies of 24-hour creatinine clearance. As such, estimated glomerular filtration rate (eGFR) presumes that the serum level of creatinine is indicative of current renal function. However, if renal function is acutely declining and clearing less creatinine, eGFR would be an overestimate of the current function. This would only be revealed in subsequent serum creatinine level on the following day.

A more accurate indicator of current renal function may be urine output. A simplified method of conceptualizing urine output is classifying it as adequate, marginal, inadequate, and anuric. Urine output of approximately 0.5 mL/kg/h has been used as acceptable urine production for adults. New-onset anuria would indicate decompensation as metabolites would not be actively cleared from the blood.

Interventions for renal dysfunction should be directed toward resuscitation to a normovolemic state with appropriate mean arterial pressures. Disturbances in potassium, magnesium, and phosphorus should be corrected. Acute renal failure may necessitate continuous renal replacement therapy, but this commonly does not need to be performed within the first hours of presentation unless the patient meets criteria for emergent dialysis.

ENDOCRINE

Patients with long-standing diabetes mellitus are prone to have underlying coronary artery disease and chronic kidney disease, and, as such, their cardiac and renal statuses must be further investigated. Blood glucoses levels obtained at the time of presentation may be indicator of systemic inflammation. Insulin-dependent diabetics who normally have well-regimented control of their blood glucoses may present with elevated but not alarmingly high levels or may report requiring higher-than-average units of insulin in the previous 24 hours. Normal blood glucose levels indicate a compensated or normal state while slightly elevated glucose levels indicate a partially decompensated state.

Extremely elevated glucose levels are indicative of a decompensated state, as seen in diabetic ketoacidosis and nonketotic hyperosmolar hyperglycemia. Both states of decompensation must be treated with volume resuscitation and intravenous insulin drips. Concerning hyperkalemia will frequently lead to hypokalemia with the aforementioned interventions. While debate exists surrounding the exact range of blood glucose levels that are ideal, glycemic control should be implemented as hyperglycemia is associated with worse outcomes.

Patients with conditions requiring chronic oral steroids, that is, prednisone, are at risk of acute adrenocortical insufficiency. In patients who are already at risk for developing septic shock, it is extremely difficult to differentiate sepsis and adrenal insufficiency. Adrenocorticotropic hormone stimulation test with cosyntropin takes hours to perform correctly. If necessary, testing can be performed at a later time when it is certain that the patient is stabilized. Patients are presumably in a compensated adrenal state unless they have inexplicable hemodynamics that appear to be refractory to both intravenous fluids and vasoactive medications. Patients with this decompensated picture may have a history of chronic steroid use, but this is not a prerequisite for developing acute adrenocortical insufficiency. In this patient population, treatment with IV hydrocortisone 100 mg every 6-8 hours empirically should be given if there is concern for adrenocortical insufficiency.

NEUROLOGIC

Altered mental status or delirium may be a sign of systemic inflammation or bacteremia. Altered mental status can be the only presenting symptom in bacteremic elderly patients, as is frequently seen in urinary tract infections and urosepsis. In most cases, a family member or medical power of attorney will be able to describe the patient's neurologic baseline. Patients who are not alert and oriented to their baseline level are neurologically decompensated. Interventions may include keeping a family member or staff at bedside to reorient the patient, antipsychotic medications for agitated patients who will not reorient, and intubation for the obtunded patient not protecting his or her airway.

HEMATOLOGIC

Systemic inflammation usually results in leukocytosis and possibly the presence of bands on the peripheral smear but on occasion will result in a depressed WBC count. These changes might not be seen in a patient on chemotherapeutic agents or immunosuppressive medications (transplant patients or patients with autoimmune disorders such as rheumatoid arthritis). Questions to patients should focus on family or personal history of bleeding or clotting disorders and medications with anticoagulant or antiplatelet properties, specifically warfarin, clopidogrel, and aspirin. Unexpected elevation in international normalized ratio (INR) should prompt investigation into liver disease, especially if the platelet count is on the lower end of normal or frankly thrombocytopenic. Hemoglobin and hematocrit levels on the high end of normal may further suggest intravascular volume depletion.

Therapeutic intervention should be geared toward maintaining an acceptable hemoglobin and hematocrit, platelet count, and INR. Packed red blood cell transfusion may be indicated, understanding that volume resuscitation may also contribute to low hematocrit levels through dilution. Platelet counts should be kept above 50K in the perioperative setting and periprocedural settings for interventional radiology or endoscopy. Elevated INR can be corrected with fresh frozen plasma and/or intravenous phytonadione (vitamin K) depending on timing of interventions.

HEPATIC AND METABOLIC

In obtaining information from a patient, one must query recent weight loss or weight gain and alcohol history, both current and remote alcohol use. Recent unexpected weight loss may cue the surgeon into the duration of the disease process at hand or the presence of another medical problem. Correlating this to an albumin level will give the surgeon an indication to the nutritional status of the patient, which is useful in determining how well a patient will recover from an operation. Prealbumin level gives a better picture of the nutritional status as it is not affected by liver dysfunction, but this laboratory value is not always readily available in most institutions. Unexpected weight gain should prompt investigation into worsening cardiac, renal, or hepatic function.

A considerable alcohol history should focus attention on determining if the patient has cirrhosis. While there are numerous causes of cirrhosis and liver damage, alcohol intake is the most common cause within the United States. On physical exam, one may palpate an enlarged liver or spleen, note a fluid wave on abdominal exam, or find peripheral musculoskeletal wasting with abdominal protuberance. Jaundice may be present, but jaundice without other exam findings generally does not occur. Laboratory findings may include thrombocytopenia or a platelet count on the lower spectrum of normal, elevated prothrombin time (PT) and INR, elevated bilirubin, low albumin, and low sodium. Along a spectrum of acute hepatic dysfunction, patients may have elevated ammonia levels, elevated PTs, and in severe cases, elevated lactate levels. Aside from correcting laboratory abnormalities, cirrhosis is an important comorbidity in the management of acute care surgery patients as it portends to higher risks of morbidity and mortality regardless of surgical intervention.

When presented with a patient, the surgeon must perform a systematic evaluation to determine the level of insult the patient is experiencing (from localized inflammation to septic shock) and the comorbid conditions of the patient. This knowledge allows one to ascertain the degree to which the patient is compensating and the physiologic reserve for further compensation or insult. The surgeon can then take this information into consideration when determining how to manage the various problems that are presented in acute care surgery. Depending on the nature of the surgical emergency, it may be prudent to delay surgery while hematologic and volume abnormalities are corrected. However, for many surgical emergencies (e.g., life-threatening hemorrhage and ischemic bowel), this is not an option, and efforts to correct abnormalities should occur simultaneous to emergent surgical interventions.

MEDIATORS OF INJURY

Discussion of the pathophysiology of acute care surgery would not be complete without mention of mediators. The disease processes that present to the acute care surgeon are varied from the hemorrhage-reperfusion physiology seen with gastrointestinal bleeds to overt sepsis seen with necrotizing fasciitis.

Pattern recognition receptors allow for signaling through both pathogen-associated and danger-associated molecular patterns. The Toll-like receptors bind a variety of exogenous ligands including flagellin from bacterial flagella and lipoteichoic acid and lipopolysaccharide (LPS) of gram-positive and gram-negative bacteria cell walls, respectively. Toll-like receptor 4 (TLR4) recognizes LPS and mediates signalings seen in overt gram-negative sepsis. LPS-TLR4 signaling leads to degradation of inhibitor of κB. This releases NF-κB, allowing its transport into the nucleus and up-regulating the transcription of a multitude of genes involved in innate and adaptive immunity, including cytokine production. TLR4 recognizes endogenous molecules including high-mobility group box 1 (HMGB1), a nonhistone nuclear protein that peaks in the blood within minutes of sterile injury. Elevated levels of HMGB1 have been associated clinically with weight loss, food aversion, and shock.

At the level of microvasculature, multiple changes occur. With hemorrhage and reperfusion, endothelial cells undergo uncoupling of the mitochondrial electron transport chain. Cytochrome c generates reactive oxygen species. In the setting of low flow and relative hypoxic conditions, xanthine oxidoreductase that normally reduces nicotinamide adenine dinucleotide to nicotinamide adenine dinucleotide phosphate is posttranslationally modified to become xanthine oxidase. With reperfusion, superoxide and hydrogen peroxide are generated. Endothelium also generates nitric oxide (NO) through the enothothelial NO synthase in response to a variety of stimuli including hypoxia, cellular injury, or endotoxin. NO causes vascular dilation and reduction in platelet adhesion and aggregation. Up-regulation of the inducible NO synthase isoform in multiple cell types may contribute to the excessive vasodilation seen in septic shock and also contribute to end organ injury in hemorrhagic shock.

At the site of injury, platelets are activated, releasing a variety of factors including serotonin, platelet activating factor, prostaglandin E_2, and thromboxane. Platelet activation leads to clot formation and chemoattraction of neutrophils and macrophages. Endothelium undergoes up-regulation of intercellular adhesion molecule-1 (ICAM-1) when exposed to the cytokines tumor necrosis factor-α (TNFα) or interleukin 1 (IL1). The presence of ICAM-1 on endothelium allows for binding by beta-integrin on leukocytes that can then migrate into the surrounding tissue to the site of injury.

As cytokine production increases at the site of injury, they begin to act systemically. TNFα rises early in inflammation and induces glucocorticoid release, cachexia, and muscle catabolism. IL1 also peaks early in inflammation. One of its clinically distinguishable effects is the production of prostaglandins in the anterior hypothalamus resulting in fever. IL6 has longer half-life in circulation than TNFα or IL1 and induces the production of acute phase proteins (e.g., C-reactive protein) by the liver as well further inducing neutrophil activation. Simultaneous to proinflammatory response, some cytokines function to dampen and control inflammation. IL10 is known to attenuate the inflammatory response to TNFα.

While cytokine levels or profiles currently are not part of clinical practice, studies have been performed in recent years to investigate their utility. One investigation in adult appendicitis (85 patients) found elevated WBC, CRP, IL6, and IL10 when comparing patients who had appendicitis with those who had negative surgical explorations. In pediatrics, one study involved 105 patients admitted with presumed appendicitis and observed for 6 hours before undergoing appendectomy. The highest specificity was in patients who had both leukocytosis and elevated IL6. Multiple studies in the ensuing years will need to be performed before cytokine levels become part of accepted clinical practice.

FUNDAMENTAL PRINCIPLES

■ **SHOCK STATES IN ACUTE CARE SURGERY**

JEREMY M. HSU AND RONALD V. MAIER

Shock is the clinical end result of inadequate tissue perfusion. The currently accepted concept was first described in 1918 by Walter B. Cannon.[1] There are multiple causes of shock; however, the common pathway is an imbalance in oxygen delivery and utilization, and ultimately cellular dysfunction. Cellular hypoxia induces the production of inflammatory mediators that may further compromise tissue perfusion through changes in the microvasculature. If this vicious cycle is not interrupted, multiorgan failure (MOF) and death result.[2] The clinical manifestations of shock are due to the autonomic neurohumoral responses to hypoperfusion and the resulting organ dysfunction.

This chapter describes the pathogenesis of shock and discusses the diagnostic and therapeutic options in current management.

PATHOGENESIS AND ORGAN RESPONSE TO SHOCK

At the cellular level, shock results in cellular hypoxia. Initially, the injury to cells is reversible; however, if it is not corrected, cell death ensues. The hallmarks of *reversible injury* are reduced oxidative phosphorylation with subsequent depletion of energy stores in the form of adenosine triphospate (ATP) and cellular swelling caused by failure of the sodium pump. In addition, massive influx of calcium occurs due to failure of the calcium pump, causing mitochondrial dysfunction. When injury becomes irreversible, the plasma membrane is disrupted; lysosomal enzymes enter the cytoplasm and digest the cell, resulting in *necrosis*.

Cellular hypoxia also predisposes to *reperfusion injury*, where new damaging processes are set in motion, causing the death of cells that might have recovered otherwise. Increased amounts of reactive oxygen and nitrogen species are generated from parenchymal and endothelial cells as well as infiltrating leucocytes.[3] These free radicals may be produced as a result of mitochondrial damage and incomplete reduction of oxygen. Endogenous cellular antioxidant mechanisms are compromised, favoring the accumulation of free radicals. Increased calcium may also enter the reperfused cells, damaging mitochondria and producing further free radicals. Hypoxic cells produce cytokines and increased expression of adhesion molecules, which recruit circulating neutrophils to reperfused tissue. The resulting inflammation generates additional tissue injury. Activation of the complement system also contributes to reperfusion injury. Select IgM antibodies are predisposed to deposit in hypoxic tissue, and when blood flow is resumed, complement proteins bind to the deposited antibodies, thus causing activation and subsequent inflammation and cell injury.

Cardiovascular Response

Decreased tissue perfusion results in the release of epinephrine and norepinephrine from the adrenal medulla due to decreased afferent impulses from the arterial baroreceptors. Systemic vascular resistance (SVR) rises to maintain adequate perfusion of the heart and brain, at the expense of perfusion to the skin, kidneys, and, primarily, the gastrointestinal tract via splanchnic vasoconstriction. This peripheral vasoconstriction occurs primarily in the arterioles, mediated by α1 receptors. However, vasoconstriction also occurs in the precapillary and postcapillary sphincters and the small veins and venules. This results in a reduced hydrostatic pressure distal to the precapillary sphincter that leads to reabsorption of interstitial fluid into the vascular space. This reabsorption functions to restore intravascular volume and is known as transcapillary refill.

Cardiac output (CO), the product of stroke volume and heart rate (HR), is a major determinant of tissue perfusion. Decreased intravascular volume leads to a reduction in ventricular preload, which in turn results in a diminished stroke volume. Compensation occurs to a degree with an increase in HR. However, shock also causes a reduction in myocardial compliance, resulting in a decreased ventricular end-diastolic volume and thus stroke volume at any given ventricular filling pressure.

Neurohumoral Response

Sustained compensatory mechanisms exist to restore intravascular volume, maintain central perfusion, and mobilize metabolic and osmotic substrates. Disinhibition of the vasomotor center results in increased adrenergic output and decreased vagal activity. Decreased renal blood flow leads to renin release. Renin induces the formation of angiotensin I, which is then converted to angiotensin II. This is a potent vasoconstrictor and stimulates aldosterone release by the adrenal cortex. Aldosterone contributes to restoration of the intravascular volume by enhancing sodium reabsorption in the cortical collecting duct, in exchange for potassium and hydrogen. Hypovolemia, as well as an increase in serum osmolarity, leads to the release of antidiuretic hormone. This has a direct vasoconstrictive effect on vascular smooth muscle and also increases reabsorption of water in the distal renal tubule. The peripheral vasoconstriction is countered by circulating vasodilators including prostacyclin and nitric oxide and, more importantly, the products of local metabolism such as adenosine. This balance between the various vasoconstrictor and vasodilator effects determines local perfusion in a deleterious, repeating hypoxia–reperfusion cycle. Additionally, shock causes release of stress hormones: ephinephrine, adrenocorticotrophic hormone (ACTH), cortisol, and glucagon. This results in glycogenolysis, lipolysis, gluconeogenesis, and insulin resistance causing a negative nitrogen balance and a high extracellular concentration of glucose. This increase in glucose acts as a major osmotic agent for intravascular restitution and anaerobic energy supply. Insulin-independent tissues such as the brain and heart have a substantial increase in glucose utilization.

Pulmonary Response

The pulmonary vascular bed responds to shock much in the same way as the systemic vascular bed. The relative increase in pulmonary vascular resistance (PVR), particularly in septic

shock, may exceed that of the SVR, potentially resulting in acute right heart failure. Shock results in tachypnea that reduces tidal volume and increases both dead space and minute ventilation, producing an early respiratory alkalosis. Hypoxia occurs due to diffuse alveolar damage, resulting in acute lung injury and subsequent acute respiratory distress syndrome (ARDS). These disorders are characterized by noncardiogenic pulmonary edema secondary to widespread pulmonary capillary and alveolar injury. Hypoxemia results from a significant ventilation–perfusion mismatch, and lung compliance is reduced due to loss of surfactant and lung volume, particularly functional residual capacity, in conjunction with an increase in intra-alveolar and interstitial edema.[4,5]

Renal Response

The kidneys respond to hypoperfusion by conserving sodium and water, with subsequent decreased urine output. Acutely, oliguria in the face of hypovolemia represents renal success, not renal failure. Early aggressive volume replacement has reduced the frequency of acute renal failure. Acute tubular necrosis is mostly due to the multifactorial interaction of shock, sepsis, nephrotoxic agents, and rhabdomyolysis. These toxic insults cause necrosis of tubular epithelium and tubular obstruction by cellular debris with back-leak of filtrate. Prolonged renal hypoperfusion results in a depletion of renal ATP stores with subsequent impairment of renal function and ultimate failure.

Inflammatory Response

The progression of shock is influenced by activation of the innate immunoinflammatory system. There is also a simultaneous anti-inflammatory response and suppression of the adaptive immune system in those surviving the initial insult. Excesses of both proinflammatory and anti-inflammatory responses are detrimental. An uncontrolled proinflammatory response results in a systemic inflammatory response syndrome, which may lead to continuing shock and MOF.[6,7] Excessive anti-inflammatory responses and adaptive immune suppression increase the susceptibility to secondary nosocomial infections.

The complement cascade is activated by hypoxia and tissue injury, resulting in the generation of anaphylatoxins C3a and C5a. Direct complement fixation in injured tissues can progress to the C5-C9 attack complex, resulting in further cell damage. In addition, concomitant coagulation cascade activation causes microvascular thrombosis, with subsequent fibrinolysis and repeated episodes of ischemic/reperfusion injury. Thrombin is a potent inflammatory mediator that increases activation of neutrophils, leading to further microvascular injury.

The membrane Toll-like receptors are a major source of monocyte/macrophage activation. These receptors recognize damage-associated molecular patterns and pathogen-associated molecular patterns, which are released following tissue injury and pathogenic microbial organisms. Monocytes and macrophages are major regulators of the inflammatory response. Macrophages release proinflammatory cytokines such as interleukin 1 and 6 and tumor necrosis factor α (TNF-α). These produce many of the shock features including hypotension, lactic acidosis, and respiratory failure. Interleukin 8 is a potent neutrophil chemoattractant and up-regulates neutrophil adhesion molecules to enhance aggregation, adherence, and damage to the vascular endothelium.

Eicosanoids, such as prostaglandins, leukotrienes, and thromboxane A2, are vasoactive and immunomodulatory products that affect vascular resistance as well as capillary permeability. LTB4 attracts neutrophils and stimulates the formation of reactive oxygen species.

CLASSIFICATION OF SHOCK STATES

Although the cellular effects of shock are the common pathway regardless of the primary cause, a classification scheme is useful to delineate the underlying process. It is important to note that a combination of two or more causes of shock frequently occurs. The primary importance of classifying the type of shock lies in the recognition of the precipitating event, and initiating appropriate therapy to correct this original cause, while simultaneously carrying out resuscitation. There are five broad categories of shock as outlined in Table 4.1.

GENERAL APPROACH TO SHOCK

The main priorities when dealing with shock include appropriate monitoring in an intensive care setting, prompt correction of tissue perfusion, and perhaps most importantly, correction or treatment of the precipitating cause. Careful and continuous assessment of physiological status and response to therapy is essential.

Physiologic Monitoring

Physiologic monitoring of the patient in shock commences with the "vital signs," and progresses as needed, using increasing technology and invasiveness.

Heart rate is commonly elevated in response to intravascular volume loss, to maintain adequate CO. This tachycardia becomes pathologic when HR exceeds 120-130 beats per minute. Above this rate, there is insufficient diastolic time to adequately fill the ventricles, resulting in decreased stroke volume. A rapid decrease in HR after a volume challenge can be a useful indicator of hypovolemia. In contrast, bradycardia is associated with severe physiologic derangement, usually hypoxia and impending cardiovascular collapse. It is also seen in conjunction with neurogenic shock, as a result of disruption to the cardiac sympathetic fibers. Frequent use of beta-blockers to treat baseline cardiac disease also produces inappropriate HR responses.

Blood pressure (BP) is a crude measure of tissue perfusion. Hypotension results in inadequate tissue perfusion;

TABLE 4.1

CLASSIFICATION OF SHOCK STATES

◾ CLASSIFICATION	◾ SPECIFIC CLINICAL CAUSES
Hypovolemic	Hemorrhage, trauma, third-space loss (burns, pancreatitis, bowel obstruction)
Obstructive	Pericardial tamponade, tension pneumothorax, pulmonary embolus
Cardiogenic	Myocardial infarct, cardiac failure, arrhythmias, blunt cardiac injury
Distributive	sepsis, neurogenic, anaphylaxis
Endocrine	Adrenal insufficiency

however, the exact definition of hypotension is variable, depending on the individual patient. Elderly patients, in particular, are frequently hypertensive at baseline and may not be perfusing tissues adequately at a "normal" BP. Chronic use of antihypertensives also makes reliance on BP as a measurement of shock inaccurate. BP may be measured noninvasively or invasively. Both methods are subject to dynamic response artifacts that may result in inaccurate measurements. Obese patients frequently have unreliable BP measurements due to positioning and poor cuff compression. Mean arterial pressure (MAP) is usually consistent, regardless of measurement method and artifact, and is thus preferred.

Urine output is often decreased in shock in an attempt to preserve and restore intravascular volume. Oliguria is one of the earliest signs of inadequate tissue perfusion. Improvement of urine output is a key monitor for shock resuscitation.

Temperature may help define etiology of shock and provide prognostic value. Hypothermia results as an imbalance between heat loss and the body's ability to generate and maintain metabolic energy. Clinically important hypothermia occurs when the core temperature is <35°C. Hypothermia is associated with an increase in sympathetic drive with resulting peripheral vasoconstriction, end-organ hypoperfusion, and metabolic acidosis from anaerobic respiration. In addition, hypothermia may exacerbate coagulopathy by causing dysfunction of the intrinsic and extrinsic coagulation pathways, as well as platelet activity. There is a markedly increased mortality in shocked patients with hypothermia.[8,9]

Pulse oximetry is a useful method of continuously monitoring arterial oxygen saturation. It utilizes the differential light absorption characteristics of oxyhemoglobin and deoxyhemoglobin to calculate the percentage saturation of oxygenated hemoglobin in blood. Pulse oximetry provides an indication of the degree of hypoxia as well as the assessment of oxygen transport balance.[10]

Biochemical markers are used to identify shock in early stages. The biochemical analysis of shock is based on the shift from aerobic to anaerobic metabolism with a resulting increase in lactate production and decreased clearance due to impaired hepatic function.[11] Shock is also associated with a base deficit on arterial blood gas analysis. The base deficit is defined as the amount of fixed base or acid that must be added to an aliquot of blood to restore the pH to 7.40. Any patient with a lactate of ≥4 mmol/L or a base deficit of ≥6 mEq/L should be considered to be in shock until proven otherwise.[12]

Invasive Hemodynamic Monitoring

Most patients in the intensive care unit (ICU) may be managed safely without the use of a pulmonary artery catheter (PAC or Swan-Ganz catheter).[13] However, in those patients with major ongoing blood loss, fluid shifts and/or underlying cardiac dysfunction, a PAC may be helpful. The current generation of PACs has been improved from the original catheter allowing measurement of pulmonary artery pressures, and continuous hemodynamic and oxygen transport assessment. The PAC is inserted percutaneously via the subclavian or internal jugular vein, to lie in the pulmonary artery.

The circulatory system consists of the systemic and pulmonary vasculature circuits connected in series. Two pressures are generated by each circuit: an outgoing pressure (MAP or mean pulmonary arterial pressure) and an incoming pressure or preload (pulmonary artery occlusion pressure [PAOP] or central venous pressure [CVP]), respectively. These pressures can be used to calculate the afterload of each circuit (SVR or PVR). Therefore, three variables are measured by the PAC: pressure, volume, and flow. From these measured variables, a number of calculated variables may be obtained, which can be useful in guiding resuscitative therapy. Table 4.2 outlines the hemodynamic variables obtained with a PAC.

TABLE 4.2

HEMODYNAMIC VARIABLES

VARIABLE	UNIT	NORMAL RANGE
MEASURED VARIABLES		
Systolic blood pressure (SBP)	mm Hg	90-140
Diastolic blood pressure (DBP)	mm Hg	60-90
Systolic pulmonary artery pressure (PASP)	mm Hg	15-30
Diastolic pulmonary artery pressure (PADP)	mm Hg	4-12
Pulmonary artery occlusion pressure (PAOP) or pulmonary capillary wedge pressure (PCWP)	mm Hg	2-12
Central venous pressure (CVP)	mm Hg	0-8
Heart rate	beats/min	Variable
Cardiac output	L/min	4-8
Right ventricular ejection fraction (RVEF)	Fraction	0.4-0.6
CALCULATED VARIABLES		
Mean arterial pressure (MAP) (SBP + 2 × DBP)/3	mm Hg	70-105
Mean pulmonary artery pressure (MPAP) (PAS + 2 × PAD)/3	mm Hg	9-16
Cardiac index (CI) CO/Body Surface Area (BSA)	L/min/m^2	2.8-4.2

TABLE 4.2

HEMODYNAMIC VARIABLES (*Continued*)

■ VARIABLE	■ UNIT	■ NORMAL RANGE
Stroke volume CO/HR	mL/beat	50-100
Systemic vascular resistance (SVR) [(MAP – CVP)/CO] × 80	dyn·s·cm^{-5}	700-1,600
Pulmonary vascular resistance (PVR) [(MPAP – PAOP)/CO] × 80	dyn·s·cm^{-5}	20-130
Left ventricular stroke work (LVSW) SV(MAP – PAOP) × 0.0136	g·m	60-80
Right ventricular stroke work (RVSW) SV(MPAP – CVP) × 0.0136	g·m	10-15
Right ventricular end-diastolic volume index (RVEDVI) SVI/RVEF	mL/m^2	60-100

Preload optimization is essential in the initial resuscitation of all forms of shock. CVP and PAOP are commonly used to estimate preload. The Frank-Starling law defines preload in terms of myocardial fibril length at end diastole. As this is not measureable, several assumptions are made to utilize PAOP to assess the preload of the left ventricle. First, left ventricular end-diastolic volume is assumed to be proportional to myofibril length. Second, assuming that ventricular compliance is constant, end-diastolic volume is equal to end-diastolic pressure. Third, assuming that mitral valve function is normal, left ventricular end-diastolic pressure is equal to mean left atrial pressure (LAP). Fourth, properly transduced PAOP is equal to LAP. Similar assumptions are applicable to the use of CVP in estimating preload status of the right ventricle. While indirectly a surrogate for intravascular volume, overall these pressures correlate poorly with volumes.[14] In addition, many of these assumptions are invalid in the critically ill patient due to changes in ventricular compliance, contractility, and intrathoracic pressures. Therefore, the trend (rather than absolute values of PAOP and CVP measurements) in response to therapeutic interventions is more useful and valid.

With the improvement in technology, current-generation PACs also allow a volumetric, as opposed to pressure-based, estimate of intravascular volume status. The right ventricular end-diastolic volume index (RVEDVI) is an accurate indicator of the effect of right ventricular preload on ventricular volume and thus output. Use of RVEDVI is significantly more accurate than PAOP or CVP in estimating cardiac preload and has been associated with a decrease in mortality and MOF when used in part as an end point of resuscitation.[15-17]

There is ongoing debate as to the utility and safety of PACs. A multicenter study in a mixed ICU population suggested that the use of a PAC was associated with an increased mortality.[18] Also, several studies have suggested that there is no advantage to using a PAC versus a CVP monitor in the treatment of a mixed population of patients with adult respiratory distress syndrome.[19] As a result, additional methods of volumetric preload assessment have been developed. Lithium dilution cardiac output (LiDCO) is a noninvasive method for measuring CO. It requires only an arterial pressure catheter and a central venous catheter. Lithium dilution is used to calibrate a pulse pressure algorithm, which allows continuous CO assessment.[20] Although comparable with PACs, the LiDCO method does not allow continuous assessment of oxygen transport.

The major problem is the loss of reliability in the acutely unstable patient.

In addition to measurements of CO, indicators of preload responsiveness including systolic and pulse pressure variation (SPV and PPV) can be obtained. These variations have been derived from observations in mechanically ventilated patients, where cyclical changes due to respiration are induced in the vena cava, pulmonary artery, and aortic blood flow. It is important to note that these arterial pressure variations are not an indicator of volume status, nor a direct marker of cardiac preload. Rather, SPV and PPV are indicators of the position on the Frank-Starling curve. Patients on the flat portion of the curve are insensitive to cyclical changes in preload induced by mechanical ventilation. Conversely, arterial pressure variations are increased in patients who are on the steep portion of the preload curve.[21-23] Thus, a PPV of >12% or SPV >5 mm Hg is indicative of preload responsiveness and need for increased intravascular volume.[20-23] The variables obtained by this method can be affected by aortic regurgitation, cardiac arrhythmia including tachycardia, irregular breathing, damped arterial line, or marked peripheral arterial vasoconstriction.

Esophageal Doppler ultrasound and transesophageal echocardiography have also been utilized in the hemodynamic assessment and monitoring of critically ill patients.[24] These modalities provide information about global and ventricular function of the heart. End-diastolic volume may be assessed and has been shown to be more accurate than PAOP in the estimate of optimal preload status. Again, while these methods are comparable to several measurements obtained with PAC use, they do not allow continuous assessment of cardiopulmonary function and provide only a "snapshot" view of a complex, potentially rapidly changing physiology. In addition, these methods suffer the common problem of noninvasive monitors in that the algorithms and validation studies have been performed in relatively healthy patients. Algorithms used to calculate CO and stroke volume may be flawed in critically ill patients with severe shock.

Invasive Oxygen Transport Monitoring

In addition to the hemodynamic variables obtained with the PAC, determination of oxygen content in arterial and

venous blood, together with CO and hemoglobin concentration, allows calculation of oxygen delivery, oxygen consumption, and oxygen-extraction ratio. The shock state induces an imbalance between oxygen demand and oxygen supply, resulting in anaerobic metabolism, lactic acidosis, and cell death. Table 4.3 outlines the oxygenation variables that may be obtained.

The assessment of oxygen transport begins with the calculation of oxygen content in blood. The majority of oxygen is bound to hemoglobin (>98%). Less than 2% is dissolved in plasma due to oxygen's low solubility coefficient. Delivery of oxygen to the tissues is highly dependent upon the hemoglobin concentration as well as the ability of red blood cells to unload oxygen, which is dependent on the 2,3-diphosphoglycerate (2,3 DPG) content and its loss during blood banking storage. Oxygen delivery (DO_2) and consumption (VO_2) may be calculated by utilizing cardiac index (CI), arterial oxygen content (CaO_2), and mixed venous oxygen content (CvO_2).

The oxygen content in the pulmonary end capillary is at its highest, as none of the oxygen has been consumed by the tissues or diluted by unsaturated blood. As the blood leaves the heart, the oxygen content is reduced due to introduction of unsaturated blood from three sources. The first is bronchial blood, which empties into the pulmonary veins. The second is intrapulmonary shunt, which may be significantly higher in those patients with pulmonary dysfunction or in shock. The third is venous blood from the thebesian veins, which drain directly into the left ventricle after supplying the myocardium. Therefore the arterial O_2 concentration can be calculated as the amount of oxygen bound to arterial hemoglobin + oxygen dissolved in arterial plasma.

After extraction of oxygen by the tissues, the blood is returned to the heart. The partial pressure of mixed venous oxygen tension (PvO_2) can be measured by a venous blood gas or via the intra-atrial port of the PAC. The venous oxygen content of blood as it returns to the heart is calculated as the amount of oxygen bound to venous hemoglobin + oxygen dissolved in venous plasma.

The difference between arterial and venous oxygen content ($CaO_2 - CvO_2$) represents the amount of oxygen extracted by the tissues. It is often elevated in shock due to increased oxygen demands and decreased oxygen delivery. A $CaO_2 - CvO_2$ of >5.5 mL O_2/dL or >35% suggests that CO is inadequate to optimally meet cellular oxygen demands.[25] Ideally, adequate resuscitation should generate a mixed oxygen saturation of >0.70.

As seen in the calculation for oxygen delivery, an important factor is hemoglobin concentration. Previously, it was thought that a hemoglobin concentration of 10-13 g/dL was optimal for oxygen delivery; however, recent studies have suggested that transfusion to this level provides no benefit in critically ill patients and is associated with a decrease in survival. A hemoglobin concentration of <7-8 g/dL is recommended as the level required to trigger a blood transfusion, in the absence of recent acute myocardial infarct, unstable angina, or ongoing blood loss.[26] Blood transfusion to maximize oxygen delivery must be balanced against the potentially harmful effects and increased risks of infection, immunosuppression, and organ failure associated with transfusion of banked blood.

TABLE 4.3

OXYGEN TRANSPORT VARIABLES

| VARIABLE	UNIT	NORMAL RANGE
MEASURED VARIABLES		
Arterial oxygen tension (PaO_2)	mm Hg	70-100
Arterial carbon dioxide tension ($PaCO_2$)	mm Hg	35-50
Arterial oxygen saturation (SaO_2)	fraction	0.93-0.98
Mixed venous oxygen saturation (SvO_2)	fraction	0.70-0.78
Mixed venous oxygen tension (PvO_2)	mm Hg	36-42
Hemoglobin (Hb)	g	13-17
CALCULATED VARIABLES		
Oxygen delivery (DO_2) $CaO_2 \times CO \times 10$	mL/min	800-1,600
Oxygen consumption (VO_2) $(CaO_2 - CvO_2) \times CO \times 10$	mL/min	150-400
Arterial oxygen content (CaO_2) $(1.34 \times Hb \times SaO_2) + (PaO_2 \times 0.0031)$	mLO_2/dL blood	16-22
Mixed venous oxygen content (CvO_2) $(1.34 \times Hb \times SvO_2) + (PvO_2 \times 0.0031)$	mLO_2/dL blood	12-17
Arteriovenous O_2 difference $CaO_2 - CvO_2$	mLO_2/dL blood	3.5-5.5
Oxygen extraction ratio (O_2ER) $[1 - (VO_2/DO_2)]$	Fraction	0.22-0.32

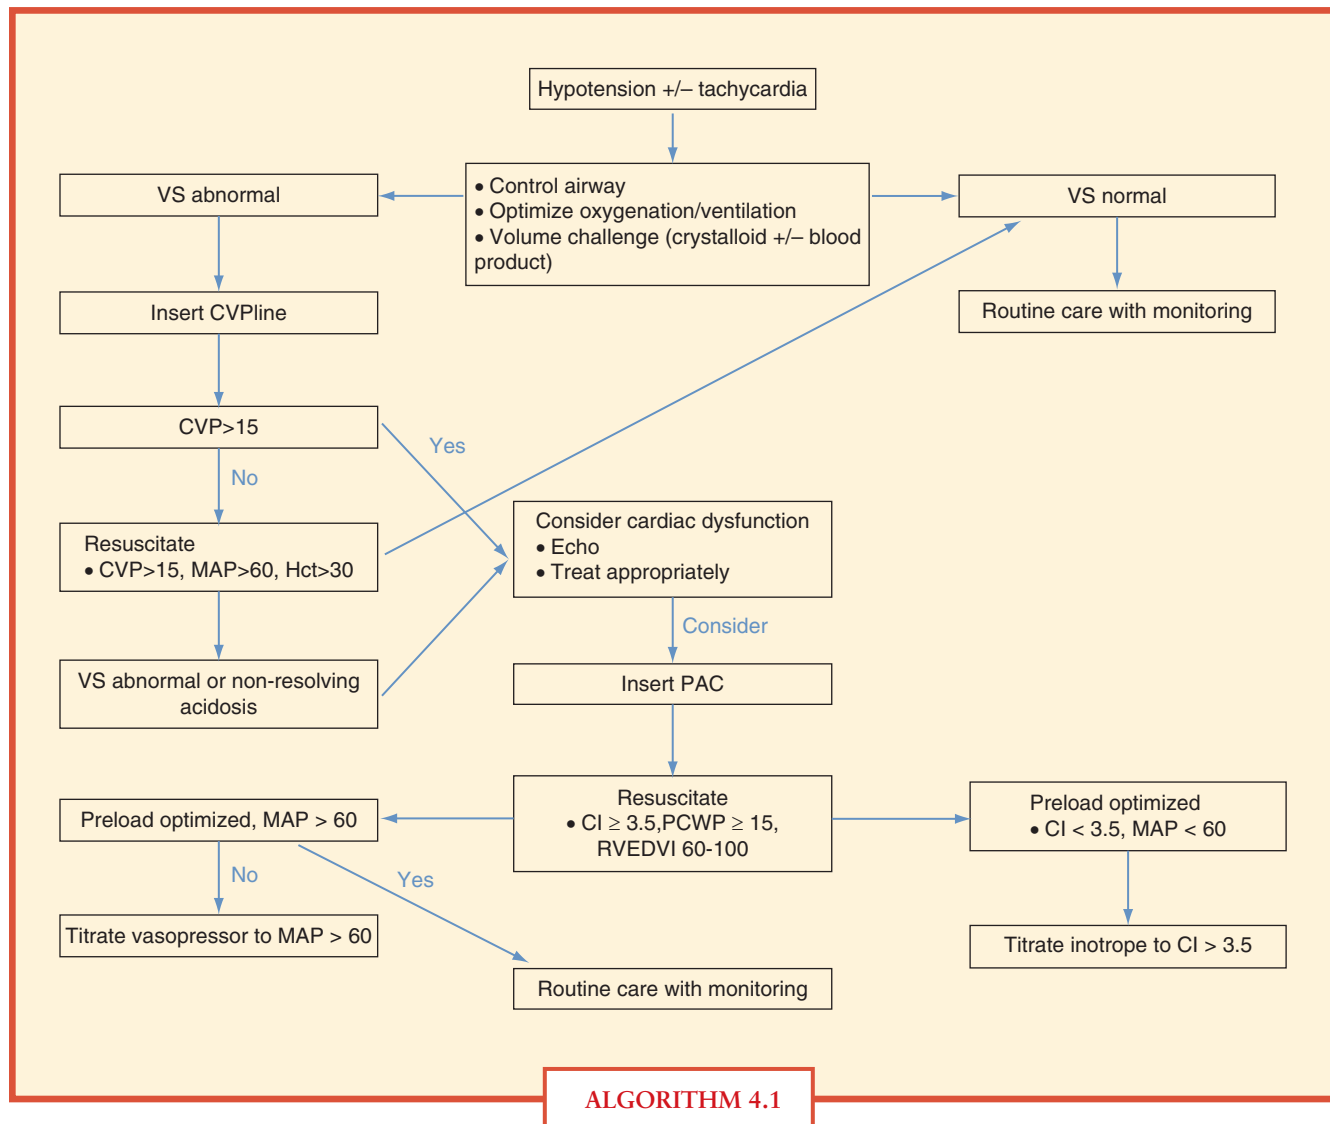
GENERAL SHOCK TREATMENT PRINCIPLES

There are three priorities in the treatment of shock. First, the diagnosis and underlying cause of shock must be diagnosed and corrected. Second, resuscitation for shock must rapidly restore tissue perfusion and optimize oxygen delivery, hemodynamics, and cardiac function. Third, end-organ failure must be prevented or function supported. Often, resuscitation will be initiated prior to or simultaneously with identifying the underlying etiology.

For resuscitation, a reasonable goal of therapy is to achieve normal mixed venous oxygen saturation and arteriovenous oxygen-extraction ratio, while simultaneously, the elevated SVR should return to normal. Oxygen delivery may be enhanced by improving hemoglobin concentration, arterial oxygen saturation and CO, individually or simultaneously.[27] An algorithm for the resuscitation of the shocked patient is shown in Algorithm 4.1.

Fluid Therapy for Shock

A decreased CVP and oxygen delivery were key features noted in the early investigations of hemorrhagic shock, and a prolonged decrease in oxygen delivery led to a reduction in oxygen consumption. After successful fluid resuscitation, oxygen delivery and consumption increased above baseline for several hours. Failure of the patient to achieve this adequate response to resuscitation was almost universally fatal. Thus, restoration of hemodynamics and oxygen transport with fluid and inotropes became the primary paradigm of shock treatment. However, it is important to note that excessive use of either modality has been shown to be detrimental to patient outcomes and survival.

It was noted by Shires et al. that additional fluid replacement beyond the actual amount of blood loss, due to ongoing interstitial "third spacing" loss, was required to improve outcomes in hemorrhagic shock.[28,29] These data led to the appropriate practice of aggressive, early fluid resuscitation. However, over time, complications from excessive fluid therapy began


ALGORITHM 4.1

ALGORITHM 4.1 An algorithm for shock resuscitation. (VS, vital signs; CVP, central venous pressure; HCt, hematocrit; ECHO, echocardiogram; PAC, pulmonary artery catheter; CI, cardiac index in (L per minute) per m²; PCWP, pulmonary capillary wedge pressure in mm Hg; RVEDVI, right ventricular end-diastolic volume index.)

to appear, such as ARDS, abdominal compartment syndrome, and detrimental elevations in intracranial pressures. Currently, resuscitation volumes have become more judicious, and earlier use of blood components is advocated.

Crystalloids are balanced salt solutions widely used as resuscitative fluids. They restore the extracellular volume, decreasing the transfusion requirement after hemorrhagic shock and restoring adequate volume in most cases. Crystalloids are inexpensive and readily available. Lactated Ringer's solution is isotonic and rapidly replaces the loss of interstitial fluid, without worsening any pre-existing electrolyte abnormality. However, recent investigations have identified the proinflammatory effects of lactated Ringer's solution containing the D(-) isomer of lactate found in some commercial forms of lactated Ringer's. D(-) lactate has been shown to increase neutrophil adhesion and increase production of reactive oxygen species.[30,31] These adverse effects of crystalloid resuscitation are not found with L(-) lactate isomer formulations. In addition, lactated Ringer's contains potassium and must be used cautiously if renal function is impaired or unknown.[32] Normal saline solution is also effective in the resuscitation of shocked patients. Large-volume administration of normal saline, though, is associated with a hypernatremic, hyperchloremic metabolic acidosis. This acidosis complicates the resuscitation of the critically ill patient.

Colloids theoretically remain in the intravascular space for a longer period compared with crystalloids, due to the increased molecular size. Commonly used colloids include albumin, modified fluid gelatin, dextran 70, dextran 40, and hydroxyethyl starch. Despite widespread use since the early 20th century, there has been no demonstrated benefit to colloid use.[33] In fact, colloid albumin infusion has been shown to increase mortality as well as prolong the resuscitation phase and delay postresuscitation diuresis. Albumin may also depress circulating immunoglobulin levels and reduce endogenous albumin synthesis. Given the lack of benefit and increased cost, colloids cannot be recommended in the current management of shock.[34]

Pharmacological Support

Pharmacological agents affecting preload, cardiac contractility, and afterload can be of major benefit in the treatment of shock. Importantly, optimal intravascular restoration must always precede cardiac augmentation. Inotropic support may be required when adequate preload fails to provide sufficient CO to meet tissue oxygen demands.[35] Pressor support may be required when the systemic vasculature is abnormally dilated with a resulting diminished SVR, as seen particularly with hyperdynamic septic shock. The effect of inotropes and pressors is dependent on the specific adrenergic receptor affinity (Table 4.4). In cases of primary cardiac dysfunction, vasodilators can reduce cardiac oxygen demand by reducing afterload and/or by dilating the venous system and reducing preload. Afterload reduction may preserve stroke volume in the failing myocardium, whereas preload reduction may relieve pressure-driven pulmonary edema.

Dopamine is a naturally occurring catecholamine that is a precursor of epinephrine. Its affinity for various adrenergic receptors is dose dependent. Low-dose dopamine was shown to augment renal blood flow and glomerular filtration rate in healthy subjects, but multiple studies have failed to demonstrate that low-dose dopamine prevents acute renal failure in critically ill patients.[36] At moderate doses, dopamine has mainly beta effects and primarily improves cardiac contractility, but at the expense of increased HR. Higher doses stimulate alpha receptors resulting in an increase in peripheral vascular resistance, BP, and oxygen consumption by the myocardium.

Dopamine must be carefully titrated in each patient due to the variable dose-dependent affinity for adrenergic receptors.

Dobutamine is a synthetic catecholamine that predominantly affects beta receptors. When its chronotropic effects are minimal, the inotropic effects of dobutamine have little effect on myocardial oxygen demand because it also induces peripheral vasodilatation. However, this decrease in SVR limits its utility in patients with risk of hypotension. Dobutamine is an excellent agent if cardiac augmentation is required to optimize oxygen delivery once intravascular volume has been function supported.

Epinephrine is released physiologically in response to stress. Beta effects predominate at pharmacological doses, resulting in increased stroke volume, cardiac contractility, and noteworthy tachycardia, with peripheral vasodilation. At higher doses, alpha-adrenergic receptors are stimulated with subsequent vasoconstriction and increased myocardial oxygen demand. In addition, cardiac arrhythmias and renal and splanchnic vasoconstriction all limit the prolonged use of high-dose epinephrine. It should be considered as a short-term agent in patients with refractory cardiac dysfunction not responsive to other agents.

Norepinephrine has both alpha and beta receptor effects; however, it is predominantly an alpha-adrenergic agonist. Combined alpha and beta stimulation typically results in an increase in afterload and glomerular perfusion pressure, with preservation of CO. It has been shown to be of most benefit in septic patients.[37] Adequate volume resuscitation must occur prior to use, due to the risk of tissue hypoperfusion from excessive vasoconstriction in the hypovolemic patient.

Isoproterenol is a synthetic catecholamine with major beta-adrenergic effects. Chronotropy may predominate over its inotropic effects. In conjunction with the peripheral vasodilatation, CO and pulse pressure increase. Myocardial oxygen demand is greatly increased, and the tachycardia limits coronary filling. As a result, isoproterenol should be considered only in those patients with hemodynamically important bradycardia, as a temporizing agent before electrical pacing.

Phenylephrine has pure alpha effects and thus increases peripheral vascular resistance. This increase in afterload increases cardiac workload and may cause a decrease in CO and stroke volume. It may be considered as a first-line agent for patients with neurogenic shock; however, its use is generally restricted to patients who require pressor support and cannot tolerate other agents such as dopamine and norepinephrine due to excessive tachycardia.

Vasopressin is released physiologically in shock. It acts on V1 receptors in vascular smooth muscle to cause vasoconstriction and increase receptivity to catecholamines. Endogenous vasopressin levels are decreased after prolonged hemorrhagic or septic shock. This relative deficiency may explain refractory hypotension in those shock states. In patients with septic shock, it is effective in increasing peripheral resistance and MAP. Vasopressin has no inotropic effects. It should be used at physiological doses to minimize associated pressor requirements.

Amrinone and milrinone are steroid-like phosphodiesterase antagonists, which increase smooth muscle cyclic adenosine monophosphate (cAMP) and alter calcium metabolism. Inotropic effects predominate with minimal positive chronotropy. The risk for vasodilatation and aggravation of hypotension is significant. The increase in CO with minimal demands on myocardial oxygen consumption offers some utility in the treatment of cardiogenic shock. Both agents have a long half-life of nearly 3 hours and thus should be used with caution in patients at risk of developing hypotension.

Nitroprusside is a potent arterial and venous smooth muscle vasodilator of very short duration. Afterload is reduced, leading to an increase in CO and stroke volume. Hypotension may limit its use, particularly in cases of inadequate preload. Nitroprusside use for more than 48 hours requires monitoring of serum thiocyanate levels and arterial pH to detect complications of cyanide toxicity.

TABLE 4.4

HEMODYNAMIC EFFECTS OF INOTROPES/PRESSORS

| DRUG | METABOLISM | SITE OF ACTION | | | | | | HEMODYNAMIC RESPONSE | | | | |

α1, vasoconstriction peripheral arterioles; β1, myocardial inotropy, chronotropy, enhanced AV conduction; β2, chronotropy, vasodilation mesenteric/skeletal bed, bronchodilation; V1 vasoconstriction peripheral arterioles, CO, cardiac output; SVR, systemic vascular resistance; BP, blood pressure; HR, heart rate.
[a]Milrinone: inhibits phosphodiesterase 3 resulting in increase in cAMP.
[b]Dopamine: dopamine receptor stimulation at low dose vasodilates mesenteric/coronary/renal beds.

Nitroglycerin predominantly affects the venous capacitance system. It is an effective treatment for acute myocardial ischemia, as it reduces excessive preload and ventricular end-diastolic pressure, thereby reducing myocardial oxygen demand.

END POINTS OF SHOCK RESUSCITATION

Resuscitation is an ongoing process, which requires constant assessment and modification dependent on the patient's response to therapy. End points can be categorized as either global or regional indicators of perfusion.[38] While BP and HR are commonly used global measures, they are relatively poor determinants of tissue oxygenation. Patient age and pre-existing medical conditions are frequent confounding influences.

Mixed venous oxygen saturation (SvO_2) can be measured continuously with a PAC. The continuously measured SvO_2 correlates well with oxygen extraction ratios calculated by laboratory measurements of arterial and mixed venous oxygen saturation, hemoglobin concentration, and CO.[39] SvO_2 is a global indicator of oxygen supply–demand balance but does not indicate the adequacy of perfusion of any individual vascular bed. A low SvO_2 (<0.65) always indicates an unfavorable imbalance in the delivery and consumption of oxygen. A high SvO_2 (>0.78) may exist in conditions of inadequate utilization such as sepsis, pregnancy, cirrhosis, and inflammation and is difficult to interpret. It implies a maldistribution of peripheral blood flow. There may be vascular areas of oxygen delivery in excess of consumption, but may be in conjunction with other areas of inadequate oxygen delivery. Therapeutic interventions should be aimed toward achieving an SvO_2 of approximately 0.7.[40]

Arterial lactate concentrations increase in conditions of shock, but can be misleading. The shift from aerobic to anaerobic metabolism causes accumulation of hydrogen ions and lactate, resulting in acidosis and cellular death. However, an elevation in lactate may be due to several mechanisms. Ongoing anaerobic metabolism and decreased lactate metabolism due to hepatic and/or renal hypoperfusion increases lactate levels. Lactate may accumulate in tissues during periods of hypoperfusion and wash out into the central circulation when perfusion to these relatively hypoxic tissues is restored. Excessive lactate production may occur in tissues that depend on glycolysis for energy production despite adequate oxygen delivery. Elevated serum lactate levels are not specific in detecting abnormal regional perfusion, and may also reflect "washout" from anaerobic tissues caused by a period of hypoperfusion that has already resolved. Importantly, a positive response toward correction during resuscitation is associated with a better prognosis.[41,42] However, "normal clearance" of lactate is controversial. The half-life of lactate in patients with normal renal and hepatic function is estimated between 2 and 4 hours. In the presence of shock, the half-life may be significantly longer. Aggressive resuscitation may result in a slight increase in lactate due to peripheral washout. This should generally correct early, and the trend should be a steady decrease.[43]

Base deficit predicts fluid resuscitation requirements, similar to lactate, but normalizes rapidly with restoration of aerobic metabolism, making it a useful end point for guiding resuscitation.[44] The magnitude of base deficit is a predictor of mortality in trauma patients.[43] As with lactate, the base deficit trend toward normal should be the intended goal of resuscitation.

The splanchnic circulation is affected early and most importantly in shock. *Gastric tonometry* has been used to measure intramucosal pH, because of loss of buffering capacity provided by the extensive submucosal blood flow, and thus provides information about a single vascular bed.[45] Increasing intramucosal acidosis indicates inadequate oxygen delivery to the intestinal mucosa and thus may be used to guide resuscitation.[46] However, the logistic difficulty of the technology and interpretation of the data has restricted the widespread use of this method.[47]

FEATURES AND MANAGEMENT OF SPECIFIC FORMS OF SHOCK

Although, the end result of impaired tissue perfusion is common to all forms of shock, specific treatment options exist for specific shock states. The hemodynamic patterns seen with specific forms of shock are shown in Table 4.5. Early recognition of these patterns helps identify the underlying etiology.

TABLE 4.5

HEMODYNAMIC PATTERNS FOR SHOCK TYPES

■ TYPE	■ CO	■ SVR	■ PAOP	■ CVP	■ SVO$_2$
Hypovolemic	↓	↑	↓	↓	↓
Cardiogenic					
Left ventricular MI	↓	↑	↑	N, ↑	↓
Right ventricular MI	↓	↑	N, ↓	↑	↓
Obstructive					
Pericardial tamponade	↓	↑	↑	↑	↓
Pulmonary embolism	↓	↑	↑	↑	↓
Distributive					
Early	↑, N, ↓	↑, N, ↓	N	N, ↑	N, ↑
Early after fluid administration	↑	↓	N, ↑	N, ↑	↑, N, ↓
Late	↓	↑	N	N	↓
Hypoadrenal	↓	N, ↓	↑, ↓	↑, ↓	↓

CO, cardiac output; SVR, systemic vascular resistance; PAOP, pulmonary artery occlusion pressure; CVP, central venous pressure; SvO_2, mixed venous oxygen saturation; MI, myocardial infarction; N, normal.

Hypovolemic Shock

The most common form of shock results from loss of red cell mass and plasma, or the loss of plasma volume alone. Physical findings stem from the cardiovascular and neurohumoral responses to shock. The signs include cold, clammy skin, tachycardia, hypotension, oliguria, and impaired mentation. Hypovolemic shock can be stratified into four classes depending on the degree of volume loss (Table 4.6).

The condition is readily diagnosed when there is hemodynamic instability and the source of volume loss is obvious. Remember, after acute hemorrhage, hemoglobin and hematocrit values do not change until compensatory fluid shifts occur or exogenous fluid is administered. Plasma loss alone results in hemoconcentration, and free water loss leads to hypernatremia. With more subtle or chronic volume losses, the etiology may be much more difficult to ascertain. A high degree of suspicion for hypovolemia should exist following all injuries or major gastrointestinal fluid losses.

In cases of hemorrhage, the focus must be on definitive hemorrhage control rather than merely aggressive replacement. Simultaneous judicious resuscitation should also occur; however, volume cannot be given rapidly enough to match massive hemorrhage.[48] In accordance with Starling's law, stroke volume and CO increase with an increase in preload. Therefore, resuscitation is initiated with a rapid infusion of isotonic saline or a balanced salt solution such as Ringer's lactate. There is no additional benefit to the initial use of colloid solutions, and in trauma patients, colloids are associated with an increased mortality.[34] Evidence of continuing or severe blood loss requires simultaneous replacement with cross-matched packed red blood cells, as well as other coagulation components including fresh frozen plasma, cryoprecipitate, and platelets. In the presence of severe or prolonged hypovolemia, inotropic support may be required to maintain adequate ventricular function, but only after blood volume has been restored.

Current concepts in the resuscitation of hemorrhagic shock include limited volume administration to restore or maintain low to normal BP and "damage control" or hemostatic resuscitation. In 1994, Bickell et al.[49] produced the landmark paper demonstrating improved mortality in those patients with penetrating torso trauma, who had a restrictive crystalloid resuscitation prior to surgical control of bleeding. The underlying premise is sound, in that aggressive restoration prior to definitive hemorrhage control may actually worsen bleeding. Interestingly, this is not a new concept. In 1918, Cannon wrote, "Injection of a fluid that will increase BP carries danger in itself. Hemorrhage in the case of shock may not have occurred to a large degree because the BP is too low, and the flow too scant to overcome the obstacle offered by a clot. If the pressure is raised before the surgeon is ready to check any bleeding that may take place, blood that is sorely needed may be lost." In addition, recent military conflicts in Iraq and Afghanistan have demonstrated benefit with a resuscitative strategy based on earlier replacement of blood and coagulation products in severely injured patients. There are military and emerging civilian data to suggest that early implementation in massive transfusion of a 1:1:1 ratio of packed red cells:fresh frozen plasma:platelets transfusion strategy results in improved mortality, ventilator-free days, and ICU length of stay.[50-54]

Hypovolemic shock may still exist despite normal or increased total body fluid volume, when such volume is not intravascular. An increase in interstitial fluid occurs in severe trauma, pancreatitis, intestinal obstruction, and burns. This is a result of both microcirculatory failure and the systemic inflammatory effect and resulting massive capillary leak. Thus, patients will require resuscitation in excess of their apparent intravascular loss. If this inadequate intravascular volume is not recognized, underresuscitation and continued tissue hypoperfusion will continue. Thus, multiple parameters should be followed to ensure adequate resuscitation and restoration of perfusion.

Obstructive Shock

Obstructive shock results from a mechanical barrier to normal CO. Reduced cardiac compliance leads to inadequate diastolic filling. Pericardial tamponade occurs due to acute or chronic collections of fluid in the pericardial space. This may be a result of trauma, myocardial rupture, and aortic dissection. Tension pneumothorax causes mediastinal shift with subsequent compression of the great venous structures, again impairing preload. Pulmonary embolus may occasionally cause profound circulatory collapse. Mechanical obstruction occurs as a result of massive clot (saddle embolus) or by pulmonary hypertension due to the release of proinflammatory mediators in response to the acute embolus.

TABLE 4.6

CLASSIFICATION OF HYPOVOLEMIC SHOCK

	■ CLASS I	■ CLASS II	■ CLASS III	■ CLASS IV
Blood loss (mL)	Up to 750	750-1,500	1,500-2,000	≥2,000
Blood loss (%)	Up to 15	15-30	30-40	≥40
Pulse rate	<100	>100	>120	≥140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal/Increased	Decreased	Decreased	Decreased
Capillary refill	Normal	Decreased	Decreased	Decreased
Respiratory rate	14-20	20-30	30-40	>35
Urine output (mL/h)	>30	20-30	5-15	Negligible
Mental status	Slightly anxious	Anxious	Confused	Lethargic
Fluid replacement	Crystalloid	Crystalloid	Crystalloid + blood	Crystalloid + blood

Adapted from American College of Surgeons Committee on Trauma. Advanced Trauma Life Support for Doctors, 8th edition.

The diagnosis of obstructive shock is often based on a combination of clinical findings, chest radiograph, and echocardiography. Pulmonary embolus is most commonly diagnosed with CT–angiography. The classic clinical findings of pericardial tamponade include hypotension, jugular venous distension, and muffled heart sounds (Beck's triad). An echocardiogram will demonstrate the fluid in the pericardial sac. Immediate pericardiocentesis or surgical decompression is indicated. Tension pneumothorax is suspected clinically when hypotension, decreased ipsilateral breath sounds, ipsilateral hyperresonance, tracheal deviation away from the affected side, and jugular venous distension are present. Treatment consists of immediate needle or tube thoracostomy. Pulmonary embolus is treated with therapeutic heparinization, while associated hemodynamic collapse may require surgical or endovascular embolectomy and/or angiographic thrombolysis.

Cardiogenic Shock

Cardiogenic shock is a result of pump failure. This may be due to myocardial infarction (MI), cardiomyopathy, ventricular outflow obstruction, acute valvular failure, ventricular filling defects, or cardiac arrhythmias.[55] Most commonly, shock is a consequence of acute MI.[56] Clinical findings include peripheral vasoconstriction, oliguria, and pulmonary and peripheral edema. A pre-existing cardiac history and other physical findings including pulmonary crepitations, cardiac murmurs, an S3 gallop, and jugular venous distension are also suggestive of cardiogenic shock. Decreased CO, with an elevated PAOP, is diagnostic. Differentiation between right- and left-sided heart failure is essential, as the management is significantly different.[57] Shock from right-sided failure is treated with ongoing volume resuscitation to improve ventricular preload. Left-sided failure often requires inotropic support and limited resuscitation. Shock due to cardiac arrhythmias often requires chemical or electrical cardioversion.

Cardiogenic shock tends to be self-perpetuating. Myocardial perfusion is dependent on the duration of diastole and the pressure gradient between the coronary artery and the left ventricle. Overly aggressive fluid resuscitation is not well tolerated and is likely to be harmful to a patient with the compromised myocardial function resulting from cardiogenic shock.

Distributive Shock

Distributive shock is a result of widespread vasodilatation and pooling of blood in the periphery. There is often a preservation or increase in CO early in the course. Septic shock is the classic example of hyperdynamic shock; however, other conditions such as anaphylaxis and severe liver dysfunction also result in a similar presentation.

Septic shock is manifested early by a decrease in SVR, normal to low PAOP, and increased CO. Despite elevated CO, oxygen extraction is impaired, in part due to mitochondrial dysfunction. This is also due to excessive blood flow to areas of normal metabolic demand and hypoperfusion of areas with increased demand. In later stages of septic shock, myocardial depression occurs, and the hemodynamics mimic that of cardiogenic shock. Septic shock is a result of complex interplay between microbial constituents and the immunologic response. Bacterial endotoxin is a lipopolysaccharide cell wall constituent of gram-negative bacteria, which induces release of proinflammatory cytokines.[58] In addition, gram-positive organisms may secrete superantigens, which are polyclonal T-lymphocyte activators that induce release of high levels of proinflammatory cytokines with resulting severe systemic inflammatory response as seen with Group A streptococcal infections.

This massive release of cytokines results in three major sequelae: thrombosis, increased vascular permeability, and vasodilatation. Proinflammatory cytokines result in increased tissue factor production, while reducing fibrinolysis by increasing PAI-1 expression. Activated thrombin is itself a major activator of proinflammatory cytokines. Other anticoagulant factors such as thrombomodulin and protein C are also decreased. The procoagulant tendency is further exacerbated by decreased blood flow at the level of small vessels. Together, these effects promote the deposition of fibrin-rich thrombi in small vessels, often throughout the body, thus contributing to tissue hypoperfusion and consumptive depletion of coagulation factors. The increase in vascular permeability causes leakage of fluid into the interstitium, resulting in tissue edema that may impede blood flow and diffusion of oxygen into tissues. Systemic vasodilatation and resulting hypotension are aggravated by the production of NO and the increases in vasoactive inflammatory mediators.[59]

Sepsis causes insulin resistance and hyperglycemia. The release of stress hormones and catecholamines along with proinflammatory cytokines such as TNF-α and IL-1 all drive gluconeogenesis. Insulin resistance occurs due to the cytokine and glucagon impairment of GLUT-4 surface expression, a glucose transporter.

The goals of septic shock treatment are to maintain tissue perfusion and institute appropriate empiric antibiotic treatment prior to culture results, insulin therapy for hyperglycemia, and, if applicable, infection source control. Intravenous fluid requirements may be high, and often a pressor agent such as norepinephrine and/or vasopressin is required to counter the systemic vasodilatation. Early implementation of goal-directed therapy has been demonstrated to improve outcomes in septic shock.[60,61] Steroids have not been shown to be effective; however, activated protein C has been shown to improve mortality in selected cases of severe septic shock with more than one organ failure.[62,63]

Neurogenic shock is another form of distributive shock, which occurs as a result of a spinal cord injury above the upper thoracic level. Disruption of the sympathetic outflow leads to peripheral vasodilatation, bradycardia, and hypotension. There is a relative expansion of the intravascular space through vasodilatation, particularly of venous capacitance vessels, and this is initially treated with judicious fluid administration. Often a pressor agent is required, and the bradycardia may require atropine to counter the unopposed parasympathetic influence, or an inotrope/pressor such as dopamine or norepinephrine. In most cases, hypotension resolves within 24-48 hours. Overresuscitation with fluid must be avoided. The diagnosis of neurogenic shock must be a process of exclusion, as it is often associated with other traumatic injuries involving concomitant blood loss.

Neurogenic shock should not be confused with spinal shock, which is defined as a loss of sensation and motor paralysis with initial loss of reflexes that gradually return. No circulatory compromise is associated with this condition and thus should not be considered a shock state.

Anaphylaxis is a severe form of Type I hypersensitivity. Exposure to the offending agent results in massive histamine release, with subsequent dermatologic reaction, respiratory obstruction, and hypotension. Occasionally, the reaction is severe enough to produce shock through myocardial depression along with massive capillary leak and edema formation. Treatment consists of volume replacement, epinephrine, steroids, and histamine receptor antagonists.

Endocrine Shock

The normal host response to critical illness is an increase in cortisol secretion to maintain homeostasis. Hypoadrenal shock occurs when unrecognized adrenal insufficiency complicates the host response to the stress induced by critical illness or major surgery.[64] Adrenocortical insufficiency may occur as a result of chronic exogenous corticosteroid use. In addition, trauma and sepsis may also induce a relative hypoadrenal state. Hypovolemia with a decrease in SVR and CO occur in hypoadrenal shock. Administration of physiologic doses of steroids to correct the relative hypoadrenal state results in stabilization of hemodynamics and possible survival benefits.[65,66] The diagnosis is established by using an ACTH stimulation test. Empiric treatment is with dexamethasone, as this does not interfere with ACTH stimulation test. If the diagnosis is confirmed by low or no response to ACTH, treatment should consist of hydrocortisone, with tapering as the patient achieves hemodynamic stability.[67] Adjunctive volume resuscitation and pressor support should also continue.

SUMMARY

Shock is a common condition that is associated with a high mortality. Although the cellular pathways are largely similar, the etiology is varied and complex. Early recognition of inadequate tissue perfusion should trigger aggressive goal-directed therapy. Key data regarding hemodynamic and oxygenation transport variables should be obtained promptly. Correction of the underlying cause in conjunction with early resuscitation reduces the potentially fatal complication of end-organ dysfunction and failure.

CHAPTER 5 ■ BASIC OPERATIVE TECHNIQUES IN TRAUMA AND ACUTE CARE SURGERY

RAO R. IVATURY

Trauma and acute care surgery is an exciting field that offers a wide spectrum of operative experience, which ranges from elective to semielective to truly emergent, in body sites and cavities from head to toe and also from minimally invasive techniques to the "maximally" invasive procedures (e.g., "trap-door" approach to the left subclavian vessels). The basic principles of these divergent procedures are essentially the same: adequate exposure, control of bleeding and contamination, attention to patient physiology, and most importantly "do no harm." The scope of acute care surgery practice is so vast that a discussion of it can only be a sketch. This chapter, therefore, outlines the accepted techniques of exposure and treatment of various injuries and diseases in different anatomic sites. A brief introduction into minimally invasive approach follows, since that will surely be the state-of-the-art in the next decade. The reader is encouraged to supplement this chapter with atlas of operative and anatomic details.

OPERATIVE APPROACH TO NECK TRAUMA

In a landmark 1969 article, Monson et al. arbitrarily divided the neck into three clinical zones.[1] Zone I is defined as the area between the suprasternal notch and the cricoid cartilage, Zone II is the region between the cricoid and the angle of the mandible, and Zone III lies above the angle of the mandible. Zone II injuries are accessible via standard cervical approaches and do not present operative difficulty. Zone I injuries by definition involve the thoracic inlet with potential injuries to major vessels, and Zone III injuries are problematic because of the difficulty in obtaining distal control. Direct operative approach is therefore preferred for Zone II, while angiography may be helpful in the other zones.[2,3]

The patient should be placed in a prone position with both arms tucked, if possible. As long as there is no concurrent spine injury, a shoulder roll should be placed to extend the neck and the table placed in a semi-Fowler's position to aid in the operative exposure. The entire thorax and abdomen should be prepped in case of Zone I injury for accessing the chest and abdomen for potential multicavitary injuries. The groin and both thighs are prepped and draped for possible saphenous vein harvest.

Innominate and Subclavian Vessel Injury

Operative exposure of Zone I vascular injuries varies with the stability of the patient. If the patient is hemodynamically unstable with a large hemothorax or excessive bleeding from the chest tube, an anterolateral thoracotomy (high in the 3rd or 4th intercostal space) will allow apical packing to tamponade the bleeding from innominate or proximal subclavian vessels. This can be done in the trauma bay of the emergency department for the patient in extremis. In the stable patient, a median sternotomy in the O.R. is a good approach for the innominate and the right subclavian vessels.

For the left subclavian artery, the incision may be extended along the sternocleidomastoid or the clavicle. This approach is superior to the morbid "trap-door" incision. The second and third portions of the subclavian are best approached by an incision along the clavicle with extension along the sternocleidomastoid, if necessary (Fig. 5.1). Subperiosteal resection of the mid or medial one-third of the clavicle will allow excellent exposure. The majority of these vascular injuries may be managed by simple lateral repair or end-to-end anastomosis. Occasionally, a saphenous vein graft may be necessary. In stable patients with a subclavian pseudoaneurysm or intimal injuries, endovascular stent grafts are an increasingly attractive option.

Carotid Artery Injury

Carotid exposure is obtained via a skin incision made along the anterior border of the sternocleidomastoid muscle (Figs. 5.1-5.3). The carotid sheath and its contents are readily identifiable. The venous and lymphatic structures are retracted in a lateral direction. Proximal and distal exposure of the carotid arteries is obtained after identifying the ansa cervicalis and 12th cranial nerve (Fig. 5.2). Digital pressure or a side-biting vascular clamp can be used to control hemorrhage while obtaining control. Proximal injury to the carotid at its aortic or subclavian origin requires more extensive exposure than the simple neck incision. Median sternotomy is the most commonly employed approach. A supraclavicular incision is useful for exposure in some cases, and dislocation or resection of the clavicle may improve the exposure (Fig. 5.1).

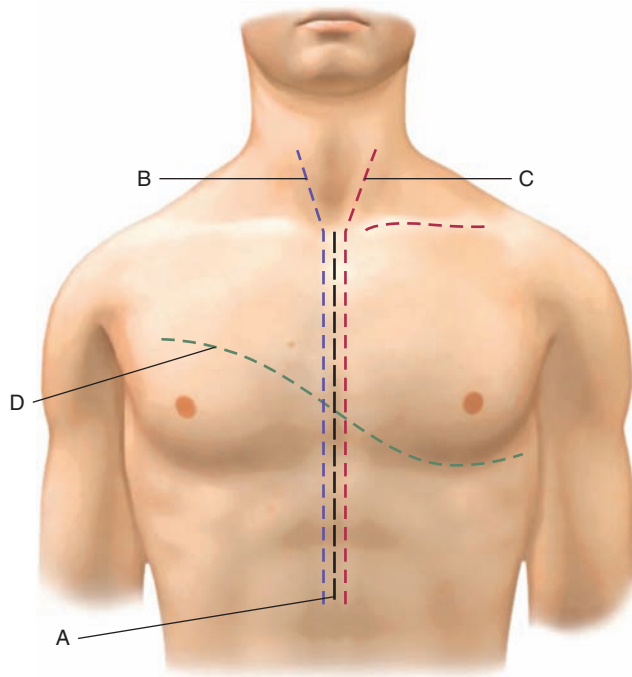
High Zone III injuries resulting in distal internal carotid laceration or disruption can be problematic in exposure and control. Anterior subluxation of the mandible can improve exposure, but only by about 2 cm. Osteotomy of the mandibular ramus may provide better exposure and mobility. Placement of a Fogarty balloon catheter to provide distal vascular control can be lifesaving during these maneuvers. Depending on the surgeon's experience in operating around the base of the skull, intraoperative assistance from either a maxillofacial surgeon or a neurosurgeon is advisable in difficult cases. Once proximal and distal control are secured, a Fogarty balloon catheter is carefully passed to remove any thrombus, and both proximal and distal ends are flushed with heparinized saline. A 5-O or 6-O monofilament polypropylene suture is used for the repair and handled with appropriate vascular technique. Except for tangential lacerations where primary repair is possible by lateral arteriorrhaphy, end-to-end anastomosis is often difficult, because the transected ends of the artery retract. Care must be taken to inspect for and repair any intimal flap at this time. This can often be done by incorporating the intimal defect into the laceration repair by utilizing a series of interrupted sutures. Also, the lumen of the artery must not be narrowed by this primary repair; if so, vein patch or interposition graft will be required. If there is a considerable destruction of the carotid artery, interposition grafting is warranted, preferably utilizing autologous tissue. Saphenous vein is generally the ideal conduit.


FIGURE 5.1. Operative approaches to neck and chest: **A:** standard median sternotomy for ascending aorta, innominate, cardiac injuries. **B:** Median sternotomy with extension to right neck for innominate, right subclavian, and common carotid artery injuries. Extension along the right clavicle will provide access to distal right subclavian vessels. **C:** Median sternotomy with left neck extension for left common carotid, aortic arch, and left subclavian vessel injuries. Extension along the left clavicle will provide access to distal left subclavian vessel injuries. **D:** Left anterolateral thoracotomy with extension to right chest as a clamshell incision providing access to all chest structures.

If adequate autologous conduit is not available, synthetic material may be used. The choice between woven Dacron and ePTFE is based on a surgeon's preference, as neither represents an ideal substitute for a vein graft.[3] If anatomy permits, the external carotid artery can be divided at a distal location, and transposed to the internal carotid artery. The use of a temporary shunt is not mandated by the available data. Increasingly, percutaneous transluminal placement of endovascular devices has become an alternative option to surgical repair.

Vertebral Artery Injury[4]

Vertebral artery injury,[4] fortunately, is not common. As warned by Matas "A glance at the surgical anatomy of this vessel as it lies deeply hidden in the skeleton of the neck, only escaping at short intervals from its osseous canal, to become immediately invested by the very important and vital cervical nerves as they issue from the spinal foramina, will at once remind us of the magnitude of the purely technical difficulties in the way of its atypical ligation, and of the errors of diagnosis that must be incurred."

   If the identification and exposure of the vertebral artery injury is uncomplicated during neck exploration, proximal and distal surgical ligation of the injured vessel is performed. If encountered at neck exploration, the following steps are indicated: (1) Gauze packing at the site of bleeding and (2)

exposure of the subclavian artery by dividing the origin of sternomastoid from the clavicle and proximal control of the origin of the subclavian artery. The neck incision is carried posterior to the ear with division of the attachment of sternomastoid and splenius capitis muscle. Distal ligation may be performed by dividing the splenius capitis and sternomastoid attachments to the mastoid, palpation of the transverse process of the atlas, and exposing the vertebral artery between the axis and atlas. Bone wax or other hemostatic agents can be used to pack and compress this area, or "blind" application of surgical clips deep into the wound may staunch the bleeding (Fig. 5.3A-C). The difficult dissection of the vertebral artery makes angiographic embolization an attractive option. Current data support the conclusion that most vertebral artery injuries can safely be managed without an operation or by angiographic embolization. Surgical intervention should be reserved for patients with severe bleeding or where embolization has failed.

Venous Injury

Injury to the innominate, subclavian, axillary, or internal jugular veins may be the source of severe hemorrhage. These veins can be ligated if the destruction is severe. In the case of severe bilateral jugular venous injury, ligation will carry significant clinical consequences. In this setting, reconstruction with an autologous conduit is advisable.[3]

Cervical Esophagus

Exposure is obtained by a left neck incision along the anterior border of the sternocleidomastoid muscle with medial retraction of the carotid vessels. Adequate mobilization behind the trachea and palpation of the nasogastric tube facilitate identification of the esophagus. The recurrent laryngeal nerve needs to be protected in the dissection and frequently may be palpated or visualized (Fig. 5.2). The esophageal perforation is identified either by direct visualization or with the help of intraluminal saline or dye. The perforation is repaired in either one or two layers. Neither the number of suture layers nor the type of suture material (absorbable or nonabsorbable) seem to influence the incidence of fistulization after the repair. If the operative exploration is delayed, repair may be difficult because of extensive inflammation in the area. In either instance (early or delayed operation), wide drainage is the key to success. Closed suction drains (Jackson- Pratt) usually are preferred.[5]
Laryngotracheal injury in the neck is uncommon but can be produced by blunt trauma, seat belt injury, or penetrating injuries. These injuries should be suspected with subcutaneous emphysema, soft tissue air in x-rays, or changes in phonation and blood in the aerodigestive tract. Primary repair with absorbable sutures without tracheostomy is the ideal approach. Tracheostomy through the injury, as once recommended, is not the preferred option. More complex injuries to the larynx are best handled with the help of ENT surgeons because of long-term complications and the need for corrective procedures.[6]

OPERATIVE APPROACHES TO CHEST TRAUMA

Emergency Department Thoracotomy

The usual incison is a left anterolateral thoracotomy (Fig. 5.1). For right-sided penetrating wounds and suspected injuries in the right chest, thoracotomy may be commenced as a right
FIGURE 5.2. A,B: Anatomy of neck demonstrating the important structures in neck exploration. The cross section shows the carotid sheath and its contents and the anatomy of trachea and esophagus.

anterolateral thoracotomy and, if cardiac arrest has occurred and open cardiac massage is needed, a separate left anterolateral thoracotomy may be added. The usual incision is in the 4th or 5th intercostal space, extending as a sweeping curve into the axilla. If exposure is inadequate or for bilateral thoracic injuries, the incision may be extended across the sternum into the right chest as a "clam shell" thoracotomy. This provides outstanding exposure but one has to look for the transected internal mammary arteries and ligate them. When a patient is in extremis from a penetrating injury at the thoracic inlet and a massive hemothorax, a higher (3rd intercostal space)

incision provides access to the thoracic vessels at the inlet that can be compressed manually while the patient is transported to the Operating Room.

Once inside the chest, a rapid assessment of the pericardium is made.[7] Tense, bluish pericardium suggests tamponade and is relieved by a knife anterior to the phrenic nerve. The pericardiotomy is then extended with a scissors parallel to the nerve. In the presence of a cardiac laceration, cardiorrhaphy may be achieved by staples, sutures, or gentle traction on a Foley catheter balloon inserted through the laceration (Figs. 5.4 and 5.5). Active hemorrhage from pulmonary

lacerations is controlled by clamping the hilum of the lung manually with fingers or by placing a vascular clamp across. Some surgeons recommend "a lung twist" after the inferior pulmonary ligament is divided. These maneuvers also aid in the prevention of air embolism and aspiration of blood into the uninjured lung. Active hemorrhage from the apex of the pleural cavity suggests a subclavian vessel injury. Temporary

tamponade of the vessels may be achieved by packing with large lap pads or pressure with a fist. The patient, if resuscitated, is then moved to the operating room. Cardiorrhaphy is completed by interrupted sutures with pledgets, taking care not to occlude the coronary vessels, if the wounds are adjacent to them. Most bleeding pulmonary injuries are best treated by resectional debridement.[8] In penetrating abdominal
FIGURES 5.3. **A:** Anatomy of the vertebral artery, showing the course surrounded by cervical transverse processes. Exposure is facilitated by retraction of the anterior paraspinous muscles and anterior longitudinal ligament. **B:** Exposure of proximal vertebral artery by a supraclavicular incision, exposing the thyrocervical trunk from the subclavian artery. **C:** Exposure of the distal vertebral artery by sternocleidomastoid incision, dividing its origin from the mastoid process and dividing the levator scapulae and the splenius cervicis muscles.
FIGURES 5.4 AND 5.5. Cardiac repair with sutures crisscrossed to close the laceration and control of hemorrhage with placement of a Foley catheter with the balloon inflated.

wounds with continuing hemorrhage, the descending thoracic aorta may be occluded initially by finger compression over the spine. Blunt finger dissection of the aorta must be performed for a proper application of a thoracic aortic clamp. A Penrose drain around the aorta applied as a tourniquet is a useful alternative technique. While doing these maneuvers, beware of injury to the esophagus or the intercostal vessels. Open cardiac massage, if needed, is best performed by a two-handed technique. Beware of the surgeon's fingers causing a rent in the soft, hypoxic ventricle.

Pitfalls of ERT: The potential problems of ERT include improperly placed incisions with severe limitation of exposure, incision through the female breast, iatrogenic injury to the lung, intercostal or internal mammary vessels, pericardium, lung, phrenic nerve, and coronary vessels. Hasty and inexperienced efforts at descending thoracic aortic occlusion may result in injury to the aorta, intercostal vessels, or the esophagus. The uncontrolled, desperate nature of Emergency Department Thoracotomy is a setup for injury to the operating team by sharp objects.

Injury to the Thoracic Esophagus

Operative repair is the treatment of choice for free thoracic perforations, for injuries diagnosed both early (<24 hours) or late (>24 hours). The presence of systemic sepsis, pneumothorax, pneumomediastinum or pneumoperitoneum is indication for early thoracotomy and repair.[5]

The operative approach consists of thoracotomy on the side of the leak (left thoracotomy for lower esophageal injury and right thoracotomy for upper esophageal injury), exposure of the esophagus, and thorough debridement of all necrotic tissue. The perforation is identified and closed. In

penetrating trauma, multiple perforations are not uncommon and should be sought diligently. The choice of suture material for closure of the perforation is variable between surgeons, as is the necessity for a two-layered closure with inner absorbable and outer nonabsorbable sutures. While various tissues are recommended as buttress for the suture, Richardson[5] used buttress by either muscle or pleura. Sternocleidomastoid muscle is used to buttress or primarily close the defects in the neck, and a flap of diaphragm is often used for thoracic perforation. Patients with perforated cancer or severe underlying disease may need esophagectomy. Whichever method is used, it is critical to drain the area extensively, usually with large caliber chest tubes placed in the vicinity of the esophageal repair.

Treatment of delayed recognition of the perforation: The problems of delayed treatment involve extensive mediastinitis, necrosis of the esophageal wall, and the difficulty of effectively closing the perforation, even with various buttressing methods. Even when repair is technically feasible, subsequent breakdown of the repair is the rule rather than the exception. It is in such patients that "exclusion" procedures were practiced at one time, largely replaced in recent times by esophageal stenting. In selected patients with controlled sepsis, esophageal irrigation and wide drainage of the mediastinum and pleural cavity are viable options.[5]

Control of Intrathoracic Bleeding

Pulmonary lacerations are best approached by localized debridement–resection of the injured lung. Staplers are useful to accomplish this rapidly and effectively. Only rarely is formal lobectomy needed. Pneumonectomy is reserved for extensive injury to the hilum and is even more uncommon.

Intercostal vessel bleeding requiring operative control can easily be performed through a thoracotomy.

Damage-control Procedures in the Chest

These are not uncommon with success of early transport and emergency resuscitation in patients with severe injury.

As described by Wall and associates, "Damage control in the chest consists of different technical maneuvers to use quicker and technically less demanding operations to accomplish the same goal."[9] These include resuscitative thoracotomy, nonanatomically stapled lung resections, pulmonary tractotomy, en masse lobectomy/pneumonectomy, intravascular shunts and vascular ligation instead of repair. The chest incision is provisionally closed by prosthetic patches or towel clips.

Tracheobronchial Injury

Richardson[6] presented a personal series of laryngotracheal injuries recently and pointed out the infrequency of these injuries and the resultant limitation of experience. This report is mandatory reading to be prepared to deal with these injuries. The basic lessons are clear: tracheal injury in the neck from blunt trauma needs resection and reanastomosis of the trachea. The need for complete excision of damaged cartilage was emphasized. The repair may be performed through the neck with a sternal extension. For injury near the carina, a right thoracotomy is preferred. Mainstem bronchial injury represents a major problem, especially from penetrating trauma. Involvement of the pulmonary hilum with major vascular injuries forces a pneumonectomy, a highly lethal procedure, especially when performed on the patient in shock. For blunt bronchial injury, end-to-end anastomosis is feasible. Preservation of pulmonary tissue is clearly preferable. Richardson[6] emphasized the poor long-term prognosis of these patients. Fortunately, these injuries are relatively uncommon and the inexperienced surgeon is admonished to call senior thoracic surgeons for help.

OPERATIVE APPROACH TO ABDOMINAL TRAUMA

Solid Organ Injury

Exploratory celiotomy is clearly indicated in patients with suspected hollow viscus injury or hemodynamic instability with solid organ injury. Prep the patient from chin to midthighs and table-to-table laterally (be prepared for possible resuscitative thoracotomy, median sternotomy, or availability of the groins for vascular access or saphenous vein harvesting). The abdomen is explored by a long midline incision. After evacuation of the peritoneal cavity of all blood, the abdomen is packed in all the quadrants and serially explored. Control the most active bleeding first.

Liver. Perihepatic packs and manual compression of the liver by an assistant will reduce bleeding from the liver. Exploration of the abdominal cavity is rapidly completed. Intestinal perforation, if present, is swiftly closed to prevent continued contamination of the peritoneal cavity. The various options in the operative treatment of the injured liver can then be considered.

Approximately 50%-60% of the liver lacerations, especially after penetrating trauma, are minor capsular tears that have stopped bleeding at the time of laparotomy. These capsular tears and minor parenchymal lacerations may be left alone.

Grade II injuries are deeper lacerations, especially central in location and may be actively bleeding at operation. Hemostasis can temporarily be achieved by pressure. If bleeding resumes after releasing the tamponade, liver sutures of an absorbable material may be applied in an interlocking mattress fashion. A better alternative is to explore the laceration by a hepatotomy and individually ligate the bleeding vessels. If a diffuse bleeding continues, absorbable mattress sutures buttressed by pledgets of gelfoam can be used to compress the parenchyma and achieve hemostasis. The majority of liver injuries, fortunately, can be controlled by these simple methods.

Burst injuries due to blunt trauma and large-caliber missile wounds cause greater destruction of the parenchyma of the liver, often involving both lobes and require more "complex repairs." Ancillary techniques as autotransfusion by a cell saver, blood warmers to combat hypothermia and massive transfusion protocols with emphasis on high Fresh Frozen Plasma (FFP) to packed cell ratios, and appropriate resuscitation are crucial for a successful outcome. Adequate mobilization of the liver by dividing its ligamentous attachments enables the organ to be delivered into the operative wound and facilitate manual compression of the liver.

Occlusion of the portal triad or Pringle's maneuver reduces vascular inflow to the liver and consequently may reduce bleeding from the liver laceration. It consists of sliding the operator's hand into the lesser sac and occluding the free edge of the lesser omentum and its contained portal and hepatic vessels between the fingers. If the procedure is effective in slowing the hemorrhage from the liver laceration, a vascular clamp may be applied across the free edge of the omentum. With reduction in the rate of bleeding by portal occlusion, the liver laceration can be evaluated to control bleeding vessels by direct visualization and ligation. Deeper lacerations may be explored by the finger-fracture technique popularized by Pachter et al.[10] The parenchyma of the liver is teased between the surgeon's fingers so that the hepatic vessels are exposed as threads traversing the teased liver substance (Fig. 5.6). These can then be individually ligated. The process is continued till the entire laceration is explored and hemostasis is achieved. The staplers are an invaluable adjunct in this setting.

In the patient with large stellate fractures or deep lacerations of the liver, the finger-fracture technique of hemostasis and debridement of nonviable liver tissue inevitably results in large defects in the hepatic lobes. Minor bleeding, usually of venous origin, may persist from the raw surfaces of the divided liver. A graft of viable omentum with an intact vascular supply can be used to fill in this dead space and control the venous bleeding (Fig. 5.7). This living tissue acts not only as a pack to control bleeding, but may serve also as a rich source of macrophages to help minimize the risk of subsequent sepsis.

HEPATIC RESECTION.
Anatomic lobectomy, or formal hepatic resection even though underemphasized in recent years, has its role. Polanco et al.[11] recently analyzed 216 patients with complex liver injury and noted 21 anatomic segmentectomies, 23 nonanatomic resections, 3 left lobectomies, 8 right lobectomies, and 1 hepatectomy with orthotopic liver transplant. The overall mortality was 17.8%, but only 9% from liver injury. Despite these impressive results, the consensus opinion in this country favors resectional debridement. Selective vascular ligation of hepatic artery, once popular, is now less commonly applied to hepatic trauma. If active bleeding persists after resectional debridement or packing, angiographic embolization is the preferred method. On the other hand, do not leave the operating room if control of surgical bleeding has not been achieved.

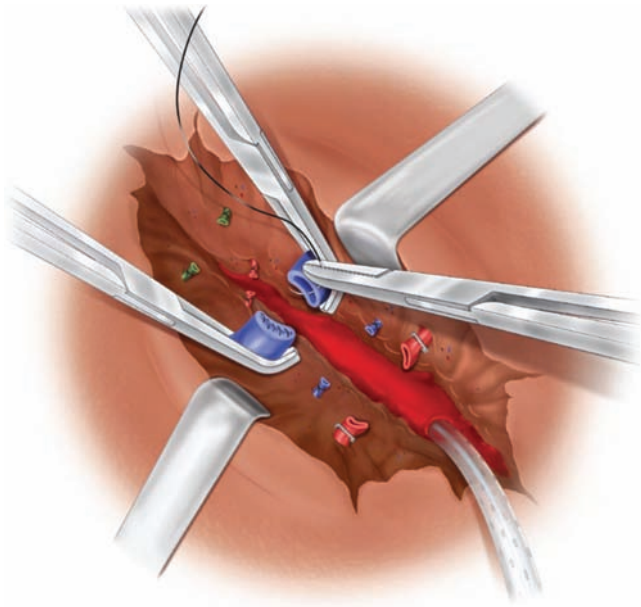
Despite these various techniques, in a small number of patients, approximately 2%-5%, profuse bleeding persists and may relate to the onset of coagulopathy. Massive red cell


FIGURE 5.6. Hepatotomy with vascular ligation.

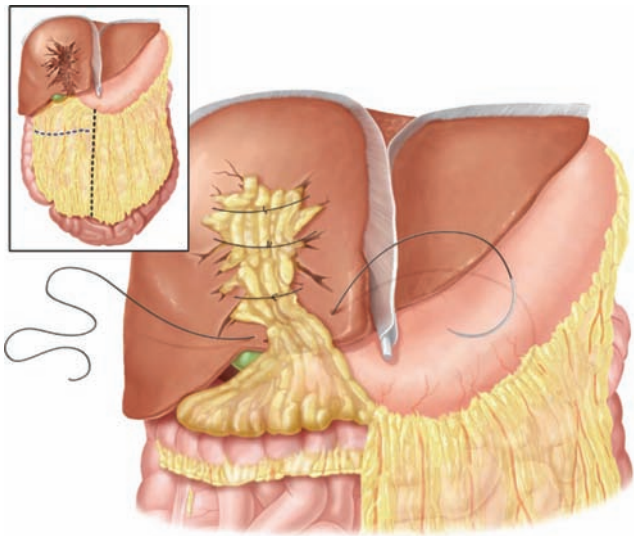
transfusion, hypothermia, and acidosis contribute to the development of coagulation defects. The liver injury, which may have stopped bleeding, may start to bleed diffusely without controllable points of hemorrhage. "Liver packing" has emerged as an important advance to control this "nonmechanical" bleeding.[12] In such patients, perihepatic packing, abbreviated laparotomy, damage control resuscitation with hepatic angiography as an adjunct have emerged as the treatment of choice. The technique of packing is by Kerlix rolls tightly in the crevices of the liver injury and over the raw areas of the resected liver. Additional packs are placed around the liver and between the organ and the diaphragm and the lateral abdominal wall. The laparotomy is abbreviated, and the patient is taken to the ICU for resuscitation. The packs are removed in 24-48 hours, when


FIGURE 5.7. Omental packing after debridement–resection of liver.

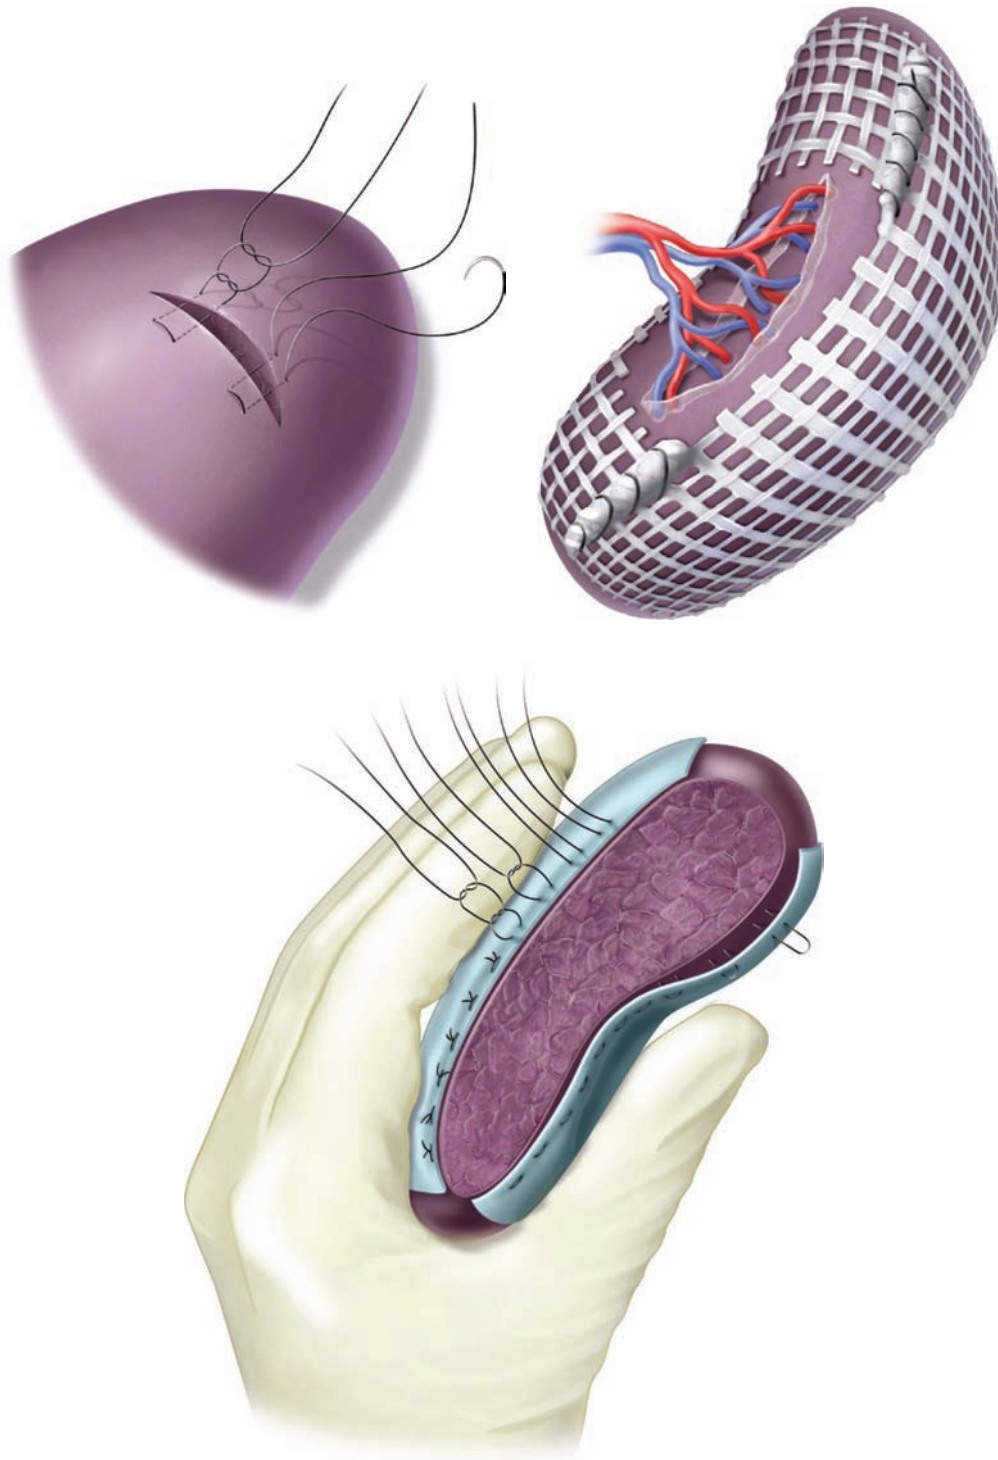
the coagulation factors have been replaced and the coagulopathy corrected. Pack removal is accomplished by copious irrigation with normal saline. The raw areas of the liver are carefully inspected and nonviable tissue is debrided. The liver laceration is drained extensively with closed suction drains.

As opposed to external tamponade, internal tamponade is a valuable method in patients with missile wounds of the liver that traverse the entire thickness of the lobes, an injury too extensive to control without a major resection. In such patients, a method of internal tamponade by a "Penrose pack," made by passage of a red rubber catheter through the missile tract and pulling a wad of Penrose drains tied to the end of the catheter through the laceration. The Penrose pack acts as a tamponading plug and controls the bleeding. The drains, brought to the exterior through the flank, also serve to drain the laceration. A similar result may be achieved by using a sterilized Sengstaken-Blakemore tube. The management of retrohepatic venous injuries is discussed under the section on abdominal vascular trauma.

Spleen. Except for high-grade splenic injuries with hemodynamic instability, nonoperative management of splenic trauma is the rule. In patients with penetrating trauma with multiple injuries and in unstable patients, splenectomy is the preferred treatment. Complete mobilization of the spleen from its ligaments, control and division of the splenic vessels at hilum, attention to the short gastric vessels and the tail of the pancreas are some of the technical details that need emphasis. Splenorrhaphy is an option when circumstances are favorable for repair: hemodynamic stability and absence of major associated injuries. Techniques include sutures with buttress of omentum, strips of gelfoam or absorbable mesh; partial splenectomy or splenic wrap with absorbable mesh[13] (Figs. 5.8-5.10).

PANCREATODUODENAL COMPLEX.[14-16]
At celiotomy, the important findings suggestive of injury to the duodeno-pancreatic complex[14,16] are bile staining of the retroperitoneum, small bubbles of entrapped air in the periduodenal tissues, small periduodenal hematoma, fat necrosis or saponification of tissues in the upper abdomen. Kocherization (mobilization of the C-loop of the duodenum from its retroperitoneal attachment) facilitates inspection of DI, DII, and a portion of DIII as well as allows evaluation of the pancreatic head, periampullary area, and distal common bile duct. The Cattell-Braasch maneuver consists of mobilization of the hepatic flexure of the colon, sharp dissection of the small bowel attachment from the ligament of Treitz to the right lower quadrant, and cephalad displacement of the small bowel. This brings D III into view along with the body of the pancreas. DIV may be evaluated by mobilization of the ligament of Treitz (Figs. 5.11 and 5.12).

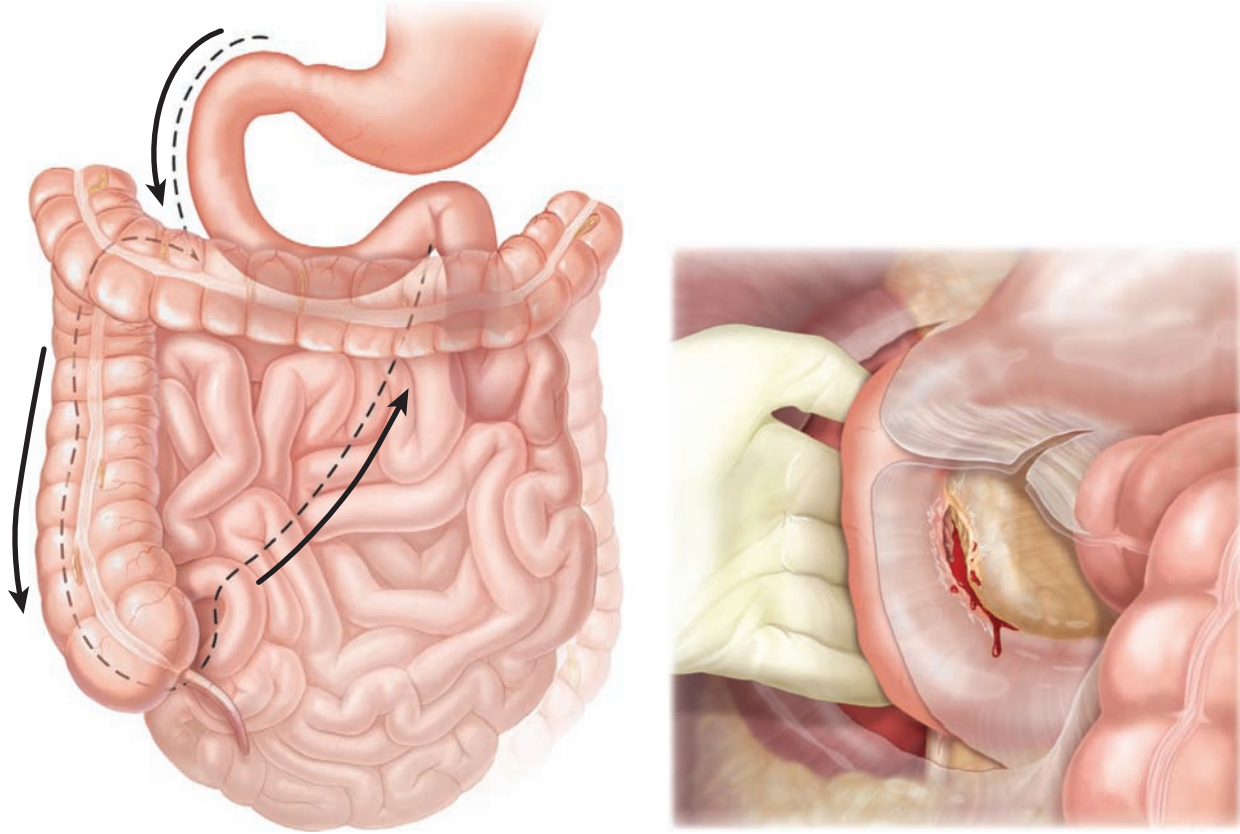
The surgical management of these injuries depends on hemodynamic stability, severity of duodenal injury, and the presence and severity of associated pancreatic injury. In the hemodynamically unstable patient, the optimal treatment is an abbreviated laparotomy with rapid, provisional closure of the duodenum by simple methods such as suture, stapling, and rapid resection without establishing continuity. Control of bleeding supersedes duodenal repair. In hemodynamically stable patients with lower-grade lesions of the duodenum and pancreas from civilian penetrating wounds and without delay in diagnosis and treatment, the vast majority of duodenal injuries may be managed by simple procedures of primary repair, duodenoduodenostomy, or duodenojejunostomy. Segmental resection and primary end-to-end duodenoduodenostomy is usually feasible when dealing with injuries to DI, DIII, or DIV.

Complex repairs: Only a small number of duodenal injuries require more involved procedures; complex grades of injuries as defined above, delayed diagnosis, or forced delayed


FIGURES 5.8-5.10. Technics of splenic salvage with sutures, mesh wrap, and partial splenectomy.

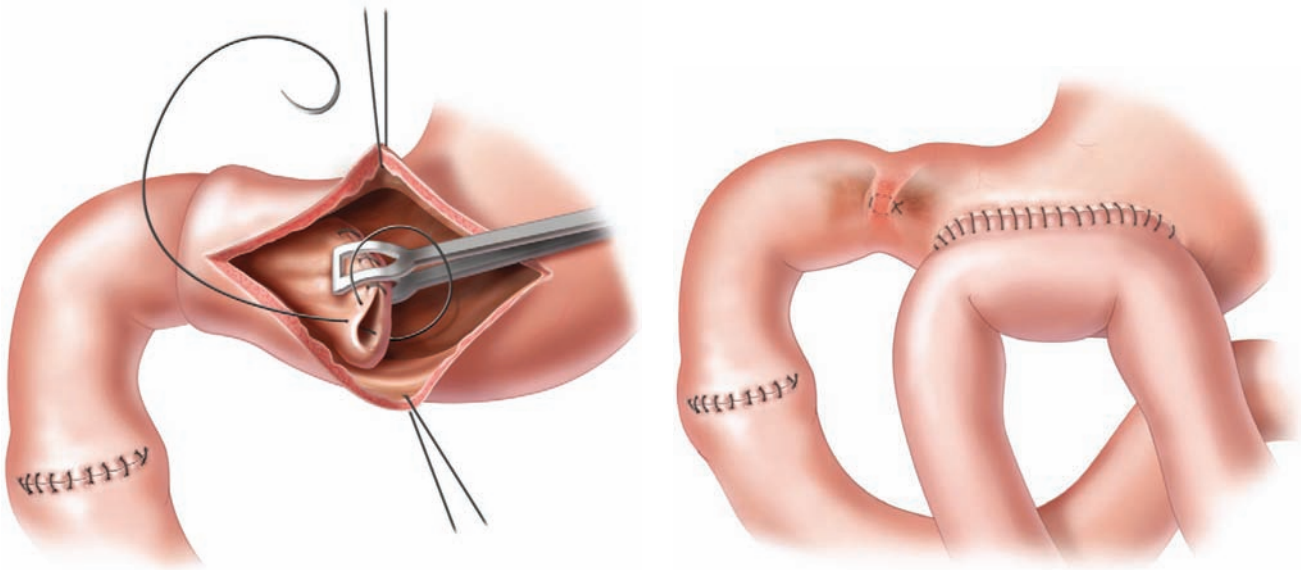
treatment by initial damage control procedure. Adjunctive operative procedures are often added to protect the duodenal suture line. Triple ostomy, particularly valuable when dealing with high-grade lesions in the difficult region of DII, consists of gastrostomy, duodenostomy, and jejunostomy. The duodenostomy may be antegrade, proximal to the injury site or retrograde, via a jejunostomy. Serosal patch and pedicled mucosal grafts are not often used currently. One preferred

option when dealing with large duodenal defects is resection and end-to-end duodenoduodenostomy or, especially in DII: either side-to-end or end-to-end Roux-en-Y duodenojejunostomy or a side-to-side duodenojejunostomy. These complex procedures, however, are seldom used in large series of duodenal injuries.

Duodenal exclusion (Figs. 5.13 and 5.14): The principle of duodenal exclusion is to divert gastric secretions away from


FIGURES 5.11 AND 5.12. The Cattell-Braasch and Kocher maneuvers for exposure of duodenum and pancreas.

the duodenal repair and allow time for adequate healing of repair and is currently performed as pyloric exclusion. This procedure consists of primary repair of the duodenal wound, closure of the pylorus with nonabsorbable sutures accomplished through a gastrotomy incision on the greater curvature of the antrum, or placement of a staple line across the pylorus. A gastrojejunostomy is then performed at the gastrotomy

site. Injury to the extrahepatic biliary system may be present and should be sought. Total or near-total transection of the common duct should be treated by biliary-enteric anastomosis. Lateral repair will lead to stenosis.[15] Pancreaticoduodenectomy is the ultimate option for extensive injuries causing uncontrollable peripancreatic hemorrhage, distal bile duct and proximal pancreatic duct or ampullary injury with extensive


FIGURES 5.13 AND 5.14. Pyloric exclusion procedure with gastrojejunostomy.

tissue destruction, and combined devascularizing injury to the duodenum and head of the pancreas. Abbreviated laparotomy in unstable patients with staged reconstruction should make this a rare operation for trauma.

Pancreas[16]

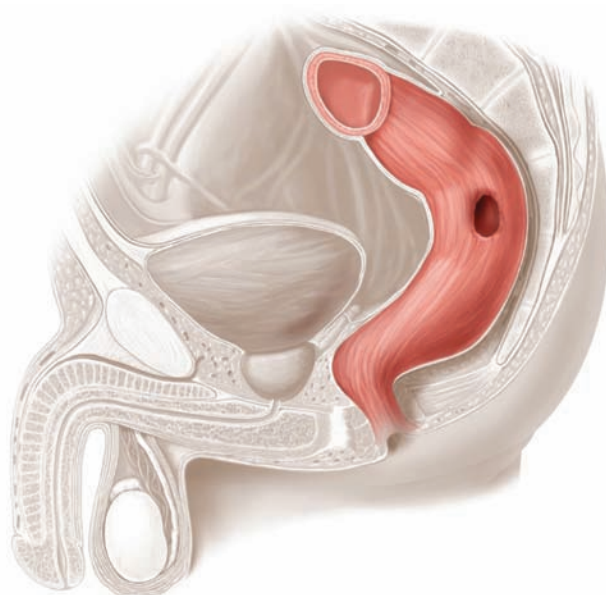
The majority of pancreatic injuries require operative treatment.[16] In the case of penetrating abdominal injury, laparotomy is the rule rather than the exception. In addition to the pancreatic injury, major associated wounds of the vascular structures around the organ, namely, the superior mesenteric vessels, portal vein, splenic vessels, inferior vena cava (IVC), and the aorta are found. Pancreatic injury, under these circumstances, takes a lesser priority than the vascular injuries. Control of bleeding and appropriate resuscitation are the immediate goals. If the patient is unstable with hypothermia, acidosis, and coagulopathy, "damage control" or an abbreviated laparotomy is indicated. In such circumstances, addressing the pancreatic injury may be deferred until the second laparotomy.

In stable patients, thorough pancreatic exploration is vital to avoid missed injury. This mandates complete visualization and bimanual palpation of the pancreas. Exploration is indicated with peripancreatic hematoma or bile staining around the duodenum or when penetrating injury traverses the lesser sac. The duodenum may be kocherized for exposure of the head of the pancreas. The lesser sac is opened and division of peritoneum along the lower border of the pancreas allows complete mobilization of the gland. All hematomas and lacerations must be explored for hemostasis. Establishing major ductal integrity is the goal: often, this can be determined by the depth and site of the laceration. In the body and tail, large and deep lacerations may be treated as if the duct is injured. In the head of the organ, it is often difficult to investigate the duct. Intraoperative ERCP is often difficult. Intraoperative pancreatography is seldom used now. If there is a concomitant duodenal laceration, the ampulla may be cannulated and a small amount of methylene blue injected to verify the ductal intergrity.. Drainage is the most critical part of pancreatic injury management. For the minor grades of injuries (Grade I and II), it is the definitive treatment. For the major grades, it is an important component of treatment. Drainage must be adequate and, preferably, of the closed suction type as opposed to sump drainage. Drains must be left in place for at least 7-10 days to establish a pancreatic fistula, should a leak from the major duct occur. Minor leaks usually stop spontaneously, without any untoward sequelae.

Resection is the preferred method of treatment of major injuries to the left of the superior mesenteric vessels. Distal pancreatectomy may be rapidly accomplished by mobilizing the gland and stapling with 4.5 mm staples. If the major duct is readily identified in the stump of the gland, it may be ligated with a nonabsorbable suture. No special treatment for the resection line is necessary apart from control of bleeding. The area is drained widely. Often, the spleen is removed because of patient instability or concomitant injury to the spleen. In stable patients with favorable anatomy, splenic salvage may be accomplished by dissecting the splenic vessels from the pancreas and removing only the distal gland.

Injury in the head of the pancreas (to the right of superior mesenteric vessels) is difficult to treat. Subtotal resection is indicated for a totally disrupted gland but is avoided if the body and tail are uninjured, since 85%-90% resection will result in pancreatic exocrine or endocrine insufficiency. In such patients, the author prefers to establish wide drainage in the region of the injury, accepting the formation of a fistula. Pyloric exclusion may be added, especially in the presence of associated high-grade injuries to the duodenum.[14]

Pancreatoduodenectomy is the ultimate treatment for the most severe combined pancreatoduodenal injuries. Current opinion reserves this procedure for devascularizing lesions of both the duodenum and pancreas. The operation may be done as a single-stage or multiple-stage procedure, depending on the stability of the patient. The infrequency with which this operation is required is quite evident in all the series; <2%.

It is important to emphasize the current trend toward conservative approach to pancreatic injuries. Resection is only performed when the remnant can be handled effectively (e.g., distal pancreatectomy). In general, enteric anastomoses to the pancreas is best avoided since the normal gland, as is often found in these patients, handles sutures very poorly and the morbidity of pancreato-enteric leaks is enormous. For complex lacerations in the head, we prefer drainage, pyloric exclusion with gastrojejunostomy, and a feeding jejunostomy.


Enteric Injury

In abbreviated operations for hemodynamic instability: contamination control from enteric perforation is important. After packing all quadrants of abdomen to reduce bleeding, all the blood in the peritoneal cavity is evacuated. Rapid visualization of the appropriate part of GI tract will identify the perforations or lacerations. These can be closed by placing Allis or Babcock clamps on the edges of the lacerations. Marking the areas of injury with these clamps, the bowel is "run" from the stomach to the rectosigmoid junction. Next, exploration of the bleeding sites must be done to control bleeding: from the solid organs and the mesentery. If a "damage control" procedure is elected, rapid closure of the intestinal lesions is the goal to facilitate abbreviated laparotomy. Several techniques are available to accomplish this: a rapid running suture incorporating all the layers of the bowel and rapid stapling of the bowel wall to close the lacerations' rapid resection of the segment of bowel where multiple lacerations are present. The segment of bowel containing multiple lacerations may be resected quickly and the ends of the bowel ligated with umbilical tapes

Stable patient: After closure of enteric perforations, the peritoneal cavity should be thoroughly irrigated to clear contaminated fluid before embarking on definitive repairs.

Next, the GI tract is inspected again from the stomach to the rectosigmoid to find all perforations. The gastroesophageal junction, the fundus of the stomach, posterior lacerations of the stomach, and all retroperitoneal portions of bowel are difficult areas that need special attention (Figs. 5.15-5.19).

Stomach. All areas of the stomach must be visualized. The G-E junction and the fundus of the stomach may be brought into view by pulling the stomach down while holding the body of the organ by Babcock forceps. These areas may then be inspected and palpated. The lesser sac is entered by dividing the gastrocolic ligament and the posterior wall of the stomach is inspected and palpated in its entirety, proceeding from the right to the left, reaching the posterior aspect of the first portion of the duodenum. Beware of the posterior gastric wall high on the fundus near the G-E junction, where injury can be missed. Evaluation of the duodenum is described above.

Small Bowel. The entire small bowel, from the duodenal-jejunal junction to the ileocecal wall must be carefully "run" visualizing both walls of the bowel. Special attention must be given to injuries near the mesenteric border. Small perforations may be hidden in this area behind the mesenteric attachment. All major mesenteric avulsions and rents must be carefully exposed and hemostasis secured by ligation of individual vessels or running a suture in the free edge of the rent. This maneuver,

FIGURES 5.15-5.19. "Potential sites of missed injuries" that deserve careful appraisal: G-E junction, ligament of Treitz, mesenteric border of bowel, posterior wall of transverse colon, extraperitoneal rectum.

as well as major rents in the mesentery may lead to ischemia of the segment of the bowel and must be sought. If bowel viability is doubtful and there is no risk for short-gut syndrome, these segments of doubtful viability are best resected.

Colon. The entire colon must be visually inspected. In areas of suspected injury, the colon must be mobilized from its retroperitoneal attachments to inspect the posterior wall. In patients with excessive fat and thick omentum, colon perforations may be hidden near the omental attachment to the transverse colon. Hepatic and splenic flexures high under the liver and the spleen and the rectosigmoid at the peritoneal reflection are the other areas that need special attention. Hematomas adjacent to bowel wall must be completely unroofed to expose bowel wall in order not to miss a perforation. One must never accept an odd number of holes in bowel unless one of the perforations has been proven to be tangential beyond any doubt.

In general, injuries from stab wounds and low-velocity gun shot wounds are small perforations of the bowel that may be repaired after debridement of the edges and control of bleeding from the edges. Injuries from blunt trauma are large rents that may need more extensive repairs or resection and anastomosis. Lacerations in the bowel wall are repaired in the transverse axis so as not to narrow the lumen. Perforations in close proximity (e.g., GSW × 2) may be combined into one and repaired. Multiple perforations in a small segment of the small bowel are best treated by resection of the segment of the intestine back to healthy edges and anastomosis in an end-to-end fashion. The mesenteric defect of the bowel segment is then closed to prevent subsequent herniation of bowel loops. A GIA stapler can be effective in resection and anastomosis of the bowel. Repair or anastomosis may be performed by a variety of techniques and is one of personal preference. No definitive data support one technique over the other: single versus two layers, interrupted versus continuous sutures, and sutured versus stapled anastomoses. It is better to avoid, in the author's opinion, stapled anastomoses when dealing with edematous bowel such as in delayed diagnosis of bowel injuries. Gastric lacerations have a propensity to bleed after repair because of the generous vascularity of the stomach. Traditionally, therefore, a two-layered repair is preferred: inner hemostatic running suture of absorbable suture and outer nonabsorbable sutures. Lacerations near the pylorus may be treated by a pyloroplasty so that pyloric channel is not narrowed.

The majority of nondestructive colon injuries may be repaired primarily with excellent results. Current opinion supports repair of the colon wounds even at reexploration after "damage control" surgery; if the colon is not edematous, the lesion does not require resection, and other conditions, locally and systemically, are favorable. Majority of the trauma centers do not recommend a primary colocolic anastomosis at the first or reexploratory operations, unless the conditions are extremely favorable. Colostomy is the safest approach under these circumstances. Intraperitoneal rectal injuries may be treated by mobilization of the rectosigmoid and primary repair. Proximal colostomy is the preferred treatment for an extraperitoneal rectal injury. Presacral drainage, colorectal washout are recommended by some for high-velocity wounds of the rectum. Their benefit in the management of all rectal wounds is unproven. If the lesion is easily approachable by proctoscopy, repair may be performed. Otherwise, repair of the lesion is not a high priority as long as the feces are diverted by a proximal colostomy.

Abdominal Vascular Injury[17-22]

Injury to abdominal vessels accounts for 27%-33% of all vascular trauma treated in urban trauma centers.[17-22] Approximately 95% of these are from penetrating trauma and occur in 10% of admissions with stab wounds and 25% with gunshot wounds. These injuries are rarely isolated and multiple visceral injuries as well as multiple vascular injuries are common. About 10% of patients with penetrating abdominal vascular injuries will present to the ED in an agonal state, without vital signs and with a distended abdomen. In these patients, a rapid left anterolateral thoracotomy in the ED will facilitate occlusion of the descending thoracic aorta with the hope of reducing intra-abdominal bleeding. However, the results of this approach have been disappointing with a survival of only 2%-7%. Some patients also need ED thoracotomy because of cardiac arrest. Survival in these circumstances is even less.

Patients who are stable or can be stabilized by resuscitative thoracotomy are rapidly transported to the operating room. The entire torso as well as the upper thighs is rapidly prepped and draped into the operative field. In hypotensive patients, a preliminary anterolateral thoracotomy may be indicated in order to prevent extensive blood loss when the distended abdomen is decompressed. Laparotomy is performed through a long midline incision from the xiphoid to the pubis.

Suspecting vascular injury: Abdominal vascular injury may be suspected by the presence of a large amount of blood in the abdomen or the presence of hematoma. The vascular zones of the abdomen are the midline Zone I (supramesocolic and inframesocolic), Zone II on either side located in the perinephric gutters, and Zone III in the pelvis. All hematomas in these zones incorporate vascular structures and need to be explored. The presence of an expanding hematoma or brisk, bright red blood through penetrating wounds will suggest a major vascular injury.

The next step is to evacuate intraperitoneal blood rapidly and pack the abdomen with laparotomy pads. The point of hematoma or bleeding is compressed manually. Volume replacement and maintenance of physiologic stability are the next goals. Proximal and distal control is rapidly obtained by dissection, often facilitated by the hematoma. Exposure of individual blood vessels is described below. The laceration(s) are repaired by the usual vascular techniques, the abdomen is irrigated with warm saline, and minor points of bleeding are ligated or sutured. Bowel perforations are temporarily closed so that contamination of the peritoneal cavity will not continue. At this point, a decision is made whether to continue with the operation or to abbreviate the laparotomy for damage control, as discussed in other chapters.

Abdominal Aorta. In the patients with hematoma in the supramesocolic space, it is important to obtain proximal control of the aorta at the aortic hiatus in the diaphragm, if not obtained already in the left chest by thoracotomy and cross-clamping in the chest (Figs. 5.20-5.23).

Abdominal control is first accomplished by medial mobilization of all the left-sided intra-abdominal viscera including the kidney (the so-called Mattox's maneuver), Figure 5.24. This will allow exposure of the celiac axis, the SMA as well as the origin of the renal arteries. An alternative approach for the suprarenal, infra-SMA abdominal aorta is by an extensive Kocherization of the duodenum medially and by incision of the retroperitoneal tissue to the left of IVC. Once proximal control is achieved, the aorta is dissected distally, exposing the perforation(s). Bleeding may, at this time, be controlled by manual compression either by sponge sticks or hand. In the majority of patients, the injuries to the suprarenal aorta are small defects in the wall that can be closed with a continuous suture of 3 or 4 polypropylene after debridement. More extensive loss in the aortic wall needs resection of a part of the aorta and insertion of an interposition graft, usually of 12-14 mm, of Dacron or PTFE. Fortunately, these injuries are not common and the majority of the series have fewer than 20 patients each with a mean survival of about 30%.
FIGURE 5.20. Aortic compression against the spine. The same effect may be obtained by two sponge forceps on either side of the aorta with a rolled gauge holding them.

Infrarenal aortic injury is easier to expose and manage by the same principles.

Celiac Axis Injury

Exposure of celiac axis is by medial rotation of viscera, as described above. Injury to the celiac axis is usually treated with ligation because of the lack of any short-term morbidity, if the SMA is patent.

Superior Mesenteric Vessels. Exposure of SM vessels is difficult and may be achieved as described for the aorta. Injury to the superior mesenteric vein also may require division of the neck of the pancreas to expose the confluence of splenic and portal veins. More distal injury may be exposed by dissection through an incision in the root of the mesentery. More proximal injury may be approached through the lesser sac and mobilization of the pancreas. Small lateral injuries are treated with 5.0 or 6.0 polypropylene suture while extensive injuries require a synthetic graft from the aorta. It is usual to plan a second-look operation after repair of SMA to detect bowel ischemia early. These injuries have a high mortality (45%-75%) because of the difficulty in exposure. Proximal injuries are best treated by ligation and a second-look operation. More distal injuries in the transverse mesocolon should always be repaired because of the high risk of bowel ischemia.

Infrahepatic Vena Cava. Injury to the IVC presents as a large hematoma next to the duodenum or with active bleeding from this site. This is best exposed by mobilization of the cecum, ascending colon, and hepatic flexure medially (Figs. 5.25 and 5.26). The C-loop of the duodenum is mobilized medially by Kocherization of the duodenum. Proximal and distal compression by sponge sticks may facilitate the exposure of the IVC rent. Usually, a large amount of bleeding will ensue, requiring manual compression of the bleeding IVC. One useful technique is to apply pressure with sponge to control the bleeding, slow withdrawal of the pack to expose small segments of the caval injury and controlling the perforation(s) with rapid application of a Satinsky clamp on the vessel. One useful technique is to approximate the edges of the laceration with Allis clamps progressively, as the pack is withdrawn. The laceration is then closed with polypropylene sutures.

A wound in the suprarenal IVC is best approached by obtaining proximal control above the renal veins by retracting the liver superiorly and applying compression on the IVC against the spine at this level. A rapid exposure of both renal veins and IVC will facilitate control of the entire IVC and exposure of the injury. Injuries to the inferior vena cava are repaired by a transverse suture of 5.0 polypropylene.

The posterior laceration IVC must be identified and repaired. The best approach for this is to repair the posterior laceration through the anterior laceration by direct visualization. The IVC may also be rotated to approach the posterior aspect. Ligation of the lumbar veins may facilitate this exposure and repair of the posterior perforation.

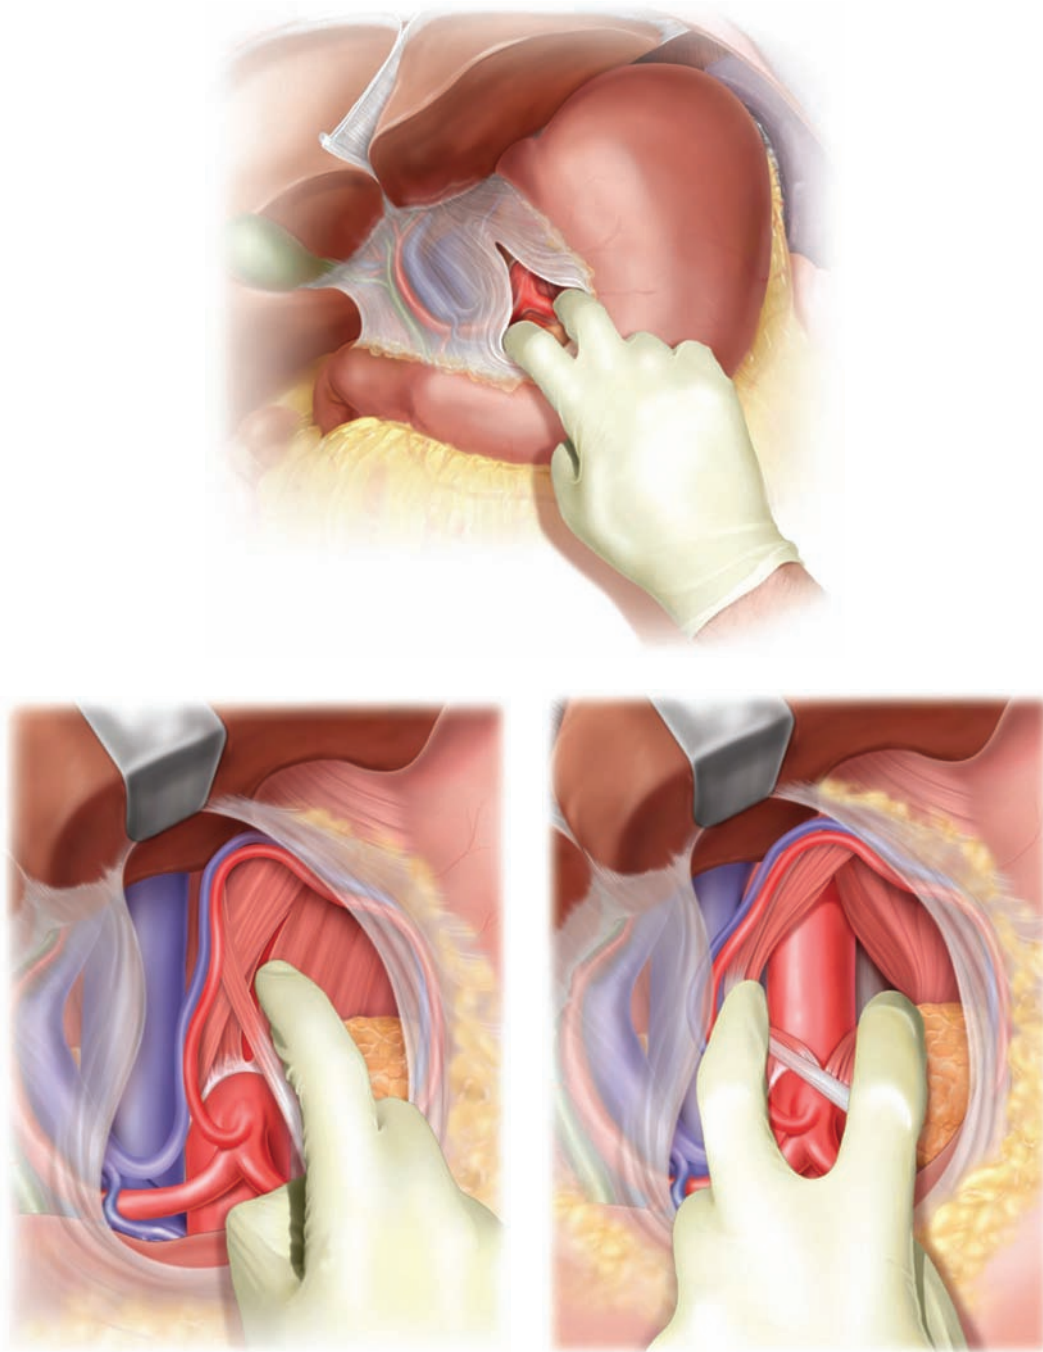
In the profoundly hypotensive patient who is coagulopathic, ligation of the IVC is an option. It is, of course, poorly tolerated by the patient in profound hypovolemia but occasional survival is possible

Portal Venous Injury, Hepatic Artery Injury, or Retrohepatic Vena Caval Injury

Massive bleeding from the hepatoduodenal ligament or from behind the liver is indicative of these injuries. Exposure of the first two is obtained by dissection in the free edge of the lesser sac and identification of the portal vein in its posterior plane. More proximal portal venous injuries at the confluence of splenic and superior mesenteric veins require transection of the neck of the pancreas. Lateral venorrhaphy is the preferred mode of repair of the portal vein. Occasionally, an end-to-end anastomosis may be necessary. More complex repairs are not needed since ligation of the portal vein is a viable option. Injured hepatic artery may be ligated and this is usually well tolerated as long as the portal vein is patent.

Bleeding from behind the liver, which is not easily controlled by a Pringle's maneuver, suggests a retrohepatic venous injury. If the bleeding can be controlled by packing, this may be all that is needed. Continuing bleeding demands exposure and repair of the bleeding veins.

Retrohepatic Venous Injury

Retrohepatic venous injury should be suspected in the presence of rapid bleeding or a large retroperitoneal hematoma behind the liver or when the bleeding is not controlled by portal triad occlusion. Once there is a suspicion of a retrohepatic venous injury, the area should be packed with laparotomy pads, portal triad occlusion completed, and preparation made for massive transfusions. Mobilization of the liver and gentle dissection may, on occasion, visualize the hepatic venous injury and repair may be carried out. More frequently, these maneuvers only accentuate the bleeding. If an atriocaval shunt and vascular isolation of the liver is decided upon, the midline celiotomy incision should be extended as a median sternotomy to gain control of the supradiaphragmatic vena cava. While a variety of tubes have been used for the shunt, a wide (no. 36) chest tube or an endotracheal tube are readily available and


FIGURES 5.21-5.23. Control of supra-celiac abdominal aorta.

serve the purpose well. Vascular isolation is achieved by securing the tube at the intrapericardial vena cava and suprarenal vena cava with umbilical tapes. The open end of the shunt beyond the atrial appendage can be used for rapid transfusion. Once vascular isolation is completed, the area of the perihepatic veins can be explored and repaired. The use of an endotracheal tube and inflation of the balloon in the suprarenal cava obviates the need for isolating the suprarenal cava.

While these steps in achieving vascular isolation of the liver by an atriocaval shunt appear relatively simple, in practice, the method is fraught with pitfalls and dangers. Burch et al.[22] analyzed a 11-year experience with 35 patients with atriocaval

shunts from Ben Taub hospital. This is the largest series of this technique yet published. They highlighted many of the pitfalls of this technique and noted that 7 patients had a total of 8 technical problems in the insertion of the shunt. These included late placement in 3 patients, tourniquets below the renal veins in 2 patients, and injury to suprarenal vena cava in 2 patients. Six of the 35 survived. All of the survivors had gunshot wounds of the retrohepatic vena cava. None of the patients who required either a resuscitative thoracotomy or concomitant hepatic resection survived.

Dissatisfied by the high mortality of atriocaval shunting for juxtahepatic venous injury, Pachter et al.[10] recommended (1)
FIGURE 5.24. Modified left visceral rotation to expose the supra and infra renal aorta.

compression of the injury site while resuscitation is in progress; (2) early diagnosis of the injury by failure of Pringle's maneuver to staunch bleeding; (3) prolonged portal triad occlusion (up to 1 hour) using topical hypothermia and steroids; and (4) extensive finger fracture of the liver parenchyma up to the site of vascular injury and primary repair or ligation of the venous injury. It should be borne in mind that not all juxtahepatic venous injuries require atriocaval shunting. On occasion, the injury may be visible on lobar mobilization and be amenable to repair by the placement of a Babcock or Satinsky clamp. Ligation of the injured hepatic vein is a viable option in patients with a tenuous physiologic status. Finally, it needs to be reiterated that tight perihepatic packing can control bleeding from injured retrohepatic venous injury and may serve as the definitive treatment.

Renal Pedicle. Injury to the renal pedicle presents as a lateral hematoma. Renal artery injury is often associated with aortic tear and the fastest and safest approach is nephrectomy after making sure that there is a contralateral kidney. In more stable conditions, these lateral hematomas are best explored after preliminary control of the renal pedicle (Figs. 5.27 and 5.28). This can be achieved by dissection at the root of the mesocolon and opening the retroperitoneum. Injuries to the renal veins are exposed as described for inferior vena cava. Small lacerations can be repaired by lateral venorrhaphy with 5-0 or 6-0 prolene sutures. In more extensive injury or with venous ligation, nephrectomy is the most expeditious recourse. Lateral perirenal hematomas from blunt trauma are often left unexplored by the majority, especially if there is no injury to the calyceal system. Blunt renal artery lesions are rarely encountered. Renal salvage after penetrating

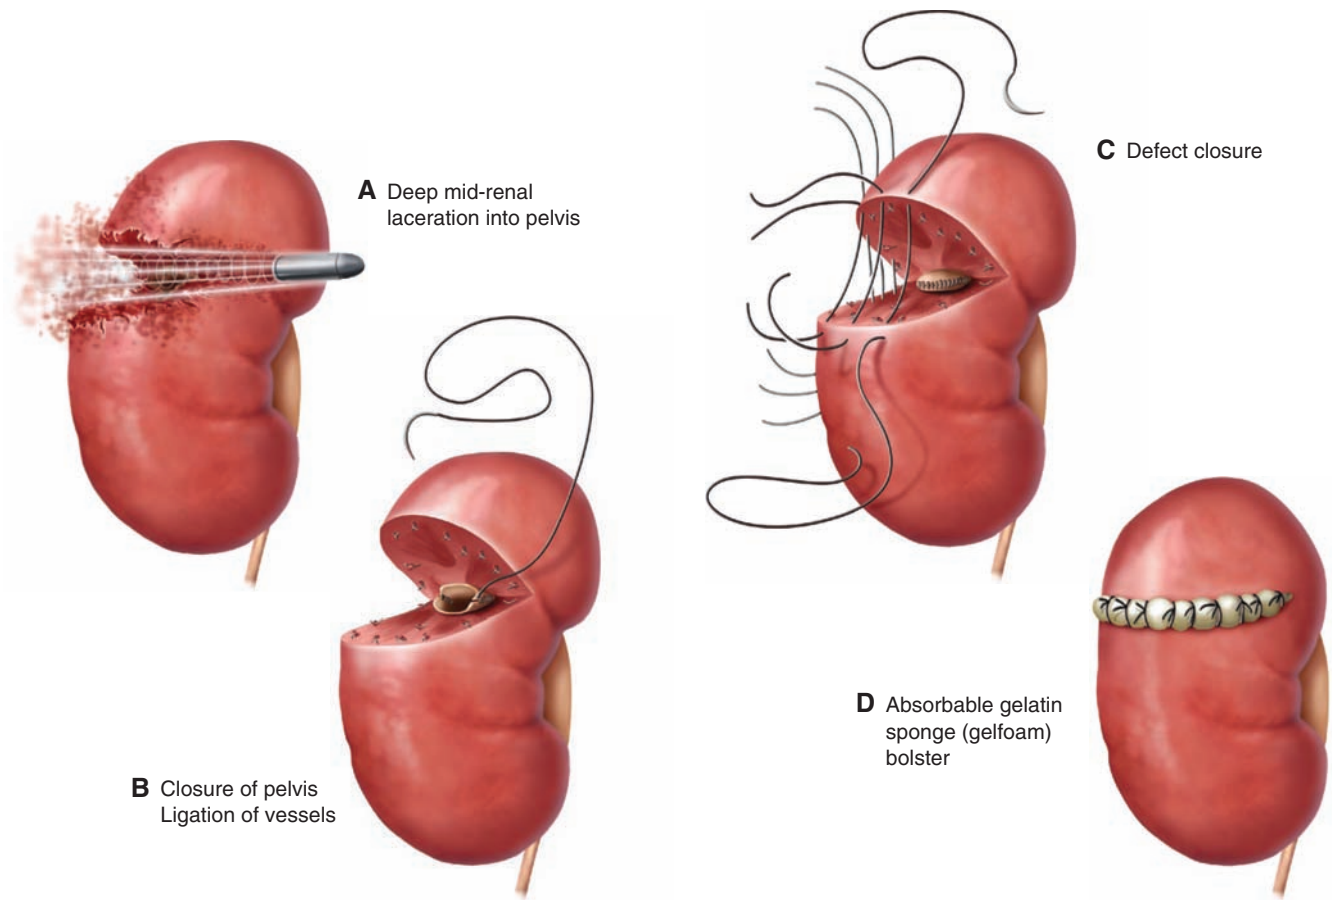
renovascular injuries is only 30%-40%. Renal preservation after injury to the renal parenchyma is possible by a variety of techniques outlined by Figures 5.29-5.31.

In the presence of a lateral pelvic hematoma, iliac vessel injury should be suspected. These are usually from penetrating trauma, but may be due to pelvic fractures from blunt trauma. Proximal and distal vascular control may be obtained at the aortic bifurcation and at the inguinal ligament. The internal iliac artery may need to be controlled to prevent back bleeding and may be ligated, if torn. Lateral repair or vein interposition graft is the optimal management approach for the external iliac artery. This is a critical artery and ligation has a high probability of resultant limb loss. Extra-anatomic bypass may be necessary when limb viability is threatened. Injury to the iliac veins is more difficult to control, especially at the confluence of veins. Ligation of the injured iliac vein is a better option than interposition grafts, if lateral venorrhaphy is not possible. This should be followed by a fasciotomy of the ipsilateral leg. The survival from these injuries will depend upon the presence of associated injuries. Isolated arterial injuries carry a survival rate of 87%, while it was about 94% for isolated iliac venous injuries.


In summary, the presence of major abdominal vascular injury is apparent early. In patients who are stable to reach the operating room, a reasonable survival may be expected. The exceptions are wounds of suprarenal aorta and the retrohepatic veins. With increasing appreciation of physiology and the application of principles of "damage control," as discussed below, survival is much improved in recent series.

Minimally Invasive Surgery in Trauma and Acute Care Surgery[23]

Laparoscopy can play a major role in the evaluation and management of the stable patient with penetrating trauma to the abdomen.[23,24] Laparoscopy is invaluable in the evaluation of thoracoabdominal wounds (the so-called intrathoracic abdomen). Laparoscopy also has a role in selected patients with

missile wounds with doubtful trajectory through the peritoneal cavity. Selective management of abdominal gunshot wounds can be accomplished without morbidity. A significant number of patients with minor grades of hemoperitoneum, minor lacerations of liver and spleen, and nonexpanding mesenteric hematomas away from bowel wall can be managed without laparotomy successfully. It is noteworthy that recent experience is encouraging in the problematic issue of bowel injury—a high index of suspicion and a low threshold for laparotomy in the presence of hematomas near or around the bowel wall and a greater proficiency in running the small bowel and mobilizing the retroperitoneal colon.

Operative Technique. A 10-mm 30 degree forward-seeing laparoscope is inserted via a 10-mm trocar placed by cutdown into the peritoneal cavity with intra-abdominal pressures limited to 15 mm Hg. First, peritoneal violation is confirmed. A 10-mm camera port is created at the suprapubic region for alternative use and two 5-mm ports are placed at right and left paramedian sites. The surgeon inspects the stomach, omentum, transverse colon, and diaphragm on the patient's left side from the umbilical camera port with the patient in the reverse Trendelenburg's position. The pancreas and the posterior gastric wall are inspected after the scope is introduced into the lesser sac if a hematoma or fluid accumulation is found in the lesser sac. Next, the pelvic organs are inspected with the patient in Trendelenburg position. For complete evaluation of the ascending colon and the small bowel, the laparoscope is inserted into the suprapubic camera port, and with atraumatic grasping forceps through the umbilical port and the left paramedian port, the bowel is "run." By changing the position to the right, the surgeon runs the proximal one-third of the small bowel and the descending colon. Once all injuries are assessed, the surgeon can decide upon laparoscopic repair, open laparotomy or hand-assisted laparoscopic resection, and anastomosis of the bowel. Some of the therapeutic procedures now successfully performed in trauma include hemostasis of bleeding solid organs, splenectomy, cholecystectomy, distal pancreatectomy,

repair of diaphragm lacerations with intracorporeal sutures or staples, and repair or resection and anastomosis of perforated hollow organs with laparoscopy-assisted procedures. A careful honest evaluation of his/her own surgical expertise, patient stability, adequacy of available in staff and tools are important prerequisites for the surgeon in the success of minimally invasive techniques in trauma.

Diagnostic and Therapeutic Laparoscopy in the Evaluation of Acute Abdomen

The principles of diagnostic laparoscopy are increasingly applied to acute care surgery.[26-28] A recent meta-analysis on the subject confirmed the excellent role in establishing the diagnosis of acute cholecystitis and intestinal ischemia in critically ill patients at level 2 and 3 evidence, as well as in cardiac surgery patients to exclude abdominal catastrophes. It is well tolerated if performed by trained acute care surgeons. The role of laparoscopy in the diagnosis of acute appendicitis in women has been confirmed as superior to CT scan. Therapeutic laparoscopy is increasingly applied in selected patients with small bowel obstruction, incarcerated hernias, perforated peptic ulcer, adnexal pathology, and acute diverticulitis. In some instances, randomized studies have proven the superiority of laparoscopic-assisted surgery over conventional open procedures (e.g., sigmoid resection for complicated acute diverticulitis).[28] The therapeutic arm of minimally invasive surgery is expanding rapidly.

The Role of Thoracoscopy in Trauma[25]

Both laparoscopy and thoracoscopy[25] are useful techniques for evaluating the diaphragm after penetrating trauma. Thoracoscopy provides excellent visualization of the posterior recesses of the thoracic cavity, areas often not well seen with the laparoscope. Consequently, it should be the preferred approach for posterior wounds from the posterior axillary line to the spine. For an anterior lower chest wound with potential injury to the dome of the diaphragm, thoracoscopy can confirm the injury, facilitate evacuation of residual blood and clots from the hemithorax, and also permit easy repair of the diaphragm. In the absence of a pneumothorax and if the wound is anterior and low in the interspaces, laparoscopy offers the following advantages: (1) An unnecessary thoracostomy tube may be avoided and (2) abdominal injuries can be assessed. Thoracoscopy may be performed by routinely available instruments such as sponge forceps, lung clamp, Yankauer suction. General endotracheal anesthesia with a double lumen tube is commonly used to allow collapse of the lung on the injured side. The full lateral decubitus position, as for a posterolateral thoracotomy, provides the best visualization of the diaphragm with the mediastinum shifting away. The modified lateral position with the patient's torso propped up with a "bean bag" and the arm suspended above the head with a screen works well, should an abdominal exploration become necessary. The optimal positioning of the camera and accessory ports is in the shape of a baseball diamond with the camera at the home plate, the area of interest at second base, and the additional

FIGURE 5.31. Technique of partial nephrectomy.

ports at first and third bases. The initial incision for the camera placement is in the 6th or 7th space or at the site of the tube thoracostomy. The placement of additional ports may be determined after the initial inspection with the thoracoscope. Generally, three or four ports are needed and should be placed so that they may be incorporated into the thoracotomy incision, should one become necessary.

Ports placed in the 3rd interspace provide excellent exposure of the apical region. Posteriorly placed (in the scapular line) port in the 3rd or 4th space provides access to the carina on the right and peritracheal regions on both sides. For inspection of the diaphragm, the camera is placed in the 5th interspace, in the anterior axillary line for anterior wounds and posterior axillary line for posterior wounds. The thoracic cavity is suctioned of all blood and clots and rapidly inspected for active bleeding. The chest wound is probed with a blunt clamp to indicate the area of the diaphragm at greatest risk. The area of concern is easily inspected with suitable retraction of the lung and mediastinum. Occasionally, herniated omentum or abdominal structures mark the presence of a diaphragmatic wound and hernia. These may be reduced, the diaphragm repaired, and the abdomen investigated by laparoscopy. For clotted hemothorax, the thoracic cavity is emptied of all blood and clots and one or more chest tubes are inserted into the chest under thoracoscopic guidance. Irrigation of the chest and efficient emptying of the chest by the thoracoscope will help prevent subsequent residual hemothorax or empyema. The ideal timing is within the 1st week after thoracic injury.

With increasing technical expertise and advanced training in minimally invasive surgery, both laparoscopy and thoracoscopy have become applicable for both diagnostic and therapeutic indications in trauma and acute care surgery.

DAMAGE CONTROL (ABBREVIATED LAPAROTOMY)[29-31]

No discussion of surgical procedures for trauma and acute care surgery can be complete without a mention of "damage control" surgery[29-31] discussed in detail elsewhere in this text.

First discussed by Stone in 1983, the technique involved saving the day for another day in battle by truncation of laparotomy, intra-abdominal packing for tamponade of mechanical bleeding, and subsequent completion of definitive surgical repair when the patient is in better physiologic condition.

Damage control consists of three separate parts: rapid control of hemorrhage and contamination; intra-abdominal packing and temporary abdominal closure (Part I), correction of hypothermia by rewarming; correction of coagulopathy; fluid resuscitation and optimization of tissue perfusion (Part II) and reexploration for definitive management of injuries and abdominal closure (Part III). This concept of abbreviated laparotomy and non-closure of abdomen has lead to profound advantages in the management of severely unstable trauma patients. These principles are now being applied to various aspects of acute care surgery. Morgan et al.[30] demonstrated this in 8 patients with exsanguinating hemorrhage and severe sepsis related to pancreatic surgery. Similar application of damage control can be applied to all critically ill patients with acute abdominal conditions.

BASIC OPERATIVE APPROACHES IN EXTREMITY INJURIES[32]

While a complete discussion of extremity surgery is beyond the scope of this chapter, the principles that deserve emphasis are temporary prevention of hemorrhage by pressure dressings or tourniquet and prompt identification and definition of impaired perfusion.[32] Arterial inflow/venous outflow is quickly reestablished by insertion of temporary intraluminal shunts, external fixators to stabilize fractures, debridement of necrotic soft tissues, and completion of fasciotomy for suspected or confirmed compartment syndromes.: This is "damage control" extremity surgery. Following orthopedic stabilization at a second operative procedure, the shunts are removed and a reversed autogenous saphenous vein graft from an uninjured lower extremity is used to restore arterial continuity. Venous drainage is reestablished even temporarily, accepting the inevitable clotting of these repairs and grafts in the venous system. Coverage of vascular suture lines and conduits under healthy tissue is the next important principle. Finally, the importance of primary amputation of unsalvageable mangled extremity to save the patient's life, while a difficult decision, cannot be overemphasized.

SUMMARY AND CONCLUSION

The basic operative techniques in trauma and acute care surgery follow the time-honored principles of caring for the critically ill or injured patient: emergency priorities focusing on restoration of normal physiology as rapidly as possible before anatomic repairs. Proficiency in acute care surgery is synonymous with the ability to use all of the currently available techniques.

FUNDAMENTAL PRINCIPLES

DAMAGE CONTROL MANAGEMENT/OPEN ABDOMEN

BRETT H. WAIBEL AND MICHAEL F. ROTONDO

HISTORY AND EVOLUTION OF DAMAGE CONTROL

While historically the management of the injured patient was done by the general surgeon, treating these patients like an elective surgery patient, with attempts at definitive repair at onset, failed to obtain satisfactory results, mainly due to fundamental differences in physiology and anatomic issues. The multisystem trauma patient has the potential for severely destructive injuries across multiple organs and/or body spaces usually not seen with the elective surgery patient. In addition, a prolonged time from injury to definitive care allows for ongoing bleeding and visceral contamination, resulting in altered physiology on presentation. The elective surgery patient presents with stable physiology, and does not suffer from uncontrolled bleeding or visceral contamination generally. Finally, the initial evaluation between these patients is necessarily different. The multisystem trauma patient may not have the physiologic reserve to undergo extensive evaluation and imaging commonly utilized with elective surgical patients. Furthermore, the shock state common in emergent trauma patients often prevents the patient from being able to provide a basic medical history. It is these essential differences of altered physiology, delay of presentation, complications from ongoing bleeding and contamination, and limited or absent preoperative medical history and evaluation that make the traditional attempt of definitive repair at presentation often futile. Ongoing bleeding from coagulopathy, initial physiologic failure from unresuscitatable shock, and subsequent multiple organ system failure later in the patient's hospital course present specific challenges that defy conventional therapy.[1-3]

While this problem was known and discussed in the first half of the 20th century, it was not until the early 1980s that the foundations for a solution were placed. H. Harlan Stone presented work in aborting laparotomy for coagulopathic bleeding using abdominal packing and Burch with hepatic injuries demonstrated improvement in outcomes over traditional approaches.[4,5] However, the term "damage control" and its sequence was not defined and refined until the 1990s by Rotondo and Schwab.[6-9]

While initially developed for abdominal injury with uncontrolled hemorrhage, damage control concepts have expanded into other areas, including vascular surgery and orthopedics.[10,11] These concepts have even altered the way the military organizes its treatment of severely injured soldiers.[12-15] In emergent general surgery, damage control techniques have been applied to those patients who develop similar physiologic instability and intolerance of the shock state.[16-20] However, with the aggressive resuscitation employed along with damage control, the incidence of abdominal compartment syndrome (ACS) and open abdomens has increased.[21,22] The increased exposure to open abdomens has allowed surgeons to gain experience in their management with development of multiple methods of obtaining temporary abdominal closure.

Additionally, recognition of ACS, both in trauma and with intra-abdominal catastrophe, and its treatment has probably been a huge source of the improved outcomes in both patient populations.[16,22,23]

New strategies have been devised to reduce the volume of resuscitation as well as deal with the metabolic alterations the shock state and the resuscitation itself creates. Permissive hypotension and "damage control resuscitation" using fresh frozen plasma in a 1:1 ratio with packed red blood cell have been recently debated in the literature.[24-28] Many novel strategies involving transfusion ratios, alternative fluids, and hemostatic dressings are currently being evaluated.[29] As resuscitative technique and our understanding of control of physiology prior to operative intervention improve, the need for damage control and its adjuncts may decrease.

DAMAGE CONTROL INDICATIONS

In the traditional approach by general surgeons, control of bleeding and contamination were achieved and followed immediately with definitive repair and closure of the abdomen at the first surgery. The core concepts of damage control surgery evolved out of the failure of traditional approaches to exsanguinating hemorrhage from traumatic injury. Damage control changed the traditional sequence via termination of the initial laparotomy after cessation of hemorrhage and control of contamination, preferably before the development of physiologic exhaustion as noted by the development of acidosis, coagulopathy, and hypothermia ("the bloody vicious cycle").[30] Instead, definitive repair is delayed until after reestablishment of the patient's physiology in the ICU. Abdominal closure may even be delayed further if the resuscitation required to treat the patient would lead to ACS (Table 6.1).

The decision to carry out a damage control procedure should be made early in the operation, before the development of hypothermia, acidosis, and coagulopathy. Waiting for the development of this triad to abbreviate the operation reduces the success of damage control surgery, as the components of this triad interact to worsen ongoing hemorrhage, ultimately leading to the patient's demise.[31] While temperature below 35°C, pH below 7.2 or base deficit exceeding 8, and evidence of coagulopathy clinically or via laboratory are often discussed as indications for abbreviating the operation in favor of damage control, no definitive values exist for consideration of a damage control procedure.[32-34]

In addition to physiology parameters, another indication for damage control is the presence of multiple injuries, both within and without the operative field, which would exceed the patient's physiologic reserve to definitively repair. Complex injuries, such as those combined to the pancreas and duodenum, may require exceedingly long operative times. Preferably, the damage control laparotomy should be <90 minutes in duration.[35]

TABLE 6.1

INDICATIONS FOR DAMAGE CONTROL

1. Hemodynamic instability
2. Coagulopathy on presentation or during operation (clinical or laboratory)
3. Severe metabolic acidosis (pH < 7.2 or base deficit > 8)
4. Hypothermia (< 35° C)
5. Prohibitive operative time required to repair injuries (>90 minutes)
6. High-energy blunt torso trauma
7. Multiple penetrating torso injuries
8. Multiple visceral injuries with major vascular trauma
9. Multiple injuries across body cavities
10. Massive transfusion requirements (> 10 units packed red blood cells)
11. Presence of injuries better treated with nonsurgical adjuncts

Injuries outside of the operative field are easily forgotten, especially those across multiple body cavities. Continuing or recurrent hemorrhage from these sites can hasten a patient's advance toward physiologic collapse and may not be immediately identifiable by the operative team. Hemorrhage control should be treated as a continuum across body cavities and regions, with the surgeon starting at the perceived most compelling source of hemorrhage and expeditiously moving to other sites as the situation develops, keeping in mind sites that are outside the operative field.

Injuries that may be better treated with adjuncts, such as angiographic embolization of hepatic or pelvic injuries, are another potential indication for damage control surgery.[36] When identified intraoperatively, such an injury can be temporized with packing followed by angioembolization. The variation in physiologic reserve across different patient populations must also be considered. The elderly, young, and those with multiple medical comorbidities have less tolerance for prolonged surgical procedures.

Thus, constant reevaluation of the patient is needed to identify those patients who would benefit from an abbreviated operative approach and subsequent aggressive secondary resuscitation. The evolving physiology, time for repair, concurrent injuries and their effects on the patient, and the patient themselves all factor into the decision to abbreviate the operation to prevent collapse of the patient's physiology.

DAMAGE CONTROL SEQUENCE

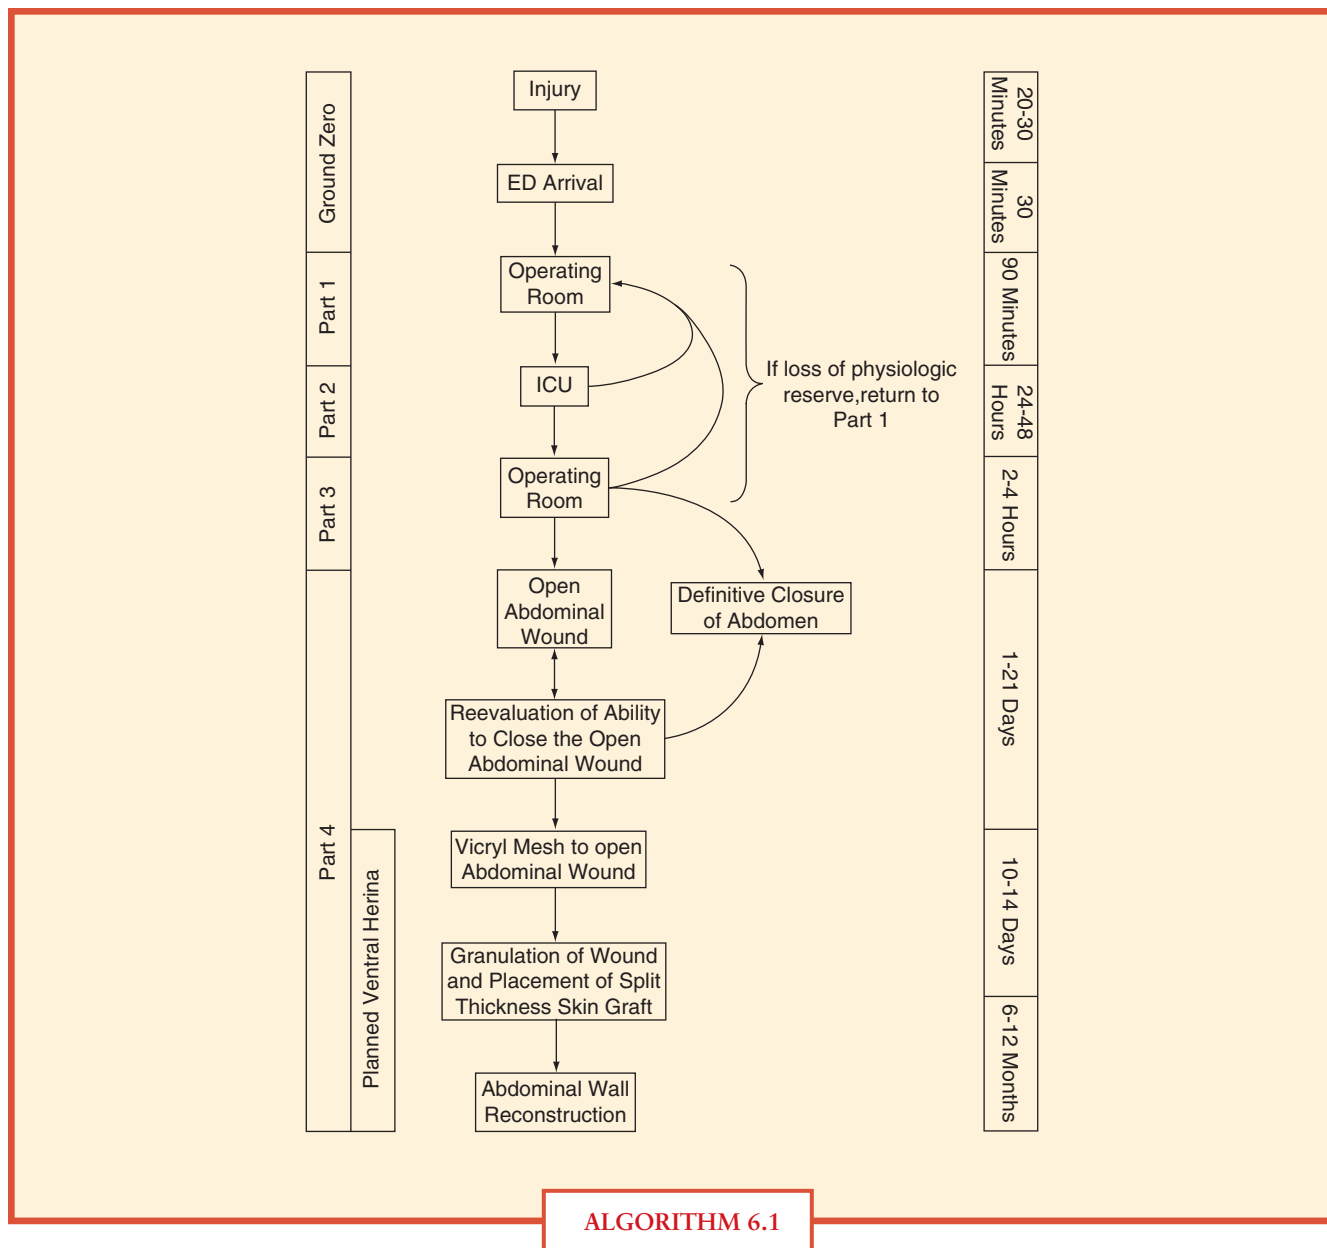
When first conceptualized for exsanguinating truncal trauma, damage control focused upon management of ongoing hemorrhage and visceral contamination from abdominal injuries (part 1). This was followed by reestablishment of the patient's physiology in the intensive care unit (part 2) before definitive repair in the operation room (part 3) and closure of the abdominal wall (part 4). With further process improvement, the significance of the prehospital setting (ground zero) and expansion of damage control to extra-abdominal injury began to be evaluated (Algorithm. 6.1). A description of the process in the exsanguinating abdominal trauma patient follows, though many parallels can be noted in other emergent surgery patients, such as those with abdominal sepsis.

GROUND ZERO: PREHOSPITAL CARE/INITIAL RESUSCITATION

The prehospital care received by the trauma patient can have profound implications on their outcomes. The need for rapid transport or transfer to definitive care cannot be overemphasized.[37,38] Theories on resuscitation have arisen recognizing the potential of traditional methods of focusing on increasing hydrostatic pressure to normal levels to restore tissue perfusion to destabilize clots and increase bleeding, which may have a deleterious effect upon the patient.[39] A moderate resuscitation goal to systolics of 80-90 mm Hg with concomitant signs of end-organ perfusion during transport may be more prudent for patients with prolonged transfer times.[24,40] Some militaries are resuscitating only to the presence of a radial pulse and cleared sensorium in austere environs.[41-43] Prehospital hypotension, despite resolution before arrival at the hospital, should be considered a warning sign for a more severely injured patient with the potential for a prolonged operation.[44] Communication between the transporting crew and hospital personnel before arrival allows for mobilization of resources to prevent delays in the care of the unstable trauma patient.

Advanced Trauma Life Support is the foundation for care at this stage.[45] Airway management and correction of breathing disorders using adjuncts like endotracheal intubation and tube thoracostomy are well described. Circulation assessment with point control of hemorrhage and alignment of fractures should be performed. Resuscitation is begun via large bore intravenous and occasionally intraosseous catheters using a combination of isotonic crystalloid and blood product. A rapid evaluation using adjuncts, such as focused abdominal sonography in trauma, diagnostic peritoneal lavage, tube thoracostomy, and radiographic imaging of the chest and pelvis, to identify sites of ongoing hemorrhage is performed. The rapidity and ease of the mentioned adjuncts makes them particularly useful, but are not absolute. Diaphragm injuries can allow for transmission of blood between cavities. The areas prone to unobserved bleeding in an unstable patient are intrathoracic, intraperitoneal, pelvic/retroperitoneal, or long bone fracture sites. One must not forget the potential for bleeding prior to arrival from external wounds, especially those associated with the scalp. Generally, fluid in the peritoneal cavity with hypotension will lead to a celiotomy, while large volume loss from tube thoracostomy (>1,500 mL) or ongoing drainage (>200 mL per hour over 3-4 hours) indicates the need for a thoracotomy. Localization of ongoing hemorrhage allows for better planning of operative intervention and can be performed in <20 minutes.

PART 1: CONTROL OF HEMORRHAGE AND CONTAMINATION (INITIAL LAPAROTOMY)

The initial operative intervention is the focus of the next phase. The goal is an abbreviated operation for control of mechanical hemorrhage and visceral contamination. The operation is abbreviated to prevent depletion of the patient's physiologic reserve and initiation of nonmechanical (coagulopathic) hemorrhage. After evacuation of the peritoneal cavity, hemorrhage control is established using abdominal packing, especially with hepatic, retroperitoneal, and pelvic injuries. Shed blood can be collected using a variety of techniques for return to the patient; however, they remove the clotting factors, leading to a coagulopathy without the concomitant use of plasma and cryoprecipitate replacement.


ALGORITHM 6.1

ALGORITHM 6.1 Damage control timeline.

While specifics of operative intervention are described elsewhere, some underlying themes can be established.[46,47] Central is full exposure of the injuries to identify ongoing bleeding and contamination. Numerous maneuvers, including Kocher, Mattox, Aird, and Cattell-Braasch, allow for exposure of the retroperitoneal structures as needed. Suture ligation and control of the vascular pedicle of solid organs is commonly used to gain rapid control of ongoing hemorrhage. Some solid organs, such as the spleen or isolated kidney with normal contralateral kidney, may be sacrificed if repair times are prohibitively prolonged. Those vessels that provide end-organ supply or outflow to vital organs/regions, such as the suprarenal vena cava and portal vein, however, require repair. Shunting techniques are available to allow temporary restoration of flow during the resuscitation (part 2) phase before definitive repair (part 3) while reducing ischemic injury.[48-53] A large variety of hemostatic agents have entered the market over the last few years.[54] While human data is limited to case series, animal data does exist showing improved outcomes in hemorrhage control. Some early generation agents released large amounts of thermal energy, leading to burns of uninjured tissues.[55,56] Adjuncts, such as angiography with embolization, may be needed to obtain hemorrhage control in inaccessible areas, such as the pelvis.

Control of intestinal injuries causing contamination of the peritoneal cavity is the second important objective. Closure of the visceral wound with suture or stapling techniques can easily and quickly control ongoing contamination. Formal repairs are avoided in the unstable patient with intestines left in discontinuity until definitive repair is performed in part 3 of damage control.

Positioning in the operating room is important, especially with multiple compartment injuries. The combined thoracic/abdominal compartment injuries are not suited by either a supine or decubitus position used in abdominal or thoracic trauma. The taxicab hailing position will often allow for practical exploration of both compartments (Fig. 6.1). The patient is placed in a supine position with the chest laterally rotated 30 degrees anterior to the coronal plane using folded blankets to one side based upon preoperative evaluation. The arm can be included into the operative field if manipulation is required. The position also allows for sternotomy if needed.

FIGURE 6.1. Taxi cab hailing position: note torso rotation to 30 degrees anterior to coronal plane with blankets. Arm abducted to 90 degrees for exposure of chest wall.

Temporary abdominal closures can further decrease the time in the operating room. Use of the abdominal pack or vacuum-assisted abdominal dressing allows for rapid reentry while preserving fascial integrity for latter closure.[57-61] In addition, effluent from the abdominal cavity can be managed and quantified to facilitate the ongoing resuscitation.

PART 2: RESUSCITATION IN INTENSIVE CARE UNIT

After the initial operation, the patient is transferred to the intensive care unit to reestablish the patient's physiology by aggressive resuscitation with intravenous fluids and blood products in conjunction with correction of hypothermia, acidosis, and coagulopathy. The fluid choice for resuscitation can have major effects. The use of normal saline in large volumes leads to a hyperchloremic (nongap) metabolic acidosis.[62] Animal models suggest the potential for proinflammatory mediator stimulation with lactated Ringer's solution.[63,64] Colloids have been suggested as an substitute resuscitative fluid; however, evidence of superiority to crystalloid does not exist, and maybe even increases mortality in trauma patients.[65-67] Hypertonic saline reduces inflammatory mediator activation in animal models, but has failed to show superior improvements in mortality or morbidity in clinical trials.[68-71] Isotonic crystalloids (normal saline/lactated Ringer's solution) are used for the majority of resuscitations.

A debate over transfusion policies in patients requiring massive transfusion protocols (>10 units packed red blood cell in first 24 hours) rages.[25-28,72-83] A host of articles on transfusion ratios have been published since 2007 with the military's report on improved survival with a 1:1:1 platelet:plasma:pRBC transfusion ratio compared to the traditional 1:4 to 1:5 plasma:pRBC ratio. While most of the civilian literature supports this aggressive transfusion policy in a small group of patients (1%-3% of civilian trauma patients), not all studies

have shown survival benefits. In addition, the optimal ratio of plasma to red blood cells has yet to be fully determined. Massive transfusion is not without complications, including the potential for acute transfusion reactions, electrolyte disorders (hypocalcemia and hyperkalemia), acidosis, hypothermia, dilutional coagulopathy, and alteration of red blood cell morphology and oxygen-binding affinity.[54]

Recombinant factor VIIa has also been evaluated for its potential in hemorrhage control due to the acquired coagulopathy of trauma. Multiple case reports and one single randomized controlled trial have been done with variable results.[84-98] On the whole, it appears to reduce the transfusion requirements, especially if given early in the course of acquired coagulopathy, and correct the coagulation profile, but mortality does not appear to be improved. The recent multicenter CONTROL trial was discontinued for futility due to low mortality rates.[99] Also, the potential for thromboembolic events has been argued given its mechanism of action.[100] Other compounds, such as prothrombin complex concentrates (PCCs), are also now being evaluated. While having a history of clinical use in hemorrhage from vitamin K antagonist coagulopathy and hemophilia with inhibitors, animal models are being developed for trauma with PCCs.[101-109]

While induced hypothermia has shown benefit in some elective surgical interventions, hypothermia on arrival to definitive care (spontaneous hypothermia) has shown almost uniform negative consequences in trauma patients.[110-117] A depletion of energy levels in the hypothermic trauma patient compared to the elective surgical patient exists.[118-121] Some of this depletion may be due to metabolic exhaustion and inability to restore the adenosine triphosphate supply, while some may be due to uncontrolled shivering in the prehospital setting and the energy consumption associated with it.[122] Recent studies on hypothermia in trauma patients have used a temperature of 36°C to define hypothermia compared to the cooler 35°C in older studies, with identification that the effects of hypothermia occur at warmer temperatures than previously

thought.[115-117,123,124] While hypothermia has some potential positive effects on cellular preservation, especially in the central nervous system, a multitude of negative effects are noted, including alterations in metabolism and drug clearance, altered renal function and diuresis, electrolyte disturbances due to ion shift and renal loss, and inhibition of the coagulation pathways and platelet dysfunction.[125] Given the increased risk of death associated with hypothermia in trauma, expedient rewarming of the patient is recommended. A multitude of noninvasive and invasive measures, including intravascular heat exchange catheters and body cavity lavage, exist.[126] However, whether prevention of hypothermia in the prehospital setting translates into improved outcomes has yet to be shown.

Metabolic issues must also be addressed during this phase. In addition to electrolyte disturbances that need to be expediently corrected, hyperglycemia is commonly present in these critically ill patients. Strict glycemic control with aggressive insulin therapy has become commonplace since Van den Berghe's 2001 study; yet, more recent studies have given variable results.[127-133] A recent meta-analysis found that intensive insulin therapy increased the risk of hypoglycemia without a survival benefit in critically ill patients; though a survival benefit was noted in the surgical population when stratified by patient type (mixed, medical, or surgical).[134] Given these recent studies, some have concluded that targeting age-normal glucose levels in units not equipped or accustomed to aggressive insulin therapy should be avoided and instead to target "to maintain blood glucose levels as close to normal as possible without evoking unacceptable fluctuations, hypoglycemia, and hypokalemia".[135]

While multiple resuscitation endpoints have been described, no single test is ideal.[136-138] Even once vital signs are normalized, the majority of patients exhibit evidence of inadequate tissue perfusion and oxygenation.[139] Given the poor response of traditional vital signs, such as heart rate and blood pressure, to detect shock, alternative measures are being developed, such as shock index and heart rate variability.[140-150] Resuscitation should continue until the shock state has resolved as determined by multiple methods of evaluation. While the medical critical care literature general shows a lack of efficacy of pulmonary artery catheter-based resuscitation, surgical literature tends to support its use, especially with right ventricular end-diastolic volume index (RVEDVI) pulmonary catheters.[151-153] This discrepancy probably exists due to the differences in the patients themselves and volumes used to resuscitate between medical and surgical disease processes. A RVEDVI pulmonary catheter can help guide the resuscitation volume and pressure use in the difficult resuscitation.

Generally, once hemorrhage is controlled, the patient can be resuscitated and prepared for return to the operating room in the following 24-48 hours. While normalization of vitals usually occurs rapidly, a short period of time to regain true physiologic reserve is needed. In hypothermic trauma patients, the energy stores lag behind normalization of vitals, even beyond 24 hours from injury.[119] Failure to regain a stable physiology in a short time is an indication that ongoing bleeding is present or the patient is developing an ACS. This should hasten the return to the operating room for reexploration before recovery of the patient's physiology.

Care should be taken to prevent iatrogenic injuries during this and subsequent phases. Inappropriate ventilator strategies can produce or extend injury. The ARDSNet studies demonstrate the ventilator as a major inducer of pulmonary injury and acute respiratory distress syndrome (ARDS).[154-157] A lung protective strategy of 4-6 mL/kg of lean body weight should be used. Sedation and analgesia are commonly needed to promote synchrony between the patient and ventilator with these strategies.[158] A small group of patients may even require neuromuscular blockade to achieve synchrony; however, their use has not shown improvement in either mortality or oxygen consumption in ARDS. Their use has been associated with higher prevalence of myopathy and neuropathy, especially with renal or hepatic dysfunction or asthma.[159-163]

ACS is a common complication seen in the severely injured patient. While normal intra-abdominal pressure is 5-7 mm Hg, pressures above 12 mm Hg are designated intra-abdominal hypertension.[164-166] In some patients, the increased visceral edema is noted at the initial surgery manifested by the inability to return the visceral block to the peritoneal cavity; while in others, a delayed presentation with development during the resuscitation takes place.[22] ACS, the clinical entity hallmarked by hypotension, increased ventilatory pressures, and oliguria in the presence of intra-abdominal hypertension, should be routinely monitored for by checking bladder pressure measurements.[167,168] Clinical examination and abdominal circumference measurements correlate poorly with intra-abdominal pressure as the elasticity of the abdominal wall is not a linear function of distention.[169-171] While intra-abdominal pressures exceeding 30 mm Hg are most associated with ACS, patients have been noted to develop this syndrome with pressures below this level.[172] In 2006, the World Society of Abdominal Compartment Syndrome (WSACS) defined ACS as sustained intra-abdominal pressures above 20 mm Hg associated with new organ dysfunction or failure.[166]

The physiologic effects of ACS are global. The cardiovascular system undergoes an increase in peripheral vascular resistance from compression of the vascular beds and increased sympathetic signaling while venous return to the heart via the inferior vena cava is decreased due to the increased abdominal and thoracic pressures.[173-175] Additionally, cardiac compression causes atrial natriuretic peptide secretion to decrease, resulting in further fluid sequestration. Eventually, the patient becomes unresponsive to volume loading.[176] Pressure measurements (central venous pressure, pulmonary capillary wedge pressure) from pulmonary artery catheters become uncoupled to volume status.[177] In this situation, RVEDVI, which does not depend upon pressure measurements, becomes the best measure of volume status.[136,152] Ultimately, a cycle of hypotension treated with volume resuscitation leads to further edema and increases in intra-abdominal pressures that worsen the clinical syndrome.

Increases in ventilatory pressures occur with ACS. While impediment of diaphragm movement from increased intra-abdominal pressure is present, resulting in 20%-80% of the intra-abdominal pressure being transmitted intrathoracic, other factors are involved.[178] Typically in these patients, aggressive volume resuscitation has led to increased chest wall edema and extravascular lung water, resulting in decreased pulmonary compliance.[179] Furthermore, increases in positive end-expiratory pressures (PEEP) are used to help in the recruitment of lung lost to a decline in negative pleural pressures that result in ventilation–perfusion mismatch, especially in the lower lung lobes. The combination of elevated PEEP along with transmission of intra-abdominal pressures results in increased intrathoracic pressures, which can further act to decrease cardiac return and output.[180] The increase in intrathoracic pressures coupled with a decline in pulmonary compliance leads to the increase in ventilatory pressures needed for lung expansion.

Renal function impairment, noted by oliguria or anuria, is the third clinical component of ACS and is independent of volume expansion and maintenance of cardiac output.[181,182] Outside of direct compression of the ureters from a pelvic hematoma, ureteral compression is not a cause of the renal failure as stenting fails to correct the oliguria. While mixed results have been seen in studies on direct renal parenchymal compression, compression of the renal vein creates ACS like failure, probably due to renal venous hypertension and decreased blood flow in the kidney.[183-185] Additionally, a decline in the filtration gradient probably occurs as the increase in intra-abdominal pressure exceeds proximal tubular pressures, leading to a decrease in glomerular filtration rate. Activation of the renin-angiotensin-aldosterone pathway further worsens

oliguria with increases in antidiuretic hormone and aldoste-rone.[186,187] The combination of decreased cardiac output and renal venous compression along with parenchymal compres-sion and endocrine alterations leads to the "dose-dependent" oliguria and anuria of ACS.

In addition to the aforementioned systems, ACS affects other body systems. Visceral blood flow is almost uniformly decreased and may be a component in intestinal anastomo-sis failure.[188-191] Additionally, bacterial translocation appears to increase with increased intra-abdominal pressures.[192,193] Transmission of intra-abdominal pressures is associated with increased intracranial pressures.[194-196] Some have advocated decompressive laparotomy for patients with head injury and intracranial hypertension.[197-199] Additionally, abdominal wall blood flow is altered with increasing intra-abdominal pres-sures.[200] Closure with increased tension and relative tissue ischemia may result in tissue necrosis and fascial dehiscence to further complicate management of the abdominal wound.

Risk factors include severe hemorrhagic shock, damage control surgery (especially with fascial closure), and elevated penetrating abdominal trauma index. Elevated pulmonary peak pressures and low gastric mucosal pH also correlate with its development.[201] Aggressive fluid resuscitation has been linked in several studies with volumes in excess of 10 L crystalloid, 10 units packed red blood cells (massive transfu-sion), 0.25 L/kg of crystalloid, or 6 L of crystalloid or units of packed cells in 6 hours associated with an incidence between 5% and 30%, depending on the patient population and definition used for ACS.[22,202,203] Tighter abdominal closures, including primary fascial closure, have the highest incidence of ACS, death, ARDS, and multiple organ failure; however, use of the temporary abdominal closures does not guarantee its prevention.[204-206] The development of ACS in patients with temporary abdominal closures has a higher mortality than in those patients with an open abdomen without development of ACS.[207] It is through delays in identification and commenc-ing therapy that increases in morbidity and mortality occur.[208] Recognition and treatment with decompression of the abdom-inal cavity improves perfusion and organ function.[209,210] In one prospective study, the mortality of severity-adjusted patients with an open abdomen approached that of patients without an open abdomen with aggressive monitoring and treatment of ACS based upon the WSACS guidelines.[23,211]

PART 3: DEFINITIVE INJURY REPAIR (SUBSEQUENT LAPAROTOMY)

Once the patient's physiologic reserve has been restored, defini-tive repair can be undertaken (Table 6.2). Abdominal packing is removed and a complete examination with identification of all injuries and control of remaining errant bleeding points is per-formed. Uncontrolled hemorrhage, hemodynamic instability, or inability to undergo a prolonged operation would prompt an abbreviated laparotomy for control of hemorrhage and visceral contamination followed by return to the ICU for resuscitation.

The definitive repairs required will depend upon the injury and organ system concerned; however, one should consider limiting the use of prosthetic material in a contaminated wound and the need to return to the operating room for further wash-outs prior to definitive closure. Some repairs can be considered that would not have been undertaken in a traditional, single operative setting. For example, isolated colon injuries have tra-ditionally been treated with an ostomy; however, in a resus-citated patient, one might consider a primary anastomosis, especially if the patient would poorly tolerate an ostomy.[212] The abdomen should be thoroughly irrigated upon completion of

TABLE 6.2
SEQUENCE OF DEFINITIVE REPAIR
1. Careful removal of packs
2. Inspection/identification of all injuries
3. Control of remaining errant bleeding points
4. Definitive gastrointestinal repair
5. Thorough abdominal washout
6. Avoid stomas and tube enterostomies, if possible
7. Nasoenteric feeding tube placement
8. Closed suction drainage, if needed
9. Temporary vs. definitive abdominal wound closure
10. Tracheostomy, if needed
11. Radiographic evaluation for retained packing before definitive abdominal closure

repairs. Closed suction drains should be used, when necessary. While definitive closure of the abdomen is preferred, a tempo-rary abdominal closure may be required. One should attempt to ensure the intestines are located below the fascial level. The omentum is useful in providing coverage of the abdominal vis-cera to provide additional protection from injury.

Stomas and tube enterostomies should be avoided if pos-sible owing to potential complications, as considerable changes in abdominal wall geometry can occur in the critically ill patient.[213-215]. However, nutritional support is incredibly essen-tial in this patient population.[216] Postpyloric nasoenteric feeding tubes provide continuous feeding, even during return trips to the operating room. Initiation of enteral feeds should be delayed in unstable patients because of the possibility for intestinal ischemia, but ought to be started after physiology is restored and proven stable. Even with an open abdomen, early enteral feeding is possible and associated with reduced septic complica-tions.[217-220] Earlier primary fascial closure, lower fistula rates, and decreased cost compared to patients with later (>4 days) enteral feeding was noted in one study of open abdomens.[221]

Since acute lung injury and ARDS manifest themselves dur-ing the 2nd and 3rd hospital days and can prolong ventilator requirements for several weeks, consideration of a tracheos-tomy should be made early.[222-228] Ventilator circuit disruption after onset of pulmonary dysfunction can have devastating consequences; a tracheostomy provides for a more secure air-way during this tenuous time. While early tracheostomy may decrease ventilator days and ICU stay, a high degree of mis-classification may exist in this literature.[229]

PART 4: OPEN ABDOMINAL WOUNDS AND DEFINITIVE ABDOMINAL CLOSURE

Before definitive abdominal closure is obtained, a radiographic evaluation is made. Given the rapid nature of the initial opera-tions and use of packing, closing counts cannot be trusted. Imaging allows for further evaluation that retained foreign bodies are not present and provides for a permanent record of complete pack removal.

Primarily due to the aggressive resuscitation used with dam-age control at present, approximately 40%-70% of patients cannot initially have primary fascial closure.[59,60,230] Tempo-rary closures are desirable for patients undergoing repeated

operations or have a distended visceral block preventing closure without ACS developing. While closing an abdomen, increases in airway pressure above 10 mm Hg from baseline indicate that fascial closure should be delayed.

Multiple temporary closure methods are available (Table 6.3).[57-59,61,230-236] Optimally, a temporary closure should control the viscera while preventing additional peritoneal cavity contamination or visceral injury. The abdomen should be sealed and effluent controlled to preserve skin/soft tissue integrity. The closure should avoid unnecessary tension to prevent subsequent ACS. Finally, fascial integrity should be preserved for latter use during definitive closure.

When closure of the abdomen is not initially possible, skin closure techniques, silo placement, or vacuum pack techniques are most commonly used. Skin closure techniques using suture or towel clips, while the easiest closures that maintain domain while avoiding fascial injury, are rarely watertight and create (towel clips) radiographic artifacts, complicating diagnostic and therapeutic adjuncts.[237] Silo placement (Bogota bag) has been replaced by vacuum-assisted abdominal closures due to their dynamic properties.[238-242] The vacuum pack dressing (Barker technique abdominal dressing) is formed from commonplace supplies and can be done outside the operating room.[57-59] An impervious dressing, created from a perforated plastic drape or surgical towel wrapped in Ioban (3M, St Paul, MN), is positioned between the visceral block and abdominal wall to prevent adhesions while allowing effluent to egress the peritoneal cavity. An interposition layer of Kerlex (Kendall, Mansfield, MA) rolls with embedded closed suction drains is placed next. A final layer of Ioban over the wound maintains a watertight system for skin preservation while suction is applied to the embedded drains for control of peritoneal fluids (Fig. 6.2). Commercial vacuum-assisted dressings, such as the KCI V.A.C. and ABThera (Kinetic Concepts, Inc., San Antonio, TX) and Renasys systems (Smith & Nephew, Inc., St. Petersburg, FL), exist. The internal portions of the dressing are replaced with a protected polyurethane sponge that facilitates fluid collection while providing continuous medial traction on the fascial edges to help prevent domain loss (Fig. 6.3).

If definitive closure is further delayed, other techniques are employed. Sequential abdominal wall closure with temporary abdominal dressings in the remaining defect is one option. Vacuum-assisted dressings can be used with interpositional meshes, and decreases in multiple organ system failure, ACS, necrotizing fasciitis, and fistula formation have been seen with interpositional mesh use.[243-246] No single mesh is entirely ideal. Some meshes, such as Vicryl (polyglactic acid, Ethicon, Somerville, NJ) and Dexon (polyglycolic acid, Davis and Geck, Danbury, CT), have low tensile strength and are prone to tearing. The polypropylene meshes (Marlex, Bard, Billerica,

FIGURE 6.2. Barker technique vacuum pack abdominal dressing.

MA; Prolene, Ethicon, Somerville, NJ; Surgipro, US Surgical, Norwalk, CT) have higher tensile strength but are associated with higher fistula rates (15%-50%) due to an aggressive inflammatory reaction.[247] Gore-Tex (polytetrafluoroethylene, Gore and Associates, Flagstaff, AZ) mesh, while nonadherent and strong, has a high infection rate in this setting due to its design.

While closure rates vary greatly in the literature, fascial closure can be achieved in most patients.[248] Interpositional meshes have fascial closure rates from 22%-88%, with most of the literature in the lower part of that range.[232,244,247,249,250] Vacuum-assisted techniques range from 29%-100%, with most studies on the higher end without increase in morbidity or mortality.[59,60,248,251-258] Only one prospective study has directly compared interpositional mesh to vacuum-assisted abdominal dressings, with no difference in fascial closure rates between them (26% vs. 31%, respectively).[259] More complex closures with permanent synthetic meshes and fascial releases or extensive skin flaps are avoided at this stage, as they carry increased infection and wound complication rates. They also complicate or prevent abdominal wall reconstruction techniques, such as component separation, at later dates.[61]

For patients for whom definitive closure is not achievable, a planned ventral hernia with subsequent abdominal wall reconstruction is a viable option. An absorbable interpositional mesh (Vicryl) is placed and followed with a split thickness skin graft once granulation tissue appears (generally 10-14 days). After 6-12 months, the underlying viscera will fall away from the skin graft, indicating that the abdominal wall reconstruction can be done then. Waiting beyond 12 months will not improve the operative field, but loss of domain issues becomes more frequent. Tissue expanders or flaps may be needed if soft tissue coverage is insufficient.[247,260] If sufficient fascia is present for closure, then a fascial closure is performed, potentially with a mesh onlay. However, an underlay mesh (allograft or prosthetic) in a subfascial or retrorectus position and/or component separation are usually necessary for abdominal wall reconstruction.[261-265] Allograft meshes have begun to be used to bridge defects, but long-term outcomes are unknown.[252,266-269] The possibility for tissue regeneration and infection resistance compared to synthetics makes them potentially superior in the future. Survivors with a planned ventral hernia feel decreased levels of physical, social and emotional health, but with definitive abdominal reconstruction, return to the general population baseline.[270]

CLOSURE OF OPEN ABDOMINAL WOUNDS

1. Immediate term
   a. Skin closure only (suture or towel clips)
   b. Vacuum-assisted abdominal dressing
2. Intermediate term
   a. Sequential fascial closure
   b. Sequential skin closure
   c. Interpositional mesh placement
   d. Vacuum-assisted abdominal dressing
3. Long term (planned ventral hernia)
   a. Interpositional Vicryl mesh placement followed by split thickness skin grafting and abdominal wall reconstruction
FIGURE 6.3. KCI V.A.C. system.

COMPLICATIONS AND DAMAGE CONTROL

Complications occur primarily in two time periods with damage control. The initial intervention and resuscitation phase has complications related to the sequelae of shock, injury, and resuscitation. These include ACS, missed injuries, and intra-abdominal infections. The later complications of enterocutaneous fistula are found during an open abdominal phase.

Given the ill nature of the patient at presentation, missed injuries have a higher potential to exist. Some injuries, such as those to the diaphragm, retroperitoneal structures (duodenum, ureters, bladder, and rectum), and difficult-to-expose structures (posterior wall of stomach, pancreas, GE junction, retroperitoneal colon, and mesenteric border of bowel), are more common due to anatomy. Repeated examinations can improve capture of these injuries, but damage control is not a substitute for complete injury identification and control.[271,272] The missed unusual or insufficiently controlled vascular injury invariably leads to the patient's death.

Intra-abdominal infection rates vary from 10% to 70% and appear linked to the duration abdominal packs are retained.[273-275] The interval between washouts, however, is highly variable depending on the clinical situation. More frequent washouts promote less abscess formation, but increase the risk of fistula formation with more bowel manipulation. While usual surveillance methods are used in damage control patients, weekly abdominal CT scans for abscess surveillance may be needed in those patients with persistent fever or leukocytosis. Ventilator-associated pneumonia and catheter-related infections are also common in the damage control patients.

Enterocutaneous fistula formation depends upon several factors, including the nature of the injuries, the degree of bowel manipulation, and care and closure technique of the open abdomen. While higher rates have been noted in the literature, fistula rates generally vary between 1% and 15%.[230,259,276,277] Unfortunately, they tend to be the more aggressive enteroatmospheric fistulae that occur within the granulating bed of the open abdominal wound with lower nonsurgical closure rates than typical fistula (around 25%).[232] When encountered, standard therapies of bowel rest and total parenteral nutrition are begun. While many techniques exist in the literature beyond use of frequent dressing changes and suction drains, all fall short of ideal in controlling the caustic effluent.[278-283] Thus, different strategies must be known as individual patients will have differing responses to a therapy. If effluent control can be obtained, a skin graft may be useful for placement of an enterostomal appliance, and the fistula managed as an ostomy. Fistula closure is normally deferred until abdominal wall reconstruction and is associated with increased complications.[284]

DAMAGE CONTROL AND ABDOMINAL SEPSIS

Emergency general surgery has adopted the techniques of damage control and the open abdomen. Many of the management concerns of the damage control trauma patient and the abdominal sepsis patient during the resuscitation and open abdomen phases overlap. The open abdomen allows for instant access to the peritoneal cavity and improved peritoneal toilet with control of effluent, when further debridement is needed or source control cannot be obtained due to patient hemodynamic instability.[16] The present studies have been small, often with mixed populations of abdominal sepsis, trauma, and ACS, and vary concerning mortality between the open and closed abdomen cohorts.[17-20,285,286] The prevention of ACS probably has most influence on outcomes after an operation for peritonitis.

However, alterations to the damage control sequence are needed for abdominal sepsis patients. An intra-abdominal catastrophe without hemorrhage needs initial stabilization of vitals, which with aggressive resuscitation can generally be done in a few hours, preceding operative intervention to prevent hemodynamic collapse on anesthesia induction. The operative goal is source control and wide drainage of the surgical process. A temporary abdominal closure is used when multiple operations are needed for debridement/source control, significant visceral edema prevents closure or further resuscitation has a high risk of creating an ACS, or the patient's hemodynamic instability precludes further operative intervention. Afterward, resuscitation is performed again. The development of a distributive shock, which is generally self-limiting to a few days, is common after operative intervention in an infected surgical field. The heretofore described open abdomen techniques can be used to manage the open abdominal wound, especially with control of effluent from the abdominal wound. They do not replace wide drainage of the surgical field, however. Compared to patients with traumatic injury, fascial closure rates may be lower.[287]

CHAPTER 7 ■ AIRWAY MANAGEMENT

MATTHEW KEITH WHALIN, CARLA IRENE HAACK, TIMOTHY G. BUCHMAN, AND PAUL S. GARCIA

HISTORY, DEFINITIONS, AND BASICS

"There is nothing living that does not breathe, and nothing breathing that does not live."
—*Lectures on the Whole of Anatomy* (Harvey, 1653)

William Harvey's recognition of the importance of ventilation marked a turning point in medical history. Prior generations of practitioners followed the teachings of Galen who opined that the lungs existed to cool the heart. Following Harvey, 18th Century European communities organized "Rescue Societies" to save drowning victims.

As airway structures were increasingly recognized for their specific roles as conduits of gases destined for the alveoli; oral and nasal devices were developed for the specific purpose of resuscitation. These were naturally adapted to stabilize airways for use with first-generation inhalational anesthetics such as chloroform. Periodically, airway emergencies would occur. Tracheostomy, which had fallen into disrepute during the middle ages, reappeared as an essential tool for anesthesiologists when performed by John Snow (who famously delivered chloroform as an obstetrical anesthetic to Queen Victoria) to save a patient's life. As anesthesia itself disseminated through surgical practice, so did the need for surgical airway skills.

Fortunately, technology has made the need for emergent surgical airways rare. Airway management progressed from natural airways and "blind" techniques, through direct visualization, and is now facilitated by video tools including videolaryngoscopy and fiberoptic laryngobronchoscopy. As emergent surgical airways are performed less frequently, some of those skills have been lost, yet operative teams (surgeons and anesthesiologists) must find common strategies to ensure that the procedure can be performed safely when needed. The need is invariably urgent or emergent. Thus, consideration of alternative airway strategies (Plan A, Plan B…, surgical airway) is an essential part of every airway plan.

IS AN ARTIFICIAL AIRWAY NECESSARY?

Before selecting a strategy for securing an artificial airway in an acute care situation, practitioners must first ask themselves whether airway manipulation is necessary. Adequate surgical anesthesia can often be accomplished by either peripheral nerve blockade or neuraxial (spinal/epidural) techniques, especially where limb or pelvic surgery is required. While these skills require advanced training and in some cases specialized equipment not immediately available in all situations, infiltrative local anesthesia should also always be considered as an option for the procedurally trained acute care physician, as it has been used successfully in several trauma situations including cesarean section,[1] craniotomy for epidural hematoma,[2] and facial injury after motor vehicle accidents that include zygomatic arch fractures and multiple lacerations.[3] Irrespective of the situation, training in airway management is crucial for every acute care physician, because unexpected events are frequent occurrences[4] and preparedness is a high priority.

Herein, we define a "secured airway device" to be a patent conduit for gas exchange that is unlikely to fail through conventional manipulation of a patient's body position encountered during a perioperative period (including transport to/from stretchers, ICU beds, and operating room tables). A "definitive airway device" is defined as a patent conduit for gas exchange that involves the trachea and a specialized plastic connection, which universally fits most ventilators and manual ventilation equipment. Current advanced cardiac life support (ACLS) guidelines use a slightly broader term (the "advanced airway device") to describe tubular conduits that facilitate ventilation.[5] By this definition, some advanced airway devices require advanced skill and training (endotracheal tubes), while others require minimal skill and training (such as the supraglottic airways [see laryngeal mask airways (LMAs) and Combi-tubes below]). In most acute care situations, a definitive airway such as an oral endotracheal tube is preferred over the supraglottic advanced airway devices. However, certain scenarios necessitate the use of an LMA or Combi-tube (or even mask) on a temporary basis.

After placement, the position and patency of all airway devices must be confirmed as soon as possible by either direct means (visualization of conduit in trachea) or indirect means (e.g., end-tidal CO_2, blood gas results, or chest x-ray). The "gold standard" for accepting any airway device as functional is end-tidal CO_2 monitoring as it provides nearly instant physiologic confirmation of cardiac output and successful gas exchange. Because a secured airway device known to exist in the trachea is a definitive airway device and a definitive airway device becomes secured with either strong adhesive tape or through the use of a mechanical strap holder, these two terms will often be used interchangeably in clinical settings. Moreover, in clinical practice of acute care surgery, the word "device" is often omitted, as in "the patient's airway was secured."

To avoid confusion with specific anatomical structures, also referred to as airways, this shortening will be avoided. For this chapter, we will assume all secured airway devices are confirmed and all definitive airway devices are confirmed and subsequently secured unless explicitly noted.

COMMON DEVICES AND TIMING OF PLACEMENT

The three most common definitive airway devices in acute surgical care patients are the oral endotracheal tube (oral ETT), the nasal ETT, and the tracheostomy tube.[6] Besides specialized semipermanent tracheostomy tubes, these devices all contain an inflatable bulb designed as a barrier to prevent the entry of stomach contents or copious oral secretions into the conducting airways (see aspiration below). The choice of device will depend on several factors such as procedure site, ease of placement, and hemodynamic stability of the patient. In most patients, the oral ETT is the most efficient way to establish a definitive airway (see below for difficult airway considerations and intubation techniques). Because placement of an oral ETT is facilitated with neck extension (and in some instances flexion), precautions must be taken in patients with

known or suspected cervical instability. Basal skull fractures are an absolute contraindication to nasal ETTs. Tracheostomy or needle cricothyrotomy as a bridge to tracheostomy (see end of Chapter) constitutes the default backup plan for any acutely ill patient in whom a definitive airway device cannot be established by other means. Although the oral ETTs are the most common airways in these patients, a tracheostomy is an acceptable (and sometimes desirable) plan "A" in patients with a suspected or known difficult airway who are likely to require mechanical ventilation for extended periods of time.

Protection of the airway is often used as a justification of the establishment of a definitive airway. Common wisdom holds that as a patient progresses through depressed levels of consciousness, the airway reflexes attenuate and the inability to cough and swallow secretions may lead to an increased risk of aspiration of stomach contents. It is prudent to consider the use of a definitive airway device in a patient whose Glasgow Coma Scale (GCS) is deteriorating. Many clinicians regard descent through a GCS of 9 as an indication to establish a definitive airway device, although the patient's history and baseline mental status must also be considered. While generally accepted as an indication for endotracheal intubation, a GCS of <9 is not necessarily a contraindication to extubation.

Aspiration has traditionally been associated with poor outcomes in trauma patients.[7,8] High morbidity and mortality is associated with the development of chemical pneumonitis or aspiration pneumonia. Prevention of aspiration is therefore a goal of airway protection. It is prudent to delay elective surgery until a patient has fasted for 8 hours or more, to allow time for gastric emptying. Some controversy surrounds the specific time interval. In 2011, the American Society of Anesthesiologists (ASA) revised their published guidelines to include special considerations for otherwise healthy patients not at increased risk for delayed gastric emptying. For these patients, the recommended minimum fasting period for clear liquids is 2 hours, and 6 hours for nonhuman milk and for light meals not containing fried or fatty food.[9] Regardless, major trauma can slow gastric emptying (as can diabetes and hiatal hernias) and, if possible, prophylactic treatment with antacids, H2-blockers, and agents that speed gastric motility are recommended as long as their administration does not impede more urgent treatments.

Other risks and complications associated with intubation are both less common and less severe than the failure either to mask ventilate or to establish a secure airway. Tooth, gum, and lip damage can occur with any oral manipulation. Nasal ETTs are traumatic to the nasal mucosa. Bleeding can be minimized with a topical vasoconstrictor, such as phenylephrine. The posterior pharynx can be inadvertently penetrated.[10] Such penetration is a major concern in patient who had previously received radiation treatment to the head, neck, or face.

MASK VENTILATION

Mask ventilation is the most fundamental and essential skill of airway management, yet it is undervalued from educational and clinical perspectives. Whether a patient requires sedation for a minor procedure or is facing pending respiratory failure, evaluation for potentially difficult mask ventilation should occur in tandem with evaluation for potential difficult intubation (see Tables 7.1 and 7.2). It is easy for mask ventilation to become an afterthought in the acute care setting since most patients in trauma surgery are generally intubated without masking to minimize aspiration risk (see section on Rapid Sequence Induction). When intubation fails in a patient who is easy to mask ventilate, there is time to call for help, retrieve additional equipment, or prepare for a surgical airway. In contrast, failed intubation of a patient who is difficult or impossible to mask ventilate can rapidly become a fatal situation. Thus, even in the

setting of emergency surgery where time is of the essence, identification of the patient who is a potentially difficult to mask ventilate should prompt a discussion between the surgeons and anesthesiologists about contingency plans for failed intubation.

It is critical to rapidly assess the adequacy of mask ventilation and make adjustments (or abandon attempts at masking) in a timely fashion. As discussed in a recent review,[11] adequacy can be difficult to define. What is considered safe in the operating room may be of questionable security in the trauma helicopter or hospital elevator. The modern anesthesia machine in most operating rooms not only provides inhaled anesthesia but is well-equipped with several monitors capable of assessing adequacy of ventilation. The flexible bag connected to the anesthesia machine will deflate and inflate with the spontaneous ventilation of a patient as long as the mask is well-placed

TABLE 7.1

SUMMARY OF POOLED SENSITIVITY AND SPECIFICITY OF COMMONLY USED METHODS OF AIRWAY EVALUATION

EXAMINATION	SENSITIVITY (%)	SPECIFICITY (%)
Mallampati classification	49	86
Thyromental distance	20	94
Sternomental distance	62	82
Mouth opening	46	89

Data derived from Wilson ME, Spiegelhalter D, Robertson J, et al. Predicting difficult intubation. *Br J Anaesth*. 1988;61:211.

TABLE 7.2

ASSESSMENT AND PREDICTABILITY OF DIFFICULT MASK VENTILATION

CRITERIA FOR DIFFICULT MASK VENTILATION
Inability for one anesthesiologist to maintain oxygen saturation >92%
Irreparable gas leak around face mask
Need for ≥4 L/min gas flow (or use of fresh gas flow button more than twice)
No chest movement
Two-handed mask ventilation needed
Change of operator required

INDEPENDENT RISK FACTORS FOR DIFFICULT MASK VENTILLATION	
PATIENT FEATURE	ODDS RATIO
Presence of a beard	3.18
Body mass index >26 ng/m²	2.75
Lack of teeth	2.28
Age > 55 y	2.26
History of snoring	1.84

From Langeron O, Masso E, Huraux C, et al. Prediction of difficult mask ventilation. *Anesthesiology*. 2000;92:1229.

("sealed") to the face. It is important to recognize that the bag for manual ventilation in the operating room performs differently from the more familiar self-inflating (Ambu TM) bag. During manual ventilation in the apneic patient, the bag in the operating room will fail to reinflate with leakage of air, and often this is a clue that the mask may need to be readjusted (see C-E technique below). The digital readout of the exhaled tidal volume can also be used to confirm delivery of manually or machine-delivered ventilated breaths. Most importantly, a persistent end-tidal CO_2 ($etCO_2$) waveform on the capnograph signals gas exchange. With most sampling systems, $etCO_2$ will only appear after several breaths. Importantly, the appearance of $etCO_2$ verifies both ventilation and perfusion. This makes $etCO_2$ monitoring an especially important tool.

Outside of the operating room, it can be challenging to assess the adequacy of mask ventilation. Bag movement is unreliable as most emergency carts are stocked with self-inflating bags. Physical examination should reveal chest rise and breath sounds with spontaneous or manual ventilation. Although less reliable than $etCO_2$, the observation of condensation in the mask is a good sign that gas exchange is taking place. Similarly, maintenance or improvement in oxygen saturation (as measured by arterial blood gas or pulse oximetry) is another indirect method that provides confidence in one's ventilation technique. However, $etCO_2$ is quickly being recognized as the gold standard monitor of ventilation. The ASA's 2010 monitoring guidelines recommend $etCO_2$ monitoring for deep sedation and the 2010 ACLS guidelines encourage its use in CPR.[5] These guidelines may translate to increased availability of these monitors outside the operating room. Local administrators and their clinical leaders should include $etCO_2$ monitoring capability as they evaluate purchasing of new equipment.

Problems with mask ventilation can generally be classified into one of two categories: (1) difficulty creating an adequate seal or (2) obstruction to airflow. Examples of the former include patients with thick beards, edentulous patients, and patients with severe facial trauma. Obstruction to airflow may occur anywhere along the airway, from bronchoconstriction or masses within the lungs to laryngospasm to collapse of the upper airway in a patient with obstructive sleep apnea. Even in the absence of sleep apnea, morbid obesity can lead to enough extrathoracic pressure to impede mask ventilation. Chest compressions performed as part of cardiopulmonary resuscitation can divert mask ventilation breaths from the lungs to the stomach, and for this reason, current (as of 2010) ACLS guidelines mandate that cycles of 30 compressions followed by two quick breaths be continued until an advanced airway is in place.[5] Subtle improvements in the technique of mask ventilation as well as airway adjuncts can alleviate many cases of difficult mask ventilation.

In traditional one-handed masking, the practitioner's left hand is responsible not only for creating an adequate seal, but also for minimizing upper airway obstruction by providing jaw thrust. The left thumb and index finger form a "C" and apply the mask to the face, taking care not to compress the bridge of the nose or interfere with the eyes. The remaining three fingers are spread along the mandible to form an "E," with the fifth digit behind the angle of the jaw to maximize vertical thrust. Novices and trainees need to be constantly reminded to "lift the face to the mask" rather than pressing the mask on the face. It is also important to remember that the jaw thrust is very uncomfortable and should not be performed on conscious patients whose airway muscular tone is adequate to prevent their tongue from obstructing their airway.

At the first sign of difficulty with one-handed masking, two adjustment techniques are available to the lone practitioner. One is to use both hands to readjust the mask seal and provide maximal jaw thrust, as sometimes it is easier to maintain a strong jaw thrust with one hand than it is to create one with a single hand. Having optimized the seal and jaw thrust, the right hand goes back to squeezing the bag. The second technique is placement of airway adjuncts (orally or nasally), often followed by the two-handed readjustment described above.

Airway Adjuncts

Placement of an oral airway is often facilitated by using a wooden tongue depressor. Without a depressor, the oral airway should initially be inserted with the curve pointing away from the tongue, and then rotated to follow the curve of the tongue as the tip reaches the posterior pharynx. Either way, care must be taken to bring the tongue forward to open the airway, but not so far that it rests between the lower teeth and the oral airway (which could lead to laceration). It is important to select a size appropriate to the patient, though a size 10 (100 mm) oral airway is adequate for most adults. A properly placed oral airway is typically very effective at facilitating mask ventilation, but this adjunct should only be placed in patients with depressed levels of consciousness, as it sits at the base of the tongue and can be uncomfortable and stimulate a gag reflex.

Nasopharyngeal airways ("nasal trumpets") are better tolerated in awake patients, though they should be avoided in patients with known or suspected skull base fractures. The nasal airway should be long enough to extend past soft tissue obstruction but not so long as it contacts the base of the tongue as the trumpet could be occluded by a large tongue or stimulate a gag reflex. Usually, size 30-34 is appropriate for adults, but it is prudent to check the fit by holding it against the side of the face to see if it extends from the nare to the angle of the mandible using its natural curve.

When repositioning and airway adjuncts do not allow adequate one-handed masking, you should progress to two-handed masking or alternative approaches to airway management. Even experienced anesthesia providers using oral airways in routine cases deliver larger tidal volumes with two-handed masking, and a two-handed technique should be used as soon as practicable.[12] Most acute care situations involve either a self-inflating mask bag or an anesthesia machine, which necessitates the aid of a second provider to squeeze the bag. There are several approaches to two-handed masking, but one common method is to apply a seal with both thumbs and use the remaining fingers to maximize jaw thrust. In some situations, a third person is needed to depress the mask at an area of leak.

It is important to remember that the total volume of most adult-sized bags is 2 L and adverse effects of delivering the entire volume in some situations can occur. In patients with a full stomach, every attempt should be made to avoid delivering high volumes and pressures to prevent emesis from stomach distention. It is estimated that delivering pressures of over 20 cm H_2O can open the lower esophageal sphincter in patients with normal esophageal anatomy. Normal tidal volumes vary between 4 and 8 mL per kg of ideal body weight. Positive-end expiratory pressure (PEEP), most commonly accomplished through the use of a specialized valve, is a preferred method for maintaining recruitment of end alveoli during manual ventilation as opposed to delivering large tidal volumes. The respiratory rate must allow for an appropriate time of exhalation, especially in patients with chronic obstructive pulmonary disease who may be more prone to "breath-stacking" or auto-PEEP.

In an emergency situation, it is time-consuming and dangerous to progress through each of these modifications in a stepwise fashion. For these cases, it is prudent to immediately place a nasal or oral airway adjunct. Outside of the operating room where patient positioning may be suboptimal and monitors of the adequacy of ventilation are less accessible, it

is appropriate to begin with two-handed masking if enough help is available. In situations of cardiac arrest, the acute care surgeon is often supervising resuscitation efforts and should be sure that ventilation is being optimized with oral airways and two-handed masking. As part of the quality improvement program at our level 1 trauma hospital, we found that these techniques were being used in only 25% of cardiac arrests in a 6-month sample set (manuscript in progress). Finally, it is important to remember that adequate mask ventilation should not be considered a long-term solution for most acute care situations as blood in the airway, facial edema and fluid shifts, or provider fatigue can quickly turn adequate mask ventilation into an airway emergency.

ENDOTRACHEAL INTUBATION

Direct Laryngoscopy: Evaluation and Performance

Should a patient require an advanced airway, whether for elective surgery or respiratory failure, an endotracheal tube is often the first choice. As with all aspects of airway management, planning and preparation are paramount even in critical situations. After taking the patient history and clinical situation into account, the next step in the process is evaluation of the airway.

Despite ongoing attempts to apply evidence-based medicine to the prediction of difficult intubations, existing tests suffer from low specificity.[13] We favor an airway evaluation that can be completed quickly and without complicated anatomical measurements or calculations. Bedside measurements in finger breadths are common. Every practitioner should be aware of exactly how many centimeters are spanned with two and with three finger breadths of his/her hand. Potentially difficult intubations are suggested by limited mouth opening, limited neck extension, limited ability to prognath the jaw, immobility of anterior neck tissues (e.g., radiation changes), and a short thyromental distance (<5 cm). The Mallampati classification (Fig. 7.1) refers to the view obtained by asking a patient sitting upright to open his mouth maximally and protrude his tongue. A view of the tonsillar pillars constitutes class I, view of part but not the entire uvula is class II, soft palate only is class III, and hard palate only is class IV. Identification of a class III or IV view raises concern for potentially difficult intubation. The test is properly performed without the patient phonating, but if a poor view does not improve with phonation, it is particularly worrisome. Practitioners must be aware that serial attempts at laryngoscopy lead to trauma, bleeding, and edema, all of which conspire to make the next attempt more difficult: every effort should be made to optimize conditions for the first attempt.

Preoxygenation is one of the cornerstones of preparation for intubation. It prolongs the time between apnea and desaturation not only by maximizing oxygen saturation of

FIGURE 7.1. Photographic examples of Mallampati class. **A-D:** Mallampati I-IV. (From Barash PG, Cullen BF, Stoelting RK, et al. *Clinical Anesthesia*. 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009.)

hemoglobin, but also by replacing the nitrogen in the patient's functional residual capacity with oxygen. One convenient endpoint to preoxygenation is delivery of oxygen to the spontaneously breathing patient until the measured expired oxygen concentration equals or exceeds 90%. Many critically ill patients will never reach this goal and outside of the operating room there is rarely access to a gas analyzer, so one must remain flexible in this regard. Even after a prolonged period of preoxygenation, patients who are obese or who have limited physiologic reserve can desaturate within seconds of becoming apneic. It is therefore essential to have all necessary equipment assembled, organized, and within easy reach. No matter what the setting, patient positioning often sets the stage for success or failure.

One aspect of positioning involves ergonomics. To facilitate visualization of the airway structures without leaning or bending, the patient should be moved up to the end of the bed and the height set so that his or her head comes to the level of the xiphoid process of the laryngoscopist. In emergent situations, it is sometimes necessary to intubate patients on the ground or in a lateral or prone position, but this increases the difficulty significantly. Another aspect of positioning involves the creation of a direct line of sight from the patient's mouth to his vocal cords. For patients with a normal body habitus, slight elevation of the head on a folded sheet and extension of the neck into a "sniffing position" can facilitate direct laryngoscopy. An obese patient should have her upper body on an incline sufficient to keep the angle of her jaw higher than her sternal notch (Fig. 7.2). When viewed from the side, the patient's upper body appears to be on a "ramp".

With the patient optimally positioned and preoxygenated, equipment should be arranged within easy reach. This equipment should include a rigid suction device, endotracheal tubes of the appropriate sizes, and working laryngoscopes. The suction device (typically a curved plastic "Yankauer" suction tip) is essential to clear debris or secretions obstructing view of the cords and to quickly remove emesis should it occur. The laryngoscope light source should be bright enough to create a spotlight on an object 5 or more centimeters from the tip. Laryngoscopes are designed to be held in the left hand.

Laryngoscope blades come in two basic styles: straight and curved.

The most common straight blade is the Miller blade, first introduced in 1941. The tip of the blade is used to lift the epiglottis to develop a straight line of sight to the vocal cords. Its use requires great control since small movements can cause the epiglottis to slide off the end of the blade. It is also challenging to maintain a view while inserting the tube and it is sometimes useful to have an assistant pull on the right corner of the patient's mouth to create more space. Although straight blades are extremely effective in experienced hands, curved blades might be considered easier to master.

Robert Macintosh introduced a laryngoscope with a curved blade in 1943 and it remains widely used today. The flange facilitates displacement of the tongue to the left side of the mouth. The tip of the blade is placed in the vallecula and the laryngoscopist applies caudad and ventral force to develop a view of the vocal cords. With both the straight and curved blades, any rocking motion of the wrist will result in dental trauma. Such rocking motion is to be avoided, but a number of other techniques can often improve a poor view.

To create a direct line of vision to the vocal cords, it is sometimes necessary to lift the patients head off the bed and further extend the neck. The right hand can lift the head to develop the view and that position is maintained by the left hand while grasping the endotracheal tube in your right hand. Another useful technique is bimanual laryngoscopy, in which the laryngoscopist's right hand applies pressure at the cricoid cartilage dorsally, laterally, and longitudinally to bring the cords into view. An assistant can then be instructed to substitute his hand in order to keep the larynx in the identical position while the laryngoscopist places the endotracheal tube.

Even with these maneuvers, it is sometimes only possible to see the arytenoid cartilage. An experienced laryngoscopist will often use an endotracheal tube that has a stylet, which maintains the tube configured with an anterior curve in order to intubate the trachea semiblind. In these situations, or when only the epiglottis is visible, an endotracheal tube introducer (e.g., bougie or Eschmann catheter) may be helpful. Introducers are plastic tubes with some shape memory and a bend

FIGURE 7.2. Achieving proper positioning of the obese patient for airway manipulation. (From Barash PG, Cullen BF, Stoelting RK, et al. *Clinical Anesthesia*, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009.)

2-3 cm from the tip. The tip is directed under the epiglottis and advanced gently until tactile resistance from the tracheal rings is felt. An endotracheal tube is then advanced over the introducer akin to the Seldinger technique for vascular cannulation. This technique is less straightforward than it seems; the endotracheal tube may be unable to move past the curve of the posterior pharynx or at the level of the epiglottis and may require additional manipulation (i.e., twisting) to move the tube into the trachea.

Following placement of an endotracheal tube, the operator is responsible for immediately seeking verification of proper placement. While condensation in the tube and chest movements with manual ventilation are reassuring signs of endotracheal placement, one must also auscultate the axillae for bilateral and symmetric breath sounds as well as verifying the absence of sounds over the stomach. Most importantly, there should be persistent exhaled CO_2 as assayed by a capnograph or a disposable color change device (but again recall that in a cardiac arrest there may be insufficient blood flow to carry CO_2 to the lungs). Advancement of the endotracheal tube too deep will result in an endobronchial intubation (typically in the right main stem). Some of the signs of endobronchial intubation are mimicked by many other conditions in the acutely ill: asymmetric breath sounds and low pulse oximetry. Hemodynamic instability can also be a sign of endobronchial intubation if the delivered tidal volume results in large enough intrathoracic pressures to periodically impede venous return through compression of the vena cava and right atrium. Endobronchial intubation should be suspected when increased peak airway pressures are noted (either quantitatively by digital monitor or qualitatively by difficult manual ventilation by bag).

Whenever the endotracheal tube location is in doubt, either immediate visualization with a fiberoptic broncoscope or else a chest x-ray should be used to confirm proper position. Besides the possibility of pneumothorax from high intrathoracic pressures, the consequences of an endobronchial intubation might be mild in comparison to the patient's overall acute health status and as long as ventilation is possible (even if suboptimal), the diagnosis of endobronchial intubation should not delay surgical intervention in the most acutely ill patient. However, we recommend confirmation of proper airway placement of endotracheal tubes (through end-tidal CO_2 monitoring) in most cases before proceeding with invasive procedures or surgery. It is also important to secure the endotracheal tube with tape or a specialized device to avoid airway disasters after a procedure has begun.

The Importance of Documentation

After intubation, it is important to document the type of blade used, number of attempts, and depth of the tube in an airway note. The note should comment on the ease of mask ventilation (one hand vs. two, with or without oral airway) and should mention any special techniques used (ramping, cricoid pressure, endotracheal tube introducer). It is also useful to record the view of the glottis. The modified Cormack and Lehane classification categorizes views as follows: entire vocal cords is grade 1, partial view of the cords is grade 2a, arytenoids only is 2b, epiglottis only is grade 3, and neither the glottis nor epiglottis is grade 4. The original system called grade 2 anything more than the epiglottis alone but less than the full cords. Subdividing class 2 gives very useful information since in one study 65% of grade 2b views were deemed difficult intubations versus only 13% of grade 2a views.[14]

If there is time, locating prior airway notes should be part of the airway evaluation. A history of difficult intubation should prompt special preparation for alternative techniques. Even a patient who was easy to intubate last year or last week may now be difficult due to weight gain, surgery, radiation treatment, or the development of edema, bleeding, or masses in the airway. If the overall evaluation of the airway suggests a potentially difficult mask or intubation, a clear plan with alternative strategies should be formulated in advance (see ASA Difficult Airway Algorithm, Algorithm 7.1, from American Society of Anesthesiologists).[15]

Alternatives to Direct Laryngoscopy

Endotracheal intubation can be achieved by a number of methods other than direct laryngoscopy. One such method is the use of a video laryngoscope such as the Glidescope or Pentax AWS. These systems have a miniature camera incorporated into the laryngoscope blade and connected to a viewing monitor. This allows the operator (and other team members) to "see around the corner" and can produce excellent views of the glottis when immobility of the neck, a large tongue, or a short thyromental distance would make a direct view nearly impossible. Nevertheless, this excellent view does not always translate into an easy intubation. Just as a direct line of sight allows a direct path for the endotracheal tube, so an indirect view implies a circuitous path for the tube to travel. A stylet is almost mandatory, and some systems come with specialized stylets to match the curve of the blade.

Another technique for indirect visualization of the glottis is fiberoptic bronchoscopy. Fiberoptic intubation was pioneered in the 1970s by Dr Andranik Ovassapian and remains the gold standard approach for a difficult airway. There are numerous variations on the technique, which are beyond the scope of this chapter. It allows placement of either nasal or oral endotracheal tubes in patients who are either apneic or spontaneously ventilating.

While fiberoptic intubation may be the gold standard in predicted difficult airways in elective surgery, only the most experienced providers should attempt this in the acute situation, and if unsuccessful, in an agreed upon time by the leaders of the surgical and anesthesia team, a surgical airway should be considered. In situations where visualization is not possible or emergencies in which specialized airway devices are not readily available, a retrograde wire technique may be used to facilitate endotracheal intubation. The method requires an 18-gauge angiocatheter connected to a syringe half-full with saline or lidocaine as well as a wire at least 70 cm long. With the angle of the angiocatheter directed cephalad, the cricothyroid membrane is entered slowly while continuously aspirating on the syringe. Entrance to the trachea is signaled by aspiration of air bubbles, at which point the syringe is held steady and the catheter advanced to its hub. After withdrawing the needle, position is reconfirmed by attaching the syringe to the catheter and withdrawing air once again. Then the wire is advanced cephalad and fished out of the mouth (or perhaps the nose) with forceps. The wire is then used to guide an oral or nasal endotracheal tube.
Retrograde intubation can be useful in an emergency but there are a number of potential complications. If the catheter is advanced too deep, it can inadvertently proceed through the posterior trachea and into in the esophagus and still give air return with aspiration. The endotracheal tube can get stuck on the epiglottis or arytenoid cartilage. Rotating the tube in 90-degree increments can sometimes address this, but some practitioners use a second wire to elevate the epiglottis.

The initial steps of placing an 18-gauge angiocatheter into the tracheal lumen are the same for needle cricothyrotomy as they are for retrograde intubation. By administering short bursts of high-flow oxygen through the angiocatheter

DIFFICULT AIRWAY ALGORITHM

1. Assess the likelihood and clinical impact of basic management problems:
   - A. Difficult Ventilation
   - B. Difficult Intubation
   - C. Difficulty with Patient Cooperation or Consent
   - D. Difficult Tracheostomy

2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management

3. Consider the relative merits and feasibility of basic management choices:

   A. | Awake Intubation | -vs.- | Intubation Attempts After Induction of General Anesthesia |

   B. | Non-Invasive Technique for Initial Approach to Intubation | -vs.- | Invasive Technique for Initial Approach to Intubation |

   C. | Preservation of Spontaneous Ventilation | -vs.- | Ablation of Spontaneous Ventilation |

4. Develop primary and alternative strategies:

A. AWAKE INTUBATION

Airway Approached by Non-Invasive Intubation — Invasive Airway Access(b)*

Succeed* — FAIL

Cancel Case — Consider Feasibility of Other Options(a) — Invasive Airway Access(b)*

B. INTUBATION ATTEMPTS AFTER INDUCTION OF GENERAL ANESTHESIA

Initial Intubation Attempts Successful* — Initial Intubation Attempts UNSUCCESSFUL

FROM THIS POINT ONWARDS CONSIDER:
1. Calling for Help
2. Returning to Spontaneous Ventilation
3. Awakening the Patient

FACE MASK VENTILATION ADEQUATE — **FACE MASK VENTILATION NOT ADEQUATE**

CONSIDER / ATTEMPT LMA

LMA ADEQUATE* — LMA NOT ADEQUATE OR NOT FEASIBLE

NON-EMERGENCY PATHWAY
Ventilation Adequate, Intubation Unsuccessful

EMERGENCY PATHWAY
Ventilation Not Adequate, Intubation Unsuccessful

Alternative Approaches to Intubation(c)

IF BOTH FACE MASK AND LMA VENTILATION BECOME INADEQUATE

Call for Help

Emergency Non-Invasive Airway Ventilation(e)

Successful Intubation* — FAIL After Multiple Attempts

Successful Ventilation* — FAIL

Invasive Airway Access(b)* — Consider Feasibility of Other Options(a) — Awaken Patient(d)

Emergency Invasive Airway Access(b)*

* Confirm ventilation, tracheal intubation, or LMA placement with exhaled CO_2

a. Other options include (but are not limited to): surgery utilizing face mask or LMA anesthesia, local anesthesia infiltration or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the Emergency Pathway.

b. Invasive airway access includes surgical or percutaneous tracheostomy or cricothyrotomy.

c. Alternative non-invasive approaches to difficult intubation include (but are not limited to): use of different laryngoscope blades, LMA as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, retrograde intubation, and blind oral or nasal intubation.

d. Consider re-preparation of the patient for awake intubation or canceling surgery.

e. Options for emergency non-invasive airway ventilation include (but are not limited to): rigid bronchoscope, esophageal-tracheal combitube ventilation, or transtracheal jet ventilation.

ALGORITHM 7.1

ALGORITHM 7.1 ASA difficult airway algorithm. (Adapted from practice guidelines for management of the difficult airway: an updated report by the american society of anesthesiologists task force on management of the difficult airway. *Anesthesiology*. 2003;98(5):1269-1277.)

into the conducting airways, oxygenation of the patient can be accomplished on an emergency basis. This procedure should only be viewed as a temporary measure until someone with experience in either retrograde intubation or more invasive techniques (see below) can provide definitive airway management. During delivery of high-flow oxygen via catheter, appropriate time must be given to allow for the egress of air from the lungs, or barotrauma will occur. For most surgeons, a cricothyroidotomy would be just as fast as and more reliable than retrograde intubation or needle cricothyrotomy.

CERVICAL SPINE PRECAUTIONS

Victims of blunt force or penetrating trauma may have acute surgical issues that take priority over known or suspected injury to the cervical spine. The management of airways in patients with possible neck injury that involves the cervical spine deserves special consideration. It is customary to have a second provider apply manual in-line stabilization prior to and throughout laryngoscopy. In a study of elective surgery patients, 55% of the in-line stabilization group had grade 3 or 4 vocal cord views and half of the group overall could not be intubated by direct laryngoscopy within 30 seconds by experienced anesthesiologists.[16] Another small study showed that in-line stabilization leads to a doubling of force applied by a Macintosh laryngoscope, which the authors postulate could paradoxically cause more motion of the cervical spine.[17] A number of studies have demonstrated that video laryngoscopes allow intubation with decreased motion of the cervical spine, and their use should be considered whenever available (reviewed in Dupanovic et al.[18]).

A blind technique called the Lightwand may have some utility in patients who cannot extend their neck due to suspected or confirmed cervical neck fractures. Custom semirigid camera or fiberoptic devices have also been developed and many practitioners can become quite proficient with frequent use, but a detailed discussion of these techniques is beyond the scope of this chapter.

ALTERNATIVES TO ENDOTRACHEAL INTUBATION

Laryngeal Mask Airway

The LMA was developed in the 1980s to provide an alternative to inhaled general anesthetics delivered by face mask.[19] In patients at low risk for aspiration undergoing procedures which do not require paralysis, the LMA provides a very effective airway. A well-seated LMA can sustain airway pressures up to 20 cm of water without an air leak. Many practitioners feel that they are best suited for cases in which the patient is spontaneously breathing, but LMAs have been successfully used with neuromuscular blockade.[20] The latest generation of devices (e.g., LMA ProSeal) claims a 30 cm of water seal and integrated channels for gastric venting and drainage. Although there are a few limited reports of this new device being used in nonacute laparotomies,[21] there is not enough evidence to support its routine use in acute trauma situations, and we recommend any supraglottic airway device only as a temporizing measure toward definitive airway management.

Although acute settings predispose to aspiration, the LMA has an important role in emergency airway management. As described in the ASA difficult airway practice guideline,[15] if initial intubation attempts fail and mask ventilation is not adequate, then successful placement of a LMA allows the luxury of time and pursuit of "nonemergency" strategies. For example, the LMA can act as a conduit for fiberoptic intubation via an exchange catheter. According to the 2010 ACLS guidelines,[5] an LMA constitutes as an advanced airway and therefore allows continuous chest compressions instead of cycles of CPR interrupted by ventilation.

Esophageal–Tracheal Combination Tubes

Although seldom placed in the hospital, airways such as the Combi-tube TM and laryngeal tube are mainstays of prehospital airway management. These devices are inserted blindly and have two cuffs: one supraglottic cuff and one tracheal. In the event of esophageal intubation with a Combi-tube TM, the breathing circuit is connected to a second lumen going to a sideport proximal to the tracheal cuff. After arrival to the hospital, leaders of the surgical and anesthesia teams should discuss when this should be changed to an endotracheal tube and what technique should be used to make this exchange.

AWAKE INTUBATION

In patients with marginal respiratory function, history of difficult intubation, anticipated difficult mask, or some combination thereof, it is safest to maintain spontaneous ventilation until an endotracheal tube is placed and its position confirmed. Whether the tube is to be placed by laryngoscope or fiberoptic bronchoscope, the key to success is appropriate preparation of the patient. This should include a conversation with the patient outlining the need for awake intubation and what to expect during the process. It is also important to administer an antisialagogue (such as 0.4 mg of glycopyrrolate given by intramuscular injection) 20-30 minutes before the procedure. Manipulation of the airway is extremely stimulating and a number of techniques are available to anesthetize various airway structures.

For nasal intubations, the nares can be topically anesthetized with viscous lidocaine, sometimes in conjunction with a vasoconstrictor to minimize bleeding. This can be accomplished with soaked cotton swabs (placed deep to block the sphenopalatine ganglia) or a nasal trumpet lubricated with lidocaine. The oropharynx may be anesthetized with either viscous or aerosolized lidocaine. Benzocaine spray is another option but carries the risk of methemoglobinemia. The vocal cords themselves are often anesthetized by spraying lidocaine directly on them via the bronchoscope channel (after warning the patient that this will make him or her cough). Alternatively, the cords may be anesthetized by a transtracheal block.

In patients with good landmarks, puncture of the cricothyroid membrane and injection of 4% lidocaine (1-3 mL) directly into the lumen can provide topical anesthesia of the trachea and larynx. This block is also referred to as a recurrent laryngeal nerve block since it locally anesthetizes the structures below the cords. Injection is performed at end expiration so that the solution is inhaled and then coughed cephalad. Vigorous coughing in and of itself may be deleterious in patients with unstable necks so use of this block should be considered with regard to clinical context. To minimize the risk of injury, either the needle should be withdrawn immediately after injection or an angiocatheter should be used for puncture with removal of the needle prior to injection of the lidocaine.

Anesthesia of the territory served by the superior laryngeal nerve may occur with transtracheal block as the local anesthetic is coughed onto the structures superior to the vocal cords. For more reliable anesthesia of the superior laryngeal nerve territory, however, blockade of the nerve itself is sometimes used. The nondominant hand is used to laterally displace the hyoid bone toward the side to be blocked. A 25-gauge needle is inserted at the level of the greater cornu of the hyoid bone and walked off the bone inferiorly until it pierces the thyrohyoid membrane. After negative aspiration of air or blood, 2 mL of 2% lidocaine is injected and the block is repeated on the contralateral side.

Since these techniques are often used in combination, it is important to be mindful of the total amount of local anesthetic delivered. The maximum dose of lidocaine varies between 4.5 mg/kg (lidocaine not mixed with epinephrine) and 7 mg/kg (lidocaine mixed with 1:200,000 epinephrine). Symptoms of lidocaine toxicity include perioral tingling, auditory or visual disturbance, and depressed consciousness. Once the endotracheal tube is placed, whether by laryngoscopy or fiberoptic bronchoscope, it is connected to the circuit and the cuff is gently inflated. After final confirmation of correct placement (either end-tidal CO_2 or collapse of the bag on inspiration), additional anesthetic, anxiolytic, sedative, and paralytic agents (as appropriate) are administered.

INVASIVE APPROACHES TO AIRWAY MANAGEMENT

Cricothyrotomy

Cricothyroidotomy is an ancient procedure (dating back to the 1500s) that remains a popular choice for rapid control of a difficult airway owing to its simplicity. It may be performed after initial endotracheal intubation attempts have failed or as the first attempt in the setting of craniofacial trauma. Properly trained individuals can even perform cricothyroidotomy in the field with good success.[22] One relative contraindication is young age as the risk for subglottic stenosis is higher than conventional tracheostomy.

Thus, emergent cricothyroidotomy should always be in the emergency airway algorithm and the necessary equipment kept at hand. Aseptic skin preparation, a scalpel and the tube destined to become the airway are all that is needed. Additional instruments may include forceps, a hemostat, some form of retractor, and suture. Frequently, a scalpel (No. 10 or No. 15 blade) is the only instrument used. The type of tube used can include cuffed endotracheal tubes with internal diameters of 5.0-7.0 mm or a tracheostomy tube (typically No. 6 or smaller). A rigid stylet can be useful in directing an endotracheal tube caudally, as it can occasionally direct itself retrograde toward the vocal cords upon insertion. While practitioners who are not surgically trained may favor the use of kits that employ "percutaneous" methods for the insertion of cricothyroidotomy tubes, familiarity and practice are important: these kits may contain advanced tools such as breakaway needles and should be mastered prior to their emergent need.

The surface anatomy of the neck should be assessed at the time initial airway attempts are being made or discussed. Skin should be cleansed quickly with antiseptic preparation solution and the anatomic landmarks clearly identified. Universal precautions should be maintained. Hyoid and cricoid cartilages are palpated, as the cricothyroid membrane lies between them. Landmark identification of anatomical structures is complicated by obesity, edema, the presence of

facial/neck hair, and cervical spine immobilization devices. The right-handed surgeon is ideally positioned at the right side of the patient, and vice-versa. This facilitates the stabilization of the trachea and larynx by using the first three fingers of the nondominant hand on the superior cornu of the larynx, allowing the dominant hand the best access to the area of interest. Laryngeal stabilization is crucial as it will allow for palpation of critical structures in the event that visualization is lost. It should be maintained until the airway is secure. Once this has been accomplished, the dominant hand makes a generous (typically, 1.5-2 cm) longitudinal incision in the midline of the neck overlying the membrane. This incision is oriented vertically to decrease the chance of lacerating the anterior jugular veins. The pretracheal tissue and fascia are divided in this manner as well. The membrane is incised transversely. This step is frequently performed blindly, as bleeding or body habitus can make visualization difficult. Care is taken to not injure the posterior tracheal wall. The incision in the membrane is then dilated digitally (the fifth finger is often perfect) or with an instrument such as forceps or a hemostat. In older descriptions of the procedure, the handle of the scalpel is used to dilate the opening in the membrane, but this has been shown to increase the incidence of iatrogenic injury, and, thus, many practitioners are now abandoning this practice. The index finger of the nondominant hand should be used to maintain control of the cricothyroidotomy and guide insertion of the tube distally into the airway. The tube should be placed with the dominant hand, using a gentle, caudally curving motion. Care should be taken to position the tube above the carina, as there is a tendency toward endobronchial intubation due to the length of the tube. Endotracheal tubes should be exchanged for tracheostomy tubes, in a controlled setting, whenever possible. Verification of tube position is essential (as discussed above) and a high index of suspicion should be maintained for endobronchial intubation. If present, the cuff should be gently inflated as to prevent air leak; high cuff pressures (>25 cm H_2O) can damage the tracheal mucosa. Depending on the setting and available equipment, the tube should be secured to the neck with tape or suture. When using a tracheostomy tube, the obturator needs to be in the cannula to facilitate device placement. Once in position, the obturator is quickly removed before connecting to the circuit or reinflating manual ventilation bag (please see the section on "tracheostomy" for additional details on placement of tracheostomy tubes). The flange on the neck plate of the tracheostomy tube is then used to secure the tube in place using suture, tracheostomy ties, or both.

Tracheostomy

Tracheostomy is indicated for patients with prolonged requirements for mechanical ventilation, inability to clear airway secretions, and with difficulty weaning from the ventilator. Advantages include decreased dead space, improved pulmonary toilet and ease of suctioning, and ease of ventilator weaning. Elective tracheostomies can be performed open or percutaneously, with similar complication profile (mortality <1%) regardless of the operative approach. Emergent tracheostomies in the hands of an experienced surgeon are typically faster with an open technique. The tracheostomy tube is built with a neck plate and flange that is secured to the patient with a collar that encircles the neck. The neck plate is frequently sutured to the patient's skin using a permanent monofilament suture that remains in place until the tracheal stoma has matured.

The neck is extended to open the tracheal interspaces. The skin from the mandible to below the sternal notch should be cleansed with sterile prep. The skin incision is made over the tracheal rings below the cricoid cartilage in a transversely oriented fashion, approximately 2 cm in length. Care should be taken at this point to quickly identify and protect (or ligate) the anterior jugular veins as bleeding will obscure the view.

Open Tracheostomy

Once the subcutaneous fat and platysma have been divided, the anterior cervical fascia is encountered and divided along the midline—the strap muscles of the neck should then be separated along their midline raphe, taking care to control bleeding. The isthmus of the thyroid is frequently encountered at this point and requires division, either between clamps followed by suture ligation or with high-powered electrocautery. Care must be taken to avoid use of cautery in the trachea, since the combination of cautery and high oxygen concentration can lead to explosion and fire. Typically, we abandon the use of the cautery as soon as the thyroid isthmus is divided. The tracheal fascia is encountered next and opened to allow for exposure of the second and third tracheal rings. Once again, care must be taken upon opening of the trachea to assess the percent of inspired oxygen that is being used in ventilating the patient. History reveals that opening the trachea might be considered the most important part of the entire operation.[23]

Frequently used methods include inferiorly based flap (Björk method), or the linear tracheotomy. In the Björk method, the trachea is opened using a scalpel to create an inverted u-shaped flap that is one-half to two-thirds of the tracheal width, as viewed anteriorly. The transverse portion is created in the intercartilaginous region between the first and second rings, and then extended inferiorly to cut through the second tracheal ring, and possibly the third. The blood supply to the trachea enters laterally and thus, cautery can prove useful in providing hemostasis in the corners of the inferiorly based flap. A permanent suture on a taper is used to secure the tracheal flap to the skin, ensuring the patency of the tracheal stoma. This facilitates the replacement of the airway should it become dislodged. The endotracheal tube can then be withdrawn under direct visualization. Once the tip of the endotracheal tube is visualized at the top of the tracheal opening, the tracheostomy tube can be advanced into the airway with the obturator in place, with a gentle, posterior, and caudally curving motion. When a linear tracheotomy is used to open the trachea, the use of a tracheal spreader can allow visualization and placement of the tracheostomy tube. Once the tube is in the airway, the obturator is removed. If a dual-cannula tracheostomy tube is employed, the inner cannula must be in place before connecting to the breathing circuit. The position of the tube is verified by chest movement and the detection of end-tidal CO_2. The time between opening the trachea and connecting the circuit should be minimized to prevent collapse of alveoli.

Percutaneous Tracheostomy

A percutaneous approach using specialized kits provides a convenient alternative and with some practice can be used electively. The skin is anesthetized prior to prepping and draping. The initial incision is the same. The pretracheal soft tissues are dissected bluntly and the trachea is exposed. The endotracheal tube is then withdrawn to just below the vocal cords. The trachea is then punctured 1-2 rings caudad to the cricoid cartilage and a guidewire is advanced into the trachea. The tracheal puncture is then dilated to allow placement of the tracheal cannula.

PEDIATRIC CONSIDERATIONS

In general, the approach to pediatric airway management is similar to adults. However, there are important anatomical and physiologic differences between pediatric patients and adults. The infantile larynx is smaller, funnel-shaped (narrowest below the vocal cords), and more anterior when compared with adults (Fig. 7.3). For these reasons, most practitioners favor a straight blade for intubation. Although it is possible to estimate the appropriate size blade, tube, and depth of tube placement from a pediatric patient's age and weight, it is necessary to have a wide variety of sizes readily available (Table 7.3). A convenient rule of "thumb" is to choose an ETT, which is approximately the size (outer diameter) of the patient's little finger. Uncuffed tubes with a larger inner diameter to decrease airway resistance are at times favored for pediatric patients <6 years old. The ETT should not be forced into the trachea of young patients. In general, an air leak around the uncuffed tubes at pressures of 15-20 cm H_2O is considered appropriate.

Because the pediatric patient has a reduced FRC and higher oxygen consumption, desaturation occurs quicker and more dramatically than in adults. In spontaneously breathing neonates, desaturation due to apneic breathing is common and can be associated with drastic bradycardia (especially in the prematurely born). Premature children are also prone to retrolental fibroplasia, which is related to prolonged exposure to high FIO_2. The target for pulse oximetry should be 93%-95% with maintenance of PaO_2 between 60 and 80 mm Hg. Although, several rare congenital disorders are associated with craniofacial abnormalities and difficult intubation (Hurler's syndrome, Goldenhar's syndrome), Down's syndrome (Trisomy 21) is also frequently associated with specific challenges in airway management because of the phenotype, which includes short neck, small mouth, large tongue, and atlantooccipital instability.

Epiglottitis is a life-threatening pediatric infection that involves the upper airway. This acute infection is typically bacterial in origin, occurring most frequently in children 3-7 years old and is accompanied by dysphagia, stridor, salivation, and fever. A common mimic easily ruled out by plain x-ray films is croup (laryngotracheobronchitis). It can also present with stridor but is typically associated with a viral prodrome, gradual onset, and characteristic "barking" cough. It is generally recommended that pediatric patients with epiglottitis go directly to the operating room for airway management.

PHARMACOLOGY AND RAPID SEQUENCE INDUCTION

It is common for experienced practitioners to administer a variety of anesthetic drugs to both render the patient unconscious and block neuromuscular activity to optimize conditions for airway management prior to intubation. It is important to remember in acute care that these drugs may not be prudent in every situation. Many anesthetic drugs can cause hypotension in acutely ill patients, especially those who are hypovolemic from bleeding. In the pulseless patient, drugs are rarely necessary, but it may be necessary to temporarily halt chest compressions during the intubation.
FIGURE 7.3. Comparison of the adult (**A**) versus pediatric (**B**) airway anatomy. (From Barash PG, Cullen BF, Stoelting RK, et al. *Clinical Anesthesia*. 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009.)

Traditionally, etomidate has been considered a good choice for hemodynamic stability. However, hypotension can still occur after administration of this drug, especially if the patient is maintaining normotension from sympathetic overactivation by fear, pain, or drug intoxication (e.g., cocaine). Because the hypotensive patient undergoing trauma surgery is at high risk for awareness under anesthesia,[24,25] benzodiazepines are frequently administered during or shortly after induction, but their use has not been proven to decrease awareness.[26] Benzodiazepines, much like etomidate, may decrease blood pressure in certain situations. Scopolamine has been used in an attempt to facilitate amnesia in trauma patients with low blood pressure but its vagolytic effects on heart rate preclude routine administration. In general, one should avoid large doses of anesthetics and pain medicines known to depress cardiac activity and therefore opioids, propofol, and inhaled anesthetics should be titrated judiciously in patients suspected to be hypovolemic. Depending on the urgency of needed treatment, cautious dosing regimens of these drugs may delay valuable time to treatment.

The NMDA antagonist, ketamine, which has dissociative and pain-relieving qualities, is an interesting choice for induction and maintenance of anesthesia in acute care situations. In normovolemic subjects, it has some symapthomimetic activity. It is generally associated with an increase in heart rate and blood pressure; however, hypotension can occur similar to etomidate if the patient's hemodynamics are dependent on high sympathetic tone. Ketamine can complicate airway management by

GUIDELINES FOR SIZE AND LENGTH OF TRACHEAL TUBES IN CHILDREN

■ AGE	■ INTERNAL DIAMETER (MM)	■ DISTANCE FROM LIPS TO MIDTRACHEA[a] (CM)
Premature	2.5	8
Full term	3.0	10
1–6 mo	3.5	11
6–12 mo	4.0	12
2 y	4.5	13
4 y	5.0	14
6 y	5.5	15
8 y	6.5	16[b]
10 y	7.0	17-18[c]
12 y	7.5	18-20
14 y	8.0-9.0	20-22

[a]Add 2-3 cm for nasal tubes.
[b]Females.
[c]Males.

increasing oral secretions and can complicate neurologic exams as it is associated with unpleasant dreams and nystagmus.

While neuromuscular blockade using succinylcholine and other neuromuscular blocking drugs have been viewed as mainstays of rapid airway management for decades, they may not be appropriate in all management situations. They should never be administered without sufficient anesthesia to decrease consciousness (including the obtunded patient). The administrators of these drugs should be highly trained and confident in their airway management skills as neuromuscular blocking drugs eliminate the patient's ability to generate diaphragmatic movements on a temporary basis and ventilation becomes the responsibility of the clinical team. The depolarizing neuromuscular blocker, succinylcholine, has many beneficial qualities for acute situations (e.g., rapid onset and short duration). However, it is essential to recall that after an adequate dose for intubation (1.0 mg per kg), there is no assurance that the drug's effects will disappear before detrimental or possibly fatal consequences of hypoxemia arise in situations where ventilation by mask or airway device is unsuccessful or impossible. This danger is magnified with the use of nondepolarizing neuromuscular blockers (e.g., rocuronium, vecuronium, cisatracurium) as their duration of action is enhanced. Although a novel cyclodextran molecule, sugammadex, is currently available in Europe for rapid reversal of aminosteroid based, nondepolarizing neuromuscular blocking agents (e.g., rocuronium and vecuronium). Should sugammadex be approved for use in the United States, the preference of neuromuscular blocking drugs in the acute setting may change.

Succinylcholine acts by first depolarizing the nicotinic acetylcholine receptors at the motor end plate before inactivating them. For this reason, muscle fasciculation and a transient increase in potassium is expected upon administration. In the acute trauma situation, succinylcholine is generally considered safe with the exception of patients suspected or known to have potassium levels high enough to cause EKG changes. Caution is also recommended for the use of succinylcholine in patients rehabilitating from extensive burns or large stroke as a large proportion of their regenerating muscle may have extrasynaptic acetylcholine receptors, which are more sensitive to the effects of succinylcholine. Use of succinylcholine in the acute burn or stroke patient is typically not a problem.

Rapid sequence induction (RSI) is a technique favored by many trained in airway management in situations where regurgitation and possible pulmonary aspiration of stomach contents is a major concern.[27] No standard RSI technique exists,[27] but administration of an IV induction agent immediately followed by administration of fast-acting neuromuscular blockade (1.2-2.0 mg per kg succinylcholine, or 0.8-1.2 mg per kg rocuronium) without any mask ventilation are the major steps involved. In RSI, mask ventilation is avoided to prevent filling the stomach with air. Cricoid pressure, originally described by Sellick in the 1950s, is applied to hopefully occlude the esophagus with pressure from the trachea. The necessity and validity of this technique has been debated.[28,29] After the administered drugs have an appropriate time to circulate, an oral endotracheal tube is placed via direct laryngoscopy in an efficient and time-sensitive manner.

SUMMARY

Through medical knowledge and practical training, the physician who tends to the most acutely ill patient should be prepared to maintain ventilation and oxygenation in critical clinical situations. Despite the existence of a large set of clinical options and technical devices available to practitioners, extensive training in a subset of airway management options is sufficient as long as definitive and invasive techniques are part

of their clinical repertoire. Each individual should approach the airway in the acutely ill patient with an honest evaluation of his or her skill set.

It is time-consuming and in some situations dangerous to exhaust all noninvasive techniques before proceeding to invasive techniques in acutely ill patients. Yet an appreciation for basic airway management principles such as preoxygenation, preprocedural airway evaluation, mask ventilation skills, and temporary use of an LMA is essential. Employment of these techniques can often turn a critical situation into one that is perhaps less acute and can prevent an urgent situation from becoming an emergent situation. A formal but flexible plan for airway management with good communication among the medical personnel involved is essential to favorable patient outcomes.

FUNDAMENTAL PRINCIPLES

CHAPTER 8 ■ PREOPERATIVE PREPARATION OF THE EMERGENCY GENERAL SURGERY PATIENT

KRISTA TURNER AND FREDERICK MOORE

Skillful perioperative care of acutely ill patients is a defining characteristic of the specialty of acute care surgery. Appropriate resuscitation and planning permit a safe operation and establish the patient's clinical trajectory. Prevailing literature on preoperative assessment emphasizes risk modification primarily for the elective patient. In an emergency situation, this luxury disappears, and the surgeon must attempt to reverse existing damage and prevent further loss quickly and based on limited information. The acute care surgeon encounters a wide spectrum of patients, with varying severity of chronic and acute illness. Although each patient will provide a unique challenge, the same concepts can be applied universally. It is helpful to follow an approach to the emergency general surgery patient similar to that to a trauma patient—initial evaluation and treatment based on urgency, followed by careful system evaluation prior to surgery.

PRIMARY SURVEY

Identification and Assessment

There is little doubt that the floridly ill 80-year-old woman with free air requires more attention prior to surgery than the healthy 18-year-old male with classic signs of early appendicitis. In between the two extremes are patients who may appear well on preliminary exam only to decompensate in the operating room later. Early identification of patients with subtle signs of shock can greatly affect their outcome when appropriately treated prior to surgery. Clinical assessment of these patients can often be limited, given the time constraints in some emergency situations.

The approach to the emergency surgery patient should include an initial brief history and physical to guide further decision making. Once a surgical emergency is established, the initial medical history can follow that of the "AMPLE" format used for obtaining a history in trauma patients. The "A" and "M" represent allergies and medications, for which particular attention should be paid to prescribed anticoagulants, insulin, and cardiovascular medications. The "P" prompts for listing of previous surgery or prominent medical problems. The "L" indicates the last meal and signifies a higher aspiration risk. The "E" refers to events that surrounded the inciting event. In the case of the emergency general surgery patient, this should focus on components of the acute illness that may attest to its severity.

Physical examination should have two components: one that focuses on the specific disease process and one that focuses on signs of systemic sequelae. The first identifies the need for surgery; the second quantifies the degree of illness. Establishing the diagnosis by physical exam is fundamental to general surgery practice. Examining the patient for systemic illness is of equal importance to the acute care surgeon. Criteria for systemic inflammatory response syndrome (SIRS) are nonspecific[1]

but highly sensitive for any type of systemic duress experienced by the patient (i.e., bleeding or tachyarrhythmia) and should prompt further investigation (Table 8.1). Modifications to SIRS scoring can be used to increase specificity for particular systemic illness. To facilitate early identification and treatment of surgical sepsis, for example, we devised a validated screening tool that combined SIRS criteria with a second-level screen to extrapolate possible infectious processes.[1,2] Signs of shock can be obvious with tachycardia and hypotension, but cellular hypoperfusion may be ongoing without such outward signs. Signs of pending organ dysfunction and failure should be sought (Table 8.2).

Basic laboratory studies and x-rays can be valuable adjuncts to identifying the patient with systemic illness. Values on the general chemistry panel, such as low serum bicarbonate and elevated anion gap, can indicate tissue hypoxia. A concentrated hematocrit may also attest to hypovolemia. More specific indicators such as a base deficit, elevated lactate, or decreased oxygen saturation on a venous blood gas can confirm shock and guide resuscitation. A preoperative chest x-ray in the patient with cardiac or pulmonary disease can guide perioperative modalities.

Resuscitation

Similar to the trauma evaluation, the first encounter the surgeon has with the patient in need of emergency surgery may require immediate life-saving measures. Often the patient with presumed surgical pathology will be triaged as such by the emergency department and given less-than-astute attention once the surgeon has been contacted. The surgeon may then arrive to find the patient metabolically deranged to the point of extremis. Simple basic life support skills are then necessary.

Airway and Breathing This is not such an anatomical issue as it is with trauma patients, but the patency of the airway should still be evaluated. These patients may suffer from altered mentation secondary to shock and require airway protection. Tachypnea is often present to compensate for metabolic acidosis and is not well tolerated in the older patient. The use of accessory muscles of breathing, paradoxical respiratory effort, and apnea should all be signs to intubate and ventilate. Pulse oximetry can be used to assess adequacy of oxygenation; however, this can lag behind actual alveolar oxygenation, and a low-normal value should always be interpreted with caution. Anecdotally speaking, if it occurs to you that maybe you should intubate the patient, then you should.

The key to successful intubation is preparation. Always ensure that the appropriate personnel and equipment are available while providing oxygen by mask. Rapid sequence intubation may be achieved with an inducing agent and short-acting paralytic. Etomidate is often favored due to rapidity of action and relative lack of hemodynamic effect. The transient

TABLE 8.1

SYSTEMIC INFLAMMATORY RESPONSE SYNDROME (SIRS) CRITERIA

1	Heart rate > 90 beats/min
2	Respiratory rate > 20 breaths/min, or Pa_{CO_2} < 32 mm Hg
3	Temperature > 38°C or < 36°C
4	Leukocytes > 12,000/mm^3 or < 4,000/mm^3 or ≥ 10% juvenile neutrophil granulocytes

NOTE: Two out of four criteria establish the diagnosis for SIRS.

adrenal suppression induced by etomidate has raised concern, and studies are mixed regarding its safety for single use.[3,4] Chest x-ray should always be obtained to visualize the tip of the endotracheal tube and avoid right mainstem bronchus intubation for the duration of the ensuing operation.

Circulation Again, trauma resuscitation basics should be followed but are often neglected. Intravenous access upon evaluation of these patients is typically poor—a single 22-gauge peripheral in the hand is simply not adequate. If the classic "two large-bore peripheral IVs" cannot be obtained, then central venous access is necessary, preferably of large diameter, and placed in the chest or neck with ultrasound guidance.

Despite the type of shock, volume loading is the first step of resuscitation. Options include isotonic crystalloids, hypertonic saline, colloids, and blood products. Crystalloids are inexpensive and readily available. Initial bolus of 20 mL per kg of either normal saline or lactated Ringer's solution should be followed by reassessment and ongoing hydration. Hypertonic saline is promising for emergency use in that it may cause less edema and has a favorable immunologic profile. This has been particularly studied in patients with traumatic brain injury.[5] While relatively safe compared to colloid infusion, the administration of large amounts of saline for volume resuscitation carries the concern for hypernatremia, hyperosmolarity, and hyperchloremic metabolic acidosis.

Colloids may provide a greater volume expansion per amount infused, although the presence of leaky capillaries may negate this advantage. Given that it offers no advantage to crystalloid use and is of limited availability, albumin should be limited to specific patient populations.[6] Hydroxyethyl starch (HES) has likewise been proposed as a resuscitative colloid. Large volumes of HES should be used with caution, as doses exceeding 20 mL/kg/d can incite platelet dysfunction and renal failure in certain patient populations.[7,8]

Provision of blood products as a resuscitation fluid should be considered carefully. The risk of infection, immunosuppression, and transfusion reaction are well known.[9] Fresh frozen plasma (FFP), cryoprecipitate, and platelets also have utility as colloids based on the coagulation profile. Each has the same adverse transfusion profile as administering packed red blood cells (pRBCs) and should only be used in combination for hemorrhagic shock or for coagulopathy. The patient with ongoing bleeding should be treated with a hemostatic resuscitation strategy that involves transfusion of plasma, platelets, and pRBCs in a ratio that mimics that of whole blood and avoids large volumes of crystalloid infusion.[10] Monitoring ongoing transfusion with platelet count, hematocrit, thromboelastrography (TEG), and venous oxygen saturation will help guide further therapy. Hypotensive resuscitation in the hemorrhagic

TABLE 8.2

SIGNS AND SYMPTOMS OF ORGAN DYSFUNCTION

■ ORGAN SYSTEM	■ SYMPTOMS OR SIGNS	■ CAUSES
CNS	Mental status changes	↓ Cerebral perfusion
Circulatory	Tachycardia	Adrenergic stimulation, depressed contractility
Cardiac	Hypotension	Coronary ischemia
Systemic	New murmurs Hypotension ↓ JVP ↑ JVP	Depressed contractility secondary to ischemia or MDFs, right ventricular failure Valvular dysfunction, VSD ↓ SVR, ↓ venous return Hypovolemia, ↓ venous return Right heart failure
Respiratory	Tachypnea Cyanosis	Pulmonary edema, respiratory muscle fatigue, sepsis, acidosis Hypoxemia
Renal	Oliguria	↓ Perfusion, afferent arteriolar vasoconstriction
Skin	Cool, clammy	Vasoconstriction, sympathetic stimulation
Other	Lactic acidosis Fever	Anaerobic metabolism, hepatic dysfunction Infection

CNS, central nervous system; MDFs, myocardial depressant factors; VSD, ventricular septal defect; SVR, systemic vascular resistance

patient is an additional emerging concept.[11] Measures to raise blood pressure (BP) with fluid administration may be counterproductive until bleeding is controlled. This approach should be used with caution as efforts to maintain vital organ perfusion (particularly the brain) should be the top priority.

Ongoing signs of shock despite adequate volume resuscitation will require the addition of vasopressors or inotropes. Sympathomimetics are the standard for raising the mean arterial pressure (MAP). Each vasopressor has advantages and disadvantages, although norepinephrine has emerged as one of the first-line agents for septic and cardiogenic shock.[12] Inotropes such as dobutamine or milrinone can be added if cardiac output remains low despite adequate volume loading and vasopressor provision. More advanced monitoring should be applied to help titrate inotrope effect.

Adjunctive measures to assist with hemorrhagic or septic source control may be considered as part of the resuscitation strategy. If interventional radiology is available and capable, a well placed drain or coil can stabilize the patient who is otherwise too acutely ill for the operating room. Shock resuscitation should be ongoing throughout this process with the intent of proceeding to the operating room for definitive control when it is safe to do so.

Endpoints of Resuscitation Deciding where surgical intervention fits into shock resuscitation may be difficult. For the less ill patient, providing a liter of crystalloid may be sufficient to restore signs of tissue perfusion prior to operating. For sicker patients, the surgical intervention is an integral part of the resuscitation and must be undertaken before any further improvement can be seen. More difficult yet, particularly in the elderly population, is the nonresponder for whom a surgical intervention will have no bearing on outcome and may put simply put the patient and family through undue duress. Luckily, most patients will fall short of this extreme.

The surgeon should have in mind what end points are to be met before operating. It is prudent that once resuscitation is initiated, the progress of the patient is closely monitored. All too often, an initial assessment and plan will be established, only to find several hours later that nothing has been accomplished. Likewise, "resuscitation" does not equal "extra few hours of sleep" for the surgeon whose patient presents in the middle of the night. While consideration should be given to availability of appropriate operating room staff based on time of day, physiologic optimization of the patient should take precedence.

For the patient in shock, various hemodynamic end points and modes of monitoring progress can be used both pre- and postoperatively. Basic monitoring in patients with shock includes heart rate and urinary output. Noninvasive BP measurements tend to give falsely elevated readings in patients who are hypotensive. An arterial catheter should therefore be placed when there is a concern for hypoperfusion. Central venous pressure (CVP) is often one of the first invasive measures employed. Although this has numerous confounders, resuscitation protocols often aim for a CVP of 12–15 mm Hg.[13] With the addition of pulmonary artery catheters, numerous additional hemodynamic parameters become available, although it is not clear that the appropriate end point is the normalization of these values, nor is it clear how these end points should be achieved. Arterial pressure waveform analysis is a promising modality. Utilizing an existing arterial catheter, it can provide reliable measures of cardiac output and volume status that can outperform pulmonary artery and central venous catheters for resuscitation.[14]

End points of tissue oxygenation may also be used for resuscitation. Mixed-venous oxygen saturation (SvO_2) has classically been employed as an estimate of global tissue perfusion, but requires a pulmonary artery catheter for measurement. Values <65% are associated with reduction in oxygen delivery, indicating reduced cardiac output or oxygen content of blood. Central venous oxygen saturation ($ScvO_2$) generates similar information from a standard central venous catheter, with values <70% significant.[15] Laboratory values such as lactate and base deficit can also help guide resuscitative efforts, with prognostic significance.[16,17] Near-infrared spectroscopy offers a method of monitoring tissue hemoglobin oxygen saturation (StO_2) in the skeletal muscle. Changes in skeletal muscle StO_2 correlate well with changes in oxygen delivery, base deficit, and lactate levels during active resuscitation.[18]

SECONDARY SURVEY: SYSTEM-BASED CONSIDERATIONS

A surgical emergency can often be the patient's first exposure to the health care system, leaving the surgeon to uncover previously undiagnosed medical problems. Special attention in the history should be given to previous problems with anesthesia, clotting disorders, as well as medications and substance use. Baseline functioning including mental status, activity level, and vital signs should also be established from family if the patient is unable to communicate. Careful physical examination can reveal other pertinent comorbidities. These include signs of pulmonary disease, vascular disease, cirrhosis, previous unmentioned surgery, and malnutrition, to name a few. The following describes components of the preoperative evaluation by system, with more pertinent topics discussed in detail.

Neurologic

Baseline function should be established through either the patient or family, particularly for elderly patients who may have dementia. Superimposed delirium from acute illness complicates this exam. Chronic neurologic disease should be ascertained, as numerous diseases such as muscular dystrophy, myasthenia gravis, multiple sclerosis, epilepsy, Parkinson's disease, and Alzheimer's disease may influence the type of anesthetic and paralytic agents used.

Substance Abuse and Dependency Patients undergoing emergency surgery often present with substance use disorders. Alcohol dependency poses the most dangerous risk to the patient in the perioperative period. Acute illness may impact the usual amount of alcohol ingested, initiating withdrawal sooner than expected. Administration of benzodiazepines prior to surgery reduces the dose of inhaled anesthetics required and prevents seizures. Preoperative morphine can help mediate the exaggerated stress response that is chronically suppressed by alcohol.[19] For the malnourished alcoholic, thiamine should be given prior to glucose administration to prevent Wernicke's encephalopathy. Nicotine and narcotic dependence should also be anticipated and treatment begun in the preoperative period. When initiated early, nicotine replacement therapy can reduce opioid requirement.[20] Narcotic dependence can be treated with short- as well as long-acting opioids, with clonidine added to help temper withdrawal symptoms.[21]

Analgesia Pain control prior to surgical evaluation is an area of debate. Concern for "masking the examination" hinders administration of appropriate analgesia and unnecessarily leaves the patient in pain. Meta-analysis of adult and pediatric patients treated with opiates shows a trend toward increased risk of altered physical exam, but no difference in subsequent management thereof.[22] Patients with chronic pain syndromes should be treated appropriately with their baseline dosing plus additional narcotics as needed for acute pain.

Pulmonary

Chronic Pulmonary Disease Patients with preexisting chronic pulmonary disease present an additional challenge for the surgeon. Emergency patients do not have the luxury of undergoing optimization or risk stratification before surgery, and therefore may present with ongoing atelectasis, respiratory infection, or bronchospasm. Smoking history and chronic obstructive pulmonary disease are clear risk factors for postoperative pulmonary complications such as pneumonia, pleural effusion, and respiratory failure.[23] Additional preoperative risks are low oxygen saturation, respiratory infection within the past month, age >80 years, and preoperative hemoglobin <10 mg per dL.[24] Avoiding these complications can be difficult in the immediate preoperative period, but a few strategies for risk reduction can be applied (Table 8.3).

Acute Lung Injury Acute lung injury (ALI) and Acute Respiratory Distress Syndrome (ARDS) are particularly devastating for the emergency patient. The combination of aggressive resuscitation strategies, profound inflammatory processes, and blood transfusions adds to this risk. Strategies to limit further barotrauma with restrictive tidal volumes (6 mL/kg), judicious use of positive end-expiratory pressure, and permissive hypercapnia have been described once the patient is diagnosed with ALI/ARDS.[25] Studies have also demonstrated that application of a low tidal volume protocol from the outset can prevent subsequent ALI/ARDS by limiting pulmonary cytokine production and inflammation.[26,27] While the initial tendency will be to increase s ventilation in these patients to help compensate for metabolic acidosis, these measures may lead to subsequent barotrauma, and use of lower tidal volumes should be encouraged.

Cardiovascular

Guidelines for preoperative cardiac assessment are abundant and revised frequently. These algorithms uniformly divert the patient directly to surgery for true emergency situations. Patients with acute coronary syndrome complicating their surgical disease should be treated according to American Heart Association/American College of Cardiology (AHA/ACC) guidelines for coronary revascularization.[28] Any attempt to temporize the acute surgical problem should be made in the face of ongoing cardiac ischemia. Coordinating care in a multidisciplinary manner for these patients is paramount. For the more common patient with stable cardiac disease, preparation for surgery is much less dramatic. The limited workup for these patients derived from the history, physical exam, and EKG can provide information regarding functional status. Preoperative optimization options are limited in a short time frame, but a few basic principles can be applied (Table 8.4).

Hypertension Although preoperative hypertension is an important predictor of postoperative morbidity, no data have established that this is remedied by preoperative treatment. This applies principally to those with long-standing moderate hypertension for which any attempt at acute reduction may result in relative hypoperfusion once general anesthesia is induced. Stage III hypertension (>180/110 mm Hg), however, requires control prior to surgery. Continuous intravenous esmolol, labetalol, nitroprusside, or nitroglycerin may be used, as may some of the newer calcium channel blockers such as nicardipine or clevidipine.[29] Invasive arterial BP monitoring for these patients is essential.

Beta-blockade Beta-blockers mitigate cardiovascular stress from surgery by suppressing catecholamine production and increasing stability of atherosclerotic plaques. Initial data regarding perioperative beta-blocker use in cardiovascular surgery demonstrated a decrease in myocardial ischemia, ventricular arrhythmias, and blunting of the hypertensive response in high-risk patients.[30,31] This led to a class I recommendation by the AHA for perioperative beta-blockade with a goal heart rate of 60 bpm for those patients with coronary ischemia undergoing vascular surgery. A class IIa recommendation was also made for patients with untreated hypertension, coronary artery disease, or other risk factors.[32]

With this evidence, perioperative beta-blockade was enthusiastically and liberally applied. Emerging data began to demonstrate unacceptable risks of bradycardia, hypotension, and stroke in certain patient populations.[33–36] When stratified per cardiac risk index, the relationship between perioperative beta-blockade and risk of death varied directly with cardiac risk: those with high risk (cerebrovascular or coronary artery disease, insulin-depending diabetes, creatinine >3 mg/dL,) showed a benefit, but those with low risk showed a trend toward harm.[37] Subsequent revisions to the ACC/AHA

TABLE 8.3

PREOPERATIVE INTERVENTIONS TO REDUCE THE RISK OF POSTOPERATIVE PULMONARY COMPLICATIONS

Incentive spirometry
Continue bronchodilators, inhaled steroids
Intravenous pulse steroids if active reactive airway disease
Restrictive fluid strategy
Antibiotics for active infection
Transfusion for critical hypoxemia
Maintain head of bed >30 degrees
Avoid noninvasive ventilation
Early intubation
Restrictive tidal volumes (6 mL/kg) on positive pressure ventilation
Short-acting neuromuscular blockade intra-op
Laparoscopy if able
Supplemental oxygen

TABLE 8.4

PREOPERATIVE INTERVENTIONS TO REDUCE THE RISK OF POSTOPERATIVE CARDIAC COMPLICATIONS

Aggressively correct electrolytes
Arterial catheter placement for BP measurement
Pulmonary artery catheter or transesophageal echo monitoring for high risk
Correct hemoglobin to 9 g/dL for those with coronary artery disease
Continue beta-blocker if on previously or if cardiac ischemia
Volume restriction in CHF patients
Adequate pain control to reduce stress
Supplemental oxygen

guidelines restrict class I indication for perioperative beta-blockade to those already on beta-blockers and to patients with known coronary ischemia undergoing high-risk surgery.[38]

Congestive Heart Failure Patients with congestive heart failure (CHF) should be cautiously managed prior to emergency surgery. Therapy is aimed at reducing ventricular filling pressures in addition to improving cardiac output. This may be a difficult balance in the face of ongoing disease processes such as vasodilatory shock or bleeding. Chronic disease may be complicated by acute ischemia or metabolic myocardial depression. Inotropes such as dobutamine or milrinone may be needed for those with systolic dysfunction. More invasive monitoring devices such as pulmonary artery catheters or continuous transesophageal echocardiography should be available intraoperatively for this patient population.

Preoperative administration of chronic medications used to treat CHF should be considered carefully. Beta-blockade has already been discussed and should be continued for those already on therapy but without ongoing hypotension.[39] Diuretics should be administered only if clinically indicated on physical exam. Ongoing angiotensin-converting enzyme (ACE) inhibitor administration should be avoided in those patients with hypotension or acute renal insufficiency, but otherwise may have a protective effect.[40] Digoxin should be held in the preoperative period, as therapy with the drug is associated with an increased cardiac risk in urgent surgical patients.[41]

Arrhythmias Perioperative atrial arrhythmias can contribute substantially to morbidity in the emergency surgical patient. Electrolytes should be aggressively corrected and home medications used for rate or rhythm control continued. Acute-onset atrial fibrillation with rapid ventricular response should be stabilized according to advanced cardiac life support protocol prior to proceeding to the operating room.[42] New arrhythmias should prompt investigation for ischemia, for which reperfusion may take precedence of acute surgical pathology. Patients with permanent pacemakers or implantable defibrillators should be identified preoperatively. If time permits, the device should be interrogated by the electrophysiology service. Otherwise, a magnet should be taped over the device en route to surgery. Magnets will reprogram pacing devices to asynchronous mode and will disable defibrillators, making them immune to electromagnetic interference that may be experienced in the operating room.

Renal

Acute kidney injury (AKI) is unfortunately commonplace in the emergency surgery patient and portends a bad outcome. The surgeon should correct issues such as hypovolemia, electrolyte disturbances, and acid/base prior to operating. Metabolic acidosis should be initially treated with volume resuscitation and correction of the underlying problem. If acidosis persists and is hemodynamically limiting, then temporizing measures with sodium bicarbonate, tromethamine (THAM), or immediate continuous renal replacement therapy should be considered.[43] Additional indications for emergent dialysis in the preoperative period (volume overload, intractable hyperkalemia, azotemia, pericarditis), whether for acute or chronic renal failure, should be considered and pursued if time permits.[44] For the patient with chronic renal failure, the surgeon should also be cognizant of appropriate positioning on the table to avoid compression of existing arteriovenous fistulas, as well as avoiding the subclavian vein for central venous catheter placement.

Acute Renal Dysfunction Most cases of renal impairment share the underlying pathology of hypoperfusion.[45]

Pre-existing renal function and patient comorbidities such as hypertension, diabetes, and vascular disease play a critical role. Inflammatory and nephrotoxic factors, in combination with type of surgery, can exacerbate these baseline factors. Renal perfusion may be preserved by adequate volume resuscitation and goal-directed therapy.[46]

Contrast-induced Nephropathy Special consideration is given to the acutely ill patient facing exposure to contrast agents for either diagnosis or therapeutic purposes. Current guidelines for prevention of contrast-induced nephropathy (CIN) emphasize provision of isotonic fluid. Normal saline should be administered at 1 mL/kg/h for 24 hours, beginning 2–12 hours before contrast administration. The lowest dose and osmolality contrast should be used. *N*-acetylcysteine (Mucomyst) is often employed with a standard dose of 600 mg every 12 hours for four doses beginning before contrast is given. Although this drug is promising as a free-radical scavenger, the data show no improvement in renal function, despite a decrease in creatinine.[47] Meta-analysis of sodium bicarbonate for prevention of CIN likewise shows no benefit over isotonic saline administration.[48] Other nephrotoxic agents should likewise be avoided. These include ACE inhibitors, angiotensin II receptor blockers, and metformin.

Gastrointestinal

The emergency general surgery patient very often has some component of ileus and is therefore always considered at high aspiration risk. A nasogastric tube should be placed prior to induction of anesthesia to help empty the stomach and prevent voluminous aspiration. Premedication with H_2-receptor blockers is typically given in this patient population prior to induction as well. If the need for future enteral feeding access is anticipated, appropriate tubes can be made available in the operating room. Signs and symptoms of liver disease should be carefully elucidated. Further management of the cirrhotic is discussed below.

Abdominal Compartment Syndrome Intra-abdominal hypertension and abdominal compartment syndrome (ACS) should be considered in certain patients presenting with emergency abdominal pathology. The triad of oliguria, elevated peak airway pressures, and elevated intra-abdominal pressure (as obtained from bladder pressure readings) defines ACS, which can be from either a primary or secondary process.[49] When suspected or diagnosed preoperatively, the surgeon should proceed expeditiously to the operating room to avoid bowel ischemia and further kidney injury. Plans for leaving the fascia open should be made prior to starting the operation so that appropriate supplies are available.

Hematology

Transfusion The concept of liberally transfusing the patient prior to proceeding to the OR with the intention of "loading them up" should be abandoned. While certain patient populations are critically dependent on optimization of oxygen content of blood, most patients needlessly risk the adverse effects associated with transfusion. Patients with active bleeding are the exception, and strategies for transfusion in this population have been described above.

Tolerance for a lower hematocrit in critically ill patients has been supported by the Transfusion Requirements in Critical Care (TRICC) trial. This demonstrated that a restrictive transfusion strategy (hemoglobin trigger of 7 g/dL) is as at least as effective and may be superior to a liberal

transfusion threshold of 10 g per dL.[50] This finding persisted for patients with coronary disease, with the exception of those with an acute ischemic event or unstable angina.[51] This was a select group of ICU patients who were considered to be euvolemic, and thus patients with active hemorrhage were excluded in this study and were not specifically identified.

A recent study using the National Surgical Quality Improvement Program (NSQIP) database examined patients undergoing noncardiac surgery.[52] An increase in mortality was shown for those older than 65 years when preoperative hematocrit levels deviated from normal. This was an observational study, however, and patients undergoing emergency surgery did not experience the same effect. A recent large prospective study likewise examined a restrictive versus liberal (hematocrit 24% vs. 30%) transfusion policy prior to cardiac surgery.[53] Thirty-day all-cause morbidity and mortality were the same for both groups; however, the number of units transfused was an independent risk factor for subsequent complications.

Anticoagulation Reversal When performing emergency surgery on anticoagulated patients, the surgeon must balance the risk of operative bleeding versus thromboembolism. For the patient with minimal clinical consequence of operative site bleeding and high risk of thromboembolism, a higher threshold should be given to acceptable INR levels or continuing anticoagulant therapy. High-risk patients with prosthetic valves in the mitral position, atrial fibrillation associated with mitral valve disease, and a history of thromboembolism should be placed on intravenous heparin therapy while warfarin is held. In this patient population, FFP may be administered to acutely reverse anticoagulation, with care taken to avoid volume overload. Vitamin K therapy should be avoided as the delayed effect will serve no purpose in the short term and complicate subsequent anticoagulation in the postoperative period.

Similarly, patients taking antiplatelet therapy should be treated with a risk/benefit approach. Prevalence of patients taking dual antiplatelet therapy with aspirin plus clopidogrel is increasing with expanding criteria for use in cardiovascular patients. Patients with bare metal coronary stents placed within the last 6 weeks or drug-eluting stents placed within the last 12 months should be considered at high risk of a fatal perioperative myocardial infarction.[54] As such, if bleeding risk is acceptable, the patient should be left on antiplatelet therapy without attempt to reverse the effects of platelet inhibition. For the patient on antiplatelet therapy without high risk of cardiac or cerebrovascular complications, a strategy to temporarily reverse platelet inhibition is desired. Ideally, platelet reactivity could be assessed by light transmittance aggregometry, but this test may be of limited availability, particularly in an emergency setting. If the bleeding risk is high, two to three pools of platelet concentrate should be administered to temporarily assist with clot formation. This strategy has been demonstrated to normalize platelet response in those treated with typical doses of clopidogrel plus aspirin.[55]

Thromboembolism Prophylaxis The risk for venous stasis and subsequent thromboembolic disease increases in the operative period due to vasodilation, inflammation, and immobilization. Most hospitals include the placement of mechanical antithrombotic devices (e.g., sequential compression devices) in the operating room checklist and emphasize placement prior to induction of anesthesia. Pharmacologic methods for deep venous thrombosis (DVT) prophylaxis are often not emphasized preoperatively; however, trials demonstrating heparin efficacy were performed with dosing started 1–2 hours before surgery.[56] Enoxaparin and subcutaneous heparin are therapeutically equivalent for preventing DVT, although renal clearance of enoxaparin makes dosing less predictable in those patients with compromised kidney function.[57] Patients at high risk of bleeding should at least have mechanical methods employed in the operating room.[58]

Endocrine

Hyperglycemia Observational evidence shows that patients with acutely elevated glucose preoperatively fare worse than those who are normoglycemic; however, no trials investigate whether acute correction demonstrates any benefit.[59] In 2001, Van den Berghe et al. published a large randomized controlled trial of surgical intensive care unit patients in which intensive insulin therapy (IIT) (target blood glucose [BG], 80–110 mg/dL) reduced in-hospital mortality by 34% when compared to standard therapy (target BG, 180–200 mg/dL).[60] This finding has been broadly applied and included in perioperative care guidelines, as well as included as a Surgical Care Improvement Project (SCIP) measure. Particular attention has been given to achieving normoglycemia intraoperatively, although results are mixed. Higher incidence of clinically manifest hypoglycemia, in addition to the findings from the NICE-SUGAR trial, has generally called into question the safety of IIT.[61] Guidelines from major societies now advocate a "reasonable, achievable, and safe" approach to tight glucose control acutely.[62]

Diabetic Ketoacidosis Diabetic ketoacidosis (DKA) is a serious diabetic emergency and should be aggressively treated preoperatively. The American Diabetic Association (ADA) defines DKA as glucose > 250 mg per dL, pH < 7.3, serum bicarbonate < 18 mmol per L, anion gap > 10, and presence of ketosis.[63] Typically, an infectious process initiates the process, so the emergency surgery patient with diabetes is at high risk. Treatment consists of aggressive hydration and provision of intravenous insulin. Electrolytes should be monitored every 2 hours, and hypokalemia corrected. When the serum glucose falls below 250 mg per dL, the IV fluid should be changed to 5% dextrose with 0.45% sodium chloride with subsequent glucose goal of 150–200 mg per dL. In the emergency setting, this process should be pursued at least with the goal of providing generous hydration and correction of hypokalemia prior to proceeding to the operating room.

Stress Dose Steroids Patients treated in the long term with exogenous steroids have a blunted hypothalamic–pituitary–adrenal axis response to surgical stress when compared to normal controls. Complete cessation of steroids in the perioperative period for those on long-term treatment can result in a 1%-2% incidence of hypotensive crisis with significant risk of death.[64] Based on these findings, the concept of "stress dose steroids" has been widely applied and is now dogma. There is no evidence that supraphysiologic doses of corticosteroids are necessary to prevent hemodynamic instability however. Numerous studies have failed to demonstrate any difference in perioperative BP when comparing normal steroid dosing with supraphysiologic levels.[65,66] Given the risks of corticosteroids (wound healing, immunosuppression, interaction with anesthetic agents, psychiatric disturbances), the concept of "stress dosing" above the baseline should be reexamined. Current guidelines recommend providing the patient with an intravenous dose equivalent to their baseline until oral medications can be resumed.[67] An important exception to this recommendation is the critically ill patient. Steroid-dependent patients requiring vasopressors should be tested for

adrenal insufficiency and started on supraphysiologic doses of 100–150 mg intravenous hydrocortisone daily until hypotension resolves.[68]

Infectious Disease

Sepsis A large percentage of patients undergoing emergency surgery by the general surgeon will have an infectious etiology. For those patients without systemic signs of disease, management is straightforward: source control (surgery) and/or antibiotics. For those patients with sepsis (SIRS plus infection), management requires more skillful resuscitation. Treatment is based on primary source control, with resuscitative efforts to limit systemic inflammatory sequelae. The specifics of sepsis management are discussed later in the chapter as it pertains to intra-abdominal catastrophe.

Surgical Prophylaxis Surgical prophylaxis refers to the administration of antibiotics in the patient with no signs of infection in an effort to reduce the risk of postoperative wound infections. Clean cases in which the gastrointestinal tract, genitourinary tract, or respiratory tract are not entered do not routinely require antibiotic prophylaxis. This is rarely the case for emergency general surgery. Antibiotics should be chosen based on operative site and predominant bacterial flora to that area. Skin flora such as *staphylococci* and *streptococci* should be covered for most cases, with additional coverage of gram-negative flora and anaerobes for cases involving the gastrointestinal tract. Antibiotics should be redosed intraoperatively based on clearance profiles for that drug, as well as for cases in which blood loss is estimated over 1.5 L.

Guidelines from the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) and SCIP provide common recommendations to further limit surgical site infection.[69] Antibiotics should be administered within 1 hour before surgical incision, but should be completed prior to skin incision to achieve maximal tissue penetration. True antibiotic prophylaxis should be completed within 24 hours of the case. Hair at the operative site should be clipped (not shaved). Additionally, hypothermia and hyperglycemia should be avoided. Specific antibiotics for use in general surgery are outlined in Table 8.5.

TABLE 8.5

SURGICAL ANTIMICROBIAL PROPHYLAXIS. COVERAGE FOR GENERAL SURGERY CASES—GASTROINTESTINAL

ANTIBIOTIC	INTRAOPERATIVE REDOSING INTERVAL
Cefotetan 2 g IV	none
Cefoxitin 1 g IV	every 4 h
Cefazolin 2 g IV[a]+	every 4 h
Flagyl 500 mg IV	every 8 h
Ampicillin/Sulbactam 3 g IV	every 6 h
Ertapenem 1 g IV	None
If penicillin allergy:	
Clindamycin 600 mg IV+	every 8 h
Gentamicin 5 mg/kg IV	none

[a]Substitute vancomycin for cefazolin in hospital with high MRSA rate

SPECIAL PATIENT POPULATIONS

Pregnant Patient

This is often one of the more feared patient populations undergoing emergency surgery. While now caring for two patients, the health of the mother takes precedence. Assessment of the pregnant patient with a surgical abdomen should proceed as in any patient, with a few additional concerns. A complete obstetric history should be obtained including issues with the current or prior pregnancies, last menstrual history, and gestational age. Most common causes of abdominal pain are similar to those in the general population and include appendicitis, cholecystitis, and bowel obstruction. Additional consideration should be given to those diagnoses more specific to pregnancy including ruptured ectopic pregnancy, abruptio placentae, rupture of uterus, preeclampsia, as well as pyelonephritis and rupture of visceral aneurysms.

Evaluation must be performed with an understanding of the physiologic changes that occur at varying points during pregnancy (Table 8.6).[70] Adjuncts to the physical exam include fetal heart tone monitoring and inclusion of a sterile speculum exam. Fetal heart tones should be continuously monitored pre- and postoperatively starting at 24 weeks of gestation. Mental status changes or seizures should prompt consideration for a diagnosis of eclampsia.

Expeditious and accurate diagnosis should take precedence over concerns for ionizing radiation when further workup is needed. Ultrasound is safe with a relatively high sensitivity and specificity for many intra-abdominal processes. This is also the test of choice for most gynecologic causes of abdominal pain. Use of ionizing radiation should be based on further need for diagnosis, and cumulative dosage should be limited to 5–10 rads during the first 25 weeks' gestation with no single dose exceeding 5 rads.[71] An abdominal/pelvis CT scan provides 5–10 rads of exposure; however, risk versus benefit of the scan should be considered. MRI without gadolinium is also considered safe in pregnancy, but time necessary to obtain such a scan should be considered in the workup and resuscitation.

Once in the operating room, additional considerations are necessary for the pregnant patient. Diminished maternal oxygen reserve and high risk for aspiration make early intubation essential. Aggressive fluid management should dominate the resuscitation, with use of vasopressors limited to phenylephrine due to its limited effects on uteroplacental perfusion. To assist with venous return, the patient should be positioned in left lateral position to move the fetus off of the vena cava. The coordination of care with an obstetrician is imperative. An obstetrician can assess fetal status, provide consultation for medication provision, assist if gynecologic or obstetric-related disease is found, and decide when emergent Caesarean section is required.

Morbidly Obese Patient

The preoperative evaluation and management of the morbidly obese (MB) patient requiring emergency surgery is challenging.[72] The first issue is making the correct diagnosis. Physical examination, plain radiography, and ultrasonography are notoriously inaccurate, and many of the super obese are too big to fit into the CT scanner. Once the decision to operate has been made, there are a variety of issues unique to this population. BP measurement by sphygmomanometry frequently overestimates BP, and an MB patient who has a normal BP may have occult hypoperfusion. Arterial lines are therefore recommended but difficult to place. Additionally, central venous catheters are frequently needed, but placement is cumbersome and risky. Airway management is especially problematic, and early consultation with an anesthesiologist is recommended.

TABLE 8.6

PHYSIOLOGIC CHANGES IN PREGNANCY

■ CARDIAC	■ PULMONARY	■ HEMATOLOGY
↑ cardiac output by 50%	↑ oxygen consumption by 20%	↑ blood volume by 50%
↓ blood pressure 5–15 mm Hg	↑ tidal volume	↑RBC volume by 30%
↑ heart rate by 15 bpm	↓functional reserve capacity	↓ hematocrit to 32%-34%
↓ systemic vascular resistance	↑ respiratory rate	
↓ central venous pressure	↑ PaO$_2$ to 104–108 mm hg	

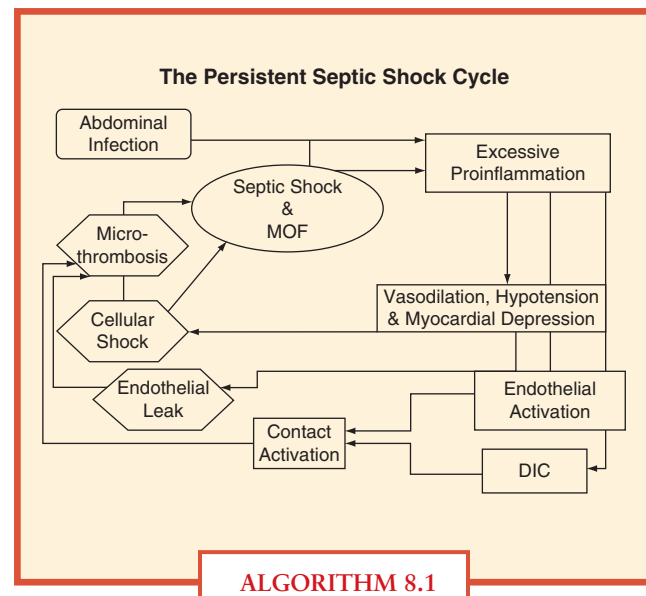
Dosing of drugs is problematic because of the high volume of distribution and increased percentage of adipose tissue. Surgical site infections are much more common in the MB, but little is known about optimal dosing of antibiotics in emergency surgery.[73] In general, antibiotic dosing should be based on a 40% correction factor.[74] Adjusted body weight is calculated by the following formula: adjusted body weight = ideal body weight + 0.4 × (actual body weight – ideal body weight). It is also felt that more frequent dosing is required for prophylaxis against gram-negative organisms.[75] Consultation with a pharmacist or an infectious disease specialist, close drug level monitoring (when available), and dosing interval determination based on creatinine clearance are recommended.

MB patients experience appreciably higher rates of postoperative complications. They have a notably high risk for cardiac complications and should be managed as outlined in Table 8.4. It is important to remember that many MB patients have significant pulmonary hypertension that puts them at risk for right heart failure. MB patients are also at high risk to develop pulmonary complication and should be managed as outlined in Table 8.3. DVT and pulmonary embolism are major concerns with most data extrapolated from elective bariatric surgery patients.[76] There is no consensus on optimal dosing of heparin or whether to use unfractionated or low molecular weight heparin. A recent study recommended 7,500 units of unfractionated heparin three times daily for patients with a BMI > 50 and 5,000 units of unfractionated heparin three times daily for patients with a BMI < 50.[77] Finally, MB patients require unique equipment for their operation including bigger OR tables, lifts, and longer instruments.

Septic Shock Patients Requiring Emergency Laparotomy

The mortality of these patients has traditionally exceeded 40%, but more recently with the broader application of "damage control" laparotomy, the mortality has been reduced substantially.[78] The rationale for utilizing damage control in septic shock is different from traumatic shock. In traumatic shock, damage control is used when there is severe bleeding and the patient is at risk of entering the "bloody viscous cycle" (i.e., hypothermia, acidosis, and hypothermia), which leads to exsanguination and death. This type of bleeding is generally not a problem when operating on septic shock patients. As depicted in Algorithm 8.1, the problem in septic shock is that the patient presents in a persistent septic shock cycle that can progress to fulminant multiple organ failure (MOF) if nothing is done. They are too ill to tolerate a general anesthetic and need preoperative optimization prior to proceeding to the OR. Optimal timing of OR source control is not known; expert opinion guideline recommendations are that it should be completed by 6 hours.[79] The goal is to quickly optimize the patient, perform a rapid operative intervention for source control to break the cycle, and then return to the ICU for completion of resuscitation.

Preoperative optimization of septic shock can be protocolized based on recommendations by the Surviving Sepsis Campaign.[78] Intravenous volume resuscitation is initiated as measured by urine output and CVP. A fluid bolus of 20 mL per kg of lactated Ringer's should be given initially, with CVP pushed to >8 mm Hg. Norepinephrine is administered to maintain MAP > 65 mmHg. Further fluid boluses (up to a CVP of 12 mm Hg) are given to insure adequate urine output (>0.05 mL/kg), and weaning of the norepinephrine is attempted. Low-dose vasopressin is started in patients requiring persistent high doses of norepinephrine. Broad-spectrum antimicrobial agents (Table 8.7) should be infused within 1 hour.[80] Adrenal function is tested, and steroids are administered if relative adrenal insufficiency is proven. It usually takes 2–3 hours to optimize the patient prior to proceeding to the OR. As the operation begins, the decision is made on whether damage control is going to be utilized. Indications are persistent septic shock (most frequent), myocardial ischemia or serious arrhythmia, and critical hypoxia.

The goals of damage control are to (1) resect dead bowel, (2) limit ongoing contamination, (3) control bleeding (pack as necessary), and (4) have limited irrigation followed by temporary abdominal closure with a vacuum-assisted devise. The patient is returned to the ICU for continued resuscitation, optimization ventilation, rewarming, correction of


ALGORITHM 8.1

ALGORITHM 8.1 The persistent septic shock cycle.

TABLE 8.7

ANTIBIOTIC RECOMMENDATIONS BASED ON SUSPECTED SITE OF INFECTION

■ SUSPECTED SITE OF INFECTION	■ FIRST-LINE DRUG REGIMEN	■ SECOND-LINE DRUG REGIMEN
CAP	Ceftriaxone 1 g IV every 24 h ± azithromycin 500 mg IV/PO every 24 h	Levofloxacin 750 mg IV every 24 h
Suspected aspiration	CAP regimen + clindamycin 600 mg IV every 8 h or change ceftriaxone to piperacillin/tazobactam 4.5 g IV every 6 h	
Early VAP (<5 d)	Cefepime 2 g IV every 24 h	
Late VAP (pseudo-monal risk)	Cefepime 2 g IV every 24 h + Vancomycin 15 mg/kg IV every 12 h + tobramycin 7 mg/kg IV	Ciprofloxacin 400 mg IV every 12 h + vancomycin 15 mg/kg IV every 12 h + tobramycin 7 mg/kg IV
UTI/urosepsis	Piperacillin/tazobactam 4.5 g IV every 6 h	Ciprofloxacin 400 mg IV every 12 h
Line infection	Remove line + vancomycin 1 g IV every 12 h + fluconazole 800 mg IV every 24 h (if risk for candidemia)	
Necrotizing fasciitis	Piperacillin/tazobactam 4.5 g IV every 6 h + vanco-mycin 15 mg/kg IV every 12 h + clindamycin 900 mg IV every 8 h	Ciprofloxacin 400 mg IV every 12 h + vancomy-cin 15 mg/kg IV every 12 h + clindamycin 900 mg IV every 8 h
Surgical site infections	Piperacillin/tazobactam 4.5 g IV every 6 h + vanco-mycin 15 mg/kg IV every 12 h	Ciprofloxacin 400 mg IV every 12 h + vancomy-cin 15 mg/kg IV every 12 h
Intra-abdominal	Imipenem/cilastatin 500 mg IV every 6 h + vanco-mycin 15 mg/kg IV every 12 h ± fluconazole 800 mg IV every 24 h	Ciprofloxacin 400 mg IV every 12 h + metronidazole 500 mg IV every 8 h + vancomy-cin 15 mg/kg IV every 12 h + fluconazole 800 mg IV every 24 h

NOTE: All doses are based on normal renal/hepatic function.
IV, intravenous; PO, per mouth.

coagulopathy, monitoring of bladder pressures, and implementation of routine ICU care (e.g., stress gastritis prophylaxis, DVT prophylaxis, tight glucose control, lung protective ventilation). After stabilization (usually within 24 hours), the patient is returned to the OR for definitive surgery and abdominal wall closure.

Cirrhotic Patient

The mortality rate for emergency surgery in a cirrhotic patient is prohibitive. Consequently, the first question is to determine whether operative intervention is really needed. Individual patient risk can be estimated by calculating the Child-Turcott-Pugh Score (Table 8.8).[81] Estimated mortality rate for emergency surgery in Class A (5 or 6 points) patients is 10%, in class B (7–9 points) is 30%, and in Class C (> 9 points) exceeds 80%.[82] Given that bleeding is major risk of operating on cirrhotic patients, correction of coagulopathy is imperative.[83] Vitamin K deficiency is common in cirrhotic patients due to malnutrition, and single dose of 10 mg is recommended. This is not going to help in the short run, and therefore, FFP should be administered to lower INR < 1.6 if feasible. Given the short half-life of factor VII (3–5 hours) in FFP, additional FFP will need to be administered just prior to surgery. Point-of-care measures such as TEG analysis can guide transfusion of plasma product, reducing considerably the amount of FFP required for hemostasis.[84] If fibrinogen levels < 100 mg per dL, administer 10 units of cryoprecipitate, and if platelet count < 20,000/mm³, administer 6 units of platelets. 1-Deamino-8-D-arginine vasopressin (DDAVP) can improve platelet function by releasing large amounts of von Willebrand factor and should be considered in cases of refractory coagulopathy.

Hypovolemia contributes to hypoperfusion with worsening hepatic function and AKI setting the stage for MOF and death. On the other hand, hypervolemia will contribute to worsening of postoperative pulmonary dysfunction (due to increased pulmonary edema and effusion) and ascites. Therefore, a central venous catheter in the internal jugular vein should be placed under ultrasound guidance. Recognizing the limitations of a single CVP measurement in assessing volume status, it is important to follow the trends in the CVP with volume loading. Additionally, because high-risk cirrhotic patients have lower BP due to vasodilation, placement of a radial arterial

TABLE 8.8

CHILD-TURCOTTE-PUGH (CTP) SCORE TO ASSESS SEVERITY OF CIRRHOSIS

| ■ PARAMETER | ■ POINTS | | |
	■ 1	■ 2	■ 3
Total bilirubin (mg/dL)	<2	2–3	>3
Serum albumin (g/dL)	>3.5	2.8–3.5	<2.8
INR	<1.7	1.71–2.20	>2.20
Ascites	None	Medication control	Refractory
Encephalopathy	None	Grade I-II	Grade III-IV

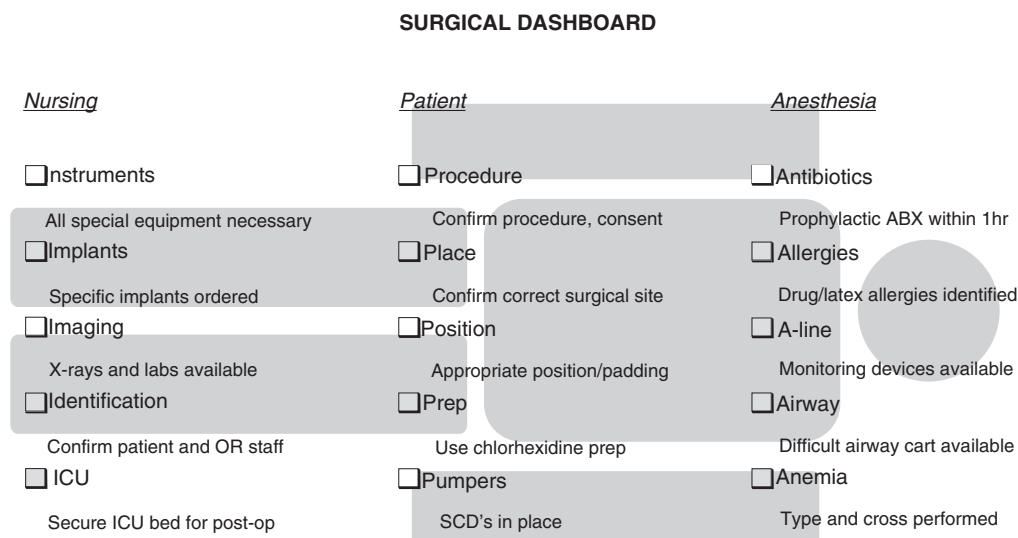
SURGICAL DASHBOARD


FIGURE 8.1. Operating room dashboard

line for more accurate BP measurement is prudent, and norepinephrine should be used to maintain a MAP > 60 mm Hg. In the mechanically ventilated patient, a minimally invasive monitor can be used to assess stroke volume variation and cardiac output.[85]

In regard to volume loading, crystalloid with high sodium content should be avoided to minimize postoperative ascites. However, cirrhotic patients who are hyponatremic and have a metabolic alkalosis may benefit from some normal saline during the preoperative period. Of note, FFP and pRBCs transfusions are good volume expanders and should be administered if indicated. Albumin is another option for volume expansion for the cirrhotic with hypoproteinemia. The last consideration is appropriate antibiotics. The cirrhotic patient should be considered an immunocompromised host and should receive extended prophylaxis for fungal infection. Given the high risk of AKI, aminoglycosides should be avoided.

THE OPERATING ROOM

Smooth transition from preoperative resuscitation to operating room to recovery requires thorough communication with the surgical team and anticipation of a myriad of problems. When possible, the surgeon should make a preemptive trip to the operating room to check the physical properties of the room and discuss the patient with the nursing and anesthesia staff. Careful attention should be paid to the temperature of the room, availability of special equipment (hemostatic agents, retractors, wound management systems, stapling devices, etc.), and positioning of the table. This is particularly important for off-hours cases in which available staff may not be familiar with equipment typical to general cases. If at all possible, involve the help of consulting surgeons or other physicians earlier rather than later. This includes specialty services such as gynecology, urology, orthopedics, vascular surgery, or interventional radiology. The operating room is a high-risk area for communication failure. The team must function at a high level to avoid undue harm to the patient, particularly in an emergency situation. Checklists have been devised to verify clinical information and confirm that specific preventative measures have been taken. The use of checklists before surgery can improve patient outcomes, operating room efficiency, and patient safety

indicators.[86,87] We have devised a surgical dashboard that contains essential elements of emergency general surgery (Fig. 8.1).

CONCLUSION

Caring for the emergency surgical patient can be a challenging but rewarding experience. Good resuscitation principles are essential, but so too is the ability to obtain details thorough secondary examination. Basic components of preparation include shock resuscitation, early interventions with appropriate medication, coagulopathy reversal, and appreciation for cardiopulmonary disease, which may require a more nuanced approach. Adequate preparation can help avoid common pitfalls in the operating room. More importantly, attention to these early interventions can improve the ultimate outcome for patients.

FUNDAMENTAL PRINCIPLES

CHAPTER 9 ■ DIAGNOSTIC IMAGING IN ACUTE CARE SURGERY

BEHROZE A. VACHHA, LEO L. TSAI, KAREN S. LEE, AND MARC A. CAMACHO

The management of acute care surgical patients, as that of all patients, has largely benefited by advances in radiology. Current imaging techniques and modalities have vastly improved the ability to noninvasively diagnose and characterize disease and injury, which has largely supplanted the need for invasive exploratory surgery. Almost equally important, imaging can reliably exclude severe illness or injury in the acute presentation. This has resulted, for example, in a major shift in the management of trauma patients, in particular, with a greater emphasis on conservative management and reduction in the attendant morbidity and mortality introduced by surgical intervention and perisurgical (e.g. ICU) care.

There is a vast array of imaging modalities in the diagnostic armamentarium currently. While radiography, angiography, and nuclear medicine have undergone advances in their own right, the advances in magnetic resonance imaging (MRI), ultrasound (US), and, in particular, computed tomography (CT) have resulted in a major expansion in applications and extraordinary increases in utilization. This has led to justified concerns regarding health care costs, the need for outcomes research, and potential deleterious effects introduced by the imaging modalities themselves (e.g. radiation dose and CT). However, these imaging modalities each exhibit unique advantages that can be exploited for specific indications to help increase accuracy of, and decrease delays in, diagnosis. Additionally, these modalities also may have associated relative and absolute contraindications, which should be considered when considering utilization for a particular patient and clinical scenario.

In this chapter, we present these three imaging modalities in detail, introduce basic background concepts, and detail advantages and disadvantages as well as optimal target patient populations, clinical scenarios, and indications. Each subsection concludes with a gallery of images representing commonly encountered acute care surgical pathology, with detailed captions.

ULTRASOUND

Ultrasound is one of the most utilized and widespread diagnostic imaging modalities in medicine. Ultrasound images are generated by transmitting an ultrasonic pulse and detecting the amplitudes and delay times from returning acoustical echoes reflecting off of tissue interfaces. Typical operating frequencies range from 2 to 12 MHz. The major advantages of this modality include the ability to perform real-time noninvasive imaging without the use of ionizing radiation, its high degree of portability, its relatively low cost, and the capability to acquire images in an infinite number of planes. Additionally, by evaluating Doppler frequency shifts from moving blood, ultrasound can provide blood flow information by producing arterial or venous waveforms and quantitatively measuring blood flow velocities.

Ultrasound is particularly well suited to evaluate the abdomen and pelvis, owing to excellent acoustical windows provided by the liver, spleen, and bladder. The liver window provides a view of the gallbladder, pancreas, right kidney, heart, and right pleural space. The spleen is used to image the left kidney and left pleural space. A full bladder can allow a thorough assessment of the uterus and adnexa. Transvaginal, transrectal, transesophageal, and endoscopic probes are also available for more detailed imaging of the pelvis, prostate, rectum, heart, upper gastrointestinal tract, and pancreas. Ultrasound is also the primary imaging method used for assessment of the fetus, as no ionizing radiation or contrast materials are required, and the transmitted acoustic energy in typical obstetric examinations is accepted as safe.[1] Furthermore, thoracentesis,[2] paracentesis, superficial abscess drainage, percutaneous cholecystostomy, and other minimally invasive bedside procedures are commonly performed under real-time ultrasound guidance.

Common uses of ultrasound in the acute surgical setting include evaluation for acute cholecystitis (Fig. 9.1),[4–6] renal obstruction or calculi (Fig. 9.2), vascular occlusion,[7] ovarian or testicular torsion (Fig. 9.3),[9,10] and appendicitis (Fig. 9.4).[11] Because of its portability and real-time imaging capability, ultrasound is also often employed in the trauma setting to assess patients who may be too unstable for a CT examination. Ultrasound can readily evaluate for solid organ injury within the liver, spleen, and kidneys. Additionally, the Focused Assessment with Sonography for Trauma (FAST) exam is a common bedside ultrasound study used to detect free fluid within the peritoneal, pericardial, and pleural spaces as a first-step measure to identify an internal hemorrhage (Fig. 9.5).[13–15]

Drawbacks of ultrasound include its limited ability to assess the brain, thorax, and bowel due to the presence of tissue–air and tissue–bone interfaces that are nearly completely acoustically reflective and therefore prevent the penetration of ultrasound waves. Ultrasound imaging of obese patients is also challenging, often resulting in low-quality images due to poor penetration of the ultrasound beam. Additionally, ultrasound can be subject to imaging artifacts from oblique scattering and multiple reflections.[16] Most importantly, quality ultrasound imaging is highly dependent on operator skill and experience.

Table 9.1 summarizes the advantages and disadvantages of ultrasound.

Figures 9.1 through 9.5 demonstrate common acute care surgical pathology optimally diagnosed via ultrasound.

MAGNETIC RESONANCE IMAGING

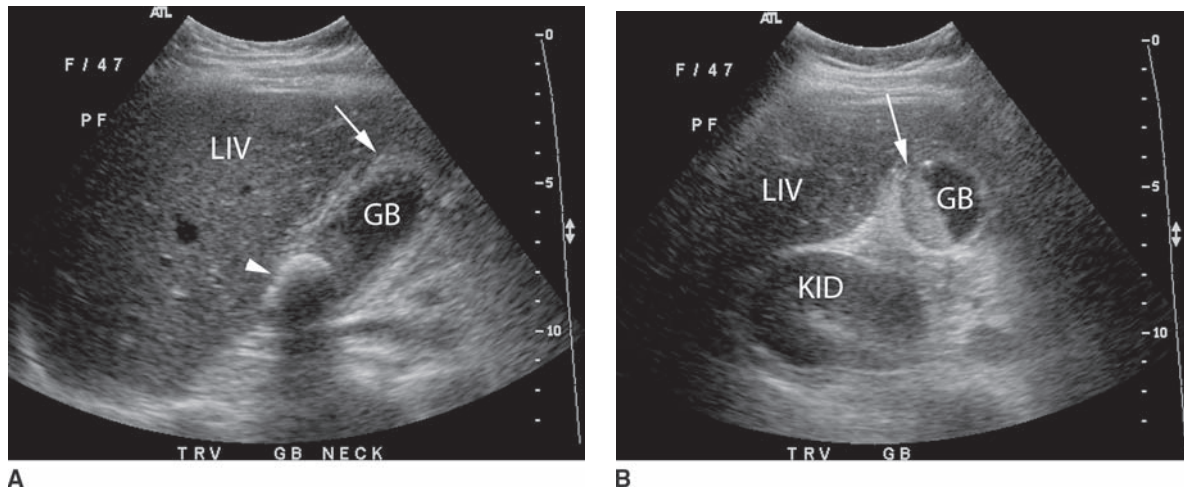
Magnetic resonance imaging (MRI) is performed through manipulation of the magnetic moment of water hydrogen protons within a static magnetic field. The behavior of these


FIGURE 9.1. Acute cholecystitis. **A:** A sagittal view shows a dilated gallbladder with a thickened wall (*arrow*) and a large shadowing stone (*arrowhead*). **B:** A transverse view demonstrates the presence of layering hyperechoic sludge (*arrow*). Sonographic signs that favor acute cholecystitis include wall thickening >3 mm, gallbladder dilation, impacted stone, the presence of a sonographic Murphy's sign, and pericholecystic fluid.[3] Acute cholecystitis was confirmed at surgery. GB, gallbladder; LIV, liver; KID, kidney.

moments, or spins, is directly related to the environment surrounding the water molecule through local effects such as magnetic fields from neighboring spins and energy exchange with nearby nuclei. Images are created after applying pulsed radiofrequency (RF) waves and magnetic field gradients at calculated times, then extracting spatial and temporal data from the subsequent signal patterns. Each programmed set of RF and gradient settings is referred to as a pulse sequence. The signal from protons within fat, protein, or free water can be isolated and highlighted through different pulse sequences, allowing for excellent soft tissue contrast that is superior to other cross-sectional imaging methods.[17] Isometric 3D MRI is now commonly used for multiplanar and curved reconstructions

of vascular and ductal structures. Multiple types of contrast agents can be used to highlight the gastrointestinal tract, vascular structures, or bile ducts.[18,19] Interventional MRI continues to be an active area of research, particularly in oncology.[20]

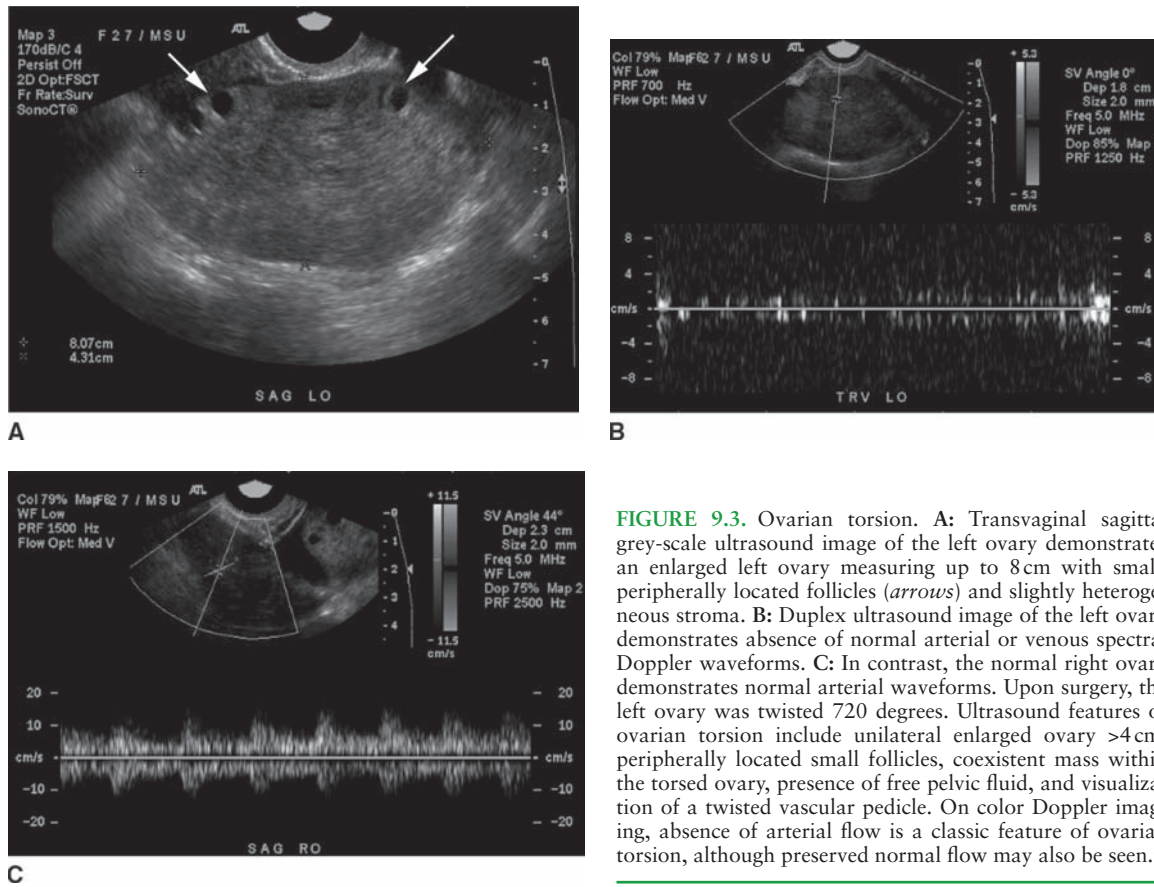
A particular advantage of MRI is that this modality does not employ ionizing radiation, and, therefore, is favored whenever there is a particular desire to limit or avoid radiation exposure, such as in the evaluation of pregnant patients (Figs. 9.6-9.8).[22,23] MRI is also increasingly considered as a primary imaging modality in the evaluation of chronic diseases where the cumulative radiation dose from frequent follow-up CT examinations would be quite substantial. Inflammatory bowel disease is one such entity, where rapid pulse sequences
FIGURE 9.2. Hydronephrosis secondary to obstructing ureteral calculus. **A:** Moderate pelvic and calyceal dilation is present within the left kidney (*asterisk*). Urine and other simple fluids appear anechoic on ultrasound. The kidney is outlined by the caliper markers (+), and the cortex is appropriately homogeneous in echotexture. **B:** A 1-cm shadowing obstructive ureteral calculus, outlined by caliper markers (+), was found at the left ureterovesical junction.


FIGURE 9.3. Ovarian torsion. A: Transvaginal sagittal grey-scale ultrasound image of the left ovary demonstrates an enlarged left ovary measuring up to 8 cm with small, peripherally located follicles (*arrows*) and slightly heterogeneous stroma. B: Duplex ultrasound image of the left ovary demonstrates absence of normal arterial or venous spectral Doppler waveforms. C: In contrast, the normal right ovary demonstrates normal arterial waveforms. Upon surgery, the left ovary was twisted 720 degrees. Ultrasound features of ovarian torsion include unilateral enlarged ovary >4 cm, peripherally located small follicles, coexistent mass within the torsed ovary, presence of free pelvic fluid, and visualization of a twisted vascular pedicle. On color Doppler imaging, absence of arterial flow is a classic feature of ovarian torsion, although preserved normal flow may also be seen.[8]
FIGURE 9.4. Acute appendicitis. A: Graded compression ultrasound imaging at the area of tenderness in the right lower quadrant demonstrates a tubular, blind-ending structure measuring 8 mm in diameter, as marked by the calipers (+), compatible with a dilated appendix, which was noncompressible. B: A transverse view demonstrates the appendix to have an abnormally thickened wall, as outlined by the calipers (+). Sonographic signs for appendicitis include a diameter >6 mm, lack of compressibility, echogenic periappendiceal fat, hyperemia on color Doppler imaging, the presence of an appendicolith, and the presence of adjacent fluid collections that would raise concern for rupture.[3] Acute appendicitis was confirmed upon surgery.
FIGURE 9.5. Hemoperitoneum in Morrison's pouch. A hypoechoic collection (*) is seen between the inferior edge of the right hepatic lobe (*L*) and the right kidney (*K*) in this patient with hemoperitoneum. Fresh blood appears hypoechoic on ultrasound. Acute clots are initially hyperechoic; the echogenicity diminishes with time.[12]

are now able to compensate for peristaltic motion, and T2-weighted, fluid-sensitive sequences are particularly useful for detecting fistulas or abscesses (Figs. 9.9 and 9.10).[25–27] While magnetic resonance cholangiopancreatography (MRCP) is commonly used for assessment of the biliary tree, liver, and pancreas for oncologic staging, surgical planning, or radiotherapy targeting,[28–31] in acute settings, MRCP is well suited for diagnosing emergent gallbladder and biliary tract conditions, including acute cholecystitis, choledocholithiasis, and acute cholangitis (Figs. 9.11 and 9.12).[32] Furthermore, magnetic resonance angiography provides an excellent alternative to CT for the imaging of vascular abnormalities (Fig. 9.13), particularly when iodinated contrast agents cannot be used due to contrast allergies or poor renal function.

Drawbacks of MRI include the need for a large static magnetic field to achieve an adequate signal-to-noise ratio, requiring large superconducting coils that are relatively expensive to maintain. An MRI suite must also be specially shielded to avoid signal interference from electromagnetic noise.

Furthermore, typical magnets have a narrow cylindrical bore that can induce claustrophobia and may not be able to accommodate obese patients or patients who require large support devices.

Another primary disadvantage of MRI is the inability to image patients with MRI-incompatible devices. The high magnetic field strengths of MRI are not compatible with ferromagnetic materials, such as many intracranial aneurysm clips. Additionally, RF pulses used to acquire MR images may interfere with electronic implants, including many current and older generations of cardiac pacemakers. MRI centers, therefore, require prescreening of all patients with a detailed checklist to ensure that the patient is safe for imaging and that all support equipment are MRI compatible.[34] Even the suspected presence of embedded metal within the orbits warrants further evaluation, typically with a radiograph, as fluctuations in magnetic fields can cause current-induced heating and particle movement. Furthermore, metallic implants that are deemed safe for MRI still cause local magnetic field artifacts that distort and obscure adjacent structures, thereby degrading image quality.

Contrast reactions with gadolinium-based agents can occur, as they do with CT agents; however, particular care must be paid to patients with severely impaired renal function, who have an increased risk of developing nephrogenic systemic fibrosis, or NSF. Typical symptoms include swelling and tightening of the skin within the extremities, but can progress to involve the internal organs, including skeletal muscle, myocardium, lungs, kidneys, and dura mater, with potentially fatal outcomes and no effective treatments.[34–36] The proposed pathogenesis is attributed to an abnormal activation of circulating fibrocytes as a response to residual gadolinium in tissues that has remained long after initial administration. Since the first description of NSF in 1997, there have been approximately 335 biopsy-confirmed cases worldwide, but virtually no new cases since 2008 due to widespread restrictions on gadolinium-based contrast use in patients with severe renal failure.[37] The use of intravenous gadolinium-based contrast agents is also not considered safe in pregnancy.[38] With the recent development of robust noncontrast MRI sequencing techniques, these issues related to contrast administration, fortunately, can be circumvented in many cases.

Motion-related artifacts are a common occurrence in MRI. Many sequences require the patient to lie still for a substantially longer amount of time than that needed for a CT or ultrasound, with some sequences lasting several minutes. Additionally, the total duration of an MRI examination can be lengthy compared to other modalities, typically lasting 40 minutes. As a result, sedation is often required in the pediatric population in order to obtain images free of motion artifact. Breath-hold imaging acquisitions can reduce the total imaging time and are frequently used to eliminate respiratory-related motion artifacts. Acutely ill patients who are unable to suspend their respiration, however, pose a challenge for MRI. The use of non–breath-hold, rapid imaging strategies can allow interpretable MR images to be acquired in these sicker patients.

Finally, MRI has a limited capability to image structures that have low water proton density. As a result, the detection of calcifications on MRI can be difficult. Furthermore, imaging of the lungs with MRI is particularly challenging as these structures contain mostly air and, therefore, generate little signal. The multiple air–tissue interfaces within the lung parenchyma also increase the rate of signal decay, further limiting the imaging of the pulmonary parenchyma.

Table 9.2 summarizes the advantages and disadvantages of MRI.

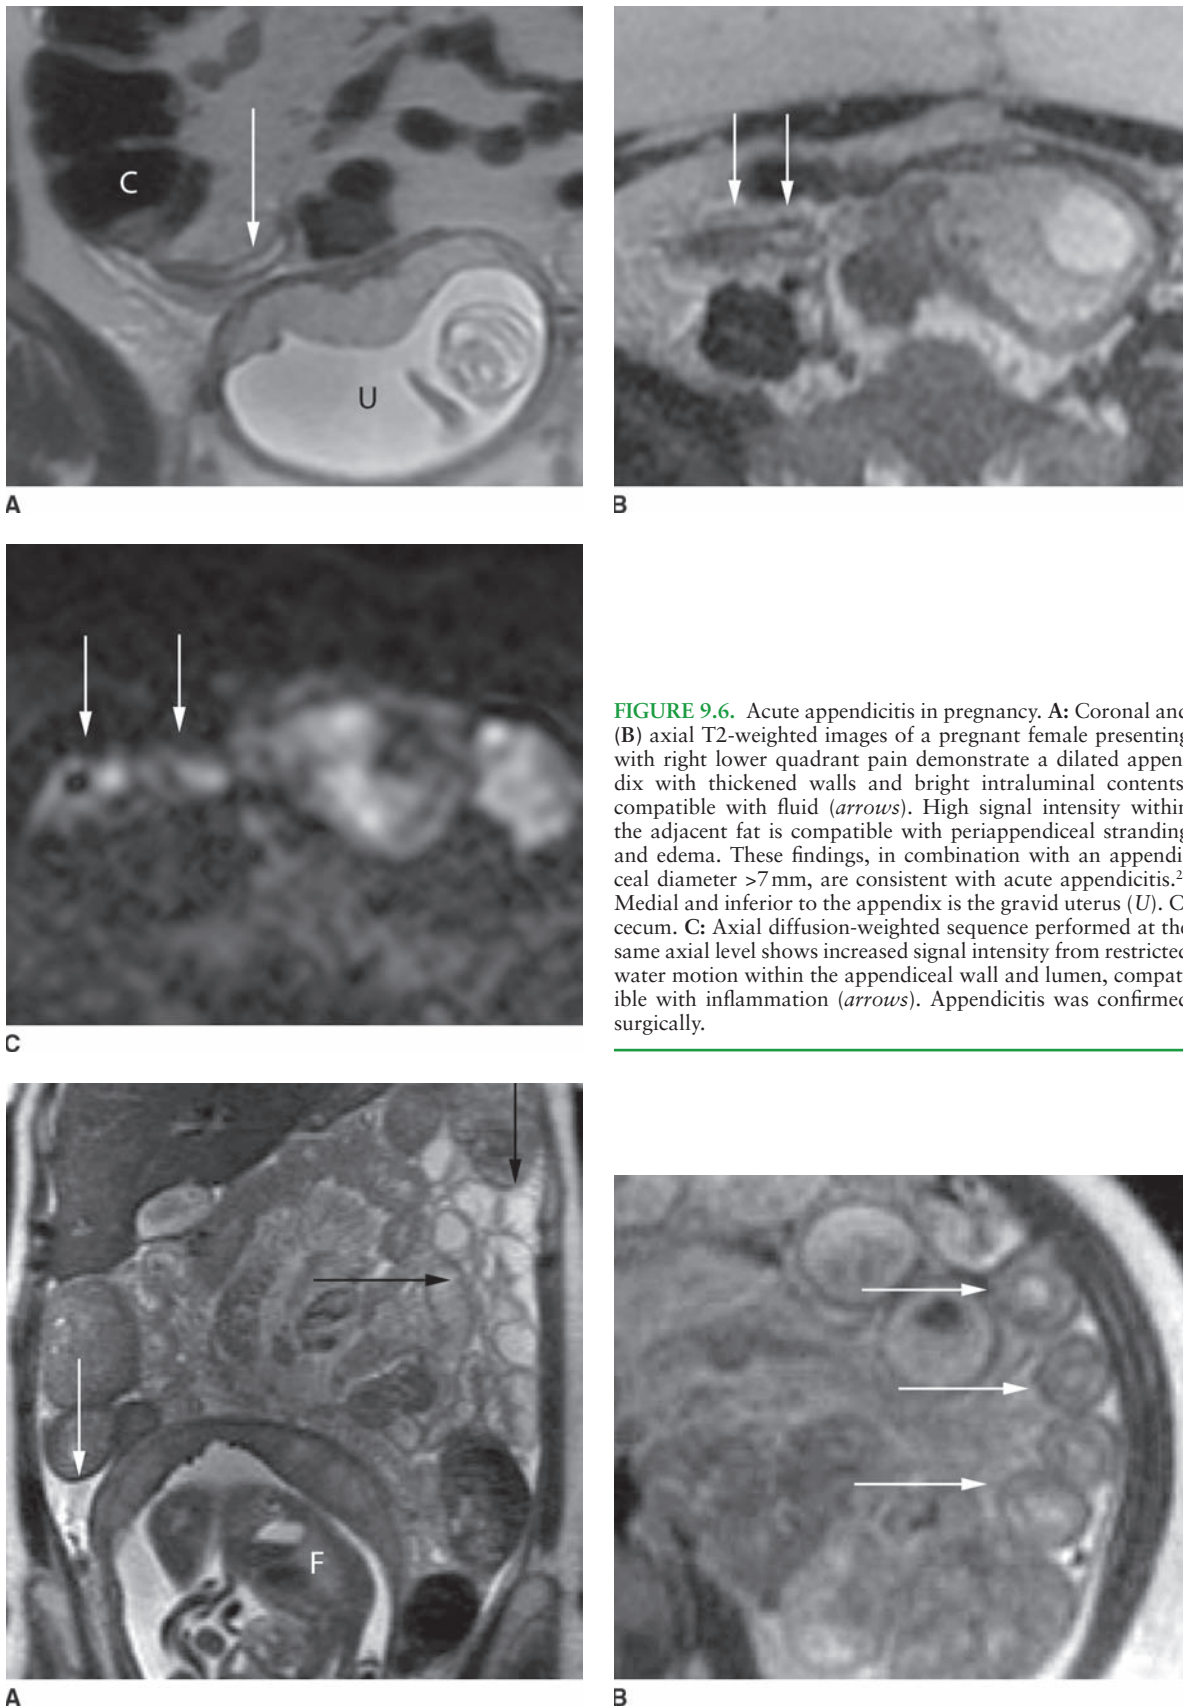
Figures 9.6 through 9.13 demonstrate common acute care surgical pathology optimally diagnosed via MRI.


TABLE 9.1

ADVANTAGES AND DISADVANTAGES OF ULTRASOUND

■ ADVANTAGES	■ DISADVANTAGES
• No ionizing radiation	• Poor penetration through bone or air
• Real-time imaging	• Limited penetration in obese patients
• Safe for pregnant patients	• Highly dependent on operator skill
• Highly portable	
• Relatively low cost	
• Can provide quantitative measurements of vascular flow	

FIGURE 9.6. Acute appendicitis in pregnancy. **A:** Coronal and (**B**) axial T2-weighted images of a pregnant female presenting with right lower quadrant pain demonstrate a dilated appendix with thickened walls and bright intraluminal contents, compatible with fluid (*arrows*). High signal intensity within the adjacent fat is compatible with periappendiceal stranding and edema. These findings, in combination with an appendiceal diameter >7 mm, are consistent with acute appendicitis.[21] Medial and inferior to the appendix is the gravid uterus (*U*). C, cecum. **C:** Axial diffusion-weighted sequence performed at the same axial level shows increased signal intensity from restricted water motion within the appendiceal wall and lumen, compatible with inflammation (*arrows*). Appendicitis was confirmed surgically.

FIGURE 9.7. Ischemic bowel in pregnancy. **A:** Coronal T2-weighted image in a pregnant woman at 25 weeks' gestational age demonstrates fluid-filled loops of small bowel (*black arrows*) in the left abdomen with free intraperitoneal fluid (*white arrow*). F, fetus. **B:** Axial T2-weighted image demonstrates thickening of the proximal loops of small bowel with a target appearance compatible with mural edema. At surgery, the patient was discovered to have a small bowel volvulus secondary to an adhesion resulting in extensive small bowel ischemia. Ischemic bowel on MRI may demonstrate wall thickening and mural stratification or a target appearance, with high signal within the wall on T2-weighted imaging indicative of mural edema.[32,63]
FIGURE 9.8. Small bowel obstruction in pregnancy. **A:** Coronal T2-weighted image in a pregnant female with a history of total colectomy for ulcerative colitis demonstrates diffusely dilated loops of small bowel and free fluid within the abdomen (*arrows*). F, fetus. **B:** Axial T2-weighted image shows dilated loops of small bowel with abrupt tapering within the end ileal loop and a transition point noted at the level of the ostomy due to a stricture (*arrow*).

FIGURE 9.9. Active Crohn's disease. Coronal, fat-suppressed, T1-weighted image of the abdomen obtained after the administration of intravenous contrast demonstrates a matted, abnormal appearance to the loops of small bowel within the midline abdomen. These bowel loops show intense bowel wall enhancement, mural thickening, luminal narrowing, and adjacent mesenteric stranding and enhancement compatible with active inflammation (*arrows*).[24]

COMPUTED TOMOGRAPHY

Computed tomography (CT) is a method of acquiring and reconstructing the image of a thin cross section of an object on the basis of measurements of attenuation.[39] CT images eliminate the problem of superimposing tissues seen with conventional radiographs and provide higher contrast due to the absence of scatter.

Technical developments since the 1990s improved upon earlier conventional CT scanners by advancing helical or spiral technology, increasing speed of gantry rotation, increasing tube outputs to maintain adequate signal-to-noise ratios, and increasing the number of x-ray detector rows. The resultant significant improvements in image quality, acquisition speed, and hence patient throughput have led to a dramatic increase in the use of CT scanners as an essential diagnostic tool for multiple clinical applications.

Spiral CT scanners are of two types: single detector (SDCT) scanners and multi-detector (MDCT) scanners. SDCT scanners have a single row of detectors that are used to record data as the gantry rotates around the patient with the simultaneous translation of the patient through the gantry opening.[39,40] MDCT scanners have multiple parallel rows of x-ray detectors with each of the rows recording data independently as the gantry rotates. Compared to SDCT scanners, MDCT scanners allow for the simultaneous acquisition of multiple slices at higher tube rotation speeds, allowing significant reduction of acquisition times without compromising image quality, particularly along the z-axis (patient–table) direction. The benefit of faster scanning times with MDCT scanners is seen in the examination of uncooperative or critically ill patients who cannot reliably suspend breathing. Additionally, MDCT scanners allow images to be reconstructed with different thicknesses after image acquisition is completed. For these reasons, MDCT scanners have largely replaced SDCT in clinical practice.
FIGURE 9.10. Complex Crohn's disease. **A:** Sagittal T2-weighted image of the pelvis demonstrates an abnormally thickened rectum (*R*) and distal sigmoid colon, in contrast to the proximal sigmoid colon (*S*), which appears normal. A superficial tract compatible with a perianal fistula is present (*arrow*). P, pubic symphysis; B, bladder; U, uterus, L5/S1: vertebral bodies. **B:** Axial T2-weighted image of the lower pelvis demonstrates abnormally thickened distal sigmoid colon (*arrows*). The adjacent proximal sigmoid is normal with smooth, thin walls. I: iliac bones. Axial (**C**) T2-weighted and (**D**) postcontrast T1-weighted fat-suppressed images of the perineum demonstrate a perianal fistula tracking along the right gluteal fold (*arrows*) with marked inflammatory enhancement within the fistula and surrounding soft tissues.

Contraindications/Limitations

Given the acuity and severity of illness or injury often encountered in acute care surgical services, the benefit of rapid and reliable diagnosis often exceeds risks that traditionally accompany CT. For the purpose of completeness, we present a discussion on relative contraindications with the caveat that utilization of CT (with or without intravenous contrast) often requires a careful evaluation of the risk–benefit ratio on a case-by-case basis, ideally via discussions between emergency medicine physicians and/or intensivists, surgeons, and radiologists.

Renal insufficiency and IV contrast: Contrast medium–induced acute renal failure or contrast-induced nephropathy (CIN) is defined as an absolute increase in the serum creatinine
FIGURE 9.11. Choledocholithiasis. Coronal thick-slab heavily T2-weighted MRCP image of the biliary tree demonstrates multiple round filling defects within the gallbladder, cystic duct, and common bile duct (*arrows*) with mild intrahepatic and extrahepatic biliary dilatation.

concentration of at least 0.5 mg/dL or a relative increase of at least 25% from the baseline value.[41–43] The incidence of CIN ranges from less than 5% in the general population[43,44] to 12%-50% in those patients with associated risk factors including preexisting renal impairment and diabetes.[44] Fewer than 5% of patients who develop CIN require dialysis; the majority of patients develop mild renal failure.[43] The main goal is prevention of CIN, and most radiology practices routinely require determination of serum creatinine levels in patients prior to administration of IV contrast. Iso-osmolar nonionic contrast agents, lower doses of contrast agents (aided by increases in

acquisition speed and improved resolution), preadministration hydration regimens, and an increased role for noncontrast studies, wherever possible, can help minimize the risk of CIN.[25,45] Additionally, the American College of Radiology has published guidelines regarding the use of contrast media in patients with renal impairment.[45]

Acute care surgical patients frequently present with predisposing risk factors for acute renal failure, namely hypovolemia, decreased renal perfusion, rhabdomyolysis, nephrotoxicity from polypharmacy, and multiorgan failure. The nephrotoxic effects of intravenous contrast are often, at least in part, mitigated by vigorous fluid resuscitation often undertaken in the usual course of care. Studies have proposed various pre-CT strategies, including oral acetylcysteine and intravenous sodium bicarbonate solution among others; however, benefits have inconsistently been demonstrated.[46–50] The time course of most acute surgical conditions usually precludes undertaking time-consuming pre-CT nephroprotective regimens for moderate impairment (estimated glomerular filtration rate [eGFR] between 45 and 60 mL per second). As previously stated, a case-by-case assessment of the risk–benefit ratio should be made with respect to precipitating risk factors, potential nephrotoxicity from IV contrast (including safety profile of type of contrast used and dose) and urgent time course of administration.

Contrast reactions and IV contrast: Adverse reactions with contrast agents are infrequent, ranging from 5%-12% for the ionic high-osmolality contrast media (HOCM) to 1%-3% for the nonionic low-osmolality contrast media (LOCM).[45,51] Immediate allergic reactions occur within an hour after injection of the contrast media and can be mild (nausea, vomiting, mild urticaria, pallor), moderate (severe vomiting, symptomatic urticaria, vasovagal reaction, mild bronchospasm, tachycardia secondary to transient mild hypotension) or severe (pulmonary edema, cardiac arrhythmias or arrest, circulatory collapse).[25,52] Delayed reactions occur hours to weeks after
FIGURE 9.12. Gangrenous cholecystitis with perforation. **A:** Axial T2-weighted image of the abdomen demonstrates a distended gallbladder (GB) with a thickened and edematous wall. **B:** Postcontrast T1-weighted fat-suppressed axial image shows inhomogeneous enhancement of the gallbladder wall and disruption of mucosal enhancement with a contained perforation (*arrow*). Characteristic features of gangrenous cholecystitis on MRI include a patchy pattern of gallbladder wall enhancement with an interrupted rim of mucosal enhancement.[32,33]

FIGURE 9.13. Abdominal aortic aneurysm with dissection. Coronal, contrast-enhanced, maximal-intensity projection image of the abdominal aorta demonstrates fusiform aneurysmal dilatation of the entire abdominal aorta with an extensive intimal flap (*black arrow*), compatible with dissection. The right renal artery is supplied by the true lumen (*white arrow*), while the left renal artery is supplied by the false lumen (*arrowhead*). Bilateral common iliac artery aneurysms are also present, with a more saccular, irregular appearance of the aneurysm on the right.

injection of the contrast medium and are usually self-limited and cutaneous (rash, erythema, urticaria and angioedema). Underlying medical conditions (asthma, heart disease, dehydration, renal disease, diabetes), medications (NSAIDS, IL-2, beta-blockers, biguanides), and prior reactions to contrast agents can predispose patients to contrast reactions. Allergy or sensitivity to seafood is not associated with an increased risk of allergic-type contrast reactions.[52] However, the history of anaphylactoid reaction to any allergen should raise concern of a potential such reaction to IV contrast. Premedication regimens with prednisone and histamine blocking agents (e.g. diphenhydramine and cimetidine) may be helpful in patients with previous allergic-type reactions to contrast media; however, such regimens are lengthy (typically at least 6 hours or more), again precluding utility in most acute care surgical settings.

Radiation: The technologic sophistication and improved clinical efficacy of CT imaging in the recent past have resulted in a dramatic increase in its use as a diagnostic and screening tool in a variety of clinical contexts. However, this widespread use has resulted in a significant increase in the population's cumulative exposure to ionizing radiation.[53,54]

Deleterious effects of ionizing radiation are divided into deterministic effects (skin erythema/necrosis, epilation, cataracts, sterility) and stochastic effects (carcinogenic and genetic effects). Deterministic effects assume a threshold (set at 2 Gy) below which no direct radiation-induced damage to tissues or organs occurs.[55] A recent study by Huda[56] demonstrated that representative organ-absorbed doses in CT were substantially lower than the threshold doses for the induction of deterministic effects. Patient cancer risk with CT imaging depends upon the dose and radiosensitivity of all exposed organs and tissues and is best quantified by the effective dose parameter, measured in milliSievert (mSv). At present, the dominant notion for stochastic effects is that no threshold dose exists. Instead, the "linear no-threshold" model accepted by many authors for stochastic effects posits a direct dose–response relationship between exposure to even low doses of radiation and the development of solid cancers.[54,57] Data most cited to provide support for this model have been extrapolated from survivors of the Hiroshima bombing, which were primarily obtained for high acute doses delivered at a high dose rate.[56] No other studies to date have verified the linear, no-threshold assumption about cancer associated with the low doses used in diagnostic imaging.[58]

Radiation doses associated with common diagnostic CT scans used in the acute care setting (Table 9.3) do not

TABLE 9.2

ADVANTAGES AND DISADVANTAGES OF MRI

■ ADVANTAGES	■ DISADVANTAGES
• No ionizing radiation	• Relatively long imaging times
• Safe for pregnant patients	• Relatively high cost
• Excellent soft tissue contrast	• Narrow magnet bore can exclude obese or claustrophobic patients
• Pulse sequences can be adjusted to highlight or suppress certain tissues	• Susceptibility and motion artifacts
• Multiplanar capability	• Many MRI-incompatible devices
• Angiography can be performed without IV contrast	• Limited imaging of low–proton density substances (e.g., lung, calcifications)

TABLE 9.3

ADVANTAGES AND DISADVANTAGES OF CT

■ ADVANTAGES	■ DISADVANTAGES
• High spatial resolution	• Significant ionizing radiation
• Excellent soft tissue contrast	• Risks from contrast-induced nephropathy (CIN) and adverse reaction (in cases with IV contrast administration)
• High-speed acquisition	• Relative high cost
• Wide array of applications, including noninvasive diagnostic angiography	• Remains prone to motion and other artifacts
• Multiplanar capabilities	

individually contribute to stochastic or deterministic risk when used appropriately.[59] However, there is growing concern about the radiation risk to patients due to the overuse of CT studies in lieu of non- or low-radiation dose alternatives, or due to multiple repeated exposures (NEJM). The American College of Radiology (ACR) supports the "as low as reasonably achievable" (ALARA) concept that encourages healthcare professionals to use the least amount of radiation needed in imaging exams to achieve the necessary results. Additionally, multiple technical options (x-ray beam filtration and collimation, manual tube current modulation tailored to patient size and indication, peak kilovoltage optimization, improved detector efficiency, noise-reduction algorithms) are now included in newer CT scanners in an effort to reduce the dose from CT exams.[60]

Overall, the deterministic and stochastic risk from urgent CT exams in the acute setting is overwhelmingly small relative to the diagnostic benefit for most acute care surgical indications. However, it is prudent to be aware of radiation dose particularly with regard to age of patient, imaging through radiosensitive organs, and repeated imaging. Consultation with radiologists to determine strategies that reduce radiation doses without compromising diagnostic accuracy or to determine applicability of nonionizing radiation alternative exams (e.g. MRI, US) will promote imaging that is both justified and optimally performed.

Table 9.3 summarizes the advantages and disadvantages of CT.

Figures 9.14 through 9.31 demonstrate common acute care surgical pathology optimally diagnosed via CT. Figures 9.14 through 9.23 depict common traumatic injuries and sequelae on CT. Figures 9.24 through 9.31 depict nontraumatic conditions.

A   **B**
FIGURE 9.14. Acute traumatic aortic injury (ATAI). Coned views of (**A**) contrast-enhanced transverse (axial) slice and (**B**) sagittal reconstruction from chest CT. Contour irregularity at the proximal descending aorta (*white arrow*) represents pseudoaneurysm at the ligamentum arteriosum in the aortic isthmus. ATAI is due to abrupt deceleration resulting in injury at fixation sites: namely the aortic root, the isthmus at the ligamentum arteriosum, and the aortic hiatus. The injury at the isthmus represents the most common site of injury overall, and the most common presenting to the hospital. CT angiography has replaced the need for diagnostic thoracic angiography in the evaluation of trauma patients.[61,62]
FIGURE 9.15. Chest trauma. **A:** Coned view from sagittal reconstruction of chest CT in bone windows demonstrating a minimally displaced fracture of the sternal body (*black arrow*), a commonly missed fracture prior to the routine use of such reconstructions from submillimeter thin slice multidetector CT. Note the pseudofractures (*arrow*) more cephalad due to respiratory motion, a common pitfall, which are invariably accompanied by corresponding irregularities of the skin surface (*arrowhead*). **B:** Coned view of anterior right lung from transverse (axial) slice demonstrating typical appearance of pulmonary contusions, geographic pattern of peripheral patchy opacities. **C:** Coned view of posterior left lung from transverse (axial) slice demonstrating a cystic lucency (*black arrowhead*) within an area of contusion representing a laceration. Lacerations are characterized by the surrounding lung injury and the clinical context of trauma. Completely air-filled lacerations are termed pneumatoceles, those filled with blood are termed hematomas.[64,65] **D:** Coned view of the left hemithorax from transverse (axial) slice demonstrating an anterior pneumothorax (*asterisk*), which was radiographically occult. Multiple studies have shown approximately 5%-15% of pneumothoraces are missed on initial conventional supine chest radiographs and subsequently seen at CT.[66–68]
FIGURE 9.16. Traumatic diaphragmatic injury. **A:** Transverse (axial) and (**B**) coronal slices from contrast-enhanced chest CT. Note the stomach (*asterisk*) herniating into the left hemithrorax. The defect in the diaphragm [*arrowhead* in (**B**)] is typically best demonstrated on nonaxial reconstructions, coronal and/or sagittal.
FIGURE 9.17. Abdominal trauma. **A:** Coned view of liver on transverse (axial) slice from abdominal CT demonstrating jagged linear hypoattenuated foci in the right hepatic lobe (*arrow*) typical of traumatic lacerations, with associated hepatorenal recess hemorrhage (*arrowhead*). Coincident right adrenal hematoma is also noted (*black arrow*, see **D**). **B:** (Different patient Coned view of the spleen on transverse (axial) slice from abdominal CT demonstrating lacerations of the spleen (*arrowheads*) with extensive perisplenic hemorrhage (*asterisk*).
FIGURE 9.17. (*Continued*) **C:** (Different patient) Coned view of the right kidney on sagittal reconstruction from abdominal CT demonstrating multiple lacerations (*arrows*) with an adjacent perirenal hematoma (*asterisk*). **D:** (Different patient) Coned view of adrenal glands and other retroperitoneal structures on transverse (axial) slice from abdominal CT. The slightly hyperattenuated (hyperdense) left adrenal gland (*arrowhead*) is normal in shape. There is a right adrenal hematoma (*arrow*) with periadrenal hemorrhage. Adrenal hematoma can also manifest as an ovoid or round hyperdensity with surrounding stranding (*black arrow* in **A**).

FIGURE 9.18. Bowel and mesenteric injury (BMI). Coned view from contrast-enhanced abdominal CT at level of midabdomen. Hazy ill-defined opacity in mesentery (between *white arrows*) supplying small bowel loops with circumferential wall thickening (*arrowheads*) representing BMI. Highly specific CT signs of BMI include bowel wall discontinuity, extraluminal air otherwise not explained, extraluminal contrast, mesenteric vascular extravasation, mesenteric vascular beading, or the termination of mesenteric vessels. Less specific CT signs include bowel wall thickening, abnormal bowel wall enhancement, mesenteric infiltration, or mesenteric hematoma. Surgical BMI is essentially present when one highly specific finding or two or more less specific findings are present.[69]
FIGURE 9.19. Pelvic trauma. **A:** Transverse (axial) and (**B**) coronal reconstructed slices from a pelvic CT with contrast. The linear focus of hyperattenuation along the course of the internal pudendal artery (*arrow*) is seen adjacent to a left inferior pubic ramus fracture (*arrowhead*) indicates active extravasation. Iliac/acetabular fractures are depicted in B (*asterisk*). **C:** Volume rendered reconstruction of the pelvis filtered for bone and contrast-enhanced vessels from the same data set as in A and B demonstrating extensive left pelvic fractures. Such reconstructions are useful for complex fracture patterns and to assist in preoperative planning as they can be rotated on an axis on the workstation. **D:** Coned view from conventional angiogram with a microcatheter (*arrowhead*) in the left internal pudendal artery and a faint contrast blush distally (*arrow*) indicating extravasation, corresponding to the abnormality on CT. This lesion was successfully embolized.
FIGURE 9.20. Bladder injury. Coned view of the bladder and pelvic structures from coronal reconstructed CT scan of the pelvis. There is mixed attenuation within the bladder lumen (*asterisk*) representing urine mixing with clot with a focus of very hyperattenuated material (*arrow*) representing active hemorrhage from an injured bladder wall artery. Note the discontinuity in the bladder wall representing intraperitoneal bladder injury (*arrowhead*) with intermediate attenuation fluid tracking in the pericolic gutters representing hemoperitoneum (*black arrows*).

FIGURE 9.21. Thoracolumbar trauma. Sagittal reconstructed image in bone windows demonstrating a Chance fracture of T12 (*arrow*) and a superior endplate compression fracture of L1 (*arrowhead*). Multidetector CT of the torso allows high-resolution reconstructions of the spine and obviates the need for conventional radiography of thoracic and/or lumbar spines reducing costs, delay in diagnosis, and radiation dose.[70,71]

FIGURE 9.22. Extremity trauma. Volume-rendered reconstruction from a CT angiogram of the lower extremity filtered for high attenuation structures (bone and contrast-enhanced vasculature). CT angiography can be integrated into the initial CT examination to investigate possible or known extremity vascular injury supplanting diagnostic conventional angiography in select patients.[72]
FIGURE 9.23. Hypovolemic shock. Coned views from transverse (axial) slices from contrast-enhanced abdominal CT demonstrating a small spleen (*asterisk* in **A**), a hyperattenuated left adrenal gland (*arrowhead* in **B**), a flat inferior vena cava (*arrow* in **C**), and hyperattenuated bowel mucosa (**D**) consistent with hypovolemic shock. The so-called hypoperfusion complex was first described in the pediatric radiology literature but now is largely accepted as indicative of shock in the adult patient population as well.
FIGURE 9.24. Esophageal perforation. Perforation of the distal esophagus following attempted dilation of an esophageal stricture is evidenced by extensive air in the mediastinum (*arrows*) and around the aorta (*white arrowhead*) on axial slice from noncontrast chest CT in lung windows. The esophagus (*black arrowhead*) is collapsed with thickened wall. Pleural effusions (*asterisk*) are common. Extraluminal mediastinal air and periesophageal contrast are the most specific findings.
FIGURE 9.25. Acute pancreatitis. **A:** Coned view of the pancreas on transverse (axial) slice from abdominal CT demonstrating pancreatic edema at the junction of the pancreatic head and body (*asterisk*) with extensive surrounding peripancreatic stranding indicating acute pancreatitis. Inflammatory stranding is noted tracking along the Gerota's fascia (*arrow*). Uniform enhancement excludes pancreatic necrosis. **B:** Coned view of the pancreas on axial slice from abdominal CT from the same patient demonstrates tracking of the inflammation into the pericholecystic space (*asterisk*) and along Gerota's fascia (*arrow*). The patient is status postcholecystectomy (*arrowhead*). **C:** Coned view of the pancreatic region in a different patient demonstrates a well-defined oval fluid collection (*asterisk*) with a clearly defined capsule (*arrow*) occupying most of the pancreatic bed consistent with a pseudocyst. There is mass effect on the superior mesenteric (*black arrowhead*) and splenic (*white arrowhead*) veins; however, these opacify well with contrast.
FIGURE 9.26. Small bowel obstruction. **A, B, C:** Coned views of the small bowel on transverse (axial) slices from abdominal CT demonstrate distended loops of small bowel with air fluid levels (*white arrowheads* in **A**) with abrupt transition point in the mid lower abdomen (*white arrow* in **B**). No ascites or bowel wall thickening noted to suggest ischemia. Surgery revealed adhesions, the most common etiology. Please note: It is very rare to see an actual adhesion on CT.[73]
FIGURE 9.27. Acute diverticulitis. Coned views of the descending colon on axial (**A**) and coronal (**B**) slice from abdominal CT demonstrates wall thickening of the descending colon with pericolonic inflammation manifested by fascial thickening and stranding in the pericolic fat (*arrowheads*). A single diverticulum is noted in the inflamed portion of the descending colon (*arrow*). Findings represent uncomplicated acute diverticulitis. **C:** Coned views of the sigmoid colon on axial slice from abdominal CT in a different patient demonstrate thickened sigmoid colon with adjacent fat stranding (*arrowhead*) and rim enhancing collection along the medial aspect of the sigmoid colon consistent with abscess formation (*asterisk*). The abscess abuts the posterolateral aspect of the bladder with focus of air within the bladder (*arrowhead*) concerning for fistula formation. Abscess, sinus, or fistula may complicate diverticulitis. D, Descending colon; S, Sigmoid colon; B, Bladder.
FIGURE 9.28. Large bowel obstruction. **A:** Coned view of the large bowel on axial slice from abdominal CT demonstrates dilation of the large bowel (*arrowheads*) from the cecum to the descending colon. The proximal small bowel is of normal caliber (*arrow*). **B:** Coned views of the large bowel on coronal slice from abdominal CT in the same patient demonstrate a transition point in the left lower quadrant at the junction of the descending colon and sigmoid colon (*arrow*). The bowel distal to the transition point demonstrates marked luminal narrowing, wall thickening, and pericolonic fat stranding consistent with inflammatory stricture (due to prior diverticulitis in this patient). The main causes of mechanical large bowel obstruction include colon cancer, diverticulitis, sigmoid volvulus, and cecal volvulus.[74]
FIGURE 9.29. Acute aortic dissection. Coned views of the chest on axial slice from contrast-enhanced chest CT demonstrate a Stanford A aortic dissection involving the ascending and descending thoracic aorta. The intimal flap (*white arrows*) is lower in attenuation than the contrast opacified blood. Circumferential calcification (*arrowhead*) within the intima helps outline the true lumen. There is extraluminal contrast (*black arrow*) in the anterior mediastinum along the medial aspect of the ascending aorta concerning for rupture. There is also a large mediastinal hematoma (*asterisk*). CT is highly sensitive and specific (>95%) in the diagnosis of aortic dissection and helps determine the aortic branches involved.[40] Specificity for involvement of the ascending aorta can be increased with cardiac gating, which requires specialized protocols and radiologic consultation.
FIGURE 9.30. Aortic occlusion. **A:** Coned view of the abdominal aorta at the level of the kidneys on axial slice from abdominal CT demonstrates complete occlusion of the infrarenal abdominal aorta (*arrow*). Foci of atherosclerotic calcification are noted (*arrowheads*). **B:** Maximal intensity projection (MIP) and (**C**) volume-rendered (VR) images of the distal abdominal aorta in the same patient as (**A**) demonstrate occlusion of the infrarenal abdominal aorta (*arrow*), extensive atherosclerotic calcifications, and extensive collateral vessels.
FIGURE 9.31. Mesenteric ischemia. **A:** Coned views of the small bowel in the mid lower abdomen on axial slice from abdominal contrast-enhanced CT in a patient with mesenteric ischemia demonstrates hypoenhancement of the bowel mucosa and mild bowel wall thickening (*arrowheads*) concerning for bowel ischemia. **B:** Coned views of the abdominal aorta abdomen on axial slice from abdominal contrast-enhanced CT in the same patient demonstrates thrombosed superior mesenteric artery (*arrow*). Findings of acute mesenteric ischemia included mesenteric arterial or venous thrombus, mesenteric venous gas, pneumatosis intestinalis, bowel-wall thickening, increased or decreased enhancement of the bowel wall. **C:** Maximal intensity projection (MIP) and (**D**) volume-rendered (VR) images of the abdominal aorta in the same patient as (A) and (B) demonstrate complete occlusion of the proximal portion of the superior mesenteric artery which is therefore not visualized (site of origin of the superior mesenteric artery is marked by *asterisk*). There is reconstitution of the distal portion of the superior mesenteric artery (*white arrow*). Celiac axis (*arrowhead*) is patent. Note the stent within the inferior mesenteric artery (*black arrow*).

CHAPTER 10 ■ HEMATOLOGIC ABNORMALITIES, COAGULOPATHY, AND TRANSFUSION THERAPY

LENA M. NAPOLITANO

HEMATOLOGIC ABNORMALITIES

Red Blood Cell Disorders

Anemia Anemia is common in critically ill and injured patients admitted to the intensive care unit (ICU), with >90% of patients anemic on ICU day 3.[1] Anemia in the ICU is associated with appreciable red blood cell (RBC) transfusion use (Table 10.1).[2–9] Furthermore, anemia persists after ICU discharge, with >50% of patients still anemic 6 months after ICU discharge.[10–12]

The World Health Organization defines anemia as Hb concentration <12 g/dL in women and <13 g/dL in men. Etiologies of anemia in the ICU include blood loss related to daily phlebotomy, hemodilution due to crystalloid fluid resuscitation, renal replacement therapies, renal disease, hemorrhage, occult blood loss from the gastrointestinal tract, bone marrow suppression due to diseases, drug-induced anemia, and nutritional deficiencies such as iron, folate, and vitamin B12 deficiency. In ICU patients with anemia and chronic kidney disease, treatment with erythropoietin-stimulating agents (ESAs) is indicated, with target hemoglobin concentrations no higher than 9 g/dL. Adjunctive iron treatment should be strongly considered, as optimal response to ESAs requires supplemental iron.

In most ICU patients, the etiology of anemia is "anemia of inflammation" or "anemia of chronic disease." Anemia of inflammation develops via three mechanisms: (1) impaired iron regulation, (2) shortened RBC life span, and (3) reduced rate of erythropoiesis related to inappropriate erythropoietin response. Hepcidin is the main iron regulatory hormone, made primarily in hepatocytes, and causes functional iron deficiency, hypoferremia, and iron-restricted erythropoiesis despite normal iron stores by blocking enteral iron absorption and shuttling iron into macrophages where it is unavailable for erythropoiesis (Fig. 10.1). Hepcidin concentrations are high in anemia of inflammation and anemia of chronic disease (ACD).[13]

ANEMIA: CLINICAL APPROACH TO DIAGNOSTIC EVALUATION

All ICU patients with anemia should undergo a diagnostic evaluation (Algorithm. 10.1) as for any patient with anemia. Determination of the causative factors for anemia will allow appropriate anemia management, which will aid in avoiding RBC transfusion solely for the treatment of anemia.

ANEMIA AND DIAGNOSIS OF IRON DEFICIENCY IN THE INTENSIVE CARE UNIT

Iron deficiency is difficult to diagnose in intensive care unit (ICU) patients, since most will have high ferritin levels related to inflammation. In these patients, one should check blood zinc protoporphyrin concentration, which will be high in iron deficiency. In the presence of inflammation, true iron deficiency is defined by a ferritin < 100 ng/mL and a TSAT < 20%, whereas functional iron deficiency is defined by ferritin > 100 ng/mL and a TSAT < 20% (Algorithm 10.2).

Total iron deficit (TID) can be calculated using the Ganzoni formula: TID (mg) = weight (kg) × (ideal Hb – actual Hb) (g/dL) × 0.24 + depot iron (500 mg). According to this formula, a person weighing 70 kg with a Hb concentration of 9 g/dL would have a body iron deficit of about 1,400 mg. Following the administration of oral iron, it takes 2–2.5 weeks for the Hb to start rising, 2 months for it to return to normal levels, and 6 months for iron stores to be replete. In anemia of inflammation or ACD, enteral iron absorption is problematic due to high hepcidin concentrations, which block enteral iron absorption, and intravenous (IV) iron should be considered. A number of safe IV iron formulations are now available for use (Table 10.2).

Polycythemia Polycythemia is not common in critical care and is defined as Hgb > 18.5 g/dL (men) > 16.5 g/dL (women) or Hgb > 17 g/dL (men) > 15 g/dL (women) if associated with a sustained increase of >2 g/dL from baseline that cannot be attributed to correction of iron deficiency. The most common cause of polycythemia is hypoxia secondary to pulmonary disease. A low-serum erythropoietin concentration in the polycythemic patient suggests the diagnosis of polycythemia vera. Management of polycythemia is control of the underlying cause (i.e., removal of an erythropoietin-secreting tumor) and limited phlebotomy as indicated if symptoms are present.

Platelet Disorders

Platelet disorders are common in the ICU. Thrombocytopenia occurs often in critical illness, perhaps in up to 41% of patients.[14] Thrombocytosis and functional platelet disorders are less common and are found in up to 25% of ICU patients. Systematic evaluation of platelet disorders in critical care is essential to accurate identification and management of the cause. Importantly, thrombocytopenia has been associated with adverse outcomes. In contrast, thrombocytosis has been associated with improved outcomes in the ICU.

Thrombocytopenia Thrombocytopenia is defined as a platelet count of <150,000/mm^3 or <150 × 10^9/L. The normal range for platelet count in adult humans is 150–450 × 10^9/L. Thrombocytopenia may result from decreased production or increased destruction of platelets. A patient is at risk for spontaneous bleeding when the platelet count fall below 20,000 and may warrant platelet transfusion.

The reported incidence of thrombocytopenia in the critical care setting varies from 23% to 41% and is associated with mortality rates between 38% and 54% in retrospective studies.[15–22] Although the incidence of severe thrombocytopenia (platelet counts lower than 50 × 10^9/L) is lower (10%–17%), the association with adverse outcomes is even stronger. Sepsis

TABLE 10.1

RESULTS OF EPIDEMIOLOGIC STUDIES ON ANEMIA AND BLOOD TRANSFUSION IN CRITICAL CARE

	n	MEAN ADMISSION HEMOGLOBIN (g/dL)	PERCENTAGE OF PATIENTS TRANSFUSED IN ICU (%)	MEAN TRANSFUSIONS PER PATIENT (U)	MEAN PRE-TRANSFUSION HEMOGLOBIN (g/dL)	MEAN ICU LENGTH OF STAY (D)	ICU MORTALITY (%)	HOSPITAL MORTALITY	ADMISSION APACHE II (MEAN)

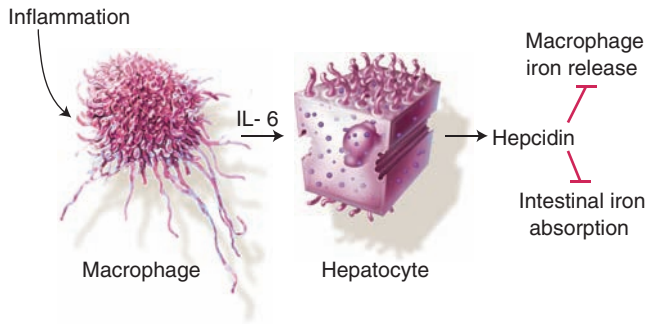

FIGURE 10.1. Hepcidin and the anemia of critical illness. Regulation of hepcidin production in inflammation. Inflammation leads to macrophage elaboration of IL–6, which acts on hepatocytes to induce hepcidin production. Hepcidin inhibits macrophage iron release and intestinal iron absorption, leading to hypoferremia.

and hemodilution are common etiologies of thrombocytopenia in critical illness, but heparin-induced thrombocytopenia (HIT) is one potential etiology that warrants serious consideration in all patients.

DIAGNOSTIC EVALUATION OF THROMBOCYTOPENIA IN THE INTENSIVE CARE UNIT

Systematic evaluation of the numerous potential etiologies of thrombocytopenia in critical care is essential to accurate identification and management of the cause (Table 10.3). Sepsis is the most common etiology of thrombocytopenia in critical illness, accounting for 48% of cases of thrombocytopenia.[23] However, >25% of intensive care unit (ICU) patients have more than one cause of thrombocytopenia.[8] Drug-induced thrombocytopenias present diagnostic challenges, because many of the multiple medications administered to ICU patients may be the cause.[24] One such commonly administered drug is heparin—the most common cause of drug-induced thrombocytopenia due to immune mechanisms.

The three most important causes of thrombocytopenia in the ICU are drug-induced thrombocytopenia, HIT, and disseminated intravascular coagulation (DIC). A number of other etiologies of thrombocytopenia may occur in ICU patients. These include autoimmune or alloimmune thrombocytopenia (ITP), posttransfusion purpura, the thrombotic microangiopathies [thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS)], and the HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome. TTP most commonly presents with a pentad of thrombocytopenia (with purpura), RBC fragmentation, renal failure, neurologic dysfunction, and fever.

Drugs can induce thrombocytopenia by a number of mechanisms. In addition to those that are directly cytotoxic, thiazide diuretics, interferon, and alcohol can cause thrombocytopenia by inhibiting platelet production in the bone marrow. More commonly, drug-induced thrombocytopenia results from the immunologic destruction of platelets. Drugs can induce antibodies to platelets either by acting as a hapten or by functioning as an innocent bystander. Drugs such as gold salts and interferon can induce an ITP-like disorder. Some common ICU drugs that are associated with thrombocytopenia are detailed in Table 10.4.

HEPARIN-INDUCED THROMBOCYTOPENIA

Heparin-induced thrombocytopenia (HIT) is an anticoagulant-induced *prothrombotic* disorder. HIT is an immune-mediated adverse drug effect characterized by platelet activation, hypercoagulability, and increased risk of thrombosis, both venous and arterial. HIT is caused by platelet-activating heparin-dependent antibodies of immunoglobulin G class. HIT should be considered when the platelet count falls to $<150 \times 10^9$/L (or by >50% from baseline) between days 5 and 14 of exposure to any heparinoid product. Rapid-onset HIT can occur if heparin is given to a patient who already has circulating HIT antibiotics, usually due to heparin given in the last 5–100 days. Thrombocytopenia in HIT is usually moderate – mean platelet count 60×10^9/L – and recovers within a few days of heparin discontinuation. Some patients will develop HITT—HIT and thrombosis (venous or arterial) with associated high rates of limb loss and mortality, ranging from 10% to 20%. A high index of suspicion is required for early recognition of HIT. A clinical scoring system is used to identify patients with HIT, called the "4 Ts" (Table 10.5), with a pretest probability score of 6–8 indicating high risk for HIT.

TABLE 10.2

INTRAVENOUS (IV) IRON PREPARATIONS AVAILABLE FOR USE

■ IRON PREPARATION		■ MOLECULAR WEIGHT (MW)	■ TEST DOSE REQUIRED?	■ DOSING ISSUES	■ ADMINISTRA-TION TIMING	■ ADVERSE EVENTS
Ferric gluconate	Ferrlicit	Low MW, unstable complex	No	Dose limitation 62.5 mg	Slow	Risk of labile iron toxicity, oversaturation of iron transport system
Iron sucrose	Venofer	Medium MW, semistable	No	Max single dose 200 mg	Slow	High pH of solution, lowest rate of adverse events reported
Iron dextran	Dexferrum, Imferon	High MW, stable complex	Yes	High single dose possible	Slow	Risk of anaphylaxis
Ferric carboxy-maltose	Ferinject	High MW, stable complex	No	High single dose possible	Fast	Low immunogenic potential
Ferumoxytol	Feraheme, iron oxide nanoparticles	High MW, stable complex	No	High single dose possible	Fast	Minimal

TABLE 10.3

POTENTIAL ETIOLOGIES OF THROMBOCYTOPENIA

Common causes
- Hemodilutional (postresuscitation and perioperative)
- Sepsis and healthcare-associated infections
- Drug-induced thrombocytopenias, including HIT
- Peripheral platelet consumption or destruction
- DIC
- MT
- Lab error-clumping secondary to EDTA in test tube need smear to examine

Less common causes
- Liver disease
- Hypersplenism
- Primary marrow disorder, bone marrow failure
- Antiphospholipid antibody syndrome/lupus anticoagulant
- Immune thrombocytopenias (ITP, TTP, PTP)
- Intravascular devices (IABP, LVAD, ECMO, pulmonary artery catheter)

HIT, heparin-induced thrombocytopenia; DIC, disseminated intra-vascular coagulation; ITP, idiopathic thrombocytopenic purpura; PTP, posttransfusion purpura; TTP, thrombotic thrombocytopenic purpura;
IABP, intra-aortic balloon pump; LVAD, left ventricular assist devices; ECMO, extracorporeal membrane oxygenation.

TABLE 10.4

COMMON DRUGS THAT CAN INDUCE THROMBOCYTOPENIA

Quinidine
Amiodarone
Captopril
Thiazide diuretics
Ibuprofen
Phenytoin
Carbamazepine
Glibenclamide
Gold
Tamoxifen
Cimetidine
Ranitidine
Sulfonamides
Vancomycin
Piperacillin

Once HIT is strongly suspected in a critically ill patient, prompt discontinuation of all heparin and administration of an alternative nonheparin anticoagulant (commonly a direct thrombin inhibitor, DTI, Table 10.6) should be initiated. The principles of treatment for suspected or confirmed HIT include the "Six A's" (Table 10.7).[25] Do not wait for the laboratory confirmation of HIT prior to initiation of a DTI—this is associated with increased risk for thrombosis and adverse outcome. When evaluating a patient for HIT, one must also consider a number of other potential etiologies of thrombocytopenia (Table 10.8).[26]

HIT diagnosis is confirmed with either a positive anti-PF4/polyanion-IgG enzyme immunoassay or a positive platelet activation assay (i.e., serotonin-release assay). Once platelet count has normalized, warfarin should be initiated with a low maintenance dose (specifically, no loading dose) and overlapped with the nonheparin anticoagulant until the target international normalized ratio has been reached and for a minimum of 5 days. The duration of warfarin therapy should be standard for venous thromboembolism (VTE), for a minimum of 6 months with consideration for a more extended course depending on clinical circumstances related to the thromboembolic event.

TABLE 10.5

A CLINICAL SCORING SYSTEM USED TO DIAGNOSE HIT: THE "FOUR T'S"

■ CLINICAL SCORING SYSTEM USED TO DIAGNOSE HIT: THE "FOUR T'S"			
	■ POINTS (0, 1, OR 2 FOR EACH OF THE FOUR CATEGORIES): MAXIMUM SCORE = 8		
	■ 2	■ 1	■ 0
Thrombocytopenia	>50% platelet decrease to nadir ≥20	30%–50% platelet decrease, or nadir 10–19, or >50% decrease secondary to surgery	<30% platelet decrease, or nadir < 10
Timing[a] of onset of platelet decrease (or other sequelae of HIT)	Days 5–10 or ≤ day 1 with recent heparin (past 30 days)	>Day 10 or timing unclear; or < day 1 with recent heparin (past 31–100 days)	<Day 4 (no recent heparin)
Thrombosis or other sequelae	Proven new thrombosis, skin necrosis, or acute systemic reaction after IV unfractionated heparin bolus	Progressive or recurrent thrombosis, erythematous skin lesions, suspected thrombosis (not proven)	None
Other cause of platelet decrease	None evident	Possible	Definite

[a]First day of immunizing heparin exposure considered day 0. Pretest probability score: 6–8 indicates high; 4–5, intermediate; and 0–3, low.

TABLE 10.6

NONHEPARIN ANTICOAGULANTS FOR HIT TREATMENT

■ DRUG	■ MECHA-NISM	■ APPROVED FOR HIT	■ HALF-LIFE	■ MONITORING	■ DOSING	■ CLEARANCE
Fondaparinux	Long-acting AT3-dependent inhibition of factor Xa	Not approved for HIT treatment in the United States	Long (24 h); avoids potential for rebound hypercoagulable state	Direct (anti-Xa levels): accurate drug levels obtained	Not established for HIT, but consider 7.5 mg once daily (prophylaxis dose is 2.5 mg daily)	Renal
Danaparoid	Long-acting AT3-dependent inhibition of factor Xa	Not approved for HIT, not available in the United States, Approved for HIT in Canada, Europe, Australia, New Zealand and Japan.	Long (17–20 h) avoids potential for rebound hypercoagulable state	Direct (anti-Xa levels): accurate drug levels obtained	Bolus: 2250 U IV only in life-or limb-threatening thrombosis;infusion, 400 U/h × 4 h, then 300 U/h × 4 h, then 200 U/h IV, subsequently adjusted by anti-Xa levels (target, 0.5–0.8 anti-Xa U/mL)	Renal
Argatroban	Direct thrombin inhibitor (DTI)	Approved for HIT treatment in the United States	Short (40–50 min); potential for rebound hypercoagulable state	Indirect (APTT): risk for DTI underdosing due to APTT elevation for non-DTI factors	No bolus; initial rate, 0.5–2 μg/kg/min (adjust to APTT); reduce in liver disease	Hepatobiliary
Lepirudin	Direct thrombin inhibitor (DTI)	Approved for HIT treatment in the United States	Short (80 min); potential for rebound hypercoagulable state	Indirect (APTT): risk for DTI underdosing due to APTT elevation for non-DTI factors	No bolus; initial rate, 0.10 mg/kg/h (adjust to APTT); reduce dose for renal dysfunction	Renal
Bivalirudin	Direct thrombin inhibitor (DTI)	Not approved for HIT treatment in the United States	Short (25 min); potential for rebound hypercoagulable state	Indirect (APTT): risk for DTI underdosing due to APTT elevation for non-DTI factors	Not established; no bolus; initial dose, 0.15–0.20 mg/kg/h has been suggested	Enzymic metabolism

APTT, activated partial thromboplastin time.
Adapted from: Warkentin TE, Greinacher A, Koster A, et al. Treatment and prevention of heparin-induced thrombocytopenia. American College of Chest Physicians evidence-based clinical practice guidelines. 8th ed. *Chest.* 2008;133(suppl 6):340S–380S.

TABLE 10.7

THE PRINCIPLES OF TREATMENT FOR SUSPECTED OR CONFIRMED HIT: THE "SIX A'S"

Two "Do's"	1. Avoid and discontinue all heparin (including low molecular weight heparin) 2. Administer an alternative nonheparin anticoagulant with a DTI
Two "Don'ts"	3. Await platelet recovery before initiation of warfarin anticoagulation 4. Avoid platelet transfusions
Two diagnostics	5. Anti-PF4/heparin antibody test for confirmation 6. Assess for lower extremity deep venous thrombosis

Adapted from: Napolitano LM, Warkentin TE, AlMahameed A, Nasrawy SA. Heparin-induced thrombocytopenia in the critical care setting: diagnosis and management. *Crit Care Med.* 2006;34:2898–2911.

Thrombocytopenia Treatment In the bleeding patient, platelet transfusion is most commonly required. HIT is treated with heparin discontinuation and substitution of an alternative anticoagulant (DTI). Plasma exchange with fresh frozen plasma is the most effective treatment for TTP. HUS is best treated with supportive therapy including dialysis. Corticosteroids and splenectomy are the mainstays of therapy for ITP.

Thrombocytosis Thrombocytosis is defined as a platelet count above the normal value, in general, > 400–600,000/mm^3 or > 400–600 × 10^9/L (normal in adults—150–450 × 10^9/L). Thrombocytosis is classified into primary and secondary forms. *Primary (Clonal) thrombocytosis* is due to clonal thrombopoiesis and most often occurs in chronic myeloproliferative or in some myelodysplastic disorders. *Secondary (Reactive) thrombocytosis* is the most common form of thrombocytosis and is due to a variety of underlying conditions involving an acute phase reaction. These include trauma, surgery, bleeding, malignancy, infection, and inflammatory diseases.[27–29] (Table 10.9) Thrombocytosis is common (up to 25% of ICU patients) in the critically ill and is associated with improved outcome.

TABLE 10.8

COMPARISON OF SELECTED THROMBOCYTOPENIC DISORDERS THAT SHOULD BE CONSIDERED WHEN EVALUATING A PATIENT FOR HEPARIN-INDUCED THROMBOCYTOPENIA (HIT)

■ DISORDER	■ COMMON CLINICAL MANIFESTATIONS	■ USEFUL CLINICAL LABORATORY ANALYSES	■ COMMENTS
Heparin-induced thrombocytopenia (HIT)	>50% present with thrombosis; venous thrombosis > arterial.	Anti-heparin/PF4 antibody testing (ELISA, functional assays).	Temporal relationship with heparin or LMWH therapy.
Antiphospholipid syndrome (APS)	Recurrent venous and/or arterial thromboembolic complications; recurrent fetal loss.	Anticardiolipin antibody and anti-β$_2$-glycoprotein I antibody testing (ELISA); lupus anticoagulant testing.	Autoimmune disorder, either primary or associated with other rheumatologic conditions (e.g., lupus); in some cases, may be drug-induced (e.g., procainamide).
Disseminated intravascular coagulation (DIC)	Hemorrhagic or thromboembolic events predominate, depending on underlying cause and clinical course.	PT, PTT, thrombin time, fibrinogen, D-dimer.	May be acute (e.g., associated with sepsis, obstetric complications, severe trauma) or chronic (e.g., associated with cancer, aortic aneurysm). DIC can complicate severe HIT.
Thrombotic thrombocytopenic purpura (TIP)	Neurologic manifestations may include stroke, TIA, altered mental status, seizures; other symptoms include fever, renal insufficiency.	Microangiopathic hemolytic changes on blood film, elevated LDH, decreased ADAMTS13 levels.	Associated with severe ADAMTS13 deficiency due to inhibitors in most patients; may be seen in patients taking ticlopidine or clopidogrel, or with other drugs, (e.g., cyclosporine, tacrolimus, mitomycin). Microangiopathy can also be seen in severe HIT with associated DIC.
Drug-induced thrombocytopenia (non-heparin)	Petechiae, purpura, and other hemorrhagic symptoms with severe thrombocytopenia.	Isolated thrombocytopenia, may be severe.	Associated with multiple drugs (e.g., abciximab, quinine, multiple antibiotics).
Post-transfusion purpura (PTP)	Hematoma, ecchymoses, purpura.	Severe thrombocytopenia that begins approximately 5 days after blood product use.	Temporal relationship to transfusion therapy; most common in multiparous females. The timing of PTP approximately one week after surgery can mimic HIT.

LMWH indicates low molecular weight heparin; DIC, disseminated intravascular coagulation; ELISA, enzyme-linked immunosorbent assay; TIA, transient ischemic attack; PT, prothrombin time; PTT, partial thromboplastin time; LDH, lactate dehydrogenase; ADAMTS13, a disintegrin and metalloproteinase with thrombospondin components–13.
Common clinical manifestations focus on thrombotic versus hemorrhagic symptoms. Comments include relationships to other disorders and/or drugs that need to be considered. HIT has also been reported to occur concomitantly in patients with antiphospholipid syndrome or DIC
From: Ortel TL. Heparin-induced thrombocytopenia: when a low platelet count is a mandate for anticoagulation. *Hematology Am Soc Hematol Educ Program.* 2009:225–232.

MAJOR CAUSES OF THROMBOCYTOSIS

1. Primary (clonal) thrombocytosis (chronic myeloproliferative diseases)
   Essential (primary) thrombocythemia
   Other myeloproliferative disorders (chronic myelogenous leukemia, polycythemia vera, myeloid metaplasia, and myelofibrosis)

2. Familial thrombocytosis

3. Secondary (reactive) thrombocytosis
   Acute hemorrhage
   Trauma
   Major surgery
   Iron deficiency anemia, hemolytic anemia
   Postsplenectomy
   Recovery ("rebound") from thrombocytopenia
   Malignancies
   Chronic inflammatory and infectious diseases (inflammatory bowel disease, connective tissue disorders, temporal arteritis, tuberculosis, and chronic pneumonitis)
   Acute inflammatory and infectious diseases
   Response to intense exercise
   Reaction to drugs (vincristine, epinephrine, all-*trans*-retinoic acid, cytokines, and growth factors)

Thrombocytosis Treatment The greatest challenge in formulating a treatment plan for ICU patients is to correctly diagnose the cause of thrombocytosis. Treatment for patients with reactive thrombocytosis should be directed at the underlying disease. The abnormal platelet count itself does not increase the risk for thrombotic complications. Therefore, antiplatelet or platelet-lowering therapy is not indicated. In contrast, clonal thrombocytosis often needs treatment to reduce platelet counts, especially for high risk patients.[30] This group includes those with a history of bleeding or thrombotic complications, age > 60 years, other cardiovascular risk factors or extremely high platelet counts (>1,500 × 10^9/L).[31] Some of the agents employed to decrease platelet counts include hyroxyurea, interferon-α, and anagrelide. Low-dose aspirin (40–325 mg) has been used to reduce the risk of thrombosis in patients with platelet counts < 1,500 × 10^9/L.[32] Platelet apheresis and phlebotomy have been used to decrease platelet counts rapidly in patients with life-threatening complications from thrombocytosis. An algorithmic approach to the management of thrombocytosis is depicted in Algorithm 10.3.[33]

COAGULOPATHY

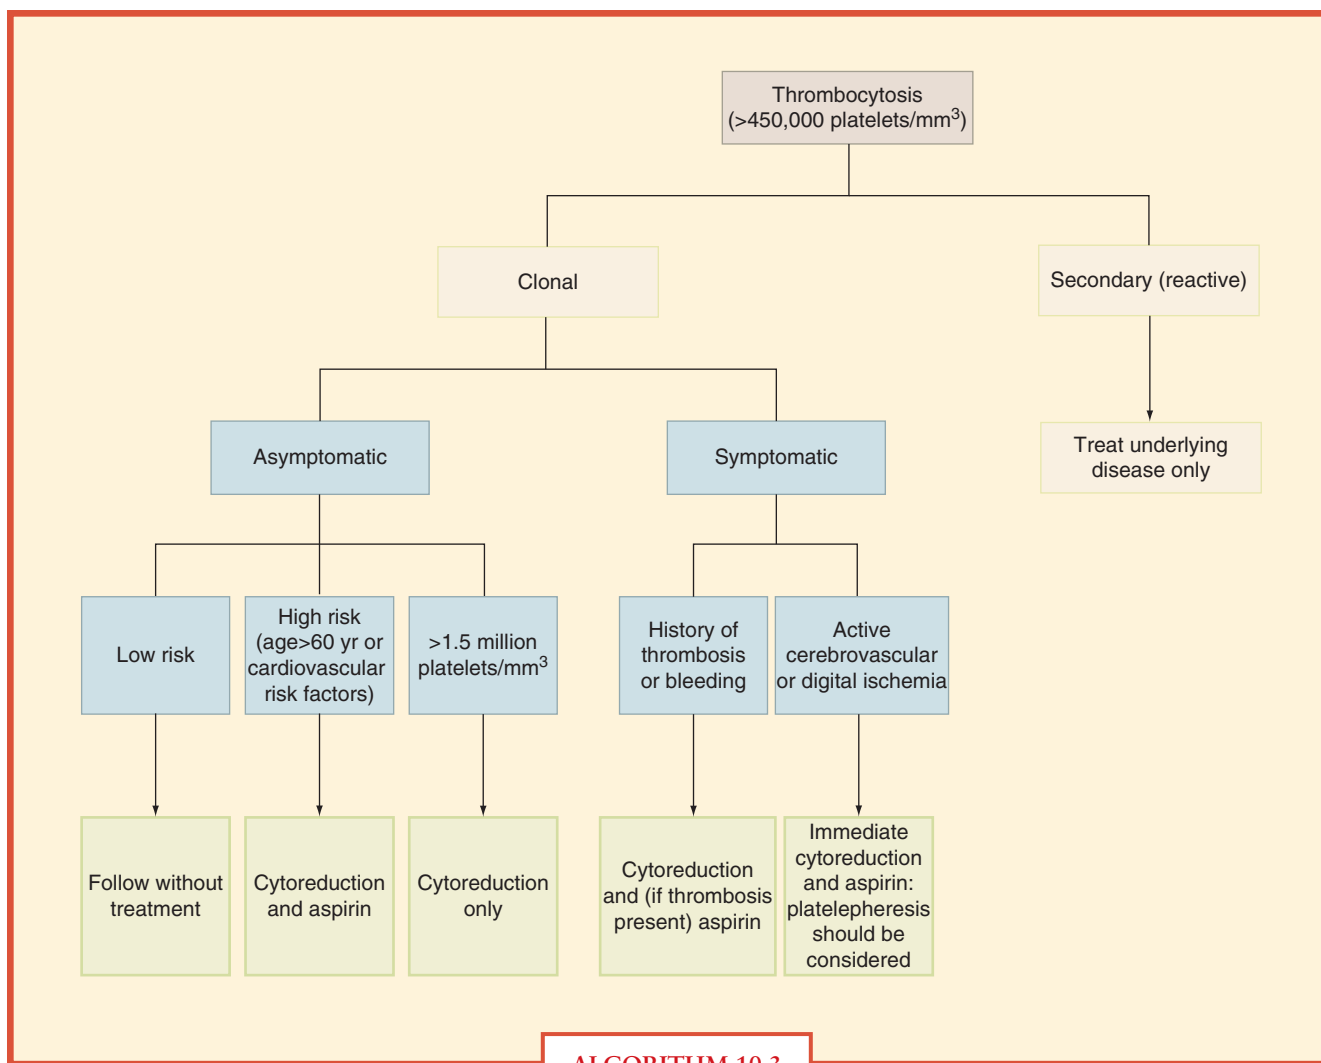
Hypercoagulable States

Hypercoagulable States (Thrombophilia) Hypercoagulable states should be considered in ICU patients who develop venous or arterial thrombosis. Hypercoagulable states are classified as inherited or acquired. Acquired thrombophilia is related to risk factors or predisposing conditions for thrombosis, including surgery, trauma, malignancy, central venous catheter, use of oral contraceptives, and others. Inherited thrombophilia is a genetic tendency to VTE. Factor V Leiden is the most common cause of inherited thrombophilia, accounting for 40%–50% of cases. The prothrombin 20210A gene mutation and deficiencies in protein S, protein C, or antithrombin account for most of the remaining cases of inherited

thrombophilia. Patients with possible hypercoagulable states should undergo diagnostic testing for thrombophilia with a comprehensive panel of diagnostic tests (Table 10.10). Prior to the initiation of diagnostic testing for hypercoagulable states, it is important to assess whether the patient is on medication or has preexisting clinical conditions that may confound interpretation of laboratory tests for evaluation of thrombophilia (Table 10.11).[34]

Treatment of Hypercoagulable States Initial treatment of venous or arterial thrombosis in an ICU patient is systemic anticoagulation. Antithrombin, protein C, or protein S deficiency carry VTE recurrence rates of 5%–15% per year, a relative increase of 2.5 compared with rates in the absence of thrombophilia. Patients heterozygous for factor V Leiden or the prothrombin G20210A mutation are much less prone to VTE recurrence with a relative risk of 1.3–1.4; VTE recurrence rates are fivefold greater with homozygosity or double heterozygosity. A mild/moderate increase in homocysteine level is associated with a 2.5 increased risk for recurrent VTE. Long-term anticoagulant therapy is recommended in selected high-risk hypercoagulable states after a first spontaneous VTE episode in antithrombin, protein C or protein S deficiency, and for patients homozygous or doubly heterozygous for factor V Leiden and/or the prothrombin mutation. For patients with lower risk for recurrence, they are treated with anticoagulation for 6 months, and then imaging for residual thrombosis or D-dimer testing is performed at the end of anticoagulant therapy, and the results are used to determine likelihood of VTE recurrence.

Coagulopathies ICU patients with coagulation defects have a four- to fivefold increased risk for bleeding compared to patients with a normal coagulation status. Diagnostic testing for coagulopathy in critically ill patients requires a panel of comprehensive tests including prothrombin time (PT), activated partial thromboplastin time, thrombin time (TT), fibrinogen, fibrin degradation products, platelet count, and bleeding time (Table 10.12).[35]

DIC is a syndrome caused by systemic intravascular activation of coagulation with formation of microvascular thrombi with clotting factor consumption and occurs in patients with infection, malignancy, trauma, amniotic fluid embolism, and others. DIC manifests as prolonged plasma clotting times, thrombocytopenia, reduced plasma fibrinogen concentration, raised plasma fibrin-degradation products, and sometimes microangiopathic hemolysis (Algorithm. 10.4). The most frequent cause of DIC is sepsis, with reduced protein C concentrations resulting in decreased endogenous fibrinolysis. ICU patients with severe sepsis or septic shock may manifest abnormalities in coagulation testing, but plasma should not be transfused unless the patient has evidence of clinical bleeding (Surviving Sepsis Guidelines, 2008).[36] In cases of DIC, where thrombosis predominates, such as arterial or VTE severe purpura fulminans associated with acral ischemia or vascular skin infarction, therapeutic doses of heparin should be considered. Patients with sepsis-induced DIC may progress to purpura fulminans, a rapidly progressive thrombotic disorder with hemorrhagic infarction of the skin and dermal vascular thrombosis. Protein C concentrations should be measured in patients with purpura fulminans. In patients with severe limb-threatening purpura fulminans and low-protein C levels, replacement with exogenous protein C should be considered. Meningococcal and pneumococcal sepses are common causes of purpura fulminans and DIC. Treatment of DIC is supportive with aggressive treatment of the underlying cause of the DIC. Treatment of bleeding in DIC requires blood component replacement therapy with plasma, platelets, and cryoprecipitate.[37]


ALGORITHM 10.3 Approach to the management of thrombocytosis. From: Schafer AI. Thrombocytosis: Current Concepts [Review]. *N Engl J Med.* 2004;350:1211–1219.

Acute Traumatic Coagulopathy and Hemostatic Resuscitation

Hemorrhage is a major cause of trauma deaths and coagulopathy exacerbates hemorrhage. Trauma patients with severe hemorrhage have early hyperfibrinolysis in addition to coagulopathy (dilutional and consumptive).[38–40] Uncontrolled hemorrhage in trauma leads to the lethal triad of acidosis, hypothermia, and coagulopathy. Most severely injured patients are coagulopathic at hospital admission, before resuscitation interventions (Algorithm. 10.5).

Prompt reversal of coagulopathy using "hemostatic resuscitation" with early use of blood component therapy is advocated as the optimal practice for patients requiring massive transfusion (MT). It is recognized that increased early use of plasma is associated with increased risk for acute lung injury (ALI) and acute respiratory distress syndrome (ARDS), but is associated with decreased mortality. An emerging consensus for hemostatic resuscitation in patients requiring MT is as follows:

- Expedite the control of hemorrhage to prevent consumptive coagulopathy and thrombocytopenia and reduce the need for blood products.
- Limit isotonic crystalloid infusion to prevent dilutional coagulopathy and thrombocytopenia.

- Hypotensive resuscitation (SBP, 80–100 mm Hg) until definitive hemorrhage control is established
- Transfuse blood products in a 1:1:1 ratio of RBCs/FFP/platelets (one five-pack of pooled platelets counted as 5 U).
- Frequent laboratory monitoring (arterial lactate to assess adequacy of resuscitation, ionized calcium, and electrolytes)

TRANSFUSION THERAPY

Indications for Transfusion of Blood Components in the Intensive Care Unit

Red Blood Cell Transfusion RBC transfusion is common in intensive care unit (ICU) patients, with 40%–50% receiving RBC transfusion during the ICU stay. The Transfusion Requirements in Critical Care (TRICC) trial confirmed that ICU patient 30-day mortality was not different in patients randomized to a restrictive (transfuse if hemoglobin < 7 g/dL) or liberal (transfuse if hemoglobin < 10 g/dL) transfusion strategy.[41] Guidelines for RBC transfusion in ICU patients recommend transfusion when hemoglobin < 7 g/dL in most ICU patients (see Guideline Executive Summary, Table 10.13). In

TABLE 10.10

DIAGNOSTIC TESTING FOR HYPERCOAGULABLE STATES

A panel of diagnostic tests is used to evaluate patients with possible hypercoagulable states:
Complete blood count
Activated Protein C (APC) resistance test
Prothrombin 20210A mutation
Antithrombin III activity
Protein C activity
Protein S activity
ELISA anti-PF4 antibody (for HIT diagnosis)
Cardiolipin antibody (IgG and IgM)
B2-glycoprotein–1 antibody (IgG and IgM)
Lupus anticoagulant
Homocysteine levels
Factor VIII activity
Fibrinogen (clottable)
Fibrinogen antigen
Plasminogen activity
Hexagonal phospholipid neut
Dilute Russel's viper venom
Aspirin and/or plavix resistance (VerifyNow rapid assay)

ICU patients with acute cardiac ischemia, the recommendation is to transfuse RBCs if hemoglobin < 8 g/dL.[42]

INDICATIONS:

These evidence-based guidelines for RBC transfusion in adult trauma and critical care[43,44] recommended the following:

1. RBC transfusion is indicated for patients with evidence of hemorrhagic shock.
2. RBC transfusion may be indicated for patients with evidence of acute hemorrhage and hemodynamic instability or inadequate oxygen delivery.
3. A "restrictive" strategy of RBC transfusion (transfuse when Hb < 7 g/dL) is as effective as a "liberal" transfusion strategy (transfusion when Hb < 10 g/dL) in critically ill patients with hemodynamically stable anemia, except possibly in patients with acute myocardial ischemia.
4. The use of only Hb concentration as a "trigger" for transfusion should be avoided. Decision for RBC transfusion should be based on individual patient's intravascular volume status, evidence of shock, duration and extent of anemia, and cardiopulmonary physiologic parameters.
5. In the absence of acute hemorrhage, RBC transfusion should be given as single units.
6. RBC transfusion should not be considered as an absolute method to improve tissue oxygen consumption in critically ill patients.

Technical Aspects RBC serology requires transfusion from patient with compatible ABO and Rhesus (Rh) groups. In patient with multiple transfusion subgroup (A1, A2) and other groups (MN, K, D, L), compatibility becomes necessary. Crossmatched blood should be used unless unavailable or in emergent situations. Rewarming blood products is a necessity as they are cold in storage.

TABLE 10.11

MEDICATIONS AND CLINICAL CONDITIONS THAT CONFOUND INTERPRETATION OF THROMBOPHILIA LABORATORY TESTING

■ CLINICAL CIRCUMSTANCE	■ AFFECTED FACTOR
Estrogens	Low Proteins S Elevated AT III
Oral contraceptives and pregnancy	APC resistance + Elevated proteins S
Inflammation/sepsis/burn injury/polytrauma	Elevated factor VIII Low AT III Low protein S
Heparin	Low AT III
Warfarin	Low protein C and S Elevated AT III
Liver disease, disseminated intravascular coagulation	Low AT III Low protein C and S
Asparaginase chemotherapy	Low AT III
Vitamin K deficiency	Low protein C and S
Acute thrombosis	Low protein C and S
Increased factor VIII or factor II, and circulating lupus anticoagulant	APC resistance
Nephrotic syndrome	Low AT III Low protein S

Abbreviations: APC, activated protein C; AT III, antithrombin III.
Prior to diagnostic testing for hypercoagulable states, it is important to assess whether the patient is on medications that may confound interpretation of these laboratory tests.
From: Houbballah R, LaMuraglia GM. Clotting problems: diagnosis and management of underlying coagulopathies. *Semin Vasc Surg.* 2010;23(4):221–227.

Room temperature is acceptable for slow and low volume transfusions but for substantial and MTs using a blood warmer is necessary to prevent hypothermia. Blood tubing with a filter should be used for transfusions, but the use of microfilters (30–40 µm pores) has not been associated with reduced complications. All patients must be monitored during RBC transfusions, with patient vital signs including temperature monitored during and after completion of RBC transfusions.

In Patients with Bleeding or Hemorrhagic Shock

Uncrossmatched blood (Type O) is used if the patient has hemodynamic instability due to hemorrhagic shock and crossmatched blood is not yet available. Type-specific blood is used as soon as possible for hemorrhagic shock to minimize exposure to anti-A and anti-B antibodies in type O blood. In patients requiring RBC transfusion in hemorrhagic shock, transfusion rate depends on bleeding rate, and we should not rely on hemoglobin as an assessment of adequacy of blood resuscitation.

COMPLICATIONS.

Citrate toxicity: metabolic alkalosis and hypocalcemia with low levels of ionized calcium in patients with impaired liver function or with MTs

Electrolytes: low ionized calcium, hyperkalemia, and hypokalemia

Hypothermia with MT, transfusion-related febrile reactions

Graft versus host disease
Transfusion related acute lung injury (TRALI)
Transfusion-associated circulatory overload (TACO)
Infection: by contamination from donor (decreasing incidence) or contamination from manipulation

Fresh Frozen Plasma Transfusion

Indications. Fresh frozen plasma (FFP) should be transfused to patients requiring MT. The optimal amount of FFP required in MT patients is controversial. The guidelines[45] recommend plasma:RBC ratio of 1:3 or more during MT with the use of coagulation studies and clinical evidence of bleeding as a guide. The guidelines did not recommend for or against plasma transfusion to patients undergoing surgery in the absence of MT. FFP should be transfused in patients with warfarin therapy–related intracranial hemorrhage but could not recommend for or against transfusion of plasma to reverse warfarin anticoagulation in patients without intracranial hemorrhage. The guidelines suggested against plasma transfusion for other selected groups of patients, including those with liver disease, hemophilia (A&B), other factor deficiency, and antithrombin deficiency in a situation requiring anticoagulation with heparin.

Technical Aspects. FFP transfusion has the same technical aspects as RBC transfusion including using crossmatched plasma for transfusions avoiding a reaction between patient RBCs and donor antibodies. ABO compatibility is required, but Rh compatibility is not required.

Complications. Identical to RBC transfusion keeping in mind that citrate content is higher in FFP and potassium transfer is not an issue. TRALI has a higher incidence with plasma transfusions.

Platelet Transfusion

Indications Prophylactic platelet transfusions are indicated in patients at risk of bleeding, for platelet count $< 10 \times 10^9$/L. Therapeutic platelet transfusions are required in hemorrhage

ALGORITHM 10.4 Differential diagnostic algorithm for coagulation abnormalities in the ICU. DIC, disseminated intravascular coagulation; ELISA, enzyme-linked immunosorbent assay; HIT, heparin-induced thrombocytopenia. From: Levi M, Opam SM. Coagulation abnormalities in critically ill patients. *Crit Care.* 2006;10(4):222.

ALGORITHM 10.5

ALGORITHM 10.5 Acute coagulopathy of trauma. The main contributing factors and potential mechanisms implicated in the acute coagulopathy of trauma. Hemorrhage in the severely injured patient may lead to shock that causes acidemia and hypothermia further triggering coagulopathy, typically termed the "lethal triad." Injudicious fluid resuscitation is closely linked to dilutional coagulopathy and hypothermia. Trauma in combination with shock causing hypoperfusion and hypoxia can also cause the "Acute Coagulopathy of Trauma-Shock" (ACoTS) associated with anticoagulation and hyperfibrinolysis. The clinical significance of inflammation for the development of acute traumatic coagulopathy still has to be fully elucidated. From Wafaisade A, Wutzler S, Lefering R, et al. Trauma Registry of DGU. Drivers of acute coagulopathy after severe trauma: a multivariate analysis of 1987 patients. *Emerg Med J.* doi:10.1136/emj.2009.088484 and Hess JR, Brohi K, Dutton RP, et al. The coagulopathy of trauma: a review of mechanisms. *J Trauma.* 2008;65:748–54.

- Transfusion of platelet concentrates near date of expiration
- Immune refractoriness. ABO antigens are weakly expressed on platelets and usually are not an important consideration in platelet transfusions. However, some patient may benefit from ABO-matched platelet transfusions. Antibodies to platelet-specific antigens are rare causes of transfusion refractoriness. HLA antibodies may cause platelet transfusion refractoriness. HLA antigens are expressed on platelets, and HLA antibodies are common in multiply transfused patients and parous women. Patients with immune refractoriness may benefit from crossmatched or HLA-matched platelets.
- Splenomegaly
- Consumption
- Bleeding, intravascular coagulation, intravascular platelet activation, graft versus host disease (GVHD), or sepsis may decrease platelet survival

Contraindications to platelet transfusions include TTP and heparin-HIT.

Technical Aspects Platelet transfusions require ABO compatibility, and RhD-negative platelet concentrates should be given, when possible, to RhD-negative patients and women in particular. A randomized controlled international multicenter trial (SToP) comparing two dosing strategies for platelet transfusion [standard-dose (300–600 × 10^9 platelets/product, equivalent to pooled five-pack of whole blood-derived platelets) or low-dose (150–<300 × 10^9 platelets/product) platelets] in patients with chemotherapy-HIT was stopped early due to a higher rate of bleeding in patients receiving the low-dose prophylactic platelet transfusions.[49]

to maintain platelet count $> 100 \times 10^9$/L, which is required to create stable clot and minimize rebleeding risk. In elective surgery, platelet transfusions may or may not be required, dependent on the procedure being performed, and, in general, platelet counts $> 50 \times 10^9$/L are adequate.[46,47]

Transfusion of one platelet pool and 1 U of apheresis platelets will typically increase the platelet count of an adult by 20,000–40,000/μL. A posttransfusion platelet count should be obtained 10 minutes to 1 hour after transfusion for best assessment of transfusion effectiveness. Platelet counts obtained later may not allow for differentiation between immune and nonimmune causes of platelet transfusion refractoriness. The corrected count increment (CCI) is usually the best assessment of transfusion effectiveness. A 1-hour CCI greater than 5,000 is typically considered a satisfactory response.[48] Causes of an inadequate response to platelet transfusion include the following:

- Insufficient dosage
- Incomplete transfusion

TABLE 10.13

EXECUTIVE SUMMARY FROM CLINICAL PRACTICE GUIDELINE: RBC TRANSFUSION IN ADULT TRAUMA AND CRITICAL CARE

A. Recommendations Regarding Indications for RBC Transfusion in the General Critically Ill Patient
1. RBC transfusion is indicated for patients with evidence of hemorrhagic shock. (Level 1)
2. RBC transfusion may be indicated for patients with evidence of acute hemorrhage and hemodynamic instability or inadequate oxygen delivery. (Level 1)
3. A "restrictive" strategy of RBC transfusion (transfuse when Hb <7 g/dL) is as effective as a "liberal" transfusion strategy (transfusion when Hb <10 g/dL) in critically ill patients with hemodynamically stable anemia, except possibly in patients with acute myocardial ischemia. (Level 1)
4. The use of only Hb level as a "trigger" for transfusion should be avoided. Decision for RBC transfusion should be based on an individual patient's intravascular volume status, evidence of shock, duration and extent of anemia, and cardiopulmonary physiologic parameters. (Level 2)
5. In the absence of acute hemorrhage RBC, transfusion should be given as single units. (Level 2)
6. Consider transfusion if Hb <7 g/dL in critically ill patients requiring mechanical ventilation (MV). There is no benefit of a "liberal" transfusion strategy (transfusion when Hb <10 g/dL) in critically ill patients requiring MV. (Level 2)
7. Consider transfusion if Hb <7 g/dL in resuscitated critically ill trauma patients. There is no benefit of a "liberal" transfusion strategy (transfusion when Hb <10 g/dL) in resuscitated critically ill trauma patients. (Level 2)
8. Consider transfusion if Hb <7 g/dL in critically ill patients with stable cardiac disease. There is no benefit of a "liberal" transfusion strategy (transfusion when Hb <10 g/dL) in critically ill patients with stable cardiac disease. (Level 2)
9. RBC transfusion should not be considered as an absolute method to improve tissue oxygen consumption in critically ill patients. (Level 2)
10. RBC transfusion may be beneficial in patients with acute coronary syndromes (ACS) who are anemic (Hb ≤8 g/dL) on hospital admission. (Level 3)

B. Recommendations Regarding RBC Transfusion in Sepsis
1. There are insufficient data to support Level 1 recommendations on this topic.
2. The transfusion needs for each septic patient must be assessed individually since optimal transfusion triggers in sepsis patients are not known and there is no clear evidence that blood transfusion increases tissue oxygenation. (Level 2)

C. Recommendations Regarding RBC Transfusion in Patients at Risk for or With Acute Lung Injury (ALI) and ARDS
ALI and ARDS are common clinical sequelae of massive transfusion. Prior studies have suggested that RBC transfusion is associated with respiratory complications, including ALI and ARDS that remains even after adjusting for potential confounders.
1. There are insufficient data to support Level 1 recommendations on this topic.
2. All efforts should be initiated to avoid RBC transfusion in patients at risk for ALI and ARDS after completion of resuscitation. (Level 2)
3. All efforts should be made to diagnose and report transfusion-related ALI (TRALI) to the local blood bank because it has emerged as a leading cause of transfusion-associated morbidity and mortality, despite underdiagnosis and underreporting. (Level 2)
4. RBC transfusion should not be considered as a method to facilitate weaning from MV. (Level 2)

D. Recommendations Regarding RBC Transfusion in Patients With Neurologic Injury and Diseases
1. There are insufficient data to support Level 1 Recommendations on this topic.
2. There is no benefit of a "liberal" transfusion strategy (transfusion when Hb <10 g/dL) in patients with moderate-to-severe traumatic brain injury. (Level 2)
3. Decisions regarding blood transfusion in patients with subarachnoid hemorrhage (SAH) must be assessed individually since optimal transfusion triggers are not known and there is no clear evidence that blood transfusion is associated with improved outcome. (Level 3)

E. Recommendations Regarding RBC Transfusion Risks
1. There are insufficient data to support Level 1 Recommendations on this topic.
2. RBC transfusion is associated with increased nosocomial infection (wound infection, pneumonia, sepsis) rates independent of other factors. (Level 2)
3. RBC transfusion is an independent risk factor for MOF and SIRS. (Level 2)
4. There is no definitive evidence that prestorage leukocyte depletion of RBC transfusion reduces complication rates, but some studies have shown a reduction in infectious complications.(Level 2)
5. RBC transfusions are independently associated with longer ICU and hospital length of stay, increased complications, and increased mortality. (Level 2)
6. There is a relationship between transfusion and ALI and ARDS. (Level 2)

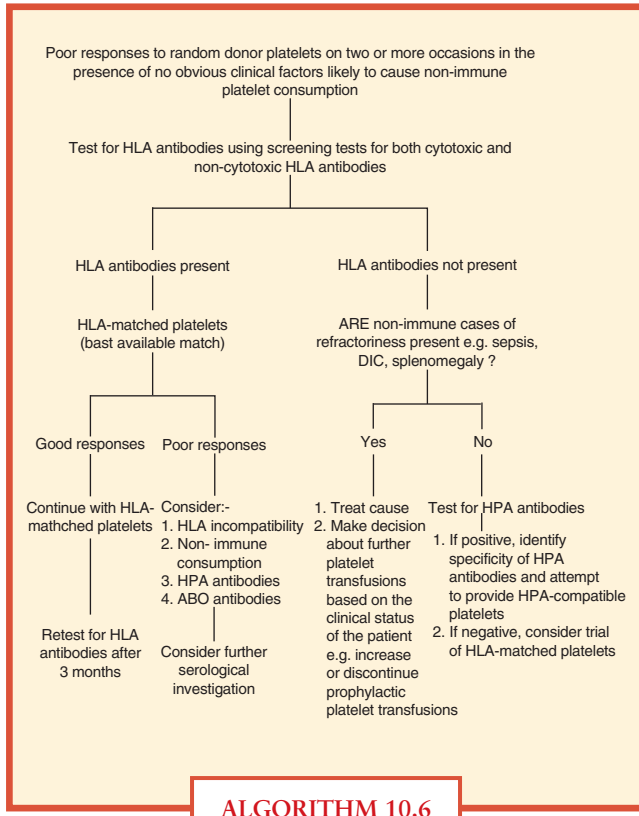
**F. Recommendations Regarding Alternatives to RBC Transfusion**
1. There are insufficient data to support Level 1 recommendations on this topic.
2. Recombinant human erythropoietin (rHuEpo) administration improves reticulocytosis and hematocrit and may decrease overall transfusion requirements. (Level 2)
3. Hemoglobin-based oxygen carriers (HBOCs) are undergoing investigation for use in critically ill and injured patients but are not yet approved for use in the United States. (Level 2)

EXECUTIVE SUMMARY FROM CLINICAL PRACTICE GUIDELINE: RBC TRANSFUSION IN ADULT TRAUMA
AND CRITICAL CARE (*Continued*)

G. Recommendations Regarding Strategies to Reduce RBC Transfusion
  1. There are insufficient data to support Level 1 recommendations on this topic.
  2. The use of low-volume adult or pediatric blood sampling tubes is associated with a reduction in phlebotomy volumes and a reduction in blood transfusion. (Level 2)
  3. The use of blood conservation devices for reinfusion of waste blood with diagnostic sampling is associated with a reduction in phlebotomy volume. (Level 2)

  4. Intraoperative and postoperative blood salvage and alternative methods for decreasing transfusion may lead to a significant reduction in allogeneic blood usage. (Level 2)
  5. Reduction in diagnostic laboratory testing is associated with a reduction in phlebotomy volumes and a reduction in blood transfusion. (Level 2)

From: Napolitano LM, Kurek S, Luchette FA, et al; American College of Critical Care Medicine of the Society of Critical Care Medicine; Eastern Association for the Surgery of Trauma Practice Management Workgroup. Clinical practice guideline: red blood cell transfusion in adult trauma and critical care. *Crit Care Med.* 2009;37(12):3124–3157.

Complications Technical issues (related to platelet unit contamination and infection risk), platelet's function (deep venous thrombosis), and immune effects (alloimmunization and hemolysis from residual ABO antibodies). Some patients will be refractory to platelet transfusions, defined as failure to achieve an appropriate increment after receiving two consecutive transfusions with fresh ABO-compatible platelets (Algorithm. 10.6). Measurement of platelet count 30 and 60 minutes following platelet transfusion will determine adequacy of platelet transfusion host response.


ALGORITHM 10.6

ALGORITHM 10.6 Diagnostic evaluation in patient refractory to platelet transfusions.

Cryoprecipitate Transfusion

Indications Cryoprecipitate is a diverse product containing factor VIII, von Willebrand factor, fibrinogen, fibronectin, factor XIII, and platelet microparticles. The most common current indication for the use of cryoprecipitate is in patients with hypofibrinogenemia in the setting of massive hemorrhage. It is also indicated for von Willebrand disease and hemophilia A (factor VIII deficiency).[50]

Technical Aspects Same as all blood products but ABO compatibility is not necessary.

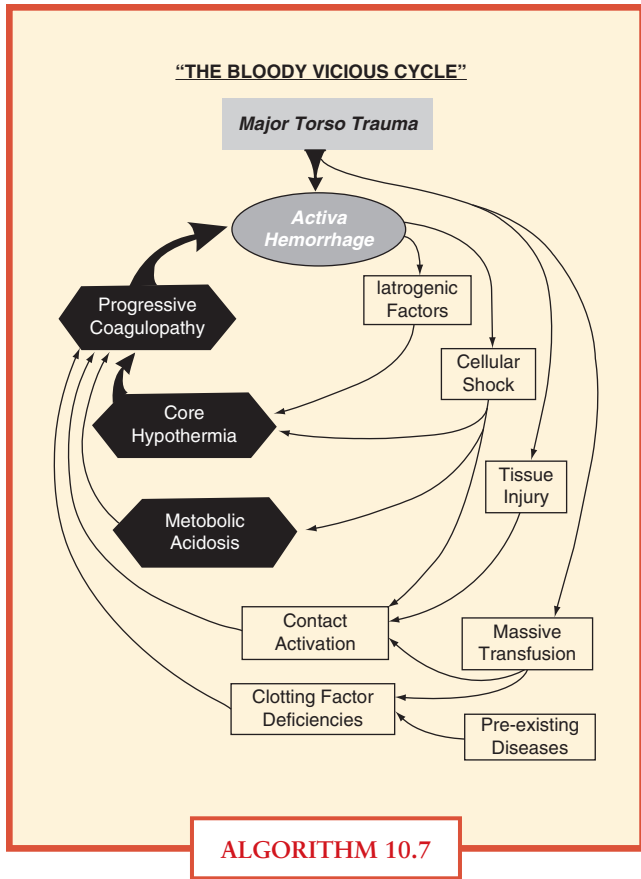
Complications Similar to all blood products and in case of large volume of ABO-incompatible cryoprecipitate is used, the recipient may develop a positive DAT and, very rarely, mild hemolysis.

BLOOD TRANSFUSION IN TRAUMA

Traumatic injuries are common and account for almost 15% of all allogeneic RBC transfusion use in the United States. Control and treatment of hemorrhage is a critical aspect of trauma care, particularly in patients with hemorrhagic shock.[51] Despite major advances in the treatment of hemorrhagic shock, hemorrhage remains a leading cause of early death in both civilian and military trauma. Failure to control and treat hemorrhage promptly in such patients resulted in a "Bloody Vicious Cycle" (Algorithm. 10.7) of hemorrhage, resuscitation, hemodilution, and coagulopathy, leading to more hemorrhage.[52–54]

At present, the only oxygen-carrying resuscitation fluid available for use in patients with traumatic injuries is allogeneic RBC transfusion. The aim of treatment of hemorrhagic shock with RBC transfusion is the rapid and effective restoration of an adequate blood volume to maximize tissue oxygen delivery. Furthermore, the goal of transfusion of blood and blood products is to maintain the patient's blood composition within safe limits with regard to hemostasis, oxygen-carrying capacity, oncotic pressure, and biochemistry. Therefore, the additional administration of other blood components (in addition to RBCs) is necessary for the prevention of dilutional coagulopathy and dilutional thrombocytopenia.

The Advanced Trauma Life Support course of the American College of Surgeons recommends starting two large-bore IVs

"THE BLOODY VICIOUS CYCLE"


ALGORITHM 10.7

ALGORITHM 10.7 The pathogenesis of the "bloody vicious cycle" following major torso trauma is multifactorial, but usually manifests as a triad of refractory coagulopathy, progressive hypothermia, and persistent metabolic acidosis. From: Moore EE. Thomas G. Orr Memorial Lecture. Staged laparotomy for the hypothermia, acidosis, and coagulopathy syndrome. *Am J Surg* 1996;172(5):405–410.

in patients who are seriously injured and, if they are hypotensive, giving 2 L of isotonic crystalloid solution.[55] If the patient remains hypotensive in shock, then RBCs should be transfused. These guidelines were based on the recognition that prolonged shock frequently led to organ failure that could be prevented by fluid resuscitation. Most frequently, uncrossmatched RBC units are administered to trauma patients requiring emergent RBC transfusion, and the increasing use of uncrossmatched RBC transfusion has been identified as an independent predictor of mortality and the need for MT.[56] The use of fresh whole blood has also been required in the combat casualty setting due to a lack of sufficient stored blood products, and therefore these combat casualty reports also document administration of fresh whole blood.[57]

Massive Transfusion

Massive transfusion (MT) is required as a treatment for uncontrolled hemorrhage, and trauma is the most common etiology.[58–60] Massive blood transfusion is commonly defined as administration of ≥10 U of allogeneic RBCs to an individual patient or transfusion of more than one blood volume in 24 hours. Other "dynamic" definitions of MT have been used, particularly in order to initiate MT institutional protocols.[61–67] Risk factors for MT in trauma include tachycardia, hypotension, acidosis, penetrating mechanism, hemoperitoneum by sonography, and anemia.[68] Several predictive models for MT have been developed, with all variables necessary to calculate the score easily available within upon emergency room arrival.[69–71]

Trauma patients requiring MT have high mortality rates, ranging from 19% to 84%. Data from more recent studies document a significant reduction in mortality in trauma patients requiring MT, with most recent series reporting a mortality rate of approximately 30%–58% (Table 10.14).[72] Mortality is directly related to the severity of the hemorrhagic shock and the total number of PRBC units transfused.[73] Interestingly, in a single-center retrospective study of trauma patients requiring MT of more than 50 U of blood products in the first 24 hours,

TABLE 10.14

MORTALITY RATES ASSOCIATED WITH MT IN PUBLISHED STUDIES

■ STUDY	■ YEAR	■ PATIENTS	■ MEAN # RBC UNITS	■ MORTALITY RATE (%)
Phillips	1987	56	33	61

Sperry	2008	415	14	33.5
Knudson	2010	380	28	54.5 (30)

the overall mortality was 57%, but there was no significant difference in mortality rate between patients who received >75 U of blood products in the 1st day versus those who received 51–75 U.[74]

Strategies to Reduce Complications Associated with Massive Transfusion

Massive transfusion (MT) protocols should be established with standardized policies to reduce complications related to transfusion therapy. Adverse effects of MT and strategies to reduce these adverse effects are shown in Table 10.15.

Massive Transfusion and Coagulopathy

The standard goal of massive transfusion (MT) in past years was to supply isotonic crystalloids and plasma-poor RBC concentrates to maintain normovolemia and tissue oxygen supply. This, however, frequently led to dilutional coagulopathy, which was frequently aggravated and accelerated by hypothermia, acidosis, shock-induced impairment of hepatic function, DIC due to tissue injury, and increased consumption of clotting factors and platelets at extensive wound sites in injured patients.

We now recognize that patients who have sustained severe hemorrhage and require MT commonly have an early and profound coagulopathy that is present on admission and worsens with PRBC transfusion due to dilutional and consumptive coagulopathy.[75–78] Traditional resuscitation techniques using large amounts of crystalloid and PRBCs without other blood products can exacerbate this coagulopathy.[79] Therefore, another key aim of modern MT protocols is the timely administration of plasma and platelet concentrates as required to halt microvascular bleeding induced by impaired hemostasis.[80,81]

Hypotensive or Delayed Resuscitation

The concept of delaying resuscitation or only resuscitating to a low to low-normal blood pressure ("hypotensive resuscitation") in the actively hemorrhaging patient until definitive hemorrhage control has been advocated based on a number of preclinical studies that documented that vigorous fluid resuscitation in uncontrolled hemorrhagic shock was associated with increased hemorrhage and decreased survival.[82] Maintaining a low-blood pressure goal with "hypotensive resuscitation" aims to reduce the amount of blood lost through the site of injury until definitive hemorrhage control is achieved.

In a randomized prospective clinical trial of immediate versus delayed fluid resuscitation in patients (n = 598) with penetrating torso trauma who presented with a prehospital systolic blood pressure of ≤ 90 mm Hg with an overall mortality rate of 34%, there was significantly increased mortality (38% vs. 30%, p = 0.04), length of stay, and postoperative complication rates in the immediate versus the delayed group.[83] In a single-center study that randomized patients (n = 110) presenting in hemorrhagic shock to one of two fluid resuscitation protocols (target systolic blood pressure > 100 mm Hg vs. 70 mm Hg) titrated to this endpoint until definitive hemostasis was achieved, no difference in overall survival (92.7% in both groups) was identified. Although no mortality benefit was identified with hypotensive resuscitation in this study, it was noted that a number of study limitations were present: failure to achieve target systolic blood pressure in hypotensive group (mean systolic blood pressure 100mm Hg vs. 114mm Hg in control group); small sample size; mix of blunt (49%) and penetrating (51%) trauma patients and lengthy time for duration of active hemorrhage (2.97 ± 1.75 hours vs. 2.57 ± 1.46 hours, p = 0.20). Despite the limitations of these clinical studies, "hypotensive" resuscitation has become increasingly accepted in the prehospital resuscitation phase of trauma, prior to definitive hemorrhage control, since aggressive fluid resuscitation may increase bleeding.[84]

TABLE 10.15

STRATEGIES TO REDUCE COMPLICATIONS WITH MASSIVE TRANSFUSION

■ COMPLICATION	■ STRATEGIES TO REDUCE COMPLICATION
Hypothermia	Warm the room Surface warm the patient with heating blankets and heating lamps Heat and humidity inspired gases for ventilators Warm all IV fluids and blood products administered
Coagulopathy	Transfuse RBC: FFP in 1:1 ratio Check coagulation testing, including fibrinogen Transfuse cryoprecipitate if fibrinogen concentration low
Thrombocytopenia	Transfuse platelets to keep platelet count >100,000 to form stable clot
Electrolyte abnormalities	Calcium depletion occurs secondary to citrate chelation, correct with calcium IV Measure blood potassium, calcium (ionized), and magnesium concentrations Replete electrolytes to normal values as indicated
Acid-base disorders	Sodium bicarbonate or tromethamine for severe metabolic acidosis with hemodynamic instability or renal failure
TRALI	Use restrictive transfusion strategy once hemorrhage controlled Use FFP from men or nulliparous women
TACO	Discontinue crystalloid fluid resuscitation Consider IV diuretic use

Hemostatic Resuscitation

Acidosis, hypothermia, and coagulopathy were identified more than 20 years ago as a deadly triad for patients presenting with exsanguinating hemorrhage. This led to fundamental changes in initial management of severely injured patients. Despite these major advances, hemorrhage remains a leading cause of early death in trauma patients. Recent studies report most severely injured patients to be coagulopathic at admission, before resuscitation interventions, and that traditional MT practices grossly underestimate what is needed to correct the coagulopathy.

Since hemorrhage is a major cause of trauma deaths and coagulopathy exacerbates hemorrhage and is commonly seen during major trauma, prompt reversal of coagulopathy using "hemostatic resuscitation" has been advocated as the optimal practice for MT in trauma.[85,86] Reversal of coagulopathy involves normalization of body temperature, elimination of the causes of DIC, and transfusion with FFP, platelets, and cryoprecipitate as needed. Some have advocated that coagulopathy can best be avoided or reversed when severe trauma victims are transfused with at least the equivalent of whole blood.[87,88]

A study in combat casualty care identified that the ratio of blood products transfused affected mortality in patients receiving MTs at a combat support hospital.[26] They performed a retrospective chart review of 246 patients at a US Army combat support hospital, each of who received a MT ($\geq$10 U of PRBCs in 24 hours). They identified that a high 1:1.4 plasma to PRBC ratio was independently associated with improved survival to hospital discharge, primarily by decreasing death from hemorrhage. The authors concluded that MT protocols should utilize a 1:1 ratio of plasma to PRBCs for all patients who are hypocoagulable with traumatic injuries.[89,90]

The practice of hemostatic resuscitation was initiated in military combat casualty care,[91] but has also been examined in civilian trauma, and the concept is now being applied to other patient populations requiring massive blood transfusion for severe hemorrhage. Multiple clinical studies in civilian trauma patient populations have addressed the topic of hemostatic resuscitation as well.[92–97] A recent systematic review of 37 studies, most of which were observational in nature, documented that in patients undergoing MT, plasma infusion at high plasma:RBC ratios was associated with a significant reduction in the risk of death (OR, 0.38, 95% CI: 0.24–0.60) and multiple organ failure (OR 0.40, 95% CI: 0.26–0.60; Fig. 10.2). However, the quality of this evidence was very low due to substantial unexplained heterogeneity and several other biases. In patients undergoing surgery without MT, plasma infusion was associated with a trend toward increased mortality (OR, 1.22; 95% CI: 0.73–2.03). Plasma transfusion was associated with increased risk of developing ALI (OR, 2.92; 95% CI: 1.99–4.29).[98] Evidence-based practice guidelines for plasma transfusion by the American Society of Hematology recommended that plasma be transfused to patients requiring MT, however could not recommend a specific plasma:RBC ratio.[99]

Although hemostatic resuscitation has been associated with reduced mortality in these retrospective studies, we must recognize that there are potential adverse effects associated with transfusion of blood component therapy, including fresh frozen plasma and platelets. A number of studies have documented increased risk for ALI and ARDS with both blood and plasma transfusions.[100–102] TRALI is now the leading cause of transfusion-associated mortality, even though it is probably underdiagnosed and underreported.[103–105]

Massive Transfusion Protocols

Massive transfusion (MT) protocols have long been in place at major trauma centers for the treatment of patients with severe hemorrhagic shock.[106] In the past, MT protocols provided PRBCs, but still required the clinician to issue specific requests for other blood component therapy, including FFP and platelets. Furthermore, it was recommended that transfusion of these additional blood components wait until laboratory evidence of dilutional and consumptive coagulopathy and thrombocytopenia were present. In the current era, MT protocols now focus on the *prevention* of coagulopathy and thrombocytopenia.

As we have noted above, a 1:1:1 ratio (i.e., equal parts PRBCs, FFP, and platelets) for blood component therapy is now recommended for MT based on a more physiologic regimen similar to whole blood transfusion. This approach has been named "Hemostatic Resuscitation" and focuses on the early correction of coagulopathy, which is thought to be associated with improved survival. MT protocols have now been revised to include other blood component therapy in addition to RBC units and have been associated with improved outcomes in trauma.[107–110]

A multicenter prospective observational study of severely injured trauma patients who require blood transfusions is underway (PROMMTT, Prospective Observational Multicenter Massive Transfusion study[111]) and aims to further investigate MT protocols that are associated with improved outcome. The results of this observational study will inform the development of a future randomized clinical trial that will test these protocols.

FIGURE 10.2. In patients undergoing MT, plasma infusion at high plasma:RBC ratios was associated with a significant reduction in the risk of death (OR 0.38, 95% CI: 0.24–0.60) and increased risk for ALI. From: Murad MH, Stubbs JR, Gandhi MJ, et al. The effect of plasma transfusion on morbidity and mortality: A systematic review and meta-anaylsis. *Transfusion.* 2010;50:1370–1383.

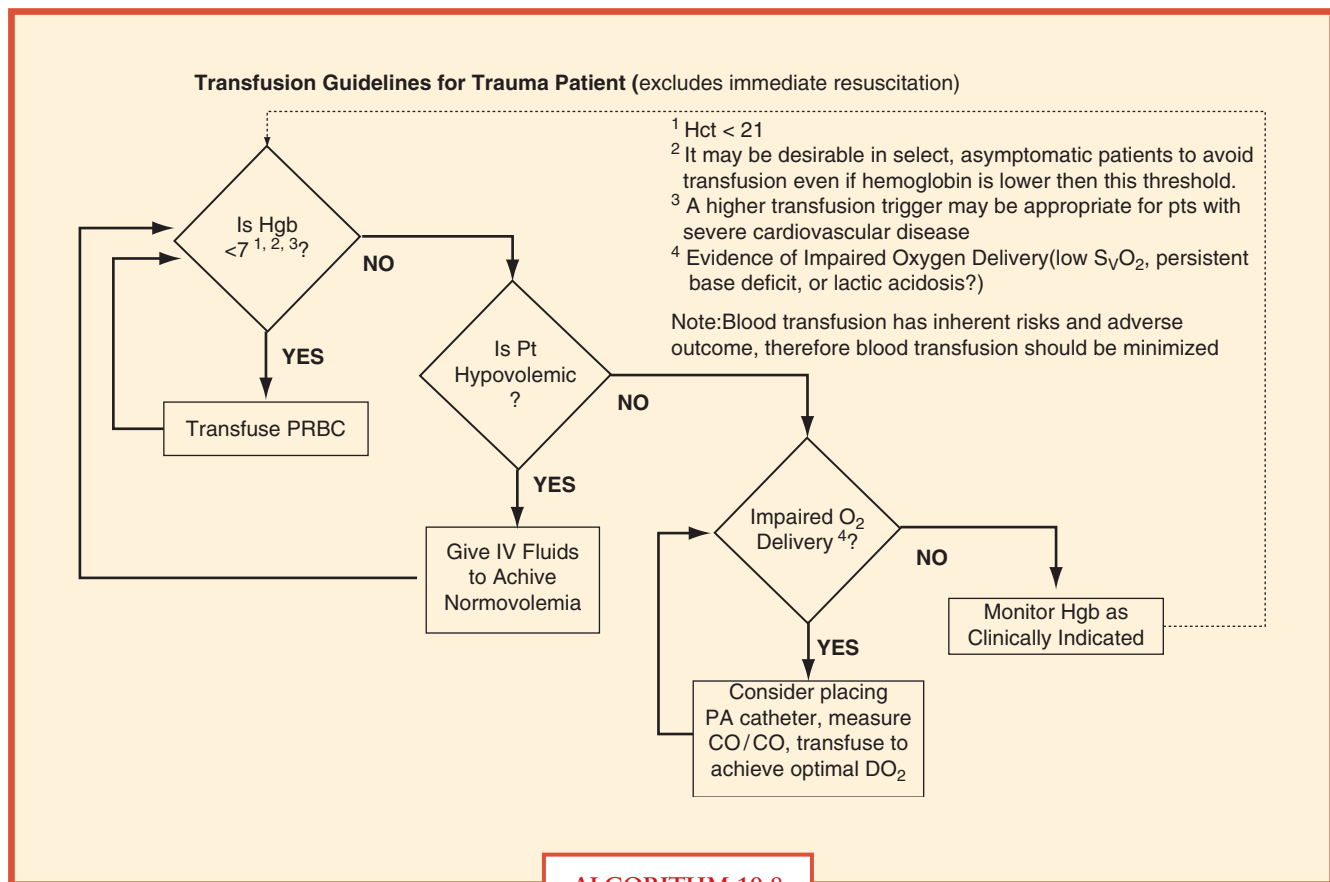
Transfusion After Hemorrhage Control

Once the definitive hemorrhage control has been established, a restrictive approach to blood transfusion should be implemented. Guidelines for transfusion in the trauma patient have been established as a standard operating procedure to guide RBC transfusion therapy for critically ill patients after the immediate resuscitation phase and to minimize the adverse consequences of potentially unnecessary transfusions. This protocol considers that the acute hemorrhage has been controlled, the initial resuscitation has been completed, and the patient is stable in the ICU with no evidence of ongoing bleeding (Algorithm. 10.8). This guideline advocates a trigger for PRBC transfusion of hemoglobin < 7 g/dL (or a hematocrit < 21%), even in patients with a history of cardiovascular disease.[112]

The recent report of the findings of the FOCUS trial confirms the use of a lower transfusion trigger in patients with stable anemia. The Transfusion Trigger Trial for functional outcomes in cardiovascular patients undergoing surgical hip fracture repair (FOCUS, sponsored by the National Heart, Lung and Blood Institute)[113] randomized 2,016 patients with asymptomatic anemia to a transfusion Hb trigger < 8 versus < 10 g/dL in 47 medical centers in the United States and Canada (8/2004–2/2009). No difference in cardiovascular outcomes (4.3 vs. 5.2%) or in-hospital mortality (2 vs. 1.4%) was identified.[114]

Efficacy of Red Blood Cell Transfusion in Trauma and Associated Risks

Adverse effects may occur with the transfusion of stored human red blood cells (RBCs). It has been documented that as human blood is stored, hemolysis occurs and increased concentrations of free hemoglobin are present in these units of blood.[115] Abnormal hemolysis in an individual RBC unit may be caused by several factors including inappropriate handling during processing of blood, inappropriate or extended duration of storage, bacterial hemolysins, antibodies that cause complement lysis, defects in the RBC membrane, or an abnormality in the blood donor. The acceptable level of hemolysis has not been established in North America, but the value of 1% is currently used to assess biocompatibility of blood storage materials.[116]

Increasing free plasma hemoglobin in aged stored RBC units, in addition to generating reactive oxygen species such as the hydroxyl and superoxide radicals, is also a potent scavenger of nitric oxide. Nitric oxide, which is normally produced by the endothelium, regulates basal vasodilator tone, inhibits platelet and hemostatic activation, and reduces superoxide concentration through radical–radical scavenging. The vasodilator activity of nitric oxide is possible only because most hemoglobin is normally compartmentalized within erythrocytes. As free hemoglobin concentration increased in aged stored allogeneic RBCs, a vasoconstrictive effect is evident (Fig. 10.3). It has been documented that RBC transfusion was


ALGORITHM 10.8 Guidelines for transfusion in the trauma patient have been established as a standard operating procedure to guide PRBC transfusion therapy for critically ill patients after the immediate resuscitation phase and to minimize the adverse consequences of potentially unnecessary transfusions. From: West MA, Shapiro MB, Nathens AB, et al. Guidelines for transfusion in the trauma patient. Inflammation and host response to injury, a large-scale collaborative project: patient-oriented research core—standard operating procedures for clinical care. *J Trauma*. 2006;61:436–439.
FIGURE 10.3. A model of the interactions of nitric oxide (NO) with erythrocytes and cell-free Hb in an arterial blood vessel. The diagram illustrates the major processes regulating NO concentration in blood vessels during pharmacologic nitric oxide delivery (**left**), under normal conditions (**center**), and under pathologic conditions, such as acute or chronic hemolysis (**right**). The overall blood-vessel NO concentration is depicted by the width of the blue band above the vessel. Within the vessel, smooth-muscle cells and a layer of endothelial cells are shown. Free Hb binds NO resulting in vascular constriction on the right side of the figure. Aged stored RBC units with increased hemolysis and early generation HBOCs may both have increased free hemoglobin concentrations and induce vasoconstriction in blood vessels.

associated with a significant increase in pulmonary vascular resistance index, which was not evident in the control cohort that received 5% albumin instead.[117]

The clinical consequences of red cell storage in trauma and the critically ill are particularly concerning (Fig. 10.4).[118] Duration of red cell storage has been associated with adverse outcomes including increased mortality.[119] In patients undergoing

FIGURE 10.4. Changes in RBCs during storage. Scanning electron micrographs of RBCs isolated from stored blood on days 1, 21, and 35. During storage, the shape of RBCs changes gradually from normal discoid to echinocytes (dented or shriveled). Reproduced with permission from Hovav et al. *Transfusion*. 1999;39:277–281.

cardiac surgery, transfusion of red cells that had been stored for more than 2 weeks was associated with a significantly increased risk of postoperative complications as well as reduced short-term and long-term survival.[120] The multicenter Age of Blood Evaluation (ABLE) trial in the resuscitation of critically ill patients is ongoing, randomizing patients to the transfusion of fresh leuko-reduced RBCs (stored less than 8 days) versus transfusion of standard issue RBCs stored 2 to 42 days.[121]

Additional studies have documented significant risks associated with RBC transfusion[122–124] and lack of efficacy.[125,126] Recent evidence suggests that in adult trauma patients, when used for treatment of anemia, RBC transfusion is associated with increased morbidity and mortality, and, therefore, current RBC transfusion practices may require reevaluation, and alternative oxygen-carrying resuscitation fluids warrant investigation.

Conclusion

Hematologic abnormalities, particularly anemia, are common in ICU patients. A careful diagnostic evaluation should be performed in all patients with anemia to determine if treatable etiologies are present. Blood transfusion is commonly

used in surgical and ICU patients. Blood and blood products are scarce resources and should be reserved for treatment of patients with acute hemorrhage. Surgical and critically ill patients with anemia who are hemodynamically stable can tolerate hemoglobin concentrations of 7 g/dL. Transfusion of the bleeding patient with RBCs and other blood products requires careful vigilance during the acute resuscitative and recovery phases. At present, RBC transfusion is the only oxygen-carrying resuscitation fluid for treatment of severe hemorrhagic shock. Newer protocols using "hemostatic resuscitation" advocate concomitant early use of plasma, and some studies report improved survival. This strategy has resulted in more liberal use of RBCs and blood products in the acute resuscitation for massive hemorrhage. Additional multicenter studies are warranted to confirm this survival benefit with hemostatic resuscitation. However, following definitive cessation of hemorrhage, all efforts to minimize the use of RBC transfusion is warranted. Efforts to reduce blood transfusion in acute care surgery require a multidisciplinary effort including the use of institutional and unit-based transfusion protocols, educational efforts, and preventive strategies to reduce blood loss.

CHAPTER 11 ■ NUTRITION IN ACUTE CARE SURGERY

JUAN B. OCHOA AND JEAN NICKLEACH

Modern care of the acutely ill surgical patient cannot be conceived without the provision of adequate nutrition. Nutrition has evolved far beyond that of being solely "supportive." Nutrition intervention therapy, in addition to providing the necessary nutrients to maintain normal metabolic processes, plays other essential roles including maintenance of mucosal integrity, modulation of immune responses, and protection against oxidative stress, among others. Nutrition intervention therapy is a powerful tool for the acute care surgeon that, when used adequately, beneficially affects patient outcomes; conversely, when poorly applied, it can cause increased morbidity and mortality and increase cost.[1] This chapter reviews the basic principles to assist the clinician with successful utilization of nutrition intervention.

Humans need food, water, and electrolytes. When digested and absorbed by the gastrointestinal tract, nutrients provide the basic elements to meet the energetic and metabolic needs for normal activity, growth and repair of cells and tissues. Under normal circumstances, a human adult is capable, through the process of eating and drinking, of ingesting a balanced amount of nutrients to meet his/her daily needs. This process occurs naturally and is regulated by physiologic processes such as hunger, thirst, and craving. Notwithstanding the epidemic of obesity, most humans achieve an equilibrium maintaining adequate hydration and electrolyte balance while satisfying the needs of macro- and micronutrients.

Eating and drinking are dramatically disrupted in the acutely ill surgical patient, obligating the clinician to replace the natural process of food intake. Balanced intravenous electrolyte solutions resolve most needs for water and electrolyte replacement and thus permit moderate periods of starvation. Ideally, resumption of oral intake is possible within a short amount of time after injury or operation; being the "golden standard," spontaneous normal eating should be allowed whenever possible.

Until 1968, a patient without a functional gastrointestinal tract was condemned to die of starvation. Evidence that total parenteral nutrition (TPN) could maintain normal growth and activity of growing pups ushered in the modern era of nutrition.[2] TPN coupled with the continued growth and sophistication of enteral diets now permits the provision of adequate nutrition intervention therapy so that normal cellular activities and tissue growth and repair can proceed. Despite its progress, any form of nutrition intervention, other than promotion of spontaneous oral intake, is artificial and does *not* replace the physiologic process of eating. Also, the nutrients provided by either TPN or total enteral nutrition (TEN) cannot be mistaken for normal food intake. As such, nutrition intervention therapy is comparable to other form of medical therapy and is associated with benefits when adequately ordered and delivered; side effects, some of which can be unexpected; and risks including severe complications and even death.

NUTRIENT UTILIZATION DURING NORMAL STATES OF HEALTH

The purpose of the creation of nutritional requirement guidelines has been the optimization of the human diet. Recommended dietary allowances (RDA) were developed by the government to sufficiently cover the nutritional requirements of most individuals (97% of the population). The Dietary Reference Intakes (DRIs) recommendations were introduced in 1997 to broaden the RDA. The DRIs include the RDA as well as adequate intakes (AIs) to provide guidance for those nutrients for which there is no RDA (i.e., vitamin D, vitamin K, fiber) or acceptable macronutrient distribution range to describe the range of intake for a particular energy source that is associated with reduced risk of chronic disease while providing intakes of essential nutrients (i.e., fat).[3] Human nutrition requirements vary widely from individual to individual depending upon multiple variables including age, gender, activity, and presence of illness. Despite their limitations, published RDA and DRI for normal states of health have provided the basis for comparisons of what is needed in the acutely ill surgical patient (Table 11.1).[3]

Protein balance (also called nitrogen balance) is a result of equal intake versus protein loss. Average healthy male adult intake necessary to maintain nitrogen balance is 0.75 g/kg/d.[3] Proteins (and amino acids) are the sole source of nitrogen, which can be measured in different nutrients, in tissues, and in urine. The average nitrogen conversion factor for mixed foods is 6.25 and is utilized universally to determine protein content. Protein losses include shed skin, losses in stool, and losses in urinary nitrogen that occur as a result of normal protein turnover.

Protein turnover is governed by anabolism and catabolism, two independent and carefully regulated processes, and balance is achieved when the same amount of protein is deposited as is broken down. Within the catabolic process, protein is broken down into amino acids. Approximately 80% of the amino acids are utilized back for the formation of new protein with loss of the remaining 20%. Illness alters both protein catabolism and anabolism in different ways. Generally, illness leads to a negative nitrogen balance, meaning that protein catabolism predominates over that of anabolic processes.

Investigators have identified several protein compartments in the body including skeletal, visceral, and circulatory compartments. Skeletal muscle constitutes a primary source of protein during stress, and its destruction is prioritized to protect visceral protein (defined as the protein compartment contained in vital organs). Plasma circulating proteins including albumin and prealbumin, although small as a compartment, are important in that they have been used as biomarkers of nutritional status. However, synthesis of albumin and prealbumin is profoundly affected by inflammatory

TABLE 11.1

RECOMMENDED INTAKES FOR MACRONUTRIENTS

■ MACRONUTRIENT	■ DIETARY REFERENCE INTAKES
Total fat	20%-33% energy[a]
Saturated fat	As low as possible
Cholesterol	As low as possible
Linoleic acid	11–17 g/d[b]
α-linolenic acid	1.1–1.6 g/d
Carbohydrates	130 g/d
Added sugars	No more than 25% energy
Total fiber	21–38 g/d[b]
Protein	46–56 g/d

NOTE: Amounts above are recommended for men and women from ages 19 to 70.
[a]Acceptable macronutrient distribution range.
[b]Adequate intake.

states, and changes in their plasma concentrations are not specific to the nutritional status of the patient during acute illness, thereby limiting their value as reliable biomarkers of nutrition status.[4]

Protein can be used as an energy source roughly providing a similar amount of calories per gram as that of carbohydrates. In the absence of carbohydrate intake, certain amino acids contained in protein (e.g., alanine) become obligate sources of glucose (gluconeogenesis), an essential process during prolonged fasting.

Lipids perform multiple essential functions; they are essential for the cell membrane architecture, serve as the substrate for the formation of signaling molecules and hormones, and are the most important source of energy storage. Healthy myocardium primarily uses fatty acids as its energy source.[5,6] Lipids often become the primary source of energy during acute surgical illness.

Glucose is an essential compound for cell function providing energy for anaerobic and aerobic metabolism. Several tissues including erythrocytes, the brain, and parts of the renal

parenchyma are obligate users of glucose. Small amounts of glucose can be stored in the muscle as glycogen, although these stores are exhausted within the first 48 hours of fasting. Dietary carbohydrates, which include monosaccharides, disaccharides, and polysaccharides, vary considerably in their presentation with more complex carbohydrates, such as starch, forming chains of monosaccharides. Glucose, a monosaccharide, is readily absorbed into the circulation while complex carbohydrates require enzymatic breakdown (e.g., amylase) before absorption. The impact of a dietary carbohydrate on circulating glucose (and therefore insulin release) is called the glycemic index (GI) and is inversely proportional to its complexity. The GI value is derived from the area under the curve for the increase in blood glucose after the ingestion of a set amount of carbohydrate in a food during the 2-hour postprandial period.[7] Complex carbohydrates require a functional gastrointestinal tract for their absorption and digestion while glucose can be delivered directly into the circulation as in TPN. The rate of breakdown and absorption is proportional to the rise in circulating blood sugar and subsequent insulin response. For this reason, GI is often used to calculate the glycemic load, an indicator of glucose response or insulin demand that is induced by total carbohydrate intake. It is calculated by multiplying the weighted mean of the dietary GI by the percentage of total energy from carbohydrate. The utilization of GI in combination with glycemic load is important in patients with insulin resistance or underlying diabetes mellitus.[8]

Micronutrients are also essential for survival. Micronutrients include vitamins, co-vitamins, and minerals. All micronutrients are contained in a balanced diet, although specific deficiencies may be observed with relative frequency. In addition, disease imposes the need for supraphysiologic supplementation of specific micronutrients (Table 11.2). The importance of micronutrients in management of the acutely ill surgical patient cannot be overstated, although an exhaustive discussion of this topic goes beyond the scope of the chapter. We provide a partial list of most frequently mentioned micronutrients to raise awareness of their importance.[3,8–11]

NUTRIENT UTILIZATION DURING ACUTE SURGICAL ILLNESS

Survival in the acutely ill surgical patient is influenced by neuroendocrine and immune activation including the release of inflammatory signals. As a result, noticeable metabolic

TABLE 11.2

SELECTED MICRONUTRIENT REQUIREMENTS

■ MICRONUTRIENT	■ NORMAL SERUM LEVELS	■ DRI—MALES (19–70 Y)	■ DRI—FEMALES (19–70 Y)
Vitamin C[9]	0.2–2.0 mg/dL (serum ascorbic acid)	90 mg	75 mg
Vitamin D[10]	30.0–74.0 ng/mL (25-hydroxy-vitamin D)	600 IU	600 IU
Vitamin E[9]	5–20 μg/mL (serum tocopherol)	15 mg alpha tocopherol	15 mg alpha tocopherol
Iron[12]	Male: 12–300 ng/mL; female: 12–150 ng/mL (serum ferritin) 30% (transferrin saturation)	8 mg	8–18 mg
Magnesium[11]	1.7–2.2 mg/dL (serum magnesium)	400–420 mg	320 mg
Selenium[9]	46–143 μg/dL (serum selenium)	55 μg	55 μg
Zinc[12]	11–19 mmol/L (serum zinc)	11 mg	8 mg

changes include an increased catabolic response, hyperglycemia, appreciable alteration in lipid utilization as an energy source, changes in synthesis and breakdown of visceral proteins, and alterations in the availability of certain micronutrients, such as amino acids and iron.

Increased protein catabolism that exceeds anabolic responses is a hallmark of the catabolic response of physical injury, be it trauma or surgery.[12] Protein losses (negative nitrogen balance) are higher than those observed with a simple starvation response. Following surgery, muscle is used as an essential source of amino acids necessary for the generation of glucose and for tissue repair and healing. Skeletal muscle serves the purpose of being the "protein store" of the body; during prolonged illness, protein becomes the "limiting" macronutrient often long before exhaustion of lipid stores ensues. As a result, protein depletion following acute care surgery leads to severe malnutrition and muscle deconditioning.[13] Thus, the major focus of nutrition intervention therapy is achieving a positive nitrogen balance as a means to prevent protein malnutrition and improve outcome.

There have been many attempts at restoring protein anabolism in the acutely ill through the provision of increased amounts of calories and protein above that of the daily normal requirements. These therapeutic strategies have been called by different names including hyperalimentation or the correction for "stress factors" that are artificially used to calculate increased metabolic requirements. The use of TPN has been a preferred treatment strategy, as it is easy to provide large amounts of calories through this route. These well-intentioned strategies have, however, failed to show benefit and in some cases are known to produce harm.[14] Failure to achieve positive nitrogen balance through dietary means alone has forced nutrition investigators and surgeons alike to focus on control of inflammation as a means to reverse the catabolic response.

The immune (inflammatory) response to acute surgical illness plays a key role in the catabolic responses observed in acute care surgery. Tumor necrosis factor, initially known as cachectin, increases muscle breakdown. Interleukin-1 increases metabolic rate and generates a febrile response. The rate of protein catabolism and negative nitrogen balance is proportional to the severity of the inflammatory response. As a result, progression towards protein malnutrition is accelerated in critically ill patients. Resolution of the inflammatory response leads to restoration between anabolic and catabolic processes and gives opportunity to an effective nutrition intervention therapy.

Insulin resistance often follows acute surgery and is frequently associated with hyperglycemia and poor utilization of glucose as an energy source. In addition, glycogen stores as a source of glucose are exhausted within the first 48 hours, making lipids a preferred fuel following surgery. The exhaustion of glucose along with insulin resistance obligates cells to utilize amino acids (particularly alanine and glutamine) as a mechanism for gluconeogenesis. Ketogenesis (from lipid oxidation) is also increased. Lipid mobilization is therefore observed, and it is common detect moderate amounts of hyperlipidemia in the acutely ill surgical patient. A depletion of circulating lipids and cholesterol is considered a marker of ensuing malnutrition and portends a poor prognosis.[15]

Little is known about the utilization of many micronutrients following acute care surgery. The use of supraphysiologic quantities of antioxidants and other micronutrients including selenium, zinc, and vitamin C have been suggested as an important adjunct to therapy in acute surgical illness. For example, vitamin C is now used routinely in high quantities during the resuscitation of burn patients. The results of ongoing studies are still not in, however, and therefore, prescription of high levels of these micronutrients should be reserved for the instances where they have found to be deficient.

The provision of the necessary substrate for cellular proliferation and repair and for the satisfaction of the energy needs in a given individual is an essential aspect of nutrition intervention therapy. As, such the acute care surgeon is obligated to provide a careful design and delivery of a well-balanced nutrition intervention.

THE PHYSIOLOGIC RESPONSE TO STARVATION AS A STARTING POINT IN THE DESIGN OF NUTRITION INTERVENTION THERAPY

Acutely ill surgical patients are often unable to maintain spontaneous food intake. As a result, many patients undergo periods of starvation, which can be prolonged at times. Starvation response has been used as a starting point to design nutritional intervention therapies. Starvation is a physiologic process. During times of famine, a series of carefully orchestrated genetic/metabolic responses occur aimed at preserving macro- and micronutrients to sustain normal organ function. The starvation response "buys time" for the individual. Several remarkable features are observed during starvation including that of decreased protein turnover (catabolism) and careful preservation of energy stores.

Obligatory protein loss in the normal individual is balanced through protein intake. As protein intake decreases, negative nitrogen balance ensues. However, in the starved individual protection of protein stores is achieved through a decrease in protein turnover.[16] Thus, in the normal individual up to 15 g of nitrogen are lost per day and need to be replaced. An otherwise healthy human subjected to starvation will decrease nitrogen loss to approximately 5 g per day. This essential adaptive process protects muscle mass and prolongs the time to the development of malnutrition.[17]

Obligatory protein loss during starvation (5 g per day) is necessary for the generation of glucose and is essential for survival. Obligatory protein loss in starved individuals can be abrogated through the provision of small amounts of glucose (700 calories a day). This process is known as the *protein-sparing effect of glucose* and decreases muscle loss considearbly.

Preservation of energy during starvation is also remarkable.[18] Starved individuals will spontaneously reduce their daily activities to meet the limited amount of energy intake. In addition, starved individuals will decrease their resting metabolic rate and thermal responses.[17] This is probably secondary to decreased catecholamine turnover and action; and decreased peripheral conversion of thyroxine (T4) to the active triiodothyronine (T3).[16] Clinical manifestations of decreased energy consumption are characteristic and include reduced interaction with the environment (apathy), hypothermia, and bradycardia.

Prolonged starvation inevitably leads to depletion of nutrients and the onset of malnutrition, a pathologic process characterized by organ dysfunction. Malnutrition negatively affects all disease processes and is associated with dramatic increases in morbidity and mortality. Malnutrition is surprisingly frequent in surgical and institutionalized patients, affecting up to one-third of patients. Attempts at its early identification and correction should be promptly instituted.

In contrast to the normal individual, acutely ill patients appear unable to mount a protective starvation response. As a result, progression towards malnutrition occurs more rapidly. In fact, patients with late multiple organ failure in the ICU will exhibit characteristics of severe malnutrition. Nutrition

intervention therapy attempts to prevent the progression towards malnutrition observed in the critically ill.

STARVATION: A PHYSIOLOGIC PROCESS IN THE ACUTELY ILL?

Some short periods of starvation are almost inevitable in the acutely ill surgical patient. For example, care of hemodynamically unstable patients requires all attention toward stabilization. In this environment, nutrition intervention becomes secondary and is frequently forgotten. It is progressively clear, however, that acutely ill (particularly critically ill) surgical patients tolerate even modest starvation poorly. In fact, better outcomes including possibly decreased mortality are observed when nutrition intervention is started early—ideally within the first 24 hours of arrival to the intensive care unit.

NUTRITIONAL INTERVENTION THERAPY

The provision of nutrients necessary to support metabolic processes is essential for the acutely ill surgical patient. However, in addition to playing a "supportive role," nutrition intervention plays essential therapeutic roles in prevention of muscle loss and increasing nitrogen retention, modulation of immune responses, and preservation of gastrointestinal function (Table 11.3).

NUTRITION INTERVENTION TEAM; MORE THAN JUST THE DOCTOR

The continued process of specialization in the care of the acutely ill surgical patient requires specialized teams that, working together, result in improved outcomes for these complex patients. The push for specialization is a result of increased knowledge and technology along with complex social and economic reasons that encourage consultative processes rather than care by only one individual. Such is the case for the formation of acute pain support teams, the emergence of the infection preventionists, and the appearance of specialized nutrition support teams. It is essential to learn how to interact with these multiple teams to produce coordinated, seamless care. Traditional nutrition support, similar to other specialties, has evolved into complex nutrition intervention teams that deliver specialized nutrition intervention (Table 11.4).

Nutrition education for medical students appears to be a logical and essential component of training. However, several

Act on the plan with careful targeted interventions
Start nutrition intervention therapy as early as possible
Monitor for side effects
Use specialized nutrition intervention following clear indications and guidelines

studies have shown that there have been major deficiencies for decades.[19,20] For example, only 25% of medical schools provide at least 25 hours or more of nutrition education to medical students during their entire 4 years of training.[21] Formal nutrition education does not appear to improve during residency training either. Major deficiencies in physician knowledge on the topic of nutrition is by no means a problem limited to the United States as it has been also reported in other countries.

Nutrition support teams first evolved to provide technical and logistical support for the provision of TPN. Typically, these teams comprise a group of people with multiple disciplines including physicians, dietitians, pharmacists, nurses, and sometimes social workers. Nutrition support teams improve the quality of nutrition intervention therapy and prove cost-effective.[22] Today, nutrition support teams focus their function on consulting services for optimization of enteral nutrition and prevention of the misuse of TPN.

HOW TO CALCULATE NUTRITIONAL GOALS

A considerable amount of research currently focuses on determination of the number and type of calories that should be provided to the acutely ill patient. It is interesting that such a basic question (i.e., how many calories should we order?) remains unanswered. Several observations demonstrate that the accumulation of a caloric debt (10,000 cal during the first week) is associated with increased morbidity and mortality.[23] Most scientific societies and clinical guidelines advocate 20–25 kcal/kg/d, regardless of the patients' metabolic state.[1] These goals attempt to achieve a middle road between overfeeding and starvation. Ongoing prospective trials currently are underway and promise to better determine the ideal amounts of calories to be provided.

To accurately assess the nutritional needs of a patient, the nutrition clinician must obtain a thorough history from the patient, family members, and medical records. Parameters that need to be identified include relevant anthropometrics such as height, current weight, weight changes over time, and a dietary history to identify any potential nutritional imbalances prior to current hospitalization. Once a valid weight history is obtained, various methods are employed to calculate estimated energy and protein goals for the patient. The Harris-Benedict Equation, Mifflin-St Jeor Equation, and the Ireton-Jones Energy Expenditure equation are among current methods available for energy estimation[3,24–27] (Table 11.5). However, a common equation utilized for daily practice due to brevity and convenience is the "kcal/kg" formulation. There

TABLE 11.5

SELECT ADULT NUTRITIONAL ASSESSMENT EQUATIONS

■ NUTRITIONAL ASSESSMENT METHOD	■ FORMULA	■ HISTORY
Calorie per kilogram	25–35 cal/kg[25,26]	Extrapolated from the WHO calculations. Estimated based on nonobese population.[26] ASPEN recommends that predictive energy requirements should fall within the range of 20–35 cal/kg.[25]
World Health Organization	Women: 18–30 y = 15.3(weight in kg) + 679 30–60 y = 11.6(weight in kg) + 879 >60 y = 8.8(weight in kg) + 1,128(height in m) – 1,071 Men: 18–30 y = 14.7(weight in kg) + 496 30–60 y = 8.7(weight in kg) + 829 >60 y = 9.2(weight in kg) + 637(height in m) – 302	Developed by FAO/WHO in 1974 for a healthy population.[27]
Harris Benedict	Women: REE = [655 + 9.6(weight in kg) + 1.7(height in cm)] ÷ 4.7(age in years) Men: REE = [66 + 1.37(weight in kg) + 5(height in cm)] ÷ 6.8(age in years)	Developed in 1919 from studies of indirect calorimetry of 239 men and women. Random error calculations female equation ($r^2 = 0.53$), male calculation ($r^2 = 0.75$).[26,28]
Ireton-Jones equations	Ventilator dependent: EEE = 1,784 – 11(a) + 5(w) + 244(s) + 239(t) + 804(b) Spontaneous breathing: EEE = 629 – 11(a) + 25(w) – 609(o) a = age (years) w = body weight (kg) s = sex (male = 1, female = 0) t = trauma (present = 1, absent = 0) b = burn (present = 1, absent = 0) o = obesity [BMI > 27] (present = 1, absent = 0)	Developed for critically ill and hospitalized patients using indirect calorimetry.[26,28]
Mifflin-St. Jeor	Women: REE = –161 + 10(weight in kg) + 6.25(height in cm) – 5(age) Men: REE = 5 + 10 (weight in kg) + 6.25(height in cm) – 5(age)	Developed in 1990 from studies of 247 women and 251 men. ($r^2 = 0.71$)[28]
DRIs for energy	Women: EEE = 354 – 6.91(age) + PA[9.36(weight in kg) + 726(height in m)] Men: EEE = 662 – 9.53(age) + PA[9.36(weight in kg) + 539.6(height in m)] PA (physical activity coefficient) Sedentary = 1.00 Low active = 1.11 Active = 1.25 Very active = 1.48	Developed in 2002 by the Institute of Medicine from studies of doubly labeled water for use in a healthy population.[29]

REE, resting energy expenditure; EEE, estimated energy expenditure.

is limited evidence in the literature supporting what weight to use to calculate these formulas, especially in the obese patient. Guidelines published in 2009 by ASPEN and SCCM have summarized an approach based on body mass index (BMI) to estimate kcal and protein requirements[1] (Table 11.6).

Estimations may lead to over- or underassessment of caloric needs based on patient scenarios, including obesity; thus, indirect calorimetry via a metabolic cart may be used in the ICU to ascertain a more concrete estimate of the Measured Resting Energy Expenditure. Also, indirect calorimetry calculates a respiratory quotient (CO_2 produced/O_2 consumed), which may validate the results of the study and also may lead to identification of over- or underfeeding. Despite limited evidence of benefit and inconvenience, indirect calorimetry remains the "golden standard" tool to assess caloric goals in the ICU.

MACRO- AND MICRONUTRIENTS GOALS

The proportion of carbohydrates, lipids, and protein to be provided to a patient can vary depending on the metabolic needs of the patient, the disease process, and the route of delivery of nutrients. Nutrition intervention (i.e., oral diet, enteral nutrition, or parenteral nutrition) should be adjusted to correct issues related to carbohydrate (i.e., hyperglycemia), protein (i.e., azotemia), or fat (i.e., severe hypertriglyceridemia) ingestion. Micronutrient imbalances should be adjusted with separate intravenous or oral supplementation; nutrition intervention should provide the minimum recommended amounts of micronutrients.

NUTRITION INTERVENTION THERAPY

All patients who come under the care of the acute care surgeon require nutrition intervention. As such, an early decision to proactively evaluate and determine a nutrition intervention plan (strategy) is strongly recommended; otherwise, nutrition intervention therapy can be delayed; delay in initiation of nutrition intervention therapy negatively affects clinical outcomes. In the acute care setting, an initial nutrition assessment should be performed on first encounter with the patient as soon as other basic priorities (such as the presence of shock) are managed.

Nutrition intervention therapy strategies fall into five categories including controlled starvation, spontaneous oral intake, provision of oral nutritional supplements, use of enteral nutrition (TEN), and use of TPN. The risks, benefits, and alternatives to these interventions are described below.

An order to stop volitional oral intake *Nil Per Os* (NPO) is frequently written on admission for the acutely ill surgical patient and may be necessary for several reasons. First, the disease process suffered by an acutely ill surgical patient may prevent adequate oral intake. Such is the case of patients with intestinal obstruction, protracted nausea, or vomiting from acute pancreatitis or in the case of poor splanchnic perfusion observed in intestinal ischemia or in shock. In addition, the clinician may determine that oral intake increases the risk of complications (such as aspiration) during procedures or surgical interventions. Control of oral intake thus serves an important role in the care of the acutely ill surgical patient. *Nil per Os* is predicated under the assumption that moderate periods of starvation are well tolerated by the patient without metabolic or clinically identifiable consequences. In fact, it is frequently suggested (and practiced) that patients can be safely maintained NPO for a week or more. This assumption easily leads to complacency in the plan and execution of an adequate nutrition intervention strategy.

Increasing evidence, however, suggests that even moderate periods of starvation may be detrimental in the acutely ill patient. For example, Lewis has provided two meta-analyses that compare early oral/enteral nutrition demonstrating an appreciable decrease in infections and postoperative mortality.[28] Similar observations have been made in critically ill patient populations in whom the provision of early enteral nutrition is associated with decreased mortality when compared to patients who are kept NPO.[1] This information suggests that in the acutely ill patient, even short periods of starvation are poorly tolerated and that every effort should be made to provide comprehensive nutrition intervention.

Two mechanisms that lead to poor outcomes with only moderate periods of starvation have been studied. The first includes the accumulation of a caloric deficit.[24] The second is the fact that profound pathologic changes occur in the gastrointestinal tract upon starvation. These changes can lead to decreased digestive capacity, increased bacterial growth, poor wound healing (particularly of gastrointestinal anastomosis) and impaired immune responses. Evidence that the prophylactic provision of TPN early after surgery fails to decrease postoperative complications (in patients who are otherwise NPO), suggests that negative outcomes in the surgical patient are a consequence of failing to maintain adequate gastrointestinal function through the provision of enteral intake while reaching delivery of caloric goals early on may not be as important.

Every effort has to be made, therefore, to provide early nutrition intervention, ideally in the form of oral or enteral nutrition. To do this, the surgeon (and her/his team), need to minimize the amount of time a patient is maintained NPO, through daily assessment and discussion. Enteral nutrition is the best alternative to normal oral intake when the patient's capacity to eat or swallow is impaired.

There have been some traditional barriers that prevent physicians from considering the use of the gastrointestinal

---

GUIDELINES FOR THE PROVISION AND ASSESSMENT OF NUTRITION SUPPORT THERAPY IN THE ADULT CRITICALLY ILL PATIENT

◼ BMI	◼ ASSESSMENT (WT)	◼ CALORIC GOALS (KCAL/KG)	◼ PROTEIN GOALS (G/KG)
<30	Actual	25	1.5

35–39.9	Ideal	22	2.0
≥40	Ideal	22	2.5

tract and achieving successful nutrition intervention and, as a result, unnecessarily prolong starvation. These include

- The use of nasogastric tubes. Nasogastric tube utilization varies considerably among surgeons denoting the lack of data to support routine utilization. Nasogastric tubes output is used as a measure to assess resolution of ileus, despite the lack of evidence that this is the case. Routinely, patients with nasogastric tubes are maintained NPO. There is a significant lack of data on the indications and utilization of nasogastric tubes. A meta-analysis performed on patients undergoing elective colon surgery suggests that even though nasogastric tubes decrease the incidence of vomiting, there is an increase in respiratory tract infections, probably as a result of increased aspiration.[29] There is also no evidence that nasogastric tubes protect gastrointestinal anastomoses. Other data demonstrate that nasogastric tubes offer no benefit for patients with acute pancreatitis. Thus, routine use of nasogastric tubes cannot be advocated. When the clinician finds it necessary to use a nasogastric tube, it should be removed as soon as possible.
- Waiting for bowel sounds and passing of flatus. The assumption that ileus is routinely observed postoperatively and this prevents successful oral intake prompts clinicians to keep the patient NPO. The presence of bowel sounds and the passage of flatus are used as evidence of recovery and are frequently awaited to start oral intake. Both assumptions may prevent early nutrition intervention. In fact, early oral intake may provide a substantial stimulus for resolution of ileus. Furthermore, there is no evidence that the lack of bowel sounds predicts success or failure of oral/enteral feeding.
- The use of a "clear fluid diet." A transition clear fluid diet is frequently utilized to "test" tolerance and used as a transition phase between being NPO and receiving a regular diet. No clear benefit has been observed with these diets, and they are of no physiologic or therapeutic value. Clear diets delay adequate oral intake and may cause substantial electrolyte imbalance. Clear diets should be avoided if possible.
- "Protecting the anastomosis" by keeping the patient NPO. A frequent reason to avoid oral or enteral intake is the idea that luminal food may harm a fresh anastomosis. Growing evidence demonstrates that oral/enteral intake is not associated with increased anastomotic leaks and in fact may even be protective. For example, Lewis, in a meta-analysis of early oral/enteral intake in elective surgery patients demonstrated a trend toward decreased anastomotic breakdown, although this did not achieve statistical significance.[28,30] Rodent studies demonstrate that allowing oral intake is associated with increased burst strength and collagen deposition at the anastomotic site.

In addition to the above, other interventions may help in achieving a successful early oral/enteral intake including

- Multimodality pain control with the use of combinations of opioids and nonsteroidal anti-inflammatory agents (NSAIDS). Nausea and vomiting are frequent side effects observed with the use of opioids. In addition, opioid utilization decreases gastrointestinal motility and may prolong postoperative ileus. Combination of opioids with NSAIDS objectively achieves better pain control than single-modality therapy and may decrease the side effects associated with opioid utilization. Objectively, the utilization of NSAIDS improves tolerance to an oral diet and decreases hospital length of stay.[31]
- Regulation of the amount of IV fluids and avoidance of major electrolyte disturbances. Judicious use of intravenous fluids is an important issue in the care of the acutely ill surgical patient. Avoidance of excess intravenous fluids has been associated in some critically ill patient populations

with better outcome, without an increase in the incidence of acute renal failure. Similarly, large fluid shifts associated with major electrolyte imbalances such as hypokalemia and hypomagnesemia may be associated with poor gastrointestinal motility and ileus. These should be avoided through early and daily correction.
- Understanding that meeting 100% caloric goals through oral or enteral intake may not be necessary at least early on. Perhaps one of the most important areas of current controversy revolves around the amount of caloric intake a patient should receive during acute illness.[23] Studies performed in critically ill patients and in patients after surgery demonstrate that patients receiving enteral nutrition will only receive 50%-70% of estimated caloric goals and they receive fewer calories when compared to patients receiving TPN. Despite evidence of decreased caloric intake, better outcomes are observed with the use of early oral intake/enteral nutrition when compared to TPN.[1] In addition, the use of higher caloric intake may be associated with risk of overfeeding and increased side effects including nausea, vomiting, bloating, or diarrhea. This has led to the creation of guidelines suggesting that during the first week in the intensive care unit, meeting only 50%-65% of caloric goals may be sufficient.[1]
- The issue of optimal caloric intake remains controversial. A recent analysis of outcomes in intensive care units in Canada demonstrated that while outcomes in the patients with normal BMI and in overweight patients was independent of caloric intakes, an increased mortality was associated with poor caloric intakes in the patients with lower-than-normal BMI and in the severely obese patients.[32] In addition, others have demonstrated that an accumulated caloric deficit is associated with poorer outcome in the critically ill. To solve this controversy, ongoing trials comparing the use of enteral nutrition alone or in combination with TPN (to meet caloric goals not met with enteral nutrition) are under way. We await the results of these trials as they may result in considerable paradigmatic changes in practice.
- Nutritional (biological) value of oral intake. Education as to the biological value of food intake is essential for all clinicians involved. All too often, early oral intake is confused with allowing the patients oral intake without supervision or guidance and result in the consumption of products with poor nutritional value. Oral intake in patients should be carefully guided to provide higher protein intake. The utilization of high-lipid diets (i.e., typical American diet) is associated with delayed gastric emptying and potential bloating and poor tolerance.

The utilization of oral nutritional supplements may facilitate the delivery of a balanced nutrition intake with the provision of a balanced amount of macro- and micronutrients in the early postoperative period. Oral nutritional supplements may help avoid the misuse of "clear diets" or inappropriately balanced diets and allow simplified postoperative transition to a regular diet. In contrast to the elective surgery, there is, however, little evidence in acute care surgery that oral nutritional supplements are associated with benefits in outcome. Nevertheless, the use of high-protein oral supplements has been associated with improved outcomes including a decrease in mortality in elderly and malnourished patients with hip fractures. In addition, perioperative utilization of oral nutrition supplements containing arginine, omega 3 fatty acids, and nucleotides are associated with a dramatic decrease in infections and other complications (including anastomotic breakdown) in patients undergoing elective surgery.[33] Thus, careful use of oral nutritional supplements may prove to be of benefit in the acute care surgery setting.

Enteral nutrition is delivered via a feeding tube using liquid diets, bypassing the processes of mastication and swallowing. As with oral intake, enteral nutrition should be started as soon as possible. There are different forms of access to the gastrointestinal tract. Deciding whether a patient needs enteral access should be part of the nutrition intervention strategy and determined early. It is particularly important to determine the type of enteral access to use in a patient with planned surgery, as the trip to the operating room provides an optimal opportunity for the placement of an enteral access device. All too often, patients leave the operating room without a plan or decision as to the type of placement of enteral access, unnecessarily delaying or complicating nutrition intervention.

Types of enteral access:

- Nasoenteric feeding tubes. These tubes are placed through the nose and advanced either to the stomach (nasogastric), duodenum, or proximal jejunum (nasoenteric). These tubes tend to be of small caliber (10–12 French) and made of flexible materials. Feeding tubes are used for short-term enteral access and can remain for 6 weeks or even longer. Feeding tubes are technically easier to place than other forms of enteral access. However, complications during their placement can arise, and thus, placement should be performed only by personnel with adequate experience. For example, misplacement of the feeding tube into the airway can lead to severe complications, including the inadvertent infusion of formula into the lung, perforation of the lung, pneumothorax, or even death. The reported incidence of airway misplacement of feeding tubes is 2%, which suggests that this complication may be observed several thousand times a year in the United States alone.[34]

Protocols and technology are available to avoid or detect feeding tube misplacement and are strongly recommended as part of quality improvement in any given institution. For example, at the University of Pittsburgh, the routine use of a trained Enteral Access Team and x-rays when the feeding tube is advanced to 35 cm effectively detects airway misplacement, prior to tube advancement into the more distal airway or lung. In addition, other devices including CO_2 detectors are used. With these strategies, complications from feeding tube misplacement can be effectively eliminated.

Controversy exists as to whether the tip of the feeding tube should lie in the stomach or more distally. Advocates suggest that more distal feeding facilitates meeting caloric goals and decreases the rate of pneumonia. In contrast, others suggest that attempts to place feeding tubes through the pylorus unnecessarily delay starting enteral nutrition.

- Gastrostomy tubes are inserted into the stomach and exit the abdomen generally in the left upper quadrant. Gastrostomy tube insertion can be performed percutaneously in the radiology or endoscopy suite (percutaneous endoscopic gastrostomy—PEG) or through open surgery. Gastrostomy tubes allow easy access to the stomach and can be kept indefinitely. Tube extensions of gastrostomy tubes that extend through the pylorus into the duodenum or jejunum are commercially available and may facilitate early enteral feeding.
- Jejunostomy tubes are placed directly into the jejunum. Similar to gastrostomy tubes, they can be placed percutaneously or in open or laparoscopic surgery. Jejunostomy tubes are associated with considearble complication rates and should be used with caution and by clinicians who have sufficient expertise in placement and care.

TPN was successfully developed in 1968.[2] Its utilization ushered the modern era of nutrition and was first tested in animal models and then in patients with severe malnutrition and a nonfunctional gastrointestinal tract. When carefully used, TPN provides an invaluable resource: a therapy that has undoubtedly saved countless numbers of lives since its inception.

Learning how to use TPN however, is not easy, requiring dedication, careful monitoring of the patient for complications, and a thorough understanding of its limitations and side effects. The most obvious barrier to the successful utilization of TPN is the false idea that it provides an interchangeable substitute to oral intake or to enteral nutrition. This misconception leads to overutilization of TPN in patients with otherwise functional gastrointestinal tracts. For example, a prospective randomized trial performed by Moore and colleagues in trauma patients demonstrated a significant increase in complications in the group receiving TPN when compared to those receiving enteral nutrition. Like any other form of medical therapy, misuse and overuse of TPN leads to increased complications including infections, hyperglycemia and other metabolic disorders, and, in some cases, increased mortality.

The use of TPN in the acute care surgery setting is indicated when it is clear that enteral nutrition will fail or has failed. As such, there is controversy as to how soon TPN should be started. The use of "prophylactic" TPN "just in case" EN fails has so far proved to be of no benefit and is not advocated. Guidelines suggest that TPN should be started within 7 days and can be started earlier in the patient who has underlying severe malnutrition.

It is important to avoid the complications associated with TPN. First, it is essential to avoid overfeeding and thus careful attention to meeting but not exceeding caloric goals is important. Use of indirect calorimetry as a means of carefully determining caloric goals is suggested, particularly in the obese and morbidly obese patient in whom calculations based on weight may be erroneous. In some instances, clinicians withhold the use of lipid formulations during the first week, particularly in the United States, where only omega-6 lipid formulas are available. Excess amounts of glucose are also avoided. In contrast, protein delivery in the form of amino acids is more liberally delivered at rates of 1.5–2.0 g/kg/d.

SIDE EFFECTS OF NUTRITION INTERVENTION THERAPY

Overfeeding

Strategies aimed at "hyperalimentation" advocated providing 30 kcal/kg/d or more. Measures to proportionately give even more calories using so called "stress factors" were also suggested. Far from achieving the therapeutic goals intended, hyperalimentation led to overfeeding with unintended severe deleterious consequences, increased morbidity, and mortality (Table 11.7). Hyperalimentation should NOT be used in modern acute care surgery. Although acute care surgery has been associated with a catabolic stress state, attempts to correct negative energy balance through the use of hypercaloric diets have not improved clinical outcome. Rather, overfeeding of the critically ill patient has led to metabolic morbidity, longer ICU and hospital length of stay,[35,36] *greater mortality* rates,[37] *longer duration o*n mechanical ventilators,[38–41] and higher rates of infectious complications.[46,47]

A study done by Reid[47] identified patient populations within the ICU who were more prone to receive overfeeding. Most commonly, patients who received nutrition through multiple routes, especially nutrient-dense EN and PN in combination, were overfed. Patients with ICU stays >16 days and those with tracheostomies were also at risk for overfeeding.

Refeeding syndrome was first described as a severe metabolic disturbance leading to death in famine (severely malnourished) victims who were offered aggressive nutrition intervention.

TABLE 11.7

COMPLICATIONS AND METABOLIC CONSEQUENCES AND OF OVERFEEDING IN THE ACUTE CARE SURGICAL PATIENT

■ COMPLICATION	■ SOURCES	■ NOTES[40]
Azotemia	40–42	
Fat-overload syndrome	40	
Glucosuria	43	
Hepatic steatosis	39–41, 44	
Hyperammonemia	42	
Hypercapnia	38–41,46	
Hyperglycemia	38, 40, 41, 44, 45, 47	Exacerbates underlying hyperglycemia associated with critically ill state
Hypertonic dehydration	40, 42	Indicated by azotemia and hypernatremia
Hypertriglyceridemia	39, 41	
Metabolic acidosis	40, 41	

Refeeding is commonly observed as a fluid and electrolyte disorder, and can include hypophosphatemia, hypomagnesemia, and hypokalemia. In addition, organ dysfunction including neurologic, pulmonary, cardiac, neuromuscular, and hematologic complications is observed. *Refeeding syndrome* occurs within a few days of initiation of nutrition intervention. The mechanisms that lead to the development of major electrolyte imbalances suggest that increased insulin release due to a change in the primary metabolic fuel source from fat to carbohydrate is the result of increased cellular uptake of electrolytes. Severe electrolyte imbalance such as hypokalemia can lead to cardiac irritability; depletion of phosphates can lead to muscle dysfunction and rhabdomyolysis. Refeeding syndrome can be observed in hospitals and may not follow the classic clinical patterns previously described, but should be suspected after initiation of nutrition intervention. Patients need to be monitored closely for abnormalities in phosphate, potassium, magnesium, glucose, and thiamine. Deficiencies should be promptly corrected.

Hyperglycemia and Glucose Control

Hyperglycemia can occur as a result of many potential issues present in the acute care surgery patient. Hyperglycemia associated with insulin resistance occurs in acutely ill patients due to adaptive activation of endocrine responses, including increased release of catecholamines, cortisol, and glucagon and a reduced capacity for glucose uptake. Meaningful debates as to the degree of glucose control with the use of insulin have ensued for the last 10 years and have caused a fair amount of confusion. Limitations in the accuracy of glucose metering technology along with significant differences in glucose intake (mostly through the use of TPN) have produced wide variations in practice. The results of the NICE-SUGAR trial demonstrate that tight glucose control (70–110 mg per dL) is impractical and may result in considearble side effects. Conversely, blood sugar levels above 200 mg per dL are consistently associated with poor outcomes. Management of hyperglycemia with pharmacological interventions (i.e., insulin) and reasonable carbohydrate intake improves morbidity and mortality in the surgical ICU.[48,49]

Remember that an important cause of hyperglycemia in acute care surgical patients is overfeeding—a major problem associated with the TPN where glucose intake may be excessive. As mentioned earlier in this chapter, overfeeding is associated with negative outcome; avoid overfeeding. Use of indirect calorimetry can assist with a more exact determination of caloric needs.

Hypertriglyceridemia

Hypertriglyceridemia is a potential complication of parenteral lipids. Parenteral lipids are cleared from the serum by the enzyme lipoprotein lipase. Hypertriglyceridemia occurs if the rate or duration of the lipid provision exceeds the enzyme's clearance capacity. Patients with hyperglycemia, renal failure, pancreatitis, or sepsis may be at higher risk for hypertriglyceridemia[50] Dosage of the lipids should not exceed 2.5 g/kg/d. Patients receiving parenteral lipids should be regularly monitored for hypertriglyceridemia. If elevated triglycerides occur, lipids in TPN should be reduced or provided on a cyclical schedule three or four times a week.

Azotemia

Azotemia can result from acute or chronic renal failure, gastrointestinal bleed, overfeeding, or administration of excessive amounts of protein in TPN. If azotemia results from renal failure and the patient is receiving dialysis, there is no need to restrict protein intake as dialysis will correct the azotemia. The presence of azotemia in the absence of renal failure may indicate GI bleed or overfeeding protein. For patients with a GI bleed, EN is typically contraindicated, and TPN should be initiated.

Gastrointestinal Intolerance

Gastrointestinal intolerance can occur following the initiation of enteral nutrition. This can manifest as vomiting, bloating, and diarrhea. Many of these symptoms are temporary and will resolve with a brief decrease in feeding rate. Additionally, medications can be helpful in symptom management. Prokinetic agents can assist with the management of nausea and

vomiting. The addition of antidiarrheals, soluble fiber, or change to a peptide-based formula can assist with bloating and diarrhea. It may appear that patients experiencing gastrointestinal intolerance should discontinue EN and initiate TPN; it is important to remember that EN is associated with improvement in intestinal permeability in comparison to TPN.[51] For this reason, it is more desirable to pursue aggressive symptom management and maintain EN.

SPECIALIZED NUTRITION INTERVENTION

Specialized nutrition formulas have evolved to provide nutrition interventions for optimized care of specific patient populations. Some of these formulas may be difficult to use and may be associated with serious side effects. Thus, the clinician is encouraged to, in conjunction with specialized nutrition teams, develop protocols for their use.

Immunonutrition

One of the most controversial and confusing areas of nutrition intervention is the use of immunonutrition. As the name implies, immunonutrients are food components that alter the inflammatory response to illness. An increasing list of immunonutrients is seen in Table 11.8. Due to the complexity and incomplete understanding of the role of these nutrients in the care of the acutely ill surgical patient, the acute care surgeon is encouraged to consult specialized nutrition intervention teams.

Arginine supplementation has been utilized in many different patient populations including the acutely ill medical patient, trauma, elective surgery patient. It has also been studied in chronic illnesses such as peripheral vascular disease and coronary artery disease. To date, Level 1 evidence of benefit (with over 28 randomized studies performed) is observed only in patients undergoing elective surgery when used in combination with omega 3 fatty acids and nucleotides. In elective surgery patients, the use of immunonutrients as an oral supplement (ideally started preoperatively and continued postoperatively) is associated with a 38%-61% reduction in postoperative infections and other complications such as anastomotic dehiscence. Improved outcomes are translated into decreased length of stay and an appreciable cost benefit. All surgical patient populations studied so far appear to benefit, including patients with head and neck cancer, patients undergoing cardiac surgery, and patients undergoing gastrointestinal surgery.

Immunonutrition with the use of arginine, omega 3 fatty acids, and nucleotides in trauma patients also holds promise, with some studies suggesting appreciable benefit. In trauma patients, however, there are limitations in the amount of volume that can be delivered enterally, preventing adequate dosing of the immunonutrients. A large controversy for the use of arginine in the septic patient still exists.

Glutamine is another intensely studied immunonutrient. The metabolism of glutamine when given enterally is noticeably different than when given intravenously due to enteric metabolism. Glutamine, when placed in solution, has a short half-life. To overcome this problem, parenteral presentations of glutamine as a dipeptide have been developed. These are currently not commercially available in the United States. The use of intravenous glutamine is associated with decreased mortality in sepsis.

Omega 3 fatty acid supplementation is also used extensively. Omega 3 fatty acids modify prostaglandin production and may alter lipid composition of the cell membrane. The modern American diet is particularly low in omega 3 fatty acids. Omega 3 fatty acids are used primarily to modulate the inflammatory response.

Nutrition for the Obese Patient

It is estimated that 25% of the patients in the intensive care units in the United States are obese with a BMI > 30. The combined prevalence of overweight (BMI > 25) and obesity in the general population is above 50%. Significant variations in obesity exist among the different States and is more frequently observed among patients with lower socioeconomic status. The incidence of obesity-related complications increases considerably in the hospital, as this patient population has an increased incidence of multiple chronic illnesses including diabetes, hypertension, coronary artery disease, and others.

The management of the obese, acutely ill surgical patient is particularly challenging. Evidence in Canada of clinical practices in intensive care units demonstrates that obese patients are grossly underfed, possibly increasing morbidity and mortality. The traditional methods of calculating caloric intake are grossly inaccurate in this patient population. Thus, the utilization of indirect calorimetry is encouraged in these patients. Controversy as to the number of calories and protein provided exists; current guidelines are therefore a compromise and attempt to provide a rational approach to the care of the obese patient and suggest that these patients should receive higher protein loads with a moderate restriction in calories.

THE FUTURE

Considerable advances in knowledge and technology suggest that nutrition intervention will evolve appreciably in the years to come. Recently, for example, specialized immune cells (myeloid-derived suppressor cells) that tightly regulate the availability of certain amino acids have been described in different patient populations, including after surgery and trauma, in certain cancers, and in chronic infections such as tuberculosis. Myeloid-derived suppressor cells express enzymes such as arginase and create states of arginine deficiency, which ultimately result in profound T-cell suppression and the incapacity to produce nitric oxide. It is thought, currently, that myeloid-derived suppressor cells worsen prognosis in these illnesses, particularly contributing to increased infections in the surgical and in the trauma patient. The development of carefully tailored diets aimed at overcoming the effects of myeloid-derived suppressor cells promises to become an integral part of the care of the acutely ill surgical patient.

TABLE 11.8

A PARTIAL LIST OF IMMUNONUTRIENTS

Amino acids
Arginine. Improves T-lymphocyte function, may increase the production of nitric oxide
Glutamine. Induces heat shock protein 70 along with multiple other metabolic effects

Lipids
Omega 3 fatty acids. Modulate inflammatory response

Micronutrients
Zinc. Supplemented in patients with open wounds
Vitamin C is used as an antioxidant. May have important clinical roles in burn patients

CHAPTER 12 ■ SEPSIS

TODD W. COSTANTINI, MIKE KRZYZANIAK, AND RAUL COIMBRA

DEFINITION

Sepsis is a common cause of morbidity and mortality in the surgical intensive care unit (SICU) accounting for an estimated 700,000 cases per year in the United States.[1] Sepsis is defined by the presence of infection in addition to a systemic inflammatory response syndrome (SIRS). Clinically, SIRS can manifest as fever, leukocytosis, tachycardia, and/or tachypnea. Severe sepsis is defined as sepsis with concomitant organ dysfunction. Septic shock is characterized by sepsis with persistent hypotension (systolic blood pressure < 90 mm Hg or mean arterial pressure [MAP] < 60) despite volume resuscitation.[2] Sepsis is currently the 10th most common cause of death in the United States, accounting for over 34,000 deaths per year.[3] Mortality rates for patients admitted with sepsis approach 20%-30%, with increased mortality seen in the nonwhite population and the elderly.[1]

PATHOPHYSIOLOGY

Sepsis occurs as a result of a complex set of interactions, incited by an invading pathogen, which result in a substantial host inflammatory response and activation of both the complement and coagulation cascades. While these responses are essential to control and eradicate the infecting microorganism, they are also capable of causing major damage to host tissues.

MICROBIAL FACTORS

Gram-positive bacteria, gram-negative bacteria, fungi, and parasites are capable of causing sepsis. Gram-negative bacteria have a cell wall that contains lipopolysaccharide (LPS) on its outer layer. The pathogenicity of gram-negative bacteria is due to LPS, which elicits an innate immune response. Extensive studies using animal models have characterized the ability of LPS to cause a significant host inflammatory response, with pathophysiologic responses similar to those seen in humans with sepsis.[4] Studies in human volunteers have further confirmed the toxicity of endotoxin itself, showing that injection of small concentrations of LPS causes fever, activation of inflammatory cells, and increased cytokine production.[5]

Until recently, gram-negative bacteria were the most common cause of sepsis in the ICU. There has been an increase in the incidence of gram-positive bacteria causing severe sepsis, now identified as the causative bacteria in up to 50% of the cases.[6] Gram-positive bacteria exert their pathogenic effects through the release of exotoxins and contain an outer polysaccharide capsule that protects against phagocytosis. Gram-positive bacteria contain a thick peptidoglycan layer that forms the cell wall. It is the peptidoglycan layer of gram-positive bacteria that is recognized by inflammatory cells of the innate immune system. Fungi remain a rare cause of severe sepsis, causing approximately 5% of cases.

INFLAMMATORY RESPONSE

The innate immune system is responsible for recognizing an invading microorganism. The innate immune system consists of peripheral blood mononuclear cells and polymorphonuclear leukocytes (PMNs). These cells recognize pathogen-associated molecular patterns (PAMPs), which are displayed by gram-positive bacteria, gram-negative bacteria, fungi, parasites, and viruses. Sepsis also results in the release of damage-associated molecular patterns (DAMPs), which are released by damaged or dying host tissues. The innate immune system initiates an inflammatory response when these PAMPs and DAMPs bind to pattern recognition receptors on host inflammatory cells.[7] In sepsis, there are high levels of DAMPs and PAMPs released, which can cause an exaggerated response from inflammatory cells, resulting in damage to host tissues.[8]

The toll-like receptor (TLR) family is an example of pattern recognition receptors that are key mediators of this inflammatory response. TLR expression is up-regulated, and TLR receptor reactivity is enhanced in patients with sepsis.[9] TLR-4 has been shown to be the receptor that binds to LPS, triggering the activation of multiple inflammatory signaling cascades.[10,11] The importance of the TLR-4 receptor in sepsis has been well documented in animal models using TLR-4 knockout and mutant mice.[12] These studies have shown that mice with mutations in their TLR4 gene exhibit endotoxin tolerance and are unable to mount an inflammatory response upon exposure to LPS.[13]

Binding of a PAMP to the TLR receptor activates numerous intracellular signaling pathways that up-regulate the production of transcriptional factors. These transcriptional factors, including nuclear factor-kappa B (NF-KB), activator protein-1 (AP-1), and phosphoinositide 3-kinase (PI3K)/Akt, activate the inflammatory response resulting in the production of cytokines, acute phase proteins, and inducible nitric oxide synthase (iNOS). Proinflammatory cytokines such as tumor necrosis factor-alpha (TNF-α) and interleukin (IL)-1β exert several downstream effects that propagate the inflammatory response. Studies in animal models of sepsis have shown that there is a relationship between increased TNF-α production and the development of organ failure and septic shock.[14] TNF-α exerts these effects through the production of other proinflammatory mediators such as leukotrienes and prostaglandins, which together mediate the inflammatory response in sepsis by increasing capillary leak, causing damage to epithelial and endothelial barriers and increasing adhesion molecules on both inflammatory cells and vascular endothelial cells. The PMN is the primary effector cell that mediates the acute inflammatory response to invading microorganisms. Activated PMNs bind to adhesion molecules expressed on endothelial cells allowing for diapedesis into the tissues. There, PMNs respond to the pathogen through phagocytosis, degranulation, and oxidative burst. Oxidative burst results in the release of reactive oxygen species (ROS), which leads to bacterial killing. While PMN activation and degranulation is essential in neutralizing the invading pathogen, the release of ROS can also be deleterious to the host tissues, resulting in organ injury.

COMPLEMENT ACTIVATION

The complement cascade is a part of the innate immune system that responds to invading pathogens. The complement system is composed of circulating plasma proteins that are normally in their inactive state. This system is highly regulated, as activation of the complement cascade can be damaging to host tissues. Once activated by a stimulus such as the presence of microorganisms, proteins of the complement system become activated. These activated complement proteins are responsible for lysis of bacteria and viruses, and for opsonization of bacteria resulting in phagocytosis by other inflammatory cells.

The complement cascade can be activated through three different pathways.[15] In the classic pathway, complement proteins are activated by immunoglobulin-G (IgG) or IgM bound to an antigen. The classic pathway is also activated by acute phase proteins that are produced in response to invading pathogens. The alternate pathway of complement activation occurs when complement binds directly to the PAMPs displayed by bacteria, viruses, and fungi and does not rely on antibodies binding to the pathogen. The mannose-binding lectin pathway is similar to the classic pathway of complement activation. Mannose-binding lectin is produced by the liver in response to infection and binds to the surface of invading pathogens, initiating the complement cascade. Activation of the complement system also alters the coagulation cascade, linking these two pathways in the response to sepsis.

COAGULATION

Sepsis increases the procoagulant balance in the host resulting in increased risk of small vessel thrombosis, decreased microcirculatory blood flow, and possible tissue ischemia. Inflammation is a potent activator of tissue factor that can initiate the coagulation cascade.[16] Activated tissue factor complexes with factor VIIa ultimately resulting in the conversion of prothrombin to thrombin. Thrombin then converts fibrinogen into fibrin leading to the formation of thrombus. The importance of sepsis-induced tissue factor activation was demonstrated in a study by de Jonge et al.[17] in which a tissue factor pathway inhibitor decreased coagulation activation after exposure to endotoxin. Sepsis also decreased the presence of anticoagulant factors in the blood, further shifting the procoagulant balance. The effects of activated protein C, antithrombin III, and the tissue factor pathway inhibitor are diminished in response to inflammation.

Disseminated intravascular coagulation (DIC) is a frequent complication in septic patients. DIC is characterized by the activation of the coagulation cascade resulting in fibrin activation and microvascular thrombosis, which is accompanied by consumption of coagulation factors and platelets.[18] Decreased microcirculatory blood flow caused by microvascular thrombosis can result in tissue ischemia and organ failure. Consumption of coagulation factors and platelets puts patients at risk for serious bleeding complications and may require transfusion of blood products. In a bleeding patient with DIC, platelets should be maintained at >20-30 × 10,[9] cryoprecipitate given to maintain fibrinogen concentration > 100 mg per dL, and fresh frozen plasma given to correct the PT and PTT.[19] Replacement therapy may be needed repeatedly until the underlying cause of DIC is treated as consumption of blood products will continue. Treatment of DIC is focused on treating the source of sepsis, as DIC typically resolves upon treatment of the underlying cause of infection.

MULTIPLE ORGAN FAILURE

The exaggerated host response to the septic insult can lead to major tissue injury, end organ dysfunction, and ultimately multiple organ failure (MOF). In fact, mortality rates in critically ill septic patients have been shown to be related to the magnitude of the host inflammatory response, rather than to the type of bacteria responsible for the infection or the extent of the infectious insult.[20] MOF is an important cause of mortality in critically ill patients, with mortality rates directly related to the number of organ systems that have failed. ICU patients who develop MOF have a 20-fold increased mortality compared to ICU patients who do not develop MOF, as well as a significantly increased ICU and hospital length of stay.[21] Therefore, the timely diagnosis and prompt treatment of the septic patient is essential for improved outcomes in this population.

DIAGNOSIS OF SEPSIS

Patients suspected to have sepsis should be monitored closely for signs of the SIRS response and evidence of end organ dysfunction. Prompt identification of the source of infection is a cornerstone in the treatment of sepsis. It is critically important to obtain specimens for culture including blood, urine, sputum, peritoneal fluid, abscess drainage, and catheter tips. It is vital that these cultures be obtained prior to beginning broad-spectrum antibiotic therapy. Culture specimens obtained following administration of antibiotics may prevent the identification of the organism responsible for the septic insult and later limit the ability of the clinician to properly tailor antimicrobial therapy. It is important to note that a clear microbiologic source of sepsis is not identified through cultures in at least one-third of cases.[22] Prompt imaging is also important in the diagnosis of the septic source, including plain radiographs and CT scans. Imaging studies should be chosen based on the clinical presentation and the presumed source of infection.

Identification of laboratory markers of sepsis or surrogates to measure the response of the septic patient is the topic of considerable research efforts. Biomarkers may play several roles in the clinical setting, including identification of patients at risk for an adverse outcome related to sepsis, to diagnose sepsis and inform treatment decisions, to rule out sepsis, for risk stratification, to monitor the response to treatment, and for use as a surrogate end point to monitor the effect of various treatment strategies.[23] The diverse host response to microbial infection and sepsis make identification of clinically reliable markers quite difficult.

Currently biomarkers are not widely used in the clinical setting to diagnose or guide the treatment of the septic patient. While hundreds of unique biomarkers have been proposed as possible markers of sepsis, a few potentially promising candidates have been studied. C-reactive protein (CRP) has been used for several years in an attempt to guide the management of septic patients. CRP has long been used as a marker of generalized inflammation. CRP levels increase within 6 hours of the onset of infection, with CRP levels doubling every 8 hours as the infection persists. CRP levels have been shown to peak near 36 hours after the onset of infection, with levels 1,000 times higher than normal physiologic levels.[24] CRP levels that remain persistently elevated in patients with sepsis are associated with worse outcomes.[25] CRP levels may help guide the effectiveness of antibiotic therapy in the septic patient, with decreasing CRP levels of the first 48 hours indicating effective antimicrobial therapy.[26]

Procalcitonin (PCT) is a precursor molecule of calcitonin, which has been shown to be released in response to inflammation

and infection. Recent studies suggest that PCT may be a superior marker of inflammation compared to CRP.[27] Increases in circulating PCT are related to the severity of sepsis, with PCT levels decreasing after institution of appropriate antibiotic therapy.[28,29] In a study of healthy volunteers injected with endotoxin, PCT levels peaked within 6 hours and maintained a plateau between 8 and 24 hours after injection.[30] Decreased PCT levels between days 2 and 3 are associated with improved survival and may represent a way to monitor the effectiveness of antibiotic therapy.[31] Measurement of PCT may allow for the rapid identification of patients at risk for developing sepsis; however, further randomized control trials are needed to further define its clinical utility.

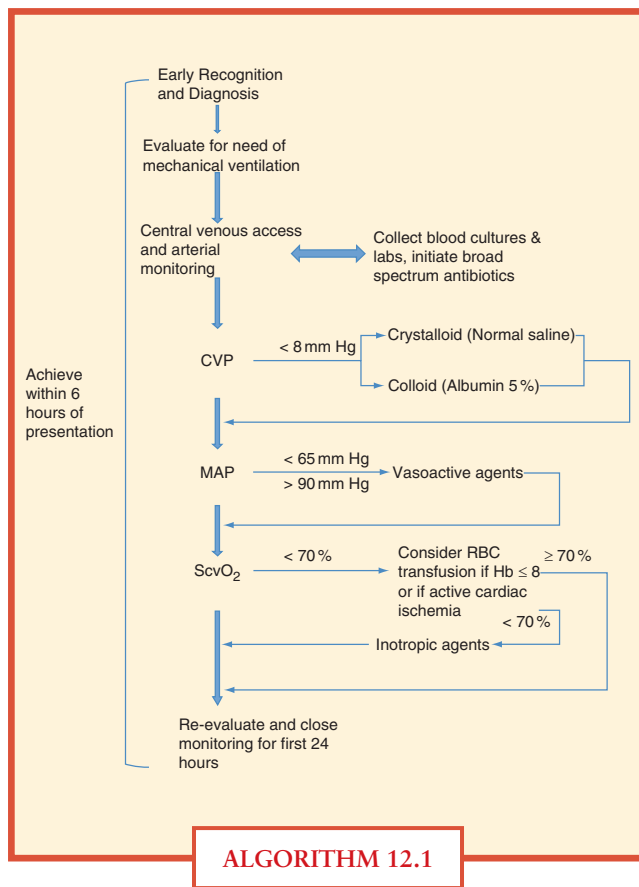
MANAGEMENT OF SEPSIS AND SEPTIC SHOCK

In the setting of acute organ dysfunction with or without hypotension, the speed and appropriateness of therapy are crucial to achieving treatment goals. In 2008, phase II of the Surviving Sepsis Campaign was published with clear guidelines for the treatment of sepsis and septic shock.[32] Since publication of those guidelines, sepsis bundles have emerged to eliminate piecemeal application of the guidelines and to make it easier for clinicians to bring the guidelines into practice.[33] In the surgical setting, life-threatening oxygenation, ventilation, and circulation deficits must be addressed quickly with complete interrogation of the patient for source of infection. Swift action with appropriate decision making is key in reducing mortality.

Specific treatment guidelines, protocols, and bundles have been shown to reduce morbidity and mortality of severe sepsis and septic shock in addition to reducing health care costs.[34-37] Although no study has been designed to give evidence of a clear causal relationship between adherence to SSC guidelines and reduction in mortality, these observational studies do provide a strong association between reduced mortality and use of the guidelines, whether in bundle format or not. Levy et al.[34] reported on the >15,000 patients registered in the SSC database and found a reduction in mortality from 37% to 30.8% over 2 years with use of SSC guidelines. Two additional studies demonstrate that compliance with a 6-hour bundle is significantly associated with an up to 50% reduction in mortality.[35,37]

Despite the attractive evidence supporting a benefit of the SSC, the guidelines that were produced have had their shortcomings. The initial goals of the campaign were to reduce the mortality related to sepsis by 25% over 5 years and provide a backbone for quality improvement in the treatment of severe sepsis and septic shock. Over the 5-year course, only a 20% reduction in mortality was achieved.[38] Although commendable, this is still regarded as failure. The majority of studies report <50% compliance with all or a major portion of the guidelines. This illustrates the difficulty in producing a large global shift in management strategies. The education, implementation, mentoring, and compliance to new policies and procedures have countless obstacles, be it resources, funding, or agreement to change practice patterns. Finally, a causal relationship between the implementation of the guidelines and an establishment of the reduction in mortality must be made through firm research, likely prospective in nature.[39]

EARLY PHASE OF MANAGEMENT

Vital signs, central venous pressure, urinary output, and physical findings do not adequately assess tissue hypoxia in severe disease. Early goal-directed therapy gives specific resuscitation end points that give a more accurate picture of adequate tissue perfusion and oxygenation (Algorithm. 12.1). Resuscitation end points include not only global indicators of perfusion (i.e., heart rate, blood pressure, urine output) but also mixed venous oxygen saturation, arterial lactate concentration, based deficit, and pH.[40] Specifically, within the first 6 hours of onset of severe sepsis or septic shock, intravascular volume should be increased to achieve CVP 8-12 mm Hg and vasopressors should be initiated for MAP < 65 mm Hg, vasodilators for MAP > 90 mm Hg. If central venous oxygen saturation measured within the superior vena cava or right atria is <70%, transfusion of packed red blood cells could be considered to achieve a hematocrit of ≥ 30%, especially in cases of active cardiac ischemia. If all these parameters are met and ScvO$_2$ remains <70%, initiation of inotropic support was recommended. Identification of the source of infection and initiation of antibiotic therapy are also of utmost importance. Initiation of broad-spectrum antibiotics, preferably after multiple blood cultures have been obtained, is absolutely necessary as early as possible. Ideally, the source of infection is also identified and addressed within the first 6 hours of presentation. Use of and compliance with early goal-directed therapy produced a statistically significant increased achievement of resuscitation end points and significant reduction of in-hospital, 28-, and 60-day mortality.[40]


ALGORITHM 12.1

ALGORITHM 12.1 This chart represents the specific goals and indicators as an example of how to manage the septic patient upon presentation.

FLUID RESUSCITATION

There has been much debate over the use of crystalloid or colloid to expand intravascular volume in hypotensive, septic patients. Two large meta-analyses produced differing results in choice of crystalloid versus colloid. Choi et al.[41] found no difference with respect to mortality and pulmonary edema. However, subgroup analysis in trauma patients did seem to favor crystalloid over colloid. Schierhout and Roberts[42] concluded a 4% increased risk of mortality when using colloid over crystalloid for initial resuscitation. One study attempted to measure the distribution of 5% albumin versus normal saline in the treatment of critically ill patients. Ultimately, through specific scientific measurements, the change in extracellular fluid volume to include both the plasma volume (intravascular) and the interstitial volume (edema) was expanded relatively equally per given MAP.[43] Although nearly three times more normal saline was needed to achieve that of 5% albumin, the cost benefit greatly favored normal saline. The SAFE trial demonstrates equivalent outcomes of either 4% albumin or normal saline in the resuscitation of critically ill patients in the ICU.[44]

The 2008 Surviving Sepsis Campaign recommends using fluid challenges to achieve an adequate cardiac filling pressure while still affecting change in overall hemodynamics. Once hemodynamic improvement is lost, fluid administration should be slowed. Overall, there is no clear consensus whether colloid or crystalloid is superior over the other. Clinicians must use good judgement in making individual assessments based on patient needs and severity of disease.

OXYGEN DELIVERY

The state of sepsis on a systemic level is a mismatch of oxygen delivery with oxygen extraction. The combination of the two leads to an oxygen debt within tissues. Oxygen delivery can be manipulated in several ways, ultimately leaving the disorder of tissue oxygen extraction in inflammatory states as the root of organ dysfunction. As the inflammatory cascade progresses leading to vascular permeability and tissue edema, oxygen extraction only becomes more difficult. Early goal-directed therapy has a clear algorithm for increasing oxygen delivery. Initially, volume resuscitation is stressed, followed by vasoactive agents with or without blood transfusion to achieve the desired $ScvO_2$ of $\geq 70\%$, and finally adding inotropic agents. The Surviving Sepsis Campaign advocates either blood transfusion to Hct $\geq 30\%$ or adding inotropic agents to achieve goal $ScvO_2 \geq 70\%$. Hébert et al.[45] demonstrated that a restrictive transfusion strategy to maintain hemoglobin concentration between 7 and 9 g per dL was associated with significantly reduced in-hospital, 30-day, and 60-day mortality compared to liberal strategy between 10 and 12 g per dL. With the exception of a subset population of patients with active ongoing cardiac ischemia, these recommendations applied to critically ill patients once euvolemia was obtained with initial resuscitation. With respect to transfusion of other human blood products, transfusion of fresh frozen plasma to correct coagulopathy should be based on circumstances in which the patient is actively bleeding or in anticipation of surgery or procedure. Platelet transfusion is indicated when counts are <5,000 per mm³ regardless of lack of ongoing bleeding, considered when counts are between 5,000 and 30,000 per mm³, and to achieve goal of $\geq 50,000$ for invasive procedure.[32]

In conjunction with raising the oxygen content of blood via transfusion, the second component of increasing oxygen delivery is affecting cardiac output after achieving a target MAP of ≥ 65 mm Hg. The SSC recommends either dopamine or norepinephrine as first-line vasopressor support for septic patients with hypotension. However, dopamine is favored as the vasopressor of choice if there is no contraindication.[32] Physiologic dosage of vasopressin (0.03 U per minute) may be added as an adjunct with expectation that vasopressin will have the same effect as norepinephrine alone. In the setting of low $ScvO_2$ after adequate fluid resuscitation, MAP ≥ 65 mm Hg, and if adequate hematocrit has been achieved, the use of an inotropic agent is recommended.[40,46] There has been debate that increasing cardiac index to levels above the normal maximal average, the "supranormal" range, may have benefit by restoring hemostasis sooner and repaying the oxygen debt. Two randomized, controlled trials, however, failed to show a benefit in mortality with supranormal cardiac indices.[46,47] In fact, a study Hayes et al. was terminated prematurely due to an increase in mortality in patients achieving supranormal physiologic conditions.

SOURCE CONTROL AND ANTIBIOTICS

Admissions to the SICU with the diagnosis of sepsis often result from specific infection. In the United States, the most common sites of infection are the respiratory tract (56.8%), the bloodstream (26.9%), the renal/urinary tract (22.2%), and the abdomen (16.6%).[48] Many of these infections require surgical or invasive intervention to control the source of infection quickly. Pathologies such as necrotizing fasciitis, ascending cholangitis, closed-loop bowel obstruction, or intestinal perforation can be treated quickly and not necessarily definitively and still have a major impact on morbidity and mortality. Often, a lower physiologic insult is the more appropriate choice. SSC guidelines recommend that source control be achieved within 6 hours of admission to the hospital/ICU.[32] For example, if available, percutaneous transhepatic cholangiography with drain placement by an interventional radiologist may be more appropriate and less stressful on a patient than operative choledochotomy for the treatment of cholangitis.

Line sepsis is a not uncommon consequence of prolonged ICU stay and can often be difficult to diagnose. Lines are frequently empirically removed or exchanged over guidewire to eliminate them as the source of infection. Older methods of blood culture often did not yield an expeditious answer and would frequently take days to determine if the indwelling catheter was truly the source of infection. New developments in laboratory technology can now provide automatic detection of microbial growth in blood cultures and measure the time elapsed between bottle inoculation and time to positivity. These technologies can provide answers within hours as opposed to days. One retrospective study found that a faster time to positivity between blood drawn centrally versus peripherally could effectively determine if the septic source was the indwelling catheter or another source.[49] Special attention should be given to the patient who presents with severe diarrhea and a history of even a single dose of antibiotics, especially clindamycin or cefoxitin, with a white blood cell count > 30×10^9 per mL. These patients should be empirically treated for *C. diff* colitis with either oral vancomycin or combination of oral vancomycin and intravenous metronidazole.[50]

In addition to source control, the initialization of antimicrobial therapy is of utmost importance (Table 12.1). SSC guidelines recommend the start of broad-spectrum antimicrobials happen as soon as possible and within the first hour.[32] If difficulty arises in obtaining blood cultures, this should not hinder the start of appropriate antimicrobial coverage. A study by Kumar et al. demonstrated that the duration a

TABLE 12.1

ANTIMICROBIAL THERAPY IN THE TREATMENT OF SEPSIS AND SEPTIC SHOCK

■ SUSPECTED SOURCE	■ COMMUNITY ACQUIRED			■ HIGH RISK/HEALTH CARE ASSOCIATED		
	1ST LINE	2ND LINE	3RD LINE	1ST LINE	2ND LINE	3RD LINE
Pulmonary Abdominal Urinary	Ceftriaxone	Ampicillin/ sulbactam	Carbepenem	4th generation cephalosporin (Cefepime or Ceftazidine)	Carbepenem (Meropenem/ Imipenem)	Pipericillin/ tazobactam
	Add fluoroquinolone or macrolide if needed			Add aminoglycoside or MRSA agent if needed		
Soft tissue	Cefazolin in MRSA low concern	Vancomyin if MRSA high concern	Daptomycin	Vancomycin	Linezolid Daptomycin Tigecycline	
Immunocompromised	Consider adding empiric antifungal or antiparasitic agent			Consider adding empiric antifungal or antiparasitic agent		

De-escalation of therapy according to organism sensitivities must occur as they become available and should occur within 4–5 d.

patient spends hypotensive prior to initiating broad-spectrum, antimicrobials has a direct effect on mortality. Time is truly of the essence. In their study, starting appropriate antimicrobials within the first hour was associated with a survival rate of 79.9%; the average rate of decline in survival was 7.6% per hour; by the sixth hour, if effective antimicrobials were not initiated, mortality rate was an abysmal 58%.[51] Therefore, empiric broad-spectrum antimicrobials (potentially providing double coverage) to cover all possible organisms based on the suspected source of infection must be initiated as soon as possible.

GLUCOSE MANAGEMENT

In critical illness, diabetics and nondiabetics often experience differences in glucose management from baseline. Infection, physiologic stress, and sepsis cause hyperglycemia. In 2001, Van den Berghe et al.[52] conducted a prospective, randomized, controlled trial comparing intensive insulin therapy via continuous insulin infusion versus conventional methods. With goal blood glucose maintained between 80 and 110 mg per dL, they demonstrated a marked reduction in overall in-hospital mortality. They also found that the greatest reduction in mortality occurred within the subgroup of patients with MOF from a septic focus. In another study, hyperglycemia was associated with increased mortality independent of severity of illness.[53] Additionally, unstable angina, acute myocardial infarction, congestive heart failure, arrhythmia, ischemic and hemorrhagic stroke, GI bleeding, acute renal failure, pneumonia, and pulmonary embolism were significantly associated with hyperglycemia and adjusted mortality. Since that time, several studies have evaluated the hypoglycemic events related to an intensive insulin regimen with concerns of ill effects related to hypoglycemia.

Two recent meta-analyses concluded that there was no benefit in mortality with intensive insulin regimens versus conventional therapy.[54,55] Most notably and recently, the NICE-SUGAR study compared an intensive insulin group with target glucose of 80-110 mg per dL to a more conventional group with goal blood glucose of <180 mg per dL. That study demonstrated not only a lower mortality rate in the conventional group but also a significantly lower number of hypoglycemic events (6.8% in the intensive group vs. 0.5% in the conventional group).[56] The deleterious effects of hypoglycemia are not completely categorized and to date, no causal relationship between increased mortality and hypoglycemia has been established. The current data are retrospective in nature but do provide compelling conclusions that warrant further study. For example, one retrospective study in trauma patients found that both mild and moderate levels of hypoglycemia were associated with mortality.[57] Corneille et al. further suggest that hyperglycemia should be minimized and any hypoglycemia excursions should be avoided. Another convincing study suggests the danger of hypoglycemic events during tight glucose-control strategies in severely brain-injured patients. Oddo et al.[58] demonstrated via cerebral microdialysis that tight glucose control (80-120 mg per dL) was associated with decreased cerebral glucose availability and increased mortality.

Although subgroup analysis of one study does demonstrate a significant reduction in septicemia/bacteremia of surgical ICU patients with intensive insulin therapy,[55] further investigation must be done to determine ideal blood glucose ranges for different subsets of patient disease and possibly demographics. At this time, both the American Association of Clinical Endocrinologists and the American Diabetes Association have published consensus recommendations for target blood glucose concentrations in both critically ill and noncritically ill patients.[59] The most appropriate approach to glycemic control appears to be intravenous insulin administration to maintain a blood glucose targeted between 140 and 180 mg per dL in critically ill patients, irrespective of cause of critical illness. The one exception may be the patient with evidence of bacteremia in the surgical ICU.

CORTICOSTEROIDS

Controversy still exists over when and if to give the septic patient exogenous corticosteroids. The diagnosis of adrenal insufficiency also remains a controversial topic. Previously, the diagnosis could be made with a baseline random cortisol level <15 μg per dL or with failure of an increase of ≥9 mg

per dL after ACTH stimulation. The retrospective CORTICUS study concluded that the change in cortisol level after corticotropin stimulation test was associated with improved clinical outcome. It was not, however, associated with improvement in mortality or with baseline cortisol level.[60] These findings are further supported in a study by Briegel et al.,[61] which concluded that only patients who have been adequately fluid resuscitated and continue to require high-dose vasopressors for longer than 1 hour should receive hydrocortisone.

An article that appeared in *Chest* in 2009 defined the critical illness–related corticosteroid insufficiency as a complex physiologic state of relative adrenal insufficiency given the severity of an individual's illness.[62,63] This definition further clouds the picture and makes for an absolute recommendation over the subject nearly unobtainable. Further evidence exists for a component of corticosteroid resistance, similar to insulin resistance, in an inflammatory state but will not be elaborated upon here. A recent Cochrane Review published in 2009 analyzed available prospective data and found that prolonged, low-dose corticosteroid treatment (200-300 mg hydrocortisone or equivalent per day) for severe sepsis and septic shock may have a lowering effect on all-cause mortality.[64] In contrast, the PROGRESS worldwide registry suggests that low-dose corticosteroid therapy is associated with higher mortality rates.[65] However, given the retrospective nature of the study, it is important to acknowledge that this relationship is truly an association and not a causal relationship. This study attempted to characterize the global use of steroids in the treatment of severe sepsis and septic shock. Given the most recent guidelines to treatment, one interesting finding in the study was that 14.2% of patients globally received corticosteroids without any evidence of shock.

Current recommendations for the usage of corticosteroids in critical illness are in situations of hypotension refractory to high-dose vasopressors in the volume-resuscitated patient. Dosing of hydrocortisone or equivalent should be between 200 and 300 mg per day divided over two to three doses with the optional addition of mineralocorticoid, fludrocortisone, 50 mg daily for patients with vasopressor-dependent septic shock for a period of 5 days.[32,63,64] Special attention should be given to any patient that has received etomidate, even single dose, for induction of anesthesia as this may suppress adrenal function for up to 48 hours.[66] The use of etomidate is therefore not recommended for use in critical illness.[32]

RECOMBINANT HUMAN ACTIVATED PROTEIN C

The use of recombinant human activated protein C is based on the results of two large randomized, controlled trials. The PROWESS study demonstrated a reduction of in-hospital mortality at 28 days compared to placebo, especially in high-risk groups defined as APACHE II score of ≥ 25 or sepsis with MOF.[67] This led to FDA approval of the use of recombinant activated protein C and the appearance of Xigris (Eli Lilly). The ADDRESS trial sought the benefit of recombinant human activated protein C in the low-risk population defined as APACHE II score < 25 or sepsis with single organ failure. This study determined that low-risk populations received no mortality benefit from the administration of recombinant human activated protein C. Another interesting finding in subgroup analysis within ADDRESS was that a significant number of surgical patients suffered more bleeding events during the drug infusion compared to placebo.[68] In October 2011, Xigris was withdrawn from the market and should no longer be considered for the treatment of patients with sepsis.[32]

SUPPORTIVE ICU CARE

The supportive management strategy must be tailored to the individual patient. However, there are some adjunctive treatments with benefit regardless of the condition of the patient. Stress gastric ulceration is a well-characterized consequence of critical illness that can lead to significant upper GI bleeding. Although no specific study has looked at the septic patient, it is reasonable to extrapolate data looking at general ICU populations. Current SSC guidelines recommend the use of either a proton pump inhibitor (1B evidence) or H2-blocker (1A evidence).[32] Research, however, questions the effectiveness of H2-blockers at maintaining the gastric pH high enough for a long enough duration to be effective.[69] Without respect to cost, proton pump inhibitors do appear to be a better choice for stress ulcer prophylaxis based on duration of gastric pH above goal of 3.5.

DVT prophylaxis in the critically ill patient has also been extensively studied. There is no question that critically ill patients need to be on DVT prophylaxis unless there is a specific contraindication such as ongoing bleeding or low platelet count at risk for spontaneous bleeding. In 1996, a randomized, double-blinded trial in critically ill trauma patients concluded that low molecular weight heparin was superior to unfractionated heparin in prevention of both distal and proximal DVT.[70] There is, however, a paucity of data in the critically ill surgical patient to effectively recommend one treatment strategy. Although, based on available literature, low-dose–molecular-weight heparin, either 40 mg per day or 30 mg twice daily, would appear to be the best option for the critically ill patient at high risk for DVT or VTE.

The nutritional supplementation of the septic patient is of utmost importance. Since the disease state is characterized by an increase in energy expenditure and catabolism, the septic patient absolutely needs nutritional support. Early nutritional support improves wound healing and immune function and has been shown to prevent intestinal mucosal breakdown. Parenteral nutrition carries with it an increased risk of line infection and may predispose to concurrent fungal infection. Thus, enteral nutrition is preferred even in the setting of decreased enteric motility associated with sepsis. Not only has research demonstrated that enteral nutrition is safe and effective in sepsis,[71] but the addition of glutamine to the enteral diet may have positive effects on host immune response.[72] In general, the septic patient should receive enteral nutrition as early as possible unless contraindicated by major GI hemorrhage, bowel obstruction, or uncorrected hemodynamic instability.[73]

The decision to initiate mechanical ventilation on a patient can be a complex issue. Frequently, however, the effect of MOF associated with septic shock requires mechanical ventilation to improve oxygenation. The reduction in oxygen saturation, increased work of breathing, increased respiratory rate, reduction of PaO_2, or any two in combination are sufficient justification to initiate mechanical ventilation. When choosing a ventilation strategy, there is clear evidence produced by the ARDSNet trial supporting lower tidal volume ventilation.[74] Current recommendations from the ARDSNet trial and supported by the most recent SSC guidelines include tidal volume of ≥6-8 mL per kg as long as plateau pressure can be maintained ≤ 30 cm H_2O.[32,74] SSC goes on to suggest that permissive hypercapnia (allowing $PaCO_2$ to rise above premorbid baseline) be allowed in ALI/ARDS if the strategy minimizes plateau pressures to acceptable levels while maintaining adequate oxygenation.[32]

When addressing the need for renal replacement therapy, guidelines are mixed as to whether continuous or intermittent therapy is more efficacious. Renal replacement needs arise when a patient becomes uremic, hyperkalemic, or acidotic, or reaches toxic drug levels. Volume overload is categorized as a

relative indication. Professional opinion typically leans toward continuous renal replacement as a gentler means of both fluid management and control of blood ions and toxins. However, within the literature, there is no clear advantage of intermittent dialysis versus continuous renal replacement. As far as administration of exogenous bicarbonate is concerned, current guidelines recommend only administering exogenous bicarbonate solution to a goal of pH of ≥7.15.[32] The best course of action is to work closely with a nephrologist in an interdisciplinary approach to meet the individual patient's needs.

ABDOMINAL SEPSIS FOR THE ACUTE CARE SURGEONS: KEY CONCEPTS

Abdominal sepsis is defined when sepsis or septic shock are secondary to intra-abdominal infection (IAI). Mortality of abdominal sepsis varies from 25% to 70%.[75-79]

The basic principles in the management of abdominal sepsis include early diagnosis, immediate and adequate drainage or removal of the source of infection, which can be accomplished by formal operative intervention (laparotomy with or without laparostomy) or less invasive techniques such as percutaneous drainage, appropriate antimicrobial therapy, and supportive critical care measures to prevent or immediately treat organ dysfunction.[80]

According to the International Sepsis Forum Consensus Conference, an IAI is an infection of any intra-abdominal organ with or without peritoneal involvement (peritonitis).[81,82] A complicated IAI implies diffuse peritoneal involvement (peritonitis) usually due to a perforated viscus. Only rarely, these cases may present as a contained abscess or minimal peritonitis.[83] Peritonitis is a complex disease process and has been traditionally divided into primary, secondary, and tertiary depending on its cause and extent. In general, the clinical course of peritonitis depends on the microbiology, the anatomical location, the degree of localization, and the presence of correctable anatomical derangements involving abdominal viscera.[81]

Primary peritonitis, also known as primary peritoneal infection or spontaneous bacterial peritonitis, is characterized by the absence of an identifiable anatomical derangement in the intra-abdominal viscera. The source of infection cannot be attributed to a gastrointestinal problem.

Secondary peritonitis, also known as secondary peritoneal infection, occurs in the presence of a clearly defined anatomical derangement of an intra-abdominal organ such as perforated viscus. The most common organisms are part of the indigenous flora of the gastrointestinal tract. Gastroduodenal perforations may be accompanied by *Candida* infections. Polymicrobial isolates remain the hallmark of IAIs.[84] *Escherichia coli* is the most common aerobe isolate, whereas *Bacteroides* is the most common anaerobe.[85-87] Enterococci are more commonly isolated in high-risk patients who failed antimicrobial treatment for IAI. When enterococci are isolated, *Enterococcus faecalis* and *Enterococcus faecium* account for 90% and 10% of episodes, respectively.[88-91]

Other enteric gram-negative bacteria such as *Pseudomonas aeruginosa* and *Acinetobacter* species have become an important problem more recently because of the increasing resistance to many antimicrobials. They occur more commonly in high-risk, debilitated individuals, in those who have received antimicrobials previously, in postoperative patients, and in those receiving immunosuppressant therapy.[86] *Staphylococcus aureus* is also a potential pathogen with inherent antibiotic resistance issues.[92] Table 12.2 presents the most common bacteria found in the biliary and GI tract.

In secondary peritonitis, antimicrobial therapy against gram-negative enteric pathogens and gram-positive and

TABLE 12.2

COMMON BACTERIA FOUND IN DIFFERENT INTRA-ABDOMINAL ORGANS

■ INTRA-ABDOMINAL ORGAN	■ COMMON BACTERIA
Stomach	Streptococci *Lactobacillus* spp.
Bilary tract	*E. coli* *Klebsiella* spp. Enterococci
Proximal small bowel	*E. coli* *Lactobacillus* spp. Streptococci Diphtheroids Enterococci
Distal small bowel	*Bacteroides fragilis* *Clostridium* spp. *E. coli* *Enterobacter* spp. *Klebsiella* spp. Peptostreptococci Enterococci
Large bowel	*Bacteroides* spp. *Clostridium* spp. *E. coli* *Enterobacter* spp. *Klebsiella* spp. Peptostreptococci Enterococci

gram-negative anaerobic bacteria is indicated. Enterococci, yeast, or fungi are not routinely treated, unless the patient has developed IAI after prior operation or is considered high risk for infection caused by one of these pathogens.[93]

The antimicrobial options, currently used in IAIs and secondary peritonitis can be found in two recent publications.[86,94] The duration of treatment is dependent on the type of infection, the immunologic status of the host, and the response to the initial treatment. In general, a course of 7-10 days of antimicrobial therapy is adequate for the treatment of patients with a normal immune system who have localized peritonitis or an intra-abdominal abscess. Patients with generalized peritonitis usually receive a longer course (10-14 days) of antimicrobial therapy. Treatment with antibiotics should continue until the infection has subsided. Culture results are important to adjust antimicrobial therapy and to detect resistance to treatment, a common cause of treatment failure and increased mortality.

Tertiary peritonitis can be defined as peritonitis that persists or recurs 48 hours following apparently successful management of primary or secondary bacterial peritonitis (source control procedure). Cultures usually show growth of nosocomial flora including coagulase-negative staphylococci, *Candida*, *Enterococci*, *Pseudomonas*, and Enterobacter.[79,93,95] The management of tertiary peritonitis is challenging due to the increased likelihood of infection with multidrug-resistant organisms.

SOURCE CONTROL

Source control is a critical element in the management of IAI and sepsis.

It is defined as "all physical measures undertaken to eliminate a source of infection, to control ongoing contamination,

and to restore premorbid anatomy and function."[96] Management success is determined by the elimination of the source and control of ongoing contamination. Restoration of anatomy and function may be performed in a delayed fashion to avoid prolongation of the initial surgical intervention in patients already physiologically and metabolically challenged (damage control strategy). Source control includes four basic principles of care: drainage, debridement plus device removal, decompression, and restoration of anatomy and function. Surgical or less invasive techniques such as image-guided percutaneous drainage of abscess may be used.

Patients with diffuse peritonitis are advised to undergo an emergency surgical procedure as soon as possible, even if ongoing measures to restore physiologic stability need to be continued during the procedure; for hemodynamically stable patients without evidence of acute organ failure, an urgent approach should be taken, intervention may be delayed for as long as 24 hours if appropriate antimicrobial therapy is given, and careful clinical monitoring is provided. Source control measures should be implemented as soon as possible following successful initial resuscitation.

Delay in diagnosis and prompt resuscitation of the patient with abdominal sepsis usually leads to delays in source control. The overuse of diagnostic tests, particularly imaging, as well as extensive evaluation in the emergency department, without focusing on quick resuscitation, correction of coagulation and electrolyte disturbances, early antibiotic administration, and early intervention has a negative impact on outcome.[93,97]

Preoperative optimization of the septic patient with a severe IAI should happen quickly, last no more than 2-3 hours, and it should not delay operative intervention.

CHAPTER 13 ■ ANTIBIOTIC USE AND MISUSE

PHILIP S. BARIE AND VANESSA P. HO

Traditionally, surgeons were only involved with infections that required invasive measures for treatment (e.g., complicated intra-abdominal infections and skin/soft tissue infections [cSS-TIs]). However, surgical patients are particularly vulnerable to nosocomial infections; therefore, the acute care surgeon must be concerned with the prevention and treatment of all infections that affect surgical patients, including surgical site infections (SSIs), central line–associated bloodstream infections (CLABSIs), urinary tract infections (UTIs), and hospital- or ventilator-associated pneumonia (HAP/VAP). Trauma patients are particularly vulnerable to infections of injured tissue as well as nosocomial infections related to environmental factors (e.g., hypothermia), host immunosuppression (e.g., inadequate glycemic control), and therapeutic interventions (e.g., multiple incisions and catheters, blood transfusion).[1,2] The overall incidence of infection following trauma is estimated to be 25%[3–6]; trauma patients may be twice as likely to become infected as critically ill general surgery patients.[7] These disease states are discussed elsewhere in this volume; this chapter discusses the use and misuse of antibiotics for prophylaxis and therapy.

Considering that the development of a postoperative infection has a negative impact on surgical outcomes, recognizing and minimizing risk and an aggressive approach to the diagnosis and treatment of such infections go hand in hand. Infection is preventable to some degree, and every acute care surgeon must do his or her utmost to prevent infection. An ensemble of tactics is required, because no single method, including antibiotic prophylaxis, is universally effective. Infection control is paramount. It must always be remembered that surgical illness and injury are immunosuppressive, as are many critical care therapeutics. Surgical incisions and traumatic wounds must be handled gently, inspected daily, and dressed if necessary using strict asepsis. Drains and catheters must be avoided if possible and removed as soon as practicable. Prophylactic and therapeutic antibiotics, whether empiric or directed against a known infection, must be used optimally so as to minimize antibiotic selection pressure on the development of multidrug-resistant (MDR) pathogens.

INFECTION CONTROL

General principles of surgical care, critical care, and infection control must be adhered to at all times. As but a few examples, resuscitation must be rapid, yet precise; both over- and under-resuscitation increase the risk of infection. Pathology must be identified and treated as soon as possible. Central venous catheters inserted under suboptimal barrier precautions (i.e., lack of cap, mask, sterile gown, and sterile gloves for the operator and a full-bed drape for the patient) must be removed and replaced (if necessary) by a new puncture at a new site as soon as the patient's condition permits. Drains should be avoided and removed as soon as possible if required.[8] Detailed evidence-based guidelines for the general prevention of SSI,[9] CLABSI,[10,11] and VAP have been published.[12,13] Hand hygiene is the most effective means to reduce the spread of infection, yet compliance is a continual challenge.[14]

Endogenous flora are the source of most human pathogens. Skin surfaces, artificial airways, gut lumen, wounds, catheters,

and inanimate surfaces (e.g., bed rails, computer terminals) may become colonized.[15] Any break in natural epithelial barriers (e.g., incisions, percutaneous catheters, airway or urinary catheters) creates a portal of entry for invasion of pathogens. The fecal–oral route is the most common manner by which pathogens reach the portal, but health care workers facilitate the transmission of pathogens on their hands.[15] In this context, antibiotics should be considered an essential component, but not a panacea, and certainly not as a substitute for best practices in all aspects of patient care.

Unfortunately, selection pressure from long-term overuse of antibiotics is a major factor in the emergence of MDR pathogens such as methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE), and gram-negative bacilli (e.g., *Klebsiella* spp., *Acinetobacter* spp., *Stenotrophomonas* spp., *and Pseudomonas aeruginosa*)[16–19] (Table 13.1) that have developed numerous mechanisms to express resistance to antibiotics. Fortunately, adherence to optimal prescribing practices, sometimes known as *antimicrobial stewardship*,[20] can improve the microbial ecology of the facility or unit and preserve the efficacy of the few extant antibiotics for MDR pathogens. Reduction of usage of antibiotics that exert substantial selection pressure (e.g., vancomycin, fluoroquinolones, third-generation cephalosporins) can be used to manage outbreaks and restore susceptibility.[19,21–24]

PHARMACOKINETICS AND PHARMACODYNAMICS

Pharmacokinetics (PK) describes the principles of drug absorption, distribution, and metabolism.[25] Dose–response relationships are influenced by dose, dosing interval, and route of administration. Plasma and tissue drug concentrations are influenced by absorption, distribution, and elimination, which in turn depend on drug metabolism and excretion. Serum drug concentrations may or may not correlate, depending on tissue penetration, but to the extent that they do, relationships between local drug concentration and effect are described by pharmacodynamic (PD) principles (see below).[25]

Bioavailability describes the percentage of drug dose that reaches the systemic circulation. Bioavailability is 100% after intravenous administration, but after oral administration is affected by absorption, intestinal transit time, and hepatic metabolism, if any. *Half-life* ($T_{1/2}$), the time required for the serum drug concentration to reduce by one-half, reflects both *clearance* and *volume of distribution* (V_D).[25] The V_D is independent of a drug's clearance or $T_{1/2}$ and is used to estimate the plasma drug concentration achievable from a given dose. Volume of distribution varies substantially due to pathophysiology; reduced V_D may cause a higher plasma drug concentration for a given dose, whereas fluid overload and hypoalbuminemia (which decrease drug binding) increase V_D, making dosing more complex. For example, dosing of hydrophilic drugs such as beta-lactams may need to be increased in the early phases of sepsis owing to the expansion of the extracellular space due to fluid resuscitation and alterations in microvascular permeability.[26]

CAUSES AND CONSEQUENCES OF BACTERIAL RESISTANCE AS RELATED TO ANTIBIOTIC SELECTION PRESSURE

■ INITIAL THERAPEUTIC AGENT	■ EMERGENT RESISTANT BACTERIA	■ TREATMENT OF RESISTANT BACTERIA
Fluoroquinolones	MRSA	Vancomycin, others (Table 13.18)
	MDR gram-negative bacilli	Carbapenem or polymyxin or tigecycline (not for *Pseudomonas*)
	C. difficile infection	Vancomycin or metronidazole or fidaxomicin
Vancomycin	VRE	Tigecycline, linezolid, daptomycin
	VISA	Ceftaroline, tigecycline, linezolid, daptomycin
Cephalosporins	VRE	Tigecycline, linezolid, daptomycin
	MDR gram-negative bacilli	Carbapenem or polymyxin or tigecycline (not for *Pseudomonas*)
	C. difficile infection	Vancomycin or metronidazole or fidaxomicin
Carbapenems	MDR gram-negative bacilli	Carbapenem or polymyxin or tigecycline (not for *Pseudomonas*)
	S. maltophilia	Trimethoprim/sulfamethoxazole
	C. difficile infection	Vancomycin or metronidazole or fidaxomicin

MDR, multidrug resistant; MDR gram-negative bacilli include producers of extended-spectrum beta-lactamases, metallo-beta-lactamases, and carbapenemases; MRSA, methicillin-resistant *Staphylococcus aureus*; VISA, vancomycin-intermediate *Staphylococcus aureus*; VRE, vancomycin-resistant *Enterococcus*.

Clearance refers to the volume of fluid from which drug is eliminated completely per unit of time, regardless of the mode of elimination (e.g., metabolism, excretion, or dialysis); knowledge of drug clearance is important to determine the dose of drug necessary to maintain a steady-state concentration. Most drugs are metabolized by the liver to polar compounds for eventual renal excretion, which may occur by filtration or either active or passive transport. The degree of filtration is determined by molecular size and charge and by the number of functional nephrons. In general, if ≥40% of active drug (including active metabolites) is eliminated unchanged in the urine, a dosage adjustment is required if renal function is decreased.

PDs are unique for antibiotic therapy, because drug–patient, drug–microbe, and microbe–patient interactions must be accounted for.[25] The key drug interaction is with the microbe rather than the host. Microbial physiology, inoculum characteristics (i.e., size, quorum sensing, presence of a device-related biofilm),[27,28] microbial growth phase, mechanisms of resistance, the microenvironment (e.g., local pH), and the host's response are important factors to consider. Because of microbial resistance, mere administration of the "correct" drug may not be microbicidal if an adequate dose/concentration is not achieved.[29,30] *In vitro* results may be irrelevant if bacteria are inhibited only by drug concentrations that cannot be achieved clinically.

Antibiotic PD parameters determined by laboratory analysis include *the minimal inhibitory concentration* (MIC), the lowest serum drug concentration that inhibits bacterial growth (MIC$_{90}$ refers to 90% inhibition) (Fig. 13.1). However, some antibiotics may suppress bacterial growth at subinhibitory concentrations (*postantibiotic effect*, PAE).[26,31] Appreciable PAE can be observed with aminoglycosides and fluoroquinolones for gram-negative bacteria, and with some β-lactam drugs (notably carbapenems) against *S. aureus*. However, MIC testing may not detect resistant bacterial subpopulations within the inoculum (e.g., "heteroresistance" of *S. aureus*),[32] which may be selected for by therapy, overgrow in the ecologic vacuum caused by treatment, and cause clinical failure.

Sophisticated analytic strategies utilize both PK and PD, for example, by determination of the peak serum concentration: MIC ratio, the duration of time that plasma concentration remains above the MIC (fT>MIC), and the area of the plasma concentration-time curve above the MIC (the *area under the curve* or AUC). Accordingly, aminoglycosides exhibit concentration-dependent killing,[31,33] whereas beta-lactam agents exhibit efficacy determined by time above the MIC.[34] For beta-lactam antibiotics with short $T_{1/2}$, it may be efficacious to administer by continuous infusion,[25,35,36] although prolonged intermittent infusion may accomplish the same while freeing up vascular access for other medications
FIGURE 13.1. A stylized elimination curve is shown for a single bolus dose of a parenteral antibiotic. Some drugs (e.g., aminoglycosides) exhibit concentration-dependent bactericidal activity; a peak concentration/minimum inhibitory concentration (MIC) ratio >10 is optimal for bacterial killing. Beta-lactam agents exhibit time-dependent bactericidal activity; the proportion (fT) of time above the MIC should be at least 40% for optimal killing. Efficacy of still other drugs (e.g., vancomycin, fluoroquinolones) is reflected by the AUC, a method of measurement of the bioavailability of a drug based on a plot of blood concentrations sampled at frequent intervals. The AUC is directly proportional to the total amount of unaltered drug in the patient's blood. A ratio of AUC: MIC > 400 is associated with optimal antibacterial effect and minimization of the development of resistance.

for a period of time each dosing interval. Some agents (e.g., fluoroquinolones, vancomycin) exhibit both properties; bacterial killing increases as drug concentration increases up to a saturation point, after which the effect becomes concentration-independent. An AUC:MIC$_{24h}$ > 125 is associated with optimal effect and reduced risk of developing resistance, whereas some authors recommend an AUC:MIC$_{24h}$ > 400 if treating a MDR pathogen. A framework for considering the dosing of individual antibiotics according to PK/PD principles is presented in Table 13.2.

Antibiotic Prophylaxis

Prophylactic antibiotics are used most often to prevent SSIs, for which the benefit has been proved in many circumstances. However, only the incision itself is protected, and only while it is open and thus vulnerable to inoculation. If not administered properly, antibiotic prophylaxis is ineffective and may be harmful. Antibiotic prophylaxis of surgery does not prevent postoperative nosocomial infections, which actually occur at an increased rate after prolonged prophylaxis,[37,38] selecting for more resistant pathogens when infection does develop.[8,38]

Four principles guide the administration of antimicrobial agent for prophylaxis of a surgical incision: safety; an appropriate narrow spectrum of coverage of relevant pathogens; little or no reliance upon the agent for therapy of infection (owing to the possible induction of resistance with heavy usage); and administration within 1 hour before surgery and for a defined, brief period of time thereafter (no more than 24 hours [48 hours for cardiac surgery]; ideally, a single dose).[39] According to these principles, quinolones or carbapenems are undesirable agents for surgical prophylaxis, although ertapenem and quinolone prophylaxis have been endorsed by the Surgical Care Improvement Project (SCIP) for prophylaxis

of elective colon surgery (the latter with metronidazole for penicillin-allergic patients) (Table 13.3). The SCIP recommendations do not consider emergency surgery.

The spectrum of bacterial contamination of surgical sites is well described.[40] Clean surgical procedures affect only skin structures and other soft tissues. Clean-contaminated procedures are characterized by controlled opening of a hollow viscus (e.g., elective aerodigestive or genitourinary tract surgery). Contaminated procedures introduce a large inoculum of bacteria into a normally sterile body cavity, but too briefly for infection to become established during surgery (e.g., penetrating abdominal trauma, enterotomy during adhesiolysis for mechanical bowel obstruction). Dirty procedures are those performed to control established infection (e.g., colon resection for perforated diverticulitis).

Most SSIs are caused by gram-positive cocci; therefore, prophylaxis should be directed primarily against staphylococci for clean cases and high-risk clean-contaminated upper abdominal surgery. A first-generation cephalosporin is preferred in almost all circumstances (Table 13.4), with clindamycin used for penicillin-allergic patients.[39] If gram-negative or anaerobic coverage is required, a second-generation cephalosporin, or the combination of a first-generation agent plus metronidazole, is the regimen of first choice. Vancomycin prophylaxis is generally not recommended, except in institutions where the incidence of MRSA infection is high (>20% of all SSIs caused by MRSA).

The optimal time to administer parenteral antibiotic prophylaxis is within 1 hour prior to incision.[41] Antibiotics given sooner are ineffective, as are agents given after the incision is closed. A 2001 audit of prescribing practices in the United States indicated that only 56% of patients who received prophylactic antibiotics did so within 1 hour prior to the skin incision[42]; timeliness was documented in only 76% of cases in a 2005 audit in US Department of Veterans Affairs hospitals.[42]

TABLE 13.2

PHARMACOKINETICS OF BACTERIAL KILLING: IMPLICATIONS FOR ANTIBIOTIC DOSING

■ CHARACTERISTIC	■ DRUGS	■ THERAPEUTIC GOAL	■ TACTIC
Time-dependent (no or minimal PAE); fT > MIC > 70% ideal	Carbapenems Cephalosporins Linezolid Penicillins	Maintain drug concentration	Maximize duration of exposure with prolonged or continuous infusion[a]
Time-dependent, concentration-enhanced (with PAE) AUC:MIC$_{24h}$ > 125; AUC:MIC$_{24h}$ > 400 for MDR pathogens?	Clindamycin Glycylcyclines Macrolides Streptogramins Tetracyclines Vancomycin	Maximize effectiveness of bacteriostatic/weak bactericidal antibiotics with prolonged PAEs. PAE is concentration-dependent	Maximize drug dosage[b] consistent with avoidance of toxicity
Concentration-dependent (with PAE)	Aminoglycosides Daptomycin Fluoroquinolones Ketolides Metronidazole Polymyxins	PAE is concentration-dependent. Achieve C$_{max}$ ([peak]) MIC >10	Maximize peak concentration[c]

[a]Continuous or prolonged infusion of linezolid is not recommended, as efficacy has not been established.
[b]Examples of maximized drug dosages include clindamycin 900 mg q8h rather than 600 mg q6h, and vancomycin 15 mg/kg/d for patients with normal renal function. Larger doses of tigecycline (a glyclcycline) and streptogramins (e.g., quinupristin/dalfopristin) may be limited by increased toxicity.
[c]Examples of dosing to achieve maximized peak drug concentrations include single daily-dose aminoglycoside therapy and metronidazole 1 g q12h rather than 500 mg q8h. Prolonging the dosing interval is not recommended for polymyxins, owing to a negligible PAE.
See text for additional explanations.
AUC, area under the concentration–time curve; Cmax, maximum drug concentration (peak concentration); fT, proportion of time; MIC, minimum inhibitory concentration; MDR, multidrug-resistant; PAE, postantibiotic effect.

TABLE 13.3

SURGICAL CARE IMPROVEMENT PROGRAM: APPROVED ANTIBIOTIC PROPHYLACTIC REGIMENS FOR ELECTIVE SURGERY

■ TYPE OF OPERATION	■ ANTIBIOTIC(S)
Cardiac (including CABG)[a], vascular[b]	Cefazolin or cefuroxime or vancomycin[c]
Hip/knee arthroplasty[b]	Cefazolin or cefuroxime or vancomycin[c]
Colon[d,e,f]	Oral: neomycin sulfate plus either erythromycin base or metronidazole, administered for 18 h before surgery Parenteral: cefoxitin or cefotetan or ertapenem or cefazolin plus metronidazole or ampicillin–sulbactam
Hysterectomy[e]	Cefazolin or cefoxitin or cefotetan or cefuroxime or ampicillin–sulbactam

[a]Prophylaxis may be administered for up to 48 h for cardiac surgery; for all other cases, the limit is 24 h.
[b]For beta-lactam allergy, clindamycin or vancomycin is an acceptable substitute for cardiac, vascular, and orthopedic surgery.
[c]Vancomycin is acceptable with a physician-documented justification for use in the medical record.
[d]For beta-lactam allergy, clindamycin plus gentamicin, a fluoroquinolone, or aztreonam; or metronidazole plus gentamicin or a fluoroquinolone are acceptable choices.
[e]For colon surgery, either oral or parenteral prophylaxis alone, or both combined, are acceptable.
[f]For beta-lactam allergy, either clindamycin plus gentamicin, a fluoroquinolone, or aztreonam; or metronidazole plus gentamicin or a fluoroquinolone or clindamycin monotherapy, is an acceptable choice.
CABG, coronary artery bypass grafting.

Most inappropriately timed first doses of prophylactic antibiotic occur too early.[41,42] Antibiotics with short half-lives (<2 hours, e.g., cefazolin or cefoxitin) should be redosed every 3–4 hours during surgery if the operation is prolonged or bloody.[43] Even though SCIP specifies a 24-hour limit for prophylaxis, single-dose prophylaxis (with intraoperative redosing, if indicated) is equivalent to multiple doses for the prevention of SSI.[44] Prolonged prophylaxis increases the risk of nosocomial infections unrelated to the surgical site, and the emergence of MDR pathogens. Both pneumonia and vascular catheter–related infections have been associated with prolonged prophylaxis,[37,38,45,46] as has the emergence of SSI caused by MRSA.[8]

Recent US data show that only 40% of patients who receive antibiotic prophylaxis do so for <24 hours.[47] As a result of ischemia caused by surgical hemostasis, antibiotic penetration into the incision immediately after surgery is questionable until neovascularization occurs (24–48 hours). Antibiotics should not be given to "cover" indwelling drains or catheters, in lavage or irrigation fluid,[48] or as a substitute for poor surgical technique.

Antibiotic prophylaxis is indicated for most clean-contaminated and contaminated (or potentially contaminated) operations. Antibiotic prophylaxis is indicated for high-risk biliary surgery; high risk is conferred by age >70 years, diabetes mellitus, or a recently instrumented biliary tract (e.g., biliary stent). By contrast, antibiotic prophylaxis is usually not indicated for elective laparoscopic cholecystectomy[49]; meta-analysis of 12 trials revealed no benefit compared with placebo for prevention of SSI (odds ratio [OR] 1.07, 95% confidence interval [CI], 0.59–1.94; p = 0.99), or "overall infection," "major infection," or "distant infection." Emergency cholecystectomy (regardless of technique) is performed most commonly for acute cholecystitis, for which antibiotic administration would be therapeutic, not prophylactic.

Antibiotic prophylaxis of clean surgery is controversial. Where bone is incised (e.g. craniotomy, sternotomy) or a prosthesis is inserted, antibiotic prophylaxis is generally indicated. Meta-analysis of randomized controlled trials shows a decrease of SSI rate for groin hernia surgery,[50] especially when nonabsorbable mesh is implanted. Twelve randomized clinical trials (6,705 patients) were identified, six of which used prosthetic material (hernioplasty). Infection rates were 2.9% and 3.9% in the prophylaxis and control groups, respectively (OR 0.64, 95% CI 0.48-0.85). Patients with herniorrhaphy had infection rates of 3.5% and 4.9% in the prophylaxis and control groups, respectively (OR 0.71, 95% CI 0.51–1.00). Patients with hernioplasty had infection rates of 1.4% and 2.9% in the prophylaxis and control groups, respectively (OR 0.48, 95% CI 0.27-0.85).

The incidence of SSI is higher for abdominal wall incisional hernia repair than for groin hernioplasty, especially for open surgery as compared with laparoscopic repair,[51,52] and is increased dramatically if an enterotomy occurs during adhesiolysis.[53] Because of the known risk of SSI, antibiotic prophylaxis is warranted, but has not been examined with rigor.

Arterial reconstruction with a prosthetic graft, especially infrainguinal, is an example of clean surgery where the risk of infection is substantial. Meta-analysis[54] of 23 randomized, controlled trials of prophylactic antibiotics for peripheral arterial reconstruction demonstrated that prophylaxis reduced the risk of SSI by approximately 75%, and early graft infection by about 69%. There was no benefit to prophylaxis for more than 24 hours, of antibiotic bonding to the graft material itself, or preoperative bathing with an antiseptic agent compared with unmedicated bathing.

Skin closure of a contaminated or dirty incision increases the risk of SSI, but few good studies evaluate the multiplicity of wound closure techniques used by surgeons. "Open abdomen" techniques of temporary abdominal closure for management of trauma or severe peritonitis are utilized increasingly. Antibiotic prophylaxis of the open abdomen is probably not indicated[55] (Table 13.5), although an inability to achieve primary abdominal closure is associated with several nosocomial infections (pneumonia, bloodstream infection, and SSI) and substantially increased cost from prolonged length of stay, but not mortality.[56]

Drains placed in incisions may cause more infections than they prevent. Epithelialization of the wound is prevented,

TABLE 13.4

APPROPRIATE CEPHALOSPORIN PROPHYLAXIS FOR SELECTED OPERATIONS

■ OPERATION	■ ALTERNATIVE PROPHYLAXIS IN SERIOUS PENICILLIN ALLERGY
First-Generation Cephalosporin (i.e., Cefazolin, Cefuroxime)	
Cardiovascular and thoracic	
Median sternotomy	Clindamycin (for all cardiovascular and thoracic cases except amputation)
Pacemaker insertion	
Vascular reconstruction involving the abdominal aorta, insertion of a prosthesis, or a groin incision (except carotid endarterectomy, which requires no prophylaxis)	
Implantable defibrillator	
Pulmonary resection	
Lower limb amputation	Gentamicin and metronidazole
General	
Cholecystectomy (high risk only)	Gentamicin
Gastrectomy (high risk only: not uncomplicated chronic duodenal ulcer)	Gentamicin and metronidazole
Hepatobiliary	Gentamicin and metronidazole
Major debridement of traumatic wound	Gentamicin
Genitourinary (ampicillin plus gentamicin is a reasonable alternative)	Ciprofloxacin
Gynecologic	
Cesarean section (STAT)	Metronidazole or doxycycline, after cord clamping
Hysterectomy (cefoxitin is a reasonable alternative)	Doxycycline
Head and neck/oral cavity	
Major procedures entering oral cavity or pharynx	Gentamicin and clindamycin or metronidazole
Neurosurgery	
Craniotomy	Clindamycin, vancomycin
Orthopedics	
Major joint arthroplasty	Vancomycin[b]
Open reduction of closed fracture	Vancomycin[b]
Second-generation (i.e., cefoxitin)[c]	
Appendectomy	Metronidazole plus gentamicin
Colon surgery[d]	
Surgery for penetrating abdominal trauma	

[a]Should be given as a single intravenous dose just before the operation. Consider an additional dose if the operation is prolonged longer than 3–4 h.

[b]Primary prophylaxis with vancomycin (i.e., for the non–penicillin-allergic patient) may be appropriate for cardiac valve replacement, placement of a non-tissue peripheral vascular prosthesis, or total joint replacement in institutions where a high rate of infections with methicillin-resistant *S. aureus* or *S. epidermidis* has occurred. The precise definition of "high rate" is debated. A single dose administered immediately before surgery is sufficient unless operation lasts for more than 6 h, in which case the dose should be repeated. Prophylaxis should be discontinued after a maximum of two doses but may be continued for up to 48 h.

[c]An intraoperative dose should be given if cefoxitin is used and the duration of surgery exceeds 3–4 h, because of the short half-life of the drug. A postoperative dose is not necessary but is permissible for up to 24 h.

[d]Benefit beyond that provided by bowel preparation with mechanical cleansing and oral neomycin and erythromycin base is debatable.

ANTIBIOTIC PROPHYLAXIS OF TRAUMA-SUMMARY OF EVIDENCE AND PUBLISHED GUIDELINES

■ CLINICAL SITUATION	■ AGENT (IF ANY)	■ DOSE/DURATION	■ EVIDENCE CLASS
Bites (mammalian)[65,66]			
"High-risk" <12–24 h postinjury	Amoxicillin/clavulanic acid (bites of the hand; deep puncture crushed or devitalized tissue, overt contamination)	875 mg BID × 3 d	II
Burn debridement[67]	Cefazolin or piperacillin/tazo-bactam	Higher doses or prolonged infusion	III
Craniotomy[68,69]			
Elective	Cefazolin	≤24 h perioperative	I
Emergency		Insufficient data	
Cutaneous wounds (acute)[70–72]	Topical	Systemic oral	Not recommended
Closed long bone fractures[73,74]	Cefazolin	Single-dose	I
Facial fractures[75–79]			
(Midface, including open, with or without sinus involvement)	Cefazolin	≤24 h perioperative only	III
Mandible	Cefazolin	≤24 h perioperative only	III
Orbital floor		Insufficient	
Open abdomen[55]	Not indicated		III
Open extremity fractures[80]			
Grade I extremity	Cefazolin	24–48 h	I
Grade II extremity	Cefazolin	48 h	II
Grade III extremity	*Single* broad-spectrum agent (aminoglycoside second agent not recommended)	48 h	III
Gunshot fractures-no ORIF	Not indicated		I
Multiple "washouts"	Prolongation not indicated	Insufficient	
Penetrating abdominal trauma[81]			
No hollow viscus injury	Second-generation cephalosporin	Single dose	I
Hollow viscus injury (including colon injury)	Second-generation cephalosporin	≤24 h	I
Placement of intracranial pressure monitor (including ventriculostomy)[82–84]	Not indicated		III
Skull fracture[85–87]		Not recommended	I
Basilar skull fracture with/without cere-brospinal fluid leak, adult or pediatric	Open, depressed	Insufficient	
Thoracotomy			
Emergency		Insufficient	
Traumatic brain injury[88]			
Tube thoracostomy[89]		Insufficient	
Emergency	First-generation cephalosporin	≤24 h	III

ORIF: Open reduction.internal fixation.

and the drain becomes a conduit, holding open a portal for invasion by pathogens colonizing the skin. Several studies of drains placed into clean or clean-contaminated incisions show that the rate of SSI is not reduced[57,58]; in fact, the rate is increased.[59–62] Considering that drains pose this risk, they should be used as little as possible and removed as soon as possible.[63] Under no circumstances should prolonged antibiotic prophylaxis be administered to "cover" indwelling drains.

For trauma, antibiotic prophylaxis may be required for operative management, but may also be indicated to prevent traumatic wounds from becoming infected. Obviously, the principle of administration within 1 hour before surgical incision does not apply in the latter case. Moreover, many surgical procedures performed for trauma are likely to be in a contaminated field (e.g., penetrating trauma, open reduction/internal fixation of open fractures). Likewise, as many as three-quarters of traumatic wounds are likely to be contaminated to some degree, the likelihood of infection is increased when the degree of contamination is higher.[64] The evidence for antibiotic prophylaxis of traumatic injury is presented in Table 13.5.[55,65–89] The evidence is most robust

for penetrating abdominal trauma, for which no more than 24 hours of prophylaxis with a second-generation cephalosporin (or equivalent) is recommended, even for colon injury. Weaker data sets that have been subjected to robust analysis include the evidence for prophylaxis of open extremity fractures.

PRINCIPLES OF ANTIBIOTIC THERAPY

Antimicrobial therapy is a mainstay of the treatment of infections, but widespread overuse and misuse of antibiotics have led to an alarming increase in MDR pathogens (Table 13.1). New agents and innovative ways to administer existing antibiotics may allow shorter courses of therapy, which is desirable for cost savings and control of microbial ecology. Effective therapy with no toxicity requires a careful but expeditious search for the source of infection and an understanding of the principles of PK (see above).

Evaluation of Possible Infection

Absent a fever, any of hypotension, tachycardia, tachypnea, confusion, rigors, skin lesions, respiratory manifestations, oliguria, lactic acidosis, leukocytosis, leukopenia, immature neutrophils (i.e., bands >10%), or thrombocytopenia may indicate a workup for infection and immediate empiric therapy. A new temperature elevation is usually the trigger for an evaluation for the presence of infection (hence, "fever workup"). However, some infected patients do not manifest fever, and may be even be hypothermic. Such patients include elderly patients; those with open abdominal wounds, end-stage liver disease, or chronic kidney disease; and patients taking anti-inflammatory or anti-pyretic drugs. Moreover, fever in the early postoperative period often has a non-infectious cause, hence fever does not equate with infection (Table 13.6).[90,91] The acute care surgeon must also bear in mind that non-infectious and infectious causes of fever may coexist, and that an infected patient may harbor more than one discrete focus of infection.

Antibiotics should not be given until evaluation has occurred, including the collection of specimens for culture. Therefore, evaluation must be expeditious, as delay in antibiotic administration is associated with an increased risk of death.[92–95] It is mandatory to remove the surgical dressing to inspect the incision as part of any fever evaluation. However, if an incision is opened and cultured, a deep culture specimen should be collected; swabbing an open wound superficially or collecting fluid from drains (if present) for culture is un-helpful because the likelihood of colonization is high. A chest x-ray is optional for evaluation of early postoperative fever unless mechanical ventilation, physical examination, abnormal blood gases, or pulmonary secretions suggest a high yield. Urinalysis or culture is not mandatory in the early postoperative period unless there is reason by history or examination to suspect a UTI. After trauma, UTI is common only after injury to the urinary tract.[96]

Traditional diagnostic criteria have low specificity for the diagnosis of HAP/VAP; therefore, culture of a lower respiratory tract sample is mandatory for nosocomial pneumonia prior to administration of antibiotics. There is controversy regarding methods of sputum specimen collection (invasive vs. noninvasive) and specimen analysis (semiquantitative vs. quantitative). The crucial issue in diagnosis of HAP/VAP is whether a sputum isolate reflects colonization rather than

TABLE 13.6
MISCELLANEOUS CAUSES OF FEVER RELATED TO NON-INFECTIOUS STATES

Withdrawal syndromes (e.g., drug, alcohol)

infection. Endotracheal suction aspirates have lower specificity than deep specimens collected by bronchoalveolar lavage or protected-specimen brush, due to an increased likelihood of contamination of the former by oropharyngeal flora,[97] although it is unclear if this makes a difference clinically. A meta-analysis of randomized trials that compared outcomes of patients with VAP managed with invasive versus noninvasive sampling showed no difference in mortality,[98] although patients in the invasive group were more likely to undergo narrowing of the antimicrobial regimen or cessation of therapy.

Blood cultures should be obtained from febrile patients when clinical evaluation does not suggest a non-infectious cause. The venipuncture site should be cleaned with either 2% chlorhexidine gluconate in 70% isopropyl alcohol or 1–2% tincture of iodine. Povidone–iodine (10%) is acceptable but not bactericidal until dry; false-positive blood cultures may result from premature specimen collection.[99] For adults, a minimum 20–30 mL sample of blood is drawn at a single time from a single site; additional guidelines apply for blood cultures taken from new or existing central venous catheters.[91] The minimum inoculum for an adult blood culture should be 10 mL/bottle. The cumulative yield of pathogens is optimized when three blood cultures (i.e., six bottles inoculated) with adequate volume (20–30 mL each) are drawn.[100] The sensitivity of blood culturing for detection of true bacteremia or fungemia is related to many factors, most importantly the volume of blood drawn and obtaining the cultures before initiation of anti-infective therapy.[100]

Empiric Antibiotic Therapy

Empiric antibiotic therapy must be administered judiciously, but expeditiously. Injudicious therapy could result in undertreatment of established infection, or unnecessary therapy in the setting of sterile inflammation or bacterial colonization; either may be deleterious. Inappropriate therapy (e.g., delay,[92,101] therapy misdirected against usual pathogens, failure to treat MDR pathogens) leads unequivocally to increased mortality.[93–95] There is urgency because delay in initiation of empiric antibiotic therapy of as little as 30–60 minutes can result in increased mortality.[101,102] Current guidelines for the diagnosis and management of severe sepsis recommend that empiric antibiotic therapy be instituted with 1 hour of presentation.[103]

Antibiotic choice is based on several interrelated factors (Tables 13.7–13.9). Paramount is activity against identified or likely (for empiric therapy) pathogens, presuming infecting and colonizing organisms can be distinguished, and that narrow-spectrum coverage is always desired. Estimation of likely pathogens depends on the disease process believed responsible; whether the infection is community-, health care–, or hospital-acquired; and whether MDR organisms are present, or likely to be. Local knowledge of antimicrobial resistance patterns is essential, even at the unit-specific level. Patient-specific factors of importance include age, debility, immunosuppression, intrinsic organ function, prior allergy or other adverse reaction, and recent antibiotic therapy. Institutional factors of importance include guidelines that may specify a particular therapy, formulary availability of specific agents, outbreaks of infections caused by MDR pathogens, and antibiotic control programs.

Antibiotic stewardship programs[20] support optimal antibiotic administration, including physician prescribing patterns, computerized decision support, administration by protocol, and formulary restriction programs. Owing to the increasing prevalence of MDR pathogens, it is crucial for initial empiric antibiotic therapy to be targeted appropriately, administered according to PK/PD principles, given in sufficient dosage to assure bacterial killing, narrowed in spectrum (*de-escalation*)[104] as soon as possible based on microbiology data and clinical response, and continued only as long as necessary.[105] Appropriate antibiotic prescribing not only optimizes patient care but supports infection control practice and preserves microbial ecology.[20,104]

Choice of Antibiotic Numerous agents are available for therapy (Table 13.10).[106,107] Agents may be chosen based on spectrum, whether broad or targeted (e.g., antipseudomonal, antianaerobic), in addition to the above factors. If a nosocomial gram-positive pathogen is suspected (e.g., wound or SSI, CLABSI, HAP/VAP) or MRSA is endemic, empiric vancomycin (or linezolid) is appropriate. Some authorities recommend dual-agent therapy for serious *Pseudomonas* infections (i.e., an antipseudomonal beta-lactam drug plus an aminoglycoside), but evidence of efficacy is mixed.[108–111] Combination therapy of a specific pathogen (e.g., "double coverage" of *Pseudomonas*) may actually worsen outcomes. Meta-analysis of β-lactam monotherapy versus β-lactam/aminoglycoside combination therapy for immunocompetent patients with sepsis (64 trials, 7,586 patients) found no difference in either mortality (RR 0.90, 95% CI 0.77–1.06) or the development of resistance.[109] Clinical failure was more common with combination therapy, as was the incidence of acute kidney injury. Regardless of the specifics of the choice that is made, initial empiric therapy of any infection caused potentially by either a gram-positive or gram-negative bacterium (e.g., HAP/VAP, hospital-acquired intra-abdominal infection) must include activity against all likely pathogens.[106,112–114]

Optimization of Therapy Conventional antibiotic dosing may not apply to the critically ill or injured patient.[26] Higher doses may be required for MDR isolates,[26,115–117] increased extracellular volume,[26,118] decreased serum albumin concentration,[119] or increased glomerular filtration rate (e.g., morbid obesity,[120] burns, traumatic brain injury,[121] multiple trauma). Underdosing of antibiotics is a major factor for the development of resistance during therapy and failure thereof.[116] By contrast, lower doses may be required with multiple organ dysfunction syndrome,[122] acute kidney injury, and chronic kidney disease (see below and Chapter 52). Dosing of vancomycin and aminoglycosides may be monitored via measurement of drug concentrations in serum,[123–125] and may be useful to limit toxicity.[126] Therapeutic drug concentration monitoring is possible for a host of other antibiotics, although not widely available.

The practical and financial challenges of performing PK studies in critically ill patients have made valuable mathematical modeling such as Monte Carlo simulation (MCS) to perform virtual clinical trials.[127] In order to utilize MCS, four conditions must be present: (1) A robust population PK model must be available for the patient population of interest; (2) descriptors of the effect of covariates that influence PK are needed; (3) the susceptibility of bacteria to the modeled antibiotic must be known; and (4) a PK/PD target must be associated with efficacy. Probability of target attainment outputs describe the proportion of patients who will achieve a prespecified PD target for any given MIC. Such analyses can then inform dosing decisions to achieve a high likelihood of achieving PK/PD targets for organisms with different MICs.

Zelenitsky et al. provided a useful example of MCS for interpreting the optimal methods for dosing meropenem, piperacillin/tazobactam, cefepime, and ceftobiprole in

[a]Yeast are also important pathogens in blood stream and UTIs.
[b]Yeast are seldom pathogens in nosocomial infection, except for solid-organ transplant recipients and
   patients undergoing antineoplastic chemotherapy.
Coag-neg, coagulase-negative.

critically ill patients.[128] For meropenem, at MICs up to 8 mcg/mL, the probability of achieving 40% fT > MIC was 96%, 90%, and 61% for 3-hour infusions of 2 g q8h, 1 g q8h, and 1 g q12h, respectively, in patients with creatinine clearances ≥50, 30–49, and 10–29 mL/min, respectively. Target attainment was 75%, 65%, and 44% for these same dosing regimens as 0.5 hour infusions.

Continuous or prolonged infusion of beta-lactam agents may be the optimal way to administer these drugs[129–132] (Figs. 13.2 and 13.3). Lengthened fT > MIC is achieved, increasing the likelihood of therapeutic success, especially against organisms with higher MICs, while minimizing the possibility of the development of resistance. Prolonged infusions may accomplish the same without monopolizing an intravenous line. Clinical reports support the use of prolonged infusions of beta-lactam antibiotics,[133–135] sometimes at lower total dose when highly susceptible organisms are being treated. However, adoption into clinical practice is not widespread.[136] Continuous-infusion vancomycin has been described,[137] but is not recommended currently (Table 13.11).

Vancomycin has been a mainstay of therapy of infections of critically ill patients, but MICs for vancomycin against MRSA have been increasing, even within the susceptible range. As a result, MIC cutpoints for resistance of *S. aureus* have been revised downward to minimize the chance of ineffective therapy (Table 13.12),[138] and higher doses of vancomycin are recommended (Table 13.11),[124,125] although at a greater risk of nephrotoxicity. Mortality in patients with MRSA HAP, VAP, and HCAP increases as a function of the vancomycin MIC, even for strains with MIC values within the susceptible range (Table 13.13).[139,140] The use of vancomycin therapy in patients with MRSA infections caused by isolates with MICs between 1 and –2 mg/mL should be undertaken with caution. Adequate therapeutic concentrations may not be achievable for *S. aureus* isolates with MICs >2 mcg/mL,[141] so alternative therapy should be considered. Linezolid retains generally excellent activity,[142] but resistance to daptomycin is being reported.[143]

Aminoglycoside therapy is resurgent owing to limited options for treatment of MDR pathogens that have resulted

TABLE 13.10

ANTIBACTERIAL AGENTS FOR EMPIRIC USE

Antipseudomonal

Piperacillin–tazobactam
Cefepime, ceftazidime
Imipenem-cilastatin, meropenem, doripenem
? Ciprofloxacin, levofloxacin (depending on local susceptibility patterns)
Aminoglycoside
Polymyxins (polymyxin B, colistin [polymyxin E])

Targeted-Spectrum
Gram-positive

Glycopeptide (e.g., vancomycin, telavancin)
Lipopeptide (e.g., daptomycin; not for known/suspected pneumonia)
Oxazolidinone (e.g., linezolid)
Gram-negative
Third-generation cephalosporin (not ceftriaxone)
Monobactam
Polymyxins (polymyxin B, colistin [polymyxin E])
Anti-anaerobic
Metronidazole

Broad-Spectrum

Piperacillin–tazobactam
Carbapenems
Fluoroquinolones (depending on local susceptibility patterns)
Tigecycline (plus an anti-pseudoomonal agent)
Trimethoprim–sulfamethoxazole (used primarily for CA-MRSA, *Stenotrophomonas*)

Anti-anaerobic

Metronidazole
Carbapenems
Beta-lactam/beta-lactamase combination agents
Tigecycline

Anti-MRSA

Ceftaroline
Daptomycin (not for use against pneumonia)
Minocycline
Linezolid
Telavancin
Tigecycline (not in pregnancy or for children under age 8 y)
Vancomycin

FIGURE 13.2. **A:** Stylized curves of bolus 30-min infusions of antibiotic at 6-h intervals. The proportion of time (fT) above the minimum inhibitory concentration (MIC) must be at least 40% for bactericidal activity in most cases. If the MIC is low, this can be achieved with conventional dosing, but not for organisms with higher MICs. **B:** Continuous infusion of antibiotic after an initial loading dose (*dotted lines*) is depicted. Not only is fT:MIC higher, but the antibiotic becomes effective against organisms with higher MICs, depending on the rate of continuous infusion. Lower total daily doses of antibiotic may be used against bacteria with low MICs. For drugs that exhibit time-dependent bactericidal activity (e.g., beta-lactams), this is the ideal mode of administration, provided vascular access is sufficient.

toxicity. Single-daily-dose aminoglycoside therapy has not been validated for children, pregnant patients, patients with burns, patients aged >70 years, or treatment of bacterial endocarditis.

Infections caused by highly resistant or pan-resistant gram-negative bacilli pose a major problem. Carbapenems, tigecycline, and polymyxins (see below) retain useful activity
FIGURE 13.3. A conventional bolus dose of antibiotic with a 30-min infusion and a 6-h dosing interval is compared with the same drug given as a 4-h infusion over the same dosing interval. fT:MIC is doubled (compare the lengths of the *short* and *long double arrows*), while organisms with higher MICs can still be treated. The interruption allows the intravenous line to be used for fluid or other medication during the hiatus, without compromising bactericidal action.

from the increasing prevalence of extended-spectrum beta-lactamase (ESBL)-producing strains and the emergence of carbapenemases, although use as part of an empiric therapy regimen remains debated.[108,109,123] Single daily-dose aminoglycoside therapy ensures that a peak:MIC concentration ratio >10 will be achieved to optimize therapy. A dose of gentamicin or tobramycin (7 mg/kg) or amikacin (20 mg/kg) is administered and a trough concentration is determined at 23-hour postdose (some protocols call for an intermediate determination as well, at approximately 16-hour post-dose, so that the elimination curve can be determined with greater precision). A trough concentration of 0.5–2 mcg/mL is sought for gentamicin or tobramycin, whereas a trough concentration of 5–10 mcg/mL is ideal for amikacin. Outcomes are comparable or better compared with conventional dosing, with decreased

against ESBL-producing organisms. MDR non-fermenting gram-negative bacilli (e.g., *P. aeruginosa*, *Acinetobacter* spp., *Stenotrophomonas* spp., and carbapenemase-producing Enterobacteriaceae) may require therapy with a polymyxin, high-dose carbapenem by prolonged infusion, or unusual combinations of agents that have demonstrated synergy *in vitro*, but remain of uncertain clinical utility.[106,107,143,144]

Duration of Therapy

The end point of antibiotic therapy is largely undefined, because quality data are few. If cultures are negative, empiric antibiotic therapy should be stopped in most cases after no more than 48–72 hours. Unnecessary antibiotic therapy increases the risk of MDR infection; therefore, prolonged therapy with negative cultures is usually unjustifiable. The morbidity of antibiotic therapy also includes allergic reactions, development of nosocomial superinfections, (e.g., fungal, enterococcal, and *Clostridium difficile*–related infections), organ toxicity, reduced yield from subsequent cultures, and vitamin K deficiency with coagulopathy or accentuation of warfarin effect.

If infection is evident, treatment is continued as indicated clinically, but the microbiology data should be examined to see if the antibiotic regime can be de-escalated to a narrower regimen (e.g., choosing a narrower-spectrum agent, changing multi-drug therapy to monotherapy). If empiric therapy has been appropriate, the need to escalate therapy at this point (e.g., choosing a more broad-spectrum agent, changing monotherapy to multi-drug therapy, adding antifungal therapy [see below]) should be a rare event.

Some infections can be treated with therapy lasting 4 days or less[105] (Table 13.14). Every decision to start antibiotics must be accompanied by an *a priori* decision regarding duration of therapy. A reason to continue therapy beyond the predetermined end point must be compelling. Bacterial killing is rapid in response to effective agents, but the host response may not subside immediately. Therefore, the clinical response of the patient should not be the sole determinant. There is increasing belief that shorter courses of antibiotic therapy that were used previously are equally effective with fewer side effects, and that therapy should continue to a predetermined end point, after which it should be stopped.

TABLE 13.12

SUMMARY OF VANCOMYCIN DOSING GUIDELINES

■ THERAPEUTIC VANCOMYCIN DOSE ADJUSTMENT AND DRUG MONITORING

Dosage
- Initial vancomycin dosages should be calculated on the basis of actual body weight, including for obese patients. IV vancomycin 15–20 mg/kg/dose (actual body weight) every 8–12 h, not to exceed 2 g per dose, is recommended for most patients with normal renal function
- For seriously ill patients (e.g., those with sepsis, meningitis, pneumonia, or infective endocarditis) with suspected MRSA infection, a loading dose of 25–30 mg/kg (actual body weight) may be considered
- Subsequent dosage adjustments should be based on actual trough serum concentrations, obtained just before the fourth dose, to achieve targeted therapeutic concentrations. Trough vancomycin monitoring is recommended for serious infections and patients who are morbidly obese, have renal dysfunction (including those receiving renal replacement therapy), or have fluctuating volumes of distribution
- For serious infections, such as bacteremia, infective endocarditis, osteomyelitis, meningitis, pneumonia, and severe SSTI (e.g., necrotizing fasciitis) due to MRSA, vancomycin trough concentrations of 15–20 mcg/mL are recommended
- Monitoring of peak vancomycin concentrations is not recommended
- Doses of 1 g should be infused over 1 h. Doses of more than 1 g should be infused over 1.5- 2 h. Continuous infusion of vancomycin is not recommended[60,61]

Procalcitonin has been evaluated extensively (11 randomized prospective trials) as a biomarker to guide duration of therapy.[105] Procalcitonin has been used to guide initiation of therapy in three trials, to end therapy in four trials, and as a guide to both in four trials. Without exception, clinical outcomes were unchanged (nine trials) or length of stay was reduced (two trials). Also without exception, procalcitonin monitoring was antibiotic sparing, reducing prescriptions of antibiotics by 32–72% in three trials and duration of therapy by 1.7–7.1 days in eight trials.

There are few data and no guidelines to inform the clinical approach to the patient who has failed a course of antibacterial therapy. There is not even a clear definition of what constitutes failure. Has the patient failed if the SIRS response persists after three days, or five or seven? When should antibiotics be changed? Is the antibiotic therapy well-chosen, but the patient has inadequate source control and requires operation (or reoperation)?[145] If a patient still has SIRS at the predetermined end point, it is more useful to stop therapy and reevaluate for persistent or new infection, MDR pathogens, and noninfectious causes of SIRS than to continue therapy uninformed or to add or change antibiotics without additional data.

MANAGING MICROBIAL ECOLOGY (INCLUDING OUTBREAKS)

Prescribing the same antibiotic regimen repeatedly is believed to lead to resistance by increasing antibiotic selection pressure on a unit. Intensive care units are frequently the epicenter of

TABLE 13.14

CURRENT RECOMMENDATIONS FOR DURATION OF THERAPY FOR SELECTED SERIOUS INFECTIONS

Bacterial Meningitis	
Gram-negative bacilli (e.g., postoperative)	21 d
Central Line-Associated Blood Stream Infection	
Coagulase-negative *Staphylococcus*	5–7 d
S. aureus	14 d[a]
Enterococcus spp.	7–14 d
Gram-negative bacilli	7–14 d
Candida spp.	14 d after the last positive blood culture
Complicated intra-abdominal infection	4–7 d
Pneumonia

nosocomial infections caused by MDR bacteria. Prevention of bacterial resistance is paramount to achieving good outcomes of critical care, but outbreaks do occur invariably, and must be managed. The microbiology laboratory supports the provision of appropriate antibiotic therapy by providing clinicians with "antibiograms" to aid empiric antibiotic choice and by providing MICs of key antibiotics so that antibiotic dosing is optimized to PD targets. Laboratories also play a crucial role in the prevention of antibiotic resistance. Molecular epidemiologic evidence of an oligoclonal outbreak of infections orients prevention measures toward investigation of common environmental sources of infection and prevention of patient-to-patient transmission. The US Centers for Disease Control and Prevention (CDC) has published several guidelines for management of outbreaks cause by MDR organisms, including hand hygiene, isolation precautions, and environmental controls.[146–149]

By contrast, evidence of polyclonality shifts the emphasis for prevention of antibiotic resistance to antibiotic management strategies. Specific antibiotics are discussed below; selection strategies for individual patients have been outlined above. Restoration of microbial ecology at the unit-specific or institutional level requires a coordinated effort. It has been demonstrated that the selective withdrawal of antibiotics that exert high selection pressure (e.g., ceftazidime, vancomycin, fluoroquinolones) is restorative of antibiotic susceptibility.[22–24,150] Whether the ecology can be maintained is still hypothetical. The underlying hypothesis states that if homogeneity of prescribing leads to increased antibiotic selection pressure, then diversity of prescribing will prevent the development of resistance.[151] Truly random prescribing cannot occur; each clinician will have his or her favored regimens, and bias is inevitable. The so-called heterogeneity of prescribing can be enforced through tactics referred to as "mixing" or "cycling." These constructs are not identical, in that in the former one antibiotic is withdrawn from use at a time, whereas cycling utilizes only a single agent for a defined period. Neither approach is clearly superior,[152] but cycling has been tested more extensively and found to be an effective tactic for both interdiction and maintenance in surgical ICUs,[102,153–156] but it is not a panacea.[157] Questions still to be answered about antibiotic cycling include which agents comprise an optimal cycle, and at what interval to cycle them.

SPECTRA OF ANTIBIOTIC ACTIVITY

Susceptibility testing of specific organisms is necessary for management of serious infections (including all nosocomial infections). Recommendations focus on agents useful for the treatment of serious/nosocomial infections; not every agent within the class will receive mention. Recommended agents for specific organisms are guidelines only, because *in vitro* susceptibilities may not correlate with clinical efficacy. Exposure to certain agents has been associated with the emergence of specific MDR bacteria, which require a different empiric antibiotic choice or modification of a regimen if identified or suspected (Table 13.1).

Cell Wall–Active Agents: Beta-lactam Antibiotics

The beta-lactam antibiotic group consists of penicillins, cephalosporins, monobactams, and carbapenems. Within this group, several agents have been combined with beta-lactamase inhibitors to broaden the spectrum of activity. Several subgroups of antibiotics are recognized within the group, notably penicillinase-resistant penicillins and several "generations" of cephalosporins.

Penicillins Penicillinase-resistant semisynthetic penicillins include methicillin, nafcillin, and oxacillin. These agents are useful as therapy for sensitive strains of staphylococci, but not as empiric agents, because of high rates of MRSA. Virtually all enterococcal species are resistant. However, if the *S. aureus* isolate is susceptible, any of these drugs is the treatment of choice (TOC).

Except for carboxypenicillins and ureidopenicillins, penicillins retain little or no activity against gram-negative bacilli. Carboxypenicillins (ticarcillin and carbenicillin) and ureidopenicillins (azlocillin, mezlocillin, and piperacillin; sometimes referred to as acylampicillins) are no longer used without a beta-lactamase inhibitor in combination (BLIC), such as sulbactam, tazobactam, clavulanic acid, which enhance the effectiveness of the parent beta-lactam agent (piperacillin > ticarcillin > ampicillin), and to a lesser extent the inhibitor (tazobactam > sulbactam ~ clavulanic acid). Piperacillin–tazobactam has the widest spectrum of activity against gram-negative bacteria and reasonable potency against *P. aeruginosa*. Ampicillin–sulbactam is unreliable against *Escherichia coli* and *Klebsiella* (resistance rate ~ 50%), but it has useful activity against *Acinetobacter* spp. owing to the sulbactam moiety. All of the BLIC agents have excellent antianaerobic activity.

Cephalosporins More than twenty agents comprise the class; their characteristics vary widely. The heterogeneity of spectrum requires broad familiarity with all of these drugs. First- and second-generation agents are useful only for prophylaxis, uncomplicated infections, or for de-escalation when results of susceptibility testing are known. "Third-generation" agents have enhanced activity against gram-negative bacilli (some have specific antipseudomonal activity), but only ceftriaxone is active against gram-positive cocci (but not MRSA), and none against anaerobes. Cefepime, a "fourth-generation" cephalosporin, has antipseudomonal activity and activity against most gram-positive cocci, but not MRSA. Ceftaroline (usual dose, 600 mg intravenously every 12 hours) has not been classified, but has anti-MRSA activity unique among the cephalosporins while retaining modest activity comparable to first-generation agents against gram-negative bacilli.[158] None of the cephalosporins are useful against enterococci.

Third-generation cephalosporins, particularly ceftazidime, have been associated with the induction of ESBL production among many of the Enterobacteriaceae (Table 13.1). Activity is reliable only against non-ESBL–producing species of Enterobacteriaceae including *Enterobacter*, *Citrobacter*, *Providencia*, and *Morganella*, but not for empiric monotherapy against nonfermenting gram-negative bacilli (e.g., *Acinetobacter* spp., *P. aeruginosa*, *Stenotrophomonas maltophilia*).

The potential of cefepime for induction of ESBL production is less than that of ceftazidime, but it, too, has no activity against either enterococci or enteric anaerobes. Similar to the carbapenems, cefepime is intrinsically more resistant to hydrolysis by beta-lactamases, but not enough to be reliable against ESBL-producing bacteria.

Monobactams

Aztreonam, the single agent of this class, has activity against gram-negative bacilli comparable to the third-generation cephalosporins, but no activity against gram-positive organisms or anaerobes. Aztreonam is not a potent inducer of beta-lactamases. Resistance to aztreonam is widespread, but the drug remains useful for directed therapy against known susceptible strains, and may be used safely for penicillin-allergic patients because the incidence of cross-reactivity is low.

Carbapenems

Imipenem–cilastatin, meropenem, doripenem, and ertapenem are available in the United States. Imipenem–cilastatin, meropenem, and doripenem have the widest (and generally comparable) antibacterial spectrum of any antibiotics, with excellent activity against aerobic and anaerobic streptococci, methicillin-sensitive staphylococci, and virtually all gram-negative bacilli except *Acinetobacter* spp., *Legionella* spp., *Pseudomonas cepacia*, and *S. maltophilia*.[159] All carbapenems are superlative anti-anaerobic agents; thus, there is no reason to combine a carbapenem with metronidazole except, for example, to treat concurrent mild *C. difficile* colitis in a patient with a coexistent life-threatening infection that mandates carbapenem therapy.

Meropenem and doripenem have less potential for neurotoxicity than imipenem–cilastatin, which is contraindicated in patients with active central nervous system disease or injury (excepting the spinal cord), because of the rare (~0.5%) appearance of myoclonus or generalized seizures in patients who have received high doses (with normal renal function) or inadequate dosage reductions with renal insufficiency. Ertapenem is not useful against *Pseudomonas* spp., *Acinetobacter* spp., *Enterobacter* spp., or MRSA, but its long half-life permits once-daily dosing.[160] Ertapenem is highly active against ESBL-producing Enterobacteriaceae and also has less potential for neurotoxicity. With all carbapenems, disruption of host microbial flora may lead to superinfections (e.g., fungi, *C. difficile*, *Stenotrophomonas*, resistant enterococci).

CELL WALL–ACTIVE AGENTS: LIPOGLYCOPEPTIDES

Vancomycin, a soluble lipoglycopeptide, is bactericidal, but tissue penetration is universally poor, which limits its effectiveness. Both *S. aureus* and *S. epidermidis* are usually susceptible to vancomycin, although MICs for *S. aureus* are increasing, requiring higher doses for effect,[124,125] and leading to rates of clinical failure that exceed 50% in some reports[140] (Table 13.13). *Streptococcus pyogenes*, group B streptococci, *S. pneumoniae* (including penicillin-resistant *S. pneumoniae*-PRSP), and *C. difficile* are susceptible. Most strains of *E. faecalis* are inhibited (but not killed) by attainable concentrations, but *E. faecium* is increasingly VRE.

Telavancin, a synthetic derivative of vancomycin, has been approved for treatment of cSSTI.[161] There appears to be a dual mechanism of action, including cell membrane disruption and inhibition of cell wall synthesis. The drug is active against MRSA, pneumococci including PRSP, and vancomycin-susceptible enterococci with MICs <1 mcg/mL. The most common side effects are taste disturbance, nausea, vomiting, and headache. There may be a small increased risk of acute kidney injury. The usual dose is 10 mg/kg, infused intravenously over 60 minutes, every 24 hours for 7–14 days; dosage reductions are necessary in renal insufficiency. No information is available regarding dosing during renal replacement therapy.

Cell Wall–Active Agents: Cyclic Lipopeptides

Daptomycin has potent, rapid bactericidal activity against most gram-positive organisms. The mechanism of action is via rapid membrane depolarization; potassium efflux; arrest of DNA, RNA, and protein synthesis; and cell death. Daptomycin exhibits concentration-dependent killing (Table 13.2), and has a long half-life (8 hours). A dose of 4 mg/kg once daily is recommended for cSSTI, versus 6 mg/kg/d for bacteremia. Daptomycin is excreted in the urine; therefore, the dosing interval should be increased to 48 hours when creatinine clearance <30 mL/min. No antagonistic drug interactions have been observed. Daptomycin is active against most aerobic and anaerobic gram-positive bacteria, including MDR strains such as MRSA, MRSE, VRE, *Peptostreptococcus* spp., *C. perfringens*, and *C. difficile*. Resistance to daptomycin has been reported for both MRSA and VRE.[143] Importantly, daptomycin must not be used for the treatment of pneumonia or empiric therapy when pneumonia is in the differential diagnosis, even when caused by a susceptible organism, because daptomycin penetrates lung tissue poorly and is also inactivated by pulmonary surfactant.[162]

Cell Wall–Active Agents: Polymyxins

Polymyxins are cyclic, cationic peptide antibiotics that have fatty acid residues[163]; two (polymyxins B and E, or colistin) have been used clinically. Polymyxins bind to the anionic bacterial outer membrane, leading to a detergent effect that disrupts membrane integrity. High affinity binding to the lipid A moiety of lipopolysaccharide may have a endotoxin-neutralizing effect. Commercial preparations of polymyxin B are standardized, but those of colistimethate (the less-toxic prodrug of colistin that is administered clinically) are not, so dosing depends on which preparation is being supplied. Most recent reports describe colistimethate use, but the drugs are therapeutically equivalent.

Dosing of polymyxin B is 1.5–2.5 mg/kg (15,000–25,000 U/kg) daily in divided doses, whereas dosing of colistimethate ranges from 2.5–6 mg/kg/d, also in divided doses. The diluent is voluminous, adding substantially to daily fluid intake. Data on PK are scant, but the drugs exhibit rapid concentration-dependent bacterial killing against a wide variety of gram-negative bacilli, including most isolates of *E. coli*, *Klebsiella* spp., *Enterobacter* spp., *P. aeruginosa*, *S. maltophilia*, and *Acinetobacter* spp. Excellent activity persists despite the widespread emergence of MDR pathogens. Combinations of polymyxin B or colistimethate and rifampin exhibit synergistic activity *in vitro*.[107] Tissue uptake is poor, but both intrathecal and inhalational administration have been described. Clinical response rates for respiratory tract infections appear to be lower than for other sites of infection.

Polymyxins fell out of favor due to nephro- and neurotoxicity, but the emergence of MDR pathogens has returned them to clinical use. Up to 40% of colistimethate-treated patients (5–15% for polymyxin B) will have an increase of serum creatinine concentration, but seldom is renal replacement therapy required. Neurotoxicity (5–7% for both) usually becomes manifest as muscle weakness or polyneuropathy.

PROTEIN SYNTHESIS INHIBITORS

Several classes of antibiotics, although dissimilar structurally and having divergent spectra of activity, exert their effects via binding to bacterial ribosomes and inhibiting protein synthesis. This classification is valuable mechanistically, linking several classes of antibiotics conceptually that have few clinically useful members.

Aminoglycosides

Although aminoglycosides were once disdained for their toxicity, a resurgence of aminoglycoside use has occurred as resistance to newer antibiotics (especially third-generation

cephalosporins and fluoroquinolones) has developed. Gentamicin, tobramycin, and amikacin are still used frequently. Aminoglycosides bind to the bacterial 30S ribosomal subunit, inhibiting protein synthesis. Gentamicin has modest activity against gram-positive cocci; otherwise, the spectrum of activity of the several agents is nearly identical. Prescribing decisions should be based upon toxicity and local resistance patterns. Nevertheless, the potential for toxicity is real, and aminoglycosides are now seldom first-line therapy, except in a synergistic combination to treat a serious *Pseudomonas* infection, enterococcal endocarditis, or an infection caused by an MDR gram-negative bacillus. As second-line therapy, these drugs are highly efficacious against the Enterobacteriaceae but less active against *Acinetobacter* and have limited activity against *P. cepacia*, *Aeromonas* spp., and *S. maltophilia*.

Aminoglycosides kill bacteria most effectively with a concentration peak:MIC > 10; therefore, a loading dose is necessary, and serum drug concentration monitoring is performed.[123] Marked dosage reductions are necessary in renal insufficiency, but the drugs are dialyzed, and a maintenance dose should be given after each hemodialysis treatment.

Tetracyclines

Tetracyclines bind irreversibly to the 30S ribosomal subunit, but they are bacteriostatic only. Widespread resistance limits their utility in the hospital setting (with the exceptions of doxycycline, minocycline, and tigecycline [IV only]). Tetracyclines are active against anaerobes; *Actinomyces* can be treated successfully. Doxycycline is active against *Bacteroides fragilis*, but used seldom for the purpose. All tetracyclines are contraindicated in pregnancy and for children under the age of 8 years, owing to dental toxicity.

Tigecycline is a novel glycylcycline derived from minocycline (both are now available parenterally).[164] With the major exceptions of *Pseudomonas* spp. and *Proteus mirabilis*, the spectrum of activity is broad, including many MDR gram-positive and -negative bacteria, including MRSA, VRE, and *Acinetobacter* spp. Tigecycline overcomes typical bacterial resistance to tetracyclines because a modification at position 9 of its core structure enables high-affinity binding to the 30S ribosomal unit. Tigecycline is active against aerobic and anaerobic streptococci, staphylococci, MRSA, MRSE, and enterococci, including VRE. Activity against gram-negative bacilli is directed against Enterobacteriaceae including ESBL-producing strains, *Pasteurella multocida*, *Aeromonas hydrophila*, *S. maltophilia*, *Enterobacter aerogenes*, and *Acinetobacter* spp. Anti-anaerobic activity is excellent.

Concern has been raised recently by a post-hoc analysis that the mortality of tigecycline-treated patients is higher in pooled Phase 3–4 clinical trials, including unpublished registration trials.[165] The adjusted risk difference for all-cause mortality based on a random effects model stratified by trial weight was 0.6% (95% CI 0.1–1.2) between tigecycline and comparator agents. However, an independent meta-analysis found no such survival disadvantage in an analysis of eight published randomized controlled trials (4,651 patients).[166] Overall, no difference was identified for the pooled clinically- (OR 0.92, 95% CI 0.76–1.12) or microbiologically evaluable populations (OR 0.86, 95% CI 0.69–1.07) from the trials.

Oxazolidinones

Oxazolidinones bind to the ribosomal 50S subunit, preventing complexing with the 30S subunit. Assembly of a functional initiation complex for protein synthesis is blocked, preventing translation of mRNA. This mode of action is novel, in that other protein synthesis inhibitors permit mRNA translation but then inhibit peptide elongation. Linezolid is bacteriostatic against most susceptible organisms. The ribosomes of *E. coli* are as susceptible to linezolid as those of gram-positive cocci, but, with minor exceptions, gram-negative bacteria are oxazolidinone-resistant, because oxazolidinones are excreted from bacterial cells by efflux pumps.

Linezolid is equally active against MSSA and MRSA, vancomycin-susceptible enterococci and VRE, and against susceptible and PRSP pneumococci. Most gram-negative bacteria are resistant, but *Bacteroides* spp. are susceptible. Linezolid requires no dosage reduction in renal insufficiency, and exhibits excellent tissue penetration, but it is uncertain whether that provides clinical benefit in treatment of cSSTI or HAP/VAP.[167] Meta-analysis suggests that linezolid is equivalent to vancomycin for HAP/VAP,[168] but some clinicians believe that linezolid should supplant vancomycin as first-line therapy for serious infections caused by gram-positive cocci.

The Macrolide–Lincosamide–Streptogramin Family

Clindamycin The only lincosamide in active clinical use in surgical practice is clindamycin, which also binds to the 50S ribosome. Clindamycin has good antianaerobic activity (although *B. fragilis* resistance is increasing) and reasonably good activity against susceptible gram-positive cocci (not MRSA or VRE). Clindamycin is used occasionally for anaerobic infections and is preferred over vancomycin for prophylaxis of clean surgical cases in penicillin-allergic patients[115] (Table 13.8). Because clindamycin inhibits exotoxin production *in vitro*, it has been advocated in preference to penicillin as first-line therapy of invasive *S. pyogenes* infections.

DRUGS THAT DISRUPT NUCLEIC ACIDS

Fluoroquinolones

Fluoroquinolones inhibit bacterial DNA synthesis by inhibiting DNA gyrase, which folds DNA into a superhelix in preparation for replication. The fluoroquinolones exhibit a diminishing spectrum of activity, excellent oral absorption and bioavailability, and numerous toxicities (e.g., photosensitivity, cartilage [especially in children] and tendon damage, prolongation of the QTc interval). These agents have a marked propensity to develop (and induce, see Table 13.1) resistance. Ciprofloxacin, levofloxacin, and moxifloxacin (which has some anti-anaerobic activity) are available parenterally and orally. Several others have been withdrawn from the market or were never approved owing to toxicity.

Fluoroquinolones are most active against enteric gram-negative bacteria, particularly the Enterobacteriaceae and *Haemophilus* spp. There is some activity against *P. aeruginosa*, *S. maltophilia*, and gram-negative cocci. Activity against gram-positive cocci is variable, being least for ciprofloxacin and best for moxifloxacin. Ciprofloxacin is most active against *P. aeruginosa*. However, rampant overuse of fluoroquinolones is rapidly causing resistance that may limit severely the future usefulness of these agents.[169] Fluoroquinolone use has been associated with the emergence of resistant *E. coli*, *Klebsiella* spp., *P. aeruginosa* and MRSA.[170,171] Fluoroquinolones prolong the QTc interval and may precipitate the ventricular

dysrhythmia *torsade de pointes*, so electrocardiographic measurement of the QTc interval before and during fluoroquinolone therapy is important. Also, fluoroquinolones interact with warfarin to cause a rapid, marked prolongation of the international normalized ratio, so warfarin anticoagulation must be monitored closely during therapy.

CYTOTOXIC ANTIBIOTICS

Metronidazole

Metronidazole is active against nearly all anaerobes, and many protozoa that parasitize human beings. Metronidazole has potent bactericidal activity, including activity against *B. fragilis*, *Prevotella* spp., *Clostridium* spp. (including *C. difficile*), and anaerobic cocci, although it is ineffective in actinomycosis. Resistance remains rare and of negligible clinical importance.

Metronidazole causes DNA damage after intracellular reduction of the nitro group of the drug. Acting as a preferential electron acceptor, it is reduced by low-redox potential electron transport proteins, decreasing the intracellular concentration of the unchanged drug and maintaining a transmembrane gradient that favors uptake of additional drug. The drug thus penetrates well nearly all tissues, including neural tissue, making it effective for deep-seated infections and bacteria that are not multiplying rapidly. Absorption after oral or rectal administration is rapid and nearly complete. The $T_{1/2}$ of metronidazole is 8 hours, owing to an active hydroxy metabolite. Intravenous metronidazole is usually administered every 8–12 hours in recognition of the active metabolite, but once-daily dosing is possible.[172] No dosage reduction is required for renal insufficiency, but the drug is dialyzed effectively, and administration should be timed to follow dialysis if twice-daily dosing is used. PK in patients with hepatic insufficiency suggest a dosage reduction of 50% with marked impairment.

Trimethoprim–Sulfamethoxazole (TMP–SMX)

Sulfonamides exert bacteriostatic activity by interfering with bacterial folic acid synthesis, a necessary step in DNA synthesis. Resistance is widespread, limiting use. The addition of sulfamethoxazole to trimethoprim, which prevents the conversion of dihydrofolic acid to tetrahydrofolic acid by the action of dihydrofolate reductase (downstream from the action of sulfonamides), accentuates the bactericidal activity of trimethoprim.

The combination of TMP–SMX is active against *S. aureus*, *S. pyogenes*, *S. pneumoniae*, *E. coli*, *P. mirabilis*, *Salmonella* and *Shigella* spp., *Yersinia enterocolitica*, *S. maltophilia*, *L. monocytogenes*, and *Pneumocystis jirovici*. Used for UTIs, acute exacerbations of chronic bronchitis, and *Pneumocystis* infections, TMP–SMX is a TOC for infections caused by *S. maltophilia* and outpatient (and sometimes inpatient) treatment of infections caused by CA-MRSA.

A fixed-dose combination of TMP–SMX of 1:5 is available for parenteral administration. The standard oral formulation is 80:400 mg, but lesser and greater strength tablets are available. Oral absorption is rapid and bioavailability is nearly 100%. Tissue penetration is excellent. Ten mL of the parenteral formulation contains 160:800 mg drug. Full doses (150–300 mg TMP in 3–4 divided doses) may be given if creatinine clearance is >30 mL/min, but the drug is not recommended when the creatinine clearance is <15 mL/min.

ANTIBIOTIC TOXICITIES

Beta-lactam Allergy

Allergic reaction is the most common toxicity of beta-lactam antibiotics. The incidence is approximately 7–40/1,000 treatment courses of penicillin,[173] and is more likely to be provoked by parenteral therapy. A history of penicillin allergy is sought commonly, and reported by 5–20% of patients (far in excess of the true incidence), therefore most serious reactions occur in patients with no history. Patients with a prior reaction have a four- to sixfold increased risk of another reaction compared to the general population, but the risk decreases with time, from 80–90% skin test reactivity at 2 months, to 20% reactivity at 10 years. The risk of cross-reactivity between penicillins and other beta-lactams (carbapenems and cephalosporins) is ~5%, being highest for first-generation cephalosporins.[173] There is negligible cross-reactivity to monobactams.

"Red Man" Syndrome

Tingling and flushing of the face, neck, or thorax may occur with parenteral vancomycin therapy but are less common than fever, rigors, or local phlebitis. The cause is believed to be histamine release due to local hyperosmolality. Although a hypersensitivity reaction, "red man" syndrome is not a true allergy owing to the clear association with too-rapid infusion of the drug (<1 hour for a 1 g dose, or <1.5–2 hours for a larger dose). Too-rapid infusion can also cause hypotension. A maculopapular rash due to hypersensitivity occurs in about 5% of patients.

Nephrotoxicity

All aminoglycosides are nephrotoxic, with little to distinguish among them. Aminoglycosides do not provoke inflammation, thus there is no allergic component to any manifestation of aminoglycoside toxicity. Mechanisms of toxicity include ischemia and toxicity to the renal proximal tubular cell (PTC).[174] Ultimately, injury manifests as necrosis of the PTC, reduction of the glomerular filtration rate, and decreased creatinine clearance but is usually reversible, and the need for renal replacement therapy is rare. Aminoglycoside nephrotoxicity is accentuated by frequent dosing, older age, sodium and volume depletion, acidemia, hypokalemia, hypomagnesemia, and coexistent liver disease. The risk of injury is ameliorated by single-daily-dose therapy.[123] If renal function deteriorates, it is advisable to discontinue therapy unless treatment is for a life-threatening infection.

Vancomycin nephrotoxicity is on the increase, owing to higher dosing and concurrent administration of other nephrotoxins.[124–126] Nephrotoxicity of polymyxins may be unavoidable; the need to use an agent with known nephrotoxic potential to treat serious infections caused by MDR gram-negative bacilli exists when alternatives are few or none.

Ototoxicity

Aminoglycosides cause cochlear or vestibular toxicity that is usually irreversible, and may develop after the cessation of therapy.[175] Repeated exposures create cumulative risk. Most patients develop either cochlear toxicity or a vestibular lesion, but rarely both. Cochlear toxicity can be subtle, because few patients have baseline audiograms, and formal screening is undertaken seldom. Few patients complain of hearing loss, yet when sought, the incidence of cochlear toxicity may be more than 60%. Clinical hearing loss may occur in 5–15%

of patients. Ototoxicity caused directly by vancomycin is documented poorly in the literature and may not occur unless vancomycin is coadministered with another ototoxin (e.g., aminoglycoside, furosemide). Hearing loss attributed to vancomycin is really neurotoxicity, manifesting as auditory nerve damage, tinnitus, and high-frequency hearing loss of acuity. There is no correlation between ototoxicity and nephrotoxicity for drugs that cause both (e.g., aminoglycosides, vancomycin).

AVOIDING TOXICITY: ADJUSTMENT OF ANTIBIOTIC DOSAGE

Hepatic Insufficiency

The liver metabolizes and eliminates drugs that are too lipophilic for renal excretion. The cytochromes P_{450} (a gene superfamily consisting of more than 300 different enzymes) oxidize lipophilic compounds to water-soluble products. Oxidation in particular is disrupted when liver function is impaired. Other enzymes metabolize drugs by conjugating them with sugars, amino acids, sulfate, or acetate to facilitate biliary or renal excretion.

Drug dosing in hepatic insufficiency is complicated by insensitive clinical assessments of liver function, and changing metabolism as the degree of impairment fluctuates (e.g., resolving cholestasis). Changes in renal function with progressive hepatic impairment add considerable complexity. Renal blood flow is decreased in cirrhosis, and glomerular filtration is decreased in cirrhosis with ascites. Adverse drug reactions are more frequent with cirrhosis than other forms of liver disease. The effect of liver disease on drug disposition is thus difficult to predict for individual patients.[176] Generally, a dosage reduction of up to 25% of the usual dose is considered if hepatic metabolism is 40% or less and renal function is normal (Table 13.15). Greater dosage reductions (up to 50%) are advisable if the drug is administered chronically, there is a narrow therapeutic index, protein binding is reduced considerably, or the drug is excreted renally and renal function is severely impaired.

Renal Insufficiency

Renal drug elimination depends on glomerular filtration, tubular secretion, and reabsorption, any of which may be altered with renal dysfunction. Kidney disease or acute kidney injury may affect hepatic as well as renal drug metabolic pathways. Drugs whose hepatic metabolism is likely to be disrupted in renal insufficiency include aztreonam, penicillins, several cephalosporins, macrolides, and carbapenems.

Accurate estimates of renal function are important in patients with mild-to-moderate renal dysfunction, because the clearance of many drugs by renal replacement therapy actually makes management easier. Factors influencing drug clearance by hemofiltration include molecular size, aqueous solubility, plasma protein binding, equilibration kinetics between plasma and tissue, and the apparent V_D. New high-flux polysulfone dialysis membranes can clear molecules up to 5 kDa efficiently (the molecular weight of vancomycin is 1.486 kDa). The need to dose patients during or after a renal replacement therapy treatment must be borne in mind; during continuous renal replacement therapy, the estimated creatinine clearance is approximately 15–25 mL/min in addition to the patient's intrinsic clearance.[177] For sustained low-efficiency dialysis, clearance rates of 60–100 mL/min may be achieved.[178] Cefaclor, cefoperazone, ceftriaxone, chloramphenicol, clindamycin, cloxacillin and dicloxacillin, doxycycline, erythromycin, linezolid,

TABLE 13.15

ANTIBIOTICS THAT REQUIRE DOSAGE REDUCTION FOR HEPATIC AND RENAL INSUFFICIENCY

Hepatic
- Aztreonam
- Cefoperazone
- Chloramphenicol
- Clindamycin
- Erythromycin
- Isoniazid
- Linezolid
- Metronidazole
- Nafcillin
- Quinupristin/dalfopristin
- Rifampin
- Tigecycline

Renal
- Aminoglycosides
- Aztreonam
- Carbapenems
- Cephalosporins (most)
- Chloramphenicol
- Fluoroquinolones
- Macrolides (except erythromycin and fidoxamycin)
- Penicillins
- Polymyxins
- Sulfonamides
- Trimethoprim/sulfamethoxazole
- Vancomycin

methicillin/nafcillin/oxacillin, metronidazole, rifampin, and tigecycline do not require dosage reductions in renal failure (Table 13.15). Conditions vary substantially from patient to patient, so dosing must be individualized and supported by therapeutic drug level monitoring when available.[179] Prolonged infusion of beta-lactam agents is not precluded.[180]

PROPHYLAXIS AND THERAPY OF FUNGAL INFECTIONS

Fungi are ubiquitous heterotrophic eukaryotes, resilient to environmental stress and adaptable to diverse environments. The most important human pathogens are the yeasts and the molds. Invasive mycoses have emerged as a major cause of morbidity and mortality in hospitalized surgical patients. The incidence of nosocomial candidemia in the United States is approximately 8/100,000 population, at a cost of approximately $1 billion/year. Fungemia is the fourth most common type of blood stream infection in the United States, but many surgical patients develop invasive infections without positive blood cultures. Host or therapeutic immunosuppression, organ transplantation, implantable devices, and human immunodeficiency virus infection have all changed the landscape of fungal pathogenicity. The surgical ICU population is an extremely high-risk group.[181] Several conditions (both patient dependent and disease specific) are independent predictors for invasive fungal infection, including ICU length of stay, extent of medical comorbidity, host immune suppression, and the number of medical devices present. Neutropenia, diabetes mellitus, new-onset renal replacement therapy, central venous catheterization, total parenteral

nutrition, broad-spectrum antibiotic administration, bladder catheterization, azotemia, diarrhea, corticosteroid therapy, and mechanical ventilation have also been associated with candidemia.[182,183]

Central Venous Catheters

Many episodes of candidemia represent a CLABSI. In non-neutropenic subjects, the most common portals of entry for catheter contamination (and subsequent infection) are from skin during catheter placement, manipulation of an indwelling catheter, and cross-infection among ICU patients attributed to health care workers. Other possible sources for primary catheter colonization include contaminated parenteral nutrition solution, multiple medication administration with repetitive violation of the sterile fluid path, and the presence of other medical devices. The secondary route of contamination for devices in direct contact with the blood stream (e.g., pacemakers, cardiac valves, joint prostheses) is candidemia originating from the gastrointestinal tract. Endogenous flora are also the most common source in neutropenic and other immunosuppressed patients. Once the catheter is contaminated, a stereotypical series of events occurs: Yeast adhere to the catheter surface and develop hyphae that integrate into a biofilm that increases in size and tridimensional complexity. Biofilms are the main reservoirs for candidemia secondary to contaminated medical devices, as they induce stasis and sequester the fungi from antimycotic medication and the immune response. In general, catheter removal is indicated following the diagnosis of systemic fungal infections and fungemia. Antifungal agents are usually continued for a defined period after blood cultures become negative after the catheter is removed (Table 13.14),[105] and *Candida* endophthalmitis should be ruled out (see below).

Prediction of Invasive Candida *Infection*

Overgrowth and recovery of *Candida* spp. from multiple sites (even from asymptomatic patients) carry a high likelihood of invasive candidiasis. Risk factors for the development of *Candida* colonization include female gender, antibiotic therapy prior to an ICU admission, a prolonged stay in the ICU, and multiple gastrointestinal operations.[184] The source of the pathogen in the surgical context is most frequently the gastrointestinal tract. Because colonization with *Candida* spp. presages invasive disease, it is desirable to identify and characterize patients further in terms of risk. Surveillance cultures may be used to screen ICU patients. Several scoring systems have been proposed to quantify the risk of invasive fungal infection (Table 13.16).[185–189] Comparisons between the *Candida* colonization index and the *Candida* score are few, but the *Candida* score may perform better.[190,191] The other scoring systems are less well validated.

The use of broad-spectrum antibiotics is a well-documented risk factor for fungal colonization and subsequent infection. Interrelations between bacteria and fungi in human disease are complex. *Candida* may enhance the pathogenicity of certain bacteria, but not others, and this interaction remains to be elucidated.[192] Antibiotics that have some antianaerobic therapy are associated with substantial increases in colony counts of yeast flora of the gut, whereas antibiotics with poor anaerobic activity are less likely to produce this effect.

PROPHYLAXIS OF FUNGAL INFECTION

The substantial morbidity and mortality of invasive fungal infections has led to the practice of administering prophylactic antifungal agents (usually fluconazole) to critically ill patients. Early on, concern was raised that increasing use of azole antifungals would lead to increased resistance to the agents.[193,194] A randomized, placebo-controlled trial of enteral fluconazole 400 mg/d was conducted among 260 critically ill surgical patients with an ICU length of stay of ≥3 days in a tertiary-care surgical ICU.[195] After adjusting for potentially confounding effects of the Acute Physiology and Chronic Health Evaluation (APACHE) III score, days to first dose, and fungal colonization at enrollment, the risk of fungal infection was reduced by 55% in the fluconazole group, but no difference in mortality was observed.

Four randomized studies comparing fluconazole to placebo for prevention of fungal infections in the surgical ICU were subjected to meta-analysis.[196] The studies enrolled 626 patients but used differing dosing regimens of fluconazole. All trials were double-blind; two were multicenter studies. Fluconazole prophylaxis reduced the incidence of fungal infections considerably (pooled OR 0.44; 95% CI 0.27-0.72; $p < 0.001$) but was not associated with a survival advantage (pooled OR for mortality 0.87; 95% CI 0.59–1.28). The absence of a survival advantage may reflect the paucity of data and a need for further study. Current guidelines recommend fluconazole prophylaxis for "high-risk" patients[197] (Table 13.17).

Antifungal Prophylaxis of Solid Organ Transplant Recipients

Solid organ transplantation is life-saving for end-stage organ failure, but invasive fungal infections remain a major cause of morbidity and mortality. Various tactics of prevention have been tested, including both systemic and topical antifungal prophylaxis. Currently, data support the use of antifungal prophylaxis with fluconazole in liver, lung, small bowel, and pancreas transplant recipients[197] (Table 13.17).

In a meta-analysis of randomized, placebo-controlled trials with fluconazole prophylaxis, the incidence of fungal infections was appreciably reduced; however, there was no survival advantage, similar to antifungal prophylaxis of critically ill general surgical patients.[198] A systematic review and meta-analysis of antifungal prophylaxis in liver transplant recipients evaluated ten randomized trials (1,106 patients) of any prophylactic antifungal regimen versus either no antifungal agent or another antifungal regimen.[199] Fluconazole prophylaxis did not reduce mortality (RR 0.84, 95% CI 0.54–1.30) but did reduce invasive fungal infections (RR 0.28, 95% CI: 0.13-0.57), while not increasing colonization or infection with azole-resistant fungi.

PRINCIPLES OF ANTIFUNGAL THERAPY

Candidemia is defined as (1) one blood culture that grows *Candida* spp. and either histologically documented invasive candidiasis, or ophthalmic examination consistent with candidal endophthalmitis; (2) at least two blood cultures obtained at different times from a peripheral vein that grow the same *Candida* spp.; or (3) one blood culture obtained peripherally and one blood culture obtained through an indwelling central

TABLE 13.16

SCORING SYSTEMS FOR RISK STRATIFICATION FOR INVASIVE CANDIDIASIS

Candida Colonization Index[185]

Number of cultures sites positive for the identical yeast isolate, divided by the number of sites cultured. At least three sites should be cultured (oral mucosa, axillae, rectum, gastric contents, and urine). A score ≥0.5 points is considered high risk for subsequent infection. Discrimination statistics were not reported

Candida Score[186]

Five dichotomous variables are awarded points. A summed total score of ≥2.5 points is strongly predictive of invasive fungal infection (sensitivity 81%, specificity 75%, c statistic = 0.847)

Total parenteral nutrition	1 point
Surgery on ICU admission	1 point
Multifocal *Candida* species colonization	1 point
Severe sepsis	2 points

Ostrosky-Zeichner Score (2007)[187]

Prediction rule that provides a dichotomous risk assessment based on the presence of at least three risk factors. Relative risk 5, sensitivity 0.27, specificity 0.93, positive predictive value 0.13, negative predictive value 0.97, accuracy 0.90
Any systemic antibiotic (days 1–3 of the ICU stay) *or*
Central venous catheter (days 1–3) *and*
At least two of the following:

- Total parenteral nutrition (days 1–3)
- Any renal replacement therapy (days 1–3)
- Any major surgery (days 7 to 0)
- Pancreatitis (days 7 to 0)
- Any steroid use (days 7 to 3)
- Any other immunosuppression (days –7 to 0)

Ostrosky-Zeichner Modified Score (2011)[188]

Prediction rule that provides a dichotomous risk assessment based on the presence of at least three risk factors. Relative risk 4, sensitivity 0.50, specificity 0.83, positive predictive value 0.10, negative predictive value 0.97, accuracy 0.81
Mechanical ventilation > 48 h (days 1–4) *and*
Any systemic antibiotic (days 1–3 of the ICU stay) *and*
Central venous catheter (days 1–3) *and*
At least one of the following:

- Total parenteral nutrition (days 1–3)
- Any renal replacement therapy (days 1–3)
- Any major surgery (days –7 to 0)
- Pancreatitis (days –7 to 0)
- Any steroid or other immunosuppression (days –7 to 0)

Shorr Candidemia Score[189]

A simple, equal-weight score (one point each) differentiated reasonably well among patients admitted with a blood stream infection, with a c statistic of 0.70
Age < 65 y
Temperature ≤ 98°F or severe altered mental status
Cachexia
Hospitalization within the previous 30 d
Admission from another health care facility
Need for mechanical ventilation

venous catheter, both of which grow identical *Candida* spp.. Patients with one positive blood culture drawn through an intravenous line and a positive semiquantitative catheter tip culture (>15 colony-forming units [cfu]) are not considered infected unless they satisfy one of the above criteria.

Severe nonbloodstream candidal infections are defined as *Candida* spp. isolated from a normally sterile body site, and the presence of at least one of the following: fever (>38.5°C) or hypothermia (<36°C), unexplained prolonged hypotension (systolic blood pressure <80 mm Hg > 2 hours, unresponsive to volume challenge), or absence of response to adequate antibiotic treatment for a suspected bacterial infection. *Candida* spp. pneumonia (which some authorities believe does not exist in immunocompetent hosts) requires the recovery of >10⁵ cfu/ mL of *Candida* spp, in bronchoalveolar lavage fluid, in addition to the appearance of a new infiltrate on CXR. Invasive

TABLE 13.17

SYNOPSIS OF CLINICAL PRACTICE GUIDELINES FOR THE MANAGEMENT OF CANDIDIASIS: INFECTIOUS DISEASES SOCIETY OF AMERICA-2009

Antifungal Prophylaxis for Solid-Organ Transplant Recipients, and Patients Hospitalized in Intensive Care Units

- Solid-organ transplant recipients:

Postoperative antifungal prophylaxis for liver (A-I), pancreas (B-II), and small bowel (B-III) transplant recipients at high risk of candidiasis, daily for 7–14 d

    Fluconazole (200–400 mg [3–6 mg/kg]

    Liposomal amphotericin B (L-AmB) (1–2 mg/kg)

- Patients hospitalized in the ICU:

Fluconazole (400 mg [6 mg/kg] daily) is recommended for high-risk patients in adult units that have a high incidence of invasive candidiasis (B-I)

Treatment of Identified Candidemia in Non-neutropenic Patients

- Initial therapy for most adult patients (A-I):

    Fluconazole (loading dose of 800 mg [12 mg/kg] and then 400 mg [6 mg/kg] daily) or echinocandin

    Caspofungin: loading dose of 70 mg and then 50 mg daily, or

    Micafungin: 100 mg daily, or

    Anidulafungin: loading dose of 200 mg and then 100 mg daily is recommended

- An echinocandin for is favored for patients with moderate-to-severe illness or for patients who have had recent azole exposure (A-III). Fluconazole is recommended for patients who are less critically ill and who have had no recent azole exposure (A-III). The same therapeutic approach is advised for children, with attention to differences in dosing
- Transition from an echinocandin to fluconazole is recommended for patients who have isolates that are likely to be susceptible to fluconazole (e.g., *Candida albicans*) and who are clinically stable (A-II)
- For infection due to *C. glabrata*, an echinocandin is preferred (B-III). Transition to fluconazole or voriconazole therapy is not recommended without confirmation of isolate susceptibility (B-III). For patients who received fluconazole or voriconazole initially, who have improved clinically, and who have negative follow-up cultures, continuation of the azole to completion of therapy is reasonable (B-III)
- For infection due to *C. parapsilosis*, treatment with fluconazole is recommended (B-III). Patients who have received an echinocandin initially, who have improved clinically, and who have negative follow-up cultures, continuation of the echinocandin to completion of therapy is reasonable (B-III)
- Amphotericin B deoxycholate (AmB-d) 0.5–1.0 mg/kg daily, or a lipid formulation of AmB (LFAmB) 3–5 mg/kg daily, are alternatives if there is intolerance to or limited availability of other antifungal agents (A-I). Transition from AmB-d or LFAmB to fluconazole is recommended if isolates are likely to be susceptible to fluconazole (e.g., *C. albicans*) and the patient is stable clinically (A-I)
- Voriconazole 400 mg (6 mg/kg) twice daily for two doses and then 200 mg (3 mg/kg) twice daily thereafter is effective for candidemia (A-I), but there is little advantage over fluconazole, and is recommended as step-down oral therapy for selected cases of candidiasis due to *C. krusei* or voriconazole-susceptible *C. glabrata* (B-III)
- The recommended duration of therapy for candidemia without obvious metastatic complications is for 2 weeks after documented clearance of *Candida* from the bloodstream and resolution of symptoms attributable to candidemia (A-III)
- Intravenous catheter removal is strongly recommended (A-II)

Empirical Treatment for Suspected Invasive Candidiasis in Non-neutropenic Patients

- Empirical therapy for suspected candidiasis in nonneutropenic patients is similar to that for proven candidiasis (B-III)

    Fluconazole (loading dose of 800 mg [12 mg/kg] and then 400 mg [6 mg/kg] daily)

    Caspofungin (loading dose of 70 mg and then 50 mg daily)

    Anidulafungin (loading dose of 200 mg and then 100 mg daily)

    Micafungin (100 mg daily)

- AmB-d (0.5–1.0 mg/kg daily) or LFAmB (3–5 mg/kg daily) are alternatives if there is intolerance to or limited availability of other antifungals (B-III)
- Empirical antifungal therapy should be considered for critically ill patients with risk factors for invasive candidiasis and no other known cause of fever, based on clinical assessment of risk, serologic markers for invasive candidiasis, or culture data from non-sterile sites (B-III)

NOTE: Strength of evidence-based recommendations is shown in parentheses.
Adapted from 197.

TABLE 13.17

ANTIFUNGAL AGENTS

ANTIFUNGAL AGENT	INDICATIONS	ROUTES/DOSAGE
Amphotericin B	*Candida albicans* (>95%) *C. glabrata* (95%), *C. parapsilosis* (>95%) *C. krusei* (>95%), *C. tropicalis* (99%) *C. guilliermondii*; *C. lusitaniae* Variable activity: *Aspergillus* spp., ferrous *Trichosporon beigelii* *Fusarium* spp., *Blastomyces dermatitidis*	IV: 0.5–1.0 mg/kg/d over 2–4 h Oral: 1 mL oral suspension, swish and swallow 4× daily, times 2 weeks
Amphotericin B liposomal (less nephrotoxicity)	*C. albicans* (>95%), *C. glabrata* (>95%) *C. parapsilosis* (>95%), *C. krusei* (>95%) *C. tropicalis* (99%), *C. guilliermondii*, *C. lusitaniae* Variable activity: *Aspergillus* spp.	IV: 3–5 mg/kg/d
Amphotericin B colloidal dispersion (less nephrotoxicity)	*C. albicans* (>95%), *C. glabrata* (>95%) *C. parapsilosis* (>95%), *C. krusei* (>95%) *C. tropicalis* (99%), *C. guilliermondii*; *C. lusitaniae* Variable activity: *Aspergillus* spp.	IV: 3–5 mg/kg/d
Amphotericin B lipid complex (less nephrotoxicity)	*C. albicans* (>95%), *C. glabrata* (>95%) *C. parapsilosis* (>95%), *C. krusei* (>95%) *C. tropicalis* (99%), *C. guilliermondii*, *C. lusitaniae* Variable activity: *Aspergillus* spp.	IV: 5 mg/kg/d
Ketoconazole	*C. albicans*	
Voriconazole	*Aspergillus* spp., *Fusarium* spp., *C. albicans* (99%) *C. glabrata* (99%), *C. parapsilosis* (99%) *C. tropicalis* (99%), *C. krusei* (99%), *C. guilliermondii* (>95%) *C. lusitaniae* (95%)	PO: 200–400 mg/daily IV: 6 mg/kg Q12 ×2 and then 4 mg/kg IV every 12 h PO: >40 kg, 200 mg every 12 h; <40 kg, 100 mg every 12 h
Fluconazole	*C. albicans* (97%) *C. glabrata* (85–90% resistant/intermediate) *C. parapsilosis* (99%) *C. tropicalis* (98%) *C. krusei* (5%) Fungistatic against *Aspergillus* spp.	Candidiasis: Prophylaxis (IV or oral): 100–400 mg/d Invasive: 400–800 mg/d Oropharyngeal: 200 mg day 1 and then 100 daily for 2 weeks
Itraconazole	Fungicidal to *Aspergillus* spp., *C. albicans* (93%) *C. glabrata* (50%), *C. parapsilosis* (45%) *C. tropicalis* (58%), *C. krusei* (69%) *C. guilliermondii*, *C. lusitaniae* Blastomycosis, histoplasmosis, chromomycosis	IV: Load 200 mg IV 2× daily × 4 doses and then 200 mg 4× daily maximum 14 d Oral: 200 mg every daily or 2× daily Life-threatening: load 600–800/d × 3–5/d and then 400–600 mg/d
Caspofungin	*C. albicans, C. glabrata, C. parapsilosis, C. tropicalis, C. krusei, C. guilliermondi, C. lusitaniae*	IV: 70 mg IV and then 50 mg IV every day
Micafungin	*C. albicans, C. glabrata, C. parapsilosis, C. tropicalis, C. krusei, C. guilliermondii, C. lusitaniae*	IV: 100–200 mg IV daily
Anidulafungin	*C. albicans, C. glabrata, C. parapsilosis, C. tropicalis, C. krusei, C. guilliermondii, C. lusitaniae*	Esophageal candidiasis: IV: 100 mg IV day 1, 50 mg/d thereafter Candidemia: IV: 200 mg IV day 1, 100 mg/d thereafter
Flucytosine	Not effective for *C. krusei* Effective for *C. albicans, C. tropicalis, C. parapsilosis, C. lusitaniae*	PO: 50–150 mg/kg/d divided QID
Nystatin	*C. albicans*	100,000 U swish and swallow QID
Clotrimazole	"Thrush" (usually not cultured)	Oral troches daily for 14 d

fungal infections in non-neutropenic ICU patients are treated if histology or cytopathology shows yeast cells or pseudohyphae from a needle aspiration or biopsy (excluding mucous membranes), a positive culture obtained aseptically from a normally sterile and clinically or radiologically abnormal site consistent with infection (excluding urine, sinuses, and mucous membranes), or positive percutaneous blood culture in patients with temporally related clinical signs and symptoms compatible with the relevant organism. Survival is more likely from candidemia than other forms of invasive candidiasis, and is strongly influenced negatively by critical illness.[200]

Antifungal Agents in the Practice of Acute Care Surgery

The repertoire of antifungal agents has expanded with the introduction of less-toxic formulations of amphotericin B, improved triazoles, echinocandins, and other agents that target the fungal cell wall.[201] Table 13.18 presents a list of available antifungal agents. Amphotericin B is a natural polyene macrolide that binds primarily to ergosterol, the principal sterol in the fungal cell membrane, leading to disruption of ion channels, production of oxygen free radicals, and apoptosis. It is active against most fungi and penetrates into cerebrospinal fluid. Tissue concentrations are not usually affected by hemodialysis. Infusion-related reactions can occur in up to 73% of patients with the first dose and often diminish during continued therapy. Amphotericin B–associated nephrotoxicity can lead to azotemia and hypokalemia, although acute potassium release with rapid infusion can occur and lead to cardiac arrest. Amphotericin B lipid formulations allow for higher dose administration with lessened nephrotoxicity, but whether outcomes are enhanced is unproved.

Nystatin is a polyene similar in structure to amphotericin B, and is currently used topically for *C. albicans*. Flucytosine, a fluorinated pyrimidine analog that is converted to 5-fluorouracil, causes RNA miscoding and inhibits DNA synthesis. It is available in the United States in oral form only, and has been used with amphotericin B for synergism against *Candida* spp., but in general there is scant evidence that any dual-agent therapy regimen for fungal infections is beneficial.[202]

The azoles inhibit the cytochrome P_{450}–dependent enzyme, 14-alpha reductase, altering fungal cell membranes through accumulation of abnormal 14-alphamethyl sterols. Fluconazole and itraconazole are available in oral and parenteral formulations and are active against *Candida* spp. except *C. krusei*, and *Fusarium* spp. Itraconazole is active against *Aspergillus* spp. As mentioned previously, *C. glabrata* and *C. krusei* resistance has been observed with fluconazole. The tissue concentrations of both fluconazole and itraconazole are influenced by many agents, such as antacids, H_2-antagonists, isoniazid, phenytoin, and phenobarbital. Biofilms produced by *Candida* spp. are penetrated by fluconazole and most other antifungal agents.[203,204]

Second-generation anti-fungal triazoles include posaconazole, ravuconazole, and voriconazole. They are active against *Candida* spp., including fluconazole-resistant strains, and *Aspergillus* spp. For the latter, voriconazole is emerging as the TOC.[205,206]

The echinocandins include caspofungin, micafungin, and anidulafungin, each of which is approved therapy for candidiasis and candidemia, but third-line treatment for invasive aspergillosis.[207] Due to their distinct mechanism of action, disrupting the fungal cell wall by inhibiting (1->3)-β-D-glucan synthesis, the echinocandins can theoretically be used in combination with other standard antifungal agents.[202] The echinocandins have activity against *Candida* spp. and *Aspergillus* spp. but are not reliably active against other fungi. Echinocandin activity is excellent against most *Candida* spp. but moderate against *C. parapsilosis*, *C. guilliermondii*, and *C. lusitaniae*. Echinocandins exhibit no cross-resistance with azoles or polyenes.[208] Prospective randomized trials have demonstrated that micafungin is non-inferior to caspofungin for therapy of invasive candidiasis,[209] and as effective as liposomal amphotericin B.[210]

With the proliferation of non-*albicans Candida* infections owing to widespread use of fluconazole, empiric therapy regimens recommend either an echinocandin or a lipid formulation of amphotericin B as the first-line agent for therapy of seriously or critically ill patients[199,211] (Tables 13.16 and 13.17). Once the pathogen has been identified as *Candida*, therapy may be de-escalated to fluconazole except for *C. glabrata* and *C. krusei*, for which continuation therapy with an echinocandin may be indicated (Table 13.18).

TABLE 13.18

USUAL SUSCEPTIBILITIES OF *CANDIDA* SPECIES TO SELECTED ANTIFUNGAL AGENTS

■ *CANDIDA* SPP.	■ FLUCON-AZOLE	■ ITRACON-AZOLE	■ VORICONAZOLE (NOT STANDARDIZED)	■ AMPHOTERICIN B	■ CASPOFUNGIN (NOT STANDARDIZED)
C. albicans	S	S	S	S	S
C. tropicalis	S	S	S	S	S
C. parapsilosis	S	S	S	S	S to I (?R)
C. glabrata	S-DD to R	S-DD to R	S to I	S to I	S
C. krusei	R	S-DD to R	S to I	S to I	S
C. lusitaniae	S	S	S	S to R	S

I, Intermediate; R, resistant; S, susceptible; S-DD, susceptible-dose dependent (increased MIC may be overcome by higher dosing, such as 12 mg/kg/d fluconazole).

CHAPTER 14 ■ PAIN MANAGEMENT

SHARON HENRY

Pain is a normal response to tissue injury or stimuli that can result in injury if sustained. This response results in neurochemical reactions that produce the perception of pain. In addition, there are humoral, sympathetic, and metabolic sequelae to pain. When pain is not controlled or poorly controlled, these humoral, sympathetic, and metabolic sequelae may be pathologic and produce serious side effects. In addition, without the development of adequate and powerful pain relievers, performing any major surgical procedure would be impossible, as successful surgical treatment requires that the pain produced by the procedure be adequately controlled.

Fredrich Wilhein Adam Sertürner isolated the active component of opium in 1806. He named this new constituent morphine after Morpheus, the Greek god of dreams. This discovery, among others, has allowed complex surgery to be developed. In 1884, cocaine was recognized as an effective local anesthetic. This allowed surgeons to perform surgery without producing substantial pain and obviated the need for systematic analgesics. As surgical complexity increased, the management of the resultant pain has continued to be a difficult problem to adequately resolve. In addition, postoperative pain is not the only form of acute pain that needs to be relieved. Pain from trauma, burns, and medical conditions like pancreatitis must also be managed.

From the 1950s until the late 1980s, pain management consisted of intramuscularly administered opioids on a fixed or *pro re nata* (prn) schedule.[1] This approach was used for its familiarity and safety and did not require specialized training or personnel. Additionally, the gradual onset of action of intramuscularly administered medication allowed time to monitor for side effects. Although arguably fairly safe, we now recognize that this approach is not efficacious. Intramuscular analgesia results in wide variability in medication levels and therefore fluctuations in pain levels (Fig. 14.1). Advances in perioperative care have transformed many procedures from mandating prolonged hospital care to requiring only abbreviated hospitalization or allowing for discharge on the day of the procedure. The management of postoperative pain under these circumstances can be even more challenging. Thus, it is important that the acute care surgeon is knowledgeable about the modalities and medications available to help control acute pain.

EPIDEMIOLOGY AND SCOPE

More than 73 million operative procedures are performed annually in the United States. Perhaps not surprisingly, 75% of patients report experiencing pain postoperatively, with 80% of those rating it as moderate or severe.[2] Pain management has become the rallying cry of insurers and governmental regulatory organizations. The American Pain Society urges health professionals to consider pain the fifth vital sign. The Joint Commission on Accreditation of Healthcare Organizations in 2000 declared pain management a patient right, as well as an education and training issue. They emphasized quantitative aspects of pain and encouraged systematic assessment and safe management[3] (Table 14.1). The United States Congress even declared 2001–2010 the "Decade of Pain Control and Research." Despite this, a 2003 survey of

postoperative patients found that 70% of patients reported having experienced moderate or severe to extreme pain at some time during their postoperative period.[4]

Increased attention is now being focused on assessing and controlling perioperative pain. An analysis of reasons for readmission from same day surgery demonstrated that pain was the most frequent cause (36%).[5] There are a myriad of factors that lead to inadequate pain control[6] (Table 14.2). One of the most important factors in the difficulty of managing pain is related to our ability to quantify it. Pain is highly subjective. Individual variation regarding tolerance to noxious stimuli is substantial. At the same time, if we are to be successful in managing pain, it is important to have a mechanism to quantify pain and to assess the efficacy of treatment of pain.

Many physicians and nurses who care for patients in pain on a daily basis misjudge the intensity of their patients' pain and the efficacy of medications given for treatment of that pain. Use of autonomic and behavioral responses by the clinician to determine pain intensity and to judge response to medication is error prone.[7] For instance, tachycardia and hyperventilation may reflect anxiety or even the anticipation of pain. There are cultural and individual differences in the expression of pain. Some people remain impassive during even the most excruciatingly painful experiences, while others are loudly vocal and demonstrative of relatively minor pain. A nonrandomized study of patients in the emergency department of a tertiary care teaching hospital demonstrated the inconsistency between patient and caregiver perception of acute pain. In this study, caregivers consistently rated patients' pain lower than the patients' own rating.[8]

For this reason, the best estimation of a patient's pain and its response to treatment is the patient's perception. Several pain scales have been developed to standardize pain measurement. Visual analog scales are useful assessment tools.[9] They are simple, sensitive, and reproducible instruments that allow the patient to give a numerical score to the severity of the pain they are experiencing (Fig. 14.2A). Use of such scales allows the nurse and/or physician to assess the efficacy of intervention by comparison of scores before and after intervention. If such scales are to be used, it is imperative that the patient be conscious and have the cognitive ability to express themselves. Behavioral scales are appropriately used when patients are unable to communicate verbally (Fig. 14.2D). Many factors affect the perceived intensity of postoperative pain and these include the following:

1. Preexisting pain
2. Anxiety
3. Age
4. Type of operative procedure performed

Anxiety is often an emotional reaction in anticipation of pain. Anxiety can produce autonomic stimulation such as an increased heart rate. It can also cause any stimulation to be perceived as painful.[10] Although the mechanism is not fully elucidated, there is support for the notion that there is age-related decrease in pain perception and report.[11]

The site of surgery may also be the most important determinant of postoperative pain.[12] Operative procedures associated with the highest analgesic consumption are emergency, major,
FIGURE 14.1. PCA paradigm. The relationship between plasma opioid concentration (ordinate), dosing interval (abscissa), and analgesic effect (Z axis), defining therapeutic effectiveness.

and abdominal surgeries. The most painful operative procedures are as follows:

1. Orthopedic procedures with major joints surgery
2. Thoracic procedures
3. Open abdominal procedures

TABLE 14.1

JCAHO PAIN MANAGEMENT STANDARDS

- *Rights and Ethics.* Recognize the right of individuals to appropriate assessment and management of pain

- *Assessment of Persons with Pain.* Assess the existence and, if so, the nature and intensity of pain in all patients, residents, or client

- As part of this standard, the organization also determines and ensures staff competency in pain assessment and management, and incorporates training on pain assessment and management in the orientation of new clinical staff

- *Care of Persons with Pain.* Establish policies and procedures that support the appropriate prescribing or ordering of effective pain medications

- *Education of Persons with Pain.* Educate patients, residents, and clients and families about effective pain management

- *Continuum of Care.* Address the individual's needs for symptom management in the discharge planning process

- *Improvement of Organization Performance.* Incorporate pain management into the organization's performance measurement and improvement program

---

Analgesic requirements can be estimated based on an assessment of the likely intensity of postoperative pain.[13]

Sequelae of uncontrolled or poorly controlled pain following surgery are well documented. Many of these are listed in Table 14.3.

PHYSIOLOGY OF PAIN

Pain can be defined as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[14] Pain is an individual and subjective experience. It is influenced by a multitude of factors that include culture, previous pain events, mood, beliefs, and an ability to cope. Pain that is of recent onset with

SEQUELAE OF UNCONTROLLED OR POORLY
CONTROLLED PAIN FOLLOWING SURGERY

- Slow recovery
- Increased postoperative morbidity
- Decreased mobility leading to thromboembolic complications
- Prolonged abnormal pulmonary function
- Nausea and vomiting
- Renin–angiotensin aldosterone activation
- Increased catecholamines
- Increased systemic vascular resistance, cardiac work, myocardial oxygen consumption
- Increased secretion of catabolic hormones (cortisol, glucagon, growth hormone)
- Inhibition of anabolic hormones (insulin and growth hormone)
- Muscle wasting
- Fatigue
- Immunoincompetence
- Impaired phagocytosis
- Impaired wound healing
- Enhanced sensitization of nociceptors
- Increased muscle spasm
- Visceral somatic ischemia and acidosis
- Renal hypoperfusion

a presumed short duration and can be related to a distinct process is termed acute pain. In general, the injured site and its periphery are the sites of ongoing pain, and as healing progresses, pain is diminished and finally disappears. Pain that persists for more than 3–6 months beyond the time required for healing or has no identifiable cause is termed chronic pain.

Pain perception requires the integration of peripheral and central processes. Nociception links the site of tissue damage and the electrochemical events that lead to the perception of pain. At the site of injury, peripheral sensory fibers that are widely distributed throughout the body in the skin, muscle, joints, viscera, and meninges are activated by mechanical, thermal, and chemical stimulus. This stimulus is transduced into an electrical signal.

Pain is perceived when there is nociceptive afferent transmission to the spinal cord and through the dorsal horn to higher centers. The A-δ myelinated fibers transmit the location and quality of the stimulus to the neothalamus and the higher cortex.[15] This prompts rapid withdrawal from the stimulus. Peripheral unmyelinated C fibers establish multiple synaptic connections within the brainstem, the midbrain nuclei, and the limbic system. When peripheral nerve injury occurs, several endogenous chemicals are released. These include bradykinin, histamine, serotonin, eicosanoids, and substance P. These substances, which are also involved in inflammation, activate receptors on sensory afferents beginning nociceptive transmission. This electrical stimulus is then transmitted to the spinal cord.

Prostaglandins, leukotrienes, and bradykinin act together to enhance the activation of the primary afferent terminal. Neurotransmitters including substance P, neurokinin A, and calcitonin gene-related peptide are released and cause increased permeability of blood vessels. Edema is produced and more

vasoactive substances are released amplifying the response and spreading the pain outward from the initial locus. Thus infection, inflammation, and ischemia can lead to stimulation of an array of chemical mediators such as prostaglandins and histamines that can sensitize receptors to increase the perception of pain (peripheral sensitization).[16]

Peripheral sensitization can lead to central sensitization. Inhibitory modulation is also possible. The dorsal horn of the spinal cord contains μ, δ, and κ opioid receptors both pre- and postsynaptically. Inhibitory neuropeptides are also released after nociceptive stimulation. Alpha-adrenergic receptors also modulate nociceptive information. These receptors are found in high concentration in the substantia gelatinosa, and α_2 adrenergic receptors are found in the dorsal horn. Centrally, multiple areas of the brain are involved in pain perception. These areas (limbic system, areas in the cortex and the thalamus) interact with the psychological and environmental factors to produce the pain experience[17].

Classification

Pain is classified as nociceptive, neuropathic, or psychogenic. Nociceptive pain can be further characterized as somatic or visceral. Somatic pain results from activation of receptors in the cutaneous and deep tissues. It is usually well localized and described as throbbing, aching, or gnawing. Visceral pain occurs when organs that are innervated by the sympathetic nervous system are injured. It is often difficult to localize and described as aching, squeezing, dragging, or pressure like. It is produced by distension, mucosal irritation, traction, or torsion on mesenteric attachments or ischemia and necrosis. Pain in tissues distant from the pathologic condition (referred pain) is sometimes produced. This is thought to occur as a result of dual innervation of multiple structures or central convergence of impulses.

Neuropathic pain results from aberrant somatosensory pathways. This includes phantom limb pain associated with amputation as well as reflex sympathetic dystrophy, which is typically accompanied by vasomotor changes. Neuropathic pain is often described as dysesthetic. The pain is often a sensation that is not the usual recognizable discomfort. It may be itching, stinging, burning, squeezing, or numbness. It is decidedly uncomfortable, even intolerable. There is often a continuous component onto which is added an intermittent element. This is often described as an electric shock or jolt or lancing pain. Many patients have an abnormal sensory threshold and may have dysesthesia, hyperalgesia, allodynia, hyperesthesia, or hyperpathia.[18] Psychological stress, anxiety, and depression can influence the perception of pain in ways that make it difficult to determine if they are the cause or the effect. Anxious patients have increased perceived pain and may even have more complications from surgery.[19,20]

Assessment

Pain can be classified in a variety of ways. It can be described by the mechanism such as nociceptive versus neuropathic. The time relative to injury as in acute or chronic may also be used to describe pain. The etiology of the pain, such as cancer or postoperative pain, may be used to classify pain. Pain reactions are individual. Strong emotions are often associated with pain. Depression, anxiety and fear may alter pain perception. Objective physiologic responses to pain do occur. These include hypertension, tachycardia, sweating, and tachypnea. Grimacing, restlessness, and immobility are other typical physical signs of pain.

The use of behavioral cues or physiologic responses, though seemly objective, is inaccurate and suffused with the biases of the observer. This method is best reserved for those who

are cognitively limited or nonverbal. Observer pain scores are notoriously unreliable.

Patient self-reporting is the best tool available for assessing pain. Several tools have been developed for use in clinical practice and are valid and reliable measures of pain intensity. They are the Numeric Rating scale, the Verbal Descriptor scale, the Visual analog scale, and the Faces Pain scale (Fig. 14.2A-D). These are one-dimensional scales and are most appropriate for assessing acute pain following trauma or operation. Multidimensional tools abstract information regarding the characteristics of the pain and its effect on the patient's life. These tools allow the emotional and physiological responses of patients to be accounted for and are more appropriate for accessing chronic pain. The McGill pain questionnaire is an example. It is a lengthy tool that incorporates categories encompassing the three major dimensions of pain: sensory, affective, and evaluative. This makes it an excellent tool to evaluate different modes of therapies and different analgesics. Its length and complexity make it a less useful clinical tool.[21]

Pathophysiology

Poorly controlled acute pain has the potential to produce deleterious effects that can lead to a host of complications, increased length of hospitalization, and even death. Several alterations in physiology are known to occur. Peripheral sensitization occurs at the site of injury and areas adjacent to it. This response is produced by the release of a combination of local mediators like bradykinin, serotonin and histamine, and cytokines like interleukin-1 beta (IL-1β) and IL-6. Additionally, sympathetic and sensory nerve endings release substance P and norepinephrine that further enhance pain sensitivity. Secondary hyperalgesia is the delayed alteration in noxious sensitivity seen in nontraumatized areas around the site of injury. Changes in spinal cord, brainstem, and limbic cortex pathways result in altered pain perception. Excitatory amino acids, aspartate, and glutamate act on N-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptors. Activation of these receptors increases the responsiveness of dorsal horn neurons to noxious input. Initially there is increased firing which is short lived followed by second longer lived period of enhanced sensitivity that does not require further noxious stimulation. This second phase of pain is much more difficult to control. This is the neurochemical basis for splinting. Pain is perceived at dermatomes above and below the site of injury and exacerbated by movement.[22]

Increased secretion of catabolic hormones occurs after extensive tissue injury. Cortisol, glucagon, growth hormone, and catecholamines are increasingly secreted, while insulin and testosterone are diminished. These hormones have the ability to negatively impact recovery through increased glucose, protein, and fat turnover producing hyperglycemia and negative nitrogen balance. Muscle wasting and fatigue can lead to prolonged convalescence. Immunoglobulin synthesis may be diminished leading to increase infection risk (Fig. 14.3).

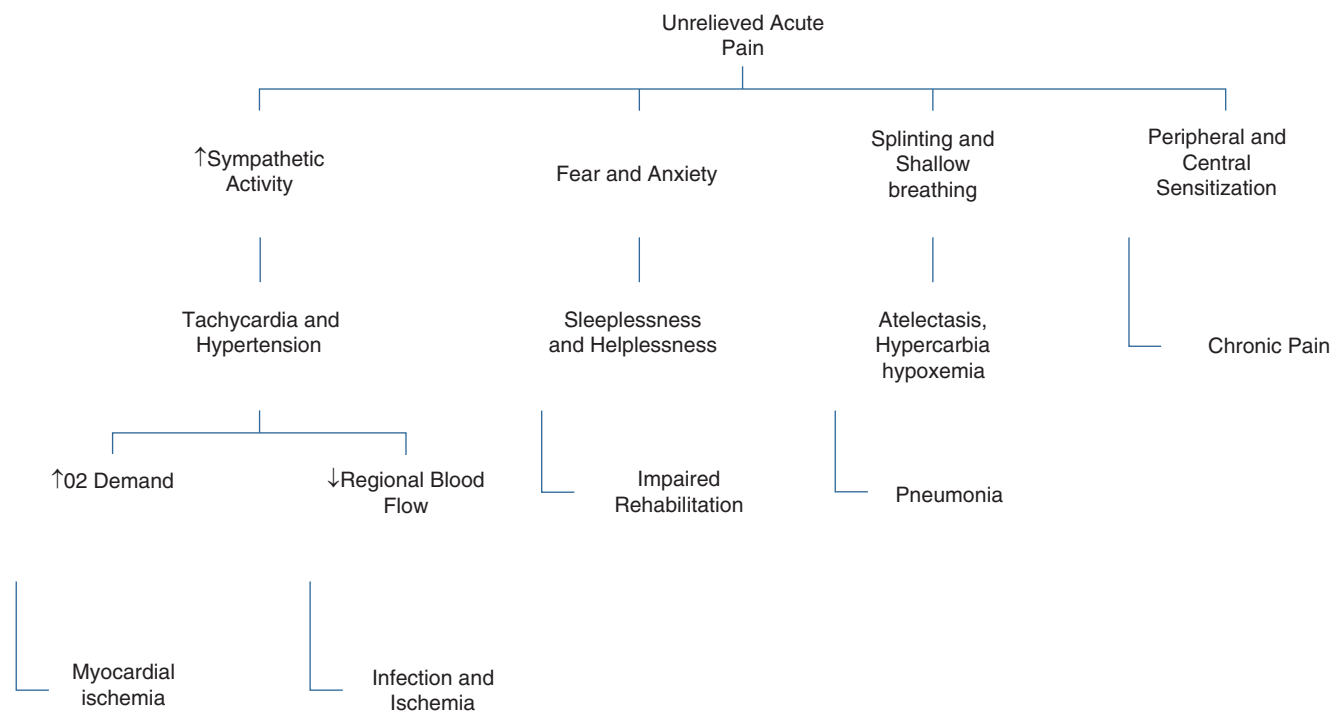
Nociceptive transmissions stimulate preganglionic sympathetic neurons on the lateral horns. This produces adaptive responses designed to maintain blood pressure and cardiac output. Prolonged pathologic alterations in blood flow may occur and produce regional hypoperfusion and end organ dysfunction. The Renin–angiotensin system is activated and there is increased platelet activation. A variety of negative sequela results from uncontrolled pain. Tachycardia and increased afterload are a consequence of adrenergic stimulation. Renin–angiotensin stimulation produces hypervolemia that can be compounded with hypoventilation from splinting and congestive heart failure, and hypoxia can follow. Increased platelet aggregation produced by the activation of arachidonic acid cascade can lead to coronary artery occlusion and myocardial infarction. Appreciable pulmonary changes can accompany poorly managed pain in the abdomen and chest. Splinting leads to hypoventilation with loss of functional residual capacity and inability to clear secretions. This predisposes to the development of pneumonia. Preexisting pulmonary disease magnifies this effect. Platelet aggregation in combination with immobility leads to an increased risk of thromboembolic phenomenon[23] (Table 14.3).


FIGURE 14.3. Sequela of uncontrolled pain.

THERAPY

Education

Before discussing potential medications for the management of pain, it is appropriate to remember the multidimensionality of pain perception. Pain is influenced by a variety of factors that include anxiety and psychosocial issues; the pain response can be affected by appropriate preparation of the patient. In the case of planned elective surgery, anxiety related to the unknown has the potential to create a circumstance where pain is magnified. Therefore, one of the most important aspects of preoperative preparation is providing information with regard to postoperative expectations.

The cognitive and emotional response to pain should not be minimized. Attempts at addressing these can lead to improved success in pain management. Psychoeducational care or information provided in preparation for surgery is beneficial at alleviating stress associated with surgery, recovery, and postoperative pain. Such measures as providing information on timing of procedures, functions of healthcare providers, pain and discomfort information skills teaching, like coughing and deep breathing, relaxation techniques, alleviating concerns, encouraging question, and problem solving are beneficial and without adverse effect though frequently omitted.[24] This approach is most applicable to patients undergoing elective procedures. Patients being treated for injury and illness can benefit from a similar philosophy of disclosure and teaching.

Medication

The World Health Organization recognized that millions of people worldwide suffer from acute and chronic pain because of a lack of standardized approach to pain management. In an effort to facilitate the adequate treatment of pain, the analgesic ladder was devised. This ladder provides for a stepwise increase in strength of the medication provided for pain relief. It was devised 20 years ago for the treatment of pain related to cancer, but the principles apply to the treatment of acute pain as well[25] (Fig. 14.4).

The first rung begins with nonopioids such as nonsteroidal anti-inflammatory drugs (NSAID), aspirin, and acetaminophen. These medications are appropriate for control of mild to moderate pain like headaches and musculoskeletal pain. Table 14.4 lists the commonly used drugs and their half-life and dosage. Aspirin was isolated from the bark of the willow tree in the 18th Century and found to have analgesic properties. Salicylic acid was subsequently synthesized in 1860 and used for its analgesic, antipyretic, and anti-inflammatory effects. Its gastrointestinal side effects were quickly recognized.[26]

Acetaminophen is equal to aspirin in its analgesic effects but has no anti-inflammatory properties. The mechanism and exact site of action are not fully known. It seems to work by increasing the pain threshold. The pathway may involve inhibition of the nitric oxide pathway mediated by a variety of neurotransmitter receptors including NMDA and substance P. Acetaminophen is metabolized by the liver through conjugation with glucuronide and sulfate and oxidation via the cytochrome P450 oxidative pathway. An intermediate metabolite conjugates with glutathione and is then further metabolized.[27] Acetaminophen daily dosing must be monitored to assure that overdosing does not occur. Hepatotoxicity with doses in excess of 4 g/d is often irreversible and can be compounded by alcohol use.[28] Both acetaminophen and NSAIDs can be combined with narcotic analgesics to decrease the required dose of narcotic.

Ibuprofen is the most highly prescribed of the NSAIDs representing one-third of NSAID use. The drug has antipyretic and anti-inflammatory effects, is rapidly absorbed, and has high bioavailability. Ibuprofen is secreted in high concentration in synovial fluid. It is metabolized by the liver and excreted as a glucuronide conjugate in the urine. Ketorolac was the first injectable NSAID available in the United States. Ketorolac has longer time to onset of analgesic action, that is, 30–60 minutes. It is often given prior to the end of surgery to

FIGURE 14.4. World Health Association "Pain Ladder." (Modified from http://www.who.int/cancer/palliative/painladder/en/)

TABLE 14.4

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

■ GENRIC NAME	■ HALF-LIFE (H)	■ DOSE SCHEDULE	■ STARTING DOSE (MG/D)	■ MAXIMUM DOSE (MG/D)	■ COMMENTS
Acetominophen	2–4	Q 4–6 h	1,400	4,000	Overdose produces hepatic toxicity not anti-inflammatory
Aspirin[a]	3–12	Q 4–6 h	1,400	6,000	Dose related GI toxicity
Choline magnesium trisalicylate	8–12	Q 12 h	1,500 × 1 then 1,000 Q 12		Less GI toxicity and no platelet dysfunction
Ibuprofen[a]	3–4	Q 4–8 h	1,200	4,200	Can delay fracture healing and has antiplatelet activity
Naproxen sodium[a]	13	Q 12 h	550	1,100	Can delay fracture healing and has antiplatelet activity
Ketorolac[a]	4–7	Q 4–6 h	30	120	Parental formulation. Higher doses associated with renal toxicity
Celecoxib[a]	11	Q 12 h	400	400	Lower GI toxicity, less platelet activity, increased adverse myocardial events

[a]Reduce dose in elderly and renal insufficiency.

reduce postoperative pain. It is not used alone for severe pain but may have narcotic sparing effect.

The side effects of NSAIDs can be considerable. NSAIDS are less sedating and do not cause ileus or constipation like narcotics. However, they do have several dose-dependent side effects that may limit their usefulness in specific patient populations. The cardiovascular side effects are the most concerning and have been highlighted recently in the lay press. By inhibition of the cyclooxygenase pathway leading to prostacyclin inhibition without concomitant thromboxane A_2 inhibition, NSAIDs can predispose to hypertension and thrombosis resulting in myocardial infarction and stroke. Gastrointestinal side effects are also well recognized. Symptomatic ulcers developed in 1%-4% of users annually. NSAIDs have also been implicated in the development of colitis and enteropathy. The intestinal wall becomes more permeable and bacterial translocation may occur.[29] Both aspirin and NSAIDs affect platelet function. Platelet aggregation is affected resulting in a 30% increase in bleeding time. Unlike aspirin, the impact that NSAIDs have on the platelet is reversible. Renal dysfunction caused by NSAIDs usually follows prolonged use. Through their effects on prostaglandins, rennin, and aldosterone release, NSAIDs may result in reduced renal blood flow and impaired excretion of water and electrolytes. Patients with preexisting dysfunction, advanced age, cirrhosis, cardiac disease, or hypovolemia are at high risk for renal complications from these medications.

When nonopioids fail to control pain, the WHO recommends stepping up to a "weak opioid." These include codeine, dihydrocodeine, and tramadol. Tramadol is an opioid agonist that weakly inhibits serotonin and norepinephrine reuptake. Codeine and hydrocodone must be converted to morphine by the enzyme CYP 2D6, a member of the cytochrome P450 mixed oxidase system. Some 20% of the populations is deficient in this enzyme and would, therefore, not get an analgesic response. Medications like amiodarone, fluoxetine, haloperidol, paroxetine, propafenone, propoxyphene, quinidine, ritonavir, terbinafine, and thioridazine inhibit this enzyme.[30] Many believe that these medications provide poor pain relief and should not be used.

The final rung in the WHO "pain ladder" is the strong opioid. Strong opioid medications should be considered if pain

relief is not adequate. As important as the medication is the timing and route of administration. When medication dosage is inappropriately timed or administered via a route in which the absorption is erratic, poor pain control can result. In addition, respiratory depression, constipation, ileus, pruritus, over sedation, dysphoria, and physical dependence can occur. Opioids bind to the opiate receptors in the dorsal horn, central gray matter, medial thalamus, amygdala, and limbic cortex. In the periphery, they act on injured tissue to reduce inflammation. In the dorsal horn, they prevent the transmission of the nociceptive impulse and supraspinally they activate inhibitory pathways that then descend to the spinal level. Synthetic and naturally occurring opiates are structurally similar and bind to receptors in a dose-dependent manner. Table 14.5 contains a representative list with their relative strengths.

Opioids have no specific maximum dose. However, at high doses the side effects become troublesome and apnea, sedation, and confusion become more common. Morphine metabolites, morphine-3- and morphine-6-glucuronide, may build up. Morphine-3-glucuronide may cause myoclonus and hyperalgesia. Morphine-6-glucuronide is a more potent analgesic. Some side effects may be mistaken for inadequately treated pain, leading to the provision of higher doses of medication leading to further toxicity (Fig. 14.5). Patients with impaired renal function are at increased risk as the metabolites are excreted in the urine.[31]

While analgesia must be individualized for each patient, a number of principles exist that allow the practitioner to approach pain management wisely. The goal of analgesia should be to prevent pain if at all possible. "Breaking the pain cycle" and trying to prevent the pain from being severe will result in a patient who is far more comfortable and one who will use fewer total milligrams of analgesics.

Early on, it may be difficult to estimate how much analgesic will be required. This is a dynamic process that requires a certain amount of trial and error. During this phase, the ideal medication should have rapid onset and a relatively short half-life. This will allow the practitioner to titrate the dose to get the patient comfortable. Thus, during this phase, short acting intravenous medication is ideal. When one is able to estimate

TABLE 14.5

OPIOID ANALGESICS

■ DRUG	■ STRENGTH	■ ROUTE OF ADMINISTRATION	■ RECEPTOR	■ EFFECT
Morphine (gold standard)	Strong for severe pain	PO/IV/IM/SC/epidural	Mu	Analgesia, decreased respiration, constipation, nausea/vomiting, euphoria, dependence, tolerance
Hydromorphone	Strong for severe pain	PO/IV	Mu	Analgesia, decreased respiration, constipation, nausea/vomiting, euphoria, dependence, tolerance
Methadone	Strong for severe pain	PO/IV	Mu	Analgesia, decreased respiration, constipation, nausea/vomiting, euphoria, dependence, tolerance

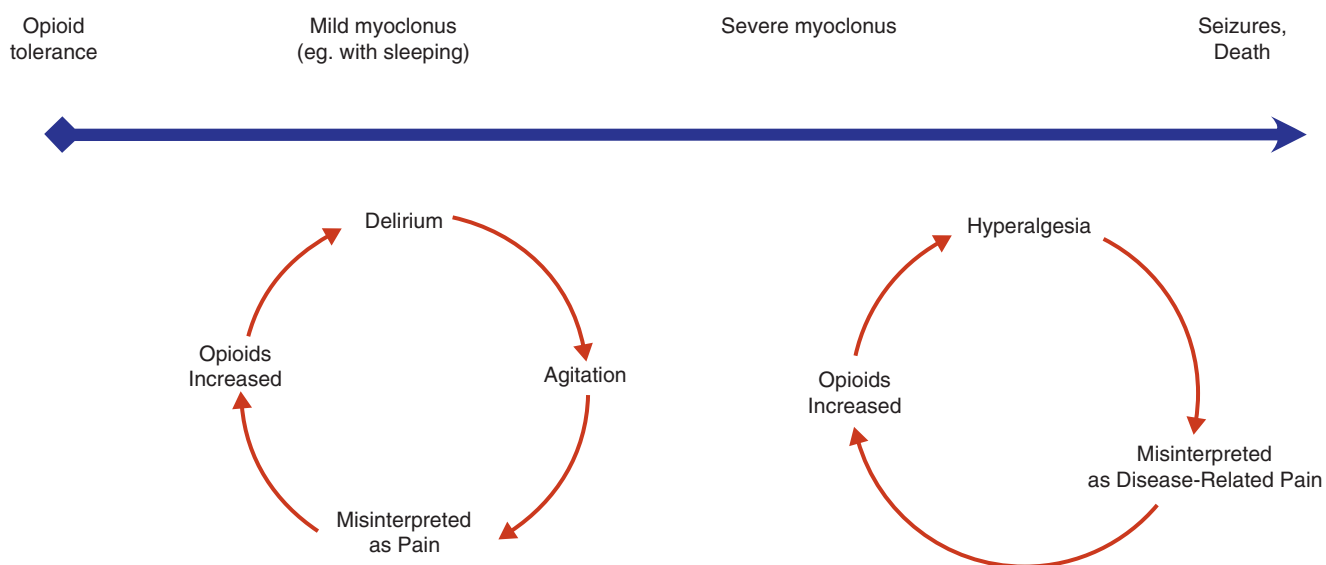
Propoxyphene	Mild to moderate pain	PO	Mu	Analgesia, decreased respiration, constipation, nausea/vomiting, euphoria, dependence, tolerance
Tramadol	Mild to moderate pain	PO/IV	Central acting	Minimal sedative and respiratory effects
Butorphanol	Strong for severe pain	PO/IV/transnasal	Delta, Kappa	Analgesia, sedation, no dependence, no respiratory depression, psychomimetic, paranoia
Buprenophine	Strong for severe pain	PO/IV	sigma	Psychomimetic, paranoia


FIGURE 14.5. Opioid toxicity.

the severity of pain, and how much medication will be necessary, longer acting agents can be titrated into the regimen.[32]

After injury or operation, the gastrointestinal tract may not be the wisest way to deliver analgesics. However, as GI motility recovers, oral analgesics become extremely attractive. Their longer duration means that dosing need only occurs a few times a day. It is wise to still supplement longer acting analgesics with shorter acting drugs to treat any breakthrough pain that may occur in between doses of the longer acting medication.[33] For patients who have prolonged GI dysmotility or have other reasons why oral analgesics are not possible, cutaneous narcotics or sublingual agents can also be quite effective.

Early on, medications can be administered either by the nursing staff or via a patient-controlled analgesic (PCA) pump. PCA is attractive, as it gives the patient control over their own pain regimen. PCA pumps can be designed with or without a basal rate. The patient can then press the button for additional pain medicine as needed. A Cochrane review demonstrated that PCA provided slightly better pain control and increased patient satisfaction when compared with conventional methods. Patients tended to use higher doses of medication with PCA and suffered a higher occurrence of itching, but otherwise adverse effects were similar between groups. This allows for a smoother, more constant analgesia.[34] Studies demonstrate that IV PCA are safe and provide efficient analgesia.[35]

Medications can also be delivered via an epidural catheter. Medications can be administered directly into the epidural space and/or can be controlled by the patient using a PCA pump.

As patients may have several components to their pain, multiple drug regimens often make sense. Addition of an anxiolytic and/or an antispasmotic may potentiate the effect of a pure analgesic. An anti-inflammatory agent may also be quite helpful, particularly after bony or soft-tissue injury where edema is quite common.

Multiple routes of administration are available for opiates including oral, transbuccal, transnasal, transcutaneous, subcutaneous, intravenous, intramuscular, and rectal. Intravenous and/or PCA routes are best used when titration is necessary. However, meta-analysis has failed to demonstrate significant clinical advantage of IV PCA over prn. VAS scores were decreased in a statistically though not clinically significant way. The side effects were equivalent.[36] Less rigorous data do show 67% of patients having moderate-to-severe pain when treated with IM analgesia versus 35% treated with IV PCA and 20% with epidural PCA.[37] Sustained analgesia can be accomplished using long acting opioids or controlled release morphine; these drugs are not useful for rapid titration because of their extended half-life. Intrathecal, epidural, and even intra-articular administration has been advocated. They are most often combined with a local anesthetic.[38]

In a meta-analysis, epidural PCA has been shown to provide superior analgesia to systemic intravenous opioids. This effect was most apparent with activity on the first postoperative day. There was additionally a decreased incidence of nausea and sedation but an increased incidence of urinary retention and pruritis.[36] A meta-analysis of epidural analgesia in patients undergoing abdominal or thoracic surgery demonstrated a decreased risk of postoperative pneumonia, but that the degree of efficacy has decreased over the last decade. This is likely due to provision of improved analgesia for those who did not receive an epidural catheter.[39]

The epidural administration of analgesia is associated with a low but potentially catastrophic incidence of adverse effects. These include epidural hematoma, epidural or spinal abscess, and catheter dislodgement. The incidence of epidural abscess may be as high as 1 in 2000 in diabetics with a mortality of 18% in patients who develop spinal abscess. Other less common complications include intracranial subdural hematoma, transverse myelitis, local anesthetic toxicity and hypotension,

and cardiac arrest.[40] The side effects of opiate medications often require the addition of medications to combat these symptoms. These medications may include cathartics, stool softeners, antiemetic, antipruritics, and stimulants.

Local anesthetics provide excellent analgesia. They can be injected locally at the site of surgery, used to block specific nerves, or be administered intrathecally or by epidural. Catheters can be left in place to provide ongoing delivery of medication by continuous infusion or a filled reservoir (Table 14.6). There has been suggestion that infiltration of the surgical site prior to incision prevents the nociceptive input from changing the excitability of the central nervous system. The theory is that NMDA-induced stimulation is blocked and release of inflammatory mediators prevented. Although this seems logical, there is no meaningful globally supportive literature. There is support for infiltration of ilioinguinal and iliohypogastric nerves prior to herniorrhapy.[41] When general anesthesia is administered and prn analgesia is provided, higher concentration of stress hormones, more intense pain, more substantial catabolism, and greater immune impairment are seen than when regional local anesthetic blockade is used.[42] Local anesthetics can be used to supplement narcotics and decrease the intensity of incisional pain in the early postoperative period.

TABLE 14.7

ADJUVANT ANALGESICS

■ CLASS	■ INDICATION	■ EXAMPLES	■ DOSING	■ STARTING DOSE (mg/d)	■ DAILY DOSE (mg/d)
Tricyclic antidepressants	Continuous neuropathic pain	Amitriptyline, imipramine	Nightly dose	10–25	50–100
Anticonvulsants	Lancinating neuropathic pain	Carbamazepine, valproate, clonazepam	Q 8 h Q 8 h Q 12 h	200 500 0.5	400–1,600 730–2,000 2–5
Second-generation anti-convulsants	Antihyperalgesia	Gabapentin, pregabalin	5–7 h 6 h	100 150	3,600 300
Muscle relaxants	Acute musculoskeletal Pain	Cyclobenzaprine (recommended only for short-term use), baclofen, carisoprodol methocarbamol	18 h 2–4 h 2 h 2 h	15 10 750 6,000	30 30 1,050 3,000

Ketamine blocks calcium channels within the NMDA receptor complex thereby decreasing neuron responsiveness to noxious stimuli in the dorsal horn. Ketamine is administered with benzodiazepams to counteract the psychotomimetic effects. It may also produce excess salivation and cardiac stimulation. Ketamine may also prevent opiate-related activation of pronociceptive systems and opiate tolerance through complex incompletely elucidated mechanisms.[43]

The addition of antiseizure or antidepressant medications may benefit patients who have evidence of neuropathic pain. Amitriptyline, carbamazepine, gabapentin, and tramadol have all been shown to be effective in treating neuropathic pain. The most common side effects are anticholinergic, sexual dysfunction, cognitive impairment, sedation, and orthostatic hypotension. Gabapentin, a second-generation antiepileptic drug, is also effective in treating neuropathic pain. Adverse effects include somnolence, dizziness, ataxia, fatigue, nystagmus, and weight gain. Pregabalin has a similar efficacy and adverse event profile.[44] Table 14.7 contains a list of adjunctive medications.

OTHER TREATMENT

Paravertebral nerve blocks result in excellent pain control evidenced by VAS score measurement and fewer side effects versus thoracic epidural in patients undergoing thoracotomy. Sciatic nerve block with continuous infusion and femoral nerve block with continuous infusion are shown to provide excellent analgesia and decrease in phantom limb pain.[45]

Meditation, massage, and acupuncture are other therapies that may have a role in pain management. As yet insufficient standardization of studies precludes unqualified support.[46]

CHAPTER 15 ■ ACUTE CARE SURGERY IN SPECIAL POPULATIONS

C. WILLIAM SCHWAB, DANIEL J. GRABO, EDGARGO S. SALCEDO, AND MICHAEL L. NANCE

ACUTE CARE SURGERY IN THE ELDERLY

Introduction

Surgical emergencies are diverse and challenging for the acute care surgeon. In patients over 60 years, age-related anatomic and physiologic changes as well as preexisting medical conditions can alter clinical presentation and management and have considerable impact on outcomes. As the population of elderly increases globally, it is important for all surgeons to understand how "aging" affects the presentation and progression of acute surgical disease.

In 1900, only 40% of the population lived to age 65; a century later, over 80% live past 65 years.[1] Two population trends will impact the age characteristics of elder patients in the near future. Significant increases in the population over 65 years will occur with the aging of the "baby boomers," the post World War II generation born between 1946 and 1964. This large cluster of seniors will accelerate the percentage of elderly.[2] The number of persons over age 65 years is expected to increase by 70 million persons by 2030.[3,4] Concomitantly, improvements in life expectancy suggest that the younger cohorts of elderly will live longer and enjoy a more active lifestyle and better health.[5] Improvements in longevity have already led to a steady increase in the numbers of the "oldest old," those over 85 years; by 2030, the number of seniors over age 80 will increase to 19.5 million persons.[3] As these two cohorts (boomers and the "oldest old") age, they will experience the common age-related chronic health conditions, consequences of senility, and the disabilities of "wearing out." They will require increasing prescription and over-the-counter drug use, physician office visits, and trips to the emergency department (ED).[6,7]

Injuries will be the most common surgical emergency among elders. While older Americans are injured at lower rates than those under the age of 65 (7,980/100,000 vs. 10,230/100,000 in 2005), they have higher injury mortality rates (118/100,000 vs. 50/100,000).[8] The percentage of emergency hospital admissions for injury increases with patient age, as well as hospitalization for injury.[4] The same types of injury are experienced in younger people; however, injury pattern, effect, postinjury course, and outcomes differ substantially.[9] Seniors aged 65–74 are usually more active and have injury patterns more similar to younger adults (motor vehicle crashes (MVSs) and falls from heights), and as they pass age 80, activity decreases, and the age-related changes, decreased vision, osteoarthritis, balance problems, low-level falls are dominant.

The presence and severity of preexisting disease, American Society of Anesthesiologist (ASA) physical status classification grade, delays in diagnosis, and time to surgery have substantial effects on morbidity and mortality.[10] Some have suggested that increasing age is an independent risk factor for operative mortality, while others report conflicting results.[10,11]

Physiologic Changes Associated with Aging

The combination of normal age-related changes that affect each organ system and the presence of chronic disease states result in a declining physiologic reserve and an enhanced susceptibility to disease.[12] The result is a diminished ability to handle the "stress" of surgery, trauma, and infection.

Cardiovascular System Cardiovascular disease is common, seen in 80% of patients over 80 years of age.[13] As the heart ages, a progressive loss of myocytes occurs with subsequent enlargement of the remaining myocytes, leading to reduced compensatory capacity and myocardial dysfunction.[14] Cardiac function is often affected by depressed myocardial contractility, decreased compliance in response to preload, and poor response to endogenous and exogenous catecholamines. Fibrosis of autonomic tissue causes conduction abnormalities, arrhythmias, and heart block.[15] Maintenance of cardiac output is difficult in elderly patients as the aged heart responds poorly to endogenous and exogenous catecholamines and is often preload dependent.[14] Cardiac medications, such as beta-blockers, calcium channel blockers, or digitalis, can blunt reflexive- or catecholamine-induced tachycardia. Arteriosclerotic vascular disease, common as we age, predisposes to impaired blood flow to organs.

Pulmonary System Respiratory function declines as the chest wall stiffens, respiratory muscles weaken, and lung elasticity decreases.[13] Arterial oxygenation decreases due to alveolar collapse and resultant diminished surface area for gas exchange.[16,17] Diminished pulmonary compliance, an inability to mount an effective cough, and impaired gas exchange often result in respiratory insufficiency and failure, especially in the setting of acute illness or injury. The elderly patient developing respiratory distress may appear comfortable as changes in chemoreceptor and respiratory drive are altered.[14] Inadequately treated postoperative or injury-related pain results in poor inspiratory effort, atelectasis, and pneumonia.[18] Epidural analgesia/anesthesia is an adjunct or alternative to commonly used enteral and parenteral opioids and nonsteroidal anti-inflammatory drugs (NSAIDs).

Renal System Structural and functional changes occur in the kidney as we age. Structural changes include decrease in effective renal cortex, resulting in 20%–25% cortical loss, hyalinization of blood vessel walls, and decrease in the number of glomeruli.[19] Functionally, decreased glomerular filtration rate (GFR) and impaired renal tubule reabsorption and secretion result in problems with solute clearance, acid–base balance, and fluid homeostasis. Hormonal responses of the renin-angiotensin-aldosterone axis and antidiuretic hormone are blunted. Despite decreased renal function, serum creatinine concentrations can remain within the normal range due to a decrease in lean body mass (BM) and creatinine production.[14] For this reason, serum creatinine concentration alone is

an inadequate measure of renal function; creatinine clearance measurement or calculation based on age and BM should be used.

Gastrointestinal System Gastrointestinal function is relatively preserved; however, the catabolic state induced by critical illness or injury leads to rapid muscle breakdown. Protein-deficient malnutrition develops more rapidly in the elderly, and 17%–65% of acutely hospitalized patients become malnourished.[14] Impaired nutrition is related to an increased mortality in older patients requiring mechanical ventilation and is an independent risk factor for infection, impaired wound healing, and longer ICU stays. Early and sufficient nutritional support reduces hospital length of stay, mechanical ventilation days, and results in improved outcomes.[20,21]

Neurologic System Many neurologic and cognitive changes occur in the elderly.[12] Cortical atrophy becomes more rapid after age 60 based on several studies of postmortem human brains.[22] Pathologic changes such as amyloid deposition and arteriosclerotic cerebrovascular disease affect most past 80 years.[13] Decreases in cerebral blood flow and brain oxygen consumption can manifest as blunted sensation (visual, auditory, and tactile), altered cognition, and blunted pain perception. Anxiety, agitation, and delirium are more common in the postoperative and posttrauma period and more difficult to manage. Alterations in cerebellar function, gait, balance, and vision increase the risk of injury, especially falls.

Pharmacology There is an altered response to many drugs in the elderly.[23] Older patients often have an exaggerated response to central nervous system (CNS) active drugs due to underlying decline in CNS function and increased sensitivity to benzodiazapines, anesthetics, and opioids. A decreased effect of beta-adrenergic agents exacerbates the changes in autonomic function, leading to decreased baroreceptor reflex and orthostasis. Lastly, caution is advised with all nephrotoxic agents, such as iodinated contrast solutions, antibiotics, diuretics, and vasoactive medications.[12]

Clinical Presentation

The elderly can present with atypical symptoms or nonspecific complaints for surgical conditions.[24] Moreover, the history of the present illness may be difficult, and even impossible to elucidate secondary to dementia or previous neurologic insult (stroke). The medical history is often complex and unless supplemented by a family member or caregiver may be incomplete. Systemic response and findings on physical examination are often benign, especially with abdominal problems and soft tissue infections.

Abdominal pain is the main complaint in 15% of ED visits for older patients. Many physicians report greater difficulty with diagnosis and management of abdominal pain in older patients. In addition, abdominal and pelvis computerized tomography (CT) frequently adds critical information, with change in the diagnosis of acute abdominal pain in elderly patients.[25] Thus, early surgical consultation, directed computed tomography, and inpatient monitoring and observation are required for the elderly with a suspected surgical illness.

Perioperative Management of the Elderly

Increasing age in and of itself is not indicative of increased mortality, and many scoring systems have been developed to predict mortality for the elderly patient undergoing emergency surgery.[26] Nearly all scoring systems have clinical limitations

because of time and amount of data required to calculate the score. The Acute Physiology and Chronic Health Evaluation II score (APACHE II) has been studied for its preoperative predictive value as well as its intended purpose of predicting ICU mortality. The Reiss Index compiles age, urgency of surgery, ASA score, presence of malignancy, and diagnosis in predicting mortality in patients undergoing laparotomy. Although the ASAs classification of fitness for surgery was not devised as a risk assessment tool, it has been used for many years in most emergent surgical cases (Table 15.1: ASA Score).[27] In six studies observing mortality after emergency surgery in the elderly, increasing ASA grade was associated with increased mortality irrespective of age. This subjective and simple-to-calculate score has been shown to be a good estimate of mortality risk even in octogenarians.[28]

As stated, the prevalence of chronic disease is quite high in the elderly. The National Center for Health Statistics reported that 80% of Americans over age 65 live with one chronic medical condition and 50% have at least two.[29] Chronic hypertension, arthritis, coronary heart disease, and diabetes are common. The management of these diseases requires medications (both prescription and over the counter), which further alter physiology and can affect a nontargeted organ. For example, NSAIDs can have deleterious effects on gastric mucosa, and beta-blockers can blunt a normal tachycardic response to hypovolemia. Thus, evaluation of the older patient with a surgical emergency is complex, and in many emergent cases complete preoperative assessment and risk stratification is impossible.

The current American College of Cardiology/American Heart Association (ACC/AHA) guidelines for cardiac risk stratification for patients undergoing noncardiac surgery can be used for preoperative assessment.[30] While the guidelines are primarily focused on patients undergoing elective noncardiac surgery, the guidelines list a Class I recommendation for patients in need of emergency surgery. These patients should proceed to the operating room without extensive preoperative cardiac assessment, followed by subsequent perioperative surveillance and postoperative risk assessment and risk factor management. The basic clinical evaluation should include a careful history and physical examination, pertinent laboratory tests (complete blood count to assess for anemia, which can impose stress on the cardiovascular system), and ECG to aid in determining the presence of active cardiac conditions. In elective surgery patients, the presence of unstable coronary artery disease, severe hypertension, uncompensated heart failure, valvular disease, or severe arrhythmia would lead to delay in surgery. However, in the emergent setting, where the risk of

TABLE 15.1

ASA GRADE

ASA GRADE	DESCRIPTION
ASA 1	Normal healthy patient
ASA 2	Patient with mild systemic disease
ASA 3	Patient with severe systemic disease
ASA 4	Patient with severe systemic disease that is a constant threat to life
ASA 5	Moribund patient who is not expected to survive

ASA, American Society of Anesthesiologists.
Modified from Owens WD, Felts JA, Spitznagel EL. ASA physical status classifications: a study of consistency ratings. *Anesthesiology*. 1978;49:239–243.

delaying the surgery would affect mortality, maximal medical therapy is instituted, and the procedure is performed. Most emergent general surgery procedures include the abdomen and fall into the intermediate cardiac risk category (1%–5%), including cardiac death and nonfatal myocardial infarction (MI).

The most frequent cause of morbidity and mortality in the elderly surgical patient is underlying cardiovascular disease.[14] Atrial fibrillation (AF) is the most common arrhythmia (1% of the general population over 60 years) and occurs in 5% of noncardiac surgical intensive care patients.[31] Advanced age (over 60), higher Injury Severity Score in trauma and increased Simplified Acute Physiology Score II, as well as catecholamine use and fluid and transfusion therapy are major risk factors for AF.[32] Patients who develop AF have considerably longer ICU length of stay, hospital length of stay, and higher mortality. Asymptomatic, hemodynamically stable patients can be treated pharmacologically with calcium channel blockers, beta-blockers, amiodarone, or digitalis to achieve either rate control or chemical cardioversion. Side effects of these medications are common. Electrical cardioversion is used for hemodynamically unstable patients or electively, often with cardiology consultation for patients with refractory AF.[33]

MI is the leading cause of postoperative death in patients over 80 years.[14] Preexisting cardiovascular disease and postoperative stressors including emergence from anesthesia and major fluid shifts contribute to myocardial ischemia and infarction in the elderly. Most postoperative MIs occur in the first 72 hours after surgery, and many are "silent." Thus, a high index of suspicion for cardiac ischemia must be present when an older patient presents with tachycardia, hemodynamic abnormalities, or chest pain. Initial management includes hemodynamic stabilization and support while addressing the underlying acute disease process, in addition to aspirin and heparin (where appropriate), beta-blockers, oxygen, and pain relief. Early cardiology consultation should be sought, particularly when coronary revascularization is beneficial.

The ACC/AHA guidelines of 2009 gave a class I recommendation that patients who were receiving beta-blockers on an outpatient basis be continued in the perioperative period.[34] Initiation and titration of beta-blockers in the perioperative setting for patient undergoing noncardiac emergency general surgery (intermediate risk) is controversial and requires cardiac risk stratification and recommendations usually made by a cardiologist. Many elderly patients have undergone percutaneous coronary intervention (PCI) with or without stent(s) (bare-metal or drug-eluting). Most are on antiplatelet therapy in the periprocedure time frame or long term to prevent stent thrombosis and subsequent MI. The ACC/AHA guidelines recommend maintenance of patients on antiplatelet therapy in the perioperative period, especially if drug-eluting stents were used. If drug-eluting stents were placed within 1 year of presentation for emergent surgery, then dual antiplatelet therapy should be considered. Obviously, the bleeding risks versus antiplatelet and coronary protective benefits must be evaluated on a case-by-case basis.

Other situations arise in which treatment of chronic medical conditions with antiplatelets or anticoagulants is necessary, such as peripheral arterial disease, deep venous thrombosis (DVT), and AF. Aspirin irreversibly inhibits platelet activity for the lifetime of the platelet (~7–10 days). Clopidogrel, however, has a long half-life and will affect newly transfused platelets. Platelet transfusion is the classic modality of treatment for platelet-associated coagulopathy. Desmopressin or DDAVP has been described in treating uremic platelet–associated coagulopathy and aspirin-induced platelet dysfunction.[35] Fresh plasma or fresh frozen plasma (FFP) has traditionally been used to reverse warfarin-induced coagulopathy. 10 mL/kg–15 mL/kg of FFP transfusion is often needed, which can result in as many as 4–6 units of plasma transfused (800–1200 mL).[36] In elderly patients with limited cardiopulmonary reserve, pulmonary edema can result. Alternatives to FFP do exist. Vitamin K is usually administered via the intravenous route (5mg or 10 mg) in the bleeding patient with warfarin-induced coagulopathy. Intravenous Vitamin K produces a more rapid response but has been associated with anaphylaxis.[37] Recombinant activated factor VIIa (rFVIIa) was initially described in the treatment of hemophilia and more recently has been used to treat moderate coagulopathy in traumatic brain injury.[38,39] rFVIIa enhances the thrombin-generating potential of activated platelets and aids in the activation of thrombin-activated fibrinolytic inhibitor, which results in a stable hemostatic plug that is resistant to premature lysis. A single dose of rFVIIa has been shown to be safe and effective in this cohort. Prothrombin complex concentrates are derived from human plasma, undergo viral inactivation, and contain vitamin K-dependent coagulation factors (II, VII, IX, and X). In the acute setting, such as traumatic brain injury, prothrombin complex concentrates have been shown to be effective in elderly patients in decreasing time to reversal of international normalized ratio.[40]

Perioperative respiratory insufficiency and failure are common and the need for mechanical ventilation is common in the elderly.[41] In addition, acute lung injury occurs more frequently with a higher mortality (60%) when compared to younger age groups.[42] Recognition and aggressive management of chronic pulmonary disease, such as chronic obstructive pulmonary disease and asthma, can minimize postoperative respiratory complications. Attention to postoperative and postinjury pain control with patient-controlled analgesia and epidural anesthesia is beneficial to the elderly patient.[43,44] Epidural or regional anesthesia promotes ambulation and provides excellent pain control while minimizing systemic opioids. In particular, patients over 65 years are susceptible to major complications after blunt thoracic trauma with even a few isolated rib fractures; mortality increases with increasing numbers of rib fractures in the elderly. Early use of mechanical ventilation that promotes spontaneous breathing and minimal barotrauma are the mainstays in management.

Specific Considerations

The common surgical emergencies in the older patient are injury and trauma, especially musculoskeletal, and diseases related to the abdomen, vascular insufficiency, and soft tissue infections.

Trauma The leading causes of nonfatal injury in older Americans are (1) falls, (2) pedestrian struck by automobiles, (3) MVC, and (4) violence.[8] Falls have become the main cause of hospitalizations for the elderly.[24] While younger adults tend to fall from heights (ladders), older adults fall from standing or sitting positions.[45] Up to 6% of falls result in fractures, with 1%–2% of these being hip fractures.[24] Pelvic fractures in the elderly have a higher risk of bleeding and of requiring interventional control.[46] Age-related changes in vision, hearing, cognition, and reflexes contribute to the higher rate of MVC in the elderly, but different driving patterns lead to more MVCs during the day. Elders account for more than 20% of automobile-pedestrian fatalities.[9] Violence is an unfortunate reality in the elderly, as older patients are more susceptible to unintentional injury and abuse.

The initial trauma evaluation and workup follow the principles of the Advanced Trauma Life Support (ATLS™) course with special attention to recognize preexisting medical conditions, chronic medications, and altered physiologic

responses.[47] In addition, while resuscitation is ongoing, contacting family, caregivers, or physicians for medical information, health status, medications, and advanced directives is important. A heightened suspicion for occult injury, blunted cardiovascular response, and potential for early deterioration is required. Early use of ultrasound, placement of invasive monitoring or echocardiography to determine volume status and cardiac performance is helpful. Pain control is essential but should be given in smaller interval doses. Establishment of baseline mental status is important and early brain CT is critical in all cases. An age-related approach to patient care is presented in Table 15.2: Age-Related Approach to Patient Care.

Abdomen While the incidence of peptic ulcer disease in decreasing in the general population, the incidence of hospitalization and mortality due to gastric and duodenal ulcer in the elderly remains high.[48] This phenomenon can be attributed to the high prevalence of *Helicobacter pylori* infection and the increasing use of ulcerogenic medications, such as aspirin and NSAIDs. The treatment option for the management of perforated gastric ulcer begins with nonoperative measures, which include nasogastric decompression, analgesics, proton pump inhibitors, and appropriate antibiotics.[49] Mortality approaches 5% for nonoperative management of perforated peptic ulcer; therefore, this approach is advocated with caution in those over age 70. Patient history and overall stability will determine if nonresectional surgery with omental patching is more appropriate than definitive acid-reducing operation.[50,51] Recent studies have advocated the use of laparoscopic exploration, peritoneal lavage, and gastric or duodenal omental patching with excellent outcomes.[52]

Patients over age 80 with gallstone disease are more likely to present with obstructive jaundice or biliary colic.[53] Nonoperative management has a high failure rate and mortality (17%). Laparoscopic and open cholecystectomy in patients over 80 years for complicated choledocholithiasis requiring endoscopic sphincterotomy is associated with increased morbidity and mortality.[54] Failure to perform early cholecystectomy often leads to readmission with an increased percentage of those patients requiring open procedures. Thus, early laparoscopic cholecystectomy is the standard of care even in the face of a multitude of comorbidities.[55] Percutaneous cholecystostomy with interval cholecystectomy remains an option in the acutely ill and septic patient.[56]

Small bowel obstruction is a common reason for emergency surgical admission. Postoperative adhesions are by far the most common etiology of small bowel obstruction, with hernia (internal and external), malignancy, and inflammatory bowel disease accounting for the rest.[57,58] A high index of suspicion for necrotic bowel is necessary in the evaluation of the elderly patient with vague complaints and misleading signs and symptoms of abdominal pain, distention, and emesis. Delay in operation can result in loss of viable bowel and possible loss of life. The principles for fluid resuscitation with correction of electrolyte abnormalities, radiographic evaluation, and management are similar for younger patients with the caveat of performing laparotomy in cases without prompt improvement.

Colorectal emergencies are common in the elderly. In cases of bleeding, perforation, and obstruction, resection with creation of an ostomy is often the safest procedure. Emergency resection and primary anastomosis can be performed with an acceptable leak (6%) and mortality (9%) rates in the elderly who present with left-sided obstructing colorectal cancer, minimal soilage, and favorable physiology.[59] Acute appendicitis presents late in the course and is more complicated and lethal.[60,61] While abdominal CT is useful in the diagnosis of appendicitis and laparoscopic appendectomy has been shown to be beneficial in terms of improved postoperative pain, neither has affected outcome with respect to mortality in the elderly population.[62–64] Early appendectomy remains the mainstay of treatment and the most effective means to avoid

TABLE 15.2

AGE-RELATED APPROACH TO PATIENT CARE

Treatment Axioms, 55 through 69 Years

1. Assume some mild decrease in physiologic reserve.
2. Suspect the presence of some common disease of middle age (diabetes, hypertension).
3. Suspect use of prescription or over-the-counter medication.
4. Assume the patient is competent to provide an accurate medical history.
5. Look for subtle signs of organ dysfunction (ABG, EKG).
6. Assume TBI with history of LOC or cognitive abnormalities and obtain head CT.
7. Proceed with standard diagnostic and management schemes.

Treatment Axioms, 70 through 80 Years

1. Accept the presence of age related and acquired physiologic alterations.
2. Accept the presence of medications to control acquired diseases. Assume higher incidence of previous surgery and transfusion.
3. Determine competency for medical history; involve relatives and personal physician.
4. Aggressively monitor patient and control physiologic parameters to optimize cardiac performance.
5. Brain imaging is mandatory for any alterations in cognition.
6. Proceed with standard diagnostic and management schemes, including early, aggressive operative management.
7. Be aware of poor outcomes, especially with severe injury to the CNS; check for advanced directives.

Treatment Axioms, 80 Years or Older

1. Proceed as in items 1 through 5 for patients 70 through 80 years of age.
2. Assume a poor outcome with moderately severe injury, especially in the CNS or any injury causing physiologic disturbance.
3. After aggressive initial resuscitation and diagnostic maneuvers, examine item 2 and discuss appropriateness of care with patient and/or family members.
4. Attempt to be humane; recognize the legal and ethical controversies involved; consider early ethics consultation and social services.

perforation, abscess formation, and sepsis. Interval appendectomy performed after a period of conservative management with antibiotics and percutaneous drainage for perforated appendicitis and periappendiceal abscess can be beneficial in adults.[65] The prevalence of diverticular disease increases to 50%–70% in those over the age of 65.[66] Chronic health conditions have been associated with poor outcomes in acute diverticulitis. Conservative management of acute noncomplicated diverticulitis with bowel rest, analgesia, and antibiotics are the initial treatment. Recurrent episodes are less well tolerated, and early resectional therapy should be considered. Surgery is reserved for abscess, perforation, or peritonitis.[67]

Hernias Elective repair of abdominal wall and groin hernias is one of the most common general surgical operations.[68] Emergencies, including obstruction, incarceration, and strangulation are frequent. External hernia repair has a 5% overall mortality, and this is largely associated with bowel resection for necrosis.[69–71] Other risk factors for unfavorable outcomes are advanced age, ASA class, coexistent disease, late presentation, and misdiagnosis. Older, stable patients who present with incarcerated body wall hernias should undergo attempts at manual reduction with appropriate sedation and analgesia as long as there are no signs of peritonitis or local cellulitis over the hernia. If reduction is successful, the patient should be observed in the hospital. If the patient develops abdominal pain, fever, tachycardia, or leukocytosis, emergent abdominal exploration to inspect the viscera and hernia repair should be completed. If attempted reduction fails or if the patient has signs or symptoms of strangulation or bowel necrosis, urgent operative intervention is necessary. If the peritoneal fluid is abnormal or the bowel is compromised, inadequately visualized, or reduces into the abdomen prior to inspection, full abdominal exploration is recommended for visceral inspection.

Vascular emergencies Mesenteric ischemia is uncommon but has a high mortality approaching 90%.[72] The three primary etiologies are acute mesenteric ischemia (arterial embolism or thrombus), mesenteric vein thrombosis, and nonobstructive mesenteric ischemia (low flow state). It is essential to maintain a high index of suspicion in the elderly patient who presents with abdominal pain out of proportion to physical exam findings and a history of comorbidities consistent with vascular disease or cardiac dysrhythmia. While angiography remains the gold standard as a diagnostic and therapeutic tool in acute mesenteric ischemia, CT angiography (CTA) is more readily available and commonly used. CTA also gives information about mesenteric vein thrombosis, bowel wall thickening, and pneumatosis. Management focuses on volume resuscitation and broad-spectrum antibiotics followed by operative exploration to determine bowel viability, resection, second-look procedures, and occasionally damage control procedures.

Acute lower extremity ischemia is a common surgical emergency, and the early recognition of symptoms can lead to limb salvage. Patients commonly present within a few hours of the ischemic event with the 6 "Ps": pain, pallor, paresthesias, paralysis, poikilothermia, and pulselessness (a late finding). A complete history and physical exam (with a detailed vascular pulse exam) will help elucidate the preexisting cardiovascular comorbidities that may have predisposed to the event, as well as the findings that identify the etiology of the event, that is, AF and embolus. The Rutherford Criteria have been used to grade the clinical severity of acute limb ischemia and are indicative of whether emergent surgical intervention is indicated and whether the limb is salvageable.[73] Category II (sensory loss, possible muscle weakness, and inaudible arterial doppler signals) represents a threatened limb that is salvageable with immediate therapy, and in category III (profound sensory loss and muscle weakness and inaudible arterial and venous doppler signals), the patient has substantive disease with an unsalvageable limb that will require amputation. Imaging should examine both inflow and outflow anatomy. Arteriography is the gold standard with magnetic resonance angiography and CTA becoming more common. Initial therapy includes systemic heparinization followed by thrombolysis, mechanical thrombectomy, or open revascularization. Endovascular advances and interventional percutaneous techniques are now common, and early consultation with a vascular surgeon is recommended. In the elderly patient, especially with substantial comorbidity and limited activity level, amputation may be a better option than surgical revascularization.

Skin and Soft Tissue The presence of underlying skin conditions and chronic disease states, such as diabetes, place the elderly at high risk for skin and soft tissue infections.[74] Necrotizing soft tissue infections (NSTI) are caused by microbial invasion of the subcutaneous tissues (SC) that occurs either through external trauma or direct spread from perforated viscus or urogenital organ.[75] Most NSTIs are polymicrobial in nature and occur in the perineal and trunk area, often in immunocompromised patients, diabetics, and patients with peripheral vascular disease. Because of nonspecific findings and a variable time course to fulminant disease, a high index of suspicion must exist to diagnose NSTI expeditiously. Erythema, pain beyond the margins of erythema, woody induration of the soft tissues, and swelling are common findings. CT of the involved body region often demonstrates inflammatory changes, abscesses, and fascial edema. Laboratory findings are nonspecific and include elevated white blood cell count and hyponatremia. The gold standard in diagnosis is operative exploration with the findings of "dishwater" or foul-smelling discharge, necrosis, and loss of normal resistance of the fascia to finger dissection. The mainstay of therapy for NSTI is wide surgical debridement well beyond the rim of cellulitis.[75] Prompt operation and adequacy of initial debridement are the most important determinants of survival. Broad-spectrum antibiotics are initiated and should include coverage for gram-positive, gram-negative, and anaerobic organisms. Antibiotic coverage for methicillin-resistant *Staphylococcus aureus* (MRSA) is also recommended. IV immune globulin and hyperbaric oxygen are additional therapies that have been described. Patients who survive NSTI have high morbidity, often necessitate multiple operations, and require prolonged ICU care. V.A.C. Therapy, nutritional support, and physical therapy are the additional mainstays of the long-term therapy. Outcomes in those over 70 years are poor.

Ethical and End-of-Life Issues

The primary objective of ICU care is to survive the acute threat to life. Success is achieved 75%–90% of the time, yet 20% of all deaths occur in the ICU.[76] Most of these are older patients in their 8th, 9th, and 10th decades. The Society for Critical Care Medicine (SCCM) guidelines call for shared decision making between the health care team, the patient, and the patient's family. Furthermore, even in cases of withdrawal or withholding of support, continued care and symptom management for dying patients is beneficial to both patient and family. Nearly 80% of the deaths that occur in the ICU occur after a decision has been made to limit life support measures (do not resuscitate or DNR).[77] Most DNR decisions are made within the first week of ICU admission, and decisions to withdraw or withhold treatments are usually made around day 7. Older age, more severe illness or injury are associated with earlier end-of-life decisions. Advances in critical care medicine and

technology have complicated decisions regarding futility and withholding or withdrawing of care. Critically ill patients who have decision-making capacity have the right to determine their level of care and treatment.[78] When elderly patients are unable to participate in decision making, advanced directive and communication with family (next-of-kin, and power of attorney) must guide the health care team.

ACUTE CARE SURGERY AND PREGNANCY

Introduction

Caring for the pregnant woman presents a unique challenge to the acute care surgeon as there are two patients to manage: the mother and the fetus. The guiding management principle is that optimal care delivered to mother is the best initial treatment to the fetus. Often, managing the pregnant patient with a surgical emergency or critical injury is a multidisciplinary effort with input from the surgeon, obstetrician, anesthesiologist, and neonatologist.

Approximately 6%–7% of pregnancies are complicated by trauma, which is the leading nonobstetric cause of maternal death. The mechanisms of trauma for pregnant patients are most commonly motor vehicle collision (49%), fall (25%), and assault (18%). Penetrating trauma and burns comprise the minority of patients.[79]

General surgical procedures will be required in approximately 1 in 500 pregnant patients.[80] The incidence of surgical diseases in the pregnant population is similar to the nonpregnant population. Presenting clinical patterns for these conditions are commonly the same for pregnant patients as for nonpregnant patients. However, expected anatomic and physiologic changes during pregnancy and the normal spectrum of symptoms associated with the pregnancy itself can make prompt diagnosis and management challenging.[81] The section to follow will review the expected changes in pregnancy and the management approaches for the most commonly encountered acute care surgical scenarios.

Normal Physiologic Changes Associated with Pregnancy

Women undergo substantial physiologic changes as they progress through the trimesters of pregnancy. These changes involve virtually every organ system. It is essential for the acute care surgeon to be familiar with the nature of these normal changes to interpret a given patient's physiologic status, diagnostic maneuvers, and clinical trajectory appropriately.

Intravascular Volume Volume expansion in pregnancy is profound and progresses throughout pregnancy until it plateaus at 32–34 weeks of gestation. The volume expansion occurs to maintain perfusion to organs and the growing uteroplacental interface. The larger plasma volume also prepares the mother for blood loss associated with giving birth. Total body water (TBW) increases by 4–5 L and is regulated by changes in the renin-angiotensin-aldosterone system, which results in increased sodium reabsorption and water retention. Most of the increased TBW is found in the fetus, placenta, and amniotic fluid. Maternal blood volume augmentation is comprised of increased plasma volume (1,200–1,300 mL) and increased red blood cell volume (300–400 mL). The much larger increase in plasma volume when compared to red blood cell volume explains why the normal hematocrit in late pregnancy is lower, 31%–35% (physiologic anemia of pregnancy).

These changes allow an otherwise healthy pregnant patient to sustain blood loss volumes up to 1,500 mL before manifesting signs and symptoms of hypovolemia.[82]

Cardiovascular System Consistent with the increase in intravascular volume to maintain organ and fetal perfusion, the cardiovascular system undergoes changes to achieve the same goals. Cardiac output increases by 50% to 6 L/min in the first two trimesters of pregnancy, primarily due to an increase in stroke volume. An increase in heart rate also occurs gradually throughout pregnancy, contributing to augmented cardiac output, reaching 10–20 beats per minute faster by the third trimester.[82,83]

As pregnancy progresses, uterine blood flow increases to approximately 25% of the total maternal cardiac output at term. Because uteroplacental perfusion lacks autoregulatory mechanisms, fetal perfusion relies primarily on maternal mean arterial blood pressure (MAP). Accordingly, maneuvers that result in decreasing maternal MAP or cardiac output may compromise fetal perfusion. A patient in the supine position during the second half of pregnancy will have compression of the vena cava and impaired venous return causing a decrease in cardiac output to as much as 30%.[82,83] Therefore, as a rule, all females in the second and third trimesters are positioned with the right side of the torso bumped up, shifting the weight of the uterus and fetus to the left. In addition, care should be taken when administering anesthesia of medications that can alter hemodynamics.

The hormone, progesterone, causes blood vessels to vasodilate. Coupled with the low resistance of the placental perfusion bed, systemic vascular resistance in pregnancy decreases by 15%. Resultant decreases in systolic and diastolic blood pressures by 5–15 mm Hg are observed by the end of the second trimester with a return to the prepregnancy range by term. Vasodilation also results in greater venous distensibility and higher venous pressures, particularly in the lower extremities.[82]

Physical findings associated with these cardiovascular changes of pregnancy include increased peripheral edema, mild tachycardia, jugular venous distension, and mild hypotension (depending on trimester). These expected changes in cardiovascular physiology warrant careful interpretation when evaluating a pregnant patient for emergency surgery.[82]

Pulmonary System Anatomical changes in the abdomen and chest wall account for a variety of changes in pulmonary mechanics during pregnancy. Resting lung volume decreases by 5% as the diaphragm elevates with displacement of the abdominal viscera by the enlarging uterus. Minute ventilation, the product of tidal volume and respiratory rate, increases in pregnancy by 30%–50%. The increase is primarily due to an increase in tidal volume as the respiratory rate in pregnancy is largely unchanged. This increase in minute ventilation results in a decrease in $PaCO_2$ levels (40 mm Hg down to 32 mm Hg) and is believed to be due to the increased levels of progesterone, a respiratory stimulant. The lower baseline $PaCO_2$ in pregnancy provides the necessary gradient to facilitate the transfer of carbon dioxide across the placenta from the fetal circulation to the maternal circulation for elimination.[82,83]

Oxygen demand increases during pregnancy because of the increased oxygen consumption of the maternal systems and the presence of the placenta and fetus. In total, these factors diminish maternal oxygen reserve. Difficult endotracheal intubation is a leading cause of morbidity and mortality in the pregnant patients. Airway edema and the generalized increase in BM of pregnancy contribute to airway obstruction and reduced glottis opening, and as such, smaller endotracheal tubes may be required.[82]

Renal System GFR increases as a result of the decreased vascular resistance and increased cardiac output. Alterations in sodium reabsorption result in water retention and plasma expansion. The higher GFR translates into decreased serum creatinine concentrations. It is important to consider the increased GFR during pregnancy to make appropriate adjustments to doses of medications cleared by the renal system. Glycosuria is a common finding during pregnancy.[82,83]

Anatomically, the collecting system dilates during pregnancy. This is mediated partially by the smooth muscle relaxing effect of progesterone. Also, the enlarging uterus compresses the distal ureters (right greater than left) in the pelvis, which also contributes to collecting system dilation. These expected findings should be noted and carefully interpreted on radiographic evaluation in the context of the patient's clinical symptoms. The ensuing urine stasis predisposes pregnant women to urinary tract and renal infections as well as renal stones.[82]

Gastrointestinal System The main alterations in the gastrointestinal system are due to the enlarging uterus in the abdomen causing cephalad displacement of the abdominal and pelvic viscera and general relaxation of smooth muscle. Intraperitoneal structures shift in position, resulting in unusual presentations of common surgical conditions. Similarly, the operative approach for managing common surgical conditions may require adjustment in incision selection to account for the gravid uterus.[82] Overall gastrointestinal motility and especially gastric emptying slow during pregnancy. The larger stomach volume and slower motility predispose pregnant women to aspiration when sedation is required during evaluation or management.[82]

Hematologic System As previously stated, the physiologic anemia of pregnancy is due to the proportionately larger increase in plasma volume compared to red blood cell volume. In addition to this dilutional anemia, iron stores are transferred to the fetus, a contributing factor to the anemia of pregnancy. Leukocytosis is observed during pregnancy and marked during labor that is endocrinologically mediated. This finding should not be mistaken for a marker of infection. Platelet counts remain relatively unchanged in pregnancy.[82,83]

The most noteworthy changes in the hematologic system during pregnancy involve the coagulation system. Essentially all procoagulant factors increase in pregnancy. Coupling this with a concomitant decrease in fibrinolysis puts the pregnant patient in a hypercoagulable state.[82,83] The incidence of venous thromboembolic events including DVT and pulmonary embolism (PE) has been shown to be five times higher in pregnant patients.[84] Following emergency surgery and trauma when additional factors of immobility, endothelial injury, and inflammatory mediators are exaggerated, the risk of DVT is even higher. As such, careful attention must be paid to DVT prophylaxis when managing pregnant patients, who often require pharmacologic prophylaxis.

Specific Considerations

Trauma The leading presenting mechanism of injury for the pregnant patient is blunt trauma after motor vehicle collision or fall.[85] As with all trauma patients, the evaluation of the pregnant trauma patient follows ATLS™ protocol beginning with a primary survey to identify and address any life-threatening injuries. The expected changes of pregnancy must be carefully interpreted and managed in the context of the patient's stage of pregnancy, mechanism of injury, signs, and symptoms. Foremost is the potential for a difficult airway, decreased oxygen reserves, and a full stomach. Substantial blood loss can occur

before any changes in maternal hemodynamics are evident, manifesting first as fetal distress. Positioning the gravid patient in some degree of left lateral decubitus or manually displacing the uterus to the left side improves venous return by relieving pressure on the inferior vena cava.[86] Early fetal assessment is essential as even if the mother's vital signs are normal, the fetus may be inadequately perfused. Tocodynamometry and electronic fetal monitoring aids the diagnosis and treatment. Continuous monitoring is preferred and should be performed when the fetus is beyond 20–24 weeks.[79] Approximate gestational age can be estimated by examination of fundal height with a fundus palpable at the umbilicus, corresponding to 20 weeks.[87] Fetal viability is likely beyond 26 weeks gestation, and birth weight may have more impact than actual gestation age, with fetuses born <500 g less likely to survive.[88]

The following points are added in the care of the pregnant patient: palpation of the uterus for tenderness or contractions and pelvic examination to evaluate for fluid, bleeding, membrane integrity, and cervical status. Vaginal bleeding is concerning for abruptio placentae, which is the leading cause of fetal demise after maternal shock and death. Uterine rupture, though rare, is possible with considerable blunt trauma. Physical examination of the abdomen will reveal pain, palpable fetal anatomy and/or inability to palpate the uterus, or abnormal uterine shape or position.[86]

The secondary survey and appropriate adjunct diagnostic tests are employed to identify other injuries. The risk for potential harm to the fetus under 8 weeks gestation (during organogenesis) should not overshadow the necessity for radiographic imaging of the injured pregnant patient when there is need for accurate diagnosis. Radiation exposure of <0.1 Gy is considered safe; refer to Table 15.3: Absorbed Radiation Dose for radiation doses of specific imaging studies.[87] Again, the best initial management of the fetus is the optimal resuscitation, diagnosis, and care of the mother linked to early fetal assessment.[79,86]

In addition to the standard battery of blood tests, a Kleihauer-Betke test is sent for Rh-negative patients. If the test demonstrates fetal blood in the maternal circulation, an appropriate dose of Rh immune globulin should be administered within 72 hours of injury. Alternatively, one can forego Kleihauer-Betke test and administer the Rh immune globulin to all known Rh-negative women.[79]

Surgical Emergencies Most acute abdominal emergencies present with the typical signs and symptoms described for surgical disease. Prompt surgical intervention minimizes both maternal and fetal risks. Diagnosis, however, may be delayed and difficult due to the normal biologic alterations in anatomy and physiology of pregnancy or the mother's misinterpretation of symptoms. Consultation with an obstetrician should assure appropriate perioperative monitoring of the mother and fetus.[81]

The most common nonobstetric surgical condition affecting pregnant patients is acute appendicitis. This comprises 25% of nonobstetric operative interventions in pregnancy. The rate of perforated appendicitis in pregnant women is higher than in the nonobstetric population and correlates with maternal and fetal morbidity and mortality. The rates of preterm contractions are appreciable secondary to uterine irritation from peritonitis, and preterm labor and delivery can reach 50% in the third trimester.[81]

The anatomic position of the appendix changes as the uterus enlarges and in most women relocates to the right upper quadrant by late pregnancy.[89] The progressive displacement of the appendix fosters missed and delayed diagnosis and higher rates of perforation. Also, the enlarging uterus may impair the ability of the omentum and surrounding bowel to wall off an inflamed appendix. Rebound tenderness and guarding is less common due to the increased laxity of the abdominal musculature and the position of the uterus between the appendix and the anterior abdominal wall.[81]

However, diagnosis of acute appendicitis can be challenging, particularly late in gestation. Ultrasound is the most common initial imaging approach as it is noninvasive, sensitive, widely available, and low risk. The specificity and sensitivity of ultrasound is operator-dependent. CT scan and MRI are both highly sensitive and specific for the diagnosis and used whenever there is high clinical suspicion and ultrasound exam is normal or inadequate. CT scan exposes the fetus to considerable ionizing radiation. Although MRI avoids radiation, its long-term effects have not been proven in long-term follow-up studies. Any use of radiation or magnetic imaging should be discussed with the mother.

The risks and benefits associated with operation must always be evaluated. Appendectomy appears to be well tolerated by the mother and fetus. The laparoscopic approach versus open approach is based on surgeon preference, uterine size, and position of the appendix. After the second trimester, laparoscopy becomes increasingly challenging. The open technique for trocar placement should be used for any laparoscopic approach to avoid injury to the uterus. The only indication for delay in surgery is active labor in which appendectomy should be performed immediately after delivery. Cesarean delivery is indicated if there is evidence of appendiceal rupture, sepsis, or septic shock. With both the open or laparoscopic approach, initial incision or trocar configuration may be altered due to the variable position of the appendix throughout pregnancy. The false-positive rate of appendicitis on pathology is higher, but acceptably so, in pregnant women as the risks to mother and fetus are significant with the complications from a delay in diagnosis.[81]

Biliary tract disease is the second most common nonobstetric surgical condition. Signs and symptoms are typical, but Murphy's sign may not be elicited as frequently. Ultrasound examination is warranted in any pregnant woman with a ***complaint of right upper-quadrant abdominal pain. The clinical presentation of acute cholecystitis in pregnant patients is similar to that of age-matched nonpregnant women.[81] Symptomatic cholelithiasis is commonly managed conservatively at first. Bowel rest, intravenous fluids, and pain control with or without antibiotics are the mainstays of treatment. If successful and with no recurrent episodes or escalation of clinical signs or symptoms, patients are scheduled to have an elective

cholecystectomy after delivery. Obviously, the risks of delayed cholecystectomy are those of progression of biliary disease or failure of conservative management.[81] Some advocate early surgical intervention to avoid the increased morbidity of complications from delayed management. The laparoscopic approach has been shown to be uniformly safe for mother and fetus. The ideal time to operate is in the second trimester because organogenesis is complete in the fetus, but the anatomic changes are not as marked in the mother.[90] Again, the open technique for initial trocar placement is safest and minimal uterine manipulation is recommended. Patients with acute cholecystitis or symptomatic choledocholithiasis are at higher risk for complication such as cholangitis or gallstone pancreatitis. If these conditions develop, maternal mortality rates and fetal loss rates increase dramatically. Intervention should not be delayed in such cases. Open or laparoscopic cholecystectomy with choledochotomy and drainage is one surgical approach. Operation with postoperative endoscopic retrograde cholangiopancreatography and sphincterotomy with or without stent placement is another acceptable option.[81]

While bowel obstruction is uncommon in pregnancy, it is the third most common reason for nonobstetric laparotomy. Nearly 60% of bowel obstruction in pregnant women is caused by adhesions from prior surgery, including previous cesarean section. Volvulus is more common in the pregnant patient and occurs more frequently during times of rapid changes in uterine size, such as during the second trimester and postpartum period.[81] Treatment of bowel obstruction during pregnancy is the same as for the nonpregnant patient. While umbilical hernia is very common in pregnancy due to abdominal wall alterations, incarceration and strangulation are uncommon.[91] Consideration should be given to repair reducible hernias electively in the postpartum period. Attempts at reduction of incarcerated hernias should be made with appropriate sedation and analgesia when no signs of cellulitis around the hernia or peritoneal signs are present. If reduction is successful, a period of observation in the hospital is warranted to monitor for signs of bowel necrosis. Operative repair is urgently undertaken for the irreducible hernia or in the case of the patient who develops peritoneal signs or fetal distress after reduction.

Anal lesions including thrombosed external hemorrhoids and anal fissures are common during pregnancy and the postpartum period.[92] Risk factors include maternal dyschezia, postdate delivery, larger babies, and perineal lacerations.[81] Treatment of hemorrhoids and anal fissures during pregnancy initially is conservative. Symptoms can be improved with topical anesthetics and steroid creams. Rubber band ligation can provide considerable improvement for patients with second- and third-degree internal hemorrhoids.[93] Intractable disease can be treated with surgical hemorrhoidectomy when fetal viability is achieved or in the postpartum period. Hemorrhoidectomy is reserved for third- and fourth-degree internal hemorrhoids, acute thrombosis, and strangulated hemorrhoids.[81]

Venous thromboembolism (VTE) is a leading cause of morbidity and mortality in the pregnant patient. DVT occurs with equal frequency in each trimester and postpartum period and is more common in the left leg.[94] PE, however, is more common during the postpartum period than during pregnancy. Diagnosis of DVT is difficult during pregnancy as the typical signs of leg swelling and pain are common. Unilateral pain and increase in leg size require evaluation for DVT. Venous compression ultrasonography is the diagnostic test of choice as it is noninvasive, safe, and inexpensive. Treatment of DVT requires anticoagulation. Low-molecular-weight heparins (LMWH) are replacing unfractionated heparin as the treatment of choice, and warfarin is only used in the postpartum period due to its teratogenic effects. Current recommendations are for anticoagulation for 3–6 months including 6 weeks postpartum. Longer courses of treatment (12 months) are

required for patients with recurrent VTE and history of hyper-coagulable state.

PEDIATRIC SURGERY FOR THE ACUTE CARE SURGEON

Introduction

The acute care surgeon should be familiar with the basic principles of pediatric physiology and the common presentation, diagnosis, and treatment of surgical diseases that affect young children and adolescents. In general, the acute care surgeon will be commonly asked to evaluate children and adolescents for injuries and multisystem trauma.[95] In addition, a number of common emergencies related to the abdomen, body wall, and groin make up an appreciable part of the work of the emergency surgeon. This section will address only a few surgical emergencies. The emergency surgeon should work closely with a pediatrician and pediatric surgeon if available. General surgeons who practice in a more remote location or in an environment where pediatric consultation is unavailable must be familiar with stabilization of the common surgical conditions of the very young child including pyloric stenosis, as well as emergency management of abdominal wall defects (gastroschisis and omphalocele).

Pediatric Anatomy and Physiology

Anatomy The unique anatomic and physiologic characteristics of the child will impact the patterns of injury and response when compared to adults. Children have a smaller BM, making them more susceptible to equivalent energy transfers and also at risk for hypothermia. The child's bony skeleton is more compliant due to incomplete calcification. As a result, energy is transmitted more readily to internal organs leading to injury, often in the absence of external signs or fractures.

Fluid Management The surgical care of the pediatric patient demands an understanding of the unique physiology that is manifested with each phase of development. A newborn infant's TBW is approximately 75% of BM.[96] This high percentage of TBW decreases rapidly in the first year of life and then trends down to 60% of BM by adolescence, approaching that of an adult. Maintenance fluid replacements must consider obligate fluid losses such as urine production, gastrointestinal losses, skin and respiratory losses, and basal metabolic requirements.[97] A weight-based algorithm (4-2-1 rule) is used to calculate fluid needs. One-quarter normal saline is usually appropriate in newborns. One-half normal saline can be used in children over 2 years old as their renal function approaches that of adults. The addition of dextrose is necessary in young children as hepatic glycogen stores are limited and must be supplemented.

Hypovolemia and Hemorrhage In children and adolescents, severe illness can result in hypovolemia, and injury can result in considerable blood loss.[98] The evaluation and management of circulation in the pediatric patient includes recognition of circulatory compromise and the principles of resuscitation with crystalloid and blood products. In children and adolescents, the primary response to hypovolemia, whether from severe illness or hemorrhage, is tachycardia (Table 15.4): Systemic Responses to Blood Loss in Pediatric Patients. Normal vital functions by age group are listed in Table 15.5: Vital Functions. Compensatory mechanisms, that is, vasoconstriction, are robust in the child and can mask the hypoperfusion and decreases in blood pressure typically seen in the adult with hypovolemia and hemorrhage. This compensation may result in a false sense of stability until much later in the clinical course. Hypotension in the pediatric patient should be treated aggressively. When shock is suspected, fluid resuscitation with boluses of 20 mL/kg of a balanced crystalloid solution is titrated to clinical response of heart rate, urine output, capillary refill, and level of consciousness as monitors of cardiac output. There is no data to support colloid over crystalloid infusion based on mortality difference. Failure to improve hemodynamic abnormalities following initial crystalloid resuscitation, particularly in the setting of trauma, raises the suspicion of hemorrhage and prompts the need to consider administration of warmed packed red blood cells (type specific or O negative in 10 mL/kg aliquots).[98] Normalization of heart rate, capillary refill <2 seconds, normal pulses and warm extremities, urine output (>2 mL/kg/h for infants, >1.5 mL/kg/h for younger children and >1 mL/kg/h for older children),

TABLE 15.4

SYSTEMIC RESPONSES TO BLOOD LOSS IN PEDIATRIC PATIENTS

■ SYSTEM	■ MILD BLOOD VOLUME LOSS (<30%)	■ MODERATE BLOOD VOLUME LOSS (30%–45%)	■ SEVERE BLOOD VOLUME LOSS (>45%)
Cardiovascular	Increased heart rate; weak, thready peripheral pulses; normal systolic blood pressure (80–90 + 2 × age in years); normal pulse pressure	Markedly increased heart rate; weak, thready central pulses; absent peripheral pulses; low normal systolic blood pressure (70–80 + 2 × age in years); narrowed pulse pressure	Tachycardia followed by bradycardia; very weak or absent central pulses; absent peripheral pulses; hypotension (<70 + 2 × age in years); widened pulse pressure (or undetectable diastolic blood pressure)
Central Nervous System	Anxious; irritable; confused	Lethargic; dulled response to pain[a]	Comatose
Skin	Cool, mottled; prolonged capillary refill	Cyanotic; markedly prolonged capillary refill	Pale and cold
Urine Output[b]	Low to very low	Minimal	None

[a]The child's dulled response to pain with this degree of blood loss (30%–45%) may be indicate by a decreased response to IV catheter insertion.
[b]After initial decompression by urinary catheter. Low normal is 2 mL/kg/h (infant), 1.5 mL/kg/h (younger child), 1 mL/kg/h (older child), and 0.5 mL/kg/h (adolescent). IV contract can falsely elevate urinary output.

and normal mental status are the endpoints of resuscitation for the pediatric patient with hypovolemia or hemorrhage.[98] Due to the high ratio of body surface area to BM in children, limited subcutaneous fat and thinner skin, the resultant increase in heat exchange with the environment leads to hypothermia. External warming efforts, such as warm resuscitation room, heat lamps, and warm blankets in addition to internal warming fluids should be employed. In the setting of severe hypovolemic shock, venous access is paramount and is preferably established peripherally. If unobtainable, intraosseous infusion via a bone marrow needle (18 gauge in infants, 15 gauge in young children) or femoral venous line is appropriate.

Specific Considerations

Trauma Injury is the most common reason for an ED visit for a child. Motor vehicle-associated injuries, whether the child is occupant, pedestrian, or cyclist, are the most common causes of injury death in children of all ages. Drowning, fire, abuse, and falls are all important causes of injury in pediatric patients. The principles of trauma management follow the standard put forth in the ATLS™ and PALS courses.[98,99] Head injuries are the most common cause of death and long-term disability in the pediatric trauma population. Hypotension and hypoxia from associated injuries will have an adverse effect on outcome associated with intracranial injury. Thoracic injuries in children are uncommon (only 8% of all injuries) but should serve as a marker for other organ system injury. Rarely do injuries in the chest require operative intervention. In abdominal trauma, single and even multiple solid organ injury can be managed nonoperatively if the child is hemodynamically stable without signs of peritonitis. Spinal cord injury is fortunately uncommon in children with only 5% of all spinal cord injuries occurring in the pediatric age group. The management of skeletal trauma in the child is similar to that for the adult. However, due to the potential for injury of the growth plate, management will often require consultation with an orthopedic surgeon familiar with these injuries. Special attention must be given to the possibility of nonaccidental trauma (i.e., child abuse) in the evaluation of all children suffering injury, trauma, and burns.

Triage is essential to effective functioning of regional trauma systems and to the proper care of the injured patient. The Pediatric Trauma Score (PTS) is an adaptation of the Revised Trauma Score (RTS) and used often to triage pediatric trauma patients to the appropriate trauma center.[100] The RTS is based on physiologic measurements on initial evaluation including blood pressure, respiratory rate, and Glasgow Coma Scale. The PTS is the sum of the severity grade of each category (weight, airway, blood pressure, level of consciousness, fracture, and wounds). The PTS reliably predicts the potential for death and severe disability. In general, injured children with a PTS less than 8 should be triaged to an appropriate pediatric trauma center, because of high potential for mortality and morbidity.

Surgical Emergencies Both congenital and acquired conditions can result in emergency surgical disease. Many neonatal surgical emergencies, such as (congenital diaphragmatic hernia and abdominal wall defects, etc.) are diagnosed *in utero* allowing planned postnatal care. Other newborns may present with surgical emergencies such as necrotizing enterocolitis or intestinal atresia, and the oncall emergency surgeon may be consulted to evaluate these infants. Malrotation causing midgut volvulus is perhaps the most feared abdominal emergency presenting in the newborn period. Malrotation occurs in 1:100 to 1:500 live births with most patients (90%) presenting within the first year of life.[101] Bilious emesis is the most common presenting symptom (93%) and should prompt expeditious evaluation and surgical consultation.[102] Bilious emesis and other signs of obstruction in infants warrant immediate investigation and consultation as delays in diagnosis and treatment threaten intestinal viability. Plain films of the abdomen may give information on the bowel gas pattern but cannot exclude the possibility of malrotation or volvulus. A contrast study to confirm normal positioning of the ligament of Treitz and retroperitoneal course of the duodenum is the gold standard for assessment. If symptomatic malrotation is present, after expeditious resuscitation, the child is taken to the operating room for a Ladd's procedure. A Ladd's procedure involves reduction (counterclockwise detorsion) of the volvulus (if present), division of abnormal peritoneal attachments or Ladd's bands, broadening of the mesentery, and appendectomy. Frankly necrotic bowel should be resected with anastomosis or diversion based on the stability of the child. If the viability of the bowel is uncertain, temporary closure and planned second look at 24 hours is recommended. The bowel

is returned to abdomen with the cecum and colon in the left hemiabdomen and the small bowel in the right.

Acute appendicitis remains the most common surgical emergency in children. Obstruction of the appendiceal lumen by fecalith or lymphoid hyperplasia is thought to lead to appendiceal distention, venous congestion, edema, and finally ischemia. Delay in treatment can lead to perforation, peritonitis, and abscess. The diagnosis of appendicitis in the pediatric patient can be particularly challenging due to the inability of the child to accurately express the classic signs or symptoms associated with appendicitis. As such, appendiceal perforation at the time of presentation is not uncommon in young children. Clinical symptoms of pain, malaise, nausea, and vomiting are matched with findings of fever, leukocytosis (white blood cells >12,000/mm^3), and C-reactive protein > 3 mg/dL in distinguishing appendicitis from other diagnoses in pediatric patients who present to the ED with abdominal pain.[103] In addition, right lower-quadrant abdominal ultrasound is a useful screening tool with a negative predictive value of 95%, and in the case of an indeterminate ultrasound or diagnostic uncertainty, abdominal CT should be employed.[104] Alternatively, for patients with an unclear clinical picture, hospital admission and reexamination is recommended. The treatment of acute appendicitis is appendectomy. Guidelines for antibiotics in pediatric patients with acute appendicitis recommend a single dose of preoperative broad-spectrum antibiotics for nonperforated appendicitis that is to be treated by appendectomy.[105] The intraoperative findings will help determine the choice of antibiotics, route of administration (intravenous or oral), and duration of therapy postoperatively. Initial nonoperative management of perforated appendicitis with IV antibiotics, percutaneous drainage of abscess where appropriate, and interval appendectomy (at 6 weeks) showed no improvement in outcomes with regard to total hospitalization, recurrent abscess rates, or overall charges when compared to initial laparoscopic appendectomy.[106] However, interval appendectomy may prove beneficial in selected cases of complicated appendicitis. Antibiotics are continued as clinical parameters such as fever, pain, leukocytosis, and bowel function are followed. Laparoscopic appendectomy is becoming the preferred procedure in children despite a slight risk of postoperative abscess requiring drainage.[107] Open technique remains the approach in complicated appendicitis or if the surgeon cannot safely complete the laparoscopic operation.

Inguinal hernias are present in 1%–3% of newborn males, in females less so. Problems related to inguinal hernias are a common reason for ED evaluation. Incarceration and strangulation are uncommon but may have severe consequences. Longer wait times for elective repair of inguinal hernia in infants and young children are associated with an increased risk of incarceration.[108] Additional risk factors for incarceration are age <1 year, female sex, and ED visit. In cases of incarceration, attempts at reduction are indicated for those infants and young children who do not manifest signs or symptoms of peritonitis or scrotal erythema.[109] To reduce a hernia, steady, gentle manual pressure is directed along the canal for several minutes to reduce the contents back through the external and internal inguinal rings and into the abdominal cavity. Judicious use of sedation can be useful in reduction efforts. There is limited literature on the clinical practice of sedation and analgesic medication use for nonoperative reduction of incarcerated inguinal hernia.[110] For children <1 year of age, or in cases that are particularly difficult to reduce, hospital admission and nonemergent hernia repair during the same hospitalization are recommended. If reduction is unsuccessful, emergency operation to reduce the hernia contents and close the sac is undertaken. In cases with suspected bowel ischemia or necrosis, a thorough assessment of the bowel is necessary. Gangrenous bowel should be resected with primary anastomosis possible

in most cases. If the hernia contents reduce without inspection and there is concern regarding the viability of the intestine, further assessment should be performed either by abdominal exploration or laparoscopy. Umbilical hernias are very common in young children. Unlike inguinal hernias, however, most spontaneously close before 4 years of age. As such, surgery prior to this time is generally limited to those patients with incarceration or strangulation. Such complications are rare but mandate urgent exploration and repair.[111]

Intussusception is a common cause of intestinal obstruction occurring in young children. There is a slight male predominance (3:2 male to female ratio), and most occur between 3 months and 3 years of age. Often an episode of gastroenteritis or viral syndrome will precede the presentation of episodic ("colicky") abdominal pain. The prodromal illness is postulated to cause intestinal lymphoid hyperplasia that, in turn, acts as a lead point with the invagination of a proximal portion of the intestine (intussusceptum) into the distal portion (intussuscipiens). Initial management is directed at fluid resuscitation. Abdominal radiograph suggestive of free air or evaluation consistent with peritonitis warrants abdominal exploration. The majority of intussusceptions are ileocolic and can be diagnosed and managed with air or contrast enema. Ultrasound has also been advocated for diagnosis of intussusception. The classic "target" sign is diagnostic. Radiologic reduction can then be attempted and ultrasound used to confirm a satisfactory result. Radiologic reduction is successful in the vast majority of cases. When radiologic attempts at reduction are unsuccessful, abdominal exploration is warranted. Depending on the level of comfort of the surgeon, such cases can be performed laparoscopically or open.[112] Necrotic segments of bowel or bowel that cannot be reduced in the operating room should be resected. The choice of anastomosis or diversion should be based on the clinical status of the patient. Much less commonly, the intussusceptions involves just the small bowel. Symptomatic small-bowel intussusceptions are often seen in the postoperative setting and typically require operative reduction. Asymptomatic small-bowel intussusception may be observed as an incidental finding and does not mandate intervention.

Ovarian torsion is an infrequent cause of abdominal pain in girls, and may be confused with other conditions.[113] Among females age 1–20 years, there is an estimated 4.9/100,000 incidence of ovarian torsion, and more than 50% of the patients will require oophorectomy.[114] Nonspecific abdominal pain, nausea, and vomiting occur most frequently, and up to 10% of patients may have a palpable abdominal mass. WBC and CRP values are lower in ovarian torsion than in appendicitis. Ultrasound is beneficial in diagnosis and for determining the adequacy of blood flow to the torsed ovary. CT scan can also help when presentation and ultrasound findings are not definitive. Laparoscopy is the surgical procedure of choice as it aids in the diagnosis of abdominal pain of unclear etiology and can effectively accomplish detorsion of the ovary.[115] In cases of uncertain viability of the ovary, detorsion and planned second-look laparoscopy is of value. Preservation of any ovarian tissue is desirable.

Testicular torsion is most common in adolescent males and requires urgent diagnosis and management.[116] Acute onset and short duration of pain (<6 hours), high-riding testicle, and loss of cremasteric reflex are all associated with testicular torsion. Ultrasound is frequently used to confirm diagnosis; however, if doppler sonography and clinical exam are unreliable, all children presenting with acute scrotal pain in whom testicular torsion is suspected should undergo scrotal exploration.[117] Salvage rates approach 95% if operative detorsion and orchiopexy is performed within 6 hours. Neonates are best served with inguinal incisions as an associated hernia or tumor might be present. A transscrotal incision along the midline raphe is appropriate in

older children unless preoperative assessment raises suspicion for testicular malignancy or incarcerated hernia. If the testicle is not viable, an orchidectomy should be performed. The detorsion technique follows the rule that the torsed testicle is twisted toward the midline along the axis of the spermatic cord. As such, detorsion reverses this process. If the testicle is successfully detorsed and regains viability, it should be appended to the wall of the scrotum. Likewise, through the same midline incision, the contralateral testicle should be sutured to the wall of the respective hemi-srotum to prevent torsion.

CHAPTER 16 ■ PREHOSPITAL TRAUMA CARE

NORMAN E. MCSWAIN JR

This chapter is divided into two parts: the first is what the acute care surgeon (ACS) needs to know about the care provided to the patient before the patient arrives in the hospital and the second is a kinematics discussion for understanding the mechanism of injury (MOI). In the best of Emergency Medical Services (EMS) systems, the prehospital providers manage the injured patient for at least the first half of the proverbial "Golden Hour." It is the responsibility of the ACS to make sure that these providers understand the care of the trauma patient during this critical time period. This care may ultimately determine the outcome for the injured patient. The ACS must teach these principles to the person caring for his or her patient in the field.

Patient care begins when the first person reaches the patient. It does not start when the patient arrives in the hospital. From his experiences in the Spanish American War, Dr. Nicholas Senn, the 49th president of the American Medical Association, surgeon general of the Wisconsin National Guard, and founder of the Association of Military Surgeons stated *"The fate of the wounded rests in the hands of one who applies the first dressing."* He was probably quoting the German physician, Johann Nepomuk von Nussbaum from the early 1800s.[1]

If physicians believe that the care in their particular community in the prehospital period is not good, then they have the duty to teach the prehospital providers the correct methods.

The American College of Surgeons endorsed PreHosptial Life support (PHTLS) training, which is an excellent example of a physician–prehospital provider educational collaboration.[2] Involvement with this educational program will go a long way to achieving these educational goals by the ACS.

The philosophy of the continuum of care, which begins in the field and continues to rehab, is an important part of the ACS's career. The ACS must ensure that the prehospital provider provides this management for trauma patients before they get to the emergency department (ED). Mismanagement in the first 30–90 minutes of care and when the patient is with the prehospital provider is critical to the outcome. It is perhaps more critical than the care provided in the ED. "The die is cast" if the prehospital care is not good.

This chapter addresses the important points of the prehospital provider's training and education. Although there are several providers who care for the patient in many locations, the goals of patient care should be the same, but the steps are different. *There is one patient with the same disease in the same condition who requires the same care by different providers using different skills at different locations* (Tables 16.1 and 16.2).

Each of these providers has different skills, different resources, and different short-term goals. They each provide *definitive care* in the situation that they encounter the patient (Table 16.3).

The aim is to provide definitive/appropriate care for the patient as quickly as possible in each individual area and then move to the next area; for example, for the patient who is acidotic in the ED with uncontrolled hemorrhage, the *definitive emergency department is for hemorrhage control*. This patient needs to be in the Operating room (OR) for hemorrhage control with clamps and ligatures (factor XIV). Keeping the patient in the ED to give crystalloids, factor VII, factor IX, prothrombin clotting complex, or to get additional images such as the CT, is inappropriate. The patient needs to be either in the OR or in the interventional radiology suite with 10 minutes in the ED for the beginning resuscitation. The patient now needs to move on.

The same concept applies to the prehospital environment. For the patient with uncontrolled hemorrhage or potential uncontrolled hemorrhage, *definitive field care* is rapid movement of the patient to the hospital after control of all visible hemorrhage. The steps are appropriate airway and ventilation management, control of external hemorrhage, packaging for transport, and rapid movement to the trauma center. The patient does not need detailed secondary survey in the field. This can be done during transport if time allows or can be deferred if the transport time is short. Correct *definitive field care* is getting the patient to a setting where hemorrhage control (damage control surgery) and restoration of energy production are aerobic with metabolism (damage control resuscitation), and can be done as quickly as possible. In the urban areas, this means bypassing a nearby community hospital to go to a trauma center.

It does not mean overloading the patient with crystalloid. Hypotensive resuscitation is the correct management in the field and in the hospital until hemorrhage control can be obtained.

The term "scoop and run" is an incorrect process and should never be the correct method of patient care either in the ED or in the field. This term implies that no care is provided for the patient when transport to the next level of care is imminent. For the prehospital provider, "scoop and run" means placing the patient on the stretcher and racing at high speed to the closest hospital. This method of patient care began to disappear when Dr. J.D. "Deke" Farington wrote his paper entitled "Death in a Ditch," which was published in the Bulletin of the American College of Surgeons in 1967[3] (Box 16.1). Fortunately for the trauma patient, such an approach to patient care no longer exists in most of the United States. Unfortunately, this process continues to exist in many third world countries, usually due to a lack of proper trauma education for prehospital providers and lack of funding to provide this education. Just as "scoop and run" is the worst possible approach of addressing the patient's needs, equally poor is attempting to address all of the patient's needs in the prehospital arena either in the field or in the back of the ambulance.[4] The judgment of the provider based on an understanding of the patient's needs will define the extent of the field care.

The question for the Emergency Medical Technician (EMT) to answer is "what is best for the patient" and "where can this care best be provided." In the management of any patient, one has to consider the needs of the patient and the ability of the provider to address those needs at a given time and a specific place where the patient currently is located. The provider should assess the patient and provide care according to the situation, the condition of the patient, the abilities of the provider, and the resources available at the scene. This is addressed by understanding principles and preferences. A principle is the specific medical needs of the patient. The preference is how the provider can best address such needs.[5] (Table 16.4)

The foundation of patient care is based on certain principles of identification and management of the patient's condition.

TABLE 16.1
CONTINUUM OF CARE

- Begins in the field
- Location of care
  - Field
  - Transportation
  - Emergency Department
  - OR
  - ICU
  - Floor
  - Rehabilitation
- Ends when return to full activity

The preferences of how these principles are accomplished are based on the following four separate concepts: (1) the *situation* the patient and the provider are in at the time of their interaction, (2) the *condition* of the patient, (2) the *skill and knowledge* of the provider, and (4) the *equipment, resources, and supplies* that the provider has to work with at the time.

As an example, the principle is that the airway must be opened. The preference is how it is to be opened. Multiple options are available to the EMT: jaw lift, jaw thrust, nasal airway, oral airway, endotracheal tube, and cricothyrotomy. Scene conditions, situation, and patient condition will dictate which airway option is utilized. An unruly crowd on scene or hazardous weather conditions outside may dictate a rapid, basic-level airway, such as an oral airway or bag valve mask (BVM). This may change in the ambulance with more protection for the patient and the providers. The situation may change more in the ED with different equipment and skills for the provider.

The EMTs in the prehospital arena must be trained with the skills to manage the patient appropriately in a field setting.

The principles are the same, but there are different preferences depending on where the patient is located (Tables 16.3 and 16.4).

Besides principles and preferences, the other concept that requires understanding is definitive care of the patient in the field for the specific patient. Definitive field care will vary depending on the etiology. A patient with *cardiac arrest* needs definitive care of restoring the rhythm and cardiac output. This can be done in the field at the paramedic level.[6] A diabetic patient can be managed definitively in the field using glucose

or insulin. A severe trauma patient most likely is suffering from hemorrhage. The hemorrhage cannot be managed in the field definitively. The patient must be transported as quickly as possible to an appropriate facility that can provide such care. The care that might be required is an expedient celiotomy to control the hemorrhage. In the urban setting, the arena for this definitive management is the trauma center that has the availability of trauma surgeons, emergency physicians, operating rooms, and a blood bank. These are the essential components. Just as it is incorrect for the EMS provider to spend more than 10 minutes in the field with a critical hemorrhaging patient, so is it incorrect for this same patient to stay more than 10 minutes in the resuscitation room.

In the rural setting, there is usually no hospital with an immediately available surgeon, operating room, and blood bank. The hemodynamically compromised patient should go to a trauma center in the urban area, but in the rural area, to the closest appropriate facility for stabilization of definitive management. EMS is a critical component of the health care network. Triage is an essential feature of prehospital care. Approximately 5% of the patients that are injured require the facilities of a trauma center. A well-trained provider has the knowledge to understand the patient's specific condition and understand where the patient can best get the most optimal care.

RURAL TRAUMA ORGANIZATION SYSTEM

Trauma care in the rural communities has been less than that available in the urban area for two major reasons: (1) lack of money to equip staff and train the hospital and EMS personnel and (2) skill deterioration in both groups with lack of severe trauma care experience in the smaller hospitals.

BOX 16.1
DEATH IN THE DITCH[3]

"Come on fellow, we'll take you and your wife to the hospital."

He was pulled from the car, placed on a stretcher, and carried to the ambulance.

Ruth soon was placed on a similar rig. The door was slammed closed and the driver and his helper got into the front seat. The ambulance leaped forward with a screech from the tires and a shriek from the siren.

TRAUMA DESIGNATION PROTOCOLS

- Directly to the trauma center from the field
  - ACS anatomic or physiologic injuries
  - CDC Revised level 1, 2 or 3[8] Bypass all hospitals unless
    - Time of transport >50 min
    - Airway problem that EMS cannot handle in the unit
    - Severe shock and needs blood or plasma during transport
    - DOA

- MOI alone to closest appropriate facility

- Patient choice does not count for bypass to trauma center

- Any patient short stopped is immediately accepted by trauma center when problem is solved

- Trauma center does not go on diversion unless;
  - Mechanical or electrical difficulties

Three trauma patients require simultaneous OR

Staff and equipment availability will always be difficult in the rural communities but the training is available to improve competence when the patient does present for care.

The first step in proper management is appropriate *field triage* and transport of the patient to the appropriate hospital. This must be coupled with an assessment of the strengths of all the hospitals in an area with appropriate bypass or delivery of the patient to the correct facility. Part of the well-developed regional trauma system is an agreement among the hospitals involved to accept the patients when presented and to either treat or stabilize those patients and quickly move them to the appropriate facility.

Such a rural trauma system could be modeled after the Joint Theater Trauma System (JTTS) Military Echelon Casualty management system.[7] Patients are taken to facilities dedicated to a specific level of care. When that care has been achieved, the patient is moved on to the next level. An example of this system in action is military personnel seen by medics (Echelon 1) and taken to an Echelon 2 facility where damage control surgery (DCS) is done (hemorrhage control only) and damage control resuscitation is initiated. The patient is sent directly from the OR to an Echelon 3 facility where definitive care is provided (or the second step of DCS). Within 24 hours when the patient is still in the ICU, he or she is moved to an Echelon 4 facility for additional definitive care if needed. Finally within 4–6 days of the injury, the patient is moved to the United States for follow-up care and rehab.

Approximately 10% of civilian injured patients will need assessment in a trauma center. The other 90% should be assessed and treated in the rural community hospital. About 80% of the patients with MOI alone will be discharged within 6 hours of admission into the ED. Of the remaining 20%, almost all will have orthopedic injures that also do not require the expertise of the trauma surgeon and can be better served by providing treatment close to the patient's family and home. Stated differently, MOI alone is not adequate reason for transporting a patient to a trauma center. These patients should be treated in the appropriate rural or regional hospital. This will also ensure financial support to the local community and community hospitals. The patients, who may require the expertise and resources of the trauma center, can be assessed in the community hospital and then transferred to the trauma center, if necessary. The additional benefit of this type of triage will prevent an overload in the trauma center with patients, who can easily be treated elsewhere (Table 16.5). It is the responsibility of the rural area to understand the resources in the various hospitals and to triage and transport patients to the appropriate hospital.

CONTINUUM OF PATIENT CARE

Patient care should be a continuum from the time the first person sees the patient until the patient is discharged to home. There should be interlinking of the various locations and individuals who provide the care, with prehospital care being an important component of this continuum. The prehospital assessment and care will vary depending on the condition of the patient. A 4 minute ride to the hospital, a 40 minute ride to the hospital, and a 4 hour ride to the hospital are vastly different rides and will require different judgments based on the knowledge[2] of the prehospital providers.

Priorities include initial airway management and ensuring adequate ventilation, and if possible, control of hemorrhage. External extremity hemorrhage is controlled with direct pressure and if that fails, then by tourniquet application. Torso hemorrhage control process in the field is only superficial pressure ; therefore, the optimal management is to get the patient to surgical care as quickly as possible. Fracture stabilization is next in priority and intravenous access/resuscitation can often be initiated en route to the hospital.

Patient care is provided based on principles, and these principles must meet the needs of the specific patient involved and the medical conditions present. Situation and available resources impact this decision. The prehospital provider makes a *judgment based on this knowledge*.[2]

Although the situation and location of patient care varies, the same basic process and the same attention to quality care exist throughout. There are unique steps, procedures, and techniques that are required to appropriately manage the patient in the prehospital arena—just as there are in the ED, the operating room, or other areas of patient care. This is the continuum of care through the time from injury to discharge. The basic concepts originate from the Advanced Trauma Life Support (ATLS) guidelines: primary assessment, resuscitation, secondary assessment, and definitive care. The degree of detail, the specific procedures, and the training of the providers will vary in each step according to the needs of the patient and the situation in which care is provided. The *ACSs* understand this concept and how they mesh in each situation to provide the best care for their patients.

HISTORY

The history of prehospital care, as the history of trauma, has chronicled major advances during active times of war. Those steps have been enhanced in times of peace (Tables 16.6 and 16.7).

The origin of prehospital care is credited to Baron Larrey, Napoleon's surgeon. He first recognized that leaving a patient for 3–30 days in the field with his or her injury was not in the best interest of the patient nor of their General (Napoleon). Therefore, he devised a system of rapid response in the field, with the rapid transport of the patient to a close medical facility to provide care. Care was provided both in the field and en route to the hospital with well-trained individuals. This remains the fundamental hallmark of prehospital care in the 21st Century: (1) rapid response to the field, (2) well-trained personnel who provide care in the field and en route to the hospital, (3) rapid transport of the patient to an appropriate hospital, (4) hospital near the site of injury, and (5) well-trained personnel in the hospital to provide care. With increasing emphasis on prioritization of management and with the advancement of patient transport systems, prehospital care continued to evolve.

  - Advanced care en route to the next medical care
  - Damage control surgery
  - Damage control resuscitation
  - Military Echelon of Casualty Management
  - Tourniquets/hemostatic agents
  - Interosseous vascular access
  - Permissive hypotension

These principles were lost in the early years of the War Between the States (1861–1865). In the first battle of Manassas (Battle of Bull Run), July 1861, injured patients were left in the field for up to 7 days before being transported. In addition, the transferring personnel were poorly trained. Medicinal alcohol was used liberally, and overall patient care was generally poor. This defect was addressed and changed by Jonathan Letterman (1824–1872) when he was made the commandant of the medical teams and they moved from the Quartermaster Corps to the Medical Corps.

PREHOSPTIAL TIME

R Adams Cowley, MD, the founder of Maryland Institute of EMS (MIEMS), developed the slogan "the golden hour" to emphasize the importance of getting a patient to definitive hospital care as soon as possible. While the 60 minute timeline should not be interpreted literally, emphasis should be placed on expeditious and effective care in order to adequately address severe injuries and critical illness. The need to move quickly for patients needing torso, extremity, and neck hemorrhage control is critical.[9]

Prior to the mid 1980s, when Dr. Crowley demonstrated the importance of a trauma center for providing timely management, the concept of limited time in the field was not well understood based on the "Golden Hour." The prehospital scene care and transport can be as little as 10–12 minutes in a well-run metropolitan EMS system or 25–30 minutes in a well-run suburban system. In the rural setting, the transport times can be hours after the initial traumatic event occurred. Prehospital time can be even longer in a wilderness setting. During this period of time, significant pathophysiologic changes can occur, resulting in deterioration of the patient's physiologic state, which can negatively affect survival, or create complications or long-term disability.

Similarly, delay should not occur in the ED for unneeded assessment or in opening the abdomen in the ED. Directing this process is the responsibility of the ACS.

PREHOSPITAL EDUCATION AND SURGICAL CONTROL OF PREHOSPITAL CARE

Once in the surgeon's hands and in the hospital, the outcome for the patient can be substantially affected by the care, or lack thereof, that occurred in the field. For this reason, *the complete trauma care of the patient, both before and after arrival in the hospital, must be **under the control of the surgeon***. This is from the instant the injury occurs until the patient is discharged from the hospital. This is the important continuum of trauma care. Fragmentation of patient care by a committee of providers is not in the best interest of the patient. Each may have a different perspective. Someone must be in charge.

For the surgeon to be involved in the prehospital care does not mean that the surgeon must be physically present in the field physically on every run. However, the surgeon must be present philosophically in the field by being involved in the education of the prehospital provider, understanding what happens in the field, engaging in quality assurance, and having confidence in the EMTs' ability and skill. The EMTs must appreciate this presence. This is achieved by (1) spending time with them, providing education both in the ED and in their classroom experiences, and (2) riding with them on the street and understanding the conditions under which they carry out their responsibilities in the field, working with the EMS committee of the medical society or the trauma center. This does not negate the responsibility of the emergency medicine physicians' involvement in EMS.

PREHOSPITAL CARE SYSTEM

Prehospital care is divided into two distinct components: (1) the EMS system and (2) the physiology, pathophysiology, and management of the trauma patient in the field. The same components are used in the hospital but in a different environment, that is, prevention of anaerobic metabolism by assuring oxygen of the RBC in the lung with delivery of those RBCs to the tissue. A major part of this process is hemorrhage control in the hospital environment. After all, "trauma is a surgical disease from beginning to end."[10] The ACS must understand and appreciate both components of care in the field, just as s/he must understand the hospital system and the physiology, pathophysiology and management of patient care in order to function effectively.

From the beginning of a surgeon's education in medical school, the day-to-day system in which the ACS functions in the hospital becomes apparent in the form of surgical schedules, patient admission, QA processes, peer review, morbidity and mortality conferences, and management of patient records including discharge summaries and operative notes. Such system information and much of the clinical/scientific information in the realm of prehospital care are often not taught to the surgeon in training. In order to ensure optimal patient care, it is imperative for the ACS to understand all of the key elements of the prehospital network and be involved in their teaching.

EMS SYSTEM AND PERSONNEL

An EMS system is to EMS and the EMT as the hospital is to medicine and the individual physician. It is the EMS system that provides a "home" for the EMTs, supervision of their function, quality assurance of their practice, delineation of their privileges, definition of their scope of practice, and financial support of the organization to provide patient care. But it does even more. The EMS system allows the hospital to get the critical and debilitated patients into the ED. Greater than 40% of the hospital admissions come through the ED. Patients would somehow get to the ED without EMS but not with the appropriate care en route and not to the correct hospital that is prepared to handle their specific problem.

The key to running an effective EMS system is strong physician oversight and quality control with attention to the details of patient outcome, skill utilization, skill success, proper judgment, and of the run report analysis.

Initially, there was only the EMT-A (Ambulance) certification available. In the early 1970s, the U. S. Department of Transportation codified the EMT into three levels, which with some small exceptions and modifications are the national standard of the 21st century. These are the EMT-Basic, EMT-Intermediate, and EMT-Paramedic. These have been abbreviated into EMT-B, EMT-I, and EMT-P. Many discussants further abbreviate this to use the term "EMT" meaning the basic EMT and "paramedic" meaning the EMT paramedic. Further references will utilize the terms EMT-B, EMT-I, and EMT-P and for the individual levels, EMT as a generic term indicating all three levels.

EMT-B

The EMT-Basic has completed a minimum of 110 contact hours of training following the objectives as outlined in the U. S. Department of Transportation's (DOT) National Standard Curriculum and tested either by the National Registry for EMTs or the individual state license exams or both. Depending on the state, reregistration is required every 2–4 years to maintain that license. Each state has varying criteria for this reregistration. EMS runs are approximately 1/3 trauma, 1/3 medical, and 1/3 cardiac. The EMT-B training program is divided essentially along these lines with emphasis on life- or limb-threatening injuries such as cardiac arrest, airway problems, childbirth, hemorrhage control, fracture immobilization, and seizures.

Additional training includes defensive driving, utilization of communication systems, ethics, legal issues, and run report writing.

EMT-I

The EMT-Intermediate has been trained to the level of an EMT-B, frequently has 1 or 2 years experience on the streets functioning as an EMT-B and takes approximately 200 hours of additional education, which includes IV fluid administration, advanced airway management, automatic defibrillation and in some states, limited use of drugs.

EMT-P

The EMT-Paramedic is trained with an increased emphasis on the utilization of cardiac drugs, medication for pain control, airway assistance (RSI in some systems), and seizure management. The drugs on the EMS unit usually consist of advanced blood pressure cardiac medications, glucose and insulin for the management of diabetic patients, pain and seizure medication, which would include morphine, a sedative, rapid sequence intubation (RSI) drugs and, perhaps, fentanyl or ketamine. The training program to reach the EMT-P level varies from state to state, but it is traditionally in the range of 1,000 to 1,200 hours in addition to the EMT-I. This includes not only didactic lectures, but time in various patient care areas, in the hospital such as the operating room, ER, ICU, and a

supervised field internship. At the completion of the training program, the student takes the state examination, the examination of the National Registry of EMTs, or both to obtain a license to function at the ALS level. Reregistration to maintain this license is required every 2–4 years depending on the state. The reregistration depends on sustainment education in trauma, cardiac, and medical conditions, as well as skill demonstration and practice such as IVs and endotracheal intubation and a backup airway.

A growing number of EMS services throughout the United States are utilizing RSI with drug control, for airway management. Research results of the use of RSI in the field have been mixed, with respect to effectiveness; it is believed to be less effective with shorter transport time.

EMT-PARAMEDICS WITH A PHYSICIAN

There is a fourth level of care that is used by some systems in the United States and Canada, which is with a physician as part of the medical response system. Much literature in North America has indicated that the use of a physician prolongs the EMS run, delays transports, and has a negative impact on outcome. However, in Central and South America, many services rely on physicians to provide field care. In Europe, many services use only nurses for prehospital care.

Many systems in the United States in the early 21st century have begun to have a physician riding the streets with a supervisor. This physician provides radio medical control, medical supervision, and education on the scene, and adds to the quality assurance process. This type of arrangement has been thought to be effective especially in the urban areas for immediate and retrospective medical control (see below) as medical director (this is usually an emergency medicine resident), and responds to scenes on an ad lib basis, and some systems, usually not in the United States, have a full-time physician assigned to the ambulance.

COMMUNICATIONS

Prehospital communication systems are divided into two major categories:

1. Dispatch/administrative communications with the EMS system control
2. Medical communications with the hospital or physician

In the United States, most of the EMS dispatch is done by an emergency citizen access arrangement, using the 9-1-1 patient access phone number. The communication arrangement may be separated into police, fire, and EMS, but some communities combine fire and EMS. Other communities combine law enforcement and EMS. There are some communities, especially in rural areas, in which all three components are combined into one unit. Other countries have a similar communication system, but a different phone number.
Regardless of the system used, the function is

> *Notification*: to receive a phone call from a patient, a family member, or a bystander and identify the type of call
> *Dispatch*: to send the appropriate vehicle and personnel and provide assistance by the telephone to the caller while the ambulance is en route
> *Scene*: to survey the scene (see scene survey below), identify additional resources or backup that are required, notify the dispatch of such needs, begin to address patient care, and get the patient ready for transport to the hospital

> *Transport*: to ensure movement of the patient to the correct hospital for care of the condition(s) found

Urban EMS response times are highlighted in Table 16.8. It is clear from the table that even the best of systems use half of the "Golden Hour" in the field. The assessment and transport times will change based on the density of the population and the difficulty of the terrain.

AeroEMS (AEMS) has been used with questionable results to address the needs of rural America. Unfortunately in the United States, the AEMS has been frequently overused. Both patients and the AEMS personnel have suffered death. It is possible to set up a good aeromedical triage process[11], but most medical directors and AEMS systems refuse to accept that responsibility.

A medical communication system can be set up utilizing a cell phone or radio communicating to a hospital and the medical control physician. Both systems are used by some services. Medical communication has three components:

1. Notification to the hospital of the patient's condition and the expected time of arrival
2. Transmission of electronic data, which may be beneficial to the hospital either to prepare for the arrival of the patient or to enhance the care of the patient while en route (Electrocardiogram are commonly used, but photos have their supporters)
3. Medical control physician or a trained nurse to alter care from the usual guidelines that have been developed for the EMS system and provide specific care for a specific patient

The transmission of electronic data, such as EKGs, has been found to be of limited use. Training of the EMT to read the EKGs and to provide care on previously developed protocols by the EMS system have been found to be much more effective. This is another example of providing an EMT with knowledge and allowing appropriate decisions to be made in the field.

Most systems now have fairly in-depth guidelines that direct EMT care without the need to contact the hospital for initial orders. Further orders and advanced medical directions can be utilized and are especially helpful with long transport times such as in rural areas or with the use of arrow medical transportation systems.

A statewide system, rather than a local one, has many advantages and improves survival. (13)

PROTOCOLS VERSUS STANDING ORDERS

The terms "protocols" and "standing orders" have produced much misunderstanding and confusion since the early days of EMS, when these terms were not properly defined. The definitions in current use are as follows:

- *Standing orders* describe the initial care (and occasionally follow-up care) *prior to* communicating with medical control.

TABLE 16.8

URBAN EMS RESPONSE TIMES

Notification	2–3 min
Assessment	3–8 min
Scene time	5–10 min
Transport	3–8 min
Ideal total prehospital time = ≤30 min	

- *Protocols* are strict orders developed by medical control as to how to provide patient care. The EMS personnel are not allowed to modify them based on the situation, conditions, or other variables on the scene or during transport unless dictated by direct medical control.
- *Guidelines* are plans for medical care that have been approved by the medical or the community EMS committee. The latter allows the EMS personnel to think and to respond to patient needs based on what is found and the situations at the time of the call.

MEDICAL CONTROL

EMTs at all levels work as surrogates of physicians. In most states, they work on the license of the medical director of the EMS service. They are not independent practitioners. The various state licenses do not allow independent nonphysician practitioners to exist within the EMS. Some fire-based systems such as in Louisiana and other states are trying to enact legislation to make fire services exempt from statewide or even local standards and allow the fire chief (who is not a physician and may have no medical training) to provide medical control, critique the medical care given in the field, and circumvent any state standards of patient care. These types of attempts to blunt the improvement of patient care should be defeated. Patient care should always be top priority.

The critical factors in quality care of the patient and the function of EMS[12] in the medical care system have three phases of medical control:

- *Prospective*
  - Initial development of the EMS system and development of needed modifications as the system matures and medical knowledge improves
  - Prior to dispatch of the unit
- *Immediate*
  - While the EMTs are in the field caring for the patients
  - Real time
  - Direct (online) medical control
- *Retrospective*
  - After the unit returns based on discussions or run report review
  - Quality assurance, discipline, education
  - Indirect (off-line) medical control

Direct Medical Control (Online)

Direct medical control is a function of a physician or designee answering the radio and talking directly to the EMTs in the field. The EMTs explain the situation, the scene, the condition of the patient, scene care provided, specify the care to be provided en route and ask for further direction in the management of the patient if required. Further direction can range from bringing the patient to the hospital as quickly as possible to providing specific drugs or undertaking procedures for the health of the patient either prior to transport or while the patient is being transported.

Several studies have shown that well-trained EMTs with effective guidelines who are allowed to make judgments based on knowledge and experience produce better outcomes in shorter scene times than those forced to use communications for all decisions.

Indirect Medical Control (Off-line)

Indirect medical control is the retrospective analysis of the run reports, analysis of statistics gained from compiling various data points from the field such as scene times, response times, time on the scene, skills, attempted versus successful procedure, knowledge and skills, and the most difficult of all, assessment of the judgment used by the EMTs in the management of the patient. Such data can be used to change protocols, add or subtract personnel or vehicles, change the ambulance placement strategy, protocol redesign, sustainment education, redesign, and skills practiced. Such quality assessment can improve the outcome of patient care.

ASSESSMENT AND MANAGEMENT IN THE FIELD

Assessment in the field is composed of two separate steps: Assessment of the scene (safety and situation) and assessment of the patient. Safety comes first.

Situation

Patient: What is the situation of the injured patients? What happened? What is the MOI? Number of patients? Overview of the condition of the patients.

Resources: Does the number of patients or the conditions exceed the resources available? How many patients are present? Is there anyone on the scene who can provide information about the situation, about any of the patients, or about additional patients who are not visible?

Safety

An injured rescuer provides no benefit to the patient if he or she gets injured. In fact, this complicates the state of affairs by adding to the number of people needing care and reducing the number of caregivers at the scene. Therefore, the safety of the rescuers is paramount.

The next component of safety is that of the patients. Chemicals, weather, perpetrators of the incident, unruly bystanders, fire, etc. are all potential hazards in an area. Questions that should always be asked by the EMS team of themselves, other professionals on the scene, and bystanders are: Are there any biological or chemical hazards in the area? Is there an unknown liquid on the ground? Is there an unusual cloud or smell in the air? Is there gasoline on the ground? Is there a fire risk? Is the patient's car in a precarious situation? Is the scene secure from the perpetrators of the incident? Is law enforcement needed?

Initial Assessment

The patient care starts when the first provider touches the patient and continues until the patient does not need further care. There are many similarities in the initial assessment on the scene and the initial assessment in the ED as both are a continuum of the same process of care for the same patient. In fact, the ATLS pattern of the initial assessment was based on a similar system used by EMS. The basic goal of the initial assessment on the scene is also similar to the basic goal of the initial assessment in the ED, in the OR, in the ICU, and on the floor. What is wrong with the patient and what steps are necessary to be able to transport the patient to the next level of care? In the field, the next level of care is the ED. In the ED, the next level of patient care is generally the operating room, the ICU, or advanced diagnostic techniques.

Just as wasting time in the ED delays moving the patient to the next level, so it is on the scene, except perhaps more so. Almost never is the field the best place to assess or to care for the trauma patient. The patient should be moved into the ambulance as quickly and as safely as possible, and the ambulance should be en route to the ED quickly, while following the dictum of "*do no further harm*".

Do no further harm means sins of *omission*, as well as sins of *commission*. Scoop and Run or to move the patient quickly without assuring that the airway is open, that the patient is breathing, that the patient has cardiac output, or without stabilizing the fractures, are sins of *omission*. Starting unnecessary IVs, doing the secondary survey in the field when the patient is crashing, doing unnecessary diagnostic tests in the field such as otoscopic evaluations, auscultation of the abdomen, cervical spine clearance, and ultrasound of anything are examples of sins of *commission*. Both of these do further harm to the patient and should not be a part of field care. Another major sin of commission is the delay in critical patient care by taking up something not critical for survival. This occurs in the field, in the ED, and in getting the patient's abdomen opened in the OR. The components of the initial assessment (primary survey, resuscitation, secondary survey, definitive care) are present in the field just as they are in the ED (PHTLS). The methods and the extent to which they are used are different. There are two major differences:

1. For the severely injured patient with hemodynamic instability, the secondary survey may never be completed in the field or in the ED. The intent of the prehospital provider should be devoted to managing life- and limb-threatening conditions while transporting the patient to the hospital. Other less severe conditions are of lesser priority.
2. The equipment used, the skills, the process of patient care is extremely different when carried on outside in the rain, snow, with a large crowd of people around, when a patient is trapped in the vehicle, or when the perpetrator of the crime may still be in the area than in the warm, dry, controlled environment of the ER or the operating room.

In addition, in the hospital, there are frequently nurses, house staff, and other personnel to provide assistance to the physician providing this care. In the field, there are only the two EMTs and, occasionally, personnel from the fire department or law enforcement department who may or may not understand completely the job of the EMT. Nor does the occasional participant in field care know where all of the supplies in the "truck" are.

In most EMS services, only two EMTs ride on a unit. One may be at an advanced level or one may be at a basic level. Occasionally, in some services, there is a trained first responder available for additional help either from the fire department, law enforcement, or a volunteer first responder in some rural areas. Manpower limitation in the field is a major factor, which can slow prehospital care. For example, the care that must be provided by two providers for a trauma patient who requires intubation includes the following:

Immobilize the patient's spine
Place the backboard in position
Apply the cervical collar
Secure the patient to the backboard
Start airway management such as oral airway or intubation
Assess proper management of the airway
Secure the endotracheal tube into position
Load the patient in the unit
Notify the hospital of impending arrival and the patient's condition
Drive the ambulance
Recheck Endotracheal tube (ET) position after movement

Check vital signs
Start an IV if appropriate
Assess for other injuries
etc.

In the hospital, there are several individuals who participate in resuscitation. Such luxury does not exist in the field. Field care is different from the ED, OR, of ICU care. In each area, the basics of care are the same and have the same goals; however, the providers are trained to operate in different situations and the resources are developed for the specific situations encountered. Therefore, their specific goals will be different.

Primary Survey

As part of the scene assessment and the primary survey, a general impression of the patient's condition is obtained immediately upon seeing the patient. In the first few seconds, the patient is assessed for the MOI, for example, when the EMT finds the patient lying in a ditch, or lying in the street with a motorcycle 30 feet away, or leaning over the steering wheel without the deployed air bag, or lying in the street with blood coming from the chest and clothes soaked with blood. Each of these provides a general impression of what is going on and prepares the prehospital care provider with a general direction toward what needs to be quickly accomplished prior to initiation of transport.

Efficiency in the field is critically important if the patient is to be moved to the hospital safely and rapidly. The initial review must identify what is wrong with the patients; what has to be done to stabilize their condition prior to getting them into the ambulance; what care would need to be provided en route to the hospital; and which hospital is best equipped with the proper resources and is immediately ready to handle the patient's specific condition. Also important is triage: the assessment of which patients are the most severely injured, and who will require attention first.

The objective of the field primary survey is to identify the severity of the patients' injuries so that they can be taken to the right hospital so that the injuries will cause no further harm.

A: Airway The airway can be managed in the field as in the hospital by manual, mechanical, or transtracheal methods.

Techniques available to verify the correct placement of an airway device (oral, nasal, supraglottic or endotracheal intubation) are divided into two groups: clinical assessment and adjunctive devices depending on the device. Depending on the device, various methods will be helpful.

Clinical assessment includes the following:

1. Identification of bilateral breath sounds and absence of air sounds over the epigastrium
2. Observation of chest rising or falling during ventilation
3. Direct observation of the tube passing through the cords
4. Observation of fogging (vapor condensation in the endotracheal tube).

Adjunctive devices include:

1. Esophageal detector
2. Carbon dioxide monitor
3. Colorimetric carbon dioxide detector
4. Endotracheal carbon dioxide monitor (capnography)
5. Pulse oximeter.[13]

None of these methods are 100% accurate. Therefore, all of the clinical assessment should be used unless impractical. In addition, at least one (preferably two) of the adjunctive techniques should be added.

Airway Backup. As with any technique, there should always be a backup technique/plan available should the primary technique fail. The ultimate device and the first step in most cases is the BVM. A study by Stockinger showed similar survival rates with both BVM and ET placement.[1]

B: Breathing and ventilation. The first step for the prehospital provider in assuring that red cells are adequately oxygenated to deliver the oxygen to the tissue cells is an open airway. The second step is to assure adequate volume expansion of the lungs (Ficke principle). Traumatic conditions that interfere with lung expansion include the physical limitation of expansion (pneumothorax), reduced expansion of the chest cavity (rib pain), and reduced neurological drive (high spinal fracture, brain injury, or alcohol or drug excess).

BVM ventilation is the initial mechanical approach to getting air into the lungs and the continuing approach if the patient cannot be intubated (no RS1 protocols, training, skills, or proximity to hospital). As stated above, some studies have shown that the outcome using BVM ventilation and endotracheal intubation is the same. Unfortunately, in the United States, randomized trials are prohibited. Most are retrospective or prospective with historical controls.

If thoracic decompression is needed for the management of a pneumothorax, the needle should be long enough to reach the thoracic cavity. Military studies have shown this to be >3.25 inch. Some experts have suggested bilateral needle insertion on all prehospital cardiac arrest patients.

C: Cardiac. The American College of Surgeons/Committee on Trauma (ACS/COT) and the National Association of EMS Physicians (NAEMSP) have developed a position paper outlining when to and when not to initiate Cardiopulmonary resuscitation (CPR) in the field on a trauma patient. This has been verified recently at the COT resident paper competition.[14]

The most important component of "C" is hemorrhage control (discussed below under resuscitation).

D: Disability. The major goal is the assessment of the brain as an end organ for perfusion and oxygenation. A mental status examination at this point is for gross assessment or a head injury such as unequal pupils and appropriate stating with the Glasgow Coma Score.

Resuscitation

The resuscitation phase of prehospital care is also different from the resuscitation in the ED. Intravenous fluid administration, as an example, is carried out en route to the hospital and not in the field as this would delay transportation. It is more difficult to start an IV in a crowded, moving ambulance than in an ER with the stable platform on which the patient is lying. However, IV access is possible with >95% success rate in a moving ambulance if necessary for good patient care. In 2012, the accepted approach to fluid replacement will be in the ratio 1:1:1 for RBC, plasma, and platelet. The prehospital step is fluid resuscitation with the goal of 80–90 mm Hg systolic pressure and rapid movement to facility where RBC and plasma are immediately available.

Secondary Survey

Another difference between patient care in the back of an ambulance versus the ED is the removal of all of the patient's clothes in the ED to do an adequate secondary survey. Environment, bystanders, and other conditions dictate that the patient's clothes usually should not be removed prior to the putting the patient in the ambulance. While en route, the patient must remain stable against the backboard and the stretcher; therefore, removing the straps to cut the clothes free is difficult and usually not productive to the long-term outcome of the patient (unless severe hemorrhage is present). However, the assessment can be incomplete if the clothes are not removed as major injuries such as a hemorrhage from the thigh can be missed. Spinal immobilization often complicates a complete secondary assessment. The EMT's assessment is limited to those parts of the body that are freely visible while immobilized.

In most situations, therefore, the secondary survey is not completed prior to arrival at the hospital. The general principle of immobilization, as a unit on the long backboard, is frequently the best method of transporting the patient and stabilizing all the fractures or potential fractures.

However, life-threatening injuries such as external hemorrhage, airway problems, pneumothorax, and flail chest should be addressed while providing rapid transport to the trauma center or local hospital. The backboard is a useful device for moving a patient to the stretcher in the field and off the stretcher in the ED. However, cervical collar use with the backboard is contraindicated in penetrating trauma without a neurological deficit, as (1) there is no benefit, (2) it delays transportation, and (3) it restricts assessment and management such as BVM ventilation.

Definitive Field Care

Like other steps in the assessment and management of the patient, definitive care in the field is different from definitive care in the ED. The definitive prehospital care is appropriate packaging and delivery of the patient safely and quickly to the ED.

SHOCK AND FLUID RESUSCITATION

The primary emphasis for the prehospital provider's knowledge base should be the following:

- Reestablishment of energy production at the cellular level when anaerobic metabolism has replaced aerobic metabolism
- Improved oxygenation of the tissue cells can be hampered by either (1) lack of oxygenation of the red cells in the lungs, (2) lack of delivery of the red cells to the tissue cells (Fick Principle), or (3) over resuscitation with crystalloid producing increased interstitial fluid, restricting oxygen transfer.
- Understanding of the physiology of fluid replacement
- Bernoulli theorem of fluid loss from an injured vessel
- Resuscitation of controlled versus uncontrolled hemorrhage

Energy Production

Metabolism produces injury utilizing oxygen and glucose as fuel with by-products of carbon dioxide and water. There are two pathways to achieve energy production: one with and one without oxygen. Aerobic metabolism is the most efficient and produces a large amount of adenosine triphosphate versus anaerobic metabolism, 38:2 per cycle.

Additionally, anaerobic metabolism increases the production of lactic and anaerobic acids with resultant total body acidosis. The increased acid will result in an increased ventilatory rate, which may be the first sign of early shock. Tachypnea frequently precedes tachycardia and certainly precedes

hypotension. Reduced energy product produces hypothermia. This change provides assessment techniques. The so-called triangle of death (hypotension, acidosis, and coagulopathy) is the outcome of decreased energy production and *symptom* of shock *not the cause*.

The outcome of a prolonged hypoperfusion will result in impairment of organ function up to and including organ death. Many of the complications that occur result from hypoperfusion and hypo oxygenation in the first hour of patient care when EMS is with the patient. These may not manifest themselves for several hours or days.

Physiology of Fluid Replacement

The determination of how and what fluids to use for resuscitation depends on the type of shock and the presence of *controlled or uncontrolled* hemorrhage.

With controlled hemorrhage, the patient can be resuscitated back to normal hemodynamics without concern. Conversely with uncontrolled hemorrhage, increasing the blood pressure and flow back to normal can significantly increase the blood loss. With controlled hemorrhage, low-volume resuscitation is preferred.

Resuscitation of the blood volume, using fluids alone (such as Ringer's Lactate), has three potential negative outcomes:

- Large volumes of Ringer's lactate without replacing red cells dilutes the red cell mass. This reduces the delivery of oxygen to the tissue cells.
- The return of blood pressure to the normal range may dislodge a clot and initiate active bleeding. It also produces a higher transmural pressure (intravascular vs. extraocular pressure), which increases the rate of flow of blood from the injured vessel (Bernoulli's Principle).
- High-volume crystalloid resuscitation, which remains in vascular system only a very short period of time, produces significant edema and decreases the function of the lung, kidneys, and other organs.
- High-volume crystalloid resuscitation creates a dilutional coagulopathy.

In face of *uncontrolled* hemorrhage, volume resuscitation in the field should be intravenous, with no attempts to increase blood pressure > 90 mm Hg to maintain oxygen delivery. In a short-term transport situation, <20 minutes from the hospital and without traumatic brain injury, IV access only with less that 500 mL of fluid is the accepted management approach. For longer transportation, the recommendation of the Committee on Tactical Combat Casualty Care (CoTCCC) for military care is an acceptable option, which advocates pulse as the main assessment tool. Rate and character abnormality in the pulse (weak and thready) indicates resuscitation fluid should be given every 30 minutes if necessary. Crystalloid should not routinely be administered in this situation. Short-term use of volume-restricted resuscitation method in one study demonstrated that there was increased mortality rate associated with hemorrhage from the thoracic cavity, but no clinically significant changes in hemorrhage from other parts of the body.

However, it is logical to believe that based on the Bernoulli Theorem, increasing intraluminal blood pressure without increasing the external tissue pressure will cause greater blood loss and therefore increased mortality rate (Table 16.9).

A decrease in the intramural pressure will decrease the transmural pressure and therefore reduce the rate of leakage out of the hole in the vessel. Conversely, an increase in the intramural pressure will increase the transmural pressure and thereby increase the rate of blood flow out of the hole. This is the theory behind the restricted fluid resuscitation technique.

TABLE 16.9

MODIFIED BERNOULLI THEOREM

Rate of leakage ~ Size of the hole × transmural pressure
Transmural pressure = intraluminal pressure/extramural pressure

Therefore, the appropriate resuscitation in uncontrolled hemorrhage is as follows:

- Reduction of intravascular pressure (hypotensive resuscitation and/or tourniquet)
- Increased extra luminal pressure (direct wound pressure and pressure bandages)
- The addition of external hemostatic agents or nontourniquetable wounds (torso) must be accompanied with 3–5 minutes of direct pressure on the wound site after application of agent.
- Movement of patient as quickly as possible to factor XIV (hemostats and ligation of bleeding vessels)

Assessment

There are a variety of maneuvers that have been successfully used to quickly assess the level of shock in a trauma patient. Pulse. Three components of the pulse need to be evaluated on initial arrival of EMS personnel.

- Rate—slow or fast tachycardia indicates, at the very least, compensated shock. A very slow pulse (<50) could indicate the early onset of bradycardia associated with myocardial ischemia.
- Strength—strong versus thready
- Location. A radial pulse indicates adequate perfusion with the systolic pressure somewhere above 80 to 90 mm Hg. The absence of a similar pulse indicates that the pressure is probably below 70 systolic and absence of carotid pulse indicates that systolic blood pressure is 50 to 60 mm Hg or less.
- Ventilation rate, increased rate, indicates increased acid production at the cellular level (anaerobic metabolism) and generalized acidosis

Skin color: Pink versus cyanotic versus pale.
Skin temperature: Cool and clammy versus warm and dry.
Capillary refilling time: Greater than 2 seconds

All of these signs are in themselves not a test of shock, but a test of perfusion of that portion of the body wherein they are detected. Perfusion can be a function of cardiac dysfunction, reduced blood volume, a function of interruption of the blood supply proximal to the point of assessment. Hypothermia, vascular trauma, dehydration, or a variety of conditions can reduce the perfusion to the point of all of the above changes.

Blood Pressure: An important sign of shock, however, hypotension is frequently not noted until 30 to 40% of the blood volume has been lost. Therefore, it is a late sign. The afore-mentioned parameters (pulse rate, skin color, temperature, etc.) are earlier indicators of possible shock.

Transtracheal airway

Although there are three methods of transtracheal airway management, the **tracheostomy** is not an emergency procedure,

either in the hospital or outside of the hospital. Therefore, EMTs are not taught this technique. Percutaneous transtracheal ventilation and surgical cricothyroidotomy are the transtracheal airway management options emphasized.

Percutaneous transtracheal placement of a large 14 or 12 gauge needle directly into the trachea is a quick and effective technique. It requires less train and sustainment training than a cricothyroidotomy.

Ventilation can be accomplished by connecting an oxygenation administration catheter to a 15 liter per minute oxygen source. Continuous flow, without pressure bags, is effective as long as the patient has spontaneous ventilation. Oxygenation without compromising CO_2 build-up has been accomplished for 45 minutes without difficulty.

Surgical cricothyrotomy can be effective but requires extensive training and retraining to maintain proficiency.

Spinal Immobilization

Backboard Immobilization The critically injured patient should be immobilized to the backboard providing a stable transfer platform. The transportation of the patient to an appropriate facility to address these issues takes precedence over neurological assessment.

Without a neurological defect, there is no indication for immobilizing the cervical spine in penetrating neck trauma. The patient should be rapidly transported to the hospital without immobilization. The long backboard can be used as a device for moving the patient, if necessary; however, the cervical collar does not need to be added.

Cervical collar application Even the best of cervical collars, including the "hard" cervical collar, provide only about 50%–60% restriction in motion in the three standard positions of anterior/posterior, lateral flexion, and rotation. The soft cervical collar is ineffective in immobilizing the neck and is not indicated in acutely injured patients.

Field Helmet Removal

Removal of motorcycle, bicycle, and football helmets is taught and practiced by every EMT in training. Physicians are generally not taught how to remove a helmet and almost none have practiced it on a consistent basis. Therefore, it is appropriate for EMS personnel to remove helmets in the field to better immobilize the patient for transport.

Traction splints: For a fractured or suspected fractured femur, the traction splint is an excellent device. Early literature from World War I reports that the use of the Thomas Whole Ring or the Thomas Half Ring Splint on soldiers receiving femur injuries reduce the mortality rate by 80%. More recent analysis of these reports indicates that the reduction of mortality may well have been closer to the range of 40%, but nonetheless, this is a significant change by the use of such a device.

KINEMATICS (MECHANISM OF INJURY)

Critical to understanding the potential of injury in a patient is the MOI. Upwards of 95% of injuries can be anticipated before even examining the patient by understanding the energy exchange on the human body at the time of impact. These are based on some very simple laws of energy and motion.

1. Body at rest or body in motion will remain in that state until acted upon by some outside force.

2. Energy can be neither created nor destroyed, but it can be changed in form.
3. Mass × acceleration = force = mass × deceleration
4. Kinetic energy = mass/2 × velocity^2

Laws of Energy and Motion

Newton's first law of motion states that a body at rest will remain at rest and a body in motion will remain in motion unless acted on by an outside force.

The *law of conservation of energy combined with Newton's second law of motion describes* that energy cannot be created or destroyed but can be changed in form. The motion of the vehicle is a form of energy. When the vehicle is started, the gasoline burns inside the cylinder, producing motion of the piston, which turns the crankshaft and then the wheels. To stop the vehicle, the motion (energy) must be changed to another form, for instance, the bending of the frame in a crash or the heat of the brake drums or disk and the tires when the breaks are applied for control.

$$Mass \times acceleration = force = mass \times deceleration$$

Force (energy) is required to put a structure into motion. This force (energy) is required to create a specific speed. The speed imparted is dependent on the weight (mass) of the structure. Once this energy is passed on to the structure and it is placed in motion, the motion will remain until the energy is given up. (Newton's first law of motion).

An example of this process is the gun and the patient. In the chamber of a gun is a cartridge that contains gunpowder. When the gunpowder is ignited, it burns rapidly creating energy that pushes the bullet out of the barrel at a great speed. This speed is equivalent to the weight of the bullet and the amount of energy produced by the burning of the gunpowder or force. To slow down (Newton's first law of motion), the bullet must give up its energy into the structure that it hits. This will produce an explosion in the tissue that is equal to the explosion that occurred in the chamber of the gun when the initial speed was given to the bullet.

Kinetic energy is a function of an object's weight and speed. The relationship between weight and speed as it affects kinetic energy is as follows:

Kinetic energy = One-half the mass times the velocity squared

$$KE = \tfrac{1}{2}mv^2$$

The velocity is exponential and the mass is linear. In a collision between a small car and a semitrailer truck or between a car and a pedestrian, the advantage goes to the vehicle with the most energy (mass and speed).

This loss of energy will be exchanged into the tissue particles and put them into motion.

The same phenomenon occurs in the moving automobile, the falling patient from a building, or the explosion of an improvised explosive device (IED)

The inverse relationship between stopping distance and injury also applies to falls. A person has a better chance of surviving a fall if he or she lands on a compressible surface, such as deep powder snow versus terminating on to a hard surface, such as concrete. The compressible material (i.e., the snow) increases the stopping distance and absorbs at least some of the energy rather than allowing all the energy to be absorbed by the body. The result is decreased injury and damage to the body. This principle applies with a restraining belt or an airbag. An unrestrained driver will be more severely injured than a restrained driver. The restraint system, rather than the body, will absorb a significant portion of the damage energy.

Once an object is in motion and has energy in the form of motion, for the object to come to a complete rest, the object

must lose all its energy by converting the energy to another form or transferring it to another object. For example, if a vehicle strikes a pedestrian, the pedestrian is knocked away from it. Although the vehicle is somewhat slowed by the impact, the greater force of the vehicle imparts much more acceleration to the lighter-weight pedestrian.

The energy in terms of acceleration imparted to the pedestrian is much more than the energy lost by the vehicle as it slows down. The softer body parts of the pedestrian versus the harder body parts of the vehicle also means more damage to the pedestrian than to the vehicle.

Energy Exchange between a Solid Object and the Human Body

As the human body collides with a solid object, or vice versa, the number of body tissue particles that are impacted by the solid object determines the amount of energy exchange that takes place. This transfer of energy produces the damage (injury) that occurs to the patient. The greater the energy exchange, the greater the damage.

The energy exchange produces similar response in the patient. The number of tissue particles affected is determined by (1) the density (particles per volume) of the tissue and (2) the size of the contact area of the impact.

The outcome of the energy exchange is determined by the organs involved.

Cavitation

Many games are based on the physics principle of energy exchange from one object to a cluster of other objects. The cluster is broken apart. The game of bowling is a classic example. The bowling ball is rolled down the hardwood floor aimed at a rack of pins in the middle of the lane. The energy given to the ball by the bowler breaks the rack apart. Pool is a similar game. The force of muscle motion of the arm is applied to the cue ball through the cue stick. The ball goes down the table to the rack of balls at the other end and exchanges the energy of motion and mass of the cue ball, into the rack of balls, which are broken apart.

A similar force on the human body occurs when the energy of the moving bullet transmits the energy into the tissues of the body and "blows them apart." This creates a cavity. The initial cavity is temporary and is produced by the rapid displacement of the tissue particle. This cavity cannot be seen a few seconds after the penetrating object has passed. The elastic tissue such as in muscle, lung, or even the liver must be mentally reconstructed as the patient is assessed. The permanent cavity can be seen or partially seen when the injured patient is assessed.

An analogy is to visualize the side of steel barrel hit with a baseball bat. Examine the dent made in the steel barrel by the baseball bat. Take the same baseball bat and swing it with the same force into a roll of foam rubber and examine the foam rubber. The cavity is directly away from the movement of the baseball bat. After the initial impact, there is no visible cavitation or dent although the hitter knows that such a cavitation was produced at the time of impact.

Such are the changes that occur within the human body, particularly when the force is spread out over an area too wide to penetrate the skin (blunt trauma). The elastic tissue of the body reforms the cavity quickly but not the damage created by the energy exchange.

For simplicity sake and ease of understanding, the forces are divided into blunt and penetrating trauma. However, the only difference in these two forces is the penetration of the object into the tissue and the direction of the cavitation.

BLUNT TRAUMA

The energy exchange in blunt trauma has four components: shear, compression (crush), overpressure (paper bag effect), and cavitation. Each, to a greater or lesser extent, is involved in every crash. These are the results of deceleration if the body suddenly stops or acceleration if the body is suddenly put into motion away from the point of impact.

To better understand the forces of blunt trauma, these are divided into motor vehicle crashes (automobiles, motorcycles, and pedestrians), falls, and blasts.

Vehicular Collisions

Vehicular impacts are further subdivided according to the direction of the forces and the vehicle in which the patient was riding. There are five separate types of collision each of which has its own individual patterns: frontal, rear, side impact, rotational impact, and rollover. As a general rule, the patient is injured on the same side as the vehicle.

Frontal: The occupant riding in the vehicle is traveling at a speed produced by the energy created in the engine from the burning of gasoline. When this vehicle strikes an immovable object directly in the front, the vehicle rapidly slows as the bending metal absorbs the energy of the momentum of this speed. If the car stops and the occupant inside the vehicle stops, then all of the energy of the momentum was absorbed by the vehicle or the patient. There are two types of energy absorption. The first shows energy absorbed locally on the front of the vehicle as energy is absorbed onto the frame.

In most modern cars, the energy of the motion of the occupant is absorbed as the energy is dissipated into the stretching of the seat belt, and the impact into the air bag in the best scenario. However, if neither safety device is available, such energy is dissipated into the tissues of the body as the passenger impacts the dash board, steering column, windscreen, or supporting pillars.

Generally, the unstrained occupant will follow two pathways, forward into the dash board or into the steering column as the energy of the vehicle is absorbed and stops (or a combination of the two): one, with the head as the lead point of the human missile, the "up and over" pathway and the second, where the knee is the lead point of the human missile into the dash or the floor. "Down and Under."

Down and Under: The vehicle stops its forward motion against some immovable object. The frame or front is bent as it absorbs the energy. The continued forward motion of the occupant's lower torso impacts the knees into the dash. The dash stops the forward motion of the knees, but the continued energy of the torso pushes into the upper portion of the lower extremity. This energy is absorbed by dislocation of the knee, fracture along the shaft of the femur, or if the femur remains intact, the pelvis continues to travel forward with the acetabulum overriding the head of the femur. The result is a posterior dislocation at the hip. As the lower half of the torso comes to rest, the upper half of the torso continues forward, bending at the hips and impacts the dash or the steering column with the patient's head or chest.

Up and Over: The chest is the lead point of the human missile. The sternum stops its forward motion against the steering column, but the continued motion of the posterior thoracic wall from behind bends and eventually fractures the ribs. The lungs are compressed between the forward motion of the posterior thoracic wall and the anterior components of the ribs and/or sternum. The heart is compressed between the vertebral column and the sternum.

If the energy forces are such that the head becomes the lead point of the human missile which impacts into the "A" pillow, the wind screen, or the roof of the car, the anterior part of the skull stops its forward motion, but the continued motion of the posterior skull pushed by the momentum of the torso fractures the area of the impact. The continued energy momentum of the brain produces compression, crush, or lacerations of the brain matter itself.

The brain is not attached to the inside of the skull, but floats in the cerebral spinal fluid. Once the skull stops, the brain continues to move forward until the energy of the momentum is absorbed by compression against the skull. This can result in contusion and laceration of the brain. Parts of the fractured skull may stick into the brain tissue itself.

The separation of the trailing edge of the brain from the back of the skull can tear the vessels loose, producing hemorrhage. This is the cause of the so-called contra coups injury. If the top of the skull is the impact point then base of the brain travels away from the base of the skull and the stretch is through the foramen magnum and the cerebrum can be pulled away from the spinal cord at the brain stem.

Once the head has stopped its forward motion, the continued momentum of the torso from behind distributes energy onto the unprotected cervical vertebrae, producing compression, hyperextension, or hyperflexion injuries. Such injuries to the cervical spine can lead to spinal cord damage at the time of impact or are unstable, leading to further injury to the patient en route to the hospital or in the hospital. Therefore, the entire spine must be appropriately protected on a backboard and a cervical collar.

Concomitant energy exchange can occur in the chest and abdomen. The anterior chest stops abruptly against the steering column. The posterior chest wall only stops when its energy of forward motion has been absorbed. This energy absorption is onto the ribs, resulting in lateral fractures, compression of the lung (pulmonary contusion) or compression of the heart. Rapid reduction of the intrathoracic volume and increase in intrathoracic pressure (overpressure) [Boyles law] can rupture the lung (like a paper bag hit with the hand), tearing the parenchyma and producing a pneumothorax. Although a sharp edge of the fractured rib can lacerate the lung, the paper bag effect is more common.

The descending aorta is firmly attached to the posterior chest wall and vertebrae, while the heart and the aortic arch are relatively mobile. The heart and the arch can decelerate at a different rate from the descending aorta. This produces shear forces at the junction of the arch and the descending aorta. The shear results in a tear of the aorta at that point. If the rupture extends into the thoracic cavity, immediate exsanguination results. In 20% or so of the situations, the blood is contained within the adventitia surrounding the aorta as a pseudoaneurysm. Such a pseudoaneurysm remains intact for several hours to several days.

The abdomen is also a closed container. The abdominal organs can be compressed between the posterior and anterior abdominal wall (crush of the liver, spleen, pancreas, or kidney) causing, for example, shear of the vascular attachments of the solid organs during differential change in motion such as deceleration (spleen and kidney); shear of the liver around the ligamentum teres (especially in down and under pathway); and overpressure to the abdominal cavity (diaphragmatic rupture into either the left or right pleural cavity).

As a starting point to estimate the energy potential and direction of the crash, a description of the damage to the vehicle by the EMTs to the trauma team, gives the ACS a visual picture of the initial energy exchange. The same type of damage occurs to the patient as happened to the vehicle.

Lateral: Lateral impact collisions are frequently the result of an intersection (T-bone) crash. This actually results in two types of collision patterns. One vehicle is involved in a lateral impact collision, the other in a frontal collision. A careful description of the crash will allow the ACS to assess the potential injuries to the individual patients.

At the time of the collision, the occupants in the target vehicle are usually traveling in a forward direction. The bullet vehicle impacts the target vehicle from the side. This energy exchange accelerates the target vehicle in the direction of the impact

and away from the bullet vehicle. The unrestrained occupants remain in the forward motion until impacted by the interior of their own vehicle. This (1) crushes the side of the patient at the impact point, (2) rapidly accelerates the patient away from the point of the impact. The occupant on the near side receives more energy exchange than the far side as the door and "B" pillows come into direct contact with the occupant. This contact and acceleration to lateral motion initially affects in four motions:

1. Impact on the femur tends to push the femoral head into and through the acetabulum. As the force continues, the door contacts the pelvis proper.
2. Impact to the lateral chest wall, the shoulder, or both. This compression fractures ribs (flail chest), contuses the lung in the chest and crushes the liver or spleen (depending on the site of the impact), and produces pulmonary contusions or pneumothorax. The acceleration, in the lateral direction, produces shear of the aorta and vascular attachment of abdominal organs. The descending aorta is attached to the torso or the spine and moves with it. The arch of aorta and the heart are not attached and move only when pulled. Approximately 25% of aortic shear injuries occur in lateral impact collisions. Approximately 75% occur as a result of frontal collisions.
3. The arm and shoulder, if positioned inside the door below the window, are impacted by the door. This compresses the upper arm and produces a fracture of the humerus, compression fractures of the ribs, and possible pulmonary contusion or intrathoracic overpressure injures. A clavicle fracture is also possible.
4. The lateral acceleration of the torso pulls the head into motion by the attachments of the neck as a secondary effect. The center of gravity of the head is anterior and superior to the attachment of the skull to cervical spine at the foramen magnum. This action causes rotation of the head toward the impact and lateral flexion of the neck in the same direction. This opens the facets on the contralateral side of the spine and rotation of the upper vertebra as the head turns. Dislocations, lateral compressing fractures, and jumped facets result.

Rear: The target vehicle is stopped or moving at a significant slower rate than the bullet vehicle as the contact between the two vehicles transpires. The bullet vehicle imparts a significant amount of its energy to accelerate the target vehicle and all components inside the car, which are attached to the car. Those components not tied to the car (which includes the occupants) start to move forward only as the parts of the vehicle such as the seats add force to them. Some of the energy is absorbed in the springs of the seat. Those portions of the occupant that touch the seat are accelerated almost simultaneously with the vehicle.

Those body parts not touching the seat (e.g., when the head is above the head rest), are accelerated by their attachments to the body. Only if the acceleration force reaches or exceeds 15g is the energy exchange at a high enough level to cause significant damage to the occupant. When the energy exchange is below 15g, the acceleration of the thorax out from under the head produces only ligaments or muscle strain.

Since the acceleration forces are in line with the body posterior to anterior, except as noted above with spinal injuries, the injuries to the occupant at the initial impact are minimal. Much force is absorbed by the springs. Additional injuries can occur if there is a second collision with the target vehicle being pushed forward into another target vehicle and the collision suddenly becomes frontal.

Rotational: If the initial impact is off-center, that part of the vehicle stops the forward motion while the rest of the vehicle continues in forward motion. This puts the current rotation

around this pivot point, and therefore the occupants can receive collisions of either frontal or lateral or both.

Rollover: In a rollover collision, the unbelted occupant flies freely throughout the passenger compartment and impacts all aspects of the vehicle. The patterns associated with these injuries are extremely difficult to predict.

Falls

The 'g'-force on earth is 32 feet per second per second (feet/s^2). The potential patient's speed significantly increases over time and distance. The greater the distance of the fall, the more energy the potential patient has when the bottom of his or her fall is reached and the energy of the falling patient suddenly stops. The initial impact is on that part of the body that makes contact first, but there is continued energy/motion of those other components that have not stopped their fall. Even though the impacting point has stopped, the continued energy of the torso, head, brain, intra-abdominal and thoracic organs must absorb the energy exchange. This includes all of the bones as well. The old adage of "in a fall one breaks his S" is very true. The energy compresses the concavity of the S and stretches the convexity. The neck of the femur, posterior lumbar spine, anterior thoracic spine, and posterior cervical spines are all aligned to encounter this energy exchange. Compression fractures such as the talus into the tibia, the calcaneus itself, the shaft of the femur and tibia are vulnerable. Deceleration/sheer injuries will occur to the kidneys, spleen, liver, and arch of the aorta.

The multiple other directions and the energy exchange in them can be figured out with just a little imagination on the part of the provider.

Motorcycle Collisions

Three different types of collisions are associated with motor cycle crashes: (1) ejection or partial ejection of the biker and impact with another object with the body parts pinned between the motorcycle tank/engine and the impacted object; (2) the unprotected (unhelmeted) head and skull hitting the object or the roadway; (3) "laying the bike down" to prevent impact with another object but sliding on the road and losing skin and other tissue during the slide.

Blast Force

Blast injuries are a result of four separate mechanisms. The primary zone, in which overpressure injuries cause damage to air-filled organs; the secondary zone, where injury is caused by flying particles and debris; the tertiary zone, where the victim becomes a missile and is thrown a distance, often into another object; and the quaternary zone where injuries are from radiation or bacterial contamination.

Penetrating Trauma

Energy Penetrating trauma is a result of the energy exchange onto the human body, impacting only a limited surface area with enough energy at the penetration site to penetrate the skin.

In blunt trauma, the energy exchange to the body produces compression forces from the initial impact, and the differential motion of the body and the organs produces shear at the point of organ attachment from the acceleration or deceleration of the tissue.

In penetrating trauma, the compression forces and stretch forces are involved. The compression forces are from the direct impact of the missile as it goes through the organs and stretch from the cavitation that surrounds the bullet pathway. The amount of energy exchange occurring on the human body to produce injury is a result of the direct impact of the penetrating object onto the human tissue. The amount of energy varies proportional to the number of tissue particles hit. The *size of the frontal area* of the penetrating object and the *density* of the tissue impacted determines the number of tissue particles hit and therefore the amount of energy exchange that occurs.

Density of body tissue is a continuum, but can be simplistically put into three categories: air density, soft (water) tissue density, and bone density. The least amount of energy exchange would occur when the bullet impacts an object containing significant amounts of air, such as the lung. The greatest amount of energy exchange would occur when the bullet impacts a very dense tissue like bone. Soft tissue density (water density) is intermediate between the two and includes solid organs and muscle.

The size of the frontal area of impact depends on the characteristics of the bullet itself. Important variables include the spin imparted to the bullet as it comes out of the barrel and the shape of the bullet (which are constructed in such a manner so that the bullet flies aerodynamically as straight as possible passing through the air).

The frontal surface area of the bullet is increased by three variables:

1. *Profile modification* such as a hollow point bullet that expands and spreads (mushrooms) on impact.
2. *Tumbling* of the bullet to present a broad side. At the 90° angle point of the rotation, the greatest exchange of energy occurs.
3. *Fragmentation* can either occur as the missile is leaving the muzzle such as a shotgun or can fragment after impact. A third level of fragmentation is explosion of the bullet after entering the body.

The two factors that influence the severity of the injury from a penetrating object are the amount of energy exchange that occurs and the organs that are involved.

The amount of energy exchange can be grossly estimated prior to examining the patient in the operating room by dividing penetrating objects into three groups based on energy.

- Low energy: a knife that creates no temporary cavity and only lacerates tissue.
- Medium energy: generally a handgun with a muzzle velocity of <1,000 feet per second and creates a temporary cavity some five to seven times the diameter of the missile.
- High-energy weapon: high velocity greater than 2,000 feet per second and can create a temporary cavity as much as 20 times the diameter of the missile. A lower velocity but a higher mass such as a shotgun or even IED produces such injuries.

SUMMARY

Patient care begins at the site of the incident and when rehabilitation is complete. Patient care is a continuum of care from beginning to end. The care of the injured is not disparate. Patient care does not start when the patient reaches the ED nor does it stop when the ED elevator doors close as the patient goes to the OR. The first step in this care is field management and transportation. Prehospital care is not a separate happening, but a component of the whole. The assessment, (primary care, resuscitation, secondary survey, and definitive care) is the same throughout, albeit each different stage (emergency

department, OR, ICU, etc.) has different levels of care and the skills of the providers are different, nonetheless it is one team from beginning to end with different providers and different locations, but there is one patient with one disease.

The ACS should have knowledge of the entire process. If the ACS ignores the prehospital component, patients may be treated in such a manner that is not compatible with the in-hospital component. The ACS has obligation to assess what the EMS personnel are providing and to educate both in the classroom and to critique at the end of each run.

Newer techniques in the management of patient in the last few years have included damage control, hypotensive resuscitation, reduced use of crystalloids, and more appropriate patient triage, particularly in the rural areas.

Appropriate prehospital management is essential in achieving optimal patient care.

CHAPTER 17 ■ DISASTER PREPAREDNESS AND MASS CASUALTY MANAGEMENT

LEONARD J. WEIRETER JR

Police find car bomb in Times Square

A crude car bomb of propane, gasoline and fireworks was discovered in a smoking Nissan Pathfinder in the heart of Times Square on Saturday evening, prompting evacuation of thousands of tourists and theatergoers………. "We were very lucky" said Mayor Michael Bloomberg. "We avoided what could have been a very deadly event"
New York Times May 1, 2010

Storms Cut through Midwest, killing 5

Hundreds of homes and businesses were damaged or destroyed Friday in Kansas, Kentucky, Illinois, Missouri and West Virginia prompting several state of emergency declarations.
New York Times May 9, 2009

Imagine for a moment being on duty in a hospital adjacent to either scene above. The destruction of the second versus the absolute luck involved in avoiding the tragedy of the first is mind boggling. How would you, as an individual, your hospital and its staff, or your community at large have responded to either event? Who would be in charge? Where would injured patients go? How would they get there? How did they get here so fast? How would we, or could we, treat them? Where are the necessary supplies? What about the worried family members flocking to the hospital to find family members? Where do they go? How do I find out who goes with whom? What do we do with the ordinary patient traffic of the day in light of either of these events?

The easy answer is that "they" will take care of it. Unfortunately, the "they," usually thought of as a governmental agency, is not able to respond fast enough in the first hours to substantially impact the situation. The "they" realistically is "us." Disaster and mass casualty situations have distinct defining characteristics that need to be understood to appreciate the mindset change needed to deal with the problems.[1] Command and control is paramount but its mechanisms are not obvious to the individuals who spend most of their professional time in hospitals engaged in routines of care. How we view patient care needs to fundamentally change in such situations. Finally, unless we are committed to understanding these differences and practicing the responses demanded, we will be doomed to fail. At that point, we will be tasked with answering why we weren't better prepared only to realize that there is no good reason. The ultimate goal of such a response is to make ours a resilient community, that is, to build a community that can withstand the insult and return to normal structure and function with minimal deformation. To this end, the objective of this chapter is to begin to lay a foundation to support "us" as we develop a methodology to accomplish this goal.

DEFINITIONS

A disaster or mass casualty event in some ways depends on where you are at the time. A two-car, five-victim crash on the interstate may be routine to the urban level 1 trauma center but devastating to the much smaller critical access hospital in a rural county. The crux of the definition lies not in numbers or severity of injuries but in relation to the capability and resources of the responding community, be that EMS or hospital. Once the demands of the response outstrip the available resources, the situation warrants the label disaster or mass casualty. Frequently, the outstripped resources represent more than just local capabilities but expand to regional if not national capabilities. The occurrence of such events is thought sufficiently rare that two things occur. First, we believe we will never be called upon to deal with such catastrophe; thus, we have little need to be prepared. Second, the event is attributed to a random, fate-driven, unpredictable occurrence over which we have no control at any level. Unfortunately, the student of history soon discovers the fallacy underlying both of these assumptions. Recent history, well documented in the lay press, is replete with examples of both natural and man-made events that fulfill the definition of needs exceeding resources at several levels. Further study of this history will reveal patterns that are common to all such events. This knowledge can form the core around which response methodologies can be developed. Rather than try to develop unique solutions for every imaginable occurrence, we can build on the common themes present in the disaster situation and the needed response. A template can be developed, trained, critiqued, and refined until there is a cogent understanding and response methodology in place.

Disasters can be natural, such as hurricane, tornado, earthquake, or flooding. They can be man-made, intentional or unintentional, such as the bombing of a building, fire through carelessness or an industrial accident in a commercial district of a city or rural area. They can be finite such as a building collapse that is confined in a particular time and place or ongoing, such as an open forest wildfire that will spread through hundreds of acres over weeks or flooding subsequent to a hurricane, the effects of which persist months if not longer. Despite the seemingly endless possibilities, there are lessons to learn if we are attentive enough. Specific injury patterns are associated with different mechanisms. Common to all these disasters is environmental exposure, either as heat or hypothermia. Burns are common. Blast effects are common as explosions frequently accompany many of these events. Inhalation of substances dispersed into the air is very common. Exposure to chemicals or radiation is common. Very important and frequently overlooked is the psychological effects of the event on both the victim population and the responding caregivers.

The importance to us as surgeons is that we are looked to as an important cog in the wheel of first responders. The infrastructure our trauma systems are built on will become paramount in mounting this response. Our background in rapid situational analysis and decision making makes us well versed in the skills now needed to overcome the event at hand. Unfortunately, we have backed away from engaging this challenge. Unfortunately, or fortunately, we are a key component of the response system the public will look to in the face of such events. This response is not empiric though. It is very different from everyday practice, even in the busiest of trauma centers. It is not even accorded any part of routine medical training at any level.

PHASES OF THE DISASTER

Important to recognize here is that the disaster has a life cycle as does any other organism. Appreciation of the phases of this cycle is a key starting point as we begin to develop our response methodology. The initial phase of the response is characterized by utter chaos. Normalcy is gone, leadership is nonexistent, and hysteria and fear prevail. How long this phase lasts is difficult to determine. Urban areas with rapid response times of organized police, fire, and rescue units may do a better job of curtailing the chaos than more rural communities just by nature of time and distance. What is true though is that until trained staff can superimpose a command and control structure, the chaos will continue. While the chaos is unabated, the population remains at risk and the situation will continue to escalate (Table 17.1).

The initial response and reorganization phase is characterized by the imposition of crisis management. This begins with the arrival of the first responders. A command structure is set up and a situational assessment made. A security methodology to minimize further injury is established. Search and rescue operations begin and patients are moved to appropriate locations. One caveat here is that good training, planning, and rehearsal will shorten the time required to set up this phase of the response. In the absence of such preparation, this may never get off the ground until far too late in the evolution of the disaster.

The initial response phase gives way to the site clearing phase. The transition can be thought of as the transition from crisis management to consequence management. Search and rescue may move to search and recovery as victims are rarely found alive beyond 48 hours after the event. Debris is cleared. Causalities are moved to hospitals for definitive care.

Finally, the event enters the phase of late recovery. Definitive medical care is rendered. Infrastructure is rebuilt. A rigorous critique of the situation and the response is carried out. The psychological health of the victims and responders

is assessed and treatment plans developed. The community determines what it needs to return to normal.[2] None of this happens a priori. How we begin to accomplish this follows next.

PLANNING

Military history can teach us much about planning. Dwight Eisenhower emphasized the planning process, not the plan per se, as the important component. George Patton espoused that plans need to be as simple and flexible as possible and made by those who will actually carry them out. All hospitals are required by the Joint Commission to have and rehearse a disaster plan on a regular basis. Thinking back to the last disaster plan discussion, much less drill, you may have participated in may give you some insight into the magnitude of the planning and preparation efforts of your institution. The disaster management cycle is illustrated in the accompanying diagram (Fig. 17.1). Ideally, we would like to begin by realizing what we need to prepare for, prepare for it, and then respond when tasked to do so. Historically, we frequently attempt to respond to the situation and make up a plan as we go. Hardly optimal. Plans are only as good as the assumptions they are based on. There are several elements deemed essential to a realistic plan (Table 17.2). There need to be valid assumptions about the threats faced; there needs to be some dependence on past performance critique; a systems approach that pulls together all components of the organization is important; everyone expected to participate in the execution of the plan needs to be part of the planning process; everyone needs to know and accept the plan; the expected participants need to be educated in the plan, both in a didactic and practical sense. Finally, the plan needs to be field tested, revised accordingly, and then retested.[3,4]

The first essential component of planning is to carry out a Hazard Vulnerability Analysis (HVA). This is a realistic assessment of the likelihood of particular events in your community. Both natural and man-made events need to be considered. For instance, living along the southeast coast of the United States, hurricane and flooding would need to be considered high on that list. Several such templates are available on the Internet, but without a realistic assessment of one's own location, the exercise is futile and the planning assumptions flawed.

TABLE 17.1

PHASES OF A DISASTER RESPONSE

1. Chaos

2. Initial response/reorganization
   {Crisis management}
   • Establish command post
   • Needs assessment
   • Security and safety procedures
   • Casualty evacuation to casualty collection areas (CCAs)

3. Site clearing
   • Search and rescue/recovery
   • Casualty distribution from CCAs to hospitals
   • Initial hospital medical care
   {Consequence management}

4. Late recovery
   • Rebuilding infrastructure
   • Definitive hospital medical care/secondary casualty distribution
   • Provider and casualty mental health follow-up
   • Postevent critique and analysis of disaster response
   • Community recovery

(From Stein M. Hirshberg A. Medical consequences of terrorism: the conventional weapons threat. *Surg Clin North Am.* 1999;1537–1552.)

FIGURE 17.1. The disaster response cycle. We usually begin by responding to an incident rather than preparing to mitigate the consequences of the event. (From *Disaster Management and Emergency Preparedness Course Manual.* Chicago, IL: American College of Surgeons Committee on Trauma; 2010 with permission.)

TABLE 17.2

ESSENTIAL ELEMENTS OF DISASTER PLANNING

- Valid assumptions of injury patterns, threats, human behavior, and needs
- A basis in the results of past disasters and established disaster response principles
- An interorganizational or "systems" approach of many elements working together
- Inclusion of the participants in a disaster response in the planning process
- Knowledge and acceptance of the plan by the participants in the disaster response
- Training and education of the participants
- Regular drills and exercises to test a plan's workability and revise as necessary

From *Disaster Management and Emergency Preparedness Course Manual*. Chicago, IL: American College of Surgeons Committee on Trauma; 2010.

TABLE 17.3

KEY QUESTIONS TO BE ADDRESSED IN A HOSPITAL DISASTER PLAN

1. Will the hospital automatically activate the plan, or will there be a situational assessment validation?
2. What command structure will be used, and how will the hospital leaders be educated?
3. How will triage be coordinated with the other facilities and EMS agencies?
4. When and how will the medical decontamination team be implemented?
5. How will the hospital sustain its operation?
6. What are the primary sources of communication available, and how will these sources assist in interacting with the community and regional activities?
7. How will an alternate care site be established? Who makes decisions?
8. What are the expectations and requirements for documentation during a response? How will an official business summary be completed?
9. How will the evacuation plan be executed? What equipment items are needed? How will this plan be communicated?
10. How will the facility and surrounding area be secured?
11. What long-range psycho-emotional plans are needed?
12. Will the hospital's emergency response impact surrounding businesses? How will this impact be communicated?

From *Disaster Management and Emergency Preparedness Course Manual*. Chicago, IL: American College of Surgeons Committee on Trauma; 2010.

Once the HVA has been completed, comes the difficult task of assessing readiness to deal with any of the events listed (Table 17.3). Who to bring to this discussion is an important decision. All the constituents of the community will own part of the response; thus, all need to be part of this analysis and discussion. This moves beyond the hospital quickly and encompasses governmental and private sector entities. The EMS community, police, fire, the media, religious organizations, local industry, and employers who will be affected all need to come to the table, be educated in and contribute to the planning process. History is also an important contributor to this discussion.

To illustrate the point, consider for a moment a situation where water pressure and electricity to an entire region were lost, generators were inaccessible, supply chains destroyed, roads impassable, and the health care infrastructure gone. Hurricane Katrina in New Orleans certainly entailed all these problems. But Hurricane Hugo in South Carolina in 1989 did all the same. What lessons were transferable and learned from one to the other should be clear to the critical reader.

A few generalizations can be made as well as some methods of deluding ourselves noted. Klein and Weigelt[5] comment on four areas of failure in disaster response. A communication system that completely collapses; no clear lines of authority; inadequate scene and hospital security and a disorganized health care system that tries to deliver care to all patients without appropriate triage. These become key considerations in the planning process. Delusion is a grand frame of mind and we fall into it regularly when we engage in disaster planning. We stage disaster drills with sufficient warning to all involved parties, we hold them during daylight hours and plan them not to inconvenience daily operations. We are not realistic in our assumptions about the consumption of supplies and minimize the need for resupply.

Finally, we will never be able to engage the disaster response adequately if we are not prepared in our own lives. The distraction of the safety of our own families is powerful yet can be tempered by attention to detail and arranging a methodology to have sufficient materials on hand at home. There are a variety of resources to guide us here, and the CDC and FEMA Web sites are excellent sources for this level of preparation.

INCIDENT COMMAND

Probably the most critical initial function of a disaster response is the establishment of an effective command and control methodology. This becomes obvious when one considers that large-scale events require multiple agencies to respond, each with their own command structure. Even within a small hospital, the issues with who is in charge or who is tasked with what responsibility in a given circumstance can be confusing. The necessity of establishing a functioning structure to control all the moving pieces is clear. The Incident Command Structure (ICS) used today grew out of the California wildfire experiences of the 1970s. The difficulty with coordination of activities among multiple responding agencies forced a better mechanism. After several iterations, the National Incident Management System was put forth by the Department of Homeland Security. The ICS was determined to be a best practice and is now the operational standard for all emergency response systems in the United States. While the ICS has its origins as a field operations tool, the inhospital equivalent parallels the field tool in descriptions and functionality. The Hospital Emergency Incident Command System is the same modular system with the same titles and responsibilities. It is intended to facilitate the coordinated response in the hospital and smooth the field-to-hospital transition.

The principles of the ICS are simple and straightforward. The goal is the rapid imposition of a command and control

system recognized by and agreed to by all response participants. Realizing that it can take up to 30 minutes to recoup every 5 minutes of chaos, such disaster situations induce a potent driver for such command and control systems. The ability to coordinate and escalate the response as needed is a key functionality of the ICS.

Structurally, the ICS allows expansion and contraction around several key positions (Algorithm. 17.1). The Incident Commander (IC) is the only position absolutely required in the construct. The concepts of unity of command and span of control are key factors that contribute to the functional success of this construct. Unity of command allows multiple agencies to coordinate activities under one overarching IC. The span of control is a recognition that everyone needs to report to only one clearly designated individual and that responders in leadership positions can only control a limited number of responders effectively, typically five to seven people. By keeping these lines of control well delineated and designated by job description rather than person, orderly progression and transfer of authority can occur.

Surrounding the IC are several key positions, all with clearly delineated responsibilities. Utilization of the same vocabulary for job titles and positions helps to ensure clear understanding of expectations and responsibilities. The IC has ultimate responsibility for all aspects of the response. The IC can delegate as seen appropriate by utilizing the staff surrounding and directly reporting to the IC. For instance, the safety officer is responsible for a safety assessment of the situation so that first responders do not unnecessarily endanger themselves. The Public Information Officer is the communication link, via the media, to the public to keep them informed of the situation. The liaison officer is tasked with coordination with other agencies as appropriate. These positions constitute the command staff.

There are four primary functionalities required to mount an effective response. All four report directly to the IC. Likewise, all four can expand or contract the response system beneath them as needed. These four are termed the general staff. They are the planning section, the operations section, the logistics section, and the finance and administration section.

The planning section is tasked with being the brains of the operation. Situational awareness is critical and keeping the IC informed of developments the key function. Likewise, the planning chief will direct the other sections as to the plan to be executed. Keeping ahead of developments and seeing where a preexisting response plan works well or needs modification are essential components of this position. The recorded lessons learned will be important in the after-action critique.

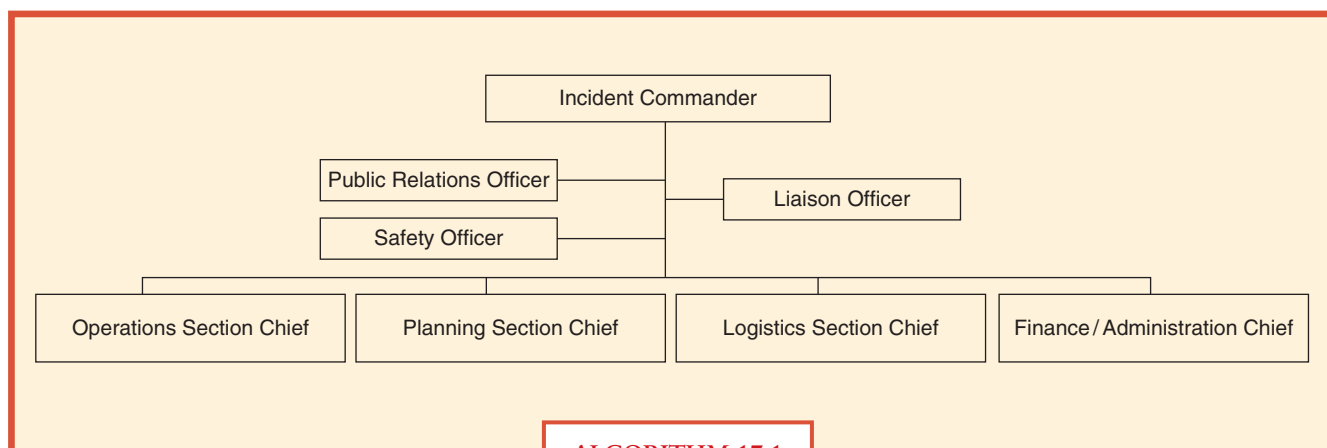
The operations section is the doer responsible for all aspects of the response. Arguably, all the other positions exist to support operations. Anything that requires something being done, from field search and rescue to evacuation to care, is the responsibility of operations.

The logistics section is responsible for all the material and manpower assets associated with the response effort. If it is needed to meet the demands of the disaster, logistics is responsible to get it or have it.

The finance and administration section is the record keeper for all activities associated with the response effort. Response personnel need time records maintained. Cost of materials needs to be tracked. Claims compensation needs to be determined. The overall cost of the response needs to be evaluated, in both human and fiscal terms, and mechanisms looked for that may bring cost savings in the future.

The interdependence of the four functionalities is very clear. The IC tasks operations with accomplishing a specific goal. The planning section informs the IC of the situation and how it compares to the predesigned response plan. Logistics supplies the people and supplies to accomplish the goal, and finance tracks the costs associated. What is also very clear is that this does not occur spontaneously. The great fallacy of Incident Command is that by assigning titles I have accomplished this goal. Individuals do not deserve one title or another based on seniority or everyday position. Without the proper education and opportunity to rehearse these positions in realistic drills, the system will fail. In similar fashion, multiple individuals need to be prepared to fulfill any role. There should be no key individual whose absence stymies the operation. Likewise, there needs to be provision for the smooth transition of individuals in a given position should the disaster continue for a prolonged time.

DEFINITIVE MEDICAL CARE

Up to this point, nothing has been said about the actual care of any injured patient or patients. That is because without the imposed structure of a disaster response plan that can function,


ALGORITHM 17.1

ALGORITHM 17.1 The incident command structure. (From *Disaster Management and Emergency Preparedness Course Manual*. Chicago, IL: American College of Surgeons Committee on Trauma; 2010 with permission.)

there is no definitive medical care. How to deliver care, where to do it, and who do we treat in what time frame are important questions that the response effort needs to answer. The mythology of disaster response needs to be appreciated as it will help guide our response.[4]

Popular mythology will contend that trained field personnel carry out initial field search and rescue operations. In reality, the survivors, or those less injured, perform this task. Similarly, the thought that the initial triage and treatment is done by trained providers is mythology. Survivors provide what they can and those injured who can move will self-transport to the closest health care facility. This uncovers another great myth, that patients are transported in an orderly fashion to appropriate hospitals. Victims of such events do not discriminate one type of hospital from another. All hospitals are equal and all are viewed as a safe haven for the injured. The hospital closest to the event will in all likelihood be flooded and overwhelmed by an influx of self-transported victims. By the very fact that these people were able to self-transport is indicative of their injury severity. The challenge for an individual hospital, and the larger response effort, is how to sort out those in need of immediate care from those with minimal or no injuries. Once identified, where do I send them and how do I do it? Can I provide the care I do everyday? Can I operate emergency services as I do every day when faced with such a circumstance?

TRIAGE

Modern American medical practice allows tremendous resource allocation toward any one patient regardless of the likelihood of survival. The resources that can be brought to bear usually so overwhelm the needs of the situation that the concept of rationing resources is virtually never considered. The modern trauma system is willing to accept tremendous overtriage in order to avoid undertriage at almost no consideration for the expenditure for that care. Quite the opposite when faced with a situation where, by definition, the resources needed to deal with a situation are outstripped by the demands of that situation. The triage process is arguably the most critical determinant of the success or failure of the response effort. Understanding the switch in mindset from an individual-based to a population-based health care ethic is crucial. The mechanics are straightforward but distinctly uncomfortable for the novice.

Triage is not a new or novel concept. The process of sorting based on severity of injury is used daily in emergency rooms around the nation. In reality, we do little real triage because of the overwhelming resources we command. The key first step to realize, when faced with a disaster or mass casualty event, is that we are no longer operating where the good of the individual is paramount. Rather, the distinctly public health perspective becomes operational and we now will make decisions based on the good of the greatest number or population as a whole. By definition, this means certain patients we would treat aggressively a few hours ago may now be relegated to delayed or expectant care. This is of course antithetical to our medical training, but without this mindset shift, the preventable mortality will increase markedly. Frykberg and associates[6–8] have demonstrated the effect of poor triage on mortality. An analysis of a large number of international events shows that the overwhelming number of patients is minimally injured with soft tissue or relatively minor orthopedic injuries. The percentage of patients with life-threatening injuries that are amenable to treatment under the constraints of treatment imposed by the event is approximately 20%. The challenge then becomes finding those 20%, initiating care in the field, and moving them expeditiously to definitive care. The concept of critical

mortality, the death rate among that 20%, has become a marker of the success or failure of the response.

Categorization of the injured for triage purposes allows for rapid initial sorting to identify who needs the most immediate care.[9] While there are a number of methods available, there are common attributes that warrant discussion. The first pass at triage, done at or adjacent to the scene of the event, will sort victims into immediate or delayed categories. The immediate victim has a life-threatening injury or injuries and requires rapid treatment (Table 17.4). The qualifier here is that the treatment rendered needs to be simple to apply. Opening an airway, compressing hemorrhage, decompression of a tension pneumothorax, providing a rescue breath may fall into this category. Anything that ties up a rescuer beyond brief moments is not applicable. The delayed category victim is hemodynamically stable and can tolerate a period of no or minimal treatment without impacting mortality. Fractures, open or closed, soft tissue injuries, some penetrating wounds, and some burns will fall into this category.

Within the delayed care category, further subdivision is possible. Those with minimal injury, the colloquial walking wounded, need little more than simple first aid and are relegated to such care when available. More difficult is the concept of expectant care and those dead. Victims without signs of life are dead. This is not the time or place for heroics that may occur in the emergency department or trauma bay under more usual circumstances. No resuscitative effort should be expended. Expectant care is care rendered to victims critically injured but who are not amenable to treatment given the constraints of the situation. If the probability of survival is so low, if the resources consumed in treating this victim would detract from the care of other more salvageable victims thus jeopardizing them, then expectant care is rendered. That is not the same as no care, as analgesia and comfort are important. Equally important is that medical personnel need to be assigned to monitor this group of victims. They may show signs of improvement that justifies moving to a higher level of care. The situation may change, resources become available that were not available before, fewer critically injured present that anticipated and now the expectant victim may qualify for treatment.[10]

The mechanics of triage are as important as the philosophy. The role of the triage officer, the error tolerance of the system, and the movement of victims from one place to another to unclog or decongest the scene or nearest hospital need consideration.

The triage officer is the individual charged with the decision making regarding who gets treatment. The position needs to be dedicated to this decision making and the individual cannot be tasked to other assignments or locations simultaneously. The decisions made are not intended to be negotiations at the site of the triage decision but rather the definitive decision. The independence of the position is critical. Practically speaking, anyone can function as a triage officer. Realistically, they need good situational awareness of both the number and types of injuries being presented and the treatment resources available at any given point in time. The triage officer does not have to be the senior clinician but can be a qualified prehospital provider, nurse, or physician. The requirements for the triage officer may change depending on the nature of the event. For example, a surgeon versed in blast injuries may be well qualified to deal with causalities of a building collapse but poorly qualified to deal with a specific chemical spill or pandemic-like situation. The ability to work in a stressful environment, make rapid, sound clinical assessments, and maintain an awareness of the entire scope of the event and response are the critical job requirements.

In such a rapid-fire decision-making atmosphere, where large numbers of victims present simultaneously, errors will

TABLE 17.4

PRIMARY TRIAGE CATEGORIES

■ ACUTE	■ NONACUTE
(Immediate, Priority 1)	(Delayed, Minimal, Expectant, Dead)
Nonambulatory Patients with Physiologic Criteria • Airway: unstable • Breathing: present • Circulation: active bleeding, lack of pulse • 2 s capillary refill • Disability: not following simple command Low GCS ≤14 Motor GCS ≤5	**Walking Wounded** • Minimal soft tissue injuries • Superficial burns **Urgent, Non–Life-Threatening Injuries** • No airway compromise • No respiratory compromise • Extensive burns (deep, >30% TBSA) • Multiple orthopedic injuries
Exposure (Anatomic Criteria) • -4 body regions injured • Penetrating head wounds • Penetrating torso wounds	**Unsalvageable Injuries** • Unresponsive, not breathing • Traumatic amputation • Open head and chest wounds
Clinical Judgment and Expertise

happen. The system needs to develop error tolerance and the triage officer cannot be frozen by the possibility of error. As victims move through the system, they need to be re-triaged at subsequent stations. This reiterative methodology will minimize errors and allow rapid decompression of the incident zone and transport of victims to other areas for staging or care. If done correctly, the victims who reach the hospital, or point of definitive care, will be the critically injured most likely to benefit from aggressive care. The mandate of identifying the 20% critically injured and minimizing that mortality can now be tackled. In the absence of any of these, the system will become overrun with victims who do not need, or will not benefit from, immediate care and a key characteristic of effective triage missed. The point is that the process is dynamic and the rules change as the situation and response changes. For instance, the sudden, unexpected availability of personnel or material resources increases the number of victims that may be attended to, whereas the sudden loss of electrical power or depletion of supplies may well have the opposite effect. A lull in the influx of new injured victims may present an opportunity to address victims previously assigned to the expectant group. Unless the triage officer is aware of these nuances, opportunities will be lost.

There are two additional methods used to help the triage system that deserve consideration. Both entail movement of victims from the scene. The concept noted above moves victims to any of a number of casualty collection points. These points are removed from the incident scene but are not the hospital. Re-triage occurs and the victim can be "leapfrogged" from the field to any of the available hospitals in an attempt to minimize overloading any one hospital and rendering that hospital inoperable. The most critically injured victims would be transported to the closest hospital for definitive care while those less injured would be transported to hospitals at a greater distance from the scene. Secondary hospital distribution is a method of redistributing victims to other hospitals with capacity and capability to deal with them. This functionally off loads one hospital and minimizes

the treatment delays that may be experienced. Both of these require a well-functioning regional incident command system with the knowledge of system-wide capabilities and the ability to move victims through the region.

The flip side of this process is undertriage. We accept tremendous overtriage every day to minimize undertriage. The process of mass casualty triage risks undertriage by its very nature. For this reason, the triage officer needs to be versed in the types of injuries presented. Different individuals with different qualifications may need to fill that role as the situation dictates. Additionally, the areas where less critically injured victims are assembled need to be staffed by medical personnel who can monitor for deterioration in clinical status, initiate appropriate treatment, and escalate care by moving the victim to a more urgent care area.

THE HOSPITAL RESPONSE

Up to this point, most of the emphasis in the discussion has been on the system-wide response to a disaster or mass casualty event. The specific role of the hospital now warrants consideration. Unless prepared, the hospital risks being overrun and rendered inoperable, not just for the disaster situation but for daily operations as well. When mobilized, the hospital incident command system will direct activities in the hospital and coordinate with other regional assets as required. Internally, there are two important concepts for the hospital to be aware of and be able to manipulate. One is the surge capacity and the other surge capability.[11] Surge capacity is the number or percentage of beds over and above maximum capacity the institution can mobilize. This is frequently up to 20% over and above the number of usually staffed beds in the hospital. Surge capability is the ability to staff those additional beds with appropriate nursing, paraprofessional, and other staff to make them usable. The effect of overtriage on surge capacity is clear. As overtriage exceeds 25%, the surge capacity is reduced dramatically. Hirshberg and associates demonstrated that with

appropriate utilization of resources, the number of critically injured victims who can be treated can be increased without the concomitant decrease in the global level of care.[12–14]

The hospital will need to have in place plans for security, staff recall, resupply, and how to deal with other non–disaster-related aspects of daily care that will continue to go on simultaneously. Record keeping is a critical issue for the hospital. Accurate patient tracking and documentation of assessment and care rendered is required. The record keeping needs to be as simple as possible, using flowsheets that are well known to the staff and that do not require learning new systems. Communications can be expected to fail and the media will arrive looking for information. How well the hospital deals with these issues is a function of how well they planned for them.

SPECIFIC INJURY PATTERNS

A number of specific injury patterns require understanding if one is to effectively triage and treat these injuries. Blast injuries accompany explosions and are arguably one of the most common presenting injury patterns known. The common occurrence of bombings internationally makes knowledge of this particular pathophysiology germane to those who will respond to and treat these victims.[15]

The typical high energy explosive is capable of creating a blast wave that can exceed 4,000 m/s velocity. The incredibly rapid rise above ambient air pressure is responsible for the shatter ability of the blast. As the marked pressure head diminishes, there is a negative pressure phenomenon that sucks debris back toward the epicenter of the event. This blast wind, or to and fro air motion, gives the characteristic explosion followed by implosion.

The mechanics of the blast determines magnitude of injury. The initial force, distance from the center, interior versus exterior location, and open air or underwater are usually considered the mechanical factors at work determining magnitude of injury. Since the blast wave dissipates as the cube of the distance away from the center, mitigation of blast effect is straightforward if one is a modest distance away. Interior blasts allow reflection of energy with resultant magnification of effect. Water allows a greater distance for energy propagation due to the density of water compared to air.[16]

Blast injuries are categorized into one of four types (Table 17.5). Primary blast injury refers to the direct effect of the blast wave as it passes through the body. Air–water interfaces are especially prone to disruption as turbulence is most severe here. The lung is vulnerable in air blasts while the gastrointestinal tract is at risk underwater. Unfortunately, most victims of primary blast lung injury die as a result of cerebral or coronary air embolus. Those who do survive to hospitalization require treatment for severe pulmonary contusion or ARDS like pathophysiology.

Secondary blast injury arises from objects set in motion crashing into a victim. A special circumstance to be aware of is the ability to pack bombs with materials that act as shrapnel, causing a multitude of penetrating wounds scattered throughout the victim's body. These victims may look surprisingly well initially except for being pockmarked all over. A high degree of suspicion will evaluate these aggressively and determine the real extent of injury.

Tertiary blast injury occurs when a victim is picked up or thrown into other more stationary objects. By and large, secondary and tertiary injuries induce typical blunt injury patterns. Quaternary injuries refer to the indirect effects of the blast such as noxious inhaled materials, burns, crush injuries, and the like.

TABLE 17.5

MECHANISMS OF BLAST INJURY

■ CATEGORY	■ CHARACTERISTICS	■ BODY PART AFFECTED	■ TYPES OF INJURIES
Primary	Unique to HE, results from the impact of the over pressurization wave with body surfaces	Gas-filled structures are most susceptible lungs, GI tract, and middle ear	• Blast lung (pulmonary barotrauma • TM rupture and middle ear damage • Abdominal hemorrhage and perforation Globe (eye) rupture Compression (TBI without physical signs of head injury) • Traumatic amputations
Secondary	Results from flying debris and bomb fragments	Any body part may be affected	• Penetrating ballistic (fragmentation) or blunt injuries • Eye penetration (can be occult)
Tertiary	Results from individuals being thrown by the blast wind	Any body part may be affected	• Fractures • Closed and open brain injury
Quaternary	All explosion-related injuries, illnesses, or diseases not due to primary, secondary, or tertiary mechanisms Includes exacerbation or complications of existing conditions.	Any body part may be affected	• Burns (flash, partial, and full thickness) • Crush injuries • Closed and open brain injury • Asthma, COPD, or other breathing problems from dust, smoke, or toxic fumes • Angina • Hyperglycemia, hypertension

From *Disaster Management and Emergency Preparedness Course Manual*. Chicago, IL: American College of Surgeons Committee on Trauma; 2010.

The literature regarding the patterns of blast wounds is replete with descriptions of predictable patterns. Interestingly, most survivors are not critically injured. The severely injured are dead. Regardless, a victim with evidence of primary blast injury, head and/or torso injury, or amputation needs aggressive evaluation to preclude serious injury. A major issue with blast injury is that the naïve triage officer will be distracted by the visual appearance and not appreciate that many of these are soft tissue wounds that can be delayed several hours. The tendency for overtriage here needs to be mitigated.

A discussion of blast injury needs to mention the second hit phenomenon at least to make the triage and treatment teams aware of the concept. Secondary delayed explosions, either intentional or otherwise, have the potential to injure the responders and markedly complicate the response. A building explosion and collapse that 30 minutes later has an explosion of a fractured gas line, when the first responders are just on scene doing search and rescue, is a devastating event that needs to have mitigation before allowing first responders in the building. In a more nefarious construct, the intentional detonation of a secondary delayed device intended to injure the response teams is well described in this literature. This serves to reiterate the primary role of scene safety for the response providers. As much as possible, the scene needs to be secured before allowing rescue personnel access to the scene.[17]

The other common mechanisms of mass casualty include chemical exposure, radiologic exposure, and biologic agents. A detailed discussion of these agents is beyond the scope of this chapter. A few brief considerations are in order though.

Chemical agents have been used as weapons since antiquity and in recent history. Their detection can be very difficult and only by the recognition of specific clinical syndromes. Industrial incidents at least have requirements for posting potential toxins and the information is frequently forthcoming from the safety officers tasked to the job site. In either case, the responders need to protect themselves and provide decontamination of the victims prior to allowing entry to the hospital. The spectrum of personal protective gear and its use should be trained and drilled by all institutions that may need to respond to such events. Triage and decontamination needs to occur outside the hospital. Frequently, simply undressing the victim and washing with soap and water accomplishes the overwhelming majority of the decontamination. More specific decontamination may be dictated by special circumstances or exposure to specific agents. Any disaster plan needs to consider decontamination. Where it will occur, when it will occur, who will be responsible for operation of and maintaining the equipment and how will the victims be trafficked through the system are all integral questions the plan needs to address.

Nuclear or radiologic exposure induces panic quickly. The reality is that nuclear exposure is far easier to contend with than chemical exposure. The nuclear-exposed victim may be very ill but is a minimal threat to the health care team. Good decontamination is essential but, as with chemical exposure, undressing and showering or washing with soap and water is usually sufficient. Electromagnetic radiation, x-rays, and gamma rays have a high degree of penetration and induce the most damage. The victim though is not "radioactive" and not a real threat to the treatment team. Particle radiation, alpha and beta particles, penetrate minimally, need to be ingested for significant injury, and can be treated easily. Local effects are burn-like symptoms that require local treatment. Decontamination proceeds as noted above. If the treatment team exercises universal precautions, they will be well protected. Clothing taken from victims needs to be contained as does runoff water.

Medical care of nuclear and radiologic contamination is generally supportive. The psychologic effects of being irradiated may be more devastating than the physical consequences, and this will need to be addressed in the treatment algorithm for these victims. From the perspective of triage decision making, the time from irradiation to first emesis is critical. If emesis occurs within an hour of exposure, then the victim likely has had a lethal exposure and warrants supportive but expectant care. In such events, specific information can be obtained from the radiation safety officer on the IC's staff.

Biologic disasters are driven by microorganisms. While anthrax has been the agent of concern in the recent past, the experience with H1N1 may actually serve as a better example of how such a situation might unfold. Unlike a blast or chemical exposure event with its dramatic occurrence, the infectious disease and public health communities, through a process of syndromic surveillance, would piece together the clues from patterns of illness presenting to emergency departments, clinics, and private physician offices to come to the realization that an event was occurring. From the perspective of the disaster response plan, very little may need to change. If correctly developed, the flexibility and fluidity in the plan will direct response actions. H1N1 raised the specter of a pandemic and many organizations rehearsed scenarios to deal with the consequences.

RECOVERY

The goal of planning is to build resiliency in our community. That means we return to normal as soon as possible. It carries the additional mandate to mitigate future risk as much as possible. The issue now is that people are tired and want to get back to life as they knew it. Unfortunately, there is still a formidable task ahead. Two issues need to be clarified. One, the response personnel will have an emotional reaction to the events that need to be acknowledged and dealt with. Failure to so do will result in downstream psychological effects for some of the providers that may be crippling. A critical incident stress debriefing methodology should be offered to all members of the response system. These are small, unit-specific, not recorded meetings that allow people to process the emotional turmoil associated with the event. Resources should be available for individuals to help deal with the aftermath of the crisis. Additionally, we all need to be on the look out for personality changes exhibited by team members over the coming months, which provide clues that someone is not dealing with the aftermath well. New destructive habits, withdrawal and isolation, social disengagement, and decrement in job performance all point in this direction.

The second issue that is critically important is the after-action assessment of the event. This is a detailed critique of the response effort. This is the time to discuss triage decisions. This is the time to compare the plan going into the event with how well it is actually performed. The notes taken by participants become an important source of information at this juncture. Every aspect of the operation needs discussion, and all participants get a voice in the discussion. The lessons learned in this critique will form the template upon which the current disaster plan will be revised. That revision will set up the training and drilling agenda in the near future. The questions raised here pose the hypothetical situations, the what-if's that need to be accounted for going forward. This is not a simple or short meeting. This can be a very ego-threatening meeting at a time when ego strength is not especially strong. The importance of not losing these lessons is so high that we need to be aware, as much as possible, of the fragile nature of the discussants.

A common critique that arises from these sessions is that the disaster plan was completely inadequate. This is an indictment of a planning process carried out in a void, without appropriate clinical input and with no acknowledgement of the history of such events. Now is the time to correct that and develop an appropriate response methodology (Table 17.6).

This "predictable surprise" has been described by Bazerman and Watkins.[18] Their thesis is that most disasters are predictable but there are operational characteristics that actively interfere with adequate preparation. First of these is that the leadership knows a problem exists that will not fix itself. Additionally, everyone acknowledges that the problem is getting worse over time. Fixing the problem will be expensive in terms of material resource, human resource, and money. While there are great benefits to fixing the problem, uncertainty, delay and cost stand in the way. They further argue that we actually favor the status quo and a small group actually benefits from inaction. Lastly, the leadership gets little if any credit for prevention, so the incentive to move forward is minimal.

How to circumvent this blockade? Returning to the HVA discussed earlier is a good starting point. A realistic appraisal of the risk stratification, especially in light of the most recent experience, can begin to set the tone for revision of the disaster plan. Incorporating lessons from the disaster literature and then using imagination to think "out of the box" and engendering a discussion of possibilities begin to sharpen the revision discussions. Unfortunately, all the planning and imaging in the world will not compensate for a lack of education and rehearsal. The modified disaster plan now needs to be vetted and communicated to the participants who will execute it. The drills need to be realistic, inconvenient, and conducted at all times of the day so as to best mimic an actual occurrence.

SURGICAL VOLUNTEERISM

In the aftermath of the Haiti earthquake in January 2010, physicians came forward in large numbers to volunteer to help. Locally, these types of "mass volunteer" events contribute to confusion and interfere with the response. Frequently, the well-intentioned volunteer has no training, background, or experience in working in such circumstances. Austere environment medicine is dramatically different from our usual everyday work condition. While the intention is not to discourage volunteers, there does need to be an element of reality injected into the discussion.

There is no substitute for education and training to prepare one to work in such conditions. There are a variety of opportunities to gain this experience. The DMAT (Disaster Medical Assistance Teams) of FEMA are a common method. International Medical Surgical Response Teams (IMSuRT) are another. A number of national organizations, both governmental and private, can provide volunteer opportunities in a variety of venues around the world. Operation Giving Back of the American College of Surgeons offers a wide range of volunteer opportunities that can accomplish the same goals. The point is that preparation counts. Joining a credible organization that has experience in austere environments and that will provide a modicum of training prior to working in those environments will prepare one well to function in disaster situations. Locally, the situation is not very different. Well-trained and prepared providers will contribute to the success of a response effort. Not everyone needs to deploy overseas to understand how this medicine is different. The appropriate education to facilitate participation in disaster response can be obtained in a variety of ways. We all should obtain a minimum of training in disaster planning and response as part of our regular ongoing education. The American College of Surgeons offers a program designed to do this through the Disaster Management and Emergency Preparedness© course. Alternatively, the National Disaster Life Support curriculum offers an excellent introduction to disaster response planning and management. Regardless of how it is obtained, this knowledge base needs to be mastered before one can realistically contribute to such a response effort.

SUMMARY

There is really very little surprise in the occurrence of a disaster or mass casualty event. History has a plethora of lessons to guide our response if we are willing to study and learn. Our reluctance to fully engage the planning, training, and drilling process probably reflects our belief that this will never happen here or to me. Unfortunately, as surgeons, we will be looked to as leaders, especially in events where trauma predominates. We need to be personally prepared, we need to push the senior administrative structures to support the planning and training effort, and we must continually advocate for integration of the disaster response plan across the entire community, encompassing the prehospital and hospital components. Once we have mastered these steps, we will have done all we can to build resiliency into our community. We may not be able to avoid a disaster or mass casualty situation, but we can be as well prepared as we possibly can to cope with it and minimize the subsequent damage.

TABLE 17.6

COMMON RECOVERY PITFALLS

1. No postevent analysis and critique.
2. Planning based on the last disaster.
3. Excluding mental health in planning.
4. Forgetting local hazard vulnerability analysis.
5. While events may not be preventable, consequences may be lessened.
6. Not learning from prior disasters reported in the literature.
7. Mistaking the role of nonlocal assets in acute disaster response.

FUNDAMENTAL PRINCIPLES

CHAPTER 18 ■ INJURY PREVENTION

JENNIFER C. ROBERTS AND KAREN J. BRASEL

SCOPE OF THE PROBLEM

Webster defines the term accident as "an unforeseen and unplanned event or circumstance" and specifically when related to an injury as "an unexpected happening causing loss or injury which is not due to any fault or misconduct on the part of the person injured."[1] While this term is commonly used when talking about unintentional injury in both the medical community and lay press, it is a misnomer. "Accidents" are actually injuries that occur under predictable and preventable circumstances. Injuries result from physical damage sustained following exposure to harmful agents, such as heat, electricity, mechanical energy, radiation, and poisons. In the United States, 59 million or 1 in 4 Americans suffer an injury annually. This results in 36 million emergency department visits and nearly 2.9 million admissions each year.[2] Injuries are also a significant cause of mortality. Unintentional injury is the fourth leading cause of death overall, accounting for over 140,000 deaths (6.5% of all deaths) annually. In children, adolescents, and adults in the 1–44 age group, it is the leading cause of death.[3] When considering other leading causes of death such as cancer, heart disease, congenital abnormalities and HIV, unintentional injury accounts for more death and years of potential life lost before the age of 75 than the other leading causes of death combined.[3]

Death following trauma occurs in a predictable, trimodal distribution (Fig. 18.1). As depicted in the graph, more than half of the deaths occur within the first hour following injury. Particularly in individuals sustaining a head injury, those that do survive to definitive care often die from their injuries despite adequate care. As a result, it is clear that trauma prevention efforts are the only mode of injury prevention that can impact this population of victims.

The following chapter describes the early development of injury prevention, key thinkers in early prevention efforts, and the contribution the field of epidemiology has made to injury prevention. Attention is then focused on key principles that should be considered when developing injury prevention programs with special consideration given to the assessment of injury prevention effectiveness. Finally, the chapter provides specific examples where these principles have been successfully applied to both unintentional and intentional injury prevention.

FOUNDATIONS OF INJURY PREVENTION

An appropriate starting point for any discussion on injury prevention is John Gordon. In the 1940s, John Gordon first described injuries from an epidemiological perspective. He noted that, like other disease processes, unintentional injury occurs in predictable patterns. Specifically, he hypothesized that injuries were a result of an interaction between the host, the agent, and the environment.[4] This "epidemiological triad" forms the basis of modern epidemiological studies. While it is true that injuries affect specific individuals, studying patterns of injury across different social groups is crucial to prevent injury at a population level.

Whereas John Gordon laid the foundations for the beginning of injury prevention research, the first true leader in the field was William Haddon Jr. Realizing that injuries result from a transfer of energy from the vehicle to the host (human body), he expanded Gordon's epidemiological triad and formulated Haddon's Matrix. Haddon's matrix is best described as a grid with three rows and four columns. Each row represents different phases of an injury: pre-event, event, and post-event. The four columns represent different factors that influence the severity of the injury: host, vector, physical environment, and social environment. In the pre-event phase, each of the four factors influences the likelihood that an event will occur. In the event phase, the factors interact to influence the severity of the event. Lastly, in the post-event phase, each factor determines the overall outcome.[5] Consider an example where an intoxicated driver strikes an elderly pedestrian at night in a rural community (Table 18.1).

As a conceptual model, Haddon's Matrix has been an invaluable tool used in injury prevention. In addition, Haddon later went on to develop 10 different approaches specifically targeted to prevent or control human injury. Like the matrix, they can be broken down into three phases: pre-event, event, and post-event. In brief, the 10 general strategies with examples are[5]: (Table 18.2).

1. Prevent the creation of the hazard. Example: Laws to prevent the manufacture of certain poisons, drugs, weapons.
2. Reduce the amount of the hazard. Example: Speed limits, boating regulations, firework laws.
3. Prevent the release of the hazard. Example: Trigger locks for guns, nuclear waste management programs.
4. Modify the rate or spatial distribution of the hazard: Example: Antilock brakes, airbags, seat belts.
5. Separate, in time or space, the hazard from persons to be protected. Example: Isolation units in hospitals, pedestrian walkways.
6. Separate the hazard from persons to be protected by means of a mechanical barrier. Example: Exam gloves, helmets, hazardous material containers.
7. Modify the hazard to reduce the potential for injury. Example: Medications with fewer side effects, guardrails, guards on hand saws.
8. Make what is to be protected more resistant to damage from the hazard. Example: Immunizations, fire resistant clothing for children, earthquake resistant buildings.
9. Counter the damage that has already been done by the hazard. Example: Trauma systems, disaster response teams.
10. Stabilize, repair, and rehabilitate the damaged objects. Example: Critical care medicine, reconstructive surgery, physical therapy.

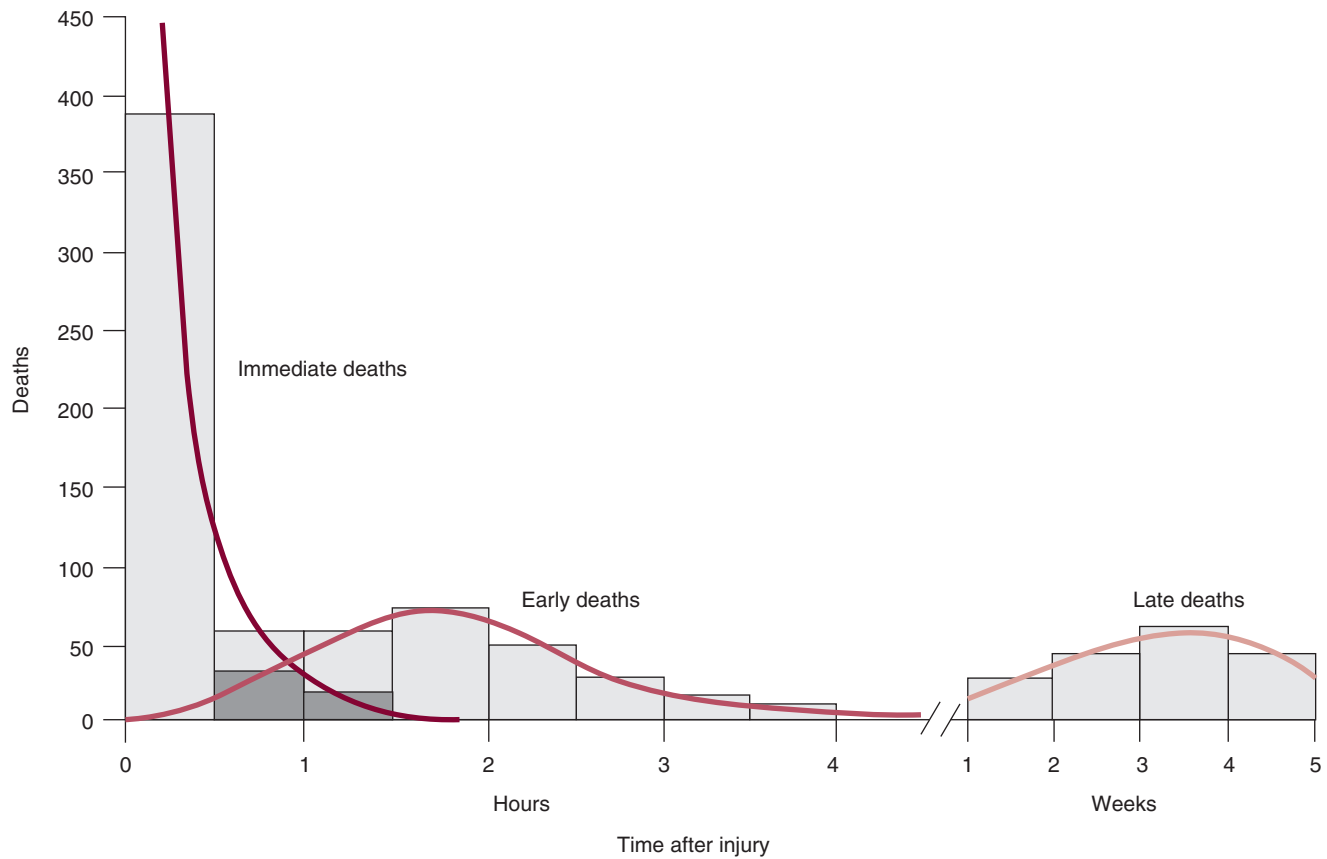
In the 1960s, Haddon noted that "It has been the consistent experience of public health agencies concerned with the reduction of other causes of morbidity and mortality that measures, which do not require the continued, active cooperation of the public, are much more efficacious than those that do."[5] The term "active intervention" now serves to describe injury prevention efforts that require people to perform an act or change in behavior such as putting on a seat belt or wearing a bicycle helmet. A "passive intervention" then is one in which


FIGURE 18.1. The trimodal distribution of trauma deaths as described in Trunkey DD. Trauma. *Sci Am.* 1983;249;28. (Reprinted from Feliciano D, Mattox K, Moore E. *Trauma.* 6th ed. New York: McGraw-Hill; 2008, with permission).

no action on the part of those being protected is required. Airbags are an example of a passive intervention. Intuitively, it makes sense that passive interventions are more efficacious in terms of preventing morbidity and mortality as the prevention is automatically built into the design of the intervention.

TABLE 18.1

HADDON'S 10 STRATEGIES TO PREVENT AND CONTROL INJURY

Pre-event phase
  1. Prevent the creation of the hazard
  2. Reduce the amount of the hazard
  3. Prevent the release of the hazard.

Event phase
  4. Modify the rate or spatial distribution of the hazard
  5. Separate in time or space the hazard from persons to be protected
  6. Separate the hazard from persons to be protected by means of a mechanical barrier
  7. Modify the hazard to reduce the potential for injury
  8. Make what is to be protected more resistant to damage from the hazard

Post-event phase
  9. Counter the damage that has already been done by the hazard
  10. Stabilize, repair, and rehabilitate the damaged objects

However, it is important to note that passive interventions usually require action on the part of society as a whole. As an example, in the late 1960s, to protect the public from unreasonable risk of injury following motor vehicle crashes (MVCs), the Federal Motor Vehicle Safety Standards (FMVSS) were put in place. The FMVSS are a set of regulations that describe the minimum safety performance requirement for motor vehicles, which must be met by all car manufactures.[6] Under the supervision of the National Highway Traffic Safety Administration, it has been estimated that approximately 10,000 to 30,000 lives per year have been saved since its implementation.[7,8]

CLASSIFICATION OF INJURY PREVENTION

It is clear that William Haddon has made notable contributions to the field of injury prevention. Through the interactions between phases and factors, Haddon's matrix is the foundation for newer concepts: primary, secondary, and tertiary prevention.[9] Primary prevention is described as the complete elimination of the hazardous event. Consider scald burns in children as an example. Young age is associated with an increased risk of scald injury.[10,11] Several studies have demonstrated that there is a clear relationship between water temperature and scald injury severity. Full-thickness burns can occur between 2 and 5 seconds at 60°C, and between 10 and 30 seconds at 55°C. At 52°C, 3 minutes of exposure is required to produce burns.[12,13] Logically, most scald burns due to tap water can be prevented by keeping the temperature in hot water heaters to

TABLE 18.2

EXAMPLE OF INTERACTIONS IN HADDON'S MATRIX

PHASE	HOST	VECTOR	PHYSICAL ENVIRONMENT	SOCIAL ENVIRONMENT
Pre-event	Impaired driver	Condition of vehicle headlights and breaks	Poor visibility	Traffic regulations
	Pedestrian crossing road	Vehicle speed	Road conditions Street signs	Law enforcement Local attitudes toward drunk driving
Event	Safety belt use	Airbags	Breakaway poles	Presence of local first responders and volunteers
	Hearing impaired pedestrian	Impact protection devices		
Post-event	Severity of injury	Severity of emotional distress of driver	Access to trauma center	Access to rehabilitation facilities
	Coping mechanisms of the injured			Community attitudes toward legal consequences

52°C or less. In 1983, Washington State passed a legislation requiring new water heaters to be set at 49°C. It also called for warning labels on water heaters, and annual notices for customers, homeowners, and landlords describing energy savings associated with lower water temperatures.[14] This legislation was extremely effective, as admissions for tap water scalds declined by 56% in two teaching hospitals in Washington state. More states adopted this legislation and since then scald-related death has decreased by half for all age groups and by 75% for children.[15]

While primary prevention efforts serve to eliminate the potential for injury before it occurs, this is not always possible. Secondary prevention minimizes the amount of injury that occurs when the event cannot be prevented. In a MVC, the most significant causes of injury occur during ejection, or collisions within the interior of the vehicle. Devices to dissipate kinetic energy in a more controlled fashion are designed to prevent this type of injury. There is little doubt that one such device, the seat belt, has saved thousands of lives (see following section on seat belts). A somewhat more controversial secondary prevention device is the airbag. Initially developed in the 1950s, first-generation airbags were made of nylon and were designed to deploy following a specific change in velocity. In 1989, the National Highway Traffic Safety Association (NHTSA) mandated the use of either driver airbags or automatic seat belts and by 1998 the NHTSA expanded this to include the installation of both driver and passenger airbags in all new cars. As a result, new patterns of injury associated with airbag deployment emerged. Particularly in children, there was an increase in facial fractures, cervical spine injuries, odontoid fractures, and extremity fractures in crashes with airbag deployment.[16–18] There was also an increase in both mild and moderate head injury when airbags are deployed.[19] As a result, second-generation airbags or "depowered" airbags are now mandated in new vehicles. Williams et al. has since reevaluated injuries associated with second-generation airbags and found that, when compared to no restraint device, airbags were associated with decreased odds of having a brain injury, or abdominal injury and had a decrease in infectious morbidity, hospital resource use, and mortality.[20]

Restraint devices have saved thousands of lives and are an excellent example of secondary prevention. Tertiary prevention can be thought of as efforts that will optimize the outcome after an injury has occurred. An example is the development of trauma centers and the trauma triage system. In the early 1970s, trauma patients were transported to the nearest hospital regardless of institutional resources. As the concept of specialized trauma centers evolved, in 1976 the American College of Surgeons (ACS) developed a document entitled "Resources for Optimal Care of the Injured Patient."[20] This resource outlined mechanistic, physiologic, and anatomic criteria that warranted transport to a trauma center following an injury. After its implementation, the first reports of improved morbidity and mortality associated with the use of specialized trauma centers emerged.[22] The American College of Surgeons Field Triage System is an extension of the "Resources" guidelines. This scheme has four steps[23]:

1. Assessment of vital signs, and level of consciousness.
2. Assessment of anatomic injury.
3. Assessment of the mechanism of injury with specific search for evidence of high-risk collisions (e.g., auto vs. pedestrian, motorcycle crash >20 mph).
4. Assessment of special patient or system considerations (e.g., age, burns, pregnancy).

The beneficial result of improved trauma systems is also considerable.[24] As an example, when controlling for other factors, in a study comparing mortality in Level I trauma centers versus non-trauma centers across 14 different states, MacKenzie et al.[25] found that the risk of death was considerably lower when patients were cared for at a trauma center.

TYPES OF PREVENTION EFFORTS

Whether primary, secondary, or tertiary prevention is the intent, the implementation of injury prevention strategies can be thought of according to the four "E's:" (1) Education, (2) Enforcement and legislation, (3) Engineering, (4) Economics. Education and efforts to promote behavioral change in high-risk groups have classically been the cornerstones of injury prevention design. This is based on the principle that knowledge will lead to behavioral changes. An example of a successful educational program is the "Just say no" campaign. As a part of the advertising strategy for the US "War on Drugs" in the late 1980s and 1990s, the slogan "Just Say No" was championed by the then first lady Nancy Reagan. When approached by an elementary school student who asked what the first lady would do if she was offered an illegal drug, Mrs. Reagan replied "Just say no." The phrase caught on immediately and

led to the formation of thousands of "Just say no" groups across the United States. Mrs. Reagan visited drug rehabilitation and prevention institutions, and enlisted the help of several community groups, including the Girl Scouts of America and the Kiwanis Club to get the message out that drugs are harmful. "Just say no" also became a part of pop culture, appearing on popular television programs, in music videos, and on billboards across the United States.[26] While it is difficult to infer a causal relationship, the National Institute on Drug Abuse reported a significant decrease in marijuana, cocaine, and heroin use amongst high school students in the 1980s.[27]

Enforcement and legislation are also important in injury prevention. Despite adequate educational attempts, there are always individuals who will resist change, even when they may benefit from the improved outcome. As an example, despite considerable evidence to support the fact that restraint belts save lives and prevent serious injury, seat belt usage in the United States is not 100%. Currently, 30 states and the District of Columbia have primary enforcement laws where police may stop vehicles solely for occupants not wearing seat belts.[28] However, in states where primary enforcement laws are in place, 86% of occupants wear seat belts versus 78% of occupants in states where seat belt use is not enforced.[29]

Engineering and technology encompass a wide variety of topics, and may have the largest impact on injury when considering long-term benefits. Examples where engineering has been useful include the development of trigger locks on firearms, earthquake resistant buildings, and built-in protective devices on manufacturing equipment. Following the 1994 earthquake that struck Northridge California, a population-based cohort study was conducted to determine factors associated with increased physical injury. This study was unique in that it sought to examine how seismic risk factors, patient demographics, and building characteristics simultaneously interacted to produce injury compared to an exposure matched cohort. When controlling for other factors, building and seismic factors were identified, which independently increased risk of injury.[30] This information was useful to give back to engineers to target points of intervention.

Funding for injury prevention programs is generally inadequate. Within the community, there is a finite supply of volunteer services, not-for-profit organizations, and donations. Economic incentives (or penalties) can serve to reinforce legislative efforts when patient participation is required for successful prevention. Insurance companies, for example, have data on risk-taking behavioral patterns. Discounted premiums can then be offered to groups with lower risks (i.e., High school drivers who meet a minimum GPA). In a different example, consider the use of child car seats. It is well recognized that, particularly in the 0–4 age group, infants and young children do not fit into adult-sized seat belts and can suffer devastating injury if unrestrained in a MVC. All 50 states currently require child car seats. The success of this legislation is seen in the reduction in childhood deaths related to motor vehicles. When compared to 1994, where primary enforcement of child car seats was not mandatory, there were 682 deaths in the United States from MVCs compared with 471 deaths in 2006.[3,31]

EVALUATION OF INJURY PREVENTION STRATEGIES

Whether the prevention strategy is education, legislation and enforcement, engineering or economic, critical evaluation of the effectiveness of a program is essential. Outcome assessment is vital to continue to fund strategies with proven benefit and is

1. Death   Most desirable
2. Injuries requiring inpatient treatment
3. Injuries requiring outpatient treatment
4. All injuries
5. Behavioral changes
6. Self-reported changes
7. Measures of knowledge or beliefs
                                                            Easiest to measure
FIGURE 18.2. Hierarchy of outcomes associated with injury prevention techniques as described by Maier R, Mock C. Chapter 3. Injury prevention (Chapter). In: Feliciano D, Mattox K, Moore E, eds. *Trauma*. 6th ed.

likewise useful to identify those that do not work. Many educational efforts consume a considerable amount of community resources and have excellent face validity, yet there may be little or no effect on outcomes. Alternatively, the outcomes affected may be only short-term or secondary endpoints. Educational programs teaching young children pedestrian safety illustrate this point. In a large meta-analysis that included 15 randomized controlled trials, which looked at the effectiveness of pedestrian safety education programs in preventing pedestrian versus motor vehicle collisions, education resulted in improved children's knowledge of road dangers and some changes in road crossing behaviors. However, the authors also concluded that the targeted "safe" behaviors in these trials were not necessarily related to decreased pedestrian injury risk.[32]

In an ideal situation, the outcomes an investigator wishes to prevent are those injuries that lead to death or major disability. In many situations, this is not possible. Injury outcomes can be described in a hierarchy. At the top are the serious outcomes that are desirable to prevent, yet difficult to access for change. Traveling downward are those that are more easy to assess for change, but of lesser importance in the prevention of serious outcomes.[33] (Fig. 18.2):

1. Death
2. Inpatient admissions following trauma
3. Injuries treated in the outpatient setting
4. All injuries
5. Behavioral change
6. Self-reported behavior
7. Measures of knowledge, attitudes, or intensions

The type of outcome measure selected for assessment depends on the population characteristics, type of intervention planned, and resources (particularly monetary) provided to the team. Clearly, all interventions should seek to impact those outcomes with the biggest impact (i.e., trauma resource utilization or mortality). This is not always possible for smaller projects. In those cases, the appropriate selection of a surrogate outcome measure with proven validity in similar situations may be beneficial. Regardless of the measure chosen, outcome assessment is crucial when developing an intervention.

THE PREVENTION OF UNINTENTIONAL INJURIES

MVC-related injures remain the leading cause of death for people between the ages of 1 and 34. In 2006, the total number of people killed in an MVC was 43,664, with vehicle-related deaths contributing 35.9% of the total unintentional mortality overall.[3] However, there have been many recent advances in automotive safety that have contributed to declining mortality over the last several years. The following section outlines some for individual discussion.

SAFETY BELTS, AIRBAGS, AND CHILD CAR SEAT RESTRAINTS

Saving an estimated 15,000 lives per year, seat belts are extremely effective in preventing injuries sustained in MVCs.[34] In 2001, as a part of the CDC's Motor Vehicle Injury Prevention program, the Task Force on Community Preventive Service concluded that seat belt laws and primary enforcement were effective and strongly recommended. The task force went on to recommend a goal of 92% overall seat belt use by 2010. In 2006, the overall prevalence in the United States was 82.4% with only four states achieving seat belt use rates >90% in self-reported surveys.[35] Interestingly, the 15 states with the highest levels of seat belt use also had primary enforcement laws. This is in contrast to 14 of the 15 states with the lowest levels of seat belt use that only had secondary enforcement or no enforcement at all.[35] So, while primary enforcement laws improve compliance with seat belt laws, there is still room for improvement nationwide.

As a form of active prevention, persuading occupants to wear seat belts remains a problem. The advent of airbags is intended to bypass the human element and as previously mentioned may contribute to decreased mortality.[30] However, combined use with a seat belt is required for enhanced safety.[36] Further, the use of a seat belt is also required to minimize airbag-related injuries.

Children represent a unique problem for injury prevention in that children and infants do not fit properly into adult-sized restraints. Also, there is evidence to suggest that restraint use among children depends upon the use of a restraint by their caregivers. Nearly 40% of children who are unrestrained travel in vehicles where the drivers are unrestrained themselves.[37] There is also an issue with the proper placement of a child in a car seat. In 2001, the National Highway Traffic Safety Administration (NHTSA) conducted a study to identify "critical misuses" of child seat restraints (CSRs). It found that 72.6% of observed caregivers had at least one critical misuse of CSRs. The commonly cited reasons were loose vehicle safety belt attachment, loose harness straps, misrouting of harness straps, parental customization of child safety seats, and CRSs being used beyond the manufacturer's expiration dates.[38]

Like CSRs, child booster seats reduce the risk of injury when compared to seat belts alone.[39] Currently, the NHTSA recommends booster seats for children until they are at least 8 years old or are >4′9″ tall. This recommendation stems from the fact that adult restraints still do not fit children in this age group. A properly placed booster seat elevates the child such that the shoulder restraint fits properly over the thorax and lap restraint over the pelvis. Currently, 38 states have adopted booster state requirements in addition to car and seat belt laws.[40]

In addition to restraint devices, children <12 years old should ride in the backseat. This eliminates the risk of injury from a front or passenger side airbag. In children and adolescents <16 years old, this is associated with a 40% reduction in the risk of serious injury.[41]

TRAFFIC REGULATIONS

The relationship between vehicle speed and injury is straightforward. The faster a vehicle is traveling, the more amount of energy that is transmitted and must be absorbed by the human body in a collision. One of the most successful traffic regulations resulting in the reduction of both morbidity and mortality was the adoption of a 55-MPH speed limit on major highways. Initially undertaken as an energy conservation measure, in 1973 congress passed legislation imposing a national maximum speed limit of 55 MPH. This resulted in the reduction of highway traffic fatalities from 54,000 in 1973 to 45,000 in 1974.[42] Eventually, the law was softened allowing for rural states to increase the speed limit to 65–75 MPH in selected areas. In 1995, citing personal freedom demands, this law was rescinded completely allowing states to control their own speed limits. This resulted in an estimated increase of fatalities by 9% and nonfatal injuries by 4%[42] Another study concluded that an estimated 2,985 lives may be saved a year if a nationwide speed limit of 65 MPH is adopted.[43] Restrictions on speed limits are not the only way to influence traffic patterns on a population level. Speed enforcement devices were developed based on the premise that enforcement requires speeding drivers to actually believe they will be caught. These pieces of equipment range from cameras over roadways to covert radar detection devices. A recent meta-analysis of 21 studies that measured the effect of SEDs on MVCs found that all reported a lower number of overall crashes (range 14%–72%), crashes causing injury (range 8%–46%), and crashes resulting in fatality (range 40%–45%).[44] Further, those trends were maintained over time. While the authors note that some of the methodologic quality was weak, speed enforcement devices remain a promising area for future research and intervention.

ALCOHOL

In addition to vehicle speed, drug- and alcohol-impaired driving is another important risk factor for motor vehicle-related morbidity and mortality. Estimates of alcohol-related injury use blood alcohol concentration (BAC) values reported to the Fatality Analysis Reporting System for analysis. In 2008, 11,773 people were killed in alcohol-related crashes. This amounts to one death every 45 minutes, and accounts for nearly one-third of all traffic-related deaths. It also poses a significant financial burden on the health care system.[45] The annual cost of alcohol-related injuries is estimated at more than $51 billion.[46] This problem does not just impact the adult population. More than two-thirds of childhood vehicular fatalities took place while riding with an impaired driver.[47]

There are common patterns in alcohol-related trauma. First, the rate of alcohol impairment in driver fatalities is four times higher at night than during the day (36% vs. 9%). Also, only 15% of alcohol-related fatalities occur during the week versus 32% on weekends. When breaking down the driver age and gender in fatal crashes where the driver had a BAC level of 80 mg/dL or higher, men are more commonly involved in a fatality and adults aged 21–24 (34%) have the greatest number of deaths. Motorcycle drivers account for the highest percentage of deaths by vehicle type (29%), followed by passenger cars, light trucks, and large trucks, respectively (23%, 23%, 2%).[48]

Given the magnitude of this problem, there are considerable resources and multiple modalities of intervention dedicated to reducing alcohol-related injuries. In terms of legislation, all 50 states, the District of Columbia, and Puerto Rico have adopted a BAC of 80 mg/dL as the legal limit for impaired driving. In 2008, this led to the arrest of over 1.4 million drivers.[49] This is only 1% of the 159 million self-reported episodes of adults driving under the influence of drink in the United States each year.[50] To increase the chance that impaired drivers will be stopped, many police agencies have increased the number of police patrols or the time officers spend patrolling. The effects of these efforts are promising. Despite some methodologic limitations, in a review performed on 32 studies testing the effects of increased police presence on traffic deaths, injuries, and crashes, a statistically significant reduction in total crashes and fatalities was identified.[51]

Enforcement efforts are clearly a large part of reducing alcohol-related injuries. However, there are a considerable amount of education programs directed at the same target population. Perhaps one of the most recognizable is Mothers Against Drunk Driving (MADD). MADD is a nonprofit organization that was formed by a Texas mother in 1980 following the death of her 13-year-old daughter from an intoxicated driver. The group now comprises over three million members, has nearly 600 community action teams with a chapter in every state.[52] Another group dedicated to education is Alcoholics Anonymous (AA). AA is an international organization that offers support via self-help groups using a 12-step approach.

Screening identifies up to 46% of the trauma population as having alcohol-use disorders.[53] Once a patient is identified as high risk for alcohol abuse, brief interventions designed to assist patients with reducing or eliminating their alcohol consumption are extremely successful. These interventions typically involve one or more short (<1 hour) sessions given as an inpatient.[54,55] Gentilello et al. reported a decrease in alcohol consumption by 21.8 drinks per week at 12 months in the intervention group versus a decrease of only 3.7 drinks per week in the control group. Importantly, this also correlated with a 48% reduction in injuries requiring hospital admission at 3 years follow-up.[56] Brief intervention programs are also cost effective. In the same study, trauma patients were randomized to a brief intervention versus control. The net benefit in reduced injury-related health care costs was $3.81 US dollars for every $1.00 spent on screening.[56] From this study and those documenting the feasibility of brief intervention programs in an acute care setting, the American College of Surgeons Committee on Trauma now requires all Level I and Level II trauma centers to have screening (for Level I and II centers) and brief intervention (for Level I centers) programs in place for trauma center verification.

HELMETS

Each year, approximately 900 people die from bicycle crashes.[57] Head injuries account for up to 75% of deaths among these patients despite the fact that this type of injury is largely preventable. For instance, between 1994 and 2005, 92% of deaths from bicyclists involved persons who were not wearing helmets.[58] Helmets protect cyclists from head and facial injuries, with an overall risk reduction in head and severe brain injuries of 63% to 88% across all age groups.[59] When mandatory helmet laws are enforced, there is an increase in helmet use from between 45% and 84% without any evidence to support any adverse effects of legislation.[59]

Like the use of bicycle helmets, motorcycle helmets considerably reduce mortality associated with crashes. Helmet use is associated with a 16% reduction in the odds for death. In addition to lives saved, one estimate of dollars saved due to ICU care related to head-injured motorcyclists is over $32 million.[60] Currently, 21 states have universal laws mandating the use of the helmet.[61] This has not always been the case. Historically, all but three states had mandatory helmet laws due to the requirement of such a law to receive federal highway funding. However, congress abolished the requirement and many states removed the helmet law requirement in the 1980s.

INJURY PREVENTION IN THE ELDERLY

As the population continues to age, geriatric trauma is increasing. Unintentional death is the ninth leading cause of death overall in those >65 years old, yet this accounts for 25% of injury-related deaths. The rate per 100,000 individuals is 113.2, which is double that of all other age groups.[3] It is also well established that geriatric trauma patients have worse outcomes compared to their younger counterparts. They have increased hospital length of stay, morbidity and case-fatality rates, particularly with less severe injuries.[62–64] The mechanism for this increased risk is thought to be due to preexisting medical conditions (PECs). PECs make it difficult for the elderly patients to rely on their own physiologic reserve in response to the stress of trauma. In a prevalence study, authors found that by age 60, 40% of the population has at least one chronic medical condition, with this percentage increasing to 69% of the population by age 75.[65]

Falls represent the most significant cause of morbidity and mortality in the elderly. In 2006, falls accounted for 45.4% of all geriatric unintentional trauma resulting in close to 16,650 deaths.[3] It is estimated that over one-third of community dwelling and half of institutionalized residents over the age of 65 will suffer at least one fall each year.[66,67] In 2005, falls accounted for 1.8 million trips to the emergency department, resulting in 430,000 admissions.[3] Between 20% and 30% of those falls resulted in moderate to severe injury, with the most common injuries reported as soft tissue injury, traumatic brain injury, and orthopedic fractures.[68,69] Unfortunately, patients with fall-related hip fractures often do not recover to their pre-fracture level of function.[70] This presents a significant burden to the health care system. In 2000, the direct costs were 19 billion in nonfatal falls and an additional $179 million in fatal falls.[69]

The prevention of falls in the elderly is multifactorial. The CDC recommends exercise programs designed to improve cardiovascular health as well as strength and coordination. Also, having a medical professional review both over-the-counter and prescription medications to avoid drug interactions and side effects, and performing yearly vision examinations is helpful. Additionally, reducing in home hazards by modifying home environment such as removing throw rugs, securing electrical cords, installing grab rails in bathrooms, and improving interior and exterior lighting is beneficial.[71] Fall prevention can also be instituted through population-based interventional programs. One example in Sweden is based on the World Health Organization Safe Communities model. In a multidisciplinary approach, members of the Red Cross, county authorities, sporting teams, and the Safety Council for the Elderly teamed up to promote safety initiatives. Some measures employed included home visits, distribution of brochures via mass media, community walking programs, and employing unskilled laborers to improve lighting in public places. Mortality rates and hospital admissions for fall injuries and unintentional injuries in geriatric patients were recorded for 1 year pre- and post-intervention in a population of 42,000 adults and in a control population from a nearby municipality. Results demonstrated a notable reduction in falls and unintentional injury in the intervention community while injuries remained the same in the control population.[72] The positive effect of population-based interventions was further supported in a recent Cochrane review where authors found that relative risk reduction in falls for well-designed interventional programs was between 6% and 33%.[73]

PREVENTION OF INTENTIONAL INJURY

According to the World Health Organization, intentional violent injury can be defined as one resulting from the "intentional use of physical force or power against oneself, another person, or group or community." Worldwide, more than 1.6 million people lose their lives to violence annually.[74]

In the United States, each year nearly 50,000 deaths and 2.2 million injuries are the result of violent crimes.[75] In 2000, the total costs due to injuries and deaths from violence in the United States totaled more than $70 billion. The majority, $64.4 billion or 92%, was due to lost productivity while $5.6 billion was spent on direct medical costs.[76] Traditionally thought to be an inevitable part of human life, fewer resources have been dedicated to the study and prevention of intentional, when compared with unintentional, injury. It wasn't until 1993 that the CDC created the division of violence prevention. Soon after, to provide researchers and communities with a better understanding of violent death, the National Violent Death Reporting System (NVDRS) was created. The NVDRS is a 17 state-based surveillance system that combines data from medical examiners, law enforcement, and vital statistics, which is designed to help design violent injury prevention efforts.[75]

With the help of increased interest in intentional injury prevention and the NVDRS, critical analysis of the root causes of intentional injury reveal that, like unintentional injury, the same factors, agent, host, and environment interact to produce injury in a predictable and preventable manner. As such, strategies using the "four E's" previously mentioned also apply to the prevention of intentional injury. The following sections describe the scope of several common types of intentional injury accompanied by prevention strategies.

HOMICIDE AND SUICIDE

Between the ages of 1 and 34, homicide is a leading cause of death. In 2006, over 18,000 people were victims of homicide representing over 600,000 potential years of life lost. Homicide affects specific populations at disproportionate rates. At nearly 5,700 deaths annually, homicide is the second leading cause of death in the 15–24 age group, with nearly 75% of the total victims being male. Minority populations are also unequally represented. Amongst African Americans between 10 and 24 years old, homicide is the leading cause of death. In the same age group, it is the second leading cause of death amongst Hispanics.[3]

Firearms are the most common method employed to commit homicide, used between 72% and 85% of the time between the ages of 15–34. Firearm availability is directly related to mortality; the correlation between the presence of a gun and suicide has been found to be 0.94, and homicide to be 0.75.[77] Also, guns are more likely to kill than any other weapon used in an assault.[78] Because of this, it is appealing to focus on prevention strategies that decrease the availability of firearms to the public. Although the law has now been repealed, the Firearms Control Regulations Act in the District of Columbia banned residents from owning handguns, automatic weapons, and unregistered firearms. It also called for guns at home to be "unloaded, disassembled, or bound by a trigger lock." This law resulted in a decline in homicides by 23% over a 10-year span. No such decline was noted in neighboring states where the ban did not apply.[79] In 2008, the US Supreme Court struck down the DC gun law on the basis that it violated the Second Amendment. Further attempts to limit the availability of firearms continue to meet resistance. Currently, the CDC recommends gun control laws that restrict ownership of handguns to those with a "clearly demonstrated need." They also call for greater enforcement of preexisting gun legislation such as waiting periods and background checks for those individuals purchasing firearms. (NCIP)

Like homicide, suicide is an important cause of morbidity and mortality in the United States. As the 11th leading cause of death overall, self-inflicted injury results in over 33,000 deaths and 359,000 visits to the emergency department each year. It represents the second leading cause of death in individuals aged 25–34.[76]. Risk factors for suicide include adolescent age,

previous attempts at suicide, history of depression or mental illness, alcohol use, living alone, and having a recent adverse event. Gender and ethnicity also contribute, with men and American Indians affected disproportionately.[75]

Suicide prevention should involve strategies directed at high-risk groups. In particular, reducing the availability of means of suicide is beneficial. Safety barriers over bridges, catalytic converters that result in less toxic vehicle exhaust, changing home gas supply from toxic coal gas, and restriction of access to unsafe pesticides have effectively reduced rates of suicide.[80] Eliminating an easily accessible means of suicide ultimately does not lead to the choice of another method, but may lead to a decision to avoid committing suicide altogether.[81] The National Strategy for Suicide Prevention (NSSP) is a national program developed from the Department of Health and Human Services. The NSSP describes a public health approach to meet specific aims: prevent premature deaths due to suicide across the life span, reduce rates of suicidal behaviors, reduce harmful aftereffects associated with suicidal behaviors and their impact on family and friends, and promote opportunities to improve resiliency, resourcefulness, and respect for individuals, families, and communities affected by suicide. To achieve this, 11 specific goals complete with objectives and activities have been outlined.[82]:

1. Promote awareness that suicide is a public health problem that is preventable
2. Develop broad-based support for suicide prevention.
3. Develop and implement strategies to reduce the stigma associated with being a consumer of mental health, substance abuse, and suicide prevention services.
4. Develop and implement community-based suicide prevention programs.
5. Promote efforts to reduce access to lethal means and methods to self-harm.
6. Implement training for recognition of at-risk behavior and delivery of effective treatment.
7. Develop and promote effective clinical and professional practices.
8. Improve access to and community linkages with mental health and substance abuse services.
9. Improve reporting and portrayals of suicidal behavior, mental illness, and substance abuse in the entertainment and news media.
10. Promote and support research on suicide and suicide prevention.
11. Improve and expand surveillance systems.

In its current form, the NSSP is one of the first times a coordinated approach to suicide prevention by public and private sectors has been attempted in the United States.

DOMESTIC VIOLENCE

Domestic violence or intimate partner violence (IPV) can be defined as abusive behavior, physical or emotional, between two people in a close relationship. This includes single episodes, ongoing violence with current or former partners. There are four specific types of IPV.[83]

1. Physical violence causing physical injury such as hitting, kicking, or assault with a weapon
2. Threats ranging from words, gestures, and other messages of intent to cause either emotional or physical harm
3. Sexual violence including the use of physical or emotional force to compel a person to perform a sexual act, completed or not, and any sexual act involving a person unable to consent
4. Emotional violence such as threatening, harassing, intimidating, or controlling behaviors including the prevention of the victim to seek help from family or friends

Domestic violence affects 4.8 million women and 2.9 million men annually. This results in nearly 1,510 deaths, of which 78% are female.[75,84] In terms of financial burden, the medical, mental health, and costs due to lost productivity amount to more than $8.3 billion dollars.[85] It is important to note that these numbers are likely an underestimation of the scope of the problem as many victims do not report IPV to the proper authorities or friends and family.[84]

The majority of IPV involves men injuring their female partners. There are several risk factors, both individual and societal, for committing acts of IPV: alcohol and drug abuse, personal history of abuse, emotional disorders, low socioeconomic status, depression, marital instability, traditional gender norms, weak sanctions against domestic violence, and social norms supportive of violence.[86,88]

Domestic violence has a significant impact on overall health. In addition to acute physical injuries, victims of IPV are more likely to have prolonged health problems. In particular, victims adopt risky behaviors including smoking, drug, and alcohol abuse, and physical inactivity.[87,88,89] They are also at an increased risk of depression, chronic pain syndromes, psychosomatic and reproductive health consequences.[87] The longer the abuse persists and more severe the incident, the greater the impact on health.[87,88]

In the past, the majority of prevention efforts have focused on limiting abuse once it occurs. Focus has been on legislation and the criminal justice system. An example is a restraining order that prohibits an abuser from contacting his or her partner. Restraining orders are civil protective documents that attempt to prohibit contact between victims and their partners. Violating an order is then a criminal offense. Currently, all 50 states have some bit of legislation authorizing the use of general civil protective orders. There is some evidence to show that these orders are useful in deterring violence if they are in place for an entire year.[90] However, multiple studies have shown that these orders are violated between 23% and 70% of the time and do not necessarily result in arrests.[91,92] Furthermore, while women may feel safer and emotionally stronger after obtaining a protective order, it may serve to anger the recipient to the point of violence.[92]

Many efforts are led by women's outreach organizations and hotlines such as the National Domestic Violence Hotline, and shelters for abused persons. There is also a movement to target adolescents. The Safe Dates Program is a school-based intervention that focuses on educational efforts specifically directed at reducing dating violence. A treatment group of eighth and ninth graders in Johnston County North Carolina underwent a ten session curriculum developed to change norms associated with partner violence. At 4 years follow-up, compared with controls, those receiving the curriculum reported 56% to 92% less physical and sexual dating violence.[93] The results of this study are promising; however, continued research and outcome assessment is needed to identify those strategies that best impact interpersonal violence.

SUMMARY

Franklin D Roosevelt once said "Nothing happens by accident, if it happens, you can bet it was planned that way." While he was originally referring to politics, his statement also applies to both intentional and unintentional injury. Haddon first formalized the concept that injuries occur under specific and reproducible circumstances. As such, his matrix and basic prevention strategies should form the foundation of modern prevention efforts, whether primary, secondary, or tertiary prevention. Equally important is the critical evaluation of prevention programs. From small community programs to large-scale nationwide efforts, prevention efforts consume a substantial amount of resources in the United States. Well-designed outcome assessment tools are important to document the success of programs and justify further funds as well as identify those strategies that need modifying.

Unintentional injury has been the focus of the majority of prevention efforts. There is no question that the invention of seat belts combined with primary enforcement laws, mandatory airbag requirements in vehicles, and highway safety regulation like reduction in speed limits saves thousands of lives each year. Efforts in the prevention of intentional injury are less common, and have been less successful. It is likely that the social, political, and behavioral factors, such as alcoholism, mentioned previously are responsible for some of the gap between unintentional and intentional injury prevention successes. What is certain is that injury prevention is best attempted with a multidisciplinary, scientific approach at both a community and national level. It is in this way researchers and clinicians can have the largest impact on injury-related morbidity and mortality.

CHAPTER 19 ■ RECOVERY AND REHABILITATION

ROBERT D. WINFIELD AND LAWRENCE LOTTENBERG

In trauma and emergency general surgery, a great deal of attention is often paid to the acute management of the injured or critically ill patient. While this focus reflects the initial and most time-sensitive aspects of patient care, it is important to remember that the traditional metrics of quality of care in this setting, namely, morbidity and mortality, tell us little about what is probably the most important outcome: the ability of the injured or ill individual to ultimately return to society as a functioning, productive citizen. This is reflected poignantly in the financial burden attributed to trauma by the CDC with 2000 data suggesting that injuries led to lifetime costs of $406 billion, with lost productivity costs totaling approximately $326 billion of this amount, or greater than four times the cost of medical care.[1] This chapter provides information on the complex multidisciplinary care essential to the recovery and rehabilitation of the injured or critically ill surgical patient. While the chapter places emphasis on post-trauma rehabilitation due to the data that exists in this field, the principles contained within are applicable to all of acute care surgery, and may be utilized as such.

ADMISSION OF THE PATIENT TO THE HOSPITAL

Whether it is a trauma patient or an emergency general surgery patient, recovery and rehabilitation should start on admission to the hospital, or upon first encounter with the acute care surgeon. The interview and history should include where the patient lives, as many acute surgical patients are from surrounding local areas, or conversely from out of the surrounding area (vacation, work, visiting relatives, etc.). Who the patient lives with is equally important, as the patient living alone has vastly different needs from one who has the support of a spouse, siblings, parents, or children. Living conditions, such as single family home, multilevel home, apartment, or as has been seen in most recent times, whether the patient is homeless, also clearly have a role in disposition planning. Frank, open discussions with the patient's family and friends will allow the clinician to gain valuable insight into the disposition planning that will need to be done once the primary surgical issues are resolved.

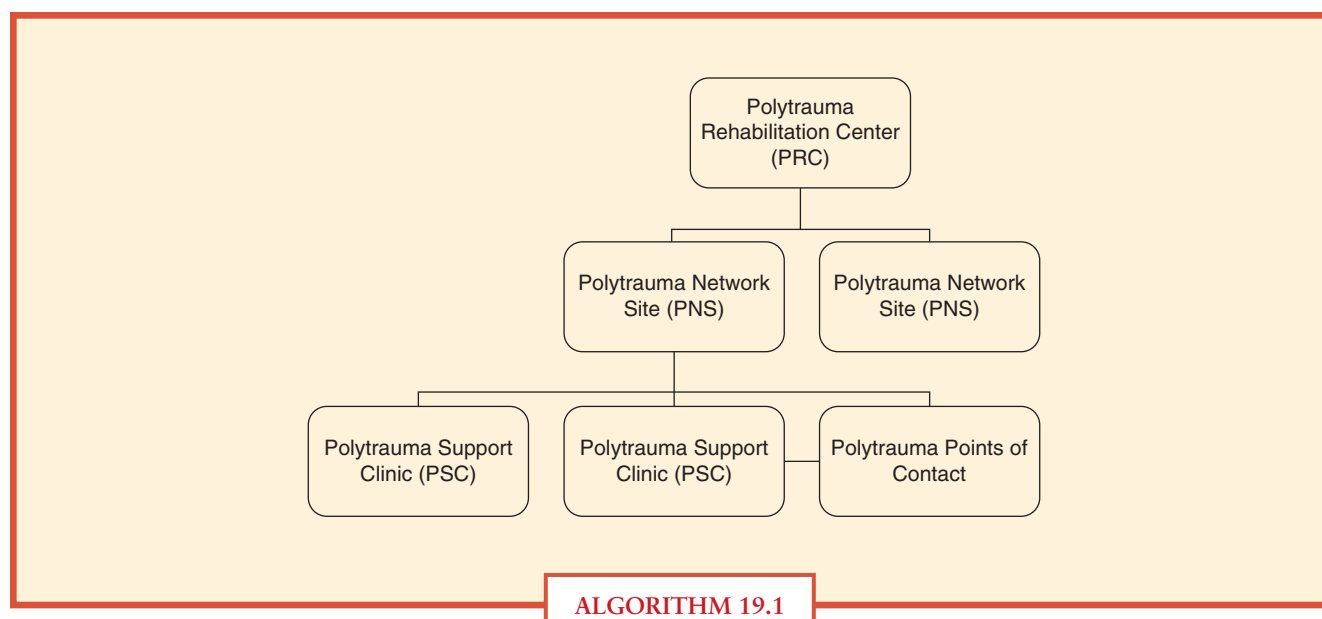
The physical examination of the acute surgical patient should also lead the physician to make certain early decisions about disposition. The multiple trauma patient with complex pelvic fractures and lower extremity fractures should lead one to conclude that ambulation may not be possible for weeks to months and a skilled nursing facility (SNF) may be a destination prior to a rehabilitation facility. A traumatic brain injury (TBI) will trigger a different set of potential destinations. An emergency general surgery patient who is going to receive a diverting or a permanent stoma will also present a different set of circumstances, and once again, open discussion with family members will yield important information regarding whether they will be comfortable caring for such a patient or whether a SNF may be needed.

MULTIDISCIPLINARY INPATIENT CONFERENCE FOR THE ACUTE CARE SURGERY PATIENT

Once the patient is admitted to the acute care hospital and once the surgical procedures have been performed, it is crucial to assemble a team of all the specialists involved in the patient's care to plan immediately for the acute and chronic care of the patient. Many acute care services have daily "sit-down" rounds with team members; however, it is the opinion of the authors that at a minimum, twice-weekly "multidisciplinary rounds" be held with a team of surgical attendings, surgical residents if in a teaching environment, staff nurses from the patient floor and the intensive care unit, physical therapist, occupational therapist, social workers, speech pathologists, dietician, rehabilitation intake specialist, quality assurance staff (trauma service coordinators), and on occasion clergy and ethics panel members. The optimal days for these twice-weekly conferences would be on Monday, after the weekend to discuss all the new admissions and on Friday, before the weekend to make destination disposition plans prior to the weekend. Such conferences should become part of standard policy and procedures on the acute care surgery service. Further, the use of frequently updated, electronically generated lists should comprise every element of the patient's status to reflect involvement of all the aforementioned disciplines. Trauma patients at designated or verified trauma centers may be bound by rules to have certain consultations from rehabilitation intake personnel and physicians within a certain time period varying from within 24 hours to 7 days of admission.

MULTIDISCIPLINARY REHABILITATION OF THE TRAUMA PATIENT

The multiply injured trauma patients must deal with the healing of both visible and invisible wounds following their traumatic insult. In order to provide optimal care, a team approach should be undertaken, and will necessarily incorporate specialists in a variety of fields to achieve the best possible outcome. As is true in the field of trauma as a whole, much has been learned about interdisciplinary rehabilitation as a result of military conflict. The recent campaigns in Iraq and Afghanistan have generated a new series of challenges that have led to innovative responses that may be employed by providers taking on the responsibility of recuperating and rehabilitating the multiply injured patient.

The Veterans Health Administration has outlined its system for interdisciplinary care, the Polytrauma System of Care (PSC), which grew out of the recognition of the complex care needs of the significant numbers of multiply injured soldiers returning from Iraq.[2,3] The PSC is a VHA-wide, regionalized, tiered system of care delivery (Algorithm. 19.1). At the core of each region is the Polytrauma Rehabilitation Center (PRC),


ALGORITHM 19.1

ALGORITHM 19.1 The Veterans Health Administration Polytrauma System of Care. (Adapted from Sigford BJ. To care for him who shall have borne the battle and for his widow and his orphan (Abraham Lincoln): the Department of Veterans Affairs polytrauma system of care *Arch Phys Med Rehabil*. 2008;89:160–162.)

which delivers comprehensive medical, surgical, and rehabilitative care within the setting of a tertiary medical center. The PRC offers all potential services needed by the multiply injured as well as their families, and doubles as a consultation and education center for practitioners employed in other components in the region of that PRC. The next tier is the Polytrauma Network Site (PNS), which is geared toward the delivery of postacute inpatient rehabilitative care and has the responsibility of ongoing coordination of rehabilitation services for veterans and their families within their local area. The final tier is delivered at the local level in the form of Polytrauma Support Clinic Teams that accept and refer veterans and provide rehabilitative care to those with stable needs, and Polytrauma Points of Contact, comprised of individuals (primarily social workers) at various VA sites who provide no direct rehabilitative services, but assist veterans in receiving needed care on a local level.

The PSC is guided by four tenets that govern care (Table 19.1). Proactive case management is carried out by nurses for clinical issues and social workers for psychosocial

ones. Tasks include regular contact with patients to ensure appropriate execution of the plan of care, identifying changes in the social situation of the patient, coordinating resources, providing support and education, and helping patients make the transition from active duty to veteran status. As substantial, major multiple traumas often lead to long-term issues, the system is designed to deliver lifelong care via the PSC closest to the veteran. All centers within the system are linked by the Polytrauma Telehealth Network, which is a system of videoconferencing utilized in the coordinated care between practitioners, and in providing education and support to veterans and their families. Finally, severely injured veterans may require long-term care and assistance within facilities or within their homes, and the PSC is committed to providing this for injured veterans.

While the PSC provides what is perhaps in theory a model system for the delivery of interdisciplinary care for the multiply injured, it is unlikely that such a system could be implemented in the current civilian health care environment in the United States. A complex system with multiple, sometimes divergent interests, in which centers compete against one another for business, in which payor concerns often dictate the location and level of care afforded, and in which long-term follow-up and care is a luxury rather than the standard, the delivery of optimal multidisciplinary care is a challenging process. That said, the components are in place, and the key aspects and providers will be reviewed individually.

TABLE 19.1

KEY COMPONENTS OF THE VETERANS HEALTH ADMINISTRATION POLYTRAUMA SYSTEM OF CARE

Proactive case management
Delivery of lifelong care
Telehealth networking between care sites
Provision of long-term inpatient, outpatient, and home-based care for chronic illness and injury

Adapted from Sigford BJ. To care for him who shall have borne the battle and for his widow and his orphan (Abraham Lincoln): the Department of Veterans Affairs polytrauma system of care *Arch Phys Med Rehabil*. 2008;89:160–162.

Social Work

The social worker is at the core of post-injury care planning and coordination. According to the National Association of Social Workers, "professional social workers assist individuals and groups to restore or enhance their capacity for social functioning, while creating societal conditions favorable to their goals. The practice of social work requires knowledge

of human development and behavior, of social, economic and cultural institutions, and of the interaction of all these factors."[4] One crucial example of an area in which social workers are widely utilized in U.S. Level I Trauma Centers is in the performance of screening and brief interventions for alcohol use.[5] The understanding possessed by the social workers of the interplay between psychiatric disorders, substance abuse, and the association of these factors with traumatic injury makes them ideally suited for this task, and for many of the other multidimensional challenges faced by the recovering injured.

Often times, it is the social worker who can really identify the impediments and challenges to a successful discharge from acute care to chronic care. The social worker is able to relate to the patient's home situation, source of income, viability of the family unit, and needs for the patient to transition to skilled nursing care, rehabilitation, or other areas prior to the patient returning to a functional life at home. It cannot be overemphasized how important a close, congenial relationship between the physician and the social worker is in implementing the recovery and rehabilitation of the acute care surgical patient.

Physical Therapy

Utilizing multimodality therapy methods to improve strength and flexibility, the goal of the physical therapist for the injured patient is to restore physical function and reduce the morbidity and discomfort resulting from injuries sustained. In the literature, the greatest amount of attention has been paid to the benefits of physical therapy following TBI, although there is a paucity of quality data regarding improvement in outcomes. In a recent review of 14 studies of efficacy in patients suffering TBI, Hellweg and Johannes[6] found support for high-intensity rehabilitation, serial casting and splinting, aerobic training, and aspects of functional training.

The physical therapist is often the first provider who will give physicians involved in acute care disposition for the patient; however, it is essential that the physicians, especially the orthopedic surgeons, write appropriate and accurate ambulation orders on each and every patient needing physical therapy consultation. The best time to write ambulation orders for orthopedic injuries is on admission if nonoperative management is to be done or immediately postoperatively in the post-op orders. Even patients in the intensive care unit should have range of motion, out of bed, or ambulation orders written early in the hospital stay. The therapist will then be able to indicate on subsequent visits with patients whether they will be able to go home with or without outpatient therapy, home with therapy, go to a SNF (usually for patients who are on required non-ambulation for more than a week), or on to a rehabilitation facility for intensive rehabilitation. At that point, consultation with the physiatrist and the rehabilitation intake specialist can be appropriately made and the social worker can begin planning.

Occupational Therapy

The occupational therapist works with post-injury patients to restore their ability to participate in the usual activities of daily living. While for many people, the term "occupation" is synonymous with one's employment, in this setting, it refers to "the breadth and meaning of everyday activity" for the recovering trauma patient, whether that be work-related, or simply the ability to perform usual functions in the home setting.[7] This should be seen as a parallel, but distinctly different, function to that served by the physical therapist, whose focus is more on redeveloping the strength and coordination necessary to do the function, rather than the performance of the function itself.

Speech–Language Pathology

The speech–language pathologist evaluates and treats disorders of speech, language, swallowing, and cognitive communication. This can be important for a variety of reasons, as the ability to speak, swallow, communicate, and understand may be adversely affected by TBI, intubation and tracheostomy, blast injuries to the eyes and ears, blunt or penetrating trauma to the structures key to these processes, or blunting of function due to ongoing emotional distress or medical therapies for pain or spasticity. As a result of the unique training and function of the speech–language pathologist, the Communication Sciences and Disorders Clinical Trials Research Group have recommended that injured veterans returning from Iraq and Afghanistan have access to these valuable providers as part of their multidisciplinary team.[8] Speech–language pathologists develop individualized plans of care tailored to the patients' needs. They may recommend alternative nutrition based upon aspiration risk when swallowing. This becomes particularly important in those patients who have had tracheostomies during their acute hospital phase and are either being decannulated or weaned from their tracheostomy. Finally, speech–language pathologists provide important education to patients, their family members and caregivers regarding impairments, disease processes, and compensatory strategies. This allows the recovering patient to identify strenghts and weaknesses to maintain swallowing, speech and language skills.

Neurocognitive Rehabilitation Services

Eighty-five thousand people suffer TBI leading to long-term disability each year in the United States, and twelve thousand people sustain spinal cord injuries over the same time frame.[1,9] Injuries to the central and peripheral nervous systems may result in a variety of forms of dysfunction, with communicative disorders, impairment of mobility, pain, and psychiatric disorders all being manifest. The rehabilitation of these patients can be particularly challenging, as it often involves relearning basic activities, developing compensation methods for loss of function, and employing nonstandard pain control regimens.[10] The neurocognitive rehabilitation specialist is familiar with the patterns of injury present in this population, and can play an integral role in developing patient-specific management plans.

Clinical Dietitian

The role of optimal nutrition in healing after injury and illness is well-established, and is an area of intense research.[11] A clinical dietitian utilizes his or her training to guide nutritional support, whether it be via the enteral or parenteral route, and can ensure that the nutritional needs of the patient with complex injuries and illnesses are met. There is data to suggest that use of the recommendations of registered dietitians enhances the quality of nutrition received, and that this has the potential to improve outcomes in long-term acute care (LTAC) patients.[12] The clinical dietitian should be consulted early to provide initial nutritional support, and his or her recommendations following reevaluation should be a part of each multidisciplinary patient care rounds.

Pain Management

The management of short- and long-term pain following injury is an expected component of post-injury recovery and rehabilitation. While most practitioners are accepting of the

need for short-term pain control strategies, in an assessment of 50 soldiers receiving inpatient rehabilitation services at the Tampa PRC, 96% were found to have pain during their stay, and this led to impairments in physical, emotional, and social functioning.[13] There is some suggestion that the pain experienced both in the acute and rehabilitative phases can influence the ultimate development of chronic pain syndromes and eventual long-term disability.[13] Pain management specialists work alongside other practitioners to prescribe and provide multimodality therapy including medications, psychiatric and psychological therapy, regional nerve blockades, nerve stimulation, and other novel forms of pain management to improve both short- and long-term function following major injury.

Psychiatric Care

Depression and posttraumatic stress disorder are the two most commonly encountered psychiatric disorders following injury; however, several types of these disorders are seen, carrying with them implications for short- and long-term management.[14–16] Comorbid TBI as well as pain issues make post-injury psychiatric care multilayered and challenging. Studies from the University of Washington suggest that early intervention in patients screening positively for PTSD can improve outcomes through a collaborative approach that includes psychopharmacology, case management, and cognitive–behavioral therapy.[17] The inclusion of the psychiatric care provider is critical to this tactic and to similar efforts to treat depression and more rare post-injury psychiatric disorders, and represents an opportunity to improve long-term mental well-being.

Physiatry

As the patient transitions from the acute care setting to a rehabilitation center, it is vital to have a team leader familiar with the needs of patients requiring rehabilitation from illness and injury. Physiatrists are physicians who complete specific residency training in physical medicine and rehabilitation and are skilled at designing coordinated treatment plans in concert with the aforementioned specialists to deliver comprehensive care to alleviate discomfort and rehabilitate the sick and injured. There are about 8,300 board-certified physiatrists in the United States. Physiatrists also treat neurologic illness including stroke, brain injury, and spinal cord injury. Also, their scope of practice includes musculoskeletal injuries, pain syndromes, and sports injuries. Physiatrists treat patients of all ages in the three major areas of the diagnosis and treatment of musculoskeletal injuries and pain syndromes, electrodiagnostic medicine (electromyography), and of course the rehabilitation of patients with severe impairments.

Care for the Caregiver

The majority of the focus in post-injury care is on the recovery and rehabilitation of the injured individual; however, the recovery of the individual places incredible stress on the family and friends who provide support and direct care with the added stress of long-term emotional investment. Loved ones who serve in the role of caregiver face the difficult tasks of assisting with medical care, helping to coordinate the various components of the multidisciplinary care process on behalf of the recovering patient, and often times are responsible for bearing the financial burdens associated with recovery. In the VA PSC, the complicated nature of caregiver involvement is acknowledged, and efforts to incorporate family into the recovery and rehabilitation process and to provide them

with therapy are ongoing.[18] This includes provision of housing, meeting basic needs, assisting financially, and providing therapy to anxious and grieving family members struggling with the reintegration of their loved one following injury. This method provides the opportunity to treat the whole patient, by recognizing that the depth and breadth of one's social support is the key to recovery, and that, at times, the family or friend requires own form of assistance to adjust to life after injury.

RECOVERY AND REHABILITATION ENVIRONMENTS

Much of the recovery following injury occurs outside of the hospital. The level and amount of supportive, professional care needed are dictated by the extent of the injuries, post-injury complications, and preexisting comorbidities. Different types of recovery sites provide these different levels of care, and these are reviewed here.

Long-Term Acute Care Facilities

Although critical illness is thought of as an issue primarily dealt with in the period surrounding and immediately following acute injury, approximately 3%-6% of patients fall under the category of being chronically critically ill.[19] For patients with ongoing critical illness unlikely to resolve in the short term, and due to the tremendous financial strain generated by the care of these individuals, LTAC facilities have been established and have the benefit of being exempt from the Medicare prospective payment system.[19] LTACs vary in the completeness of services offered, but provide the personnel and facilities to manage patients needing prolonged mechanical ventilation as well as other complex care including provision of parenteral nutrition, wound management, and on-site hemodialysis.

Skilled Nursing Facilities

SNFs exist in order to treat, manage, observe, and evaluate patients with subacute needs. This includes services requiring the services of skilled professionals, such as provision of injectable medications by nursing, physical and occupational therapy, and ongoing speech and language therapy.[20]. As with LTACs, SNFs vary with regard to the services offered, but generally provide a site of convalescence and rehabilitation for patients with lower acuity and fewer care needs.

Rehabilitation Centers

For patients whose long-term needs are primarily related to their ability to regain physical function, a rehabilitation center provides an environment in which providers of these services (physical and occupational therapy, speech–language pathologists, etc.) work together in an interdisciplinary fashion to meet patient needs. Nursing care can be provided in this environment, and physician care is provided by physiatrists; the medical needs of patients tend to be at a higher level than that seen in a SNF, and intensive rehabilitation efforts can be undertaken. The brain-injured patient must be of sufficient functioning level so as to follow commands to participate in rehabilitation.

Any rehabilitation center should be surveyed and approved by the Commission on Accreditation of Rehabilitation Facilities (CARF), which is designed to provide standards for excellence for care of injured and ill patients.

Outpatient and Home-Based Recovery and Rehabilitation

For patients not requiring 24-hour nursing supervision or intensive rehabilitation, outpatient and/or home-based care may be arranged to allow the recovering patient to convalesce in a familiar and comfortable environment. Patients may receive a wide variety of services in this way, to include physical and occupational therapy, wound care, and injectable medications courtesy of visiting nurses, or the patient may visit an infusion center to receive intermittently dosed intravenous medications.

SUMMARY

The recovery and rehabilitation of the multiply injured or critically ill patient can be a challenge for patients, their caregivers, and their loved ones; however, this is clearly an important component of care as it focuses on the transition from being a patient to being a functioning member of society. This may require the assistance of a host of professionals, each with specialized training that can be employed to facilitate the process. Through the conflicts in Iraq and Afghanistan, the U.S. Armed Forces has recognized the value of a coordinated, multidisciplinary approach to this process, and through the PSC has created a model for delivery of care that is comprehensive in nature. Although the current civilian health care system in the United States possesses the manpower and features necessary to deliver this type of care, coordination of the various pieces needs to progress to the levels of the military and the Veterans Administration systems; however, with new legislation addressing the financing and delivery of health care and a developing interest in regionalization of services, opportunities may be emerging for the creation of a streamlined system of rehabilitative care, and a chance to maximize our ability to return the injured and sick to optimum levels of functioning and productivity.

CHAPTER 20 ■ THE EVOLUTION OF TRAUMA CARE IN THE UNITED STATES

DONALD D. TRUNKEY

PAST

The history of trauma care is inextricably linked to wars and wounds. Trauma antedates recorded history, and there are examples of anthropological findings showing trepanation of the skull dated to 10,000 BC. These skulls have been found in the Tigress-Euphrates Valley, along the shores of the Mediterranean, and in Meso-America. It is most likely these operations were done for depressed skull fractures, and possibly epidural hematomas. The surgery was most likely performed by priests or shamans within the various cultures. Some of these skulls show that the operation was done more than once; and there is ample evidence that there was success since there was healing of the man-made hole. There is also evidence that they were able to treat fractures and dislocations with successful knitting of the bones.

The first solid evidence for war wounds came from a mass grave found in Egypt and dated to approximately 2000 BC.[1] The bodies of 60 soldiers were found in a sufficiently well-preserved state to show mace wounds, gaping wounds, and arrows still in the bodies. The Smith Papyrus records the clinical treatment of 48 cases of war wounds and is primarily a textbook on how to treat wounds, most of which were penetrating. According to Majno, there were 147 recorded wounds in Homer's Iliad, with an overall mortality of 77.6%. Thirty-one soldiers sustained wounds to the head, all of which were lethal. The surgical care for a wounded Greek was crude at best. However, the Greeks did recognize the need for a system of trauma care, and theirs is one of the first examples of a trauma system. The wounded were given care in special barracks (*klisiai*) or in nearby ships. Drugs, usually derived from plants, were applied to wounds.

Further east, there was evidence of another trauma system that had been established by the Indian army. This was a system that rivaled that of the Greeks and Romans. India was divided into several kingdoms, and the Far East kingdom was Magadha. It was ruled by Ashoka, the third of the Maurya Dynasty. Ashoka was responsible for developing three sets of documents describing governance, the third of which described some of the care provided to his soldiers when he invaded the kingdom of Kalinga. The *Artasastra* documented that the Indian army had an ambulance service well-equipped with surgeons and women to prepare food and beverages and to bandage wounds. Indian medicine was specialized and it was the "shalyarara" (surgeon) who would be called upon to treat wounds. Shalyarara literally means "arrow remover," as the bow and arrow was the traditional weapon for Indians.

The Romans perfected the delivery of combat care and set up a system of trauma centers in all parts of the Roman Empire. These trauma centers were called "valetudinaria"

and were built during the first and second centuries AD. The remains of 25 such centers have been found, but importantly, none were found in Rome or other large cities. It is noteworthy that there were 11 found in Roman Britannica, more than currently exist. Some of the valetudinaria were designed to handle a combat casualty rate of up to 10%. There was a regular medical corps within the Roman legions, and at least 85 army physicians are found in the records, mainly because they earned an epitaph.

The concept of shock was not appreciated during this period of time. In fact, it was not until the late 19th and early 20th centuries that shock was finally described.[2] The Greeks understood that hemorrhage could lead to death, and they also empirically treated this with herbs, specifically ephedra nebrodensis, which came from Sardinia. The same treatment was used in China, where it was called Ma-Hung, and it was also ephedra. It is most likely that these two distant cultures shared the discovery of ephedra via the "Silk Road." Hippocrates and Galen did not use the tourniquet. This was partially based on the evidence of Largus, who stated that if you took a pig stomach, filled it with liquid, and then wrapped a rope around it, tightening the rope would increase expulsion of the fluid out of the bag orifice.

Over the first millennium, military trauma care did not make any major advances until midway in the second millennium, just before the Renaissance. Arabic surgery did thrive for two to three centuries, but it was up to French military surgeons, who lived 250 years later, to bring trauma care into the Age of Enlightenment. Ambrose Paré (1510–1590) served four French kings during the time of the French and Spanish civil and religious wars.[3] His major contribution to treating penetrating trauma included the treatment of gunshot wounds, the use of ligature instead of cautery, and the use of nutrition during the post-injury period. Paré was much interested in prosthetic devices and designed a number of them for amputees.

It was Dominique Larrey, Napoleon's surgeon, who addressed trauma from a systematic and organizational standpoint.[4] Larrey introduced the concept of the "flying ambulance," the sole purpose of which was to provide rapid removal of the wounded from the battlefield. Larrey also introduced the concept of placing the hospital as close to the front lines as feasible to undertake wound surgery as soon as possible. His primary intent was to operate during the period of "wound shock" when there was an element of analgesia, most likely due to endorphins, but also to reduce infection in the postamputation period.

Larrey had an understanding of problems that were unique to military surgery and system development. Some of his contributions can best be appreciated by his efforts before Napoleon's Russian campaign. Larrey did not know which country

Napoleon was planning to attack, and there was even conjecture of an invasion of England. He left Paris on February 24, 1812, and was ordered to Mentz, Germany. Shortly thereafter, he went to Magdeberg and then on to Berlin, where he began preparation for the campaign, still not knowing precisely where the French army was headed. In his own words, "Previous to my departure from this capital, I organized six divisions of flying ambulances, each one consisting of eight surgeons. The surgeon-majors exercised their divisions daily according to my instructions, in the performance of operations and the application of bandages. The greatest degree of emulation and the strictest discipline were prevalent among all the surgeons."

The 19th and 20th centuries were notable in the improvement of surgical care in combat. Antisepsis was introduced during our Civil War, and there was a gradual decline in patients who died from their wounds (Table 20.1) The surgical mortality for head, chest, and abdominal wounds also decreased after the First World War (Table 20.2). Between WWI and WWII, the first civilian trauma system was created in Austria by Böhler. Although initially designed for industrial accidents, by the time of WWII, it also included motor traffic accidents.

The most remarkable development of a statewide trauma system occurred early in the 1970s in Germany.[5] At that time, road traffic accidents accounted for 18,000 deaths annually. Since 1975, this has been reduced to approximately 7,000. In 1966, two trauma centers were started in the United States: one in Chicago at Cook County (Robert Freeark) and one in San Francisco (F. William Blaisdell). The first statewide trauma system was initiated in 1969 by R.A. Cowley in the state of Maryland. It was at approximately the same time that the American College of Surgeons Committee on Trauma (ACSCOT) started to develop criteria for trauma systems. In 1976, the first Optimal Criteria document was published, followed shortly thereafter by the ATLS course, which was designed for emergency physicians and surgeons, and defined criteria for resuscitation during the first hour following injury. Subsequently, there were two other significant developments by the ACSCOT, including the Multiple Trauma Outcome Study, which has now gone on to be the National Trauma Data Bank, and a verification program for existing trauma centers. The College recognized early on that the designation of trauma centers was a political and legal process, and the verification program simply examined patient medical records and program improvement documents to verify whether or not the hospital met the designation criteria. By 1995, a report in the *Journal of the American Medical Association* showed that five states had statewide trauma systems.[6] This was followed by another study in 1998 published in the *Journal of Trauma* documenting that the five states continued to meet all eight previously described criteria for trauma systems[7] and 28 states met at least six or seven criteria, whereas an additional four states met at least four criteria. Finally in 2006, another study evaluating the efficacy of trauma center care on mortality showed that the mortality from trauma was 7.6% in designated trauma centers compared to 9.5% in hospitals that were not designated.[8] One year after discharge, the significance continued with a mortality of 10.4% versus 13.8%. Another study published in 2006 from Florida showed that in counties with a trauma center, the mean fatality rate was 50% less than in counties without a trauma center.[9] It can be seen from this data that the effectiveness of a trauma center is irrefutable as shown by these two recent studies and the data from Germany. Finally, a more recent study shows that trauma centers are more cost effective than hospitals that are not trauma centers.[10]

PRESENT

I think it is fair to state that the training of a general surgeon over the last 40 years has changed fairly dramatically. To illustrate this, I will compare my own training with the current resident training.

Data from Trunkey D. History and development of trauma care in the United States. *Clin Orthop Relat Res*. 2000;374:36–46.

I spent 4 years in medical school between 1959 and 1963 at the University of Washington. During my senior year, I decided that I would go into internal medicine, and did a 3-month sub-internship on the medical wards at Harborview Hospital. At the end of 3 months, I was confused and disheartened because I had not enjoyed internal medicine that much. Unfortunately, there was a paucity of role models in surgery and I applied and got accepted to the University of Oregon in Portland to do a rotating internship. My first rotation was on general surgery with Dr. Dunphy. Within 3 weeks, I had made the decision to pursue surgery as a career. After my internship, I did 2 years in the military and then joined Dr. Dunphy at the University of California San Francisco for my residency between 1966 and 1971. This residency was a true general surgery training program. During that period of time, I did vascular surgery, thoracic surgery, general surgery, and I had 3 months of orthopedic surgery, 3 months of anesthesia, 3 months of pathology, and 2 months of neurosurgery. Following this training, I did an NIH trauma fellowship at Southwestern Medical Center in Dallas with Dr. Tom Shires. This was the same year that I first contacted the American Board of Surgery. I had sent in my cases, which were a little over 1,300. This was again reflective of a general surgery training program at that time. During a 4-month period with Dr. Jack Wiley, I did 137 major vascular cases and this did not include the vascular cases that I did at San Francisco General Hospital or in some of the community hospitals. I turned in almost 80 thoracic cases, of which approximately one-half were due to trauma and half were due to cancer and tuberculosis. I had also done a number of orthopedic procedures, including hip nailings, ORIF of femurs and tibias, and reduction of dislocations. I also had an equally good experience in neurosurgery. After submitting these cases, I did the written exam in November, and after passing this was immediately offered the oral exam in December. Every general surgeon remembers their board examiners, and I am no exception. Fortunately, I passed, and out of the 1,100 candidates that year, the failure rate was 18%. However, two-thirds of these individuals then went on to get specialty training, and the remaining one-third (300 diplomats) stayed in general surgery. How many went into rural practice or urban practice is not a number that I can determine.

Moving forward in time, I would now like to contrast my surgical training and my experiences with the American Board of Surgery. In 1975, I became a guest examiner and received an appointment to the Board in 1980. Interestingly, the same number of total residents was being examined and then this decreased slightly. However, the number that now goes into general surgery is approximately 200. This may be misleading, since a number of people who get specialty training also do general surgery. The year that I came on the American Board of Surgery, the Vascular Board had been just voted in the previous January and for reasons that I cannot explain, they made me chairman of the new certification committee for vascular surgery. This became a very contentious issue. One of the issues that impacted negatively on general surgery training was the decrease in the number of vascular cases residents were allowed to do. This has been compounded recently by the shift of vascular management to endovascular stents and interventional procedures. This has also been exacerbated by the creation of a subspecialty board in surgical oncology, and the separation of cardiothoracic into subspecialty boards of cardiac, thoracic, and pediatric cardiac surgery. Another issue in the 1980s was whether or not to have a certificate for trauma and acute care. Trauma was eventually eliminated from the process due to two surgeons on the board who were vehement that trauma was part of general surgery. Alex Walt argued persuasively that we should still proceed with critical care as a counter to anesthesiology and pulmonary medicine, who he thought would be the only ones who could do critical care if the American Board of Surgery did not provide for this. This eventually came to pass and although we tried to have a common certificate with anesthesiology, pulmonary medicine, and cardiology, this failed. Eventually, the critical care training in surgery became synonymous with trauma. Only time will tell what impact emergency general surgery will have on general surgery training.

Since my initial experiences with the Board, there have been many additional pressures and distractions placed on general surgery, not the least of which is subspecialization within general surgery, including hepatobiliary surgery and pancreatic surgery. Much of this subspecialization is ostensibly done because "experience" leads to better results. However, there is a caveat. In a wonderful article in the *British Medical Journal*, Sir David Carter made the following comments: "There is now abundant evidence that hospitals with higher volumes of activity tend to have better outcomes and emerging evidence that surgeons' volume of work is also a determinant of outcome. Certain cancers, cardiac surgery, liver transplantation, and vascular surgery show technical skill is vital, but it is by no means the only essential ingredient for success. Thorough training, compassion, sound judgment, good communication skills, and knowledge are all critically important. However, words of caution are needed. The relation is not linear; some low-volume units achieve good results, whereas higher levels of activity do not necessarily guarantee good outcome."[11] I would ask the question: why can we not teach general surgeons to achieve good results even if they have low volumes?

I articulated in the first portion of this introduction the evolution of trauma centers and trauma systems in the United States. The multiple distractions and pressures against general surgeons are felt keenly by the trauma community. It has been well-documented that many general surgeons, neurosurgeons, and orthopedic surgeons do not want to take trauma call.[12] The reasons articulated are busy elective practices that can be negatively impacted following the day after trauma call. Many of the patients do not have insurance and there is a fear of increased malpractice risk when one takes care of trauma patients.[13] This has led hospital administrators to initiate on-call pay for general surgeons and some specialty surgeons. This on-call pay varies from $1,000 a shift (general surgeons) up to $7,000 a shift for some of the specialties (neurosurgery). Some of these on-call pay schedules could be interpreted as greed versus need. I recently reviewed the American College of Surgeons data on Level I and II hospitals on the number of emergency procedures done by neurosurgery and orthopedic surgeons within the first 24 hours of admission. In 2008, there was a range of seven craniotomies to 137 craniotomies; the average was 43 per year. In 2009, it ranged from six craniotomies to 137 craniotomies per year, for an average of 62, which is a 50% increase over 2008. For orthopedic cases in 2008, the average was 494 cases with a range of 20 to 1,604. In 2009, it was 558 cases, with a range of 106–1,890. It does not take a mathematical genius to determine that the neurosurgeons average one craniotomy every seven to eight nights, and yet may be paid up to $7,000 a night just to take call. It is highly unlikely that Congress and/or the public will understand or be sympathetic to such payments, particularly with the increasing annual costs in health care and the median total compensation for surgeons. The public might be more sympathetic if hospitals reimburse the surgeons for uncompensated patient care services or

TRAUMA

assisted specialty groups in recruitment to fulfill trauma care need and obligations.

The Division of Advocacy and Health Policy of the American College of Surgeons has recently come out with a very timely white paper that highlights other issues impacting general surgery.[12] In the introduction of the article, it was pointed out that:

- "A majority of surgeons take ED call 5–10 days a month; some surgical specialists take call far more often."
- "Many surgeons provide on-call services simultaneously at two or more hospitals, and a notable number say they have difficulty negotiating their on-call schedules."
- "Hospital bylaws typically require surgeons to participate in on-call panels, although older individuals are often allowed to 'opt out,' and they are more frequently taking advantage of this option."
- "A notable number of surgeons have been sued by patients first seen in the ED, and some physicians are offered discounts on their liability coverage if they limit or eliminate ED call."

The Advocacy and Health Policy Division goes on to point out the importance of emergency rooms as a safety net for patients and their role in trauma care. A study by the Lewin group in 2002 showed that neurosurgeons, orthopedic surgeons, general surgeons, and plastic surgeons were among the specialists in short supply for emergency department (ED) call panels.[14] The Lewin study was confirmed by the Schumacher Group in 2003, reporting that one-third of EDs lacked surgeon specialty coverage, causing 76% of those responding to go on divert status.[15] More recently, similar surveys were conducted by the American College of Emergency Physicians in 2006, and they showed that nearly three-quarters of ED medical directors think that they have inadequate on-call specialist coverage, compared with two-thirds in 2004.[16] In the most recent survey, orthopedic, plastic, and neurologic surgeons, as well as otolaryngologists and hand surgeons, were reported as most often being in short supply. The American College of Surgeons Bulletin white paper also points out that surgeons are older, with a noteworthy number taking emergency call at 55 years or older. Furthermore, there is a decrease in surgeons providing charity care. The Emergency Medical Treatment and Active Labor Act (EMTALA), which was originally designed as an "antidumping" federal measure, has created a "dumping" problem: an unintended consequence. Finally, malpractice continues to be a problem to any surgeon who provides emergency care.

The crisis in general surgery is further compounded by two studies published by R. A. Cooper, who states, "The physician shortage is here now and will become worse by 2020, when the deficit may be as great as 200,000 physicians.[17,18] Many of these will be surgeons, gastroenterologists, and cardiologists." As noted above, there is a particular crisis in general surgery. Of the approximately 1,000 surgeons who successfully pass their boards, only 200–250 remain in general surgery. Most are getting subspecialty training, and very few of these want to take trauma call. There is also a decline in interest in general surgery because of lifestyle issues, gender, and mentorship. A particularly poignant study by Bland and Isaacs showed a trend toward lifestyle medical specialties rather than surgical specialties.[19] There is a fairly dramatic fall from 1978 to 2001 in the interest of fourth-year medical students in general surgery. Orthopedics may have slightly increased, but neurosurgery, otolaryngology, and urology have stayed relatively flat. There is a particular issue as it relates to gender. Graduating medical students are at least 50% female, and very few apply to general surgery (7% or a little more than 500 applicants). Part of this disinterest in general surgery is the hours of work during the surgical residency, part of it is lifestyle, part of it is a desire to combine a professional career with a traditional

role as a mother, and part of it because the programs have not provided protective time so that they can do both. However, there seems to be some recent positive changes in application to surgical programs since the institution of the 80-hour work week.

Recently, the American Association for the Surgery of Trauma, working in concert with the American Board of Surgery, has proposed a solution to attracting medical students into trauma and critical care surgery and retaining them once they pass their boards. The proposed solution essentially expands trauma and surgical critical care to also include emergency general surgery. To accomplish this, it is most likely that surgeons would have to rotate in shifts to cover the hospital 24 hours a day. This might be particularly attractive to women and single parents who would have more control of their time, since they could do 12- to 13-hour shifts a month, leaving the rest of the time for parenting.

Another major problem by 2020 will be the 30% increase in the elderly population in hospitals. It used to be that the peak in death rate from injury was in the 16- to 24-year age group. We are now seeing a bimodal distribution, with an increased death rate in the elderly. The elderly are more active, and unfortunately, the mortality rate for Injury Severity Score >15 is 3.5 times more than those of their younger counterparts.[20] These patients spend more time in the intensive care unit, and unfortunately, do not always have a good return to independent living status or quality of life after their trauma episode.

The lack of general surgeons also impacts negatively on the Department of Defense (DOD) and its need for surgeons.[21–25] Approximately 20% of DOD surgeons are active-duty surgeons; 80% must come from the reserve. Studies after Desert Storm by the General Accounting Office showed that surgeons were not being trained properly for trauma, particularly the active-duty surgeons; however, the DOD has improved this during the past 4 years.

Another negative impact on trauma care is that many trauma centers are closing or downgrading their level of care. Since 2003, "dumping" has become an increasing problem for Level 1 and II trauma centers. This phenomenon is characterized by community hospitals calling the trauma centers and speaking to an emergency physician or surgeon, telling them they have a trauma case that they cannot provide care for, either because of a lack of personnel or because the patient's case is too complex. Many of these patients, once they reach the trauma center, are observed and then discharged the following morning.

Another issue for concern in trauma care is that rehabilitation beds are not available after a severe injury. The General Accounting Office performed a study showing that only one in eight patients with a traumatic brain injury receives appropriate rehabilitation after acute care.[10] Rehabilitation is particularly a problem for patients who have no insurance. I had a patient approximately 6 years ago who was 36 years old, married, and had four children—all boys. He started his own construction company, but unfortunately, he did not have enough money to buy health insurance, which would have cost $6,000 per year for a family of six. He fell while constructing a building and became paralyzed. As a result of the accident, his acute care was provided by my hospital free of charge, but we could not find a rehabilitation facility that would take him. We taught his wife the bare necessities of care for a paraplegic, but, obviously, he is at high risk for complications, and home care with his wife performing most of the care will not allow her to work and provide for the family.

There are other issues as well. Of some concern to acute care hospitals is the recent growth in free-standing ambulatory surgery centers. In many instances, these centers are owned by specialty surgeons, and one of the advantages to them is that

they do not have to take night call. In addition, they often will not accept patients with Medicaid or Medicare insurance, thus increasing the burden on the "safety net" hospitals

Finally, we must address the issue of specialty surgical coverage to EDs, and specifically those that are designated trauma centers. The lack of consistent coverage, obviously, adversely affects outcomes, and when a hospital diverts, it puts more stress on other parts of the trauma system. Optimally, the solutions would come from professional societies that represent the surgical subspecialties. Not only does this problem apply to trauma centers in this country, but it also has an impact on our ability to deliver trauma care to the military.

FUTURE

This last section is to ponder on the future of emergency general surgery and trauma surgery. To do so, we have to ask the question: is there a future for trauma in general surgery, and is it good for the community we serve? I think the answer is an unequivocal "yes." In order for this to happen, however, we have to train a general surgeon who is comfortable working with the neck, chest, abdomen, and is comfortable dealing with vascular injuries and compartment syndromes (Table 20.3) This would include the mangled extremity, and in some instances, emergency neurosurgical and orthopedic procedures.

As stated in the previous section, there have been a number of negative impacts on training the general surgeon in the last 40 years. To summarize, these include:

- Establishment of vascular surgery boards and changes in the management of vascular disease and injury,
- The subspecialty of general surgical oncology,
- Changes in the boards within cardiothoracic surgery, which has now been fragmented into pediatric cardiac surgery, thoracic surgery, and cardiac surgery,
- Other surgery fellowships within the house of general surgery, including hepatobiliary and pancreatic fellowships.

The creation of these specialists and subspecialists has had a profound effect on the number of cases the general surgery resident has access to for training. An obvious solution to this problem is to establish opportunities for general surgeons to train in suburban and even rural hospitals where these cases are still being done by general surgeons. This would have tremendous advantage to the university program in establishing goodwill within these hospitals. Obviously, the "farming out" of these residents would have to be done in a very calculated and careful process. An associate program director would have to be appointed; legal requirements would have to be met; and a clear definition of what the surgical resident can do, the amount of proctorship, and the amount of supervision needed would have to be carefully defined. This might very well solve the issue of training somebody who is truly general surgery trained, and it would certainly help solve the

demand for general surgeons who would go into rural surgical practice. The resident could then rotate back to the university hospital for experiences in pediatric surgery, trauma, and emergency general surgery. It would also be an opportunity to avoid having general surgery residents doing scut work on subspecialty surgical services.

The second issue regarding the future of emergency general surgery and trauma surgery relates to the overall shortage of general surgeons that has been predicted by Cooper and the number of medical students who even apply to general surgery. The link to this is the number of general surgeons, upon completion of their American Board of Surgery, who choose to go into subspecialties, leaving only 20%–25% who make general surgery their life endeavor. I personally think this is linked to issue number one discussed above. If we can make general surgery attractive by reestablishing the general surgeon as a true generalist from a surgical standpoint, in addition to making it intellectually challenging, this problem could be solved. Related to this is the issue of hours of work during training and later in the professional life. This would solve the gender issue as well. By doing shift work and having reasonable hours, such as the 80-hour work week for residency and 12-hour shifts as an attending, it would mean that in a 1-month period, almost half would be devoted to family and outside interests. It is of interest that the National Health Service in Great Britain has recently announced that their experiment with the 56-hour work week has been an abysmal failure.

The third issue is touched upon above, but I would like to expand on the rural general surgery issue. Many rural surgeons do trauma care, and staff Level III and Level IV hospitals. Many of these hospitals are so-called "critical access hospitals," of which there are 1,307 in the United States. These are critical to rural areas, and not only provide trauma care, but also emergency general surgery care. For example, in Oregon we have 22 of these critical access hospitals, 18 of which have a general surgeon on staff. Four of the hospitals have no general surgeon. These critical access hospitals get a marginal increase (5%) in Medicare payments. These hospitals are vital to the community they serve. They provide jobs and a service to the community. In order to encourage surgeons to go to rural areas to practice, we have established a 1-year training program in a community of 30,000 people in southwestern Oregon. During this 1-year period, the resident or residents who go there would do a wholly different type of general surgery and trauma care than in the parent university hospital (Table 20.4). These residents are usually on 24-hour call, and will assist three general surgeons who provide the care for this community. This 24-hour call can be very onerous if you're the only general surgeon in some of the smaller communities. One solution is to transfer emergency general surgery cases to a higher level of care. In at least one instance, the university hospital in Oregon has contracted to a hospital 30 miles away in a smaller community to take four out of seven night calls. If a patient comes into the hospital emergency room on the night the university is on-call, the patient is quickly transported to the university emergency room. This relieves the general surgeon from having to take call 24/7/365.

This does not solve all of the problems in the rural areas. Many of these surgeons have to get locums to come in and do 2 weeks of call so that they can go on vacation, and if they want to go to medical meetings, then they must work out some type of alternative call. This could possibly be solved by having general surgeons in these communities rotate to the university, where a faculty would go out and take a call for a week at a rural hospital. Another solution is to have at least one mid-level provider, such as a physician's assistant or a nurse practitioner, to take care of minor surgical problems like lacerations and reduction of closed fractures so that the surgeons can at least get a good night's rest.

A fourth area of concern is the DOD, as mentioned in Part II of this manuscript. The wounds that are being treated by military surgeons are devastating wounds. Most involve the extremities, neck, and face. Body armor has been a godsend since it allows many of these soldiers to survive, but they still end up with very disabling injuries. Suicide bombers create a new threat: parts of the suicide bomber may penetrate the skin and thus lead to viral infection and transmission of disease. It is extremely difficult to train surgeons for our current conflicts. There have been many wars since World War I, but there are notable hiatuses between these conflicts and each generation has to learn from the previous generation. That includes avoiding some of the same mistakes. The DOD has also initiated a program where military surgeons spend a period of time in civilian trauma centers, but again, this is not quite as devastating as what they will be called upon to treat. DOD is also set up so that its hospitals have civilian trauma centers. Again, this does not mimic the types of wounds that it might see except in rare instances. An alternative solution that has been recommended is for DOD to fund a program where reserve surgeons could serve in civilian trauma centers on a regular basis but be subject to deployment as needed. This would mean that there would be an overage of personnel at times, and at other times, depending on the number deployed, there could be a shortage. The Air Force has a program already in place where it has reserve Air Force pilots working for commercial airlines and these individuals will do 3-month rotations to areas of conflict.

Another area of potential concern is the rise in the number of surgical hospitalists. This position is on the increase, but

has yet to be fully defined. Ostensibly they are hired by the hospital to provide surgical coverage, usually on a 12-hour shift basis. Is this the same as emergency general surgery? Do all of these individuals have training in critical care? What is their incentive? Many are paid a flat salary and they are given an office (small) and their malpractice is paid for. This is attractive to many individuals, since they can have a professional career as a surgical hospitalist and yet have almost half of the month off to do other things. In many instances, these individuals are foreign medical graduates who have passed USMLE or have trained in this country.

Possibly the most contentious of the problem areas is in the area of trauma surgery. The future of trauma surgery could be very grim or it could be a time of opportunity. There are some problems that were outlined in Part II, not the least of which is the decrease in the number of open cases currently being done by trauma surgeons. Part of this is due to decreased penetrating trauma, and another is an improvement in diagnostic studies such as CT and MRI that allows one to avoid opening a body cavity. There is also the problem of competing with other specialists, particularly those in thoracic surgery and vascular surgery. This was not a problem 30 years ago, but in large academic centers, it is increasingly problematic. In my opinion, every trauma surgeon should be able to open a chest and be comfortable dealing with emergent problems. Similarly, many vascular cases do not lend themselves to endovascular arterial repairs and need to have open surgery. Who should do this when the patient arrives emergently? The trauma surgeon? The vascular surgeon? Another problem is the shift toward shift work. This creates problems in regards to continuity of care and dealing with the family. Many institutions have overlap of the shifts so that they can make rounds together, pass the baton, and discuss issues with the family. This still needs to be refined. There are also contentious areas with other specialties, including neurosurgery and orthopedics. How much should the trauma surgeon do, and when is the right time to call in a specialist? Should the trauma surgeon insert intracranial pressure monitoring devices or even intraventricular catheters? Should the trauma surgeon reduce fractures and do external fixation? There are certainly models around the world where this is done. The European model is particularly interesting, since in one instance you can train for 4 years as a general surgeon and then two or three additional years as an orthopedic surgeon, and then do both at a Level I center. In other parts of the world, such as Australia, Malaysia, and New Zealand, the general surgeon may have to do a decompressive burr hole or craniotomy because of the tyranny of distance. This is somewhat problematic in the Rocky Mountain West. In the near future, it would be optimal if trauma surgery leaders and leaders from other specialties would sit down and try to design a model that is best for the patient. This is problematic since there appears to be a shortage of specialists in the near future, such as in neurosurgery and orthopedics.

The last contentious problem that will have to be dealt with soon is the impact of health care reform on the trauma systems. I think it is fair to say that >90% of Level I trauma centers are in the traditional safety net hospitals. How will these safety net hospitals cope under health care reform? Health care reform did *not* solve all of the access problems, nor did it solve cost and quality problems. In fact, there are very few examples of systems of health care; however, trauma is probably a very notable exception. Similarly, transplantation and the STEMI program are models. Probably the biggest failure of health care reform is that there is no public option. Public option would be a clear advantage to the government and to patients if the government could contract to the safety net hospitals to provide all emergency care. In addition to these issues, health care reform has not addressed the deficiency in rehabilitation, and it certainly did not adequately address tort reform. It is the opinion of this author that we cannot wait for the next generation to solve these issues.

CHAPTER 21 ■ INITIAL EVALUATION OF THE TRAUMA PATIENT

LESLIE KOBAYASHI, RAUL COIMBRA AND DAVID B. HOYT

The assessment and management of the injured patient is a unique situation in which time and efficiency are of the essence. There is ample evidence in the literature that standardization of care improves outcomes and reduces morbidity and mortality in trauma patients.[1] Multiple trauma systems exist in the United States and throughout the world. However, one well-regarded and widely practiced system of trauma patient assessment and management has significantly shaped the care of the trauma patient in the last 25 years.

Advanced trauma life support (ATLS) is a course provided by the American College of Surgeons; it is meant to prepare a variety of clinicians to treat, triage, and transport the broad spectrum of trauma patients. Introduced in 1978 and rapidly adopted throughout the United States, it is now taught in more than 50 countries. Now in its eighth edition, it is the gold standard for trauma patient assessment and management. ATLS protocols are based on a comprehensive review of the international literature to date.[2]

In ATLS, the initial assessment of the trauma patient is broken down into many components including; triage, preparation, the primary and secondary surveys and their radiologic adjuncts, ongoing resuscitation, and transfer to definitive care.

The primary survey consists of the ABCDEs (airway, breathing, circulation, disability, and exposure/environment). Adjuncts to the primary survey include plain radiographs of the chest and pelvis, and the focused assessment with sonography for trauma (FAST). The secondary survey is a quick head-to-toe physical examination, the purpose of which is to rapidly identify critical injuries and determine if these injuries are going to require further imaging or necessitate transfer to another facility for definitive care. The secondary survey may include simple or advanced imaging such as extremity plain films or computed tomography (CT) scans.

Throughout the primary and secondary surveys, resuscitation of the patient must be ongoing and continually reassessed. Upon completion of the initial assessment and resuscitation of the patient to a stable or semi-stable state, a decision must be made regarding transfer to definitive care. Transfer to an appropriate setting (operating room, intensive care unit [ICU], interventional suite) or facility (tertiary care center, level I trauma center, burn center) should be initiated as soon as possible after completing the initial assessment.

With timely diagnosis and intervention being the driving force in trauma evaluation, we need to determine if our emphasis on speed is supported by the data. Much has been described regarding the Golden Hour of Trauma, the 1 hour following injury when lives may be lost or saved by proper medical attention, but is this truth or myth?

The classical trimodal distribution of trauma deaths was first described in the seminal article by Trunkey in 1983, in which he demonstrated that almost half of all trauma deaths occurred in the first hour after injury.[3] The other two peaks occurred within the next 1–4 hours and after the first week of injury. Trunkey considered many of the deaths occurring during the second peak (hours 1–4), as potentially preventable, and identification and treatment of these patients during the Golden Hour became the focus of the initial assessment.

Great strides have been made in trauma systems management, prehospital emergency medical technology, resuscitation, and ICU care since this seminal paper. These advancements have resulted in more patients surviving to reach hospitals alive, and surviving after admission to the ICU, further emphasizing the need to concentrate on the early hours of trauma evaluation and resuscitation.[4,5] In a study by Bansal in a level I trauma center in San Diego, while the majority of deaths still occurred within the first hour, a second peak occurred within hours 1–3, and hemorrhage continued to contribute to deaths up to 6 hours post injury[4] (Fig. 21.1). A study by Demetriades et al.,[5] also in a mature level I trauma center in Los Angeles, revealed similar information, with the majority of deaths upon arrival and a second peak of trauma deaths between hours 1–6.[5] These studies also revealed that mechanism of injury (MOI) and body cavity involved affected time of death considerably.

TRIAGE

The concept of triage is an essential element in modern medical care where resources are nearly universally exceeded by demand, even in highly developed, technically advanced centers. The basic tenants of triage incorporate accurate assessment of victims, victim acuity and available resources, and quickly assign the proper resources to the proper patients.[6]

Many protocols exist for prehospital triage of victims, determining the optimal distribution of patients to hospitals in the area based on victim factors such as acuity and age, and the resources of the area such as number of, and distance to, specialty trauma or burn centers. The ACSCOT has a protocol for this in Resources for the Optimal Care of the Injured Patient 2006.[7]

Outside of mass casualty and disaster management situations, categorization of traumas is generally based on patient acuity. Prior to the patient's arrival, as much data from prehospital personnel should be gathered as possible. The components that determine level of acuity include clinical factors and MOI. Clinical indicators are subdivided into physiologic factors such as vital signs and level of consciousness, and anatomic factors such as body system involved—head, neck, thoracoabdominal, or isolated extremity trauma.

Trauma victims are generally classified into trauma team activations, urgent consults, or routine consults based on highest, medium, and lowest level of patient acuity and risk of substantial or operative injury. Trauma team activations (TTAs) are the highest level of trauma victims and generally require the presence of the most experienced trauma physician or surgeon, and the presence of the entire trauma team if one exists. Additional personnel who should be present at this level of acuity include an anesthesiologist or other airway specialist, radiology technologist, respiratory technologist, and trauma/emergency room/surgical ICU nurses. Additional personnel who may be helpful include a pharmacist, social worker, and ultrasonographer. Specific guideline for who must be present at TTAs for level I verification exist in the ACSCOT Resources for Optimal Care of the Injured Patient 2006.[7]
FIGURE 21.1. Distribution of in-hospital deaths over time for the first 24 hours after admission to trauma center (Data from Bansal V, Fortlage D, Lee JG, et al. Hemorrhage is more prevalent than brain injury in early trauma deaths: the Golden Six Hours. *Eur J Trauma Emerg Surg.* 2009;35:26–30.).

Many studies have validated this tiered system of trauma patient evaluation. A study by Petrie et al.[8] in 1996, comparing TTAs requiring the involvement of the trauma team in the patient's initial assessment and resuscitation to non-TTA trauma patients, revealed a notable improvement in the number of survivors compared to non-TTA patients per 100 population. This improvement in mortality occurred despite a considerably higher injury severity score (ISS). A similar study 10 years later by Cherry et al.,[9] in 2007, revealed similar results: TTA protocols correctly identified patients with higher ISS, and early (<4 weeks) mortality, and TTA patients had significantly improved survival compared to their less injured non-TTA counterparts.

Clinical Criteria

Clinical criteria for level of trauma acuity include physiologic derangements of heart rate, blood pressure, and level of consciousness. In most trauma centers, patients with significant tachycardia (heart rate ≥120), hypotension (systolic blood pressure <90), or depressed mental status (Glasgow Coma Scale (GCS) < 8) are classified as a TTA. Additionally, most patients who were intubated in the field or require assisted ventilation also meet TTA criteria.

Clinical criteria have been repeatedly validated as useful triage tools.[9–12] Although debate does exist in the literature as to specific cutoff values for triggering a TTA, several studies have confirmed hypotension with systolic blood pressure <90 as an excellent predictor of mortality and injury severity.[9–11] Tachycardia with heart rate >120 beats per minute is also a validated triage criteria, though it appears to be less specific than hypotension. Depressed mental status with GCS < 8 is also highly predictive of mortality.[9]

Mechanism Criteria

Penetrating mechanisms such as stab wounds and gunshot wounds to the trunk or neck should be considered high-level traumas. Blunt mechanisms that indicate significant force include falls over 15 feet, automobile versus pedestrian, and high-speed motor vehicle crashes. Additional factors denoting involvement of great forces in the trauma are accidents with fatalities at the scene, crashes with significant passenger space intrusion, steering column deformation, ejection of the victim from the vehicle or rollover of the vehicle.

It must be kept in mind that MOI criteria in isolation have a very low predictive value in identifying severely injured patients.[9–11] MOI criteria are most helpful when taken into account with additional patient variables such as heart rate, GCS, and anatomic area of injury. Some studies suggest that experienced EMTs are very helpful in improving the positive predictive value of MOI criteria by exercising proper discretion upon application of MOI criteria in stable and evaluable patients in the field.[10]

Age Criteria

In the Primary Survey chapter of ATLS 8th Edition, care is taken to emphasize the increased incidences of comorbidities and need for specialized resuscitation strategies for the elderly trauma patient.[13] While no specific age criteria for field triage currently exist in the ACSCOT guidelines, multiples studies confirm the unique characteristics of the elderly trauma patient.[14–18] The older trauma patient has less physiologic reserve and a much lower ability to respond to injury compared to younger patients. Elderly patients are at increased risk for substantial and more advanced comorbid conditions such as hypertension, diabetes, coronary or peripheral vascular disease, chronic obstructive pulmonary disease, and emphysema. Because of these comorbidities, the elderly are more likely to be on medications such as beta blockers, calcium channel blockers, and diuretics; these medications may mask tachycardia, worsen hypotension, and interfere with efforts at resuscitation. Additionally, elderly patients with significant injuries may not meet traditional hemodynamic criteria for a TTA. The hypertensive patients may have a normal appearing blood pressure, but compared to their baseline this may be relative hypotension; alternatively, if the patient is on a beta blocker, substantial hemorrhage may be ongoing but the compensatory tachycardic response may be blocked. Elderly patients are also more likely to be on medications such as antiplatelet agents or anticoagulants, which considerably increase their risk of bleeding. In addition, elderly patients may have a baseline alteration in mental status or dementia, or have hearing or visual deficits, making communication and evaluation more difficult.

Several studies have demonstrated increased mortality in the elderly trauma patients even after correcting for injury severity.[14,19–21] Additionally, analysis of mortality by age has identified 70 years or greater as the cutoff for considerably increased mortality.[14] Using an age of 70 years or greater alone as a TTA criteria has demonstrated improved outcomes in trauma patients.[19,20] In a series of studies by Demetriades et al., he noted that many patients 70 years or greater had severe injuries without meeting typical hemodynamic criteria for TTA (HR > 120, SBP < 90). The authors have also demonstrated improved survival in these patients after age alone was instituted as a TTA criteria.[19,20] An additional study by Scalea et al.[22] demonstrated that the elderly trauma patient had improved survival when early invasive monitoring was instituted.

Over and Undertriage

Because any triage system will not be perfect, they should be evaluated routinely to ensure over and undertriage rates are at acceptable levels. The ACSCOT has determined an acceptable under triage rate (seriously injured victims not taken to a trauma center) to be ≤5%, while the acceptable overtriage rate may vary from 25% to 50%. Because overtriage results primarily in overutilization of resources, while undertriage can result in missed injury, delay in treatment or death, there is a need to err toward overtriage rather than undertriage.

PREPARATION FOR PATIENT ARRIVAL

Given the importance of time in the initial assessment and management of the trauma patient, proper and thorough preparation prior to patient arrival is essential, and can prevent the loss of pivotal minutes in treatment after patient arrival. All monitoring devices, ECG leads, blood pressure cuffs in a variety of sizes, and pulse oximeter should be available. Warmed intravenous fluids, lactated ringers or normal saline should be available, as should blood products, O negative blood, and in some level I trauma centers, thawed universal donor plasma. Multiple intravenous access devices, angiocatheters in a variety of sizes, and central or intraosseous (IO) lines should be available, along with vacutainers for blood samples. Adjunctive devices such as suction canisters, laryngoscopes, masks and bags for ventilation, oral and nasal airways, urinary and nasogastric catheters, splinting or casting material, pelvic binders or sheets, and basic surgical instrument trays should also be available and kept stocked in standard locations that are easily and quickly accessible.

Prior to patient arrival, personal protective gear should be donned by all members of the assessment team. Universal precautions are necessary for all personnel coming into direct patient contact. Precautions should include occlusive gown, gloves, face shield or, at a minimum, eye protection, a mask and surgical cap if any sterile procedures are anticipated, and shoe covers. Protection is worn not only for the protection of the patient about to undergo sterile procedures, but for the protection of the staff from blood-borne infection. The incidence of blood-borne infections, most importantly HIV and Hepatitis C, vary in the literature, with recent studies revealing HIV in 1.4%–1.9% and Hepatitis C in 3%–8% of trauma patients.[23–25] However, a series of studies from John Hopkins University revealed much higher rates of infection among trauma patients, 26% for HIV and 33% for Hepatitis C.[26,27] The true incidence of HIV and hepatitis infection among trauma populations likely varies according to geography and type of hospital; however, full-barrier precautions should be universally employed.

PRIMARY SURVEY

The primary survey is a quick simple way to assess every trauma patient in a few minutes. Patients, upon arrival to the evaluation and resuscitation area, are visually surveyed for injuries; devices such as noninvasive blood pressure cuffs, pulse oximetry, and electrical cardiac monitors are used to obtain vital signs; large-bore intravenous access is established, and the patient is completely disrobed. The primary survey is performed by an experienced physician who should be designated prior to the patient's arrival, and is performed while simultaneously addressing any life-threatening situations in real time as they are identified.

The physical examination of the primary survey is broken down into five basic components, ABCDEs. The ABCDEs are a sequence of physical examinations that are taught in ATLS to occur in a specific sequence. This sequence has been derived to address the most quickly life-threatening injuries most rapidly; as such, airway obstruction, which can lead to death in 1–5 minutes, is first, while equally important but less rapidly lethal conditions such as hypoxia and hypotension are second and third, respectively. In reality, many of the components of the primary survey occur simultaneously; equally, many problems in one area of the primary survey impact on other areas of the primary survey. For example, a tension pneumothorax, primarily a breathing problem, may result in the appearance of airway obstruction as the patient demonstrates air hunger or inability to vocalize, and may also impact circulation by decreasing preload and resulting in hypotension. Because of this, while the protocol of the primary survey addressing ABCDE in a strict sequence is done for medical priority, the informed clinician must also be able to keep the big picture in mind. Although not part of the list of life-threatening conditions, hemorrhagic shock remains the most common cause of death following injury. However, it is unlikely that patients arriving alive to trauma centers will die of exsanguinating hemorrhage within the first few minutes after admission. These individuals may still be bleeding, but compensatory mechanisms such as vasoconstriction and tachycardia, in addition to clot formation, develop to slow down bleeding and maintain perfusion to vital organs.[6,28,29]

Adjuncts to the primary survey exist in each of the categories; in the past, these have focused primarily on plain x-rays of the cervical spine (cross-table lateral view), chest, and pelvis. In most level I trauma centers today, less emphasis is placed on plain radiography of the cervical spine during the initial assessment when protection of the cervical spine far outweighs the need to diagnose injury. The most important adjuncts of the primary survey today include a single anteroposterior view of the chest and pelvis, and ultrasonography or FAST, which includes views of the abdomen and pericardium.

During evaluation of the ABCDEs, resuscitation should be ongoing and titrated to improvements or deteriorations in vital signs. A type and screen for type-specific blood and plasma transfusion should be the first priority in obtaining blood samples. Blood should also be drawn to obtain hematologic, chemical, and coagulation profiles. Pregnancy tests should be done in all females. In addition, every effort should be made to obtain an arterial sample for the analysis of oxygenation, hypercapnia, and acid–base status.

It is important to keep in mind that the primary survey is applicable to all trauma patients; while the anatomic and physiologic responses to injury may vary, the priorities for pediatric, geriatric, and obstetric trauma patients are the same.

AIRWAY

Addressing the airway is the highest priority in the initial assessment because obstruction, occlusion, or loss of airway is the most rapidly lethal of all injuries. The clinician must assess if the airway is patent, if it is protected, and if there is an evolving injury that may impact the future patency of the airway.

The easiest way to rapidly assess for both patency and protection of the airway is to ask the patient a simple question—"are you ok?", "what is your name?" If the patient responds appropriately in a normal tone, timbre, and volume, you have assessed that they are conscious enough to protect their airway and that the airway is patent. The presence of hoarseness, weakness, or inability to speak in full sentences is an indication of impending airway compromise. Additionally, if there is gurgling, coughing, or obvious aspiration of material, this is definite evidence of obstruction. Lack of a verbal response, combativeness, or restlessness indicates inability of the patients to protect their airway. All of the above abnormalities require immediate intervention.

If airway compromise is diagnosed, the clinician should perform simple maneuvers such as the jaw thrust or chin lift, to bring the tongue and soft palate out of the oropharynx and provide high-flow supplemental oxygen by face mask. The oropharynx should be cleared with suctioning; care should be taken to avoid deep suctioning to prevent activating the gag reflex, causing vomiting and aspiration. Supplements to airway patency such as the nasal trumpet and oral airway can be considered. Care must be taken to use the oral airway only

in completely obtunded patients again to avoid vomiting and aspiration. The oropharyngeal airway is placed with the aid of a tongue blade; in adults, it is inserted upside down, the end sliding along the palate, then rotated 180 degrees into proper position behind the base of the tongue; this is to avoid having the device push the tongue posteriorly during insertion and worsen obstruction. This maneuver is not used in children because of potential for injury to the palate. The nasal airway is generally well tolerated by conscious or semiconscious patients, and should be equivalent in length to the distance from the nares to the angle of the mandible. The nasopharyngeal airway should be lubricated, and then placed into one of the nares; however, it should not be used in the presence of obvious midface injury or possible facial fractures to avoid displacement of bone fragments or the device itself into the cranial vault (Fig. 21.2).

A more advanced temporary airway is the laryngeal mask airway (LMA). This soft plastic device, invented in 1983 by British anesthesiologist Archie Brain, comes in a variety of sizes and is meant to fit the posterior oropharynx. The LMA is placed in the supraglottic position and an inflatable cuff is deployed to seal the oropharynx for spontaneous or manual ventilation. A drawback of the LMA is that it does not fit into the trachea, so communication between the esophagus and trachea remains completely open and aspiration remains a significant risk. Some improvements in the design of the LMA have included esophageal drainage ports, and the ability to use the LMA to guide placement of an endotracheal tube (ETT). This last option may be attractive in patients with known or highly suspected cervical spine injuries where minimization of neck movement is of the utmost importance, and laryngoscopy may be difficult or impossible. However, optimal placement of the LMA, similar to intubation, often requires extension of the head on the neck, and, at a minimum, the jaw must be thrust forward for optimal placement. As with any airway maneuver, LMA placement is not risk free, and must be undertaken while simultaneously protecting the cervical spine with in-line traction.

Other supraglottic airways include the King Laryngeal tube and the esophageal/tracheal Combitube. These devices are meant to be inserted blindly or with the aid of a laryngoscope; they contain a large superior cuff to seal the supraglottic pharynx, and a smaller inferior cuff. In the case of the King Laryngeal tube, the smaller cuff is preferentially inserted into, and inflated in, the esophagus. Ventilation is achieved through port holes between the upper and lower cuffs in the supraglottic pharynx just above the trachea; the superior cuff prevents air leakage from the mouth and nose, and the inferior cuff prevents insufflation of the stomach and decreases risk of aspiration. The Combitube is also inserted blindly, and the superior cuff is inflated to prevent air leakage from the mouth and nose. However, the tube may be inserted into either the trachea or the esophagus; the distal portion of the tube enters the esophagus in over 90% of insertions.[30] Once the tube is placed, both cuffs are inflated. Once the cuffs are inflated, there are two ports to ventilate through—a distal port below the distal cuff can be used if the end of the Combitube is within the trachea—and ventilation proceeds as with any ETT. If, in contrast, the distal tube is in the esophagus, the patient is ventilated through proximal ports located between the superior and inferior cuffs, and ventilation proceeds through the supraglottic oropharynx, and the distal cuff prevents esophageal/stomach insufflation, as in the King Laryngeal tube. A comprehensive review of acute airway management is beyond the

FIGURE 21.2. Basic airway adjuncts—mask with reservoir, oral and nasal airways.

scope of this chapter and can be found in the Airway Control Chapter 12 of Trauma 6th Edition.[31]

All above-mentioned maneuvers are temporizing and if the airway compromise does not resolve, a definitive airway is indicated. Strict indications for a definitive airway include obvious or impending airway obstruction, obtundation with GCS < 9, and respiratory insufficiency (hypoxia, hypercarbia, apnea). Definitive airways include orotracheal or nasotracheal intubation and surgical airways—cricothyroidotomy and tracheostomy.[32]

Placement of a definitive airway in the comatose patient can generally be accomplished without sedating or paralyzing medications, which has the benefit of avoiding pharmacologic interference with neurologic examination and possible hemodynamic compromise that is a side effect of many such agents. Additionally, the use of a paralyzing agent can often turn an urgent airway situation into an emergent airway; loss of the small amount of muscular tone in the pharynx can cause partial obstruction to turn into complete obstruction, making bag-mask-valve ventilation impossible. Occasionally, in the comatose patient, increased muscular tone and biting in the semiconscious patient make sedating and paralytic agents a necessity, as does intubation of the conscious patient. If the clinician tests jaw rigidity by performing a jaw thrust or attempts to gently open the jaws with the scissor technique and meets resistance, a sedative and paralytic should be used prior to any attempt at obtaining a definitive airway. Rapid sequence intubation is a technique of administering bolus doses of a sedative and paralytic simultaneously while using cricoid pressure (the Sellick maneuver) to prevent aspiration and the use of minimal or no preoxygenation to prevent gastric insufflation and minimize aspiration risk. One common agent used, Etomidate, is a short-acting sedative with relatively minimal cardiodepressive effects; the dosage is 0.3 mg/kg and induction occurs in 30–60 seconds. There is some suggestion in the literature that Etomidate may result in adrenal suppression and relative adrenal insufficiency, but this is still an area of active research. Some alternative sedatives include Propofol, which is also very rapid in onset, and short acting, or benzodiazepines. However, both may result in significant cardiac depression and hypotension. A popular paralytic agent is Succinylcholine, which has a rapid onset and brief duration of action. The induction dosage is 0.6 mg/kg, and the onset of action is typically within 60 seconds with a duration of 2–3 minutes. Succinylcholine is a depolarizing agent, and may result in malignant hyperthermia, and can cause cardiac arrest due to severe hyperkalemia in certain patients, including victims of burns, drowning, spinal cord transaction, and severe crush injury. In such patients, a non-depolarizing agent such as Vecuronium or Rocuronium should be considered; although the onset of action of these agents is slightly slower, their duration of action can persist much longer than with Succinylcholine, which may interfere with future neurologic examinations. If paralytic agents are used, it is important to obtain a very quick neurologic assessment prior to their administration. If 5–10 seconds can be spared, an assistant should ask the awake patient to move his or her arms/legs and briefly assess sensation, and perform a pupillary exam. In the comatose patient, painful stimuli should be applied to the arms/legs to see if any movement is elicited.

Once the patient is properly anesthetized, the preferred definitive airway is orotracheal intubation. It provides a rapid definitive airway, and the materials required to accomplish it are readily available in most health care settings. Preparation is the key in the successful intubation of a trauma patient. The most experienced physician should be utilized, and several well-trained assistants should be used to bag the patient, provide requested supplies, and maintain in-line cervical spine stabilization in addition to cricoid pressure. Equipment should include a laryngoscope with several types and sizes of blades and the light bulb should be checked for function prior to

patient arrival. Other equipment includes several sizes of ETT, a stylet, equipment to suction the oropharynx, and a syringe for inflating the cuff. A minimum of three people should be involved in the intubation of the trauma patient, if at all possible. The most experienced person should be located at the head of the bed in position to intubate, the second most experienced should be in position below and to the side of the head of the bed to maintain the cervical spine in neutral position, and a third should be to the side of the bed to apply cricoid pressure if necessary and hand equipment to the person performing the intubation. All extraneous material should be removed from the patient's head and neck; the anterior portion of the C-collar be removed. The assistant maintaining cervical spine precautions must ensure that the head is maintained in line, and that the head is not extended during intubation.

Once intubation is accomplished, appropriate positioning of the ETT should be confirmed, clinically by observation of chest movements and auscultation, with a carbon dioxide detector, and radiographically. Clinical confirmation of placement is notoriously unreliable, and such markers as equal chest rise, symmetric bilateral breath sounds, and condensation on the ETT cannot be used alone for confirmation.[33] Capnography is most reliable for confirmation that the ETT is in the airway; if this is not available, colorimetric carbon dioxide detectors can be used. False-positive color change can occur with gastric intubation, but will generally fade after the first few breaths. False-negative color change can occur in patients in cardiac arrest as carbon dioxide production may be below threshold levels for detection. These instances all make continuous capnography much preferable to colorimetric detectors. Lastly, once the primary survey is completed and the patient is stable or semi-stable, a chest x-ray can confirm placement of the ETT in the trachea. Care should be taken to ensure it is not in one of the mainstem bronchi and that both lungs are equivalently inflated. Once successful tracheal intubation is confirmed, the rigid cervical collar should be reapplied. It is important that all personnel involved in the intubation remember that protection of the cervical spine is necessary at all times. Other devices such as the long backboard, sandbags, and struts with binding tape can also be used to immobilize the cervical spine.

Even after the placement of the ETT has been confirmed and it has been secured in place, care must be taken to repeatedly check that it has not been dislodged or become obstructed. Particular care must be taken to inspect for proper placement of the ETT after the patient has been moved or repositioned.

In some cases, traditional orotracheal intubation can be difficult or impossible; some high-risk situations include the obese patient, patients with substantial oromaxillofacial trauma or blood loss, mucus or emesis in the airway, patients with facial burns or inhalation injury, and patients with trauma to the neck. If available, every effort should be made to involve a clinician with advanced airway training such as the trauma surgeon, anesthesiologist, or otolaryngologist. In high-risk cases, the tools for a surgical airway should be immediately available and consideration should be given to using advanced airway adjuncts. Advanced airway tools include the bougie, Glide scope, fiberoptic intubation, and retrograde intubation (Fig. 21.3).

The bougie is a semirigid, long plastic tube with an upward angled tip; it can be passed blindly, or with laryngoscopic guidance, the upward angle preferentially directs it toward the tracheal aperture and away from the esophagus, as does the presence of cricoid pressure. The physician should be able to feel the tip pass the tracheal rings as bumps, then stop advancing when it encounters the carina, and in most cases, turn sharply right following the right mainstem bronchus. The bougie can then be used as a guide for placement of the ETT in a Seldinger-type technique.
FIGURE 21.3. Definitive airway devices—ETT, LMA, bougie.

Other advanced airway techniques include use of a Glide scope, fiberoptic intubation, and retrograde intubation. The Glide scope is a laryngoscope with a camera located on the end of the laryngoscope blade. The image is sent to an attached video screen, allowing the clinician to more easily visualize the vocal cords, especially in a very anterior airway. It also allows for successful intubation with less risk of hyperextension of the neck in patients with possible cervical spine injury. Fiberoptic intubation is also an option in the potentially challenging airway. However, because fiberoptic intubation requires specialized equipment and training, it is not recommended for emergency airways, rather it is more suited to the semi-elective situation. It is particularly useful in patients that are stable or semi-stable but have injuries that make impending airway loss a high risk, such as burn patients without immediate airway compromise, patients with neck injury with possibility of expanding hematoma, or stable patients with oromaxillofacial trauma. Fiberoptic intubation ideally should take place in the operating room with surgical airway tools available should it fail. Another advanced airway technique is retrograde intubation, which is a hybrid between orotracheal intubation and surgical cricothyroidotomy. The airway is accessed via the cricothyroid membrane as in cricothyroidotomy, a wire is passed through the membrane and retrieved from the oropharynx with Magill forceps, the wire is held taught with clamps on either end and Seldinger technique is used to pass an ETT over the wire into the airway in a blind fashion.[34–36]

If the airway cannot be secured using the above techniques, or in cases where airway injury is suspected and attempts at intubation risk further injury, the goal should be to obtain a surgical airway immediately. Definitive surgical airways include cricothyroidotomy and tracheostomy. In the case of suspected or known laryngeal injury, a cricothyroidotomy would be above the level of the injury and in this case, emergent tracheostomy is the preferred airway. In all other cases, cricothyroidotomy is the preferred surgical airway. Cricothyroidotomy can be performed with percutaneous or open technique. In the traditional open technique, very few pieces of specialized equipment are necessary; a scalpel, small retractors, a Kelly, and ETT or tracheostomy tube are the only essential items. The patient's neck is exposed, again, an assistant is used to maintain strict cervical spine immobilization, the cricothyroid membrane is palpated between the thyroid and cricoid cartilages, a vertical midline incision is made in the skin, the membrane is exposed and divided in the transverse direction to avoid injury to the overlying vocal cords, and the ETT or tracheostomy tube is placed into the airway. Clinical exam and capnography are then used to confirm placement into the airway. In the obese patient or the patient with significant soft tissue injury that distorts the traditional landmarks, the cricoid cartilage can be located by placing the smallest finger of the clinician's right hand into the sternal notch; the index finger is then located immediately above the cricothyroid membrane. Many companies manufacture kits for percutaneous cricothyroidotomy. The kits will generally include a scalpel to create the incision, a large-bore needle for accessing the airway through the membrane, a wire to pass through the needle, a plastic dilator to create a passage, and a small rigid tube similar to a tracheostomy tube for ventilation.

There is some debate as to whether or not cricothyroidotomy tubes need to be replaced with a formal surgical tracheostomy for long-term ventilation. Traditionally, all cricothyroidotomies were converted electively to tracheostomies for fear of subglottic stenosis caused by irritation of the airway.

However, recent studies in trauma and ICU populations have demonstrated no increased risk of stenosis compared to tracheostomies.[37–40] These studies reveal that the rates of tracheal stenosis up to 60 months following decannulation are lower than previously thought (overall <3%), and are comparable to rates of stenosis following tracheostomy.[39] They additionally show equivalent rates of successful decannulation, and some reveal a significantly higher rate of complications associated with conversion to tracheostomy.[37,40] Although long-term use of cricothyroidotomy is still an area of controversy, its routine conversion to tracheostomy should be questioned.

In certain patients, the airway may be patent and protected upon initial inspection but may be in danger of rapidly becoming compromised. These high-risk patients benefit from elective placement of a definitive airway in a controlled fashion prior to the development of symptoms or frank airway compromise. Elective intubation to secure a definitive airway is particularly important if the patient will require transport to another location for definitive care, or if prolonged diagnostic studies are planned. Such situations include patients with significant burns, especially if the burn involves the face, or if there is evidence of inhalational injury, patients with substantial oromaxillofacial or neck trauma, where subsequent soft tissue swelling or copious bleeding or secretions may rapidly obstruct the airway, and patients with significant traumatic brain injury where declining or waxing and waning GCS may lead to inability to protect the airway. Finally, agitated and combative patients or those with acute alcohol or drug intoxication may be unable to protect their airway and should be promptly intubated as well.

Pediatric Airway

Intubation of the pediatric trauma victim requires knowledge of the anatomic and physiologic differences in pediatric patients. Children are obligate nasal breathers, so keeping the nasopharynx clear of obstruction, mucus, and blood is of paramount importance. Supplemental oxygen must be directed toward nasal breathing. If definitive airway is indicated, orotracheal intubation is again the preferred route, but it may be more challenging, especially to the inexperienced clinician. In particular, the pediatric airway is more challenging not simply due to smaller size but also because the epiglottis is proportionally larger and more floppy in children than adults and more difficult to maneuver around. Additionally, the airway is higher and more anterior, making visualization during direct laryngoscopy more difficult. Because of these anatomic features, intubation may be easier with the use of a straight or Miller blade, which can be used to directly lift up the epiglottis, allowing visualization of the true vocal cords. Lastly, the airway is proportionally shorter in children, this coupled with their smaller stature overall makes bronchial intubation a much higher risk in children. Outside of the airway itself, children have a more pronounced vagal response and may develop considerable bradycardia, which is also more likely to be severe and rapid in onset in response to hypoxia. Because cardiac output is primarily determined by heart rate in children, bradycardia will result in notable hypotension and hypoperfusion. Therefore, atropine should, at a minimum, be available during any airway maneuver, and prophylactic administration prior to laryngoscopy is widely practiced.

Proper sizing of the ETT can be determined by three general methods. First, the Broselow tape can be used to estimate the patient's weight and all equipment and drug dosages required for intubation; second, the patient's small finger is a rough estimate of the external diameter of the ETT; lastly, the modified Cole formula can be used. The (childs age + 4)/4 will give the optimal internal diameter of the ETT. The ETT should be inserted to a depth of three times the internal diameter of the ETT used. Again, care must be taken to confirm appropriate position of the ETT after intubation, keeping in mind the much higher risk of bronchial intubation. Tracheal placement can be confirmed with auscultation of symmetric breath sounds over both lateral lung fields, equivalent chest rise bilaterally, return of carbon dioxide on capnography or colorimetry, and lastly, with radiographic evaluation.

One area of controversy is the use of cuffed versus uncuffed ETTs in the pediatric population. Traditionally, it has been taught that all children <8 years of age should be intubated with an uncuffed ETT, to avoid compression of the tracheal mucosa against the nondistensible cricoid ring, which in children is the narrowest portion of the airway. This was thought to prevent post-extubation stridor and tracheal stenosis. However, there has been little in the literature to support such claims of damage. Additionally, ETTs today are technically advanced over earlier models and the low-pressure, high-volume cuffs much less damaging. Recent changes in pediatric guidelines from the American Heart Association in 2005 and the Resuscitation Council of the United Kingdom in 2005 regarding CPR in pediatric and neonatal patients state that cuffed ETTs may be used in infants and children (except newborns), and that provided proper cuff pressures (<20 cm water) are used, they are as safe as uncuffed ETT.[41,42] Additionally, rather than age, the primary determinants for use of cuffed or uncuffed ETT in children should be the underlying reason for intubation and suspected duration of intubation.[42–46] In particular, patients with burns or severe pulmonary injuries that are likely to require prolonged intubation with higher levels of ventilatory support will likely benefit from the use of cuffed ETT.[44,45] In these patients, the use of cuffed tubes will aid in the delivery of adequate ventilation at higher pressures, and prevent the need for dangerous ETT exchanges due to air leaks, which occur frequently in this population.[44,45] Even in the elective surgical population, there is level I evidence that the use of a cuffed ETT decreases the number of re-intubations or ETT exchanges due to sizing or air leak without any increase in unsuccessful extubations or post-extubation stridor in patients younger than 5 years.[46] While these studies apply primarily to the in-hospital population, there is a growing body of evidence to support the use of uncuffed ETT in the prehospital setting as well, though further studies are required before this can be recommended.[43]

If orotracheal intubation is unsuccessful, a surgical airway is indicated as in adults. However, cricothyroidotomy is not recommended for pediatric patients under 12 years of age. Instead, the airway is accessed with percutaneous placement of a large-bore needle into the cricothyroid membrane and jet insufflation is used to temporarily oxygenate the patient. Air is insufflated at high pressures using jet insufflation in order to overcome the high resistance of the long, narrow catheter. Insufflation is performed for 1 second with intervening 4-second intervals to allow passive release of carbon dioxide. Ventilation is necessarily restricted and carbon dioxide levels will predictably rise over time. Conversion to a tracheostomy or repeated attempt at intubation with advanced airway adjuncts or more experienced personnel must be performed within the next 45 minutes once oxygenation is improved to prevent the accumulation of unacceptable levels of carbon dioxide.[47]

BREATHING

Once the airway has been assessed as patent or a definitive airway has been secured, the primary survey moves on to breathing. Breathing encompasses a brief inspection of the chest and assessment of the adequacy of oxygenation and ventilation. Conditions in this realm that should be diagnosed in the primary

survey include tension pneumothorax, open pneumothorax (or sucking chest wound), massive hemothorax, and flail chest.

Assessment begins with visual inspection of the thorax, all clothing must be removed and the anterior and posterior chest and axillae should be inspected for lacerations, ecchymoses, open wounds, air bubbling from wounds, symmetry of chest rise, paradoxical motion of any portion of the chest, and the use of accessory muscle for respiration. Pulse oximetry should be applied as soon as the patient arrives, and continuously reassessed for sufficiency. The chest should be palpated for crepitus, tenderness, and instability of the sternum or ribs. The chest should be auscultated for the presence and symmetry of breath sounds, and dullness of cardiac or breath sounds. Lastly, a chest x-ray should be performed as soon as is feasible to radiographically evaluate the soft tissues, bones, lung parenchyma, and thoracic cavities. Throughout the assessment, high-flow oxygen should be administered to the patient.

Tension pneumothorax is the most rapidly life-threatening of all breathing problems. It occurs when air continuously enters the thoracic cavity from the lung, airway, or atmosphere and cannot escape. The pressure causes collapse of the lungs, preventing oxygenation and ventilation on the ipsilateral side, and eventually causes deviation of the mediastinum away from the tension pneumothorax. This causes compression of the superior and inferior vena cava, decreasing preload to the heart and resulting in hypotension. Tension pneumothorax should be recognized immediately by air hunger, hypoxia, tachypnea, hyperresonance, unilateral absence of breath sounds, deviation of the trachea away from the affected side, distended neck veins, hypotension, and tachycardia. Crepitus may be felt as well, but is nonspecific. The tracheal deviation may be difficult to visualize with a rigid cervical collar in place, and may be prevented from occurring if the patient is intubated as a greater pressure is required to deform the more rigid plastic ETT. Additionally, distended neck veins may not be present if the patient has concomitant hypovolemia. Lastly, tension pneumothorax may be confused with pericardial tamponade as both result in distended neck veins, a feeling of impending doom or restlessness, and hypotension. However, tamponade will result in muffled heart sounds and does not cause tracheal deviation or asymmetrical breath sounds. If tension pneumothorax is suspected, emergent decompression must be performed. ATLS recommends needle decompression with large-bore needles or angiocatheters placed in the second intercostal space in the midclavicular line. If the needle is properly placed, a rush of air should be observed with an immediate improvement in vital signs, as the tension pneumothorax is converted to a simple pneumothorax. This should then be followed by the placement of a chest tube for more permanent decompression of the affected hemithorax, and drainage of any blood that may be associated with the tension pneumothorax.

If no air is noted, the needle may be in the subcutaneous tissue, there may be no pneumothorax, or the wrong side may have been accessed. A second decompression of the contralateral chest should be undertaken; if no rush of air is again noted, tension pneumothorax is unlikely and cardiac tamponade should be considered, and rapid FAST should be performed to assess for pericardial fluid. Occasionally, in the obese patient or in patients with significant soft tissue edema/hematomas, needle decompression may not be possible as the device may not be long enough to reach the thoracic cavity in this situation, or if the clinician is very comfortable with chest tube placement, needle decompression may be skipped in favor of immediate chest tube placement.

Chest tubes in experienced hands can be placed in <60 seconds. The most important step is the entry of the thoracic cavity to allow escape of the air trapped there, which is accomplished even more rapidly and occurs once the thorax has been entered by blunt dissection. The chest tube should be placed in the midaxillary line in the fourth or fifth interspace at the level of the nipple in males, and the inframammary fold in females. A small incision, approximately 1.5–2 cm in length, is made with a scalpel, a clamp is used to bluntly dissect the subcutaneous tissue until the bony rib is felt. The clamp is then used to bluntly enter the thoracic cavity immediately over the top of the rib to avoid injury to the neurovascular bundle located beneath each rib. Significant force may be required to create this entry. A rush of air or blood should be observed upon entry into the pleural cavity, immediately relieving intrathoracic tension and improving the patient's vital signs. The clamp is then used to bluntly spread the soft tissues, creating an opening in the intercostal tissue to accommodate a 36 French chest tube. Digital manipulation should be used to guide the tube posteriorly and cephalad to drain the thorax. In most adults, insertion of 10–12 cm of the tube should be adequate to ensure the last side port is within the chest cavity. In all cases, further advancement of the tube should be stopped as soon as resistance is felt. The tube is then secured in place with a suture and the insertion site dressed with an occlusive dressing. The end of the tube should then be connected to a closed drainage system. In all trauma patients, this collection system should be prepared sterilely with citrate, an anticoagulant, so that any collected blood can be autotransfused back into the patient if desired.

In cases where the tension pneumothorax has been converted to simple pneumothorax by needle decompression or in cases of simple pneumothorax or simple hemothorax, care should be taken during placement of chest tubes to maintain sterility. A cap, mask, gown, and sterile gloves should be worn by the clinician and a cap and mask should be worn by everyone in the room. Chlorhexidine preparations are preferred over povidone antiseptics as they have a decreased risk of surgical site infections. The site should be properly cleansed and anesthetized and completely draped to avoid contamination of the site, instruments, or chest tube. A single dose of pre-procedure antibiotics with gram-positive coverage has proven as effective as a 24-hour course of periprocedure antibiotic prophylaxis. Antibiotic prophylaxis longer than 24 hours is not effective in preventing infection or empyema and is not recommended.

Massive hemothorax may also present with tension physiology. Hypotension may be a result of decreased preload from tension physiology as well as from massive blood loss. Treatment is immediate placement of a chest tube to the affected side. In contrast to tension pneumothorax, massive hemothorax rarely results in distended neck veins because of associated hypovolemia. Blood loss of >1,500 mL defines a massive hemothorax and is an indication for operative exploration. Additional indications for thoracotomy include massive continuous air leak, which may indicate massive parenchymal lung injury or injury to a major airway, and blood loss of 200 mL an hour for >4 hours. Again, every effort should be made to collect shed blood in a sterile fashion so that it may be autotransfused. Anticoagulation can be accomplished by the addition of citrate, in a 1:7 ratio, to the blood being transfused. After the addition of citrate, the blood can be immediately transfused back into the patient with the use of a standard blood filter and tubing. Many studies have demonstrated the safety of autotransfusion of blood collected from traumatic hemothorax.[48,49] Though the character of the autotransfused blood has not been extensively studied, available data would suggest that this blood is inherently depleted of coagulation factors, particularly Factor VIII and fibrinogen, as well as platelets; however, studies of circulating blood after autotransfusion show only mild increases in PT/aPTT, and a moderate decrease in circulating platelets.[50,51] Consideration should be given to additional transfusion of platelets when massive autotransfusion occurs.

Open pneumothorax, or sucking chest wounds occur when a defect in the chest wall is full thickness and large enough for air to communicate between the thoracic cavity and the environment. During inspiration, negative pressure in the thoracic cavity sucks air into the hemithorax, preferentially over the lungs, resulting in hypoxia. The wound should be grossly decontaminated by removal of metal, dirt, and other visible objects, and an occlusive dressing should be applied and secured on three sides. This prevents air from being sucked into the thoracic cavity, but if intrathoracic pressure builds, it may escape from under the fourth side, preventing tension physiology from developing. A chest tube should be placed to relieve the pneumothorax as soon as possible. When the initial assessment is completed and the patient is stable, the wound should be cleansed, debrided, and closed in the operating room.

A flail chest occurs when three or more contiguous ribs are broken in two places, creating a segment of bone and muscle that can move independently of the thoracic wall (Fig. 21.4). This independent segment will move paradoxically with spontaneous respirations, pulling inward with inspiration secondary to negative intrathoracic pressure. This paradoxical motion can cause significant pain to the patient as the broken ribs grate upon one another, resulting in desire to take rapid shallow breaths, causing atelectasis and hypoxia. Additionally, the force required to create a flail segment is excessive and usually also results in significant underlying pulmonary contusion further increasing hypoxia. Lastly, the flail segment may be associated with a hemothorax or pneumothorax. These are treated with a chest tube as previously described. Treatment of the flail segment varies according to patient presentation. If stable, supplemental oxygen, aggressive pulmonary toilet, and adequate analgesia are suitable. Pain can be controlled with oral medications, intravenous medications, patient-controlled analgesia, local anesthetic with rib blocks, or catheters that deliver a continuous stream of local anesthetic, or with epidural anesthesia. There is evidence that epidural pain control is superior to other methods.[52,53] In unstable or semi-stable patients, intubation and positive pressure ventilation are the best treatments. The intubation allows more aggressive pain management and sedation; the positive pressure ventilation can be used to recruit atelectatic lung, and support contused lung to improve oxygenation. Additionally, the positive pressure ventilation splints the flail segment so that the paradoxical motion is halted and the entirety of the thoracic wall can move in synchrony, relieving pain and allowing healing of the soft tissue and bones. The elderly patient is particularly susceptible to deterioration after chest trauma, and pain management and pulmonary toilet should be very aggressive, with a low threshold for intubation. Avoidance of fluid overload in patients with flail chest and large pulmonary contusions is also advisable.

Once the most immediately life-threatening injuries have been addressed, adjuncts to the breathing assessment such as arterial blood gas and plain radiographs can be obtained. Arterial blood gas is especially important in the head-injured and comatose patient as significant hypercapnea may be present and is difficult or impossible to assess clinically. The ability to
FIGURE 21.4. Chest x-ray showing multiple left-side rib fractures (flail chest).

monitor capnography in the trauma or resuscitation bay will help with the diagnosis of hypercapnea, although a baseline correlation with an arterial blood sample is recommended. Arterial blood gas can also be helpful in assessing oxygenation in patients in whom pulse oximetry may be unreliable such as very cold patients, patients who are very anemic, patients with significant soft tissue injury, making placement of the monitor difficult, patients with hypotension in whom peripheral vasoconstriction makes measurements unreliable, and burn patients. Burn patients also benefit from co-oximetry of arterial samples to detect carbon monoxide. Chest x-ray is an essential adjunct to the primary survey and can aid in diagnosis and guide treatment for both airway and breathing problems. It can be used to assess correct positioning of definitive airways and chest tubes, detect pneumothorax, hemothorax, pulmonary contusion, and broken ribs. Chest x-ray can also reveal a widened mediastinum, which can indicate thoracic aortic injury or thoracic spinal fracture, and enlarged cardiac silhouette that might indicate the presence of pericardial fluid.[54] Chest x-ray is quickly obtained, results in minimal exposure to ionizing radiation, and is easily repeatable. Additionally, the FAST can be extended to examine the thorax in the FASTER (FAST + extremities + respiratory) exam. In the FASTER exam, the ultrasound is used to look for sliding of the parietal pleura over the visceral pleura; absence of this sign indicates a pneumothorax. Several studies have shown the FASTER exam can be easily performed and is repeatable with excellent sensitivity.[55,56]

CIRCULATION

After securing the airway and restoring oxygenation and ventilation, attention can be turned to the circulation. Assessment of circulation is primarily an assessment of the presence or absence of shock. Shock is the inability of the body to maintain end-organ perfusion. The types of shock include cardiogenic, redistributive, and hypovolemic. Hypovolemic shock due to blood loss is the most common of the three, and should be assumed to be the cause of hypotension in all trauma patients until all obvious and occult blood loss has been completely ruled out.

Cardiogenic shock results from abnormalities of conduction or myocardial function with subsequent decrease in cardiac output. In trauma, blunt cardiac injury may rarely result in myocardial depression to the point of cardiogenic shock. However, this is extremely rare. Additional cardiac sources of hypotension in trauma patients include cardiac tamponade and tension pneumothorax. With cardiac tamponade, external compression of the heart, as well as decreased preload due to pericardial fluid result in hypotension. Clinical indications of tamponade include a feeling of restlessness and impending doom, inability of the patient to lie supine, distended neck

veins, muffled heart sounds, and pulsus paradoxus. Diagnosis can be confirmed with pericardial FAST, which is highly sensitive and specific, nearing 100% in most studies.[57–60] If tamponade is confirmed, treatment is median sternotomy in the stable or semi-stable patient, and resuscitative thoracotomy in the Emergency Room in the unstable patient.[61] If no surgeon is present, pericardiocentesis via the subxiphoid window can be used to temporize the patient until surgical capabilities exist. Additionally, these patients should be given large volumes of fluids to increase preload and assist cardiac output.

Redistributive shock occurs as a result of increased vascular capacitance and occurs with sepsis and in neurogenic shock after high spinal cord injury where sympathectomy results in massive vasodilation. Neurogenic shock primarily occurs after cervical or high thoracic spinal cord transection. It is characterized by hypotension without evidence of blood loss, and if the transection occurs in the mid- or high cervical spine, it is often associated with inappropriate bradycardia due to unopposed vagal tone on the heart. Neurogenic shock is treated with volume expansion with crystalloids and, if necessary, vasopressors or inotropes. It is a diagnosis of exclusion in trauma patients and should not be considered the definite etiology of hypotension until hemorrhagic shock is exhaustively ruled out. Signs of neurogenic shock include evidence of spinal cord injury such as quadriplegia and apnea; occasionally, evidence of peripheral vasodilation can be seen with the lower half of the body becoming hyperemic with a linear demarcation at the level of cord injury.

By far the most common type of shock encountered in trauma is hemorrhagic shock. Hemorrhagic shock is classified according to severity, with class I shock being minor and generally asymptomatic, and class IV shock being severe, with loss of over 40% of circulating blood volume or 1,500 mL, and results in multisystem organ failure[6,28,29,61] (Table 21.1).

The clinical examination consists of measurement of heart rate, blood pressure, palpation of pulses in all extremities, and localization of blood loss. Indicators of shock include cool clammy extremities, pale skin, increased skin turgor, low urine output, dry mucus membranes, and alterations in mental status. In certain patients, the clinician must keep in mind that significant blood loss can occur, or be ongoing, with little derangement of heart rate and blood pressure. In particular, pediatric patients and young healthy athletes have excellent cardiovascular reserve and compliant vessels that are able to vasoconstrict considerably to prevent drop in blood pressure even in the presence of a great volume of blood loss. In these patients, often the first sign of hemorrhage is a narrowed pulse pressure as the body responds to blood loss with peripheral vasoconstriction, raising diastolic pressure, while maintaining normal systolic pressures. Narrowing pulse pressure may then be a sign of imminent cardiovascular collapse. Additionally,

TABLE 21.1

CLASSES OF HEMORRHAGIC SHOCK

	■ CLASS I	■ CLASS II	■ CLASS III	■ CLASS IV
EBL	<15% 500–750 mL	15%–30% 750–1,000 mL	30%–40% 1,000–1,500 mL	>40% >1,500 mL
HR	Normal	100–120	120–140	>140
BP	Normal	Decreased pulse pressure	Decreased SBP	Severe hypotension
Mental status	Anxious	Confused	Very confused	Obtunded
UOP	Normal	Normal	Decreased	Severely decreased or anuric

elderly patients often lack the intrinsic ability to mount a tachycardic response to hemorrhage, and may also be on beta blockers. The elderly often also have underlying hypertension and present with apparently normal blood pressure, which for them is relatively hypotensive. The lack of physiologic reserve in the elderly often results in patients presenting initially with apparently normal vital signs, then rapidly decompensating with complete cardiovascular collapse.

Resuscitation

Concomitant with examination to localize and control sources of blood loss, resuscitation should be ongoing. Resuscitation begins with placement of two large-bore intravenous lines or placement of an IO or central line if peripheral venous access is not possible secondary to peripheral vasoconstriction, or extremity trauma. IO lines can be placed into several areas, including the tibia, humerus, sternum, and clavicle. Traditionally, IO lines were only used for pediatric patients, but newer electric drills and increasing experience in both military and civilian populations have shown excellent results in adult populations.[62–68] Compared to peripheral and central venous access in a challenging multi-trauma patient, especially in combat, or transport settings, or if the treating team must wear protective (radiation, toxin, biological) gear, IO access is quicker and easier and may result in fewer exposures of staff to blood-borne infections.[65,66] The rate of infusion of crystalloid and blood products, and the range of medications that can be infused through an IO line are excellent and comparable to peripheral venous access.[62,66] Recent guidelines by the Eastern Association for the Surgery of Trauma (EAST) in 2009 recommend IO access in the prehospital setting if peripheral intravenous access is difficult or impossible.[69] As with any invasive procedure, complications from IO insertion do occur, such as compartment syndrome, osteomyelitis, and fracture; however, in most studies, the complication rate is very low.[62–68] The more traditional central venous catheter is also an option in patients in whom peripheral access is difficult or has failed. Locations for central lines include jugular, subclavian, and femoral. The choice of location should depend on the clinician's level of comfort and experience with each site, and location of injuries. Care should be taken to avoid placement of central lines when significant vascular injury proximal to the access site is suspected. The femoral sites and subclavian sites are easily accessible, while the jugular site tends to be less accessible due to the presence of cervical immobilization devices and need for access to the head for airway control. Other choices for venous access include saphenous vein cutdown at the ankle or groin, or cutdown to the cephalic or basilic vein in the antecubital fossa.

Once access has been obtained, resuscitation should begin with warmed fluids. Traditional teaching, including ATLS, suggests immediate infusion of 2 L of warmed crystalloid if hypotension is present. If the systolic blood pressure fails to improve to over 90 mm Hg with crystalloid bolus, O negative, or type-specific, (if available) packed red blood cells (PRBCs) should be transfused. However, there is data to suggest that in penetrating torso trauma, a strategy of permissive hypotension may be beneficial until patients can reach a location where definitive hemostasis can be achieved.[70] A study of penetrating torso trauma in which patients were randomized to traditional fluid resuscitation protocols, or delayed resuscitation receiving no more than 100 mL of fluid prior to arrival in the operating room, revealed a significant survival benefit in patients with delayed fluid resuscitation, as well as fewer complications and shorter hospital lengths of stay.[70] Proponents of permissive hypotension, including the military,[71] suggest that administration of crystalloid may aggravate the inflammatory response, dilute clotting factors, induce hypothermia, and

increase blood pressures, resulting in higher levels of blood loss prior to definitive hemostasis, and result in increased transfusion requirements and worse outcomes. Opponents suggest that untreated hypoperfusion causes more tissue ischemia and resultant inflammation and reperfusion injury, and may increase secondary injury in patients with traumatic brain injury.[72] Additionally, few studies have been able to replicate the positive effects of delayed resuscitation.[73,74] At this time, there is still active debate as to the benefit of permissive hypotension and its application to any group other than penetrating torso trauma victims. The mainstay of the treatment of hemorrhagic shock continues to be active fluid resuscitation with warmed crystalloid followed by warmed blood and immediate localization and source control of bleeding.[6,29,75]

Once blood transfusion has begun, another area of controversy is the optimum ratio of red cells to fresh frozen plasma (FFP) and platelets in patients requiring ongoing massive transfusion. Massive transfusion is variably defined in the literature but is generally accepted for any patient requiring >10 units of PRBCs within the first 24 hours of hospitalization.[76] At this level of transfusion, hemodilution of fibrinogen, platelets, and clotting factors can occur as whole blood continues to be lost, and is replaced with only PRBCs. The goal of massive transfusion protocols (MTPs) is to standardize the replacement of platelets and clotting factors in the optimum ratio to red cells to prevent coagulopathy, but avoid increased risks of multisystem organ dysfunction and increase efficiency of transfusion.[77,78] Traditionally, MTPs have focused primarily on early and aggressive transfusion of PRBCs;[76] however, recent experience in both military and civilian settings have suggested that earlier aggressive transfusion of platelets and FFP can result in decreased mortality.[76,79–83] Two studies from the military revealed decreased mortality in a step-wise fashion with increasing plasma to red cell ratio, with optimal results approaching a ratio of one to one.[79,82] Civilian literature has also reflected improved mortality with a FFP:PRBC ratio approaching 1:1.3 to 1:1.5.[80,83,84] In addition to supporting a higher FFP:PRBC ratio, these studies found that the impact on mortality was most prominent in early and operative deaths, suggesting that the immediate replacement of clotting factors and the prevention of coagulopathy are most important in preventing deaths due to traumatic hemorrhage. Additionally, a study from Spain et al. found that while the institution of a MTP in their institution did not change the FFP:PRBC ratio, already high at 1:1.8, the protocol did result in faster times to transfusion of first blood products and decreased mortality.[81]

Another adjunct to balanced transfusion strategies is the use of pharmacologic agents to treat and prevent coagulopathy. One such agent undergoing scrutiny is recombinant human Factor VIIa. This agent was originally developed for the treatment of hemophilia. It has since enjoyed off-label use in a number of clinical scenarios, including treatment of coagulopathy in trauma and reversal of anticoagulation in patients with traumatic brain injury. A randomized controlled trial of recombinant Factor VIIa demonstrated a decrease in PRBC transfusion requirements and a reduced need for massive transfusion in blunt trauma patients, without an increase in complications compared to placebo.[85] A follow-up study from the same group confirmed the benefit of decreased transfusion requirements, and additionally demonstrated lower rates of multisystem organ failure and ARDS with the use of activated Factor VIIa.[86] However, no mortality benefit has been found in trauma patients, and concerns regarding increased thromboembolic complications exist. Equally effective is prothrombin complex, which has all four vitamin K-dependent coagulation factors: II, VII, IX, X.[76]

Other adjuncts to balanced transfusion include resuscitation with alternative crystalloid solutions, one of the most well studied being hypertonic saline. There is experimental evidence that hypertonic saline has anti-inflammatory effects in both

humans and animal models, when compared to isotonic crystalloids.[87–93] Those data also demonstrate decreased lung and intestinal injury from hypoperfusion with hypertonic saline resuscitation.[88–90,93] There is also good clinical evidence to suggest that hypertonic saline resuscitation in trauma patients may improve survival compared to traditional resuscitation fluids, especially in the presence of hemorrhage requiring massive transfusion, surgical intervention, or depressed GCS.[94–97] It has additional benefits for patients with traumatic brain injury as it acts as an osmotic agent to decrease cerebral edema.[98–100] Hypertonic solutions also create more intravascular volume expansion than isotonic fluid on a volume-by-volume basis, making it an ideal resuscitation fluid for the military where portability and limited storage capacity must factor into all clinical decision making.[101,102]

Localizing Blood Loss

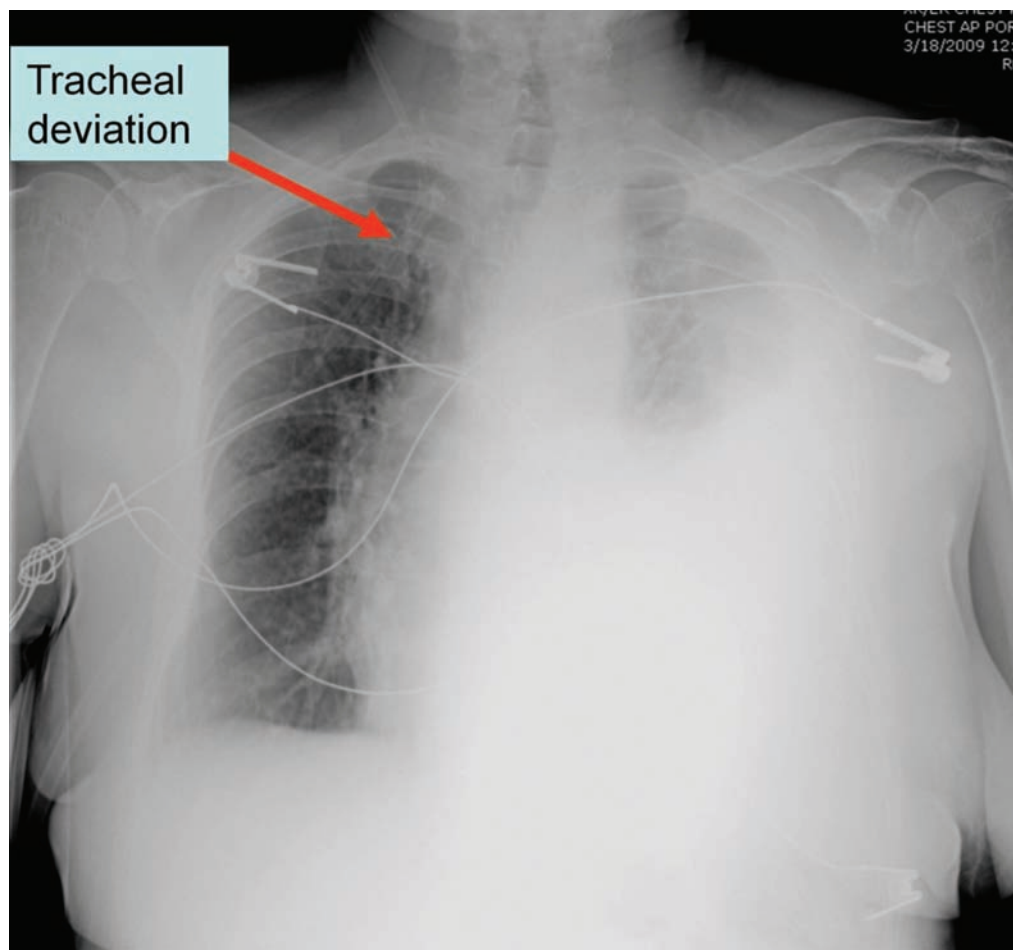
Areas where significant blood loss can occur include external loss onto the gurney or at the scene from open wounds, into the chest, into the abdomen, into the pelvis or retroperitoneum, and into the extremities.

Wounds

Open wounds and lacerations should be inspected for arterial or high-volume bleeding. Active bleeding should be addressed as soon as possible in the operating room or trauma bay.

Temporizing measures in areas without surgical capabilities include application of pressure, manual compression dressings, tourniquets, or application of advanced local hemostatic agents. Hemostatic agents fall into a number of broad categories including cellulose based, desiccating agents (zeolite, chitan), collagen- and fibrin/thrombin-based products. A number of promising studies have arisen from military experience with application of tourniquets and advanced local hemostatic agents including chitan and xeolite based agents.[103–105] More superficial lacerations, especially if located on the scalp, should be closed with staples or sutures to tamponade bleeding as soon as is feasible.

Thoracic Cavity

Bleeding into the chest can be clinically apparent if massive hemothorax with tension physiology occurs, or if chest tubes are placed. More frequent bleeding into the thoracic cavity is clinically occult, with evidence of shock, but no obvious signs of thoracic source on clinical exam. Some subtle signs may be decreased breath sounds on auscultation on the ipsilateral hemithorax, and external evidence of trauma to the chest wall. In patients *in extremis*, bilateral chest tubes should be placed immediately to assess for thoracic source of bleeding.[61] The primary method of diagnosing a thoracic source of blood loss in stable patients is with chest x-ray. Pleural effusion, appearance of elevated hemidiaphragm, and "white-out" of the affected lung field are all indications of hemothorax and should be treated with immediate placement of a thoracostomy tube (Fig. 21.5). As stated previously, the collection


TRAUMA

FIGURE 21.5. Massive hemothorax left chest, with tracheal deviation to the right side.

system should be prepared for autotransfusion, and collected blood should be returned to the patient.

Abdomen

The evidence of significant abdominal trauma on physical exam includes seat belt signs, abdominal wall hematomas or lacerations, or abdominal distension.[106] Hemoperitoneum may also cause peritonitis and significant abdominal pain. Patients with peritonitis should be taken emergently for laparotomy regardless of hemodynamic status. Traditional teaching held that blood did not result in peritonitis and that significant abdominal pain signified hollow viscus injury rather than intra-abdominal bleeding. However, research done by Brown et al. revealed that in patients who are hemodynamically stable upon presentation following trauma and undergo laparotomy secondary to peritonitis alone, a large number had hemoperitoneum without hollow viscus injury and developed hypotension or required blood transfusion intraoperatively. A considerable minority also had major abdominal vascular injury.[107]

In patients without peritonitis, especially in the presence of hypotension, FAST should be performed immediately. FAST consists of four ultrasonographic views; the pericardium (subxiphoid or parasternal), hepatorenal fossa, splenorenal fossa, and pelvis around the bladder. The ultrasound is able to distinguish fluid in each of these potential spaces, indicating pericardial fluid, or hemoperitoneum. FAST is easily accessible, can be performed in <2 minutes by most clinicians in any setting, is portable, easily repeatable, inexpensive, and noninvasive. As discussed previously, the specificity and sensitivity for pericardial fluid is excellent;[57–60] however, sensitivity is significantly lower in the abdominal views, 20%–60%.[108,109] In the abdomen, results of ultrasonography appear to be much more operator dependent. Additionally, there appear to be inherent limitations to the sensitivity of the exam. Some studies with experienced ultrasonographers reveal a reliable detection rate with intraperitoneal volumes of 130–150 mL;[110] however, a study of emergency medicine, radiology, and surgery attendings and residents found that only 10% of participants were able to detect <400 mL, and the mean volume of fluid required for detection on FAST was 619 mL regardless of operator experience, and the volume required to achieve a sensitivity of 97% was 1 L.[111] A positive finding is reliable with specificity of 96%–100%.[59,108,109] The presence of a positive FAST in a hypotensive patient is an indication for immediate laparotomy (Fig. 21.6). However, an equivocal or negative FAST, especially in the hypotensive patient, cannot reliably rule out intra-abdominal bleeding as the source.

In the unstable patient, if the FAST is negative or equivocal, diagnostic peritoneal aspiration (DPA) should be performed. A small incision is made in the infraumbilical region and a large-bore needle is inserted into the abdominal cavity; aspiration of blood indicates a positive finding and need for surgical exploration. If no blood is aspirated, a wire can

FIGURE 21.6. FAST demonstrating fluid stripe.

be passed through the needle and a multichannel soft plastic catheter is inserted using Seldinger technique. The catheter is also aspirated; if blood returns, this is also a positive DPA, and is an indication for immediate laparotomy. If again no blood returns, consideration can be given to diagnostic peritoneal lavage (DPL), during which 1 L of saline or 10 mL/kg of saline in pediatric patients is administered through the catheter, then allowed to return via the catheter into a bag placed to gravity drainage. If gross blood or mucus is noted, this is a positive finding and immediate laparotomy is indicated. If at least 75% of the infusate is returned but grossly negative for blood, bile, or mucus, microscopic examination can be undertaken. If >100,000 RBC/mm^3 (blunt) or 1,000 RBC/mm^3 (penetrating), >500 WBC/mm^3, or food particles are found, this is also considered a positive finding, necessitating laparotomy. In practice, if the DPA is negative, it is unlikely that intra-abdominal bleeding is the source, and DPL is a cumbersome and technically difficult exam to perform. Waiting for microscopic examination of infusate is impractical in the hypotensive patient, and the infusion of large volumes of fluid into the peritoneal cavity may make interpretation of future radiographic investigations (FAST, CT scan) difficult.

Pelvis

If FAST and DPA are negative in patients with abdominal trauma, retroperitoneal and pelvic bleeding are potential sources of hemorrhage. Retroperitoneal hemorrhage can occur with renal injury, injury to the great vessels of the abdomen (IVC, aorta, iliac arteries and veins), or with pelvic fractures. Clinical indications of retroperitoneal bleeding are rare, but can include hematomas of the flank and back, back pain, and hematuria with renal injury. Pelvic hematomas can also be a cause of hypotension and occur with pelvic fracture. Clinical examination includes palpation of the pelvis for lateral and anterior–posterior stability and bilateral hip range of motion. A stable pelvis on examination with full active range of motion of both hips nearly excludes significant pelvic fracture. In comatose patients, this may not be possible, and the mainstay of diagnosis is plain film of the pelvis (PXR). If pelvic fracture is diagnosed on clinical exam or PXR and hypotension is present, the pelvic ring should be reapproximated using an external compression device. Devices for pelvic stabilization and compression include pelvic binders, external fixators, and sheets. Pelvic binders come in a range of sizes and models, but consist of a padded firm girdle, which is fitted over the anterior–superior iliac spines superiorly, and the femoral heads inferiorly. The binder is then tightened with ties, Velcro, or buckles. If no commercially made binders are available, a plain bed sheet can be folded lengthwise into a long strip approximately 12 inches wide; the sheet is wrapped around the patient's pelvis in the same position as a binder and the ends twisted tightly and fixed with clamps. If orthopedic surgeons are available, an external fixation device can be placed quickly in the evaluation area and tightened to reapproximate the pelvic ring. The placement of stabilization devices closes the pelvic ring, decreasing pelvic volume to encourage tamponade of bleeding. They also help stabilize the broken ends of bone, preventing further laceration of nearby tissues and vessels, and decrease pain with repositioning and transport.

Hemorrhage associated with pelvic fracture can cause substantial hypotension, and severe pelvic fractures alone carry a high mortality.[112] The majority of bleeding in these patients is from the rich sacral venous plexus. Occasionally, bleeding may be from an arterial source. In stable or semi-stable patients with isolated pelvic hemorrhage, angiography should be considered for diagnostic and therapeutic purposes. If considerable arterial bleeding is found, selective embolization can be performed. If no arterial bleeding is found, bilateral internal iliac artery embolization with gelfoam or other temporary agent, or even permanent coil embolization can be performed to decrease pelvic vascular inflow, and allow venous injury to tamponade. The rich collateral circulation in the pelvis prevents ischemic complications in most patients. Very rarely, complications such as necrosis of pelvic organs or gluteal compartment syndrome can occur. In a series of patients undergoing bilateral internal iliac artery embolization, short- and long-term complications were identical to those found in patients with similar fractures not undergoing embolization.[113,114] In patients who are unstable and have suspicion for intra-abdominal injury, laparotomy should be performed. If a pelvic hematoma is found, consideration can be given to bilateral internal iliac artery ligation.[115,116] This performs the same function as angioembolization, with reduction in pelvic vascular inflow. If no intra-abdominal injury is suspected, operative pre-peritoneal packing can be performed. In this procedure, a midline laparotomy incision is made to the level of the anterior rectus sheath, the incision is stopped prior to entry into the abdominal cavity, and the preperitoneal space is dissected toward the sacral venous plexus and packed with sponges. Excellent results have been seen with this technique;[117] however, its use is not yet widespread, and it is difficult in the hypotensive patient with abdomino-pelvic trauma to definitively rule out intra-abdominal source of bleeding, even with FAST and CT scan.

Extremities

After eliminating the scene, chest, abdomen and pelvis as sources of bleeding, attention can be turned to the extremities. In the primary survey, extremity exam is brief, only to diagnose gross deformity or instability of the major long bones (humerus, femur, tibia), actively bleeding wounds, or hard signs of vascular injury including unexplained hypotension or anemia with extremity injury, arterial bleeding, pulsatile or expanding hematoma, lack of pulses distal to the site of injury, and bruit or thrill. Hard signs of vascular injury require immediate operative intervention. If surgical capabilities are lacking, the injured extremity should be reduced and splinted. If there is expanding hematoma or active bleeding, local pressure should be applied. In some cases, tourniquets can be considered. Recent experience from the military has shown that the proper application of tourniquets and their swift removal once definitive hemostasis is achieved can result in excellent survival.[118,119] If no hard signs of injury are present, the injured extremity should be reduced and splinted to prevent further injury and decrease pain and blood loss.

DISABILITY

After securing the airway and restoring oxygenation, ventilation, and adequate circulation, the patient's neurologic status should be ascertained. Within the primary survey, this consists of the Glasgow Coma Scale (GCS) (Table 21.2), pupillary exam, and gross determination of movement and sensation. With the exception of a very brief determination of motor response prior to administration of paralytic agents for airway control, the neurologic examination should be deferred until restoration of adequate oxygenation, ventilation, and circulation as any derangements can render the exam inaccurate. Additionally, hypoxia, hypercarbia, and hypotension all considerably increase secondary brain injury, with a single episode of hypotension or hypoxia resulting in doubled mortality.[120] Other factors that may alter the GCS and pupillary exam include intoxication with drugs or alcohol, hypothermia, and

hypoglycemia. After restoration of oxygenation and circulation, any pupillary abnormalities or alterations in GCS should be presumed to be due to traumatic brain injury until advanced imaging has definitively ruled it out. Urine or plasma toxicology screens and alcohol levels can be drawn, and serum glucose level should be rapidly assessed; however, they should not be assumed to be the primary cause of altered GCS. Any patients with presumed brain injury should undergo CT scan as soon as possible after the primary survey is completed. Patients with a GCS of 8 or less, and two of the following; age >40, hypotension, or lateralizing signs are at significantly increased risk of intracranial hypertension, and should undergo placement of an intracranial pressure monitoring device regardless of CT findings.[120]

Patients with suspicion of intracranial hypertension, or definite clinical evidence of herniation such as unilateral pupillary dilation, bradycardia, hypertension, and irregular respirations (Cushings Triad) should be treated immediately with maneuvers to decrease intracranial pressure (ICP). These maneuvers include elevation of the head of the bed if spinal fracture is not a concern, removal of all tight or binding materials from around the neck to encourage venous drainage from the cranium, mild hyperventilation with goal carbon dioxide 32–35 mmHg, adequate sedation and pain control, and administration of osmotic agents such as Mannitol and hypertonic saline, or diuretic such as Lasix. However, in the trauma patient, the administration of Mannitol and Lasix may cause or worsen existing hypotension. An attractive alternative is hypertonic saline, which is an osmotic agent that will decrease brain edema by drawing fluid back into the intravascular space without causing hypovolemia/hypotension. Multiple studies have proven its effectiveness in decreasing ICP, and it appears to be equally, if not more effective than Mannitol.[95,99,100,121]

The other half of the disability exam in the primary survey is the assessment of spinal cord injury. Patients should be examined for motor and/or sensory deficit; in comatose or semiconscious patients, this may be challenging. If there is concern for, or definite evidence of spinal cord injury, full spinal precautions must be maintained with protection and immobilization of the entire spine. Previously, in patients with definite evidence of blunt spinal cord injury, steroid bolus followed by continuous infusion for 24–48 hours was recommended. However, a growing concern over limitations of the studies these guidelines were based on, and failure of subsequent studies to demonstrate a definite benefit to steroid administration have led ATLS to remove recommendations for the use of steroids in spinal cord injury from the 8th edition.[2] Steroids should now only be administered under strict guidance from a neurosurgeon or orthopedic spine surgeon on a case-by-case basis.

As with any portion of the primary survey, the GCS and pupillary exam should be repeated continuously to assess for improvement or deterioration; however, special consideration should be given to the anticoagulated trauma patient. Patients on antiplatelet agents or anticoagulants should all be imaged with CT scan given their high risk for intracranial hemorrhage even following minor head trauma. Patients on anticoagulation are also at risk for delayed hemorrhage, and consideration for routine repeat imaging with CT scan of the head, in addition to repeated physical examination, should be given to all such patients regardless of clinical appearance.

If intracranial hemorrhage is found, anticoagulation should be reversed with FFP, recombinant Factor VIIa, or prothrombin complex to prevent progression of hemorrhage and speed time to surgical intervention if necessary. While a recent Cochrane review reported no reliable evidence that the use of Factor VIIa decreased mortality or disability,[122] several studies have demonstrated benefits from Factor VIIa administration, including decreased hematoma progression, decreased transfusion requirements, decreased time to surgical intervention, and decreased cost.[123–127]

EXPOSURE

In order to complete the primary survey, the patient must be fully disrobed to reveal all injuries, and log rolled maintaining full spinal precautions to assess the back and perineum for injury or deformity. Generally, the patients' clothes are removed as soon as they enter the evaluation area by assistants while the primary clinician proceeds with the assessment of ABC and D. If only one person is available to perform the primary survey, the patient should be completely undressed at this point if any remaining clothing articles remain.

After complete visual inspection, the patient should be covered as quickly as possible with warm blankets, as thermal homeostasis is often disrupted in trauma patients and hypothermia can set in quickly. Hypothermia is a particular risk in pediatric patients with a much larger surface area to mass ratio and decreased ability to maintain normothermia. Hypothermia if allowed to occur can interfere with the neurologic examination, alter drug metabolism, and most importantly, worsen coagulopathy in the bleeding patient.

Interestingly, several studies of victims of nontraumatic cardiac arrest and patients undergoing cardiac or neurologic procedures have shown notable improvements in outcome with induction of mild–moderate hypothermia with core temperatures of 32–34 degrees centigrade.[128,129] Other patients who may benefit from therapeutic hypothermia include stroke victims and victims of drowning.[129] This has led to a reexamination of hypothermia in trauma patients; however, the results are less encouraging. In a multicenter,

prospective, observational study of trauma patients, hypothermia was seen in 43% of patients and was associated with a significantly higher rate of multisystem organ dysfunction.[130] In another study of injured trauma patients undergoing cavitary surgery, hypothermia immediately after surgery was found to be an independent predictor of mortality with an odds ratio for death of 3.2 (95% CI 1.9–5.3, $p < 0.001$).[131] Traumatic brain injury, in particular, has also been well studied. In the largest multicenter, randomized, prospective trial of hypothermia in traumatic brain injury, there was no benefit in survival or neurologic outcome with therapeutic hypothermia.[132] Multiple studies of hypothermia in children for elective surgical procedures as well as traumatic brain injury show no benefit, and may even demonstrate an increase in mortality.[133,134] At this time, hypothermia should still be considered detrimental in both the adult and pediatric trauma population.

COMPLETION OF THE PRIMARY SURVEY

Once Airway, Breathing, Circulation, Disability, and Exposure have all been assessed and all life-threatening injuries have been addressed or stabilized, the entire primary survey should be repeated to ensure nothing has changed since the beginning of the evaluation. If the patient remains stable, the bladder and stomach should be decompressed. Continuous urine output monitoring is a helpful tool in gauging response to resuscitative efforts, and is a necessity in comatose or paralyzed patients. Gastric decompression aids in the prevention of aspiration, especially in the intubated patient. Care should be taken that the nasogastric route is avoided in patients with potential facial fractures to avoid insertion into the cranium. At this time, results of all laboratory and radiologic adjuncts to the primary survey should be reviewed and the clinician should determine if definitive care can be delivered locally, or if transfer to higher level of care is likely to be required. If transfer to another facility is definite, contact with the accepting facility should be initiated.

SECONDARY SURVEY

Upon completion of the primary survey, the secondary survey can be started. The secondary survey consists of a brief directed history and complete physical exam. The history should follow the AMPLE model of Allergies, Medications, Past illnesses/operations, Last meal, and Events/Environment related to injury. The history should be directed at detection of preexisting conditions, or medications that may alter management of life-threatening injuries. Physical examination should include brief inspection from head to toe, ensuring that full spinal precautions are kept during the evaluation.

The head and neck exam should include visual inspection and palpation to detect lacerations, hematomas, fractures and tenderness, otoscopic evaluation to detect hemotympanum, a sign of temporal bone fracture, and assessment of all cranial nerves in the conscious patient. The primary adjuncts to the head and neck assessment are CT scans of the head, face, and neck. CT scan of the head will reliably detect intracranial hemorrhage and skull fracture. CT scan of the neck is the screening exam of choice to detect cervical spine fractures, and has largely replaced plain films that have a notoriously low sensitivity, and are often inadequate. CT of the neck can also be performed with intravenous contrast to assess the soft tissues and CT angiography can be used to detect vascular injury to the carotid or vertebral arteries or jugular veins with high sensitivity.

The majority of the thoracic exam is undertaken in the primary survey, where physical exam, chest x-ray, and FASTER will detect most injuries. The two major exceptions are thoracic aortic injury and thoracic spine fracture.[54] Both may present with widened mediastinum, and back pain. Any patient with significant external evidence of thoracic trauma or with a widened mediastinum on chest x-ray or with midline thoracic spinal tenderness should undergo CT scan of the chest with intravenous contrast. The CT scan of the chest will reliably diagnose spinal fracture, give additional information on parenchymal lung injury (contusion, laceration, occult pneumothorax), and is now the screening exam of choice for thoracic aortic injury. Compared to angiography, the traditional gold standard, CT scan of the chest is faster, easier to obtain, requires less technical expertise, requires a lower contrast load, does not require arterial puncture, and has equivalent, possibly improved sensitivity and specificity.[135–137]

As with the chest, the majority of the abdominal and pelvic exam is performed during the primary survey. An adjunct to the secondary survey is a CT scan of the abdomen and pelvis. All stable patients who are unevaluable due to intoxication or depressed GCS should undergo CT scan of the abdomen and pelvis with intravenous contrast to detect fractures of the thoracolumbar spine, and be assessed for solid organ injury and pelvic fracture. Additionally, in the presence of concerning pelvic fractures, or gross hematuria, delayed phase images can be obtained. These images can detect contrast extravasation from the urinary collecting system and diagnose bladder and ureteral injuries. CT scan of the abdomen and pelvis cannot be relied upon to detect hollow viscus injury. Some signs of hollow viscus injury on CT scan include free fluid without solid organ injury, focally thickened bowel wall, and free intraperitoneal gas; however, these signs are neither sensitive nor specific. The gold standard for detection of hollow viscus injury remains serial observation and laparotomy.

A complete musculoskeletal survey should also be performed during the secondary survey, all joints should be assessed for passive and active range of motion, long bones should be assessed for instability, the limbs should be examined for external signs of trauma or violation of the joints, and a sensory examination of all dermatomes should be performed to assess for peripheral nerve injury. A complete assessment of all peripheral pulses should also be performed. If any asymmetry is noted, and in cases of obvious fracture or deformity even if pulses are present in the affected limb, an ankle–brachial index (ABI) or brachial–brachial index (BBI) should be performed after reduction of fractures to rule out occult vascular injury. The blood pressure should be taken below the level of injury. If the ABI or BBI is >0.9, occult arterial injury is unlikely, and if it is <0.9, further imaging should be obtained.[138,139] Ultrasound is an excellent option in the lower extremity below the inguinal ligament and in the upper extremity below the shoulder; however, the examination can be limited in the presence of soft tissue injury, is operator dependent, and can be difficult to obtain after hours. An alternative is CT angiography, which has excellent sensitivity and specificity.[140–142] CT angiography has the benefits discussed above over traditional angiography. Additionally, examination of both limbs can be performed simultaneously with the same contrast load. CT angiography is more reliable for proximal vessels such as the subclavian and iliac arteries than ultrasound, and has the added benefit of giving information on the associated soft tissue and bony injuries. Another adjunct in the secondary survey is the extremity portion of the FASTER exam. Ultrasound is used to detect cortical defects, ligamentous injuries, and soft tissue edema. A study of FASTER in nonphysicians with brief training revealed excellent sensitivity in detecting fractures and ligamentous injury.[143]

Extremities must be monitored frequently for the development of compartment syndrome. Compartment pressures

should be measured if any symptoms such as pain out of proportion to exam or with passive range of motion, or signs such as edema or tense compartments develop. Elevated compartment pressures are an indication for emergent fasciotomy.

Musculoskeletal injuries are the most likely to be missed or delayed in diagnosis. Many facilities have instituted the tertiary survey, a complete physical examination performed after the initial assessment and resuscitation are completed to reduce the frequency of missed injuries.

COMPLETION OF THE SECONDARY SURVEY

Once the secondary survey has been completed, if the decision to transfer the patient to another facility has been made, transfer should not be delayed for adjunctive imaging, and appropriate level of transport care should be determined and arranged. All necessary interventions should be completed, with consideration to prophylactic intubation, or placement of chest tubes in anticipation of worsening hemothoraces or pneumothoraces. The stomach and bladder should be decompressed, and if the need is anticipated, warmed fluid and blood products should be provided. The patient should be attached to portable monitors and results of tests and hospital records readied for transfer.

CHAPTER 22 ■ TRAUMATIC BRAIN INJURY

PETER B. LETARTE

The acute care surgeon is certain to encounter neurologic disease while treating the acutely ill patient. Trauma will clearly be the source of most neurologic pathology encountered by the acute care surgeon. The serious nature of many neurologic emergencies, their dramatic forms of presentation, and their complexity can distract providers in the early stages of resuscitation. A preplanned, methodical, but efficient approach to these patients provides the best hope for a quality outcome.

INITIAL DECISIONS— EMERGENCY DEPARTMENT MANAGEMENT

The Advance Trauma Life Support Course has ensured that adequate resuscitation is provided to the victims of trauma. It is important to remember that other neurologic emergencies also require prompt primary resuscitation. In the case of trauma, management of airway, breathing, and life-threatening bleeding is essential.

Airway and Breathing

Epidemiology has demonstrated that patients with traumatic brain injury (TBI) who are allowed oxygen saturations <90% have poorer outcomes. Work with brain tissue monitors has demonstrated that hypoxic insults are additive. This means that multiple brief hypoxic insults add up to a total time of hypoxic insult. Studies have shown that a total of 30 minutes of hypoxia time can result in significantly poorer outcomes.[1-3]

It would seem that limiting such small insults via a well-secured airway would be best for the brain-injured patient. For this reason, orotracheal intubation has been advocated as part of prehospital care for all patients with a Glasgow Coma Score (GCS) < 9. Interestingly, when the impact of prehospital intubation on patients with severe head injuries was studied, patients who were intubated actually had worse outcomes.[4,5]

The factors contributing the increased morbidity in patients intubated in the field appear to be hyperventilation and poorly performed intubation. Hyperventilation has been implicated for some time as a source of secondary brain injury due to its capacity to cause cerebral vasoconstriction and cerebral ischemia.[6] Work in the last few years has demonstrated the tendency for patients intubated in the field to be hyperventilated and has demonstrated inferior outcomes in this same patient group. However, hypoventilated patients also appear to have inferior outcomes. Further complicating the issue of airway management in patients with TBI are concerns about the increased morbidity of poorly performed intubation. Many of the early providers of care to severely brain-injured patients will have poor intubation skills, only performing intubations on patients one to two times in 1–2 years.

Optimum care appears to be intubation at the earliest, safest time. This involves balancing the skill of the intubator with the time to intubation. In an urban setting, this might mean delaying intubation for the 10 minutes required to transport to an emergency department (ED) with an anesthesiologist available, while in a rural setting immediate intubation by a less skilled provider might be required.

Once intubated, pCO_2 should be maintained in the 35–40 mm Hg range per the Brain Trauma Foundation Guidelines, thereby avoiding both hypoventilation and hyperventilation. Recent data suggest that best outcomes may result from slightly lower levels, in the 30–35 mm Hg range, but this will require further validation prior to changing the recommendation.[7,8]

There should be no confusion that hyperventilation in the presence of signs of herniation is appropriate. In the prehospital or ED environments, before intracranial pressure (ICP) monitoring has been instituted, patients who manifest clinical signs of herniation such as a unilaterally dilated pupil, an asymmetric motor examination, or a declining GCS should be hyperventilated in an attempt to blunt the impact of herniation. What is to be avoided is prophylactic or inadvertent hyperventilation.

While end-tidal CO_2 ($ETCO_2$) has many uses in the early management of injured patients, it lacks the accuracy, sensitivity, and specificity to manage the pCO_2 parameters for ventilation in TBI. This is because concurrent conditions such as hypotension, cardiac failure, pulmonary contusion, and even frequent patient movement severely confound the correlation between Arterial and $ETCO_2$. A recent study confirmed this poor correlation and found that patients presenting with $ETCO_2$ in the 35–40 mm Hg range were likely to be underventilated (pCO_2 > 40 mm Hg) 80% of the time and severely underventilated (pCO_2 > 50 mm Hg) 30% of the time.[9]

Circulation

Even a single episode of systolic blood pressure below 90 mm Hg can result in poor outcomes for the victims of TBI.[3,10] For this reason, victims of TBI require vigorous resuscitation of their systolic blood pressure to >90 mm Hg. Ninety millimeters of mercury has traditionally been the threshold used in studies of outcome after head injury. Its basis lies in historical precedent, and it may be that sharp changes in mortality are actually observed at a different threshold.[11]

There is a trend in trauma surgery to set lower resuscitation thresholds and to limit crystalloid resuscitation, especially in penetrating abdominal trauma, to prevent exacerbation of physiologically staunched severe bleeding and to prevent dilution of oxygen carrying capacity. Both of these concerns argue that lower systolic blood pressure resuscitation end points may be appropriate. Without denying the validity of either argument, the fact remains that epidemiologically, TBI patients with systolic blood pressure <90 have poorer outcomes. While further research is needed to determine if another cutoff might make more sense from a physiologic, mortality, or outcome point of view, for now the data support resuscitation of patients with suspected brain injury to 90 mm Hg and all efforts should be expended to assure that patient's systolic blood pressures are kept at this level.

Neurologic Assessment

Pupillary Response. Pupillary asymmetry, the clinical manifestation of temporal lobe herniation, has high diagnostic and prognostic utility. Pupillary asymmetry is defined as a difference of >1 mm between pupils. A dilated pupil is >4 mm. A fixed pupil shows no response to bright light. Pupillary asymmetry and its duration should be carefully documented.

It should be remembered that multiple factors can create this finding. Hypotension, hypoxia, and direct orbital trauma are common causes of pupillary dilation. One iatrogenic cause is the belladonna alkaloids commonly used by ophthalmologists for detailed ophthalmologic examinations. Hypoxia and hypotension should be corrected as herniation is being excluded as the cause for pupillary dilatation. Orbital trauma can be excluded using a swinging light test that assesses the direct and consensual response of each pupil.

Until mass effect has been ruled out, pupillary dilatation should be assumed to be due to mass effect.

Glasgow Coma Score. An important part of the primary survey is to obtain an accurate GCS. The GCS[12] is critical in classifying the severity of head injury and determining its subsequent management. Patients with a GCS of 14–15 are classified as having mild head injury; they have a 2% chance of elevated ICP, a 2% chance of any lesion on computed tomography (CT), and <0.1% chance of that lesion being surgically significant. Moderate head injuries have a GCS of 9–13, a 20% chance of elevated ICP, and an approximately 10% chance of having a lesion on CT scan. Severe head injuries need to be intubated and have an approximately 50% chance of having elevated ICP. Severely head-injured patients with a normal head CT do not need ICP monitoring unless they are in a high-risk group defined as having two of the following three characteristics: age >40, a history of hypotension (systolic blood pressure <90), or unilateral or bilateral motor posturing. Severe head injuries have a GCS of 3–8.[12-14] Unfortunately, in as many as 44% of patients, a full GCS cannot be obtained, especially early in the course of care. Patients who are hypoxic, hypotensive, hypothermic, or hypoglycemic have depressed mental status due to a poor environment for the brain and not due to brain pathology. These conditions should be corrected prior to relying on the GCS for management decisions. Similarly, the common use of paralytics and sedatives in rapid sequence intubation introduces confounding factors that must clear prior to relying on the GCS.

Recent work has questioned the utility of the GCS for certain applications, suggesting other methods for classifying TBI. There also continues to be discussion about whether patients with GCS 13 should be treated as mild or moderate head injuries. It is the author's practice to treat them as moderate.[15]

Penetrating Injuries

Penetrating Brain Injuries (PBI) to the head, particularly gunshot wounds to the head, can carry as high as 90% mortality. Decisions on who should be resuscitated can often be particularly difficult.

Important factors to assess in making this decision are the age of the patient, the circumstance of the injury, and the caliber of weapon. In addition, it is useful to classify Penetrating Brain Injury (PBI) as tangential, penetrating, or perforating injuries. Tangential injuries, which strike but do not enter the calvarium, have a lower mortality rate.[16] A penetrating injury occurs when the projectile enters the calvarium, often driving bone before it into the brain, but remains lodged within the calvarium. A perforating injury occurs when the projectile also exits the brain, creating a tract completely across the head. Traditional PBI

teaching has been that injuries that cross the midline are the most lethal, and some class III data support this.[16,17]

Victims of penetrating head trauma who present with a GCS of 3–5 have only a small chance of an acceptable outcome. At the same time, several studies have shown a reasonable prognosis for patients with PBI and GCS 13–15.[16,18-20] It should be remembered that these assumptions are based on postresuscitation GCS.

Patients with a depressed respiratory rate or hypotension on presentation after penetrating trauma are likely near death and are at greater risk for a poorer outcome.

DETERMINING THE NEED FOR EMERGENCY SURGERY

Emergency Radiologic Studies

Cervical Spine Management. Patient who have sustained TBI are at a higher risk for cervical spine injury. Identification of patients who have sustained cervical trauma is crucial since they are at a greater risk of further, possibly, catastrophic injury. Conversely, the morbidity of a prolonged time in a cervical collar, such as decubiti and infection, and the impediments to care created by cervical collars make identification of patients who are at acceptable low risk for further injury to the cervical spine also important, since in these patients the collar can be removed. The goal is to have a process that is very sensitive to detecting high-risk cervical spine injuries and very specific, able to exclude patients who are not at high risk for a major cervical spine injury.

Traditionally, screening was done via imaging. The plain cervical x-rays have been estimated to be 92%–96% sensitive and 78%–97% specific, with some estimates running lower.[21] CT has been estimated to be 96%–100% sensitive and 90%–100% specific for anatomical abnormalities.[21,22] Imaging modalities, however, detect anatomical abnormalities. Judgment is still required to determine which of these abnormalities are substantive or constitute an increased risk to the patient. Judgment is required to determine which patients have an acceptable risk, that is, which patients are "cleared."

Criteria other than imaging have been developed to identify low-risk patients. The National Emergency X-Radiography Utilization Study (NEXUS) criteria use characteristics of the history and physical to screen for low-risk patients. Per the NEXUS criteria, patients who can reliably answer questions and who are neurologically intact, without pain at rest, without pain with palpation of the neck and without pain or other symptoms with motion of the neck have a 99.8% chance of being free of cervical injury (negative predictive value) and may have their collar removed without imaging.[23] Unfortunately, only 12% of presenting patients meet these criteria.

The Canadian C-Spine Rule adds features of the mechanism of injury to the examination and history to screen for high-risk patients. The Canadian C-Spine Rule has a 100% negative predictive value.[24]

The goal of all these techniques is to identify to the practitioner both patients at an acceptably low risk for further neurologic injury, that is, those who are "cleared," and those who remain at increased risk and who warrant further protection and management of their cervical spine. Until this determination is made, all victims of TBI should have their cervical spine protected in a rigid cervical collar.

Computed Tomography of the Head
MILD HEAD INJURY
Since the overwhelming majority of head injuries that present are mild and insignificant, multiple organizations have

released guidelines on which brain injury patients should undergo CT scanning, in an effort to limit its unnecessary utilization. The summary of these guidelines is that it is not necessary to obtain a head CT in patients who have no loss of consciousness and are neurologically normal. Problems arise, however, in defining what is meant by "neurologically normal." All guidelines define this as the absence of posttraumatic amnesia (PTA), confusion, or impaired alertness.[25-27] Some of these features may be present with a GCS of 15, depending on the method used for obtaining the GCS. While tests for PTA and screening tests for mild head injury are available, they are not in wide use in emergency rooms today and their utility in this busy environment is questionable.[28] It is therefore difficult to reliably identify and document patients who may not require CT scanning. While it is possible to omit CT scanning in some patients, in most cases, it appears to be cost-effective and safer to triage head-injury patients, including mild head-injury patients, with CT.

TIMING OF CT

CT scanning should be obtained as early as is safely possible in the patient's care. Patients should be adequately resuscitated prior to being taken to the CT scanner.[26] In many urban trauma centers, CT scans can often be obtained within minutes of arrival in the ED, indeed within minutes of the injury. These "ultra early" CT scans can be obtained prior to substantial accumulation of intracranial blood or swelling. Note should be made of patients who receive "ultra early" scanning and subsequently decline in mental status. Such patients may warrant repeat scanning.

FEATURES ON CT

The focus of the CT examination is to identify intracranial hematomas. There are several other features of the scan that are important.

Compression of the basal cisterns is important to note. Basal cistern effacement is the anatomic correlate for progressing temporal lobe herniation. Effaced or compressed basal cisterns are a warning of progressing herniation. Absent basal cisterns are a grim marker of well-advanced herniation.

Midline shift is also important; its use as a criterion for removal of various hematomas is discussed elsewhere. It is important to note that midline shift is caused not only by hematomas but also by cerebral edema.

Traumatic subarachnoid blood is, in fact. While tSAH does not create significant mass effect, it is a prognostic marker for increased ICP and poorer outcome.[136]

CT scanning also allows good imaging of the skull and the skull base. Many fractures can be identified on CT. Particular attention should be paid to skull fractures in "ultra early" scans since they may portend delayed development of a hematoma.[29]

In penetrating head injury, perforating lesions carry a higher mortality with perforating lesions that cross the midline being the most lethal; these lesions can be seen on CT. One exception worth noting is bilateral frontal lobe involvement. Kaufman noted a mortality rate of 12% in this group and good outcomes in 30%, considerably better than the outcomes for bihemispheric lesions in general.[30] Conversely, if the tract is further posterior in the brain, more critical structures will be damaged. Such a posterior tract is likely to traverse the ventricles and ventricular penetration by the tract has been shown to have a strong association with increased mortality.[18,31,32]

Because of the great reliance on CT scanning by many therapies for TBI, comparison of various therapies during research trials requires a standardized description of CT scans to allow classification and comparison of these scans. Marshall proposed such a classification in 1991.[33]

CT findings were divided into mass lesions and diffuse injuries. Mass lesions were further divided into evacuated (any lesion surgically evacuated) and not evacuated (high or mixed density lesion >25cc; not surgically evacuated).

Diffuse injury II, cisterns present with midline shift of 0-5 mm and no high or mixed density lesions >25cc but may include bone fragments and foreign bodies; Diffuse injury III, cisterns compressed or absent with midline shift of 0-5 mm and no high or mixed density lesions >25cc; Diffuse injury IV, midline shift >5 mm; no high or mixed density lesion >25cc.

The Marshall Scale has become a standard for classifying CT scans for research and clinical work. In addition, it has also been used as a tool to study the prognostic value of CT scans. This concept of performing risk analysis of various CT findings has been carried forward by several researchers.[34] Knowledge of a particular injuries natural history via quantitative risk analysis provides a more precise tool for determining who might require surgery for mass lesion evacuation, ICP monitoring or other interventions.

Magnetic Resonance Imaging. As new magnetic resonance imaging (MRI) technologies evolve, the role of MRI in the evaluation of the head-injured patient is changing. While there is much interesting research in this area, there is little that is ready for routine clinical use.

SURGICAL MANAGEMENT

Removal of Mass Lesions

After resuscitation, the most important decision is that of surgical management. One important factor in patients with some form of intracranial bleeding is the volume of the hematoma. Many CT scanners will estimate the hematoma volume. If such an estimate is not available, hematoma volume can be estimated by a technique described by Kothari.[35]

Acute Epidural Hematoma. All epidural hematomas with a volume >30 cm^2 need to be evacuated, regardless of the patient's GCS. The criteria for nonoperative management are a volume on CT < 30 cm^2, a thickness of <15 mm, and a midline shift <0.5 mm in a patient with a GCS > 8 and no focal deficit. All of these criteria should be met for the patient to be managed nonoperatively.[36]

Patients with an acute epidural hematoma, anisocoria, and a GCS < 9 should undergo craniotomy as soon as possible, regardless of the size of the hematoma.[36]

Acute Subdural Hematomas. For subdural hematomas, those with a thickness >10 mm or a midline shift >5 mm should be evacuated regardless of the patient's GCS. A patient with an acute subdural hematoma that is <10 mm thick and midline shift <5 mm but with fixed and dilated or asymmetric pupils, an ICP > 20 mmHg, or a decline in GCS of 2 or more points from the time of injury to hospital admission should also have their hematoma removed. Patients with acute subdural hematomas also need to have their clots removed as soon as possible.[37] Subdural hematomas should be removed using craniotomy. All patients with a GCS < 9 and an acute subdural hematoma should be monitored with an ICP monitor.[37]

Parenchymal Lesions. Parenchymal lesions consist of intraparenchymal clots and contusions. Their management has always been less clearly defined than the management of epidural and subdural hematomas

Focal parenchymal lesions should be removed in three circumstances. Any patient with a parenchymal mass lesion

TRAUMA

and signs of progressive neurologic deterioration due to the lesion, medically refractory intracranial hypertension, or signs of mass effect on CT scan should be treated operatively. Any patient with any lesion >50 cm^3 in volume should be treated operatively. Patients with GCS scores of 6–8 with frontal or temporal contusions >20 cm^3 in volume with midline shift of at least 5 mm and/or cisternal compression on CT scan should be treated operatively.[38] Craniotomy with evacuation of mass lesion is recommended for these patients.[38]

Patients with parenchymal mass lesions who do not show evidence for neurologic compromise, have controlled ICP, and have no major signs of mass effect on CT scan may be managed nonoperatively with intensive monitoring and serial imaging.[38]

Posterior Fossa Lesions. Posterior fossa lesions are particularly dangerous. These lesions often do not manifest their mass effect by mental status change but rather by vital sign changes. These changes are often subtle and missed, with the ensuing tonsillar herniation often presenting as cardiopulmonary collapse.

Patients with mass effect on CT scan or with neurologic dysfunction or deterioration referable to the lesion should undergo operative intervention. Mass effect on CT scan is defined as distortion, dislocation, or obliteration of the fourth ventricle; compression or loss of visualization of the basal cisterns; or the presence of obstructive hydrocephalus. The operation should take place as soon as possible. A suboccipital craniectomy is the procedure most commonly performed.[39]

Patients with lesions and no major mass effect on CT scan and without signs of neurologic dysfunction may be managed by close observation and serial imaging.[39]

Surgical Management of Diffuse Brain Swelling—Decompressive Craniectomy

As with many techniques, the term decompressive craniectomy has been used by authors to refer to several different operations. A wide hemispheric craniectomy and bifrontal craniectomy with several different methods of dural opening have all been described.[40-42] Clinical experience has created the impression that decompressive craniectomy can have significant clinical value. Its true clinical efficacy is awaiting the outcome of multiple current ongoing studies (ClinicalTrials.gov identifier NCT00155987).

The quandary in decompressive craniectomy is its use in treating isolated diffuse cerebral swelling. Decompressive craniectomy may be done incidental to a craniotomy for removal of hematoma, but the decision making in this case is driven by the need to remove the hematoma. The more difficult problem is the decision and timing of surgery where the only indication is diffuse cerebral swelling.

Currently, it is felt that decompressive craniectomy should not be a "last-ditch," salvage procedure; rather, it should be a deliberate part of the treatment protocol that is aggressively invoked early in the patient's care when lower-tier therapies fail. Expert guidelines suggest that for patients with diffuse cerebral swelling, bifrontal decompressive craniectomy within 48 hours of injury is a treatment option. These patients should have diffuse, medically refractory posttraumatic cerebral edema and resultant intracranial hypertension.[38] In addition to bifrontal decompressive craniectomy, other decompressive procedures, including subtemporal decompression, temporal lobectomy, and hemispheric decompressive craniectomy, are treatment options for patients with refractory intracranial hypertension and diffuse parenchymal injury with clinical and radiographic evidence for impending transtentorial herniation.[38]

Depressed Skull Fractures

Patients with open (compound) depressed cranial fractures should undergo operative intervention to prevent infection and decompress the brain if clinical or radiographic evidence of dural penetration, major intracranial hematoma, bone depression >1 cm, frontal sinus involvement, gross cosmetic deformity, wound infection, pneumocephalus, or gross wound contamination is present. Nonoperative management is appropriate for patients without any of these findings.

Elevation of the fracture and debridement of the skull, scalp, and brain followed by closure of the dura is the surgical method of choice. Replacement of the bone at the time of surgery is appropriate, although the risk of infection must be considered when one is replacing bone fragments associated with an open wound. However, such replacement can be safe if thorough irrigation and debridement have been utilized. Antibiotics can be started on all patients with open (compound) depressed fractures.[43] Early operation is recommended to reduce the incidence of infection.

Closed (simple) depressed cranial fractures that are less than the width of the skull deep may be treated nonoperatively.[43]

In children, ping-pong fractures, or large depressions on the convexity of the skull reminiscent of the depressions commonly seen on old ping-pong (table tennis) balls, sometimes require elevation if the depression is deeper than the thickness of the skull. These fractures may be elevated by simply drilling an adjacent burr hole, carefully sliding a stout instrument underneath the fracture, and levering the fragments outward.

Fractures at the base of the skull, which involve the frontal sinuses or ethmoid sinuses, are more complex to manage and often require a collaborative approach with otolaryngology, plastics, or oromaxillofacial surgery.

Penetrating Injuries

The goals of surgery for the victim of PBI are to remove mass effect, control bleeding, control infection, to prevent cerebrospinal fluid (CSF) leak and to close the scalp. Although advocated in the past, aggressive removal of all bone and bullet fragments is no longer a goal for this surgery.[44-48]

Retained bullet and bone fragments do not have a large impact on the post-PBI infection rates, but CSF leakage does.[44,46] Tight dural closure is a mainstay of surgery for PBI. Scalp lacerations that result from PBI are often complex. Scalp incisions for PBI operations should be planned to allow for complex scalp repair at the end of the case.

Cerebrovascular Injury

Patients who present with arterial hemorrhage from mouth, nose, ears, or wounds, expanding cervical hematomas, cervical bruit in patients younger than 50 years old, or incongruous lateralizing neurologic deficit not explained by CT or other findings should have carotid dissection considered in their diagnosis. In addition, trauma patients who present with evidence of cerebral infarction should have carotid as well as vertebral artery injury considered in the diagnosis, although like contusion, infarction does not present on CT for 12–24 hours after the infarction. Patients suspected of harboring a carotid injury should undergo angiography on an emergent basis if they are otherwise stable. Coordination of the appropriate management for both the vascular and the intracranial injuries requires a well-coordinated multispecialty approach.[49]

INTENSIVE CARE UNIT MANAGEMENT

Intracranial Pressure

Early workers in TBI used ICP upper limits ranging from 20–30 mm Hg as the intraventricular pressure threshold for the treatment of ICP.[14,50-52] Analyzing data from the National Trauma Coma Data Bank (NTCDB), Marmarou found 20 mm Hg to be the critical cutoff identified by regression analysis.[53] Current guidelines recommend keeping the ICP below 20–25 mm Hg water.[54]

Placement of an intraventricular catheter, however, requires a certain level of skill and practice. Placement cannot always be achieved. They can require a high level of maintenance and they carry an approximately 2% infection rate. A common alternative is the intraparenchymal/intraventricular fiber-optic or microsensor ICP monitor. These are easier to place and have a lower infection rate. Their use can be coupled with a ventriculostomy.

Hyperosmolar Therapy. Hyperosmolar therapy for cerebral edema and elevated ICP has been in use since the 1950s. The first agent was urea, which was then superseded by Mannitol. More recently, hypertonic saline has been used as a hyperosmolar agent for TBI. Mannitol has long been accepted as an effective tool for reducing ICP.[55-59] Numerous mechanistic laboratory studies support this conclusion. Its impact on outcome has never, however, been directly demonstrated via a class I trial testing mannitol against placebo.

There is a commonly held belief that mannitol administration can cause or exacerbate hypotension in the early resuscitation of trauma victims. There are class III data that show infusion of mannitol at rates of 0.2–0.8 g/kg/min can lead to transient drops in blood pressure.[60-62] From these observations, a rate of no higher than 0.1 g/kg/min or 1 g/kg delivered over 10 minutes or more is recommended.[63] Careful monitoring of urine output with aggressive replacement of this fluid loss is also recommended to prevent hypotension associated with the use of mannitol.

Mannitol and other osmotics are known to be able to briefly open the blood brain barrier. Furthermore, at rates of administration that exceed the rate of excretion of mannitol, mannitol can accumulate in the extracellular space. These factors lead to the accumulation of mannitol in extracellular spaces and a reverse osmotic gradient that can lead to a "rebound effect" or movement of water into the brain. Class III data suggest that this effect is more likely with continuous infusion of mannitol, as opposed to bolus administration.[64-66]

Class II and III data have shown that doses of 0.25–1.0 g/kg of mannitol may be needed to achieve a reduction in ICP. This required dose varies from patient to patient and even may vary from time to time in the same patient.[29,57,65,67]

Hypertonic Saline. Hypertonic saline offers an attractive alternative to mannitol as a therapy for elevated ICP. Its ability to reduce elevated ICP has been demonstrated with class II and III data in the intensive care unit (ICU) and in the operating room.[68-71]

Hypertonic saline has been used in two very different ways in the resuscitation of trauma victims. In addition to being proposed as a hyperosmolar agent for the management of elevated ICP, it is also advocated as a low-volume resuscitation fluid. While the qualities that make it useful both as a low-volume resuscitation fluid and as a brain-targeted therapy are related, its efficacy in one role does not guarantee its efficacy in the other. Each therapeutic endpoint must be analyzed independently.

Previously, there had been no consensus on what was meant by "hypertonic saline." Concentrations of 3%, 7.2%, 7.5%, 10%, and 23.4% have all been used and described in the literature. Many current clinical trials have used 7.5% saline.[68-70,72]

In addition, hypertonic saline is described in the literature as being administered in a variety of different ways, the two principle ones being as a bolus or as a continuous drip.

When hypertonic saline is given as an infusion, the goal of the therapy is to elevate serum sodium to 155–160 mEq/L, although some investigators have gone as high as 180 mEq/L. This elevated serum sodium is thought to help stabilize ICP and reduce the therapeutic intensity required to manage elevated ICP.[73,74]

The more common route of administration, especially in early resuscitation, is to use hypertonic saline as a bolus to achieve an immediate reduction in ICP. This method takes advantage of the rapid rheologic improvement and improved cerebral blood flow (CBF) that, like mannitol, hypertonic saline can create.

Multiple animal studies and several human studies have demonstrated that hypertonic saline, as a bolus, can reduce ICP in a monitored environment such as the operating room or ICU where ICP monitoring is present.[75-77]

In two prospective clinical trials, however, hypertonic saline did not demonstrate any advantage over normal saline on neurologic outcome when given as a prehospital resuscitation fluid.[78,79] Further trials are continuing.

Hyperventilation. Hyperventilation has been used since the earliest days of ICP management to limit ICP by cerebral vasoconstriction. The cost of this intervention is the ischemia induced by this same vasoconstriction. Hyperventilation is considered mild when the arterial pCO_2 is kept between 30–35 mm Hg. Severe hyperventilation occurs when the arterial pCO_2 is below 30 mm Hg.

The only study of hyperventilation's impact on outcome demonstrated that at 12 months there was no difference between patients who were hyperventilated and those who were not. However, at 3 and 6 months, patients who were hyperventilated had poorer outcomes.[6]

The outcome data, combined with a body of data concerning the low blood flow and the near-ischemic conditions found in newly injured brains, raise concern about hyperventilation's ischemic potential.[80-82] In the 1990s, published guidelines discouraged hyperventilation except in the presence of impending herniation, as manifest by elevated ICP or clinical signs of herniation. This position has remained the therapeutic recommendation since. Recent work has shown the best outcomes for patients reliably kept in the 30–39 mm Hg range during the ED phases of their resuscitation.[83] In the prehospital environment, best outcomes are seen in the 30–35 mm Hg range.[7]

Hyperventilation is an acceptable modality in the presence of impending herniation for short periods of time or in the presence of elevated ICP refractory to sedation, paralysis, CSF drainage, or osmotic diuresis.[84]

Barbiturate Therapy. Barbiturate therapy or barbiturate "coma" can be used as a third-tier therapy for elevated ICP when other more standard therapies have failed. It has been demonstrated to be effective in reducing ICP.[85]

Barbiturate therapy also carries with it a high morbidity.[86] Barbiturates affect the function of not only the brain but also the heart and kidneys, among other organs. Substantial declines in the functioning of both of these organ systems can occur during therapy. For this reason, barbiturate coma should not be initiated if the victim of malignant ICP is also hemodynamically unstable. Patients should be carefully monitored to assure maintenance of hemodynamic stability during therapy.

TRAUMA

Hypothermia. Hypothermia has been shown to reduce elevated ICP.[87-90] There are also some clinical data that demonstrate that hypothermia has a beneficial effect on the outcome from TBI.[87,91,92]

The National Acute Brain Injury Study: Hypothermia (NABISH) study was a large randomized prospective clinical trial designed to demonstrate this beneficial effect for hypothermia on the outcome from TBI. It failed to do so.[93]

Although the NABISH study failed to demonstrate the efficacy of hypothermia, many still believe that it has potential value as a therapy. Multiple clinical trials are in progress to explore its utility.

Therapeutic hypothermia for TBI is considered to be the rapid reduction and maintenance of a core body temperature to 32°C–35°C for 48 hours or less. The decision to induce the hypothermia must be made almost immediately upon presentation, and the patient must have the hypothermia induced and reach target temperature within 60 or perhaps even 30 minutes of presentation.[94] The therapy has not demonstrated efficacy as a third-tier therapy and should not be instituted several days into treatment as other therapies fail.[94]

Hypothermia is a complex therapy, which should only be performed at centers that are willing to make the substantial commitment to doing it correctly. It appears that marginal or inept application of this therapy at best will do no good and at worst will harm the patients.[95]

It has been shown that hyperthermia results in a poorer outcome from TBI.[96] Efforts to prevent excessive temperatures in the victims of TBI are appropriate.

Cerebral Perfusion Pressure

Cerebral perfusion pressure (CPP) is the difference between the mean arterial pressure and the ICP (CPP = MAP – ICP). The role of CPP in TBI is complex and our understanding of it is incomplete and controversial. Establishing what the correct CPP should be is therefore difficult.

There are actually many reasons cited to maintain an adequate CPP.[97] The most common is to reduce the incidence of secondary insults to the injured brain. This approach focuses on inadvertent hypotension to the brain and reduces the number of secondary insults, that is, the numbers of hypotensive episodes. A second reason to maintain adequate CPP is to assure that the brain is functioning within the autoregulatory limits. The third reason to maintain adequate CPP is to assure adequate oxygen delivery to the brain, the $PbrO_2$. In these studies, above a certain CPP threshold, $PbrO_2$ is no longer dependent on CPP. This number is commonly thought to be 60 mm Hg.

Robertson et al. examined some of these issues in a study published in 1999. In this class I study, patients were randomized to either a CBF-targeted therapy or an ICP-targeted therapy.[98] While the CBF-targeted group in this study showed better performance for many of the surrogate markers for CPP success, the study failed to show any improvement in outcome for CBF-directed therapy over ICP-focused therapy. Further, the study showed that patients with CPP of 70 mm Hg had a higher incidence of acute respiratory distress syndrome.[98]

The current synthesis of the data is that, except in cases of regional ischemia, a CPP of 60 mmHg is adequate and no benefit and some harm may come from elevating CPP to 70 mm Hg.[99]

Advanced Cerebral Monitoring

Oxygen delivery to the brain is traditionally monitored via pulse oximetry. However, knowing that blood oxygen saturation is >90% is not sufficient to determine if oxygen delivery to the brain is adequate.

Several methods for measuring oxygen delivery to the brain are available. One method is to measure the arterial-venous oxygen difference across the brain, the AVO_2: This value requires a sensor or sampling catheter high in the jugular vein.

Estimates of the adequacy of oxygen delivery to the brain can also be made by measuring the saturation of blood leaving the brain in the jugular bulb, the $SjvO_2$. This is most commonly done via a jugular bulb catheter. Most patients have an $SjvO_2$ of 55%–69% in the blood leaving the brain.

$SjvO_2$ appears to adequately reflect the status of oxygen delivery to the brain. While it has never been shown that maintaining $SjvO_2$ in the normal range improves outcome, multiple studies have shown that patients with increased numbers of episodes of $SjvO_2$ desaturation <50% have worse outcomes.[100-104]

A more direct approach is to measure cerebral tissue oxygen tension. This can be measured via cerebral tissue oxygen monitoring. Normal cerebral tissue oxygen pressures, $PbrO_2$, are approximately 32 mm Hg. Studies have shown that patients whose $PbrO_2$ is allowed to dip to 15 or lower have poorer outcomes.[101,105,106]

It appears that active management of cerebral oxygen delivery has the potential to improve outcomes from TBI. Applying technologies that allow the $SjvO_2$ to be kept above 50% and the $PbrO_2$ above 15 mm Hg is now a reasonable option to pursue in the management of TBI

Penetrating Injury

PBI can lead to delayed posttraumatic cerebral aneurysms. Between 3% and 33% of all victims of PBI may have a posttraumatic aneurysm.[107,108] Such aneurysms can develop as late as 2 weeks after the injury, and an early negative cerebral angiogram does not exclude an aneurysm later in the patient's course. Any patient who develops delayed or unexplained subarachnoid hemorrhage or other delayed bleeding should be suspected of harboring a posttraumatic aneurysm and should undergo cerebral angiography.

CSF leaks and subsequent infections are an important source of morbidity and mortality in the victims of PBI. Half of all CSF leaks may occur at sites remote from the entry or exit sites in the calvarium. These CSF leaks will not be apparent at surgery and will manifest after surgery. Seventy-two percent of these leaks will appear within 2 weeks of surgery and forty-four percent will seal spontaneously.[109]

Current infection rates for PBI in a military setting are 4%–11%. Current civilian rates are at 1%–5%.[110] Half (55%) of all intracranial infections occur within 3 weeks of the injury and 90% occur within 6 weeks.[110] Factors affecting infection risk are CSF leaks, air sinus wounds, and wound dehiscence. Because of the high infection rates with this injury, long-term antibiotics are commonly used.

In PBI, 30%–50% of victims develop posttraumatic epilepsy PTE.[48,111] This is slightly higher than the estimates of 4%–42% for nonpenetrating TBI.[112-114] Early seizures in the TBI literature are defined as seizures in the first 7 days after injury, when the vast majority of early seizures occur.[114] Current guidelines for antiepileptic therapy after PBI are the same as after TBI.[115]

The risk of PTE after PBI appears to decline with time. While 18% of victims may not have their first seizure until 5 or more years after the injury, 80% will have their first seizure within 2 years of the injury and 95% of patients who remain seizure free for 3 years following injury will remain seizure free.[48,111] Followed out to 15 years, 50% of patients who do develop PTE will stop having seizures.[48]

Systemic Management

The management of systemic parameters in head-injured patients is similar to the management of other trauma patients. Cardiovascular, pulmonary, renal, and other organ systems must be watched closely and supported as necessary with the goal of preventing secondary cerebral insults. There are some unique aspects of critical care management for brain-injured patients that should be highlighted.

Hypoglycemia and Hyperglycemia. Both elevations (hyperglycemia) and decreases (hypoglycemia) in blood sugar jeopardize ischemic brain tissue. The disastrous impact of significant hypoglycemia on the nervous system, during injury and at other times, is well known. In the absence of glucose, ischemic neurons can be permanently damaged. However, it is also true that prolonged serum glucose of >150 and perhaps >200 mg/dL may be harmful to the injured brain and should be avoided.[116,117]

Steroids. Although steroids were commonly administered to head-injured patients in the past, multiple studies have failed to show any benefit to mortality or outcome for steroid administration. The largest study to date, the CRASH trial, was terminated early after accrual of 10,008 patients when analysis showed a substantially increased risk of death for the head injury population receiving steroids.[118] There is currently no known benefit to administering steroids to brain-injured patients for the purpose of neuroprotection or ICP control.

Anticonvulsants. Current guidelines for antiepileptic therapy after TBI distinguish between two uses for antiepileptic drugs post injury, treatment and prophylaxis. Antiepileptic drugs do appear to be effective in treating an established posttraumatic seizure disorder and in preventing immediate postinjury seizures in the first week after injury. They do not appear to be effective in reducing the incidence of posttraumatic epilepsy. Maintenance of TBI victims on prophylactic doses of anticonvulsant medications beyond the first week of therapy does not appear to reduce the incidence of posttraumatic seizures. The recommendation for TBI is to treat the patient with anticonvulsants for 7 days and then discontinue the medication, only restarting it if seizures develop.[95,115]

Prevention and Management of Complications

Coagulopathy. Unlike most critically injured trauma patients, who tend to have low plasma antithrombin (AT) activity, those with closed head injury tend to have supranormal plasma AT activity, perhaps explaining in part the frequent occurrence of coagulopathy after TBI.[119] DIC is often associated with the development of potentially dangerous delayed or recurrent intracranial hematomas in head-injured patients and can cause expansion of otherwise small hematomas and contusions.[120]

In addition, the increasing use of anticoagulants in treating various cardiac, vascular, and neurologic conditions has resulted in an increasing older population of patients with iatrogenic coagulopathy. These patients are also at risk for expansion of seemingly insignificant clots into life-threatening masses. Special caution should be observed in the elderly if the initial CT scan is a "hyperacute" scan, that is, one obtained very soon after the precipitating trauma.

Fresh-frozen plasma is a commonly used and effective empiric treatment for patients with coagulation defects. Unfortunately, reduction of an elevated INR to acceptable levels for surgery can sometimes take several hours. The decision to operate in the face of significantly elevated INR can easily lead to surgical disaster.

Recombinant factor VIIa offers a potential solution to this dilemma, with the ability to rapidly reverse an elevated INR and allow almost immediate surgery.[121-123] This use of factor VIIa is currently an off-label indication, and work is ongoing to investigate the safety and efficacy of this drug in the treatment of the victims of TBI.[124]

Thromboembolic Events. Head-injured patients are at increased risk of deep venous thrombosis (DVT) and pulmonary embolism (PE). In a large series of trauma patients, 4.3% of those with head injury were diagnosed with DVT, twice the rate seen in patients without neurologic injury.[125]

Neurosurgeons are concerned about potentially catastrophic postoperative hemorrhagic complications and prefer DVT prophylaxis techniques that avoid compromise of the clotting cascade.

Pneumatic compression stockings are one such technique. In several clinical series of patients with various types of neurosurgical disease, such devices were associated with an incidence of DVT of 1.7%–2.3% and PE of 1.5%–1.8%.[126,127] These results have not been uniformly demonstrated by all studies, but pneumatic stockings are a mainstay of DVT prophylaxis.

Experience with low-molecular-weight heparin used in conjunction with pneumatic compression suggests that this regimen is even more effective than pneumatic compression alone in general neurosurgery patients[127] and is safe and effective in trauma patients (including those with head injury).[128]

Treatment of thromboembolic events in head-injured patients must weigh the dangers of PE with the risk of bleeding. There are scant data relating the risk of bleeding to time after injury. Anticoagulation may be deferred from 72 hours to as long as 6 weeks after injury in an attempt to prevent recurrent bleeding, depending on local custom.

Thromboembolic events within this window are usually best treated by insertion of an inferior vena cava filter (IVCF). Prophylactic use of IVCFs in all high-risk patients is controversial.

OUTCOME

Of the patients who survive to reach the Emergency department, 80% have mild injuries. Moderate and severe injuries each account for 10% of the total. Survivors of TBI are often left with varying degrees of disability, which occur in roughly 10% of mild, 50%–67% of moderate, and >95% of severe closed TBI survivors.[129] The most widely used tool for assessing outcome after TBI is the Glasgow Outcome Scale,[130] although more refined assessment tools are constantly being sought.

Outcome Prediction

Many prediction models have been developed over the years. Different indicators of outcome have different significance and different precedence depending on the population to which they are applied. A grim prognostic indicator in the elderly might have much less dire implications for a younger patient. As a result, generalization of findings from a specific population and prediction model to the general population is often inappropriate.[131,132] Care needs to be used when applying prediction models in everyday practice.

Although very good and very bad outcomes can usually be predicted with a high degree of confidence early after injury, it is much harder to prognosticate about patients in intermediate

categories. Studies have shown that even with the diligent application of known indicators, physicians tend to overestimate the likelihood of poor outcome and underestimate the likelihood of good outcome early in the care of head-injured patients. In one study, physician's predictive accuracy was only 56%.[133] This "false pessimism" phenomenon takes on greater significance when combined with work demonstrating that providers will alter their care based on these predictions, increasing the use of therapies considered beneficial for those thought to have a good outcome and decreasing it for those felt not to have a good prognosis.[134] Care should therefore be exerted when offering predictions or withholding care of the brain-injured patient early in the course of their treatment.

BRAIN DEATH AND ORGAN DONATION

The diagnosis of brain death is made when there is no clinical evidence of neurologic function in a patient whose core temperature is >32.8°C, whose mental status is not impacted by sedating or paralyzing medications, who is completely resuscitated with a systolic blood pressure >90 mm Hg and whose oxygen saturations are >90%.[135]

The absence of neurologic function must be scrupulously established and documented. Most errors in declaring brain death are the result of poorly performed neurologic examinations. Nationally recognized standards for examination can be found in the references.[135]

Many clinical protocols and some state statutes also require that brain death be confirmed by further neurologic tests, an ancillary test such as radionucleotide CBF studies or EEG.[135]

The physiologic definition of brain death described above is the one commonly used in the United States. Various hospitals and systems will have differing methods for declaring brain death and the states have varying legal statute on who may declare death and brain death and how it is to be declared. Those interested should ask within their local system.

CHAPTER 23 ■ MAXILLOFACIAL INJURIES

NATHANIEL MCQUAY JR AND DANIEL LADER

Maxillofacial trauma encompasses injuries to the soft tissue and skeletal and visceral organs of the face. Fractures occur when forces that exceed their tolerance are applied. Although facial injuries are often not life threatening, their significance cannot be understated. Facial injuries may interfere with nasal, auditory, mandibular, or ocular function. The potential for postinjury disfigurement and disability can be associated with long-term physical and psychological sequela.

The management of maxillofacial trauma can be traced back to ancient times. The Edwin Smith papyrus (1550 BC), the oldest known medical papyrus, contains detailed descriptions of the surgical management of facial skeletal and soft tissue injuries. Hippocrates described the timeless methods of closed reduction of mandible dislocations, wiring of teeth and jaw immobilization of mandible fractures, and closed reduction of nasal fractures.[1] The management of these injuries in isolation is straightforward. However, facial trauma is often associated with other injuries that may be life threatening, requiring immediate attention. So when does one begin to address the maxillofacial injuries in the multiply injured patient? It is the purpose of this chapter to review the mechanisms of injury, clinical presentation, diagnostic modalities, and the initial management of the wide spectrum of maxillofacial injuries. The priority-based approach to the polytrauma patent is reviewed as pertains to the patient with facial trauma.

INITIAL ASSESSMENT

Airway

The initial assessment of the acutely injured patient, irrespective of the injury complex, remains unchanged. The Adult Trauma Life Support® (ATLS) program provides a standard prioritized approach to the initial evaluation and management of the trauma patient.[2] The first priority is that of the airway. In the patient with maxillofacial trauma, the airway may be compromised by lack of support from the tongue, unstable skeletal support, or obstruction of the airway due to foreign bodies or bloody secretions. An organized approach should be utilized in managing the airway to optimize patient outcome (Algorithm. 23.1). The oral cavity should be first cleared of secretions, supplemental oxygen given, an oral airway placed, and the jaw thrust maneuver applied to assist with the opening of the posterior pharynx. The cervical spine is immobilized assuming the presence of a cervical spine injury, which occurs in approximately 1%–5% of patients with facial fractures.[3–6] Immobilization is maintained until the cervical spine is both radiographically and clinically evaluated to exclude an acute fracture. Patients with immediate or persistent airway problems require placement of a definitive airway defined as a cuffed tube within the trachea. The definitive airway of choice is a translaryngeal endotracheal tube.[2] Care should be taken to avoid iatrogenic injury to the maxillary central incisors during intubation. Nasally placed tubes (nasotracheal, nasogastric) should be avoided in the setting of facial trauma as central bony fractures may be present allowing passage into the cranial vault. When the difficult airway is encountered, a surgical airway, cricothyroidotomy, is the definitive airway of choice.[2]

Breathing

Patients with facial trauma may present with oxygenation and ventilatory difficulties. Although airway compromise is often assumed, a respiratory etiology must also be sought. Penetrating injuries should be assessed for trajectory as missiles may be present in the neck or thoracic cavity. The presence of subcutaneous emphysema should prompt further investigation to rule out injury to the upper airway, aerodigestive tract, or tracheobronchial tree. A supine portable CXR serves as the initial adjunct study for further assessment of the hypoxic patient. Clinical findings consistent with a tension pneumothorax (absent breath sound, tracheal deviation, hypoxemia, and hemodynamic lability) require immediate needle decompression with subsequent thoracostomy tube placement. Hypoxemia in the stable patient with evidence of a pneumothorax or hemothorax is managed with placement of a thoracostomy tube.

Circulation

Acute hemorrhage continues to be the second most common cause of death in the trauma population.[7] Fatal traumatic hemorrhage accounts for a large portion of early deaths, with the majority of exsanguinations occurring within the first 48 hours.[8,9] Following stabilization of the airway and breathing, circulation with hemorrhage control is the next priority in assessing acutely injured patients. The vascular supply to the face is vast and in the setting of diffuse soft tissue injury may serve as a source of considerable blood loss. The best way to control hemorrhage in the acute setting is with well-placed direct pressure. This concept is central even in the setting of oral and maxillofacial injuries. Following placement of intravenous access, the site of hemorrhage is assessed to determine the method of pressure to be applied. Nasal fractures are often associated with bleeding. Direct pressure on the nares often controls epistaxis from an anterior source. Substantial bleeding from a posterior source may require nasal packing, balloon compression, or both to obtain hemostasis (Fig. 23.1). Patients with complex facial fractures due to either blunt or penetrating trauma have multiple sites of bleeding that may prove difficult to control. Encompassing the concept of direct pressure, facial packing and compressive dressings techniques have been described to achieve hemostasis.[10] Packing of the oropharynx following airway control is in essence similar to the four-quadrant packing of the abdomen in an attempt to obtain hemorrhage control.[11–14] When bleeding is refractory to compressive methods, angioembolization is employed for definitive control (Algorithm. 23.2).

DEFICIT AND ENVIRONMENT

The initial neurological evaluation includes the assessment of the pupillary response and the computation of the Glasgow Coma Score (GCS).[15] Abnormal pupillary response and/or a low GCS score indicate the presence of a traumatic brain injury (TBI) requiring computed tomography (CT) scan of the brain

for further assessment. Certain facial fractures, are often associated with an intracranial injury. When a TBI is diagnosed, prompt neurosurgical consult should ensue. Exposure of the patient by removing all clothing allows for unobstructed evaluation of associated injuries. During the initial evaluation, the environment should be controlled. Warm fluids and external warming methods are used to prevent hypothermia as it may contribute to the development of coagulopathy.

SECONDARY SURVEY

Only upon stabilization of the patient and completion of the primary survey can one proceed with the secondary assessment. Potential life-threatening injuries are assessed and managed during this stage of the evaluation. A history and complete "head-to-toe" physical examination should be performed. The information provided by the prehospital personnel about the mechanism of injury and surrounding events guides the astute provider in the assessment for possible associated injuries. Patients with facial injuries due to a blunt mechanism (MVC, falls, assaults), often have associated injuries. Once the less life-threatening injuries have been excluded, then evaluation of the maxillofacial region can begin. The approach to the maxillofacial examination should include evaluation of the soft tissues, skeleton, dentition, and nerves. In the awake patient, focused questioning can provide clues to the presence of underlying skeletal fractures (Table 23.1). The physical examination must be organized and methodical to minimize missed injuries. Inspection and palpation serves as the basis for the maxillofacial examination. Drainage from the nose, rhinorrhea, or the external auditory canal, otorrhea, should be carefully inspected for the presence of cerebral spinal fluid (CSF). Clinically the diagnosis is made upon observing the "double ring" sign (small central blood ring surrounded by a larger peripheral clear ring) that is produced when the fluid is placed on a paper towel. If there is a high index of suspicion of CSF leak, the fluid should be sent to the laboratory for a β_2-transferrin (which is present only in CSF) or a quantitative glucose analysis. The presence of β_2-transferrin or a glucose level >30 mg/100 mL is consistent with the presence of CSF. The oral cavity is then inspected for lacerations, soft tissue injuries, abnormal dentition, and bleeding. The tongue is often a source of non–life-threatening bleeding, but may require suture placement for hemostasis. Lacerations of the soft tissue and gingival, bony irregularities, tenderness, and numbness must be adequately evaluated to diagnose an underlying skeletal fracture. The presence of numbness is due to the involvement of the sensory branch of the trigeminal nerve and, in mandible fractures, the inferior alveolar nerve. Avulsed dentition may serve as a possible source of airway obstruction when aspirated; therefore, a CXR should be obtained. Once the examination is completed, appropriate imaging studies, (CT scan, panorex) are performed. Complete CT scans of the face with coronal views aid in the diagnosis of facial fractures and planning of operative intervention if required.

Soft Tissue Injuries

Soft tissue injuries to the maxillofacial region present a considerable challenge in management as there can be untoward cosmetic and functional deficits if not addressed in an appropriate manner. Complex facial lacerations can cause substantial bleeding as the face is very well vascularized with the terminal branches of the external carotid artery as its main supply. This vast vascular supply also allows for lacerated tissues with small pedicles to survive if managed carefully.[16,17] Therefore the initial approach to soft tissue injuries includes copious irrigation, appropriate antibiotics, and limited debridement. Primary closure of facial wounds, for up to 24 hours postinjury, is employed when adequate tissue is present. Good cosmesis is generally achieved due to an abundant blood supply and repeatable patterns of soft tissue injury.[18] Proper suturing technique is essential to minimize potential disfigurement. Layered closure with approximation of deep layers using braided absorbable sutures to eliminate potential dead space and fine monofilament sutures for skin closure that is tension-free minimizes scarring. Skin sutures should be removed in 3–5 days as this also minimizes scarring. The patient should be advised to apply sunscreen to the affected area during the first year of healing to prevent discoloration of the scar.

Lip laceration repair requires careful attention. Wound management follows the general principle of soft tissue management of the face. Thorough irrigation should be used prior to closure and antibiotics that cover gram-negative anaerobes should be considered. The wound is inspected for the presence of foreign body and tooth fragments from associated dentoalveolar injuries. Wound depth evaluation is crucial as unrecognized penetration through the oral mucosa may allow salivary contamination. The oral mucosa should be approximated to prevent salivary contamination. The muscle fibers of the orbicularis oris run in a transverse manner and tend to pull the wound edges apart, giving the appearance of an avulsive tissue loss, which is rarely the case. Alignment of the vermilion border is central in the closure technique to obtain a good cosmetic result.[19] When it is properly performed, cosmetic results are maximized, and scarring is minimal.

Avulsive maxillofacial injuries are typically the result of an impact with high kinetic energy. Close-range gunshot wounds (GSW) and high-speed MVC impact can lead to large full-thickness soft tissue loss. These wounds are frequently associated with other life-threatening conditions such as hypovolemic shock and airway embarrassment. Soft tissue injury management is best performed with serial dressing changes of saline-soaked gauze in the multi-injured patient. Once stabilized, extensive reconstructive procedures are often required to address large soft tissue loss. Injured soft tissue surrounding the area of initial trauma progresses to an evolving pattern of tissue loss and necrosis requiring serial debridements. Once all devitalized tissue is removed, a variety of tissue transfer techniques (local, regional, free flap) can be employed to obtain skeletal coverage.[20–24] Early reconstruction provides better cosmetic and functional results as compared to delayed secondary repair.[20,25]

Dentoalveolar Injuries

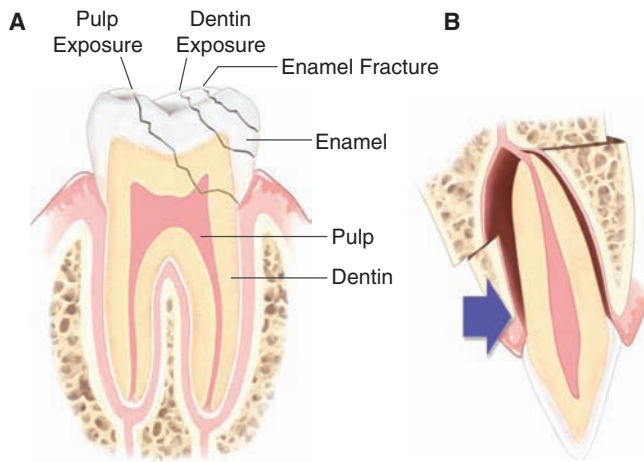
Traumatic facial injuries frequently involve the dentition and dentoalveolar structures. Common causes of dentoalveolar trauma include MVC, falls, sports injuries, and assaults. Involvement of the maxillary incisors due to their prominent position in the mouth is common. Injury patterns range from various fractures of the teeth to fractures involving the supporting bony alveolus (Fig. 23.2). Lacerations of the lips and gingiva are frequently associated with dentoalveolar trauma and can complicate their management. Prompt diagnosis and treatment of these injuries are important when


FIGURE 23.2. **A:** Level of tooth fractures. **B:** Dentoalveolar fracture.

one considers the esthetic implications of tooth loss, especially since these injuries tend to occur in children and young adults.

A complete physical exam of the maxillofacial region should be performed when assessing dentoalveolar injuries to rule out associated injuries. The Universal Tooth Designation System is most commonly used in the United States as a standard in tooth identification (Fig. 23.3). It is important to take note of any missing teeth as they may have been aspirated or displaced into other structures such as the facial soft tissues or nasal cavity. In the severely injured or obtunded patient, imaging of the chest should be included to locate aspirated teeth. Timely diagnosis is critical as tooth reimplantation and fracture reduction should ideally be performed within 1 hour of injury to minimize delayed loss of teeth. Injuries to the coronal portion of teeth can result in fractures of the crown that may be limited to the enamel or involve the innervated dentin and pulp. Fractures limited to the enamel are not emergent and can be treated at a later time. Injuries with exposed dentin or pulp are quite uncomfortable and require more immediate attention and restoration. Tooth injury with associated loss of the crown at or below the gingiva or a fracture involving the tooth root may not be amenable to restoration. Complete tooth avulsion requires immediate attention as successful reimplantation is a time-sensitive process. Reimplantation rate decreases as the periodontal tissues attached to the tooth desiccate and become nonviable. Teeth can be reimplanted within 20 minutes if not placed in a suitable transport medium verses up to 3 hours when immediately placed in an appropriate solution such as milk, or Hank's balanced salt solution found in Save-A-Tooth kits (3M Health Care, St. Paul MN).[26,27] Once the tooth is reimplanted, it must be stabilized with either a splint or an arch bar for several weeks. Fractures of the supporting alveolar bone and subluxation tend to involve prominent anterior teeth and require reduction of the subluxed tooth or entire alveolar segment. This can usually be performed with local anesthesia; however, more severe injuries or uncooperative patients may require conscious sedation or general anesthesia in the operating room. Treatment involves adequate reduction to re-establish the dental occlusion and placement of either a splint or an arch bar for 4–6 weeks.

Orbital Fractures

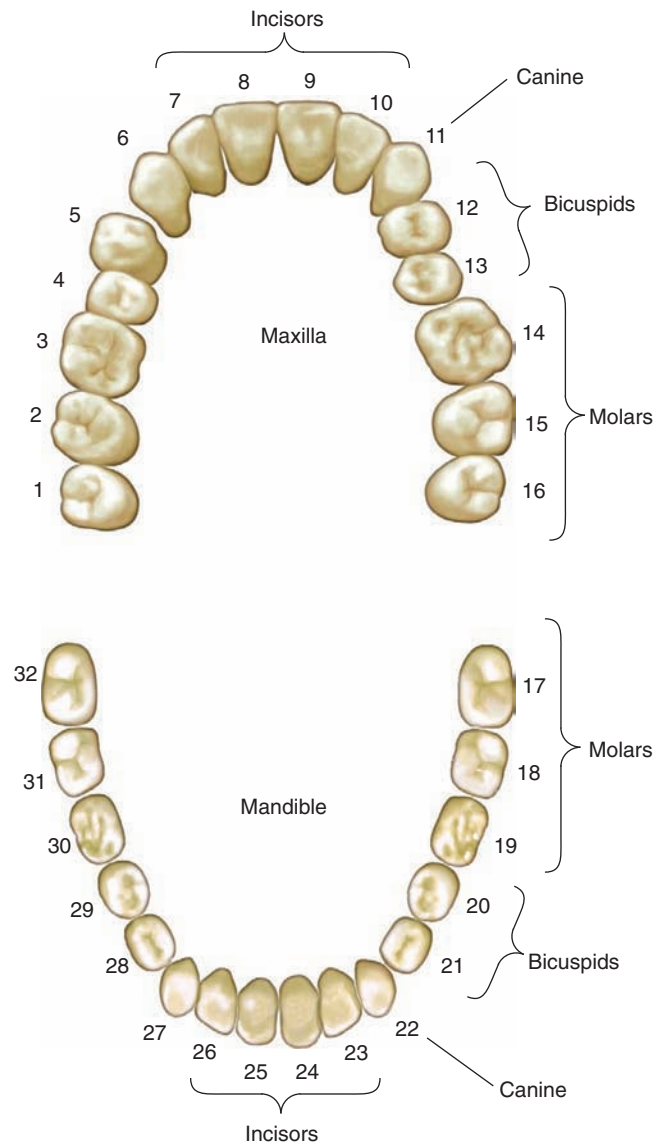
Blunt trauma (MVC, Assault, Sports injuries) accounts for the majority of isolated orbital fractures. The force of impact


FIGURE 23.3. The universal tooth designation system. A drawing of the occlusal and incisal surfaces of the maxillary and mandibular adult dentition. The numerals 1 to 32 give the Universal numbering code commonly used for record keeping.

is transferred to the thin orbital bones, which fracture in a "blow-out" fashion. This repeatable pattern of injury most likely serves as a protective mechanism against globe injuries. Both the orbital floor and medial wall of the orbit are often fractured, with the former occurring more commonly. The orbital floor also functions as the roof of the maxillary sinus, and this injury typically leads to air emphysema. Due to the proximity of the inferior rectus and the inferior oblique muscles to the orbital floor, muscle entrapment may occur. Findings on physical examination include diplopia and restriction of the upward gaze in the ipsilateral eye. A forced duction test is recommended to differentiate muscle entrapment from other muscle or nerve complications. As with other facial fractures, orbital fractures warrant a thorough ophthalmologic evaluation as associated globe injuries (corneal abrasion, hyphema, globe rupture) occur. Exophthalmos and epistaxis are often present initially. As the edema resolves, enophthalmos develops due to retraction

TRAUMA

of the eye into the ocular cavity. Radiological evaluation of orbital fractures with coronal CT is useful in evaluating orbital injuries and soft tissue details. Findings include disruption of one or more of the orbital walls, air fluid level in the maxillary sinus, and herniation of periorbital fat into the sinus.

Indications for surgical intervention include muscle entrapment, enophthalmos, positive force duction test and globe malposition. Symptoms of concomitant oculocardiac reflex (bradycardia, heart block, nausea, vomiting, or syncope) warrant immediate surgical intervention as they may be fatal.[28] Surgical repair of the orbital floor may be delayed until swelling subsides as this allows for better incision placement and improved cosmesis. Proper reconstruction is essential to prevent cosmetic deformity, delayed enophthalmos, or persistent diplopia. Small or nondisplaced fractures are often amendable to nonoperative management.

Le Fort fractures

I   II   III

FIGURE 23.5. Lefort classification of midfacial fractures.

Maxillary Fractures

Trauma to the midface can result in a fracture of the maxilla (Fig. 23.4). Maxillary fractures usually involve the teeth-bearing segments and follow certain fracture patterns (Fig. 23.5). The Lefort classification is widely used to describe fracture patterns of the maxilla and midface.[29] A Lefort I fracture represents a *horizontal* fracture located above the roots of the teeth. Clinically the maxillary fragment is mobile due to the separation of the upper jaw from the cranial base. Lefort II fracture follows a *pyramidal* outline and involves the nasal bones. Lefort III fracture results in complete *craniofacial separation* in which the entire midface is separated from the cranial base.

Traumatic midfacial injuries can present with substantial bleeding from the nose and oral cavity. This may require the use of nasal packing, balloon compression, or angioembolization to control associated hemorrhage. The use of nasogastric tubes in patients with midfacial injuries is contraindicated as passage through a fractured cribiform plate and into the cranial vault is known to occur. Patients sustaining midfacial injuries are usually subject to considerable blunt force trauma and often have associated injuries. As with other facial fractures,

paresthesia in the distribution of adjacent nerves is present. In addition to various fracture combinations, substantial malocclusion can occur and the upper jaw can appear to be freely mobile. CT is the most appropriate imaging modality in evaluating midfacial injuries. Definitive treatment usually requires some form of open reduction and internal fixation for displaced fractures.

Mandible Fractures

Mandible fractures are the second the most commonly encountered facial skeletal injuries. As with most facial injuries, the severity of the fracture is proportional to the location and force of impact. Fractures tend to occur at the local site of impact and in areas of weakness. The weak points of the mandible include the condyle, angle, and symphysis regions at which mandibular fractures commonly occur (Fig. 23.6). Depending on the location, mandible fractures may serve as a source of airway compromise due to posterior displacement of the tongue into the oropharynx. Substantial bleeding from mandible fractures is rare; however, when this is present, fracture reduction and stabilization usually achieves hemostasis.

There is also a 10% incidence of an associated cervical spine injury and head injuries that must be considered when managing mandibular injuries.[4,5]

There are several important factors regarding the diagnosis and treatment of mandibular fractures relative to the anatomy of the mandible. The mandible has a dual articulation with the base of the skull at the glenoid fossae commonly referred to as the temporomandibular joints. Multiple muscles (masseter, medial and lateral pterygoids) insert into the mandible where they tend to distract fractured segments along the vector of contraction. The inferior alveolar nerve, which represents the third division of the trigeminal nerve, enters the mandibular ramus along its medial aspect and courses through a bony canal within the mandibular body and exits via the mental foramen. This nerve is frequently injured in mandibular fractures and can lead to a subsequent paresthesia along its distribution.

Patients who present with mandibular fractures will typically demonstrate several key clinical findings. The inability to bring the teeth into proper occlusion (malocclusion) or restriction of mouth opening (trismus) assists with identifying mandible fracture location. Dental injuries can accompany mandible fractures and may serve as a source of intraoral bleeding. In addition, there may be sublingual hematoma formation resulting in elevation of the tongue. Facial lacerations may also be present resulting in an open or compound fracture. Several imaging modalities are utilized in diagnosing mandibular fractures. The panoramic radiograph gives an excellent view of the entire mandible, the joints, and dentition. However, its use may be limited by availability or contraindications secondary to patient factors. If a panoramic radiograph is unavailable or contraindicated, a series of radiographs (lateral oblique, posteroanterior, and a reverse Towne's view) have been used to diagnose skeletal fractures. These are often not applicable in the trauma patient as they require cervical spine clearance for head manipulation. CT scanning has mostly replaced plain film evaluation of the mandible. CT images offer better views of fracture lines and segments. Three-dimensional reconstruction allows for a fracture to be viewed from multiple planes, thereby providing a more detailed preoperative model facilitating surgical planning.

Nasal Fractures

Nasal fractures are the most common facial fracture due to the prominent position of the nose on the face. Nasal bones are relatively thin and tend to fracture with little force. Laterally displaced fractures of the bony skeleton often produce a nasal deformity as well as impairment of inspiration secondary to deviation of the nasal septum. In more severe fractures (nasoorbitethmoid fracture), extension to the frontal and ethmoid bones frequently occurs, resulting in posterior displacement of the bony structures. Clinically, facial edema, ecchymosis, nasal deformity, bony crepitus, and epistaxis are the usual findings. The mucosal lining of the nasal cavity is well vascularized, which may serve as a substantial source of hemorrhage. A nasal speculum should be used to look for evidence of septal deviation and hematomas. Septal hematomas should be promptly drained to prevent complications including perforation, septal necrosis, abscess formation, and the development of a saddle nose deformity.[30] Epistaxis may require the use of a nasal packing, balloon compression, local anesthesia with a vasoconstrictor, or a combination of the above to obtain hemorrhage control.

Although the diagnosis of nasal fractures is mainly clinical, CT scanning is the imaging modality of choice. Facial CT tends to better define the anatomy and severity of the fracture assisting in treatment planning. Closed reduction under local anesthesia with or without mild sedation is usually adequate to address simple nasal and septal injuries. In the setting of a severely displaced fracture, nasal retrusion, open fractures, or persistent postreduction deformity, open reduction under general anesthesia is performed.

Zygoma Fractures

The zygoma is a prominent bone and provides contour to the lateral aspect of the midface. The body of the zygoma is relatively thick in comparison to its articulations and tends to fracture with a distinct "tripod" pattern involving the zygomaticomaxillary complex (ZMC). A fracture of the ZMC will typically occur at the zygomatic arch, frontal bone articulation, and along the anterior wall of the maxillary sinus extending through the inferior orbital rim and orbital floor. Frequently the infraorbital nerve is affected, leading to paresthesia along its distribution of the ipsilateral cheek. Appreciable facial emphysema secondary to the disruption of the maxillary sinus wall is commonly present on initial presentation. Often, patients report that after sustaining facial trauma they blow their nose, and there is immediate profound swelling that prompts them to seek care. Other common presenting symptoms are periorbital ecchymosis and edema. After the initial edema subsides, there can be substantial loss of soft tissue support and flattening of the malar prominence. Trismus may be present if the depressed zygoma leads to mechanical impingement of the underlying coronoid process of the mandible. Palpable bone step deformities may be present along the zygomaticofrontal suture, zygomatic arch, and inferior orbital rim. CT scan is the imaging study of choice for ZMC fractures. Typical findings include soft tissue air emphysema, layering of blood in the maxillary sinus, and the "tripod" fracture pattern. Additional involvement of the sphenoid interface is described as the "quadramalar" fracture pattern. Associated globe injuries are common for which some authors recommend routine ophthalmologic examination prior to surgical repair.[31] Open reduction with internal fixation of displaced fractures is the surgical technique often applied. Nondisplaced fractures may be treated nonoperatively as the zygoma is not a load-bearing bone.

Ocular Injuries

Eye injuries are the leading cause of monocular blindness in the United States.[32] Sources of injuries include blunt objects, penetrating injuries, impalements, and MVC with airbag deployment. Orbital fractures are often associated with ocular and periocular injuries. Although ocular injuries may be obvious when caused by penetrating trauma, those caused by blunt trauma are sometimes difficult to detect as serious and potentially blinding injuries may go unnoticed. Routine ophthalmological evaluation in all patients with orbital fractures to address delay in diagnosis and management of serious injuries has been proposed.[31] Careful history and physical examination play an important role in decreasing the time to diagnosis especially in the multiple injured or comatose patients. Inquisition about the wearing of eyeglasses or contacts, preexisting ocular conditions, as well as the circumstances surrounding the injury event should occur. Physical findings of orbital pain, visual changes, eno- or exopthalmos, hyphema, or decreased extraocular motor activity should lead one to evaluate not only for an ocular injury but also an associated orbital fracture. Visual acuity is the first step in the evaluation of ocular trauma. Documentation of light perception and projection should be performed in the injured globe and compared to the uninjured globe. Initial gross examination should

TRAUMA

be performed without placing pressure and ocular injuries classified.[33] Upon completion of the physical exam, CT scan is often obtained to further assess soft tissue injury and rule out orbital fractures, retained foreign bodies, or a ruptured globe.

Early ophthalmology consult is indicated in penetrating injuries or decreased visual acuity. A ruptured globe is the most serious injury requiring early evaluation. The involved globe should be protected with an eye shield, and precautions to reduce intraocular pressure are instituted.[34] Signs and symptoms of a possible globe rupture include loss of vision, traumatic hyphema, hemorrhagic chemosis, or a displaced lens. During the ocular exam, refrain from applying pressure to the globe as this may cause extravasation of intraocular contents. Intravenous prophylactic antibiotics are administered, as topical eye drops should be avoided. Operative intervention should include primary repair when possible. Enucleation is sometimes required when loss of vision in the injured eye is irreversible and to prevent the development of sympathetic ophthalmia in the uninjured eye.

Parotid

Parotid gland injuries are relatively uncommon, but when present must be appropriately addressed to prevent long-term complications. The identification and definitive management of a parotid duct injury is crucial in order to prevent formation of a sialocele or a salivary fistula. The parotid duct, or Stenson duct, measures approximately 7 cm in length coursing the middle third of a line drawn between the tragus of the ear and the middle of the upper lip. For any facial injury that crosses this line, parotid duct involvement is assumed until proven otherwise. Injury to the duct is often associated with injury to the buccal branch of the facial nerve due to its close proximity. Parotid duct injury identification is facilitated by gentle message of the gland inducing saliva secretion or by cannulation of the intraoral papilla located opposite the upper second molar. Several

operative techniques, primary anastamosis[35,36], duct ligation, and duct fistulization into the oral cavity have been described.[37] The operative technique most often utilized is primary anastamosis. The injury is repaired over a stent with fine absorbable sutures. Instances in which there is extensive tissue damage precluding primary repair, duct ligation is often performed.

Nerve

The trigeminal and facial nerves serve as the main source of sensory and motor innervation to the face respectively. During the physical examination of the patient with facial trauma, the identification of the nerve branches for primary repair is not necessary as in other anatomic regions. This is due to the lack of severe disfigurement and minimal functional loss. Injury to the branches medial to the lateral canthus of the eyes need not be repaired as with good skin approximation, nerve regeneration is accomplished via neurotization of muscle. Sensation in the involved area usually returns within a year. Nerve lacerations laterally located require primary anastomosis, ideally at the time of initial operation. When segmental loss of nerve tissue exists, interposition grafting using either the auricular or the sural nerves is used.[38–40]

Antibiotics for Facial Fractures

The role of antibiotic therapy has been one of great debate for many years.[41,42] Andreasen et al.'s[43] evidence-based analysis of the use of prophylactic antibiotics in relation to surgical management of mandibular injuries is informative. The authors' review of four randomized control trials[44–47] revealed a significant decrease in infections when comparing the antibiotic group to the control group (Table 23.2) This benefit was also noted to be procedure specific when open versus closed reduction procedures were compared.[41] In the open reduction group,

x, Number of infections.
From Andreasen JO, Jensen SS, Schwartz O, et al. A systematic review of prophylactic antibiotics in the surgical treatment of maxillofacial fractures. *J Oral Maxillofac Surg.* 2006;64(11):1664–1668.

prophylactic antibiotic administration resulted in a decrease in infections (8% antibiotic group vs. 62% no antibiotics). Antibiotic prophylaxis was not beneficial in the closed reduction group as the infection rates were similar whether given or not (23% antibiotic group vs. 28% no antibiotic group). While some may argue that these studies are too heterogenous to make definitive conclusions regarding the use of antibiotics in facial fractures, our practice is to use antibiotic prophylaxis for mandible fractures without condylar involvement, for open fractures, and when open reduction is the operative procedure to be performed.

Chemoprophylaxis with antibiotics in head trauma to prevent posttraumatic meningitis is another area where variation of practice is controversial. Patients with basilar skull fractures (BSF) and possible CSF leak are often thought to be at increase risk of developing posttraumatic meningitis. The prevention of possible serious complications has served as the basis for administering prophylactic antibiotics with little evidence of efficacy. Ratilal et al.[48] have recently performed a systematic review of the best evidence on the efficacy of prophylactic antibiotics for the prevention of posttraumatic meningitis. Their review found no significant differences in the frequency of meningitis or all-cause or meningitis-related mortality between the treatment and control groups. The presence or absence of CSF in subgroup analysis revealed similar findings.

In conclusion, the management of maxillofacial trauma requires a multidisciplinary approach. Injury priority based on the standardized ATLS approach is paramount to optimize outcomes. Upon stabilization and addressing life-threatening injuries, the clinical assessment and diagnostic evaluation of potential facial injuries may commence. Injury-specific management is carried out by the surgical specialist (plastic surgery, oral and maxillofacial surgery, ophthalmology) with the goal of restoring function with good cosmesis.

CHAPTER 24 ■ SPINAL COLUMN AND SPINAL CORD INJURY

KHALID M. ABBED AND KIMBERLY A. DAVIS

Injuries to the spine, including injuries to the vertebral column, ligaments, and cord, are common. Spine injuries occurred in 106,762 patients in 2008, representing 17% of the population of patients reported to the National Trauma Data Bank.[1] According to the Foundation for Spinal Cord Injury Prevention, Care and Cure, the incidence of spinal cord injury, excluding those who die at the scene, is approximately 40 cases per million population in the United States, or approximately 12,000 new cases per year.[2]

Spinal cord injury is a disease of young male adults. The average age at injury during the 1970s was approximately 28 years with most injuries ranging between the ages of 16 and 30. However, as the median age of the population has increased, the average age at injury has also steadily increased to approximately 42 years in 2005. Spinal cord injury affects males more commonly than females, with a ratio of 4 to 1. The most common etiology of spinal cord injury in the United States is motor vehicle crashes (42.1%) followed by falls and acts of violence (primarily gunshot wounds). The proportion of injuries due to sports has decreased over time.[2]

Injuries to the spinal cord are devastating: 30% of patients have incomplete tetraplegia, 25% have complete paraplegia, 20% have complete tetraplegia, and 18.5% have incomplete paraplegia. Less than 1% of patients experience functional neurologic recovery by the time of hospital discharge. The median hospital length of stay in an acute care hospital has declined over the last three decades, averaging 12 days in the years 2005-2008. Similar downtrends are noted for days in rehabilitation, averaging 37 days in the years 2005-2008. Overall median hospitalized days including acute care and rehabilitation were greater for neurologically complete injuries.[2]

Spinal cord injuries represent a major societal economic burden. Although more than half of patients with spinal cord injury (57.5%) report being employed at the time of their injury, this drops significantly to 11.5% at 1 year postinjury. Additionally, in 2008 dollars, the average first year postinjury costs range from $236,109 to $801,161 with each subsequent year's cost ranging from $16,547 for incomplete motor function at any level to $143,507 for a patient with high tetraplegia (C1-C4). These costs noted are only direct costs and do not acknowledge the indirect costs, including loss of future wages, fringe benefits, and productivity. As >95% of patients survive their initial hospitalization, the lifetime costs of injury in a young spinal cord injury patient with a high cervical spine injury (C1-C4) are in excess of $3,160,000. Indirect costs have been estimated at approximately $64,443 per year in December of 2008.[2]

Spine injuries occur in mobile spinal segments: the cervical spine and the thoracolumbar spine. In the cervical spine, 25% of all injuries occur in the upper cervical spine, while 75% occur between C3 and C7. Multiple-level spine injuries have been estimated to occur in 4%-20% of all cases. In the thoracolumbar spine, the anatomic distribution of injury is most common around the thoracolumbar junction.

The most common spine fracture is a vertebral body compression fracture. Anterior column wedge fractures are the most common type of compression fractures and are the typical compression fractures seen in osteoporotic patients. Fractures occurring from major flexion and distraction forces often disrupt the posterior ligamentous complex causing these fractures to be relatively unstable. These fractures are often caused by lap belts in motor vehicle accidents. High-energy axial loads to the spine may cause compression fractures with retropulsion of bone fragments into the canal. These fractures are called burst fractures, which have a higher risk of causing neurologic deficit and instability. A combination of compression, tension, rotation, and/or shear forces causes fracture dislocation injuries that disrupt all three columns of the spine. Fracture dislocations are the most unstable type of spinal fracture.

Cervical spine injuries occur in a bimodal fashion, involving either the young (age 15-45 years) or elderly (age 65-85 years).[3] While cervical spine injury is more common in younger patients, the elderly (age 50-80) are more likely to sustain thoracolumbar fractures.[4]

The main tenet of prehospital care for spinal cord injury is effective spinal immobilization to prevent further injury. It is estimated that 3%-25% of spinal cord injuries occur after the initial trauma, either during transport or in the initial phases of evaluation and treatment. Effective spine immobilization includes the use of a rigid cervical collar and a backboard, with the head of the patient secured to the backboard with head blocks and straps. The practice of immobilization with sandbags and tape is not recommended.[5,6]

BONY AND LIGAMENTOUS ANATOMY OF THE VERTEBRAL COLUMN

The vertebral column, which along with the skull and rib cage comprises the axial skeleton, provides support and protects neural elements. It consists of 33 vertebrae, 24 of which are mobile and 9 immobile. The mobile vertebrae include 7 cervical, 12 thoracic, and 5 lumbar vertebrae. The immobile vertebrae include 5 sacral and 4 coccygeal vertebrae, which are fused to form the sacrum and coccyx, the caudalmost portion of the vertebral column.

The adult spine has natural curves in the sagittal plane that form an S-shape. This S-shape is formed by lordosis in the cervical and lumbar regions and kyphosis in the thoracic region. This natural curvature of the spine allows for shock absorption, maintenance of balance, and body movement. The basic motion segment is comprised of two adjacent vertebral bodies, intervening disc, facet joints, and the stabilizing ligaments. These spinal motion segments allow flexibility and motion while maintaining stability.

Because of anatomic and kinematic differences, the cervical spine is often differentiated into upper (C1-C2) and lower (C3-C7) regions. The pedicles of C2 are a transition zone between the upper and subaxial spine and are oblique in order to connect the anterior C1 facets to the posterior

C3 facets. The occiput and the upper cervical spine form a complex and highly mobile unit. C1 articulates with the occipital condyles as well as the dens and facets of C2. The occiput–C1 articulation allows for flexion–extension and lateral bending. C2, also known as the axis, has a distinctive odontoid process that articulates with the anterior arch of C1 and is stabilized by the transverse ligament. The C1-C2 (atlantoaxial) articulation allows for 50% of head rotation. The vertebrae of C3-C7, also known as the subaxial cervical spine, are more uniform and, because of the shingle-like orientation of the facets, allow primarily flexion and extension in this region.

The 12 vertebrae of the thoracic spine form a long, rigid column with limited motion due to their attachments to the rib cage and sternum. The thoracolumbar junction is a transition zone from the rigid thoracic spine to the mobile lumbar spine. In this region, the facet joints gradually change from a more coronal orientation to a sagittal orientation. The five lumbar vertebrae are the largest vertebrae in the spine. The facets of the lumbar spine are oriented at 45 degrees of sagittal angulation allowing flexion–extension, rotation, and lateral bending. The lumbosacral junction is another transition zone between mobile and rigid segments that has significance when surgical stabilization procedures are being considered.

Spinal ligaments and intervening discs stabilize the mobile segments of the vertebral column. In the cervical spine, the intervertebral discs and the anterior and posterior longitudinal ligaments stabilize the anterior column. The posterior column is stabilized by the facet capsules, ligamentum flavum, interspinal and supraspinal ligaments, and the ligamentum nuchae. The odontoid process of C2 is stabilized by the alar, transverse, and apical ligaments.

First described by Denis, the spine can be divided into three longitudinally oriented columns.[7] The anterior column includes the anterior longitudinal ligament, the anterior annulus, and the anterior half of the vertebral body. The middle column includes the posterior longitudinal ligament, posterior annulus, and the posterior half of the vertebral body. The posterior column is comprised of the pedicles, facets, laminae, and posterior ligamentous complex (Fig. 24.1).

ANATOMY AND PHYSIOLOGY OF THE SPINAL CORD

The spinal cord is an extension of the brainstem that begins at the foramen magnum and continues down through the vertebral canal to the first lumbar vertebra, where the spinal cord tapers to form the conus medullaris. A cluster of lumbosacral nerve roots below the conus medullaris forms the cauda equina. Along the length of the spinal cord, ventral and dorsal nerve roots emerge together bilaterally to form spinal nerve roots, exiting through the neural foramen at each intervertebral space.

The spinal cord is held in position at its inferior end by the filum terminale, an extension of the pia mater that attaches to the coccyx. Along its length, the spinal cord is held within the vertebral canal by denticulate ligaments that are lateral extensions of the pia mater attaching to the dural sheath. The subarachnoid space between the spinal cord and dura is an extension of, and communicates directly with, the subarachnoid space around the brain, containing cerebrospinal fluid (CSF) that acts as a shock absorber.

The spinal cord has variable diameters along its length. In the upper spinal cord, between C4 and T1, the spinal cord widens as the cervical enlargement, which is where spinal nerves innervating the upper extremities originate and terminate. The lumbar enlargement, between T9 and T12, is a widening in the lower part of the spinal cord where spinal nerves innervating the lower extremities originate and terminate.

The cross-sectional anatomy of the spinal cord consists of white matter located on the periphery and gray matter located centrally. The white matter contains myelinated axons that form the ascending and descending spinal tracts. The gray matter contains primarily neurons and unmyelinated axons and is divided into three "horns": anterior, posterior, and intermediate. The anterior horns contain lower motor neurons that innervate the muscles of the neck, trunk, and extremities. The upper motor neurons that synapse with these lower motor neurons originate in the contralateral cerebral cortex or brain stem and descend as the lateral and anterior corticospinal tracts prior to synapsing in the anterior horn. The posterior horns contain neurons that synapse with afferent

sensory axons. The intermediate horns contain the preganglionic autonomic sympathetic neurons between T1 and L3 and the parasympathetic neurons between S2 and S4 (Fig. 24.2).

Sensory signals originate in somatic or visceral receptors and are transmitted via axons to the dorsal root ganglion. From there, sensory afferent axons enter the posterior horns of the gray matter and travel within varied regions of spinal cord white matter toward sensory regions of the brain. Pain and temperature signals cross immediately and ascend in the contralateral lateral spinothalamic tract. Touch also crosses immediately and ascends mainly in the anterior spinothalamic tract. Proprioception and vibration ascend in the ipsilateral dorsal column and cross in the brainstem. The dorsal columns are divided into the fasciculus gracilis and the fasciculus cuneatus. The fasciculus gracilis is located medially and carries sensory signals from the lower extremities, whereas the fasciculus cuneatus is located laterally and carries sensory signals from the upper extremities.

ACUTE VERTEBRAL COLUMN INJURIES

Spinal Instability

The determination of spinal instability is a complex and controversial subject, and spinal instability is often difficult to precisely ascertain. A widely accepted definition of clinical instability is the loss of the ability of the spine, under physiologic loads, to maintain its pattern of displacement so that there is no initial or additional neurologic deficit, no major deformity, or no incapacitating pain.[8] Although many theories of spinal instability have been proposed, Denis' previously described three-column theory is most widely accepted.[7] The integrity of the middle column is of the utmost importance as an injury to two adjoining columns defines an unstable fracture. Punjabi and colleagues have validated the three-column theory of instability using high-speed trauma models of thoracolumbar spinal fractures and demonstrated that the integrity of the middle column correlated best with eight of nine flexibility parameters.[9]

Occipitoatlantal Dislocation

Among traumatic injuries to the cervical spine and causes for occipital–cervical instability, occipitoatlantal dislocation (OAD) is one of the most severe. A hyperflexion–distraction injury resulting in ligamentous disconnection of the skull from the cervical spine, OAD is often immediately fatal because of associated neurologic and vascular injuries. Any high-impact injury should arouse suspicion of OAD. Although plain radiographs of the cervical spine may reveal prevertebral soft tissue swelling and an increase in the basion–dens interval, which should measure 12 mm or less, more definitive diagnosis is made with reconstructed computed tomography (CT) images of the craniocervical junction. Magnetic resonance imaging (MRI) and CT are comparable in terms of diagnosing OAD, but MRI identifies the specific ligaments injured. OAD injuries can be defined in three broad categories. Type I injuries are characterized by anterior displacement of the occipital condyles on the C1 lateral masses; Type II injuries are characterized by displacement of the occiput and C1 in the vertical plane, and Type III injuries are marked by posterior displacement of occipital condyles compared to C1. These injuries are rare and usually fatal. If the patient survives and there are no contraindications, posterior occipital–cervical stabilization and fusion are required.

Occipital Condyle Fractures

The Anderson and Montesano scheme classifies occipital condyle fractures into three main types.[10] These fractures are seen in 1%-3% of blunt trauma to the craniocervical region. Type 1 fractures are comminuted, and result from axial loading injuries. Type II fractures are linear fractures that originate in the squama of the occipital bone and extend into the condyle. Type III fractures are avulsion fractures of the condyles and are most prone to instability and OAD. While types I and II fractures are generally stable, type III fractures are potentially unstable. Stable fractures can be treated in a cervicothoracic brace; however, unstable fractures mandate stabilization and fusion.

BONY AND LIGAMENTOUS INJURIES TO THE CERVICAL SPINE

C1 Fractures and Transverse Ligament Injuries

Fractures of the atlas are usually defined in relation to the lateral masses and extent of arch involvement.[11] They can involve any parts of the ring in isolation or in combination,

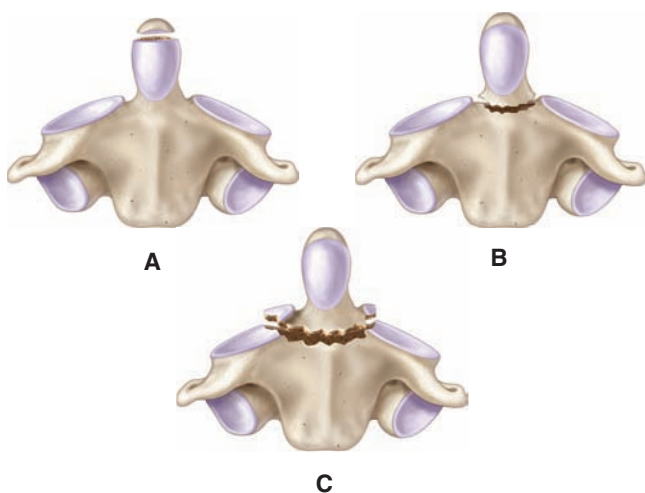
ranging from single unilateral fractures to burst-type fractures involving all aspects, also known as a Jefferson fracture. Since isolated atlas fractures without ligamentous injury are stable and heal with simple immobilization, clinical decision making is based on the identification of injuries to the transverse ligament, the vertebral artery, and other associated spinal fractures. The most commonly cited radiographic criteria indicating unstable disruption of the transverse ligament include the rule of Spence (lateral displacement of C1 lateral masses over C2 > 6.9 mm) and the atlantodental interval > 3 mm.[12,79] However, when feasible, this author prefers MRI evaluation of all atlas fractures to assess for concomitant ligamentous injury, which is an indication for surgical fixation.

Atlantoaxial Joint Injuries

Atlantoaxial subluxation occurs when the transverse ligament is disrupted. This is an extremely unstable injury with a high risk for neurologic deficit. Traction may be appropriate initially to achieve reduction. Definitive treatment mandates posterior cervical fusion of C1-C2.

C2 Fractures

Odontoid process fractures commonly affect the elderly. The most common classification scheme for fractures of C2, the Anderson and D'Alonzo scheme, relies on the location of the fracture line within the odontoid process or body of C2.[13] In this scheme, type I fractures involve the tip of the dens, type II fractures run through the junction of the dens and the body of C2, and type III fractures course through the vertebral body of C2 (Figs. 24.3 and 24.4).

Management of C2 fractures is determined by type. Type I fractures are an avulsion of the alar ligament and are usually stable. Cervical collar immobilization for symptomatic management is usually sufficient. Type II fractures are the most common type of dens fracture and are more often subject to nonunion, especially in patients older than 50 years of age and those with displacement >5 mm. When choosing treatment strategies for type II fractures, the integrity of the transverse ligament, age and orientation of the fracture,


displacement and/or angulation of the fractured process, and patient-specific factors such as medical comorbidities, and body habitus should be considered. Type III fractures extend into the C2 vertebral body. This fracture type can be mechanically unstable but generally heals well with immobilization. As such, treatment usually entails cervical immobilization in either a rigid cervical orthosis or a halo vest for 12 weeks.

Fractures of the C2 pedicles (also known as traumatic spondylolisthesis or hangman's fractures) are often classified based on the mechanism of injury, where flexion (type III) and flexion–distraction (type IIa) are often unstable and require surgical fixation, especially type IIa injuries with >4 mm distraction and/or >11 degrees of angulation.[15,76] Other fractures of the axis can include isolated fractures of the C2 vertebral body or fractures of the C2 spinous process or lamina, which are usually stable and can achieve good union with nonoperative immobilization.

Injuries of the Subaxial Cervical Spine (C3-C7)

Subaxial cervical spine injuries include fractures, dislocations, subluxations, and a combination of these injuries. Unilateral facet injuries can cause nerve root irritation and radiculopathy, whereas bilateral facet injuries frequently cause spinal cord compromise. Both unilateral and bilateral facet disruptions are treated initially with closed reduction with traction. If this reduction can be maintained, unilateral injuries can be definitively treated with halo immobilization. Bilateral facet injuries, however, are grossly unstable and require surgical fusion for definitive treatment.

Compression Fractures. Compression fractures are anterior column injuries with wedging of the anterior portion of vertebral body. The posterior portion of the vertebral body and the spinal canal remain intact. As a result, neurologic compromise is rare. These are generally stable injuries, but if angulation exceeds 11 degrees, wedge compression exceeds 25% of the anterior vertebral body, or translation exceeds 2.5 mm, brace immobilization may not be sufficient. If the anterior vertebral body wedge compression exceeds 50%, there is a greater likelihood that the posterior ligamentous complex has been disrupted. This unstable form of compression injury requires surgical stabilization.

Burst Fractures. Burst fractures are characterized by disruption of both the anterior and middle columns, have some degree of spinal canal compromise, and are commonly associated with neurologic deficit and instability. These injuries are caused by a large axial load applied to a cervical spine while in a straight position. If there is no neurologic deficit or malalignment, halo immobilization may be an acceptable treatment. If, however, neurologic deficit is present and/or reduction cannot be achieved, anterior decompression and fusion is indicated. Anterior and posterior stabilization may be required if there is associated posterior ligamentous injury.

Other Cervical Fractures. Other common cervical injuries include lateral mass fractures, laminar fractures, spinous process fractures, flexion tear drop fractures (Fig. 24.5), extension tear drop fractures, and ligamentous injuries. These are generally stable injuries except for flexion tear drop fractures, which result from a flexion–compression mechanism. In this very unstable fracture, all three columns are involved, and there is a high incidence of neurologic compromise. In contrast, extension tear drop fractures are a stable avulsion injury involving only the anterior column.

Injuries to the Thoracic Spine

Unlike the cervical and lumbar spine, the thoracic spine is inherently stable. As a result, thoracic spine fractures are usually caused by high-energy mechanisms, and associated injuries occur in about 75% of patients. Stable thoracic spine fractures without neurologic deficit can often be treated nonsurgically with bracing or vertebroplasty/kyphoplasty (Fig. 24.6). Unstable thoracic spine fractures are usually associated with neurologic deficit and malalignment and require surgical reduction and stabilization (Fig. 24.7).

Injuries to the Thoracolumbar Spine

Thoracolumbar spine fractures are extremely common due to the relatively mobile characteristics of this region compared to the adjacent rigid thoracic spine and sacrum. Fractures in this location include compression fractures, burst fractures, fracture–distraction injuries, and fracture dislocation injuries. Flexion–distraction injuries consist of both bony and ligamentous disruption without loss of vertebral height. Most of these injuries are treated surgically, especially if there is substantial disc or ligamentous involvement. Fracture dislocations consist

of varying degrees of rotation, flexion, and translation and are extremely unstable injuries. The majority of these injuries are associated with neurologic deficit, and require surgical decompression and stabilization (Fig. 24.8).

ACUTE SPINAL CORD INJURY

Mechanism of Injury

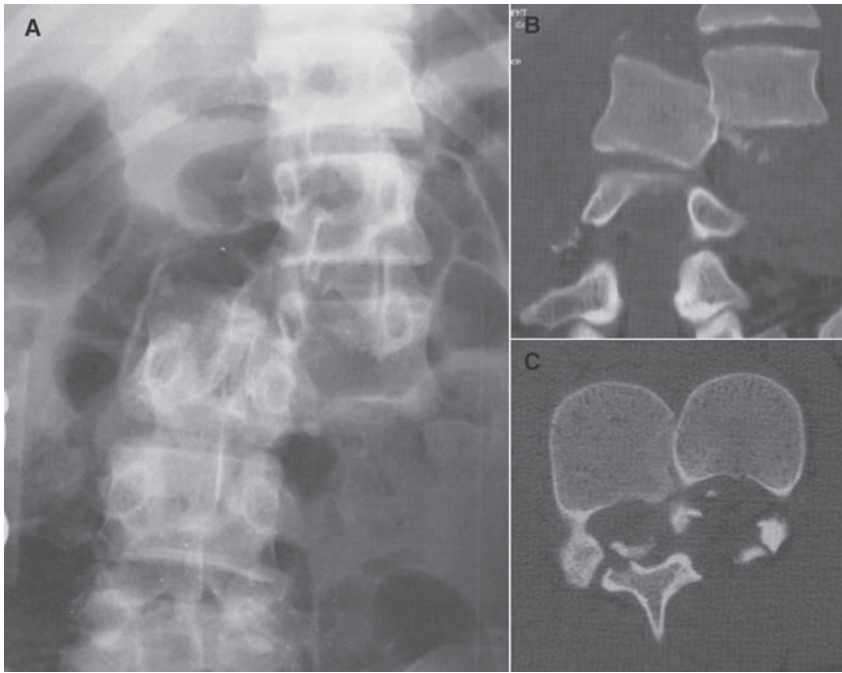
Based on the mechanism of injury, spinal cord injury can be categorized as direct/penetrating or indirect/blunt injuries. The direct or penetrating injuries are caused by a space-occupying lesion as a result of a focal injury to the neural elements at the site of impact (Figs. 24.9 and 24.10). These are most often caused by a gunshot wound or a knife laceration and most often result in complete neurologic deficit. The indirect or blunt injuries are caused by stretching, shearing, or compressive forces on the spinal cord (Fig. 24.11). These often occur in the setting of a motor vehicle accident, fall, or sport-related activity and are the most frequent type of spinal cord injury encountered in clinical practice.

Morphologic and Functional Changes

Spinal cord injuries can be further subclassified as primary or secondary injuries. Primary traumatic lesions are due to direct mechanical disruption of the cord parenchyma, typically occurring at the time of the injury. Secondary traumatic lesions evolve as a consequence of injury-related factors such as edema, ischemia, or mechanical injury from persistent pressure on the cord or improper immobilization. Although structural damage of neural tissue is irreversible, the prevention of secondary spinal cord injury is the major goal for early intervention in spinal cord injury.

The secondary events, triggered by the mechanical injury to the neural tissue, are a complex cascade of biomechanical and

TRAUMA
A
B

FIGURE 24.7 Noncontrast axial (**A**) and sagittal (**B**) CTs demonstrate an L1 burst fracture with retropulsion of bone fragments into the spinal canal.


cellular processes that are poorly understood. Several theories have been proposed to explain the pathophysiologic events of secondary injury such as the neurotransmitter theory (which implicates increased levels of the excitatory amino acids, glutamate and aspartate), free-radical theory (which implicates free radical accumulation), calcium ion theory (which implicates the influx of extracellular calcium ions), the inflammation theory (which implicates the accumulation of inflammatory mediators such as prostaglandins and leukotrienes), and others; in reality, the synergistic effect of all of these events most likely occurs.[16-19]

The gray matter, within the central substance of the spinal cord, is most susceptible to direct injury, due to the higher metabolic rate of gray matter and the presence of neurons, which are responsible for repair, existing within the site of injury. In contrast, the neuronal cell bodies of white matter are located at a remote site.[20]

Similar to the ischemic penumbra seen in strokes and closed head injuries, spinal cord tissue adjacent to the site of injury is at risk. Following initial injury, inflammation spreads throughout the adjacent areas of the cord, and neurogenic shock, manifesting as autonomic dysfunction, hypotension, and bradycardia, can develop further impairing spinal cord perfusion and increasing ischemia. Management strategies for neurogenic shock include resuscitation from hypovolemia as appropriate with crystalloids and blood or blood products, although the often profound hypotension of neurogenic shock may be refractory to fluid resuscitation alone. Therefore, the administration of pressors may be required with the goal of maintaining mean arterial pressure of 85-90 mm Hg for the first week after injury to improve spinal cord perfusion and prevent secondary injury. Pressors with intrinsic β1 agonist and chronotropic activity, including dopamine and dobutamine, may be particularly useful as they address not only the vasomotor component of neurogenic shock but also

the cardiogenic component. However, current recommendations are the use of neosynephrine in the management of these patients. Duration of pressor requirement in these patients is generally between 3 and 7 days but can extend as long as 14 days, and patients should be carefully monitored in an intensive care unit or other monitored setting until their hemodynamic status normalizes.[21]

Clinical Presentation

Presenting signs and symptoms vary depending on whether upper or lower motor neuron function is impaired. Patients with spinal cord injury often have symptoms of lower motor neuron injury at the level of the injured segment and upper motor neuron symptoms to all segments below the level of injury. Upper motor neuron signs and symptoms, such as spastic paralysis with inability for voluntary movement, increased deep tendon reflexes, loss of superficial reflexes, and positive Babinski sign and clonus, can occur from injury to white matter tracts within the spinal cord. Lower motor neuron signs and symptoms, such as flaccid paralysis with inability for voluntary movement, loss of all reflexes, and atrophy of muscles, can occur from injury to peripheral nerves and anterior horns of the spinal cord gray matter. Spinal shock, unlike neurogenic shock, is a transient state of physiologic reflex depression of cord function below the level of injury with an associated loss of sensory and motor function. Hallmarks of spinal shock include flaccid paralysis, bladder dysfunction, and occasionally sustained priapism. These findings can last from hours to days following injury until the reflex arcs below the level of injury resume function. Following spinal cord trauma, the presence or absence of the bulbocavernosus reflex, referring to anal sphincter contraction in response to squeezing of the glans of the penis or tugging on the Foley catheter, carries prognostic significance. Return of the bulbocavernosus reflex represents sacral sparing and may portend an improved outcome.

Severity/Grading of Spinal Cord Injuries

Numerous classification schemes have been devised to describe patients with spinal cord injury over the years. The first standardized neurologic assessment scale for spinal injury was proposed by Frankel and associates in 1969.[22] In this classification scheme, a five-grade scale ranging from A to E is used to grade spinal cord injury patients based on the degree of motor and sensory function preserved after injury. Frankel grade A patients have complete motor and sensory lesions with no

preserved function. Grade B patients have preserved sensory but no motor function below the level of injury. Grade C patients have some nonfunctional motor and some preserved sensory function. Grade D patients have functional, but not normal, motor function below the level of injury. Lastly, grade E patients have completely normal motor and sensory function. The Frankel scale provided an excellent framework from which several classification schemes have been derived. The main deficiencies of this scale were the difficulty in discerning grade C from grade D and relatively poor interobserver reliability. The American Spinal Injury Association (ASIA) Impairment Scale (Fig. 24.12) is one of the most studied and useful spinal cord injury neurologic classification schemes. It is a permutation of the original Frankel scale that provides objective parameters to better assess the significance of the preserved motor function.

Spinal Cord Syndromes

Central Cord Syndrome. Central cord syndrome is a common pattern of spinal cord injury occurring in older patients with preexisting cervical spondylosis who sustained a hyperextension injury. This injury involves the central portion of the spinal cord resulting in upper extremity greater than lower extremity motor and sensory deficit, due to the more central positioning of the upper extremity axons within the tracts of the spinal cord. The prognosis for recovery from central cord syndrome is fair, but patients may have some limited return of upper extremity function.[23]

Anterior Cord Syndrome. Anterior cord syndrome is caused by injury to the anterior two-thirds of the spinal cord. The mechanism of injury is usually a compression- or flexion-type injury that causes vascular injury. Patients present with complete loss of motor function and loss of sharp pain and temperature sensation but retain proprioception, vibration, and deep pressure sense. The prognosis for recovery is very poor.[24]

Brown-Sequard Syndrome. Brown-Sequard syndrome results from transection of one side of the spinal cord resulting in unilateral damage to the corticospinal and spinothalamic tracts. Patients present with loss of ipsilateral motor and dorsal column function, and contralateral pain and temperature sensation. Considerable improvement may occur with this syndrome.[25]

Posterior Cord Syndrome. Posterior cord syndrome involves the dorsal columns and is rare. It leads to loss of proprioception and vibration with preserved motor function. The prognosis is generally good.

Conus Medullaris Syndrome. The conus is usually located around the T11-L1 vertebral levels. Injury to the conus can result in a clinical picture with mixed upper and lower motor neuron symptoms. Injury in this region can also cause loss of bowel and bladder control. The prognosis for recovery is very poor.

Cauda Equina Syndrome. The cauda equina is composed of lumbar and sacral nerve roots. Injury to these nerve roots results in lower motor neuron symptoms with variable motor and sensory loss. Patients may also present with bowel and/or bladder dysfunction. The prognosis for motor recovery is good.

Clearing the Spine

Clearance of the cervical spine is a matter of some controversy, which has been addressed on three occasions by the Eastern

FIGURE 24.12 ASIA Standard Neurological Classification of Spinal Cord Injury worksheet. Reprinted with permission from American Spinal Injury Association: International Standards for Neurological Classification of Spinal Cord Injury, reprint 2008; Chicago, IL.

Association for the Surgery of Trauma Practice Management Guidelines committee, most recently in September 2009.[26] Removal of cervical collars should be accomplished as soon as feasible after trauma, to avoid the development of device-related complications. While all patients with blunt trauma should have a cervical collar placed prior to transport, in the patient with penetrating trauma to the brain, immobilization of the cervical spine is not necessary unless the trajectory suggests direct injury to the cervical spine. In fact, placement of collars following penetrating trauma has been associated with adverse outcomes in a number of studies.[27]

In the awake, alert trauma patients without neurologic deficit or distracting injury who have no neck pain or tenderness with full range of motion of the cervical spine, imaging is not necessary, and the cervical collar may be removed ("clinical clearance"). All other patients in whom cervical spine injury is suspected should have radiographic evaluation, including those with pain or tenderness, neurologic deficit, altered mental status, and distracting injuries. In a change from prior practice management guidelines, the primary screening modality in the multiply injured trauma patient has become axial CT from the occiput to T1 with sagittal and coronal reconstructions in place of plain radiographs. Formal spine consultation should be obtained for patients with identified fractures and patients with a neurologic injury attributable to the cervical spine. In the latter group, MRI is also recommended.[26]

Controversy persists regarding the management of the neurologically intact awake and alert patient complaining of neck pain with a negative CT examination. Options for further evaluation include imaging with MRI or adequate active flexion–extension films. For the obtunded patient with a negative CT and gross motor function of extremities, passive flexion/extension radiography should not be performed. Options for management in this patient population vary by institutional preference but include early MRI imaging, continued cervical spine immobilization until a clinical examination can be obtained, or removal of the cervical collar on the basis of the CT results only, recognizing a small risk of potentially unstable undiagnosed ligamentous injury may exist. A recent meta-analysis comparing CT alone to CT and MRI in the obtunded patient demonstrated that the addition of MRI identified injuries in 12% of patients, and changed management in 6% of patients.[12] If MRI is chosen as the management strategy, the collar may be safely removed if the MRI is negative.[26] A suggested algorithm for spine clearance can be found in Algorithm 24.1.

Clearance of the thoracic and lumbar spine follows similar guidelines. In the awake, alert trauma patients without neurologic deficit or distracting injury who have no back pain, tenderness or palpable step-off, imaging is not necessary, and the backboard may be removed. All other patients in whom thoracic or lumbar spine injury is suspected should have

Algorithm for Cervical Spine Clearance

¹Options include removing the collar without further imaging, recognizing a small incidence of missed injury; performing passive flexon/extention films (not recommended); or maintaining the cervical collar for 6 weeks, with the attendant risk of device related decubiti

TRAUMA

radiographic evaluation, including those with pain or tenderness, neurologic deficit, altered mental status, and distracting injuries. Plain anteroposterior and lateral radiographs are adequate for clearance of the spine, but are often difficult to obtain in the multiply injured trauma patient. Therefore, axial CT with sagittal and coronal reconstructions from images of the thoracic and lumbar spine obtained during abdominal and pelvic CT scanning has become an increasingly common method of thoracic and lumbar spine clearance.[28,29] All areas of bony abnormality identified on either plain or CT imaging studies should undergo further evaluation with dedicated CT imaging of the level in question. As with the cervical spine, MRI imaging should be considered in those patients with a neurologic injury attributable to their thoracic and lumbar spine.

Therapeutic Interventions

Pharmacotherapy in Spinal Cord Injury. The role for pharmacotherapy in the treatment of spinal cord injury is an area of controversy. The concept of neuroprotection has recently been coined to characterize those measures that might be utilized to attenuate the extent of spinal cord injury. The theory behind neuroprotective intervention is based on the premise that neurologic outcome can be improved by both the elimination of secondary injury mechanisms and by allowing damaged neural tissue to recover functionally.

One of the classes of drugs most heavily studied as neuroprotective agents is high-dose corticosteroids. Steroids effectively limit both cellular and molecular events of injury-induced inflammation, thereby theoretically decreasing the extent of secondary injury on neural tissue.[30] To date, high-dose methylprednisolone is the only steroid that has been tested as a neuroprotective agent in controlled multicenter clinical trials. The National Acute Spinal Cord Injury Studies (NASCIS-2 and NASCIS-3) recommend that methylprednisolone should be given as a bolus of 30 mg/kg over 15 minutes, followed by 5.4 mg/kg/h, and continued for 24 hours for patients within 3 hours of injury, and for 48 hours for patients within 3-8 hours of injury. Steroids should not be given for patients with penetrating injuries and patients who arrive >8 hours after injury.[31-36]

Recently, however, several studies have questioned the efficacy of methylprednisolone in the management of acute spinal cord injury. Although a number of retrospective trials questioned the efficacy of methylprednisolone, one randomized controlled study demonstrated no difference in functional recovery as defined by ASIA score with steroid administration.[37] Furthermore, concerns regarding several aspects of both NASCIS studies have been raised, including questions regarding the statistical analysis of the data and the documentation of the results.[38,39] In addition, several studies have documented an increase in complication rates in patients treated with methylprednisolone, including higher rates of pneumonia, longer hospital stays, pulmonary embolism, wound infection, gastrointestinal hemorrhage, and sepsis.[32,34,40,41] As a consequence of the above findings, recent guidelines for the management of spinal cord injuries states, "treatment with methylprednisolone for either 24 or 48 hours is recommended as an option in the treatment of patients with acute spinal cord injury that should be undertaken only with the knowledge that the evidence suggesting harmful side effects is more consistent than any suggestion of clinical benefit."[42]

Other neuroprotective agents have been tried with limited success, demonstrating only modest improvement in neurologic recovery following spinal cord injury.[43-45,77] For monosialotetrahexosylganglioside (GM-1) gangliosides,[19,20,46,78] tirilazad mesylate,[33,47] naloxone[44] and nimodipine,[48] more substantial evidence regarding their clinical efficacy is needed.

Hypothermic Management of Acute Spinal Cord Injury. Systemic hypothermia has been extensively studies as a neuroprotective agent following brain injury, stroke, and cardiac arrest. Local and systemic hypothermia has also been used as a spinal protective measure during aortic revascularization and replacement surgeries. Recently, attention was directed toward this novel management strategy following its use in a professional football player who sustained a C3/4 fracture dislocation with complete injury (ASIA A). Systemic hypothermia was utilized in association with early decompression, with subsequent considerable improvement in neurologic function (ASIA D).[49] Similar results have been reported by the Miami Project to Cure Paralysis at the University of Miami. Systemic hypothermia, with intravascular cooling to a temperature of 33°C maintained for 48 hours, in conjunction with early decompression and maintenance of mean arterial pressures >90 mm Hg, resulted in a 42.7% improvement in neurologic outcomes as compared to age- and injury-matched controls.[50] The safety demonstrated in this initial phase 1 trial, with apparent associated improvements in neurologic outcome may justify the pursuit of further phase 2 and 3 clinical trials.

Nonoperative Management of Spine Injuries. No definitive treatment algorithm has been universally accepted for the determination of whether a spinal injury should be treated operatively or nonoperatively. The surgeon must examine the injury in relation to neurologic impairment and structural integrity of both the osseous and the ligamentous components. One difficulty in treating spinal fractures is that the definition of instability is ambiguous because of the large spectrum of spinal disorders. The goal of treatment is neurologic recovery, prevention of neurologic decline and spinal deformity, and maximizing pain relief.

For most acute spine injuries, this can be accomplished nonoperatively, which usually consists of external immobilization. As most bony injuries have potential to heal with immobilization, nonsurgical management is often an acceptable definitive treatment for stable injuries without neurologic deficit. Major ligamentous injury, on the other hand, often requires surgery.

Cervical traction is often an initial treatment modality used to reduce spinal deformities, decompress neural elements, and provide cervical spine stability. Traction can be done using a head halter, tongs, or a halo ring. Cervical traction can begin with an initial weight of 10-15 pounds, which should be immediately evaluated with lateral radiographs. The traction weight is then incrementally increased by 5-10 pounds with lateral radiographs obtained 10-15 minutes after each incremental weight increase. Analgesia and muscle relaxants are often required to relieve muscle spasm. The maximum amount of weight that should be used is controversial; Crutchfield recommended a maximum of 5 pounds per level of cervical injury, in addition to 10 pounds for the head.[51]

Spinal orthoses are external braces that can restrict spinal motion and are a mainstay of nonoperative treatment of spinal trauma. Bracing of the cervical spine and thoracolumbar spine is challenging due to the considerable amount of normal movement. The inherent rigidity of the thoracic spine makes this region more amenable to bracing.

Conservative management of cervical injuries is usually achieved with rigid immobilization of the cervical spine with either rigid cervical collars, such as the Aspen collar or Miami J collar, and cervicothoracic orthoses, or with halo vests. Cervical collars provide good sagittal motion restriction in the upper cervical and subaxial spine. However, they are easy to remove and have variable rates of user adherence. Halo vests provide good upper cervical and subaxial sagittal motion

restriction. They also provide superior axial plane motion restriction compared to cervical collars. In addition, halo vests are secured to the skull and cannot be easily removed by users. Halo vests are associated with a higher morbidity and mortality rate, especially for elderly patients. For these reasons, halo vest use in the aging population, while sometimes unavoidable, should be approached with caution.

Adequate stabilization of the thoracolumbar and lumbar spine often requires extension of the brace to include as much as four or five levels proximal and distal to the unstable segment. Available thoracolumbar and lumbar orthoses include lumbosacral corsets, Jewett braces, and full-contact, custom-molded orthoses.

Surgical Management of Spinal Injuries. Unstable injuries, with or without neurologic deficit, requires surgical treatment. The goals of surgery include reduction of spinal deformity, restoration of stability, and decompression of neural elements. With modern-day techniques and technologies, spine surgeons can now approach the spine from nearly any direction: anterior, direct lateral, posterolateral, posterior, or any combination of these approaches. Posterior reduction and stabilization is the most frequently utilized approach for thoracolumbar spine fractures. The injury type and the time to surgical intervention determine the most appropriate approach.

The optimal timing of surgery following spinal injury is controversial. Progressive neurologic deterioration and unstable fractures with incomplete or no neurologic deficit are indications for immediate surgery. Early stabilization and mobilization of spinal patients has reduced the incidence of complications such as acute respiratory distress syndrome and deep venous thrombosis.[52]

PENETRATING SPINE TRAUMA

Thirteen percent of all spinal column are a result of gunshot wounds, the third most common mechanism of injury following motor vehicle crashes and falls. However, gunshot wounds are responsible for 25% of injuries to the spinal cord, second only to motor vehicle crashes.[53] Gunshot wounds can be devastating injures due to the high kinetic energy of the missile, and the cavitation that the missile creates during its passage through tissue. Neurologic injury results not only from the immediate trajectory of the bullet but also the concussive effects of the bullet's cavitating effects.[54]

The evaluation of any gunshot wound victim requires attention to the tenets of ATLS.[5] After stabilization and resuscitation, a detailed neurologic examination should be performed to determine the neurologic status of the patient as defined by ASIA Scale (Fig. 24.12). Concomitant injuries should be considered, particularly those of a vascular nature. Evaluation of the spine can be performed with either plain films or CT scan, or both depending on local practice paradigms. MRI is contraindicated due to the artifacts created by the missile fragment as well as their ferromagnetism.[55] Although most gunshot injuries to the spine are considered inherently stable, recent literature suggests that this may not be true, particularly for injuries to the cervical spine.[56] Postinjury administration of either steroids or prophylactic antibiotics is controversial, but neither is likely indicated, although consideration should be given to the administration of antibiotics in those patients in whom the bullet penetrates the gastrointestinal tract prior to injuring the spine.[57] Spinal cord decompression for neurologic deficit may be indicated only in the face of progressive neurologic deterioration, and is often complicated by an increased incidence of infection and cerebral spinal fluid fistula.[58]

COMPLICATIONS FOLLOWING SPINAL CORD INJURY

In discussing complications associated with spinal cord injury, it is important to differentiate between those that are related to the management of the injury and those that are systemic in nature. Acute complications, defined as those occurring within the initial hospitalization, range from hemodynamic instability to infections including pneumonia, urinary tract infections, and sepsis, as well as thromboembolic phenomenon. Many of these complications require preventive and/or prophylactic measures in order to reduce their occurrence in both the inpatient and outpatient settings.

Complications of spinal cord therapy have also been frequently reported. Most complications are a result of failure to achieve and maintain adequate reduction due to either poor bone quality or failures of instrumentation. Postoperative wound infections are also common after spinal surgery with a risk ranging between 1% and 6%. However, the most devastating complication is neurologic progression of the injury. This may be caused by several factors including direct neural injury during surgical repair or the development of a postoperative expanding epidural hematoma. Finally, cerebral spinal fluid leakage may complicate spine trauma surgery. This can be caused either by the initial injury or by iatrogenic laceration of the dura. Any injury identified intraoperatively should be repaired at the time of surgery. If the CSF leakage is identified postoperatively, treatment options include reoperation and repair, recumbency, and lumbar drains.

Systemic complications are also common after spinal cord injury. Pulmonary complications represent a significant cause of morbidity and mortality in both the acute and chronic setting. The majority of patients with high cervical spine injury will require prolonged mechanical ventilation and often necessitate tracheostomy. This is due to a lack of function of the ipsilateral phrenic nerve. Injuries of the lower cervical spine and upper thoracic spine similarly may cause respiratory failure due to a lack of innervation of the intercostal musculature, resulting in reduced lung volumes, intrapulmonary shunting, and decreased oxygen saturation.[59] The excessive use of analgesia and sedation can further depress respiratory function. In order to decrease the incidence of respiratory failure and subsequent pneumonia, early aggressive pulmonary toilet regimes should be implemented. Additionally early mobilization, if possible, serves to improve overall pulmonary function.

Another common systemic complication after spinal cord injury is venous thromboembolic phenomenon including deep venous thrombosis and pulmonary embolism. In the immediate postinjury population, there is a 500-fold increase in the risk of dying from a pulmonary embolism in the first month following injury when compared to both age and gender match controls.[60] Although this risk of venous thrombolic disease declines proportionally from time of injury, those with complete injury have a perpetually elevated risk due to immobility. For this reason, prophylaxis for at least 3 months following injury has been suggested as a standard of care in spinal cord injury patients.[61] The use of prophylactic regimens has been shown to reduce the risk of DVT following spinal cord injury. In the event that patients have contraindication to anticoagulation, inferior vena cava filters are recommended.

Spinal cord injury results in genitourinary complications. Alterations in detrusor motor functions and bladder sensation as well as compromised sphincter activity all play a role in incomplete bladder emptying. This results in the development of infection and elevated bladder pressures and contributes to the development of bladder and renal calculi. In order to limit these complications, a strict bladder regimen is recommended. While Foley catheters are recommended during the

intensive care unit course, intermittent clean catheterization is recommended every 4-6 hours with the goal of maintaining bladder volumes of <500 mL. Prophylactic antibiotics are not recommended. However, any suspected urinary tract infection should be treated.

As with all critically injured patients, stress ulcer prophylaxis to prevent the development of gastrointestinal hemorrhage is recommended. Standard prophylaxis with histamine-2 (H2) blockers or proton pump inhibitors (PPI) until gastric feeds have been initiated remains the standard of care. In the event that patients are fed directly into the small bowel, it is recommended that gastric prophylaxis with either an H2 blocker or a PPI continue. Development of an adynamic ileus is also common. Patients often require aggressive bowel regime including a combination of stool softeners, a high-fiber diet, intermittent digital stimulations, suppositories, and intermittent disimpaction.

In areas of bony prominence, in the setting of neurologic injury, the development of pressure ulcers is a major source of discomfort and a potential route of significant morbidity and mortality due to infection-related complications. The incidence of ulcerations requiring surgical debridement within two years of spinal cord injury is approximately 4%.[62] Early mobilization, protective devices including specialized mattresses, and frequent skin inspection are preventive measures for the development of decubiti.

Mortality following spinal cord injury can be divided into the acute and chronic phases. Despite advances in medical management, approximately 10%-20% of acute spinal cord injuries do not survive their initial hospitalization.[60] For those who do survive their acute hospitalization, the major cause of mortality is infection, often pulmonary in nature. Suicide is also a frequent cause of death in paraplegics, with higher rates in patients under the age of 25 at the time of injury. Spinal cord injury lowers patients' life expectancy with the average patient surviving only 30-40 years, depending on the level of injury.[63]

Novel Therapies for Spinal Cord Injury. Current strategies to restore motor functions after spinal cord injury include prevention of secondary damage, promotion of axonal regeneration, replacement of lost cells, training of central patterns generators (CPGs), and reduction in spasticity. Secondary lesional processes induce further death of neurons and myelinating oligodendrocytes.[64] Neurotropic/growth factors like brain-derived neurotrophic factor or neurotrophin-3 have neuroprotective properties and can limit secondary damage.[80] Riluzole, which reduces glutamatergic neurotoxicity, markedly enhances the survival of injured motor neurons, even after treatment delays.[65]

After incomplete lesions, progressive partial restoration of motor control can occur due to axonal sprouting.[66] The glial scar at the lesion site forms a physical barrier for regenerating axons, producing chondroitin sulfate proteoglycans that further inhibit axonal growth. Administration of chondroitinase ABC can promote plasticity and long-distance axonal regeneration of injured fibers, improving functional recovery after partial spinal cord injury in primates.[67] Elevation of intracellular levels of cAMP in adult neurons, by means of db-cAMP and/or rolipram, is neuroprotective, promotes axonal regeneration, and improves functional recovery.[68] Finally, some endogenous metalloproteinases seem to promote angiogenesis, neuroprotection, neurogenesis, and remyelination.[69]

The previously described strategies work only when the two ends of the spinal cord remain in proximity with one another. For larger defects, the gap may be bridged using peripheral nerve segments, or Schwann cell transplants, which can also facilitate remyelination of injured axons.[70] Cell replacement strategies also exist. Transplantation of human spinal cord stem cells into the rat spinal cord after injury following directed differentiation to oligodendrocyte lineage prior to transplantation increases remyelination.[71] Adult autologous bone marrow stromal cells, transdifferentiated prior to transplant, will migrate to the site of spinal cord injury after systemic injection, and promote axonal regeneration.[72]

Stimulation of the neuronal network responsible for the rhythmic movements underlying locomotion (the central pattern generator) with pharmacologic or electrical stimulation and locomotor training has shown promise. Serotonin pathways have shown particular promise in this area and may be capable of reactivating the CPG.[73] Training, using manually assisted stepping by therapists or robotic devices, is also effective in humans with clinically complete spinal cold injury, resulting in increased electromyography (EMG) activity in the ankle extensor muscles and increased weight-bearing function.[14] Restoration of postural control is also extremely important for recovery of locomotor function after spinal cord injury. Postural corrective movements are typically absent when the ventral cord is injured, but recover within 2 weeks if the dorsal cord is injured. Tilt table training, with or without the intrathecal administration of serotonin at the lumbar level, increases correctly phased EMG responses.[74]

Combinations of the above strategies have resulted in clinical improvement in spinal cord–injured patients. There is at least one report in the literature documenting improvements from an ASIA A to an ASIA D classification, resulting in the ability of patients with spinal cord injury to stand up and walk with varying degrees of effectiveness.[75]

TRAUMA

FRANCIS L. COUNSELMAN AND SHANNON M. McCOLE

Hippocrates was the first person to record the association between facial trauma and blindness.[1] Trauma is responsible for bilateral blindness in more than one million people worldwide; unilateral blinding injuries have an estimated incidence of 500,000 cases each year.[2] It is estimated that ocular trauma represents 3% of all emergency department visits in the United States.[3] In the United States alone, there are approximately 900,000 cases of occupation-related eye injury each year.[4] The majority of patients are male (75%–83%) and young (median age of 27–31-years old)[5–7] The most common cause of orbital fractures is motor vehicle accidents and assaults. Sports-related injury, especially basketball and baseball, is also a common cause of ocular trauma.[8] While many eye injuries are minor in nature, some require urgent evaluation and management and even immediate surgical intervention to preserve sight (Table 25.1).

HISTORY

A thorough history should be obtained, including the timing and specific events surrounding the injury. A history of grinding or hammering raises the risk for the presence of a foreign body. Important questions regarding ocular history include past visual acuity, need for corrective glasses or contact lenses, and history of glaucoma or cataracts. Specifically inquire about visual symptoms, including change in vision, floaters, flashing lights, pain, discharge, or diplopia.[3] Previous ophthalmic surgery (i.e., radial keratotomy and lens implant) may make the eye more susceptible to injury. A past medical history of hematologic disorders (i.e., sickle-cell disease or trait), coagulopathy or use of anticoagulation medications (i.e., warfarin and enoxaparin) increases the risk of bleeding complications, especially in hyphema and retrobulbar hemorrhage. Tetanus immunization status and medication allergies should be elicited.

PHYSICAL EXAMINATION

External Exam and Motility Exam

A general observation should be made for overt abnormalities or defects of the periorbital region and lids. Any evidence of enophthalmos (one eye appearing further back than the other) or proptosis (one eye more anterior than the other) should be noted, as this may indicate damage to the bony orbits. Eyelid position and function, along with any evidence of damage such as lacerations, contusions, or edema should be noted. Pay special attention to any injury that may involve the canalicular region (medially). An observation of the entire ocular surface can be performed by holding the lids open while asking the patient to look up, down, left, and right. The bony structures should be palpated to help identify fractures. Examine for any sign of hemorrhage or foreign body on the surface of the globe. Do not place pressure on the globe if a perforating injury is suspected (see Fig. 25.1).

Assess extraocular movements by having the patient look in all eight cardinal positions, noting eye alignment and smoothness of pursuit, while asking the patient to report any diplopia or pain. Abnormalities may be indicative of muscle entrapment or orbital hemorrhage, which may require urgent intervention.

Visual Acuity

The traditional way to test visual acuity is to have the patient read the Snellen chart at 20 feet. Each eye should be tested individually and then together. If eye pain is present, placing a drop or two of topical ophthalmic anesthetic can greatly facilitate obtaining an accurate visual acuity. See Table 25.2 for the list of medications. Each eye is then assigned a two-digit score (i.e., 20/50).[9] The first number is the distance between the patient and the chart; the second number refers to the smallest line the patient is able to read. If the patient wears corrective lenses, they should be allowed to use them (but document it). For patients who do not have their corrective lenses or their vision is altered, visual acuity should be tested using a pinhole. A pinhole corrects for most refractive errors by ensuring that only light striking the lens perpendicularly reaches the retina.[10] If the visual acuity corrects with a pinhole, the problem is likely due to refractive error. If it does not correct, the problem is usually more serious.[10]

For patients who cannot read English, a tumbling E chart may be used, in which the patient identifies the orientation of the letter E (i.e., facing right, facing up).[9] For patients confined to the supine position, a near-vision card can be used, held 14 inches from the patient's face.[9] For patients who cannot read the Snellen chart or near-vision card, the patient should be asked to count the examiner's fingers at a distance of 2 feet. If the patient is unable to count fingers, assess the patient's ability to detect hand motion from a distance of 1–2 feet. Finally, if unable to detect hand motion, test for light perception. Turn off all lights in the room, completely cover the eye, and test for light perception.[9,11] If the patient is unable to detect light, then that eye is considered completely blind.

Pupils

First, perform a general observation of the pupils in ambient room light, noting the shape and size of each pupil while having the patient focus on a distant target. With room lights dim, re-examine the pupils using as little light as possible, noting: shape, size, symmetry, and direct and consensual reaction to light. A relative afferent pupillary defect (RAPD) can be assessed with a rapid swinging light technique while observing the pupils. If the lids are swollen, it may be necessary to have an assistant gently hold the lids open to assist in the examination. A RAPD indicates damage to the anterior visual pathways (optic nerve or retina).

Slit Lamp Examination

The slit lamp is a three-part machine, consisting of a table-mounted binocular microscope with an attached special adjustable light source and a patient headrest.[12] Magnification can be adjusted from 6× to 16×. For the examination,

TABLE 25.1

EMERGENT AND URGENT OPHTHALMOLOGIC INJURIES

Ophthalmic conditions requiring immediate surgical intervention
Corneal laceration
Suspected open globe
Intraocular foreign body

Conditions requiring urgent evaluation and treatment
Chemical burn
Hyphema
Retrobulbar hemmorrhage
Sudden decreased vision

TABLE 25.2

COMMONLY USED MEDICATION IN OPHTHALMOLOGY

I. Topical local anesthetics/white caps
  1. Proparacaine 0.5% solution
    One drop; rapid onset; 10–20-min duration
  2. Tetracaine 0.5%
    One drop; rapid onset

II. Mydriatic and cycloplegic agents (for dilation)/red caps
  1. Phenylephrine 2.5% and 10%
    One drop; max effect 20 min; 3-h duration
  2. Tropicamide 0.5% and 1%
    One drop; max effect 20–30 min; 3–6-h duration
  3. Homatropine 2% and 5%
    one drop; max effect 20–90 min; 2–3-d duration
  4. Atropine 0.5%, 1%, and 2%
    One drop; max effect 30–40 min; 1–2-wk duration

III. Antibacterial agents/tan cap
  A. Sulfonamides
    1. Sulfacetamide 1%, 10%, and 30%; ointment 10%
      Dose q3–4 h
  B. Fluoroquinolones
    1. Ciprofloxacin 0.3%; ointment 0.3%
      Dose at least QID
    2. Ofloxacin 0.3%
    3. Levofloxacin 0.5%
    4. Gatifloxacin 0.3%
    5. Moxifloxacin 0.5%
      Dose up to 6/d
  C. Aminoglycoides (for pseudomonas)
    1. Tobramycin 0.3%
    2. Gentamicin 0.3%
  D. Others
    1. Erythromycin 0.5%
    2. Polymyxin B/trimethoprim
      Dose up to 6/d

IV. Nonsteroidal anti-inflammatory agents
  1. Diclofenac 0.1%
    Dose QID
  2. Ketorolac 0.5%
    Dose QID

V. Treatment for increased IOP
  A. Alpha agonists
    1. Apraclonidine 0.5% and 1%
      Dose TID
    2. Brimonidine tartrate 0.15%
      Dose TID
  B. Beta-adrenegic antagonists
    1. Timolol maleate 0.25% and 0.5%
      Dose BID
    2. Timolol hemihydrate 0.25% and 0.5%
      Dose BID
    3. Betaxolol 0.5%
      Dose BID
  C. Miotics/green tops
    1. Physostigmine 0.25% and 0.5%
    2. Pilocarpine hydrochloride 0.25%

VI. Corticosteroids
  1. Prednisolone acetate 0.12%, 0.125%, or 1%

Adapted from Ehlers JP, Shah CP, Fenton GL, et al. *The Wills Eye Manual: Office and Emergency Room Diagnosis and Treatment of Eye Disease.* 5th ed. Philadelphia, PA: Lippincot Williams & Wilkins; 2008 with permission

the patient is seated, and the chin is placed on a padded rest with the forehead pressed firmly against the forehead bar. The chin rest should be adjusted, so that the patient's eyes rest at the level of the marker on the vertical poles of the slit lamp.[10] The height of the slit lamp is adjusted, so that the light beam is centered on the patient's eyes. The light source has several adjustments, which allow the beam to be varied from a narrow slit to a wide beam, from short to long, and from dim to bright.[12] Most slit lamps allow for changing the filter on the beam, from neutral to cobalt blue (for evaluation of flourescein staining) and red free.[10]

The examiner should adjust the diopter rings on the ocular piece to account for their individual refractive error and accomodation.[10] It is the examiner's choice to wear their corrective lenses. The patient should be asked to focus on a fixed object (i.e., examiner's ear). The light beam should be at 45 degree from the patient–clinician axis, using a low-voltage, wide beam. Using the lowest magnification level, the joystick is used to move the device on the chassis until focused.[10] Once the eye is in focus, the examiner should conduct a systematic examination of the individual structures. Typically, start with the most external structures (i.e., eyelids and eyelashes) and work deeper, culminating in examination of the anterior chamber (looking for blood, cells, flare, etc.). Magnification can be modified as needed.

FIGURE 25.1. Ocular anatomy as seen when examining a patient.

Flourescein Staining

Flourescein staining should be performed in all patients with ocular trauma. The only absolute contraindication is flourescein allergy.[10] To do this, the eye should be anesthetized first, and then a few drops of sterile saline placed in the eye to moisten it. The fluorescein strip is then placed on the conjunctiva of the eye, and the patient is asked to blink several times to distribute the dye in a thin film over the entire eye.[10] The lights should be turned low/off, and the eye examined with a cobalt blue light (i.e., hand-held, Wood's lamp, or using the slit-lamp). Injured epithelium (i.e., abrasion) will appear yellow green. The location of the abrasion should be documented, normally using the clock method (i.e., 3-mm linear abrasion at 7 O'clock). A variation of this, called the Seidel test, can be performed when a full thickness corneal disruption or open-globe injury is suspected. For this test, a large amount of flourescein dye is placed on the eye, causing the entire eye to appear orange. Then, with the lights out, the globe is examined for a dark stream interrupting the flourescein, indicating leakage of aqueous humor and a globe rupture.[10]

For this to be best observed, the patient needs to be in an upright (i.e., seated) position (see Fig. 25.2).

Tonometry

Tonometry is the measurement of intraocular pressure (IOP). Normal IOP is between 10 and 20 mm Hg. The most common condition for low IOP in the setting of trauma is perforating globe injury with loss of aqueous fluid. However, if a perforated globe is suspected, tonometry should not be performed because of the possibility of causing further extrusion of intraocular contents. High IOP (i.e., >30 mm Hg) in the setting of orbital trauma is commonly observed in hyphema, anterior lens dislocation, or retrobulbar hemorrhage. A baseline IOP should be measured in all patients with blunt orbital trauma, except in the case of suspected globe rupture or perforating globe injury.

The most common tools used for performing tonometry are a portable hand-held device (i.e., Tonopen) or the older Schiotz tonometer. The hand-held device is digital, has good interexaminer reliability, and can be used with the patient in any position. The Schiotz tonometer requires the patient to be in the supine position. Both methods determine IOP by
FIGURE 25.2. A positive Seidel test in a patient with a full-thickness corneal laceration. Note the downward streaming of aqueous humor. (Reprinted with permission from Ehlers JP, Shah CP, Fenton GL, et al. *The Wills Eye Manual: Office and Emergency Room Diagnosis and Treatment of Eye Disease.* 5th ed. Philadelphia, PA: Lippincot Williams & Wilkins; 2008.)

measuring the amount of corneal indentation produced by a certain amount of force. Both methods also require the eye to be anesthetized and the patient cooperative. It is best to repeat measurements several times in order to obtain a reliable reading.

Direct Fundoscopic Exam

The direct ophthalmoscope allows a fundoscopic examination with approximately 15× magnification. Since the examiner performs the exam using only one eye, the view is not stereoscopic. Although a view may be obtained through a small pupil, pharmacologic dilation will enhance the view. The instrument field of view is limited to about the equator, making it inappropriate for a full peripheral funduscopic examination. The examination is performed with the eye that corresponds to the eye being examined. The focusing lens is rotated to the examiner's refractive error or starting at zero and rotating until fundus details come into view. Focus first on a blood vessel and then trace it back to the optic nerve, noting color, clarity of disc margins, and cup to disc ratio. Note any abnormalities such as hemorrhages, exudates, or pigment changes.

IMAGING IN OCULAR TRAUMA

The decision for imaging patients with suspected ocular trauma should be guided by the mechanism of injury, clinical presentation, and physical examination. Frequently, the history and physical exam may be limited due to the severity of the injury, associated injuries, and/or facial swelling. The decision on which imaging study to order will depend on resource availability, local practice and custom, and the type of injury suspected. That said, computed tomography (CT) is considered the imaging study of choice in the evaluation of orbital trauma.[3,13]

Radiographs

Radiographs are being used less frequently. While the sensitivity of radiographs for detecting fractures is 64%–78%, it is very poor in identifying orbital content injuries.[14] Radiographic findings suggesting fracture include an air-fluid level in, or opacification of, the maxillary sinus (from bleeding secondary to an orbital floor fracture) and the tear drop sign (orbital contents herniating into the maxillary sinus due to an orbital floor fracture). If there is a low suspicion for metallic orbital or intraocular foreign body (IOFB), a Water's view x-ray may be a cost-effective test. However, if the pretest probability is high or the suspected foreign body is nonmetallic, radiographs play no role.

Ultrasound

Ultrasound has been used in the evaluation of the multitrauma patient for some time. It is now being increasingly used for the evaluation of ocular trauma. Ultrasound can be performed directly at the bedside and is fast, safe, noninvasive, and avoids the use of ionizing radiation. Ocular sonography has been shown to be used successfully by nonradiology and nonopthalmology physicians.[15]

A high-resolution linear array 10 MHz transducer (or vascular probe) should be used. The output and gain should be minimized to prevent image distortion by eyelid echos and to maximize image quality.[16] The eye should be closed,

ultrasound gel applied, and scanned in the sagittal and transverse plains. Injuries identified by ultrasound include retrobulbar hemorrhage (hypoechoic lucency deep to the retina), lens dislocation (abnormal position of the lens within the globe), vitreous hemorrhage (echogenic material within the vitreous body), IOFB (echogenic foreign body visualized within the globe), and globe rupture (difference in globe size between the eyes).[16] There is some controversy regarding the role of ultrasound in evaluating suspected globe rupture. It appears that the majority of experts feel that ultrasound is contraindicated in suspected globe rupture due to potentially causing extrusion of intraocular contents.[3,13,17] Those in favor of ultrasound recommend placing a large amount of ultrasound gel over the closed eye, so that the probe never actually exerts pressure on the eye.[16] Regardless, if there is an obvious anterior perforation, ultrasound should not be performed.

Computed Tomography

CT is considered the standard imaging modality in the evaluation of mid-face fractures and orbital trauma.[3] Typically, thin slices (i.e., 1 mm) with multiplanar reformation has the best results.[11,13] The sensitivity of CT for orbital fractures is 79%–96%, with a lower sensitivity for infraorbital rim injury.[18] CT identifies open-globe injuries with a sensitivity of approximately 71%.[19] Findings suggesting open-globe injury on CT include a change in globe contour, an obvious loss of volume, a deep anterior chamber, scleral discontinuity, and intraocular air.[13] The sensitivity of CT for detecting clinically occult open-globe injuries is slightly less, varying from 56% to 68%.[13] When an IOFB is suspected, CT is usually the study of choice. It can demonstrate metal fragments <1 mm in size.[13] It is also the best study for detecting glass, compared to US and magnetic reasonance imaging (MRI). Glass fragments of at least 1.5 mm diameter are detected 96% of the time and 48% for glass fragments 0.5 mm in size.[20] Other injuries detected by CT include corneal laceration (decreased volume of the anterior chamber with decreased anterior–posterior dimension compared to normal globe) and lens displacement/dislocation (abnormal lens position).

Magnetic Resonance Imaging

Given the limitations of MRI, including availability, contraindications (i.e., presence of metal), and length of imaging time, MRI is not recommended as the initial imaging modality in orbital trauma. Currently, it is most useful in identifying intraorbital wood or organic material when CT results are either negative or equivocal.[3,13]

CORNEAL ABRASION

Patients will present with pain, foreign body sensation, photophobia, and tearing. Frequently, there is a history of trauma, but sometimes the patient does not recall any specific event. Placing a drop of topical ophthalmic anesthetic in the affected eye will allow for a more efficient history and physical examination. The immediate pain relief following placement is characteristic of corneal abrasion. Physical exam reveals conjunctival injection, tearing, and decreased visual acuity if the abrasion is large or lies within the visual axis. Fluorescein staining and examination under the slit lamp or use of a cobalt-blue light will reveal fluorescein uptake if there is an epithelial defect. The size and location should be documented. The anterior chamber should be examined for cells, flare, and blood. Always examine the eye carefully for the presence of

foreign bodies, including everting the upper and lower eyelids. Treatment includes the use of cycloplegics to decrease ciliary spasm (and pain), topical ophthalmic antibiotic ointment, and analgesia (see Table 25.2). Pain may be managed with topical or po nonsteroidal anti-inflammatory medications or a short course of po narcotics. Patching the eye has been shown to offer no benefit for simple corneal abrasions and should not be used.[21] Never give or prescribe the patient topical anesthetic agents, as their repetitive use will cause ocular toxicity. Because contact lens wearers are at risk for pseudomonas infection, topical ophthalmic tobramycin ointment should be used in these patients. Patients with corneal abrasions should be instructed not to wear their contact lenses until the abrasion is completely healed. All patients should be re-examined within 24 hours.

CORNEAL FOREIGN BODY

For a corneal foreign body, the presentation, evaluation, and management (after foreign body removal) are similar to corneal abrasion. Patients complain of foreign body sensation, pain, photophobia, and tearing. Vision may be affected if the foreign body is large or within the visual axis. Similar to corneal abrasion, placement of a drop or two of topical ophthalmic anesthetic will facilitate the history and physical examination. Foreign bodies are frequently visible without magnification; however, if available, a slit lamp exam should be performed. Examine the eye closely for any other injuries. Make sure to evert the lids to inspect for foreign bodies. The majority of corneal foreign bodies are superficial and can be safely removed in the ED. Full thickness corneal foreign bodies require ophthalmology consultation. Foreign bodies are best removed under slit lamp magnification. A 27-gauge needle on the end of a tuberculin syringe or a moistened Q-tip will usually work well in removing the foreign body. Both eyes should be anesthetized to decrease reflex blinking. During removal, the patient's forehead should be pressed firmly against the slit lamp, the lids held open with the physician's nondominant hand, and the dominant hand (holding needle or Q-tip) should rest against the bar of the slit lamp machine to stabilize it. Using the bevel of the needle, the motion should be a gentle scraping motion, away from the patient, and parallel to the eye.

Corneal rust rings are a complication of metallic foreign bodies. If the rust ring is superficial, not over the visual axis, and an ophthalmic burr is available, removal can be attempted. All patients should be referred for ophthalmologic follow-up within 24 hours. Rust ring removal is actually easier the following day due to corneal edema and anterior displacement of the foreign material.

Postremoval treatment includes cycloplegics, ophthalmic antibiotic ointment, and analgesia, as in corneal abrasion. If the foreign body is organic (i.e., plant or vegetable material), a topical ophthalmic fluoroquinolone should be used (see Table 25.2).

CHEMICAL INJURIES

The spectrum of injuries to the eye caused by exposure to chemicals varies from mild to very severe with potential blindness. The most common agents include alkalis (i.e., lye, plaster, cement, airbag powder or agents containing ammonia, sodium hydroxide, or lime), acids (sulfuric, sulphurous, hydrofluoric, acetic, chromic, and hydrochloric), solvents and detergents, and cyanoacrylate (superglue).[22] We will discuss cyanoacrylate injury separately.

The severity of the chemical injury is related to the properties of the chemical, the duration and extent of exposure,

and other concomitant injuries to the eye, including thermal exposure. In general, alkali injury is more severe than acid. Alkali injuries are especially damaging due to rapid, deep tissue penetration; complete corneal opacification and melting can occur. Acid burns cause denaturation of tissue proteins, which then acts as a barrier to further penetration, thus limiting their damage.[23] Solvents and detergents typically result in chemical conjunctivitis.

Conjunctival and eyelid hyperemia, chemosis (conjunctival swelling/edema), and corneal punctuate epithelial defects are frequently observed in mild injuries. Conjunctival hyperemia or blanching (due to limbal ischemia), corneal haze, or opacification can be observed in severe cases.

Treatment should be instituted immediately and without delay, even before obtaining a visual acuity or pH testing. The only exception is in the case of a suspected open-globe injury, in which further damage may be caused by the force of irrigation.

A topical anesthetic should be placed into the eye along with an eyelid speculum. The treatment involves copious irrigation of the corneal surface with normal saline or Ringer's lactate (preferred) for at least 30 minutes. This can be performed by attaching IV tubing to the irrigation solution and directing the flow of fluid into the eye. Tap water irrigation can be used if these solutions are unavailable. The upper and lower lids should be everted and inspected for retained particulate, which should be removed if present and then copiously irrigated. After 30 minutes of irrigation, wait 5–10 minutes and then check the pH by placing litmus paper in the inferior fornix. Irrigation should then continue until a neutral pH of 7.0 is reached. The volume of irrigation fluid and time needed to reach neutral pH varies widely and may involve as much as 8–10 L of irrigation.[24]

Cyanoacrylate (i.e., Super Glue and Krazy Glue) in the eye is managed differently. The most common injury following cyanoacrylate administration into the eye is a corneal and/or conjunctival abrasion. Cyanoacrylate bonds only with dry surfaces; therefore, fusion of the upper and lower lids occurs predominantly through bonding of the eyelashes.[25] Collections of hardened glue particulate will tend to occur in the inferior fornix. Periocular skin irritation and dermatitis can also occur.

Initial management includes attempting to remove any loose glue stuck to the lashes and to gently open the eye. The use of ophthalmic ointment gently rubbed into the lashes may facilitate glue removal, especially if it is allowed to penetrate before attempting to mechanically remove loose glue. Avoid use of alcohol or other solvents. Cutting of the lashes may be necessary to open the eye. The eye should then be irrigated with normal saline or Ringer's lactate for at least 15 minutes. Topical anesthetic and fluroscein should be used to aid in inspection of the cornea for any abrasions or glue debris, which should be removed. The upper and lower forniceis should be inspected for retained glue particulate. Any associated corneal abrasion or persistant glue on the lashes can be treated with ophthalmic antibiotic ointment. Most reported cases suggest spontaneous separation of the upper and lower lids will occur within 1 week from initial application of cyanoacrylate.[25] Associated dermatitis can be treated with periocular skin lubrication, such as ophthalmic ointment. Cycloplegic agents may be used to increase patient comfort in the case of associated ciliary spasm or photophobia. Patients with corneal involvement should have ophthalmic follow up within 24 hours.

CONJUNCTIVAL LACERATIONS

Lacerations of the conjunctiva are usually associated with intraocular foreign bodies or scleral perforation.[3] For these reasons, it is important to exclude a ruptured globe. Conjunctival lacerations may appear as a conjunctival defect or presence of fat. Slit lamp examination will usually be necessary to differentiate superficial from deep lacerations. Superficial lacerations <1 cm in length do not usually require repair and will normally heal quickly.[3] Lacerations >1 cm should be repaired by ophthalmology, normally using 6–0 to 8–0 absorbable sutures. All patients should be treated with prophylactic antibiotic ointment or drops.[3]

LID LACERATIONS

The upper and lower eyelid skin is very thin, with minimal dermal tissue. Directly under the skin and dermis is the orbicularis muscle, responsible for eyelid closure. The muscle completely surrounds the lid fissure and is attached medially and laterally by the medial and lateral canthal tendons, which are adherent to the orbital rim. The orbital septum extends from the orbital rim and attaches superiorly to the levator aponeurosis and inferiorly to the lower lid retractors. The orbital septum separates the lid from the underlying orbital fat. The tarsus is the dense connective tissue deep to the orbicularis muscle, which gives the lid rigidity. Conjunctiva lines the lids and lid fissures and is continuous over the surface of the globe (see Fig. 25.1).

Multiple mechanisms of injury may result in laceration of the eyelid. It is critical that the patient presenting with a lid laceration be meticulously examined for the possibility of concurrent injuries such as canalicular lacerations, corneal or sclera lacerations, orbital wall fractures, an intraocular or embedded foreign body or injury to the extraocular muscles. Beginning with the external examination, an attempt should be made to ascertain the depth of the injury. If orbital fat is prolapsed through the wound, the orbital septum has been violated, and the fat will require repositioning. The presence of orbital fat at the wound should alert the practitioner to the possibility of deeper injuries involving the globe. In cases of possible high-velocity fragment injury, one should suspect penetration into the eye or perforation into the globe and obtain CT imaging. A foreign body should only be removed if there is no evidence of deeper extension into the globe or orbit.

Avulsion of the canalicular apparatus, which is medial, can occur with lateral traction injuries to the eyelid; this can commonly be seen in assault and dog-bite injuries. These injuries will require specialized surgical intervention to repair the lacrimal drainage system and prevent chronic tearing and lid malposition.

The presence of ptosis in a patient presenting with a lid laceration may indicate injury to the underlying levator muscle. Such injuries may require subsequent surgical intervention following initial repair in order to restore lid function. Cleansing of lid wounds should be performed using povidone–iodine 5% solution, only after the integrity of the globe has been established.

In extensive lid injuries in which closure of the eye is affected or when surgical repair needs to be delayed, saline-soaked dressings should be applied to the area to promote viability of the tissue.

For repair of lid lacerations, general anesthesia is used in children and in uncooperative adults. Otherwise, local anesthesia is used in adults (2% xylocaine with epineherine 1:100,000). Because direct injection of local anesthetic causes tissue distortion and bleeding, use the minimal amount of anesthetic necessary to obtain adequate pain control. Make sure that there is no injury to the globe before attempting eyelid repair. Place a drop of topical anesthetic into the eye to facilitate patient comfort. The wound should be irrigated thoroughly with normal saline or Ringer's lactate.

Use toothed forceps or cotton-tipped applicators to gently open the edge of the wound to determine depth of penetration. The lid tissue should be realigned and repaired in layers. Any injury involving the lid margin or canalicular region will require specialized repair by an ophthalmologist or surgeon specialized in lid anatomy and surgical procedures. Lid margin injuries require precise apposition of tissue to prevent lid notching. If the tarsus is involved, use 5–0 absorbable sutures.[26] Extreme care must be taken to avoid injury to the underlying globe. A corneal shield can be placed to avoid such injury, although it can make the repair more difficult due to its bulk and distortion of tissue. The orbicularis/deeper tissue can be repaired using 6–0 interrupted vicryl sutures, and the skin closed using 6–0 interrupted silk or nylon sutures. Care should be taken to evert the wound margin to avoid depressed scars. In some cases, where patient follow up may be limited, or in the case of children when it may be desirable to avoid suture removal, the skin may be closed with 6–0 fast absorbing gut or vicryl suture. Topical ophthalmic antibiotic ointment is applied to the wound. Generally, silk or nylon sutures are removed within 5–7 days. Contaminated injuries should be treated with systemic antibiotics: dicloxacillin or cephalexin, 250–500 mg PO QID in adults and 25–50 mg/kg/d divided into four doses for pediatric patients.[26] In animal bite injuries, infection and rabies prophylaxis require consideration.

TRAUMATIC HYPHEMA

Hyphema is defined as blood in the anterior chamber. In urban settings, two-thirds of traumatic hyphema are due to blunt ocular trauma and one-third due to traumatic globe rupture.[27] The source of bleeding is usually from the iris or ciliary body. The amount of blood present in the anterior chamber determines the grade of the hyphema: grade 0—microhyphema with red blood cells detected only by slit-lamp examination; grade 1—blood occupying less than one-third of the anterior chamber; grade 2—blood filling one-third to one half; grade 3—one half to less than total; and grade 4—chamber filled completely with blood (also known as an eight ball).[3] The majority of hyphemas are grade 1 (see Fig. 25.3).

Patients will present with complaints of pain, photophobia, and decreased visual acuity. The hyphema is usually visible as a meniscus in the anterior chamber (with the patient's head upright) on gross exam. If possible, however, all patients should undergo slit-lamp examination to evaluate for other possible injuries (i.e., globe rupture) and to better estimate the size of the hyphema. The following factors are associated with a good prognosis: small size (i.e., height < 4 mm, measured from the inferior 6 O'clock limbus), light red color of the blood, and normal IOP.[28]
Recurrent bleeding and elevated IOP are the two most serious complications of hyphema. Frequently, there is a moderate elevation (<24 mm Hg) in IOP after the injury due to mechanical obstruction of the trabecular meshwork from blood.[28] Recurrence of hemorrhage usually occurs between the 3rd and 5th day postinjury and is secondary to normal blood clot dissolution. The incidence of rebleeding is variable (0.4%–38%).[28] Risk factors for rebleeding include large hyphemas (greater than one-third of the anterior chamber), sickle-cell disease/ trait, anticoagulant medication, and elevated IOP on initial exam.[28,29] Management involves elevating the patient's head, placing a metal shield over the eye (not patch), topical ophthalmic atropine 1% one drop tid to the affected eye and ophthalmic prednisolone acetate 1% one drop QID.[11] If increased IOP is present (i.e., >30 mm Hg), administer a topical beta-blocker (i.e., timolol 0.5% one drop). If the IOP remains elevated, give 1 g/kg mannitol IV and po or IV acetazolamide 500 mg. However, if the patient has sickle-cell disease/trait, acetazolamide is contraindicated. Patients with small hyphemas (less than one-third of the anterior chamber) and normal IOP may be treated as an outpatient with close and reliable follow-up; all others should be admitted. Avoid aspirin and nonsteroidal anti-inflammatory drugs for pain control because of their antiplatelet effect, which can increase the incidence of rebleeding.

LENS SUBLUXATION/ DISLOCATION

The lens is a convex, transparent structure held in place behind the iris by the zonule fibers, which connect to the ciliary body[9] (see Fig. 25.4). Blunt trauma can cause damage to these zonule fibers, resulting in lens subluxation or dislocation. Incomplete disruption of the lens zonule fibers results in subluxation.[29] If complete disruption occurs, the lens is displaced posteriorly

FIGURE 25.3. Grade 1 hyphema in a patient struck in the eye with a ball. (Reprinted with permission from Ehlers JP, Shah CP, Fenton GL, et al. *The Wills Eye Manual: Office and Emergency Room Diagnosis and Treatment of Eye Disease.* 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2008.)

(most common) or anteriorly into the anterior chamber. Patients will present with fluctuating vision, blurred vision, or monocular diplopia with subluxation if the lens remains in the visual axis.[3,29] Visual acuity testing will reveal decreased vision, ranging from mild (subluxation) to marked (dislocation). If displaced anteriorly, the lens may be visualized on gross or slit-lamp examination. Dilation of the pupil is usually necessary to observe the lens if dislocated posteriorly.[3] Another helpful finding is iridodonesis, a tremor of the iris after rapid eye movement observed in posterior lens dislocation.[3] If the lens is dislocated anteriorly, then IOP should be measured, as the dislocated lens can obstruct the outflow of aqueous humor and cause acute angle closure glaucoma and elevated IOP. The management of lens subluxation and dislocation will frequently involve surgical repair. In the case of an anterior lens dislocation causing increased IOP, repair should be performed emergently.

TRAUMATIC IRIDOCYCLITIS

Traumatic iridocyclitis results from blunt trauma to the globe. This causes inflammation of the iris and ciliary body and resulting ciliary spasm. Patients typically complain of pain, photophobia, and blurred vision. Visual acuity may or may not be affected. Conjunctival injection and a small, poorly dilating pupil can be observed.[3] The slit-lamp examination will reveal the presence of cells (small, floating particulate matter within the aqueous humor) and flare (scattered light caused by the presence of inflammatory proteins in the aqueous humor) in the anterior chamber.[10] The condition is self-limited and the management symptomatic. A topical cycloplegic agent will usually be enough. One may consider a topical ophthalmic steroid to decrease inflammation. However, if a corneal epithelial defect (i.e., abrasion) exists, its use is contraindicated.

ORBITAL WALL FRACTURES

Orbital wall fractures can be classified as either blow-out or blow-in. Typically, blow-out fractures involve either the orbital floor and/or medial wall. Blow-in fractures are usually either superior or inferior. Each will be discussed separately.

Blow-out fractures occur in response to blunt force to the eye. They account for approximately 11% of fractures involving the orbit.[30] The orbital rim may or may not be involved. The most common location for a blow-out fracture is the middle one-third of the orbital floor. The second most common location is the medial wall. Medial wall fractures may either occur in combination with orbital floor fractures (most common) or as an isolated fracture.

While most patients with a blow-out fracture will have some complaint other than pain, on rare occasion, they can be otherwise asymptomatic. A common complaint in orbital floor fractures is diplopia, which is often vertical and worse with attempted upward or downward gaze. Patients may also complain of numbness of the cheek and gum on the injured side, due to infraorbital nerve injury. Visual acuity may be normal or decreased. Physical examination can reveal periorbital swelling and ecchymoses. Enophthalmos (sunken eye) may be present if the orbital contents have prolapsed into the maxillary sinus. Similarly, there may be limitations of vertical eye movement if there is entrapment of the inferior rectus muscle within the fracture. Decreased sensation in the distribution of the infraorbital nerve (i.e., cheek and upper gum) will be present on exam if the nerve is trapped in the fracture site or contused.

For medial wall fractures, epistaxis and subcutaneous emphysema (due to communication with the ethmoid sinus) are common. Diplopia can be present, but with medial and

lateral gaze. Patients may complain of increased periorbital swelling with noseblowing (i.e., due to increased subcutaneous emphysema).

The eye should be thoroughly examined for associated injuries, which may occur in 10%–25% of patients with orbital floor fractures.[30] Globe rupture, hyphema, iridodialysis, lens dislocation/subluxation, and retinal injuries can all be found in association with orbital wall fractures. It is extremely important to examine the full range of extraocular muscles, looking specifically for any limitations.

Findings of orbital wall fracture on x-ray include the tear drop sign or the presence of air fluid levels or opacification of the sinuses. CT scan of the face or orbits, with 1.5 mm cuts, is the best imaging study for identifying the fracture, complications of the fracture (i.e., inferior rectus muscle entrapment, etc.), and associated injuries (i.e., globe rupture; see Fig. 25.5).

Blow-in fractures also occur secondary to blunt trauma, but with the force directed primarily against the frontal bone or maxilla. Blunt trauma against the frontal bone can result in an orbital roof fracture, with displacement into the orbital space. This can result in injury to the optic nerve or compression of the superior rectus and levator palpebrae muscles. If the force is directed primarily against the maxilla, an inferior blow-in fracture of the orbital floor can occur. Similar to blow-out fractures, the inferior rectus and inferior oblique muscles can be entrapped in fracture fragments. Assume a high index of suspicion for an associated globe injury for both blow-in and blow-out fractures.

Management for both types of fractures is emergent in the case of visual impairment, entrapped muscle(s), or globe rupture. If none of these are present, patients can be treated as outpatients with instructions to apply ice and avoid noseblowing, valsalva maneuver, and nasal decongestant sprays. Broad spectrum antibiotic prescription is controversial; if adjacent sinusitis is present, however, they should be used.

PERFORATING INJURIES OF THE CORNEA OR SCLERA/OPEN GLOBE

Blunt or sharp trauma to the eye may result in a corneal or scleral laceration. Symptoms include pain, decreased vision, and tearing, or "loss of fluid" from the eye. The patient should be examined using a penlight and avoid placing pressure on the

FIGURE 25.5. CT scan of orbital blow-out fracture. Note disruption of the orbital floor and blood in the maxillary sinus. Philadelphia, PA: Lippincott Williams & Wilkins; 2008.)

eye. Physical findings, which can sometimes be subtle, include a flat anterior chamber (compared to the unaffected eye), extension of the iris to the corneal wound, pupil irregularity, severe subconjunctival hemorrhage or hematoma, or evidence of pigmented tissue (uvea) on the surface of the sclera. Suspicion for an open-globe injury should be high in cases of lid laceration or extensive subconjunctival hemorrhage. Intraocular contents, including the lens, may have exited the wound or be displaced into the anterior chamber or vitreous. Blood within the anterior chamber or in the vitreous may be present. Posterior eye findings such as retinal swelling, tears, or detachment may not be visible if there is major hemorrhage within the anterior chamber or vitreous.

Gentle ultrasound may be needed to localize a posterior rupture site or to rule out intraocular foreign bodies not visible on CT scan (i.e., nonmetallic and wood). Ultrasound should not be performed if an obvious anterior rupture is present.

At times, the depth of a deep corneal injury may be uncertain; however, all suspected cases of a full thickness eye injury should be approached as an open globe until proven otherwise. The patient should be kept still and quiet and should not bend, strain, or apply pressure around the orbit. The Seidel test can be performed to help determine if a full-thickness corneal wound is present.

Once the diagnosis of a possible or probable ruptured globe is made, further examination should be deferred until the time of surgical repair by an ophthalmologist in the operating room. This is to prevent extrusion of intraocular contents. A hard plastic shield (or paper cup if shield in unavailable) should be placed over the eye, with great care taken to avoid any pressure to the eye or periorbit. Obtain a CT scan of the brain and orbits with fine 1 mm axial and coronal sections to rule out IOFB.[31] The patient should be admitted and maintained NPO for surgery and should avoid valsalva maneuvers. Administration of antiemetics should be considered to avoid vomiting. Although randomized, prospective studies of open-globe injuries treated with or without systemic antibiotics are not available, systemic antibiotics are generally administered within 6 hours of injury. For adults, consider cefazolin 1 g IV q8h or vancomycin 1 g IV q12h. The addition of systemic fluroquinolone therapy (i.e., ciprofloxacin 400 mg p.o./i.v. b.i.d, gatifloxacin 400 mg daily, or moxifloxacin 400 mg daily) is beneficial for antimicrobial activity against *Bacillus* and for good vitreous penetration.[32] For children, consider cefazolin 25–50 mg/kg/day IV in three divided doses and gentamicin 2 mg/kg IV q8h.[31] Surgical repair by an experienced eye surgeon should be performed as soon as possible.

INTRAOCULAR FOREIGN BODY

Injuries that result in an IOFB, whether in the anterior chamber or in the posterior segment, are considered ophthalmic emergencies. Prompt evaluation and surgical intervention are necessary. An IOFB enters the eye through a break in the cornea or sclera. These injuries are most common with small particulate, high-velocity perforating trauma, such as occurs with hammering on metal, grinding accidents, or shrapnel such as glass in a motor vehicle crash. The entry site may be small and difficult to see on examination and may even be self-sealing. A history consistent with possible ocular perforation should raise the clinician's index of suspicion for a foreign body. If there is an obvious perforation site, the remainder of the examination may be deferred until the time of surgery. Signs and symptoms include decreased vision, pain, a visible entrance site, or visualization of foreign material anteriorly on slit-lamp examination, or posteriorly on funduscopic examination. These open-globe injuries have a much higher incidence of endophthalmitis and ocular demise. Rates of endophthalmitis

following globe perforation are reported to be 3%–17%. A recent study showed that eyes with an IOFB had a higher percentage of endophthalmitis than those without.[33]

A CT scan of the brain and orbits should be obtained to evaluate the position and extent of foreign material within the eye and the orbit (coronal and axial views with 1-mm sections through the orbit). MRI is contraindicated in case of metallic foreign body.

Management of patients with IOFB includes hospitalization, made NPO for surgery, and an eye shield placed to protect the globe from external pressure. Intravenous antibiotics should be administered; accepted regimen include vancomycin 1 g IV q12h or ceftazidime 1 g IV q12h or ciprofloxacin 400 mg IV q12h or moxifloxacin 400 mg IV daily or gatifloxacin 400 mg IV daily.[34] Surgical repair of the globe and removal of intraocular foreign bodies requires the expertise of ophthalmologists and vitreoretinal specialists with extensive experience in such cases.

RETINAL INJURY AND VITREOUS HEMORRAGE

Blunt trauma can damage the retina, vitreous, and other intraocular layers in various ways. Blunt trauma to the eye can result in a retinal tear, especially in patients who are myopic or who have a history or family history of retinal holes, tears, or detachments. The patient may present with varying degrees of decreased vision, dependent upon the location and extent of the injury, or may experience a defect in vision affecting a specific part of the visual field. Some may report seeing flashes of light or floaters.

Retinal Commotio

One of the milder forms of injury to the retina is retinal edema, or commotio, caused presumably by a disruption in the photoreceptor outer segments and decreased function of the retinal pigment epithelium.[35] Retinal commotio appears as retinal whitening ophthalmoscopically and, depending upon its location, can result in substantial decreased vision. In general, the vision will improve as the swelling decreases over several weeks.

A careful ophthalmoscopic examination is necessary to rule out the possibility of associated retinal holes, tears, or even retinal detachment.

Retinal Holes/Tears/Detachment

Blunt trauma can lead to retinal or macular holes. The mechanism of injury involves rapid displacement of the vitreous causing vitreoretinal traction with resultant retinal hole formation. The most common area of retinal break in trauma is the superonasal or infratemporal quadrant.[35] Retinal breaks are usually treated using cryotherapy or laser photocoagulation by a qualified ophthalmologist to decrease the possibility of subsequent retinal detachment. Retinal detachment occurs when liquefied vitreous passes through a retinal hole, detaching the retina from the globe. Since most trauma patients are young, with firm, nonliquefied vitreous, retinal detachment is not a common presentation at time of trauma. However, large retinal tears (>3 clock hours) or macular holes may lead to traumatic retinal detachments presenting at the time of injury[35] (see Figs. 25.6 and 25.7).

Such detachments are treated by vitreoretinal specialists using an encircling element "scleral buckle" along with
FIGURE 25.6. Large retinal detachment. (Reprinted with permission from Ehlers JP, Shah CP, Fenton GL, et al. *The Wills Eye Manual: Office and Emergency Room Diagnosis and Treatment of Eye Disease.* 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2008.)

advanced vitreous surgery to remove any tractional component on the retina. In addition, a variety of intraocular gases or fluids can be used to flatten the retina and tamponade the break in the hope of reattaching the retina. Resultant visual acuity is dependent upon a number of factors including location of the detachment, amount of time prior to surgical intervention, other confounding ophthalmic conditions, tissue integrity, and surgical technique.

Vitreous Hemorrhage

The vitreous is the gelatinous substance that fills the globe posterior to the lens and provides structural integrity. It is most adherent to the retina at the most anterior portion of the retina, the optic disc, and along the retinal vessels. The composition tends to change with age from a more firm gelatinous substance to a more liquid form. As this change occurs, the vitreous may detach from the retina which may be an asymptomatic event or may be accompanied by "photopsias" or visual images such as flashes of light or lines. Photopsias indicate tension on the retina. In trauma, rapid displacement of the vitreous may cause substantive tension on the retina and retinal vessels and produce vitreous hemorrhage. The patient presents with varying degrees of decreased vision or clouding of
FIGURE 25.7. Ultrasound demonstrating retinal detachment. (Reprinted with permission from Ehlers JP, Shah CP, Fenton GL, et al. *The Wills Eye Manual: Office and Emergency Room Diagnosis and Treatment of Eye Disease.* 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2008.)

vision and may also experience photopsias. Fundus examination through a dilated pupil will reveal varying loss of fundus detail, blood obscuring the view of the posterior pole or retina, or red "debris" seen within the vitreous. All trauma patients with vitreous hemorrhage require a careful bilateral ophthalmologic examination for retinal holes, tears, or detachment by an ophthalmologist.

If the view of the retina is obscured by blood, ultrasound should be performed to assess for underlying retinal detachment. Experienced practitioners can differentiate between vitreous hemorrhage, vitreous detachment, and retinal detachment using ultrasound.

Underlying diseases that increase risk of vitreous hemorrhage include diabetes, sickle-cell disease (especially SC disease), clotting disorders, and hypertension.

Treatment of associated retinal pathology is performed by an ophthalmologist. If the patient has no retinal tears, treatment is activity restriction, avoidance of aspirin containing medications or nonsteroidal anti-inflammatory medication, and maintaining head-up positioning to promote inferior settling of the blood. The patient is followed closely for any retinal pathology as the hemorrhage clears and view of the fundus improves.

TRAUMATIC RETROBULBAR HEMORRHAGE

Following blunt trauma to the periorbit, bleeding behind the globe may result in retrobulbar hemorrhage with resultant decreased ability to move the eye and the risk of optic nerve damage due to compressive optic neuropathy. Symptoms include pain, decreased vision, diplopia, and an inability to open the eye in the case of severe swelling. The patient is typically proptotic with major subconjunctival hemorrhage and chemosis. Pressure upon the globe reveals resistance to retopulsion. Ominous signs include an afferent pupillary defect, increased IOP, and vision loss. Prolonged intraorbital hemorrhage with excessive congestion may result in vascular occlusion and permanent damage to the optic nerve.

Funduscopic examination should be performed to assess for any vascular congestion or optic nerve edema. A CT scan of the orbit should be obtained to visualize retrobulbar hemorrhage, which usually appears as a diffuse increased reticular pattern seen within the orbital fat. The degree of proptosis and evidence of tension on the optic nerve should also be assessed. Optic nerve straightening may be seen, and, in severe cases, "tenting" of the globe may be evident. It should be noted that CT scan examination should be deferred if the vision is threatened, and attention should first be directed toward decreasing orbital pressure.

The treatment of retrobulbar hemorrhage is aimed at timely decompression of the orbit. If there is evidence of optic neuropathy (i.e., progressive visual loss, afferent pupillary defect, or retinal vessel and disc congestion), emergent decompression is necessary. This is accomplished at the bedside by lateral canthotomy and cantholysis. The goal of the procedure is to allow soft tissue decompression via disinsertion of the lateral canthal tendon, which adheres the lower lid to the periosteum.

In order to perform a lateral canthotomy, one needs blunt tip (i.e., Westcott) scissors, hemostat, and toothed forceps. Anesthetize the lateral canthal region using lidocaine 2% with epinephrine. Place a hemostat horizontally at the full thickness of the lateral canthus from conjunctiva to the skin. Clamp for approximately 1 minute to compress the tissue and reduce bleeding. Use the scissors to perform a full thickness canthotomy, approximately 1 cm in length. In order to obtain adequate decompression, a cantholysis must then be performed

to cut the inferior crus of the lateral canthal tendon. This procedure is performed by locating the tendon by feel with one blade of the scissors and excising the tissue. When the canthal tendon is cut, the eye should further proptose, and the lid should no longer be apposed to the globe (see Fig. 25.8).

Pressure on the incision site should be adequate to control hemostasis. If the procedure is successful, the IOP should begin to decrease and retinal perfusion be re-established within approximately 15 minutes.[36] The vision may or may not improve at this point. If the procedure is unsuccessful, the patient should have orbital decompression into the sinus by an experienced surgeon.

If there is no evidence of compressive optic neuropathy (i.e., no afferent pupillary defect, vascular compromise, or decreased vision), but the IOP is elevated, the patient can be first treated with glaucoma drops such as a topical beta blocker, an alpha agonist, or, in more severe cases, a hyperosmotic agent (i.e., mannitol 1–2 g/kg IV over 45 minutes).[36] Topical drops may require repeat administration every 30 minutes. The patient should be monitored closely for the evidence of evolving optic nerve compromise (i.e., check vision and IOP frequently) and treated as outlined earlier if their condition deteriorates. Cool compresses or ice packs should be used to decrease swelling.

TRAUMATIC OPTIC NEUROPATHY

Traumatic injury to the optic nerve may occur with blunt or penetrating head trauma. The optic nerve injury may be accompanied by any number of ocular or periocular injuries, but can also present without evidence of external injury, such
FIGURE 25.8. **A:** Lateral canthotomy. **B:** Pull the lower lid inferiorly and then anteriorly. **C:** Cut the lateral canthal tendon. Philadelphia, PA: Lippincott Williams & Wilkins; 2008.)

as in the case of a whiplash type injury. Following injury to the nerve, edema may cause further damage and result in traumatic optic neuropathy (TON) with severe visual loss. TON should be suspected in the case of a patient presenting with decreased vision following trauma, but without evidence of anterior segment or retinal pathology to explain the deficit.

The patient should have a complete ocular examination including assessment of visual acuity and a careful pupillary examination. Visual fields can be tested by confrontation. If possible, color vision testing can be very helpful (i.e., if one eye reveals a relative decrease) in detecting optic nerve compromise. Fundus examination may reveal evidence of acute optic nerve swelling, optic nerve pallor, or even an optic nerve avulsion. Frequently, the optic nerve appears normal in the acute stage.

A CT scan of the orbit with attention to the optic canals (1 mm axial and coronal cuts at the canals) should be obtained to rule out the possibility of an impending fracture or foreign body causing pressure on the optic nerve.

Treatment is aimed at the causative mechanism of the TON. In the case of a traumatic retrobulbar hemorrhage, lateral canthotomy and cantholysis may be necessary. Evacuation of an orbital foreign body or optic sheath hematoma may be necessary. Optic canal decompression surgery may be required by an experienced oculoplastic surgeon. There is no effective treatment for an optic nerve laceration or optic nerve head avulsion.

Historically, the use of high-dose corticosteroids in TON has been common. Despite this practice, the majority of clinical and experimental evidence shows no support for this treatment.[37] Steroids have actually been shown to result in poorer outcomes if administered >8 hours postinjury.[37]

CHAPTER 26 ■ BLUNT AND PENETRATING NECK INJURY

JOSEPH DUBOSE AND THOMAS M. SCALEA

The complex anatomical relationships within a small area make the diagnosis and management of both penetrating neck injuries (PNI) and blunt neck injuries (BNI) challenging. Radiographic evaluation continues to evolve, with a shift from invasive to noninvasive diagnostics. Despite advances in both diagnosis and therapeutics, the optimal management of neck injuries remains a matter of active investigation.

PENETRATING INJURIES

Epidemiology

Firearms are responsible for approximately 43%, stab wounds for 40%, shotguns for 4%, and other weapons for 12% of all PNI.[1] Overall, about 35% of all gunshot wounds (GSW) and 20% of stab wounds (SW) to the neck cause major injuries, but only 16% of GSW and 10% SW require surgical therapy. Even though transcervical GSWs cause major injuries in 73% of victims, only 21% require surgery.[2] The most common injury after PNI is vascular.[1,3] Spinal cord injuries and injuries to the aerodigestive tracts and various nerves are also common.[1]

Anatomical Zones

The neck can be divided into three anatomical zones for evaluation and therapeutic strategy purposes (Fig. 26.1). Zone I comprises the area between the clavicles and the cricoid cartilage. Critical structures include the innominate vessels, the origin of the common carotid artery, the subclavian vessels and the vertebral artery, the brachial plexus, the trachea, the esophagus, the apex of the lung, and the thoracic duct. Surgical exposure in zone I can be difficult because of the presence of the clavicle and bony structures of the thoracic inlet. Zone II comprises the area between the cricoid cartilage and the angle of the mandible and contains the carotid and vertebral arteries, the internal jugular veins, trachea, and esophagus. This zone is more accessible to clinical exam and surgical exploration than the other zones. Zone III extends between the angle of the mandible and the base of the skull and includes the distal carotid and vertebral arteries and the pharynx. The proximity to the skull base makes zone III structures less amenable to physical exam and difficult to explore. Overall, zone II is the most commonly injured area (47%) after PNI, followed by zone III (19%) and I (18%).[4] In 16%, injuries will involve more than one zone.[1]

Airway Management

Approximately 8%–10% of patients with PNI present with airway compromise.[2,5–7] In patients with laryngotracheal injuries, about 30% require the establishment of a secure airway in the ED.[7] Airway compromise may be due to direct trauma, airway edema, or from external compression by a large hematoma. Small penetrating airway injuries by knife or low-velocity bullets are less likely to result in respiratory problems than laryngotracheal transections or high-velocity GSW.[1]

Air bubbling through a neck wound is pathognomonic of airway injury. Firm manual compression over the wound reduces the air leak and will usually improve oxygenation. Orotracheal intubation in the ED after PNI should be performed by the most experienced provider, recognizing the potential need for emergent surgical airway. The severity of respiratory distress, hemodynamics, the size and site of hematoma, presence of a large air leak, and the experience of the trauma team will determine the best technique. For patients with large neck hematomas who are not in respiratory distress, fibreoptic intubation may be safe. However, this procedure requires experience and skill and can be performed only semielectively; there is a reported failure rate of approximately 25%.[7]

The use of neuromuscular paralysis during intubation in the ED after PNI remains controversial. Orotracheal intubation without neuromuscular paralysis increases difficulty. Coughing or gagging worsens bleeding. However, pharmacologic paralysis may prove dangerous if the cords cannot be visualized secondary to distorted anatomy from a compressing hematoma or edema. Loss of the muscle tone after paralysis may further displace the airway, leading to total obstruction. In a recent review of PNIs, 21% required ED airway. In 12% of patients, orotracheal intubation failed, requiring emergent cricothyroidotomy.[8]

In the presence of large midline hematomas, cricothyroidotomy is difficult and may be associated with severe bleeding. Large laryngotracheal wounds can be intubated under direct view into the distal transected segment through the neck wound itself. The distal airway should be grasped with forceps before insertion of the tube to avoid complete tracheal transection or retraction into the mediastinum.

Initial Control of Hemorrhage

External bleeding due to PNI is controlled by direct pressure in most cases. However, bleeding from behind the clavicle, near the base of the skull, or from the vertebral artery is often difficult to control by external pressure. Digital compression with an index finger through the wound can help. Ballon tamponade techniques may also help.[2,9] A Foley catheter is inserted into the wound and advanced as far as possible without resistance. The balloon is then inflated until the bleeding stops or moderate resistance is felt. If the bleeding continues, the balloon is deflated, and the catheter is slightly withdrawn and reinflated. Substantial bleeding through the catheter is suggestive of distal bleeding and indicates the need for repositioning.

With periclavicular injuries, bleeding can occur into the thorax. In these cases, the Foley catheter is advanced into the chest through the wound, the balloon inflated, and the catheter pulled back until resistance is felt, compressing the bleeding vessels against the first rib or the clavicle. Traction is maintained with a clamp placed on the catheter just above the skin until operative exposure is obtained.[9] Blind clamping of bleeding is rarely successful and may cause vascular or nerve damage.

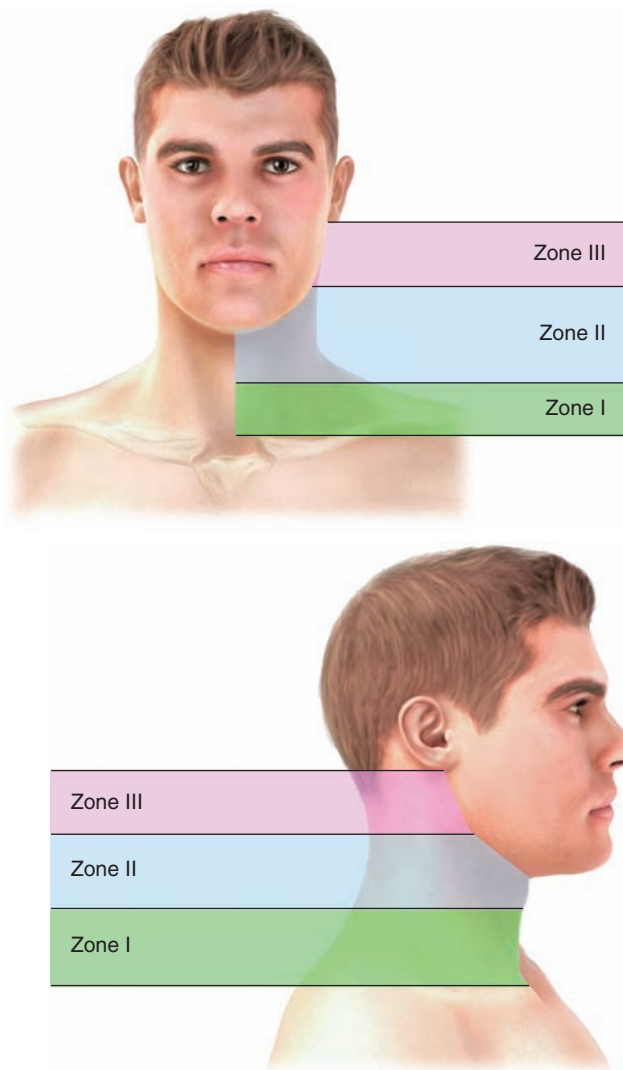
329


FIGURE 26.1. Surgical zones of the neck: zone I is between the clavicle and the cricoid, zone II between the cricoid and the angle of the mandible, and zone III is between the angle of the mandible and the base of the skull.

Initial Evaluation

Physical examination, preferably according to a written protocol (Algorithm. 26.1; Table 26.1), remains the most reliable initial diagnostic tool. Physical exam should be systematic and specifically directed to look for signs or symptoms of injuries to the vital structures. Signs can be classified into "hard" signs, which are pathognomonic of injury, and "soft" signs, which are suspicious but not diagnostic of injury[1,10] (Table 26.2). In GSW, the most common sign is a moderate or large hematoma (20.6%). Following SW, painful swallowing (14.3%) and hemo/pneumothorax (13.5%) are most common.[1] Subcutaneous emphysema occurs in about 7% of PNIs.[1] This may be secondary to laryngotracheal or esophageal injury or an associated pneumothorax. Only about 15% of patients with soft signs have substantive laryngotracheal injury.[1]

In one of the largest series of patients with PNI, patients with hard signs of vascular injury required operation as compared to about 3% with soft signs.[1] Of the patients with soft signs who underwent angiographic evaluation, 23.5% had an angiographic abnormality, but only 3% required operation.[1]

Evaluation for Nervous System Injuries

Although the diagnosis and management of spinal cord injuries are covered elsewhere in this text, the initial evaluation warrants mention. The clinical examination after PNI should include assessment of the Glasgow Coma Scale (GCS) score, localizing signs, pupils, cranial nerves (VII, IX-XII), spinal cord, brachial plexus (median, ulnar, radial, axillary, and musculocutaneous nerves), the phrenic nerve, and the sympathetic chain (Horner's syndrome). The GCS may be abnormal from ischemia secondary to a carotid injury or associated intracranial missile injury.

The Value of a Protocolized Approach to Physical Exam

A protocolized exam provides reliable identification of the majority of major injuries requiring therapeutic intervention.[1,4] In one large prospective study with predominantly SW to the neck, 80% was found to have no symptoms or signs suggestive of vascular or aerodigestive injuries and were selected for nonoperative management. Only two of the observed patients (0.7%) required semielective operation for vascular injuries. In both cases, a bruit was detected the day after admission, and angiography demonstrated an arteriovenous fistula.[4]

In another prospective study of predominantly GSW, 71.7% had no clinical signs suggestive of vascular injury. None of these patients required operation or other form of therapeutic treatment (negative predictive value [NPV] 100%). Angiography was performed on 127 of the asymptomatic patients from this series, revealing 11 vascular injuries (8.3%), but none required intervention. None of the patients without signs or symptoms of aerodigestive injuries had an injury requiring operation (NPV 100%).

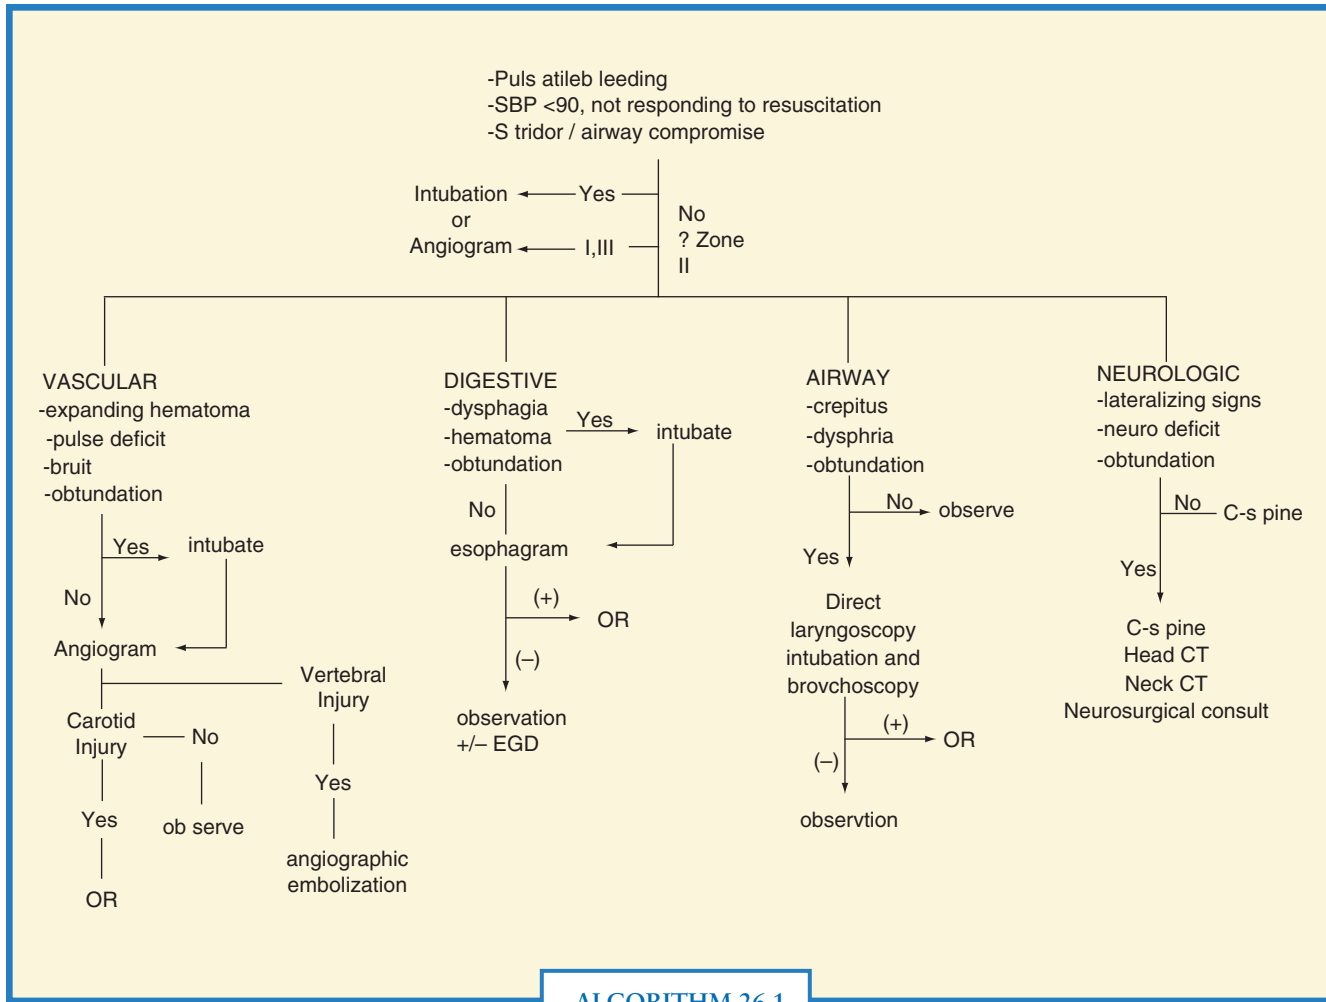
For patients with soft signs of injury, including concerning wound proximity, additional investigations are warranted. The specific protocol will vary based on institutional capabilities. The utility and limitations of the respective possible investigations following PNI are outlined in the following sections.

INVESTIGATIONS

Plain Chest and Neck Films

Chest films should be obtained in all stable patients with penetrating injuries in zone I or any other wounds that might have violated the chest cavity. Approximately 16% of GSWs and 14% of stab wounds to the neck have an associated hemo/pneumothorax.[1] Other important radiological findings include a widened upper mediastinum suspicious for thoracic inlet vascular injury, subcutaneous emphysema, fractures, and missiles.

Angiography

Angiographic evaluation of the neck vessels following PNI once was standard.[10–12] However, angiography in asymptomatic patients is low yield and offers no benefit over physical exam combined with noninvasive investigations.[1,2,4,6,13–18] In a prospective study, asymptomatic patients were evaluated


ALGORITHM 26.1 Protocol of examination and initial evaluation of penetrating neck injuries. (Modified from Demetriades D, Salim A, Brown C, et al. Neck injuries. *Curr Probl Surg.* 2007;44(1):13–85 with permission.)

angiographically at a cost of $254,000 and 11 vascular injuries not requiring treatment were identified. Additionally, the combination of clinical examination and Color Flow Doppler (CFD) in this series diagnosed all vascular injuries.[1] In another prospective study, 80% were selected for nonoperative management. Angiography was performed on only seven patients. There were no deaths or substantial complications. Early and late follow up demonstrated no substantial missed vascular injuries.[4]

Some studies have suggested that clinically occult, angiographically identified injuries have a benign prognosis and require no treatment.[19,20] There is, however, concern regarding the natural history of such lesions and adequacy of physical exam for their detection. Although the absence of hard clinical signs reliably excludes substantial injuries requiring treatment, the presence of soft signs of vascular injury does not reliably differentiate patients who require operation.[1,15] In one study, a subgroup of 34 patients with soft signs of vascular injury had angiography.[1] Eight (23.5%) had vascular injuries but only one (3%) needed intervention. Some form of imaging is needed to follow identified injuries. Several noninvasive modalities are alternatives.

TABLE 26.1

HARD AND SOFT SIGNS OF INJURY AFTER PENETRATING NECK TRAUMA

■ HARD SIGNS OF INJURY	■ SOFT SIGNS OF INJURY
Active arterial hemorrhage	Stable hematoma
Absent peripheral pulse on affected side	Trajectory
Expanding hematoma	Dysphagia
Air or saliva from wound	Pulse abnormality on affected side
Bruit	Nerve deficit
Hemoptysis	

Color Flow Doppler

CFD has been suggested as a reliable alternative to angiography in the evaluation for vascular injuries following PNI.[1,2,15,21–25] In a prospective study conducted by Demetriades et al., CFD diagnosed 10 of 11 angiographically detected

injuries and missed only one small intimal injury, which did not require subsequent operation. In a subsequent prospective study with 25 patients with PNI evaluated by both angiography and CFD, Corr et al.[22] demonstrated the same results. CFD is operator-dependent and may miss injuries of the proximal left subclavian artery, the internal carotid artery near the base of the skull, and the vertebral artery under the bony vertebral canal.

Computed Tomography

Computed tomography (CT) with adequately phased IV contrast protocols has become a useful tool in the evaluation of PNI, especially in GSW, and has become the first line investigation in hemodynamically stable patients with PNI to the neck in many centers. Prior to CT, the entry and exit of the bullet should be marked with radioopaque markers. In addition, 3-mm CT cuts should be obtained between the markers or between the entry and the retained bullet. Identifying bullet trajectory may help in determining the need for further invasive investigations, such as angiography or endoscopy. Patients with trajectories away from the major structures require no further evaluation.[16,26–29]

Munera et al.[27,28] compared conventional angiography and helical CT angiography. CT angiography had a sensitivity of 90%, specificity 100%, PPV 100%, and NPV 98%. Another study of 175 patients also suggested CT is a valuable investigation for the evaluation of suspected arterial injuries of the neck.[28] CT may have some important limitations, however, particularly when images are obscured due to artifact from metallic fragments or excessive air in the soft tissues.[29] In these cases, conventional angiography may be necessary for adequate exclusion of vascular injury.

CT also provides information about the site and nature of associated spinal fractures, involvement of the spinal cord, the presence of fragments in the spinal canal, or hematoma compressing the cord. A brain CT scan is also indicated for patients with PNI and unexplained central neurological deficits. In these instances, CT should be used to evaluate for possible anemic infarction secondary to a carotid artery injury or an associated direct brain injury due to a missile fragment.

Esophageal Studies

Esophageal studies are indicated in stable patients with soft signs and in cases with a CT scan bullet trajectory near the esophagus. Contrast esophagography is commonly used but may miss small injuries. Armstrong et al.[30] reported that contrast esophagography diagnosed only 62% of perforations, compared to100% with rigid esophagoscopy. The technique of esophagography may be important to minimize false-negative studies. Esophagography should first be performed with a water-soluble contrast, such a gastrographin. If no leak is identified, the study is repeated with thin barium, as gastrographin alone may miss small injuries.[31]

Esophagoscopy, if performed by an experienced endoscopist, may also be useful. Flexible endoscopy has been shown to have a NPV of 100% but a positive predictive value of only 33%.[32,33] This is the study of choice in many centers for patients who cannot undergo esophagogram because of a depressed level of consciousness or during intraoperative evaluations. Rigid esophagoscopy may be superior to flexible endoscopy in the evaluation of the upper esophagus, but requires general anesthesia, and many surgeons are not experienced with the technique.[34]

Studies for Laryngotracheal Evaluation

Indications for laryngotracheal evaluation include proximity injury, soft signs suspicious of airway injuries (minor hemoptysis, hoarseness, and subcutaneous emphysema) or CT scan findings showing a bullet tract near the larynx or trachea.

Flexible fibreoptic endoscopy is the investigation of choice, and it can be performed in the ED. The most common abnormal findings are blood or edema in the laryngotracheal tract and vocal cord dyskinesia.[1] GSWs are more likely to be associated with abnormal findings than SW (24.6% vs. 8.5%). However, only 20% of patients with abnormal findings require operation.[1,34]

Operative versus Nonoperative Management of Penetrating Injuries

For many years, mandatory operation for all patients with penetrating injuries of the neck that violated the platysma was standard. The rationale was that clinical examination was not reliable. In addition, it has been suggested that routine operation avoids expensive investigations and does not prolong hospital stay.[35] Routine surgical exploration is associated with an unacceptably high incidence of unnecessary operations, ranging from 30% to 89%.[35,36] Improved appreciation of the reliability of physical exam, combined with noninvasive diagnostic capabilities, has resulted in the use of selective nonoperative management at most centers.[1,4,14,15,19,37,38]

GSWs are associated with a higher incidence of substantial injuries requiring operation than SW. However, more than 80% of GSW to the neck does not require an operation, and there is strong evidence that these patients can be identified and spared an unnecessary operation.[1,4,6,15,39,40]

Transcervical GSWs are associated with a much higher incidence of substantial injuries than GSW that have not crossed the midline (73% vs. 31%).[15] It has been suggested that all such patients undergo exploration, irrespective of clinical exam.[41] However, many of these injuries, such as spinal cord or nerve injuries, do not require operation. In one prospective study of transcervical GSW, 73% of patients had injuries to vital structures, but only 21% required operation.[15,34] Several studies have demonstrated that CT angio with thin cuts can reliably identify those patients who do not need further investigation or those who might benefit from specific studies.[16,17,29–32,42]

BLUNT INJURIES

Although physical exam and initial management priorities for BNI are much the same as for penetrating injuries, a knowledge of the differences in injury patterns is essential for prompt diagnosis and management. We will focus on BNI causing laryngotracheal, pharyngoesophageal, and vascular trauma.

Epidemiology

Although BNI is common, when cervical spine injuries are excluded, injuries to the remaining structures are rare. Injuries to the aerodigestive tract are typically from direct force to the anterior neck.[43,44] Both laryngotracheal and pharyngoesophageal are rare after BNI, occurring in 0.04%–0.3% of patients.[45,46] Similarly uncommon, but far more lethal, are blunt cerebrovacsular injuries, including injury to the vertebral and carotid arteries. With increased appreciation and availability of noninvasive diagnostics, the rates of these injuries are now between 1.0% and 2.0%.[47–54]

INVESTIGATIONS

Plain Radiographs

Plain x-rays of the neck and chest are a rapid noninvasive method of evaluating patients with suspected BNI. Cervical or mediastinal emphysema has been reported in as many as 95% of aerodigestive injuries. Cervical spine fractures are a risk factor for blunt cervical vascular injury.[47,50] In particular, vertebral artery injuries are associated with complex cervical spine fractures with subluxation, extension into the foramen transversarium, or fractures to the higher cervical vertebrae.[48]

CT and Oral Contrast Studies

CT is the cornerstone of initial imaging for blunt trauma patients. Though aerodigestive injuries are best visualized with panendoscopy, CT and contrast studies may help patients with a high suspicion of injury. For laryngotracheal injuries, CT is more sensitive than plain radiographs in identifying cervical emphysema. CT also identifies small amounts of cervical air or contained leak after pharyngoesophageal injury. Gastrograffin or barium swallow will reveal an abnormality in 75%–100% of cases of cervical esophageal perforation.[55]

At many trauma centers, CT angiography has emerged as the initial screening test of choice for blunt carotid and vertebral injuries.[53,56–61] However, there remain conflicting results as to the utility of CT angiography after BNI. Berne et al.[59] found CT angiography to have a sensitivity of 100% and specificity of 94% when screening patients for blunt cerebrovascular injuries (BCVIs). In contrast, Biffl et al.[51] found the sensitivity and specificity for CT angiography to be 68% and 67%, respectively. Further studies are needed directly comparing conventional angiography and CT angiography.

Color Flow Doppler

CFD after BNI may help identify dissections, thrombosis, or pseudoaneurysms of the carotid and vertebral arteries. Its limited visualization of the distal carotid arteries and the portions of the vertebral arteries protected by the cervical spine can be a problem. In a multicenter trial, Cogbill et al.[62] demonsrated that duplex was able to identify 86% of injuries.Likewise, both Fry et al.[21] and DiPerna et al.[63] found that CFD did not miss a substantial carotid injury in patients with BNI. Both these studies, however, consisted of a limited number of patients.

Angiography

In the past, four-vessel angiography was the mainstay of diagnosis of vascular injuries in the neck. The indications remain controversial. Cothren et al.[47] recommend four-vessel angiography for all patients with signs or symptoms of cerebrovascular injury on clinical exam as well as high-risk mechanisms and any of the following: severe facial or cervical spine fracture, basilar skull fracture with carotid canal involvement, near-hanging injury with anoxia, and diffuse axonal injury with depressed mental status.

Endoscopy

Endoscopy is useful to evaluate suspected aerodigestive injury after BNI. Though both rigid and flexible endoscopies are options, flexible endoscopy does not require general anesthesia and can be performed while maintaining cervical spine immobilization in a collar. For laryngotracheal injuries, the combination of flexible laryngoscopy and bronchoscopy can be used to rule out an airway injury. Injuries to the pharynx and cervical esophagus may be difficult to visualize due to blood in the pharyngeal space. If the area of interest cannot be visualized clearly or if there is any suspicion of an esophageal injury, the patient should have a contrast swallow.

SPECIFIC NECK INJURIES

Cerebrovascular Injuries

BCVIs were previously thought to be rare. Increased screening has revealed an incidence ranging from 1% to 2% after trauma.[47,49,50,56,57] While controversy remains regarding patients at risk, failure to identify and treat these lesions may result in mortality between 25% and 59% of patients.[50,51,62,64,65]

Clinical Presentation

Many patients die before reaching a hospital or present to the ED in cardiac arrest. Those surviving to reach the hospital may be completely asymptomatic have subtle findings or active arterial hemorrhage, neck hematoma, and hemodynamic instability. Associated injuries may mask BCVI, but they should be suspected in any patient with a suspicious exam (such as the seatbelt sign; Fig. 26.2), concerning mechanism, or neurologic deficits or deterioration not explained by head CT.

Many patients initially with vascular injury are asymptomatic only to develop symptoms hours to days later, missing the window for intervention. In 1996, Fabian et al.[65] found an average time to diagnosis of 53 hours, with a range of 2–672 hours. The majority (78%) developed neurologic deficits prior to diagnosis. After initiating screening criteria, they demonstrated reduced the mean time to diagnosis of 20 hours, with 38% of injuries diagnosed based on the screening criteria alone. Only 34% of patients developed ischemic symptoms before diagnosis.[66]

Management of Cerebrovacular Injuries

Carotid repair and/or reconstruction is indicated for most patients with PNI. Optimal treatment of patients with coma or dense contralateral neurologic deficits is less clear. While some earlier reports warned against revascularization in the presence of neurologic deficits due to the concern of converting an ischemic infarct to a hemorrhagic infarct,[67] subsequent studies support that the best chance for neurologic improvement is early revascularization.[68] However, patients with coma (>4 hours) have an extremely poor prognosis regardless of treatment, and revascularization often exacerbates cerebral edema and intracranial hypertension.[69,70] In these patients, one should procede with revascularization only if there is no infarct present on CT.[71]

Most blunt carotid injuries occur at the base of the skull, making them inaccessible by standard neck incision. Options include observation, anticoagulation, antiplatelet therapy, endovascular stenting and operation. Biffl et al.[51,52] developed a widely used grading scale that can be used to make treatment decisions (Algorithm. 26.2). These investigators found that grade I injuries healed in the majority of cases with or without anticoagulation. Only 10% of grade II injuries healed with anticoagulation, with the majority (60%) progressing to grade III lesions (pseudoaneurysms) on repeat angiography. Almost all grade III lesions (85%) remained unchanged, with 1 of 13 healing with the use of IV heparin. No grade III lesion healed without treatment.

FIGURE 26.2. "Seatbelt Sign" after motor vehicle accident.

Endovascular stents were used to treat the majority of persistent grade III lesions, with an 89% initial success rate. Grade IV injuries (occlusion) remained unchanged despite anticoagulation but none of the patients treated with heparin developed a stroke. Grade V injuries were uniformly fatal in this series, despite attempts at angiographic embolization in two of the four patients. The authors also suggested categorizing arteriovenous or carotid-cavernous fistulae as grade II or grade.

Angiographic embolization, balloon occlusion or angioplasty, or stents may be used as a temporizing bridge to surgical repair for definitive treatment. Angiography with possible endovascular intervention should be considered in (1) hemodynamically stable patients with either physical exam or radiographic evidence of a distal internal carotid artery injury, (2) stable patients with evidence of an arteriovenous or carotid–cavernous sinus fistula, (3) ongoing facial or intra-oral hemorrhage from external carotid branches, and (4) small intimal defects or pseudoaneurysms in surgically inaccessible locations or high-risk surgical candidates. Stents/grafts may be particularly useful for patients with post-traumatic false aneurysms, arteriovenous fistulae, or arterial stenosis. Expanding experience with the use of interventional techniques for arterial injury is likely to better elucidate the optimal indications, timing, techniques, and outcomes.[72]

There is class III evidence that systemic anticoagulation or antiplatelet therapy improves survival and neurological outcome after blunt carotid injury.[65,66] Although anticoagulation may be more effective in carotid dissection than pseudoaneurysms.[73] Some studies, however, failed to show any obvious benefit from systemic heparin.[74]

A recent study conducted at our own institution by Stein et al.[49] highlighted the difficulties with any approach to therapy for BCVI as nearly one-third of patients were not candidates for therapy. While treatment reduced the risk of infarction, strokes that did occur were not preventable. In the absence of prospective, randomized data regarding treatment, management decisions must be based on the injury pattern, associated injuries, clinical condition of the patient, and the currently available literature. The algorithm for our present management approach of BCVI at R Adams Cowley Shock Trauma Center is shown in Figure 26.3 and Algorithm 26.2.

Operative Management—Carotid Injuries

The patient is placed in slight Trendelenburg with neck extended and the head rotated away from the side of injury. The patient should be prepped from the chin down to the knees in anticipating the need for a thoracic incision or saphenous vein harvest.

The most common incision for exposure of the unilateral carotid artery is a vertical oblique incision made over the anterior border of the sternocleidomastoid muscle (SCM), from the angle of the mandible to the sternoclavicular joint. Retracting the SCM laterally will expose the internal jugular vein, with the carotid artery lying medial and deep to the vein. The vagus nerve is located in the posterior carotid sheath. Division of the facial vein exposes the carotid bifurcation and allows mobilization and control of the internal and external carotids. Simple lacerations of the internal jugular vein or external carotid artery may be repaired, but, in most cases, veins can be ligated without sequla.

Cerebrovascular Injury Grades

Grade I	Luminal irregularity or dissection / intraluminal hematoma with <25% luminal narrowing
Grade II	Dissection or intraluminal hematoma of ≥ 25% of the lumen
Grade IIa	Dissection or intraluminal hematoma of 25-50% of the lumen
Grade IIb	Dissection or intraluminal hematoma of ≥ 50% of the lumen or intimal flap
Grade III	Pseudoaneurysm
Grade IV	Vessel occlusion
Grade V	Vessel transection

FIGURE 26.3. Grading scale for cerebrovascular injuries.

Some zone I injuries may be controlled and repaired through a cervical incision, but proximal zone I injuries may require extension inferiorly into a median sternotomy. Mobilization and superior retraction of the brachiocephalic veins will expose the aortic arch, brachiocephalic artery, and proximal common carotid arteries. Care should be taken to avoid the recurrent laryngeal nerves ascending posterior to the vessels.

Zone III carotid injuries are the most difficult to expose and get distal control. The cervical incision should be extended superiorly into the posterior auricular area and the digastric muscle divided, avoiding injury to the hypoglossal, glossopharyngeal, and facial nerves. Anterior subluxation of the mandible, further improved by mandibular osteotomy, excision of the styloid process, and removal of the anterior clinoid process improve exposure (Fig. 26.4). Temporary control of uncontrolled zone I or III hemorrhage may be obtained by insertion of an embolectomy catheter through the arterial defect or an arteriotomy and inflation of the balloon.

Most external carotid injuries may be ligated without consequence. Ligation of the common or internal carotid artery can result in devastating neurologic sequelae if collaterals are inadequate. Carotid ligation should be reserved for patients in whom repair is not technically possible, such as injuries at the base of the skull or patients with an established anemic cerebral infarction. In unstable patients, placement of a temporary intraluminal shunt and delayed reconstruction is an option.

Intravenous heparin should be administered if there are no other sites of hemorrhage or intracranial injury, preferably before clamping the artery. Alternatively, local administration of heparin at the site of injury may be used. Adequate collateral flow may not be present. Use of an intraluminal shunt to provide antegrade flow in complex repairs requiring a graft may be wise. Small lacerations may be primarily repaired using an interrupted or running suture after adequate debridement of wound edges. If primary repair is not possible, then a vein or prosthetic patch plasty of the defect is performed. Clean transections, such as stab wounds, may be repaired by mobilization of the proximal and distal artery and primary end-to-end anastomosis if this can be achieved without stenosis or tension.

Many carotid injuries, particularly from GSW, are not amenable to primary repair or anastomosis after debridement. Reconstruction with either a vein or prosthetic interposition graft is needed. Saphenous vein is preferred for internal carotid artery reconstruction, with some evidence of improved patency and lower infection rates compared to prosthetic graft.[75,76] Alternatively, reconstruction of the proximal internal carotid may be performed by transecting the proximal external carotid artery and transposing it to the distal transected internal carotid (Fig. 26.5).

Common carotid artery injuries are best repaired using a thin-walled polytetrafluoroethylene graft, which has a better size match with the native artery and excellent long-term patency. An intraluminal shunt may be used here as well. If associated injuries to the aerodigestive tract have been repaired, well-vascularized tissue such as a SCM flap should be placed between the repairs.[77]

If the injury or dissection extends into the distal internal carotid artery (zone III), exposure and repair are substantially more difficult. Ligation or catheter-assisted thrombosis of the injured vessel should be considered in the asymptomatic patient or if the appropriate expertise is not available to perform distal revascularization. Extra-cranial to intracranial carotid bypass may be performed, but requires substantial exposure of the intracranial carotid artery. Alternatively, saphenous vein bypass from the proximal internal carotid to the petrous carotid artery or middle cerebral artery has been reported. This technique avoids intracranial dissection of the carotid artery and has been associated with excellent associated long-term outcome and graft patency.[75,78]

Operative Management—Vertebral Arteries

Operative management is almost always necessary when there is severe active bleeding from the vertebral artery. The head is turned away from the injured site and the neck is slightly extended. A generous incision is made on the anterior border of the SCM. The fascia is incised and the SCM retracted laterally. The omohyoid muscle is divided, and the carotid sheath is exposed and retracted while the midline structures are retracted medially. A tissue plane anterior to the prevertebral muscles is opened, taking care to avoid the ganglia of the cervical sympathetic chain. Next the anterior longitudinal ligament is incised longitudinally. The transverse processes are palpated, and the overlying longus coli and the longissiuns capitis muscle should be mobilized laterally with a periosteal elevator (Fig. 26.6). The anterior aspect of the vertebral foramen is then best removed with rongeurs to expose the underlying vertebral artery. The artery can then be ligated. The cervical roots are just behind the artery, and care should be taken not to injure them. Blind clamping or clipping should be avoided. Although the artery can be identified between the transverse processes, this is technically challenging. In addition, the venous plexuses can be troublesome.

Another option for rapid control of the proximal vertebral artery is to approach it at the base of the neck where it comes off the subclavian artery. One method is to extend the incision toward the clavicle and transect the SCM off the clavicle, retract the subclavian vein caudal, and transect or retract the anterior scalene muscle laterally. The first portion of the subclavian artery is medial, and it gives off the vertebral artery, the thyrocervical trunk, and the internal mammary muscle.

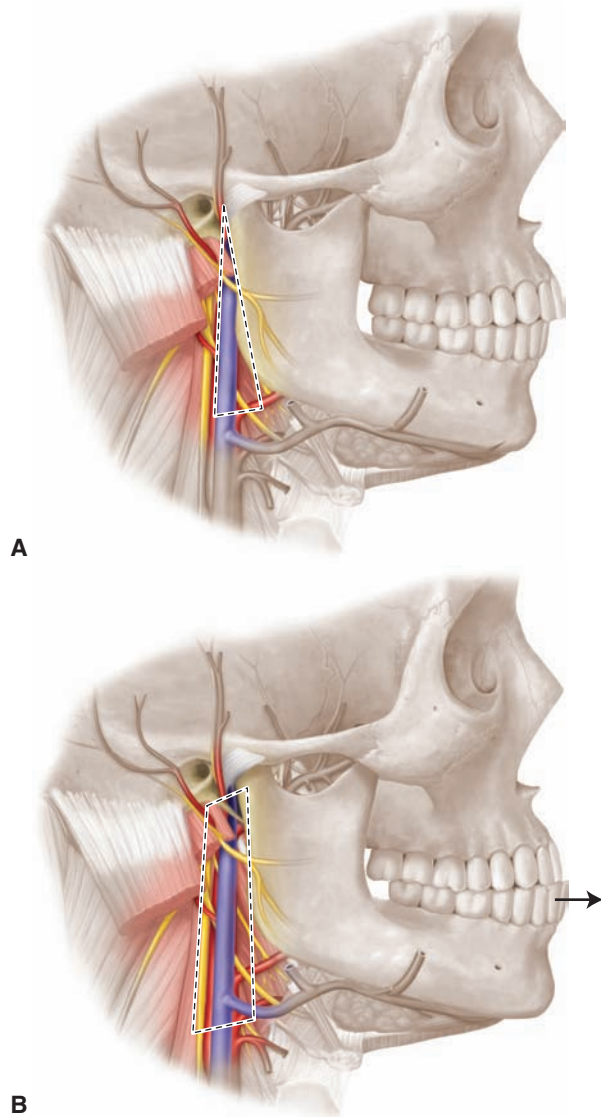

FIGURE 26.4. Exposure of Zone III carotid injuries.

FIGURE 26.5. Reconstruction of the proximal internal carotid by transecting the proximal external carotid artery and transposing it to the distal transected internal carotid.

The vertebral artery comes off the dorsosuperior aspect of the ascending subclavian artery. When approaching the left vertebral artery, care should be taken not to injure the thoracic duct. The second method is to cut down directly on the clavicle and open the periostium. The clavicle can be disarticulated at the sternal boarder and resected with towel clamps as a handle. This can be a rapid way of identifying the artery. Repair of the vertebral artery is extremely difficult and is not usually attempted. The collaterals are usually sufficient to not cause an ischemic stroke. When dealing with an active bleeding vertebral artery and obtaining vascular control is difficult, packing is an option if bleeding can be controlled in this manner.[79]

LARYNGOTRACHEAL INJURIES

Injuries to the larynx and trachea are uncommon. The risk of airway compromise makes prompt diagnosis and intervention mandatory. Although certain injuries to the larynx and trachea may be managed nonoperatively, most require early operation.

Epidemiology

Laryngotracheal injuries account for 1 in 30,000 ED visits.[80] The incidence varies between 2% and 4% in patients with PNI. Blunt trauma to the neck is an uncommon cause of laryngotracheal injury, accounting for <1% of blunt trauma admissions.[46] In a large review, laryngotracheal injuries were found in only 0.34% patients.[34] Direct blows to the anterior neck, decelereation injuries such as in high-speed traffic accidents, and anteroposterior crushing injuries to the chest with in a sudden increase of the intratracheal pressure against a closed glottis can also cause these injuries.

Clinical Presentation

Laryngotracheal injuries vary from subtle disorders of the vocal cord to lacerations and fractures of the larygotracheal skeleton. Presentation varies from dysphonia to stridor and impending airway obstruction. In awake patients, careful clinical examination can reliably diagnose or exclude injuries. In the absence of any suspicious clinical findings, it is unlikely that a substantial injury exists. In a prospective study of 223 patients with penetrating trauma, 152 patients were awake, alert, and had no symptoms of aerodigestive tract injuries. None of these patients had injury requiring treatment.[1]

Air bubbling through a penetrating neck wound is the only hard sign diagnostic of laryngotracheal trauma. This finding is confirmed by asking the patient to cough. Other signs

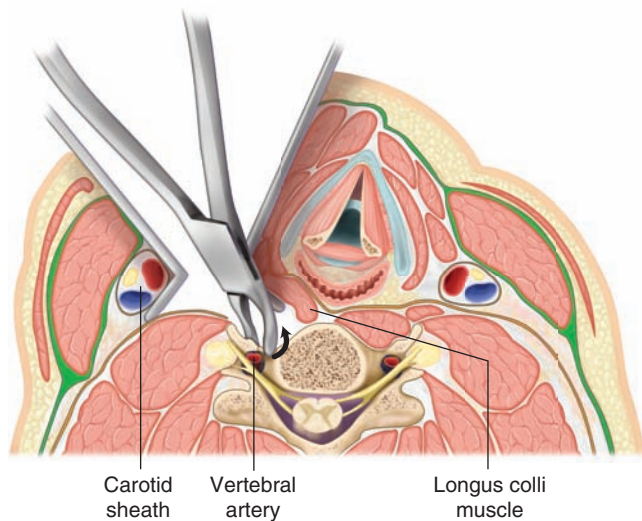
Carotid sheath   Vertebral artery   Longus colli muscle


FIGURE 26.6. Vertebral artery exposure.

and symptoms seen with both blunt and penetrating injuries include subcutaneous emphysema, hemoptysis, odynophagia, hoarseness, and dyspnea.[34,46,80] Tenderness on palpation, cervical ecchymosis, or hematoma suggests laryngotracheal injury in BNI.[43] Though rare, cricotracheal separation may present with a triad of cervical ecchymosis, aphonia, and subcutaneous emphysema.[44]

MANAGEMENT

Nonoperative Management

Patients with minimal intralaryngeal injuries, nondisplaced fractures of the laryngotracheal skeleton, minor mucosal lacerations, and lacerations of the trachea less than one-third the circumference can safely be managed nonoperatively.[34,44] In penetrating trauma, small tracheal wounds with no tissue loss and well opposed edges on endoscopy can be safely observed.[81] In one prospective study, 80% of patients with abnormal endoscopic findings were successfully managed nonoperatively.[1]

Nonoperative management requires close observation and serial endoscopies. The role of steroids or prophylactic antibiotics is controversial, as is the use of prophylactic antibiotics. With nonoperative management of appropriate injuries, good results in terms of voice quality and airway patency are expected.

Operative Management

A collar incision, approximately 2 cm above the sternal notch, gives the best exposure to the larynx. Patients with substantial endolaryngeal injuries require a midline thyrotomy. For patients with proximal tracheal injuries, a transverse collar or an anterior sternocleidomastoid incision is appropriate. For more distal tracheal injuries, a partial sternal split exposes virtually all injuries not requiring a thoracic approach. For injuries in the distal third of the trachea, or injuries at the carina, a right posterolateral thoracotomy is preferred. Small tracheal wounds are primarily repaired with interrupted 3–0 synthetic absorbable sutures. Prophylactic tracheostomy in these simple

repairs is generally not necesary and may increase infection-related morbidity.[82]

More complex and extensive tracheal injuries require individualized surgical technique. It is essential to achieve a tension-free, well-vascularized, mucosa-to-mucosa anastamosis. The blood supply to the trachea runs in the lateral aspects, so that mobilization should be performed by anterior and/or posterior dissection. If the total length of damaged or debrided trachea is less than 2 or 3 cm, reapproximation of the free edges with interrupted absorbable suture without tension is feasible. For larger defects, more complicated release maneuvers may be necessary. Thyroid or suprahyoid release, with flexion of the neck, can provide up to 6 cm of further mobilization. Flexion of the neck is then maintained for 1 week postoperatively by securing the chin to the presternal skin. Retention submucosal sutures can also reduce anastomotic tension. When wound closure cannot be achieved because of extensive defects, musculofascial flaps or synthetic material can be used. Tracheostomy alone is reserved for large anterior wounds or in cases in which instability prohibits prolonged surgical explorations, and tracheal reconstruction is postponed for a later time.

PHARYNGOESOPHAGEAL INJURIES

Pharyngoesophageal injuries are rare. A multicenter study involving 34 trauma centers over a 10.5-year period only identified 229 patients with cervical esophageal injuries.[83] Pharyngoesophageal injuries are not immediately life threatening, and so associated injuries often take higher priority. The first and most urgent priority is to ensure adequate airway. While there are no "hard" signs, diagnostic of pharyngoesophageal injuries, "soft" signs include odynophagia, subcutaneous emphysema, or hematemesis or hemoptysis. These symptoms are present in about 23% of patients PNI, and they are not specific.[34] Only about 18% of patients with these findings have pharyngoesophageal injury.[1] Absence of these findings, combined with the absence of subcutaneous emphysema on radiologic evaluation, makes it highly unlikely that the patient has an injury requiring treatment.

Operative Management

Early surgical repair of esophageal injuries reduces septic complications and leaks. Velmahos et al.[84] showed no deaths occurred among patients treated within 24 hours, whereas with delayed (more than 24 hours) treatment, 36% died due to uncontrollable sepsis. Others have also reported that deaths were all associated with delayed repair.[85]

A sternomastoid or transverse incision provides good exposure to the pharynx and cervical esophagus. The SCM retracted laterally, and the omohyoid muscle either retracted or divided. The carotid sheath is retracted laterally while the trachea and thyroid are retracted medially. The inferior thyroid artery and middle thyroid vein may be divided. Care should be taken to avoid injury to the recurrent laryngeal nerves located in the tracheoesophageal groove. Identification of this nerve is important if circumferential mobilization of the esophagus is needed.

A nasogastric tube or foley catheter inserted into the posterior pharynx can be insufflated with air to look for bubbling to identify small injuries. An alternative is to infuse fluid such as methylene blue but this risks aspiration even with the endotracheal tube in place. During the insufflation, the distal esophagus should be manually compressed. Injuries can

be repaired in one layer with absorbable suture or two layers with absorable sutures followed by a nonabsorbable layer. For SW, debridement is usually not necessary but it usually is for GSW. The strap muscles are placed between the trachea and vascular injuries if possible. The wound is closed over a drain.

In neglected injuries requiring debridement, T-tube drainage is an option.[86,87] This converts the injury to a controlled fistula. Esophagectomy in the acute setting is rare, and external diversion or exclusion is usually reserved for injuries with infection and abscess due to late presentation.

CHAPTER 27 ■ CHEST INJURY

AMY N. HILDRETH AND J. WAYNE MEREDITH

Chest trauma is a significant contributor to patient morbidity and mortality. Thoracic injuries are often accompanied by substantial injuries to other regions. These injuries contribute to approximately 50% of all trauma-related deaths in this country and are the leading cause of death in those under 40-years-old.[1–3] Fortunately, most of these injuries can be managed with skills easily acquired by physicians involved in the initial care of the trauma patient. Only 10%-15% will require operative intervention for life-threatening thoracic injuries. The skill set involved in treatment of these severe thoracic injuries is complex and requires a thorough knowledge of thoracic anatomy and cardiopulmonary physiology. This chapter will discuss the diagnosis and management of the spectrum of thoracic injuries as well as indications for intervention.

INITIAL ASSESSMENT

Initial evaluation of the trauma patient follows the guidelines common to evaluation of any patient suspected to have multitrauma. The evaluation begins with a rapid assessment of the elements of the primary survey to evaluate and quickly treat any immediate life-threatening problems. The primary survey is discussed elsewhere in this text, but the specifics of this survey as they relate to thoracic trauma deserve mention here. Injuries that should be identified during the primary survey include tension and open pneumothorax, massive hemothorax, flail chest, and cardiac tamponade. The specifics of treating these injuries will be discussed later in the chapter.

Establishment of an adequate airway is the first priority during this survey. Severely injured patients will require nasotracheal or orotracheal intubation. Some patients with extensive maxillofacial trauma may require cricothyroidotomy or tracheostomy. Once the airway is deemed intact, the next priority is determining the adequacy of ventilation. If the patient is not breathing, endotracheal intubation is indicated immediately. Other sources of ventilatory insufficiency include the presence of open or tension pneumothorax. These injuries must be promptly addressed as soon as they are recognized.

The next priority is hemorrhage control and restoration of adequate circulation. External hemorrhage is best controlled with direct pressure. Inadequate perfusion is most often a result of either hypovolemia or an inadequate pump. Ongoing internal hemorrhage contributing to hypovolemia must be addressed operatively. Distended neck veins signal one of four common traumatic causes of pump failure: tension pneumothorax, pericardial tamponade, coronary air embolism, or cardiac contusion/myocardial infarction. One must rapidly undertake treatment of these problems to restore circulation.

SECONDARY SURVEY AND RADIOLOGIC ADJUNCTS

If there are no immediately life-threatening injuries identified during the primary survey, the trauma team can progress to a more thorough evaluation and physical examination. Secondary survey of the thorax should focus on identification of potentially life-threatening injuries not identified in the primary survey and discovery of other thoracic injuries. Important injuries to recognize during the secondary survey include simple pneumothorax, hemothorax, pulmonary contusion, tracheobronchial injury, blunt cardiac injury, aortic transection, and diaphragmatic injury. Pain from clinically relevant rib fractures will be evident upon palpation of the chest wall. Pneumothorax and hemothorax may become evident at this stage of evaluation if they were not discovered on primary survey. Visualization of chest wall movement during spontaneous respiration can diagnose flail chest.

Important adjuncts to the secondary survey include the portable chest radiograph, the standard and extended Focused Assessment with Sonography for Trauma (FAST) exam, formal echocardiography, and CT angiography. Chest radiography remains a vital first imaging step in the injured trauma patient. Pneumothorax, hemothorax, rib fractures, and mediastinal abnormalities may be identified on a chest radiograph. Extended FAST is useful in rapid diagnosis of pneumothorax and may also assist in diagnosis of pulmonary contusion.[4–6] FAST also has an excellent ability to evaluate for hemopericardium with reported sensitivities of 96%-100% and a specificity of 100%.[7] The accuracy of these examinations is significantly operator-dependent. Formal echocardiography may be used in later stages of evaluation to assess cardiac function, but it is time consuming and requires appropriately trained personnel. CT angiography is recommended in stable patients with evidence of blunt multisystem trauma, even among those without obvious signs of injury as a substantial number of patients with a normal chest radiograph will have findings of thoracic injury on CT scan.[8,9]

INDICATIONS FOR OPERATION

Emergency Department Resuscitative Thoracotomy

Emergency department resuscitative thoracotomy (ED-RT) is a drastic measure employed only in patients in extremis after penetrating and, to a lesser extent, blunt trauma. The purpose of this procedure is to attempt to stabilize the patient for transport to the operating room for definitive repair of their injuries. For this reason, the ED-RT must be performed expediently and with clear goals in mind. These goals include relief of cardiac tamponade if present, control of hemorrhage, effective cardiac compression, cross-clamping of the pulmonary hilum in the presence of major lung hemorrhage, air embolism, or massive broncho-pleural fistula, and cross-clamping of the descending aorta for lower torso hemorrhage control. The average survival rate to discharge following this procedure is approximately 7%.[10–12]

RT has the best chance of success when reserved for those who arrive at the ED and subsequently deteriorate or those who suffered cardiac arrest just prior to arrival. RT should not be performed in those who have had prehospital CPR for longer than 10 minutes in the setting of blunt trauma and 15 minutes in the setting of penetrating trauma or when the initial presenting rhythm is asystole. The survival rate for patients injured by blunt mechanism undergoing ED thoracotomy is

reported to be around 1%.[12] Survival rates are significantly better for those undergoing this procedure following penetrating trauma; survival to discharge rates of 16%-57% have been reported.[10–14] Better outcomes are seen when ED thoracotomy is performed for stab wounds than for gunshot wounds. Worse outcomes are described when ED thoracotomy is performed following multiple gunshot wounds.[13]

To perform ED thoracotomy, a left anterolateral thoracotomy incision is used to enter the chest. Attention is directed first to the injury. If there is exsanguination from a great vessel, the hemorrhage is controlled with pressure. If air embolism is the cause of the arrest, the hilum is clamped, and air evacuated from the left cardiac chambers. Otherwise, the pericardium is opened anterior and parallel to the phrenic nerve. The hemopericardium is evacuated, the cardiac injury is controlled with digital pressure, and a temporary repair is performed. After the cause of the arrest has been addressed, the descending thoracic aorta is occluded with a vascular clamp or digital pressure, and intrathoracic cardiac compression is initiated. The patient's intravascular volume is restored, and electrolyte imbalances are corrected. If the patient can be saved, he or she is transported to the OR for definitive repair and closure.

URGENT THORACOTOMY

Urgent thoracotomy in the trauma patient is indicated for suspicion of life-threatening injuries that may require surgical repair. Indications for operative treatment of thoracic injuries fall into four broad categories: (1) hemorrhage, (2) major airway disruption, (3) cardiac and vascular injuries, and (4) esophageal disruption. For hemorrhage, operative intervention is indicated by the volume of chest tube output in combination with the hemodynamic profile of the patient. In general, thoracotomy is indicated when chest tube output initially exceeds 1,500 mL initially or if ongoing bleeding exceeds 300 mL per hour for 3 hours. There are, however, pitfalls inherent in this method of determining need for operation. A caveat to chest tube output as an indication for thoracotomy is chest trauma with a delayed presentation and the presence of a coagulopathy. Patients presenting with chest trauma in a delayed fashion may have a substantial hemothorax that has accumulated in the time it has taken the patient to arrive in the ED. Furthermore, in some instances, a tube thoracostomy is malpositioned, kinked, or clotted, allowing accumulation of a hemothorax prior to arrival. In these situations, placement of a second chest tube and/or evidence of ongoing bleeding rather than an absolute amount may be a more reliable indicator of the need for thoracic operation.[15] In addition to chest tube output, patient physiology suggestive of ongoing hemorrhage should play a role in the decision for operative intervention. Low-tube thoracostomy output due to a malpositioned tube may also be misleading. As a result, a chest radiograph should be obtained following tube placement to determine whether the hemothorax has been adequately evacuated. Complete lung re-expansion should also be confirmed on this film, as hemostasis in the chest often will not occur until expansion is complete. Massive air leak after chest tube placement or the presence of gastric or esophageal contents in the chest tube effluent are also indications for operation.

The order of an exploratory thoracotomy should proceed in a logical and orderly fashion. If the diagnosis is uncertain, a posterolateral thoracotomy is the incision of choice. With a known diagnosis, the incision should be chosen to provide optimal exposure of the injury. First, the remaining hemothorax should be evacuated. The lung is then packed out of the field; this procedure may be facilitated by the division of the inferior pulmonary ligament. The mediastinum and pericardium should be evaluated carefully for bleeding. It is difficult to detect the presence of blood in the pericardium by simple visual inspection. A small (5 mm) pericardotomy that can be expanded as necessary is useful to confirm or exclude the presence of hemopericardium. The presence of clear fluid in the pericardium precludes the need for creating a larger pericardial incision. Major vascular injuries are isolated using proximal and distal control; hilar control can be used in cases of pulmonary parenchymal bleeding. Formal repair of injuries may then proceed. The use of a double lumen endotracheal tube or bronchial blocker may be useful and should be considered when patient physiology and injury pattern permit.

INCISION CHOICE

Appropriate incision choice is essential for obtaining adequate exposure of thoracic injuries requiring operative intervention. The choice of incision varies according to several factors, including suspected site of injury and the indication for operation, the urgency of the situation, the presence of associated injuries, the mechanism of injury, and the results of preoperative studies. For injuries that are suspected or diagnosed preoperatively, the choice of approach to the affected structure is greatly simplified (Table 27.1). Preoperative imaging using CTA in the stable patient, even with penetrating mechanism, can assist with the identification of specific injuries and operative planning.[16]

A median sternotomy is one of the more versatile thoracic incisions. It can be opened and closed more quickly than a thoracotomy, is associated with less postoperative pain, and may be less likely to result in contamination of the dependent hemithorax, which may occur with the patient in a lateral position during thoracotomy. In general, a median sternotomy provides the best exposure of the right-side cardiac chambers, the ascending aorta, the aortic arch, and the arch vessels (excluding the left subclavian artery), and it provides adequate exposure of the right lung and hemidiaphragm. A sternotomy may be extended into the neck or supraclavicular fossa to enhance exposure of the great vessels. The main limitation of this incision is that it does not provide exposure of the posterior mediastinal structures (Fig. 27.1).

For the exploration of lateral stab or gunshot wounds or massive hemothorax, a posterolateral thoracotomy on the side of the injury is the incision of choice. The fifth interspace thoracotomy is the most versatile approach to ipsilateral pulmonary and mediastinal pathologic states. Exposure can be markedly enhanced by the removal of the fifth rib. Right thoracotomy is an excellent approach for right lung, tracheal, and proximal left mainstem bronchial injuries. Most injuries of the thoracic esophagus can also be accessed in this manner, except in the case of distal esophageal injuries, which are best approached via left thoracotomy. The right atrium and ventricle are easily exposed by a right thoracotomy as well. Left thoracotomy is ideal for the exposure of the left lung, left pulmonary hilum, aorta, proximal left subclavian artery, left heart chambers, distal esophagus, and distal left mainstem bronchus (Fig. 27.2). In urgent/emergent situations, a clamshell incision, formed by extending a left anterolateral thoracotomy incision transversely across the sternum, provides access but only suboptimal exposure of intrathoracic and mediastinal structures except the right ventricle and atrium (Fig. 27.3).

THORACIC DAMAGE CONTROL

While damage control is critically important in abdominal trauma, it is less frequently needed in thoracic trauma. In most instances, serious bleeding from thoracic structures is unlikely to be controlled with packing; however, severe coagulopathy

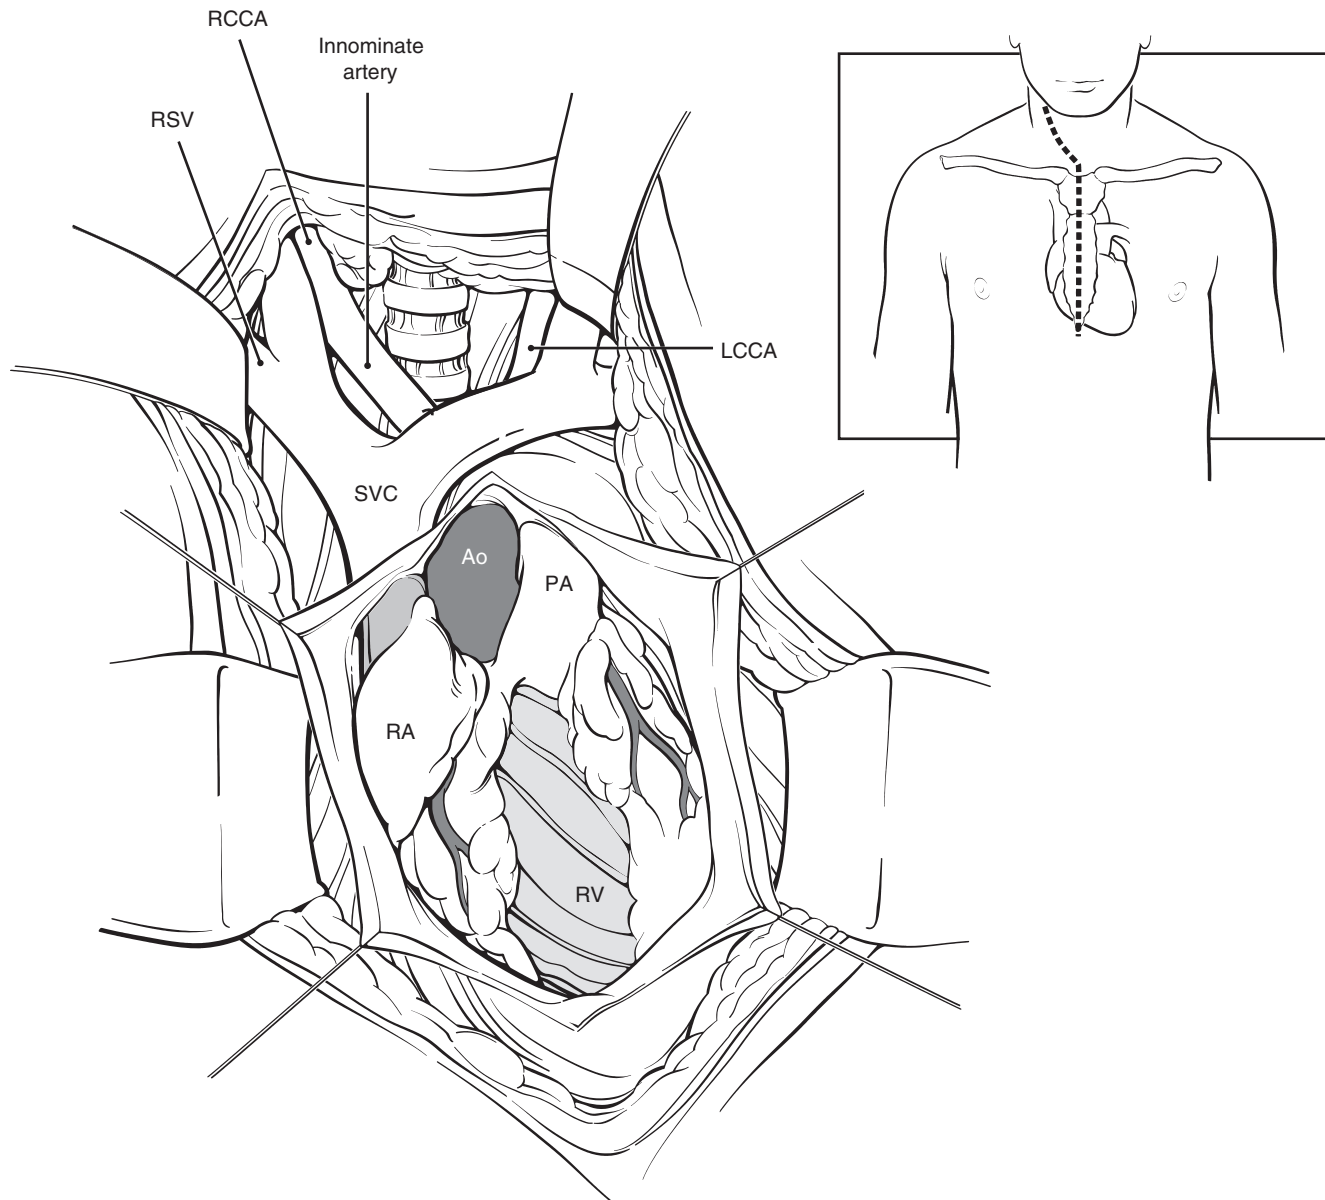
TRAUMA


FIGURE 27.1. Median sternotomy with optimal extension. A median sternotomy provides excellent exposure for the right atrium and ventricle, the superior vena cava, atrial appendage, right pulmonary artery, and lung. If necessary, the incision may be extended into the neck or supraclavicular fossa (**inset**) to enhance exposure of the great vessels. Ao, aorta; LCCA, left common carotid artery; PA, pulmonary artery; RA, right atrium; RCCA, right common carotid artery; RSV, right subclavian vein; RV, right ventricle; SVC, superior vena cava.

occasionally prevents definitive repair and necessitates abbreviation of surgery and temporary closure of the chest by suturing or stapling the skin incision only.[17] The two most common locations of injury in these scenarios are the lung and the chest wall. Hemorrhage from lung lacerations in patients with metabolic exhaustion generally should not be treated with formal anatomic resection: stapled wedge resection, tractotomy, or simple suture repair is more appropriate. In patients with persistent chest wall bleeding that is not associated with a major vessel, treatment with lung re-expansion for local tamponade and correction of coagulopathy usually suffices. Patients who have air embolus or massive bronchopleural fistula will require temporary clamping or twisting of the pulmonary hilum on the affected side, so that the patient may be stabilized prior to proceeding with definitive operation. In rare circumstances, complex esophageal injuries may be associated with extensive loss of tissue, necessitating rapid exclusion and proximal diversion. In most patients with any chance of survival, however, the surgeon should attempt primary closure of the injury, buttressing the repair with autologous tissue, and employing wide drainage. Even with large defects, this approach has a surprisingly high rate of ultimate success. The VAC dressing may be employed for temporary closure when definitive closure of the thorax is not possible.

INDICATIONS FOR DELAYED THORACOTOMY

Indications for delayed thoracotomy include missed tracheobronchial injuries, traumatic aortic rupture, intracardiac injuries, retained hemothorax, and posttraumatic empyema. Specifics of intervention for these injuries will be discussed in the ensuing sections.
FIGURE 27.2. Left posterolateral thoracotomy. A left posterolateral thoracotomy (**inset**) provides excellent exposure of the left pulmonary hilum, left lung, proximal left subclavian artery, descending aorta, distal esophagus, and left diaphragm. LCCA, left common carotid artery; LPA, left pulmonary artery; LSA, left subclavian artery.

MANAGEMENT OF SPECIFIC INJURIES

Chest Wall Injuries

Rib Fractures. Rib fractures are quite common following blunt trauma and can be present in as many as 10% of total trauma admissions. These injuries rarely require operative stabilization, but they do contribute significantly to patient morbidity and mortality. Rib fractures carry a risk of 12% for mortality and 33% for pulmonary complications.[18] Rib fractures in the elderly are associated with especially high morbidity and mortality. The mortality associated with rib fractures is twice as high in patients older than 65 years than in younger patients, and the relative increase in the incidence of pneumonia in older patients is even higher, even after patient comorbidities are considered.[19,20]

The main pathophysiologic consequences of rib fractures are pain, splinting, and prevention of adequate cough, impeding pulmonary toilet. The diagnosis should be suspected if pain or splinting occurs on deep inspiration, and it is confirmed by careful physical examination, consisting of anterior–posterior and lateral–lateral manual compression. If an alert patient feels no pain with these maneuvers, clinically important rib fractures can be excluded. Although rib fractures are often identified on routine chest radiographs, they are more likely to be detected on rib-detail films, which are rarely clinically indicated. A variant of rib fracture that falls into the same physiologic category is costochondral or costosternal separation. This condition is usually detected during physical examination or on CT scan of the thorax but is not seen on routine chest radiographs.

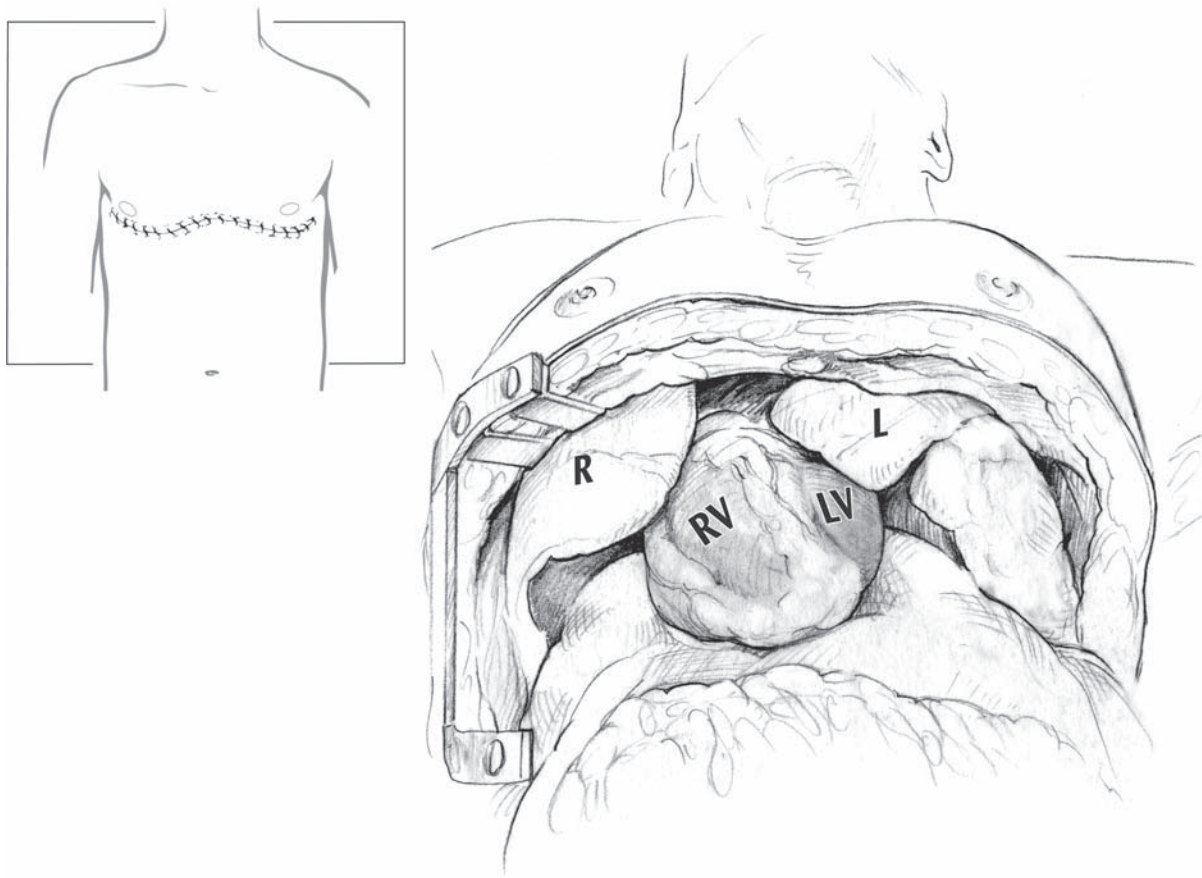
Pain from isolated rib fractures can usually be adequately managed with oral or parenteral analgesics, encouraging good pulmonary toilet, and use of thoracic epidural anesthesia (discussed below) in select patients. We mention chest wall strapping, taping, and bracing only to condemn these practices. Binding devices generally restrict tidal volume and thus promote rather than prevent atelectasis and pulmonary complications. Increasingly, reports have demonstrated the feasibility of rib fracture repair using a variety of different methods including wire sutures, intramedullary wires, staples, and various plating systems.[21] Potential indications for operative repair


FIGURE 27.3. Clamshell extension of left anterolateral thoracotomy. In urgent/emergent situations, a clamshell incision, formed by extending a left anterolateral thoracotomy incision, transversely across the sternum, provides access but only suboptimal exposure of intrathoracic and mediastinal structures except the right ventricle and atrium. R, right lung; RV, right ventricle; LV, left ventricle; L, left lung.

of rib fractures include flail chest, painful, and mobile rib fractures, which are refractory to conventional management, chest wall deformity/defect, rib fracture nonunion, and during thoracotomy for other indications. In isolated reports, clinical outcomes have been excellent when repair is undertaken. However, there is a need for clinical trials documenting the superiority of rib fracture repair versus conventional management in select patient populations and defining indications for repair.[22,23]

Sternal Fractures. Sternal fractures commonly result from motor vehicle collisions and are associated with the use of three-point restraints. Isolated sternal fractures are relatively benign, having a low incidence of associated cardiac, great vessel, and pulmonary injuries. Sternal fractures in unrestrained occupants and victims of crush injuries, however, are commonly associated with underlying visceral injuries, which must be excluded.[17,24]

The diagnosis of sternal fracture is based on the presence of severe pain, often associated with instability on sternal palpation. In many cases, physical examination can clarify the nature of the fracture. Sternal fractures are almost invariably transverse, with the majority occurring at the sternomanubrial joint or in the midbody of the sternum. They may be characterized as simple (two fragments) or comminuted (multiple fragments), as displaced or aligned, or as stable or unstable. The fragments of an unstable fracture move substantially with activity.

Initial management of a sternal fracture is directed toward resuscitation and identification or exclusion of other life-threatening injuries. In patients with isolated sternal fractures, a normal electrocardiogram and a normal chest radiograph suggest that associated serious injuries are unlikely. If the pain is controlled with oral analgesics, these fractures can usually be managed on an outpatient basis. Displaced fractures may be reduced by the simple (albeit painful) maneuver of having the patient simultaneously raise his or her head and legs from the bed. Such a position requires contraction of the rectus abdominis, which distracts the caudad segment inferiorly, and the sternocleidomastoid muscles, which retract the cephalad segments superiorly. The physician can then depress the anterior segment and allow the patient to relax. This measure often suffices for alleviation of subsequent pain and sometimes constitutes adequate long-term treatment.

The vast majority of sternal fractures heal without repair. Those that are unstable or are displaced by more than 1 cm of overlap are more likely to exhibit malunion or nonunion and subsequent chronic pain; they may require open reduction and internal fixation. Occasionally, a patient with a clinically stable, minimally displaced sternal fracture associated with lower extremity injuries who requires crutches for ambulation, experiences such disabling sternal pain during ambulation that fracture repair is necessary. Sternal fractures may be repaired with either of two operative techniques. In both, the sternum is approached via either a vertical midline incision or a sweeping transverse inframammary incision similar to that

used for repair of pectus excavatum. The fracture is exposed, and the ends are mobilized and fixed with either reconstruction plates or No. 6 sternal wires. Both wire fixation and plate fixation are well tolerated and are appropriate for properly selected patients.

Flail Chest. Flail chest is defined as the presence of two or more ribs fractured in two or more places, resulting in paradoxical movement of a section of the chest wall. It is the most serious of the chest wall injuries caused by blunt trauma. Although flail chest may present as an isolated injury, it is much more commonly associated with other injuries.[25] The diagnosis may be suspected based on radiologic findings and confirmed by examination of the spontaneously breathing patient. The flail segment may be overlooked in the patient receiving mechanical ventilation because of the absence of paradoxical movement.

There are three important pathophysiologic components that contribute to the severity of flail chest. The first is the alteration in chest wall mechanics secondary to the flail segment. Although this is usually not the most clinically important abnormality, the paradoxical motion of a large flail segment occasionally impairs the patient's ability to achieve an adequate tidal volume or an effective cough. The second important pathophysiologic component is underlying pulmonary contusion. In the vast majority of serious flail chest injuries, this is the most important physiologic aberration.[26] In the contused portion of the lung, there is extravasation and accumulation of blood and fluid in the alveolar air space, which results in sufficient shunting to produce hypoxemia. The third factor is the pain of multiple rib fractures, leading to splinting and diminution of tidal volumes; it prevents adequate coughing and pulmonary toilet. The combination of depressed tidal volume and inadequate cough leads to hypoventilation, atelectasis, and often pneumonia.

Central to management of the flail chest is the concept that the injury is not static but is in constant evolution. Frequent re-evaluation is essential; prompt intervention should be undertaken when patient physiology changes. All awake and alert patients with adequate oxygenation and ventilation deserve a trial of management without intubation.[27] Pain cannot be eliminated entirely, but it usually can be diminished sufficiently to allow an adequate tidal volume and a forceful cough. Oral analgesics rarely suffice for patients with even a small flail segment; stronger agents are required for all but the most stoic of patients. Parenteral narcotics are effective, especially when administered in a patient-controlled analgesia (PCA) device. Potential disadvantages of parenteral narcotics include excess sedation, cough suppression, and respiratory depression.

When PCA analgesia is not adequate or is contraindicated, other modalities of analgesia may be considered. These methods include epidural analgesia, intercostal nerve block, intrapleural anesthesia, and thoracic paravertebral block. Each of these modalities has inherent risks and benefits, and choice of analgesia should be based on patient physiology, injuries, and medical history.

Epidural analgesia is the most common method used for the treatment of chest wall pain. It consists of insertion of a catheter into the thoracic or lumbar epidural space with infusion of a narcotic, a local anesthetic, or most commonly, a combination of the two medications. Purported benefits include improved analgesia as well as improvement in respiratory mechanics and decrease in proinflammatory cytokines.[28,29] The benefits of epidural analgesia may translate into decrease in ventilator days, decrease in pulmonary complications, and lower mortality.[19,30] Disadvantages include the potential for epidural infection and hematoma as well as direct spinal cord trauma. Hypotension (when local anesthetic agents are used), peripheral neurologic effects, and pruritus are also potential side effects.

The Eastern Association for the Surgery of Trauma (EAST) has published recent guidelines regarding the use of analgesic adjuncts. These guidelines state that epidural analgesia is the preferred method of pain relief for blunt chest wall injury. They recommend epidural analgesia for patients who are ≥65-years-old if there is no contraindication, and they state that it may be considered for those under 65 years as well.[31] When epidural analgesia is contraindicated, another regional anesthetic technique may be considered. These other techniques, including intercostal nerve block, intrapleural analgesia, and paravertebral block, are relatively safe but have not been studied extensively in the trauma population.

The decision-making process for the management of flail chest should begin with the assessment of the patient's ability to cough. If the patient is able to clear tracheal secretions, then observation in an acute care setting with small, infrequent doses of narcotics, is appropriate. If the patient has no cough or has a very truncated cough that moves secretions but does not propel them into the oropharynx, an aggressive program to promote pulmonary toilet should be instituted. If a sufficiently vigorous cough cannot be achieved and there is no specific contraindication, an epidural catheter is considered, and the patient is followed closely with frequent physical examinations in the intensive care unit. Ambulation is encouraged, and frequent coughing is required. It is important that management decisions be made early, so that effective therapy can be started expeditiously. There is no role for antibiotic prophylaxis or steroid use in the management of patients with flail chest or pulmonary contusion.

Any patient with flail chest demonstrates that further deterioration of pulmonary function as evidenced by worsening hypoxia or hypercarbia should undergo endotracheal intubation and mechanical ventilation. Goals of mechanical ventilation include the establishment of tidal volume adequate for normal chest wall excursion and maintenance of normocarbia through an adequate respiratory rate. Hypoxia is managed by increasing the fraction of inspired oxygen (FiO_2) and applying sufficient positive end-expiratory pressure to achieve adequate oxygenation (usually defined as arterial oxygen saturation >90%) with nontoxic levels of FiO_2.

A few patients with severe disruption of chest wall mechanics as a result of flail chest continue to require positive pressure ventilation even though adequate pain control has been achieved, and the pulmonary contusions are beginning to resolve. Some of these patients may benefit from internal fixation of the multiple rib fractures, which restores chest wall stability and eliminates much of the fracture-related pain. A variety of methods have been described to stabilize the ribs and obtain compression osteosynthesis of each fracture site. Two single institutional series describe the efficacy of this procedure in patients with flail chest.[32,33] Further clinical trials are needed to better define indications for fracture repair.

Penetrating Chest Wall Injury

In most cases of penetrating thoracic trauma, the injury to the chest wall is vastly overshadowed by the injury, or potential for injury, to the intrathoracic structures. The notable exceptions to this general rule are hemorrhage and open chest wounds.

Hemorrhage. Stab wounds and low-caliber gunshot wounds to the anterior chest are common in urban areas. Once serious injury to intrathoracic organs has been excluded, such injuries often can be managed with tube thoracostomy or observation alone. Indications for urgent thoracotomy have been discussed previously.

In patients with persistent hemorrhage from chest tubes who require thoracotomy, the most common source of the

bleeding is a lacerated internal mammary or intercostal artery. Attempts to control bleeding from these vessels nonoperatively usually fail. Angiography to localize the bleeding vessel is unnecessary and delays definitive care; coupled with embolization of the lacerated vessel, it is more time-consuming than surgical intervention and does not address associated injuries and hemothorax.

Penetrating wounds to the midportion of the pectoral muscle occur with surprising frequency, possibly as a result of an assailant's erroneous conception of the location of the heart. Such injuries often lacerate the pectoral branch of the thoracoacromial artery, which courses along the posterior surface of the pectoral muscle. Control of this troublesome bleeding is extremely difficult to achieve if exploration is attempted directly through an extension of the entrance wound. Exposure is much improved if exploration is attempted through an oblique wound along the lateral pectoral margin after entry into the subpectoral plane.

Open Chest Wounds. The diagnosis of an open chest wound is usually obvious, and treatment of this wound depends on the size of the wound the chest wall defect. Most small open pneumothoraces can be managed initially with occlusive dressings, but there is usually an underlying pulmonary injury with air leakage, which necessitates early tube thoracostomy to prevent tension pneumothorax. Once the patient's condition is stable, the wound can be débrided and closed. Occasionally, primary skin closure must be delayed.

Larger chest wall defects pose a challenging therapeutic problem. Such wounds usually result from high-velocity missiles or shotguns fired at close range. Initial management is directed toward restoration of respiratory mechanics with early intubation and mechanical ventilation.

The next priority is to address any underlying intrathoracic injuries, which may range from mild pulmonary contusion to massive hemorrhage in conjunction with severe lung or hollow viscus injury. When associated intrathoracic injuries are present, the first step in the closure of the defect is to select an appropriate operative approach. Although the primary objective in this situation is to provide adequate exposure for repair of what may be life-threatening injuries, whenever possible, the thoracotomy should be performed in such a way as to preserve the blood supply and muscle mass of the chest wall adjacent to the defect.

After definitive repair of intrathoracic injuries and debridement of devitalized chest wall tissue, planning begins for wound closure. Such planning requires a degree of familiarity with current and developing techniques and an understanding of pleural drainage, respiratory mechanics, and techniques of tissue transfer. Collaboration with plastic and thoracic surgeons is often helpful. Most chest wall defects can be closed with viable autogenous tissue, usually through rotation of local myocutaneous or myofascial flaps of the pectoral muscle, the latissimus dorsi, or the rectus abdominis.

Pleura and Lungs

Pneumothorax. Pneumothorax occurs when there is injury to the lung and/or tracheobronchial tree, resulting in air in the pleural space. A simple pneumothorax requires tube thoracostomy when it is large enough to be seen on plain chest radiograph. With the advent of modern imaging techniques, even clinically insignificant pneumothoraces may be identified during evaluation of the patient. If a pneumothorax is seen on thoracic CT but not on plain chest radiograph, it is known as an occult pneumothorax. Studies have examined the need for tube thoracostomy in these cases. The majority of evidence indicates that asymptomatic occult pneumothoraces may be

observed, regardless of the need for positive pressure ventilation.[34–38] Patients with occult pneumothoraces who are treated without tube thoracostomy should be observed for at least 24 hours with repeat chest radiography to ensure the pneumothorax has not enlarged.

Progression of simple pneumothorax leads to tension pneumothorax, a life-threatening injury that should be recognized on primary survey. Air released from the lung parenchyma and tracheobronchial tree continues to accumulate in the pleural space, leading to an increased intrapleural pressure. This pressure is transmitted to the cardiac chambers and vena cava, impeding venous return to the heart and ultimately resulting in cardiovascular collapse. This entity may be recognized by unilateral decreased breath sounds, tympany on the affected side, tracheal deviation, and distension of neck veins. However, these signs may be absent or go unrecognized in a busy ED. The diagnosis is often suggested by the presence of shock accompanied by the evidence of inadequate venous filling on physical examination as well as recognition of asymmetric chest wall motion.

Radiographic evaluation should not delay treatment of a suspected tension pneumothorax with tube thoracostomy in patients with hemodynamic compromise.

Hemothorax. Hemothorax may occur in isolation or present in combination with pneumothorax. Hemothorax may be recognized on plain chest radiography as well as on thoracic CT. If the volume of hemothorax is great enough (massive hemothorax), physiologic compromise occurs in a manner similar to that of tension pneumothorax. Initial treatment of hemothorax is similar to the treatment of pneumothorax. After placement of tube thoracostomy, initial tube output as well as ongoing output should be carefully monitored. Indications for urgent thoracotomy based on tube thoracostomy output have been previously outlined.

The goal of treatment with tube thoracostomy is complete removal of blood. Prophylactic antibiotics for tube thoracostomy placement are not currently indicated.[39] Complications such as atelectasis and empyema after chest trauma are clearly related to the presence of residual blood, fluid, and air, as can occur secondary to improper positioning (i.e., within a fissure) or obstruction of the tube. A retained hemothorax is suggested by the presence of a persistent opacification in the pleural space in a patient with a known previous hemothorax. However, plain chest radiography can be misleading and often underestimates the amount of fluid in the chest. The radiodensity seen can be confused with adjacent pulmonary contusion or atelectasis. Thoracic CT confirms the diagnosis, providing information about the size and location of the hemothorax that can be used intraoperatively to make the appropriate incision. Evacuation of hemothorax is indicated, as blood can serve as a nidus for infection.[40] If the hemothorax is incompletely evacuated using a functional single tube, placement of a second tube is unlikely to be helpful in removing clotted blood and may likely increase the risk of infection.[41]

Thus, an operative approach is needed. When used early (<5 days after injury), video-assisted thoracic surgery (VATS) has been shown to be cost-effective method for managing clotted hemothoraces and free-flowing blood in patients who ideally can tolerate single-lung ventilation. However, VATS reduces the surgeon's ability to control bleeding and perform definitive repair of injuries; thus, in patients who have ongoing bleeding, posterolateral thoracotomy is required.[42–44] It is our practice to routinely obtain chest CT when patients have persistent pleural effusion after tube thoracostomy on chest radiograph within 48 hours of injury. In patients confirmed to have a persistent pleural effusion, we proceed directly to VATS as it is well documented that delaying the operation increases the technical difficulty of the procedure and rate of conversion to thoracotomy.[45,46]

Empyema Thoracis. Empyema thoracis is a troublesome complication after chest trauma, occurring in approximately 1.5%-5% of patients.[39,40,47,48] Possible causes include retained hemothorax, pneumonia with parapneumonic effusion, persistent foreign body, ruptured pulmonary abscess, bronchopleural fistula, esophageal leakage, and tracking through the intact or injured diaphragm from an abdominal source. Empyema may be difficult to diagnose in the posttraumatic setting and must be differentiated from pleural thickening, pulmonary contusion, or uninfected effusion. Thoracic CT with intravenous contrast usually demonstrates a fluid collection with loculations or an enhancing rim. Such findings, coupled with a clinical scenario of low-grade sepsis, worsening respiratory function, or failure to thrive, are diagnostic. Analysis and culture of fluid obtained at thoracocentesis or chest tube placement typically confirm the diagnosis, but the fluid may be sterile if the patient is already receiving antibiotics.

Antibiotic therapy, either broad-spectrum or specifically directed against cultured organisms (usually gram-positive pathogens), is certainly an important component of therapy for empyema thoracis, but the primary goal is the removal of the infection while the fluid is still thin. When this goal is met, a more modest therapeutic procedure can be performed, there is less risk that a restrictive pulmonary peel will develop, and the injured patient recovers faster overall. Rarely, in the early stages, tube thoracostomy may suffice for treatment; more commonly, the infected pleural process cannot be completely evacuated via chest tube because of thicker fluid, loculations, or pleural adhesions. In these cases, VATS or a formal thoracotomy with decortication is generally required.

Decortication is the cornerstone of effective therapy for posttraumatic empyema. Emphasis should be placed on completely removing the visceral pleural peel to allow complete lung expansion postoperatively. Decortication should not be undertaken in the face of severe sepsis. Instead, antibiotics and drainage (via tube thoracostomy, CT-directed catheter placement, or open rib resection) should be employed until the sepsis is controlled. Once the patient's condition has stabilized, decortication may be performed. In cases of early empyema, VATS has been successfully used for lysis of adhesions and removal of fluid.[48,49] Because of the limited capacity for performing pleurectomy with this procedure, VATS should not be used when thick peel or a trapped lung is present.

Pulmonary Contusion. Pulmonary contusions are bruises to the lung that are caused by either blunt or penetrating trauma. The contused segment of the lung has a profound ventilation–perfusion mismatch, which produces an intrapulmonary right-to-left shunt and hypoxia. The clinical sequelae of lung contusion vary from simple shortness of breath to respiratory failure requiring mechanical ventilation. Lung contusion results in systemic activation of the innate immune system as evidenced by local and systemic production of various inflammatory mediators such as the interleukins, prostaglandins, and chemokines. This resultant inflammatory response contributes to the evolution of pulmonary and remote organ dysfunction.[50] The contusion is usually not fully evident on plain chest radiograph but is better imaged with thoracic CT. The size of the contusion has been found to be directly proportional to the risk of developing acute respiratory distress syndrome.[51] Lung contusion is a well-established risk factor for pneumonia, and the bruised lung also may serve later as a source of sepsis.

Most pulmonary contusions that are not complicated by excessive attempts at resuscitation or by superinfection resolve over 3–5 days. Cardiovascular and ventilatory support is provided. In general, pulmonary contusion is treated in much the same fashion as flail chest. Patients with rib fractures and painful chest wall excursions must be given sufficient analgesic support to allow them to produce a forceful cough. Intubated patients should undergo suctioning frequently. Patients with pulmonary contusions who require substantial volume resuscitation should be considered for pulmonary arterial catheter monitoring. Steroids are not indicated, because they have no effect on the development or resolution of the contusion and because they set the stage for subsequent infection. Diuretics and prophylactic antibiotics are also unnecessary.

Pulmonary Lacerations. Bleeding pulmonary lacerations can be oversewn, resected, or explored via pulmonary tractotomy. Bleeding from small or shallow lacerations can be controlled with a continuous monofilament suture. Bleeding from deeper lacerations is controlled with resection or tractotomy. Most pulmonary resections for trauma should be stapled, nonanatomic resections. However, anatomic lung resection is required in rare instances, and trauma surgeons should remain familiar with the technical aspects of this procedure. Mortality is proportional to the amount of lung tissue resected: with suture repair alone, mortality is 9%; with tractotomy, 13%; with wedge resection, 30%; with lobectomy, 43%; and with pneumonectomy, 50%.[52,53]

Tractotomy is especially useful for deep through-and-through injuries that do not involve the hilum.[54] In this technique, the injury tract is opened with a linear stapler or between two aortic clamps. If clamps are used, the cut lung edges are oversewn and the tract left open (Fig. 27.4). Tractotomy exposes bleeding vessels and air leaks inside the tract and permits selective ligation. Occasionally, it exposes an injury to a major vascular or airway structure that must be treated with a formal resection. Because of the risk of exsanguination or excessive devitalization of lung tissue, tractotomy is not indicated when the injury traverses the hilum or when the entire thickness of a lobe will be cut.

Central lung injuries often cause massive hemorrhage. In addition, they may be sources of pulmonary venous air emboli when both a major pulmonary vein and a large airway are disrupted. A common scenario involves an intubated patient who exhibits sudden deterioration of central nervous system (CNS) and cardiac status shortly after being placed on positive pressure ventilation. Emergency thoracotomy must be performed and the pulmonary hilum clamped or twisted. The diagnosis is confirmed by visualizing air in the epicardial coronary arteries. Aspiration of air from the left-side cardiac chambers and elevation of central blood pressure are useful maneuvers. Most central lung injuries are associated with extensive parenchymal injury in gravely ill patients. Selective repair of hilar structures is usually impractical in this setting, and lobectomy or pneumonectomy is the salvage procedure of choice.

Tracheobronchial Injuries

Although tracheobronchial injuries are often lethal, a high index of suspicion for the existence of the injury, a timely diagnosis, and appropriate intervention can improve the chances of a successful outcome. The reported incidence of tracheobronchial injury in blunt chest trauma patients ranges from 0.2% to 8%.[55–57] Concomitant injury is the rule rather than the exception, but the patterns of associated injury vary widely. More than 80% of tracheobronchial ruptures occur within 2.5 cm of the carina.[58]

Clinical presentation of injury to the tracheobronchial tree is dependent upon severity and location of injury. In the neck, airway involvement may create severe respiratory distress that results in death before emergency care can be given. Alternatively, patients with cervical tracheal injuries may present

with stridor, hoarseness, hemoptysis, or cervical subcutaneous emphysema. The presentation of thoracic tracheobronchial injury depends on whether the injury is confined to the mediastinum or communicates with the pleural space. Injuries confined to the mediastinum usually present with massive pneumomediastinum. Injuries that extend to the pleural space create an ipsilateral pneumothorax that may or may not be under tension. A pneumothorax that persists despite adequate placement of a thoracostomy tube with a continuous air leak is suggestive of tracheobronchial tree injury and bronchopleural fistula. Dyspnea may actually worsen after insertion of the chest tube because of the loss of tidal volume via the tube. Of note, these injuries are rare, and most pneumothoraces that do not resolve with multiple tube thoracostomies do not represent

tracheobronchial injury; malpositioned or clotted tubes are a much more likely culprit.

The diagnosis is typically suspected on the basis of the clinical history and the characteristic signs and symptoms. The advent of spiral CT with multiplanar reconstruction has led to increased use of this modality to evaluate tracheobronchial injury. There are an increasing number of reports demonstrating the utility of CT technology in diagnosing tracheobronchial injuries with a sensitivity approaching 100%.[59,60] Because of its excellent negative predictive value, CT may be employed as a screening tool to look for these injuries in stable patients; however, at present, diagnostic bronchoscopy remains necessary to reliably exclude the diagnosis of tracheobronchial injury. In stable patients with transmediastinal
A

gunshot wounds, thoracic CT may be employed to detect proximity of the missile tract to mediastinal structures, directing subsequent evaluation.[61] Indications for bronchoscopy in this setting include a large pneumomediastinum, a refractory pneumothorax, a large air leak, persistent atelectasis, and possibly marked subcutaneous emphysema.[62]

The first priority in the treatment of tracheobronchial injury is airway management. If the patient is maintaining his or her own airway and is adequately ventilated, a cautious noninterventional approach is probably the best choice until further diagnostic workup is performed or other life-threatening injuries are stabilized. Careless handling of the airway can be disastrous and may compound the injury. The best method to secure an airway in a patient with neck trauma, and possible tracheal injury is a matter of debate. With blind endotracheal intubation, the path of the tube distal to the larynx is unknown, and it is possible to lose the lumen or create a false passage. With intubation over a flexible bronchoscope, the tube can be visualized as it passes beyond the site of injury, and some of the dangers of blind intubation are thereby mitigated. However, some degree of sedation is usually required, and if the patient is oversedated, the airway that was being spontaneously protected may be lost. For this reason, paralytic medications should generally be avoided in this setting. Urgent

tracheostomy, performed in the OR, is advocated by many as the safest and most secure way of obtaining airway control. If the trachea is completely transected, the distal trachea can usually be found in the superior mediastinum and grasped for insertion of a cuffed tube. The approach taken to airway control must vary with the resources and expertise available at each institution. One must also keep in mind that even after the airway is secured, it may still be possible to exacerbate the injury by means of aggressive ventilation with high airway pressures. Tube thoracostomies should be appropriately placed at this time and connected to suction, even though dyspnea may worsen. Once the airway is controlled, there is time for orderly identification of concurrent injuries, esophagoscopy, laryngoscopy, arteriography, transport to definitive care areas, and, if necessary, celiotomy.

Selected tracheobronchial tears may be managed nonoperatively. Lesions suitable for observation must involve less than one third of the circumference of the tracheobronchial tree. The lungs must be fully re-expanded with tube thoracostomy. Prophylactic antibiotics, humidified oxygen, voice rest, frequent suctioning, and close observation for sepsis and airway obstruction are required. Small penetrating wounds with well-opposed edges and no evidence of loss or devitalization of tracheal tissue may be effectively treated with temporary

endotracheal intubation.[58] The cuff of the endotracheal tube should be inflated below the level of injury and left undisturbed for 24–48 hours while the wound seals. If a conservatively managed patient's clinical condition deteriorates, bronchoscopy should be liberally repeated.

More commonly, operative repair is required. Intrathoracic tracheal, right bronchial- and proximal left mainstem bronchus injuries are best repaired through a right posterolateral thoracotomy at the fourth or fifth intercostal space, because this approach avoids the heart and the aortic arch. Distal left bronchial injuries more than 3 cm from the carina are approached through a left posterolateral thoracotomy in the fifth intercostal space. Optimal repair includes adequate débridement of devitalized tissue (including cartilage) and primary end-to-end anastomosis of the clean tracheal or bronchial ends. The anastomosis can be accomplished without tension by mobilizing the structures anteriorly and posteriorly, thereby preserving the lateral blood supply. Tension may also be released with cervical flexion, which can be maintained postoperatively by securing the chin to the chest with a suture. The repair may be buttressed with pleura, pericardium, or an intercostal muscle flap.

Esophageal Injury

Injury to the esophagus, though relatively rare, poses particular problems for the treating physician because of the complexity of the presentation, the workup, and the treatment options. Despite diagnostic and therapeutic advances, the morbidity and mortality associated with esophageal injury remain high. Most esophageal injuries result from penetrating trauma. If surgical exploration is performed for all penetrating cervical wounds that violate the platysma, the esophagus is found to be injured approximately 12% of the time. Penetrating intrathoracic esophageal injuries are less common, however, occurring in about 0.7% of all penetrating chest wounds.[63]

Signs and symptoms of esophageal injury include odynophagia, dysphagia, hematemesis, oropharyngeal blood, cervical crepitus, pain and tenderness in the neck or chest, resistance to passive motion, dyspnea, hoarseness, bleeding, cough, and stridor. Fever, subcutaneous emphysema, abdominal tenderness, and mediastinal crunching sounds (Hamman's sign) may be observed. Pain is the most common presenting symptom (71% of patients), followed by fever (51%), dyspnea (24%), and crepitus (22%).[64] Overall, the signs and symptoms associated with esophageal injury are fairly nonspecific, and a high index of suspicion must be maintained to make the diagnosis.

Evaluation of potential esophageal injuries due to penetrating trauma is usually performed surgically: either the tract is found to be inconsistent with esophageal injury or direct inspection of the esophagus reveals it to be uninjured. If neither option is feasible, diagnostic testing is necessary. Plain radiographs, CT scans, and contrast esophagrams are all commonly used imaging modalities with varying sensitivities and specificities. Endoscopy may add to the diagnosis, but the results depend on the operator's technique and experience, and there is a risk that it may exacerbate an esophageal tear or further injure an unstable cervical spine. In an otherwise asymptomatic patient who is awake, alert, and able to cooperate, a simple contrast swallow is usually sufficient to exclude injury. Injuries resulting from low-velocity projectiles and stab wounds do not cause large tissue defects; for these injuries, barium gives superior anatomic detail and is the agent of choice. Injuries from large-caliber or high-velocity projectiles usually cause more damage, and, thus, the contrast agent tends to spread more widely throughout the mediastinum during a diagnostic swallow. If contrast studies are indicated in this setting, a water-soluble agent may be used first. Such agents cause

pulmonary damage when aspirated, however, and should not be used if tracheoesophageal fistula is suspected.

In cases of blunt trauma, determining when further study is needed is a vexing task. In general, whenever a patient has pneumomediastinum that is extensive or is associated with any of the symptoms of esophageal injury, the esophagus should be evaluated. Simple pneumomediastinum seen on thoracic CT without other indication of aerodigestive injury rarely warrants evaluation of the esophagus.[65] Regardless of the diagnostic studies obtained, evaluation must be carried out expeditiously. Considerable delays in management can increase the incidence of esophageal injury-related morbidity by as much as a factor of two.[66]

Injuries to the distal third of the thoracic esophagus are most easily approached via the left chest. More proximal injuries are best approached through the right chest or via a combination of chest and cervical incisions. The incision should be made so as to facilitate subsequent buttressing of the repair (e.g., with a pedicle from an intercostal muscle or the latissimus dorsi). Surgical repair entails local débridement, wide drainage, primary repair of the perforation with absorbable suture, and buttressing of the repair with a viable muscle flap. Primary repair can usually be accomplished when the perforation is repaired within 24 hours of occurrence. Placement of a gastrostomy tube for gastric drainage and jejunal feeding tube for enteral feeding access should be considered in all these patients. In the absence of distal obstruction, almost all late-presenting esophageal perforations heal after primary repair and tissue flap coverage. Generally speaking, techniques such as esophageal exclusion, diversion, and resection should be needed only when perforation occurs in the setting of a primary esophageal pathologic condition (e.g., cancer); esophageal perforation in this setting is rarely managed by trauma surgeons.

Thoracic Duct Injuries

Chylothorax after blunt or penetrating chest trauma is rare: only case reports and small case series are found in the literature. Much of the management of this condition is extrapolated from management of iatrogenic thoracic duct injuries, which are much more common. Most patients with traumatic chylothorax show evidence of other axial injuries to the chest, especially spine fractures.[67] The diagnosis is made by finding chylomicrons and high levels of triglycerides in a typically large pleural effusion of milky appearance. Drainage of as much as 1,000 mL per day is not unusual and results in severe nutritional and immunologic derangements, which are the main causes of the high mortality associated with this condition.

Treatment usually begins with limiting oral intake of short- and long-chain triglycerides, which cause increased flow of chyle. Diets high in medium-chain triglycerides must often be given enterally, because they are not palatable. Some clinicians recommend instituting total parenteral nutrition with complete abstinence from oral intake. Administration of octreotide may also help decrease chyle production.[68] These treatments, in conjunction with adequate pleural drainage and lung expansion, are successful in approximately 50% of cases after 2–6 weeks.

Operative strategies for managing thoracic duct injuries are generally undertaken only after conservative measures fail. Preoperatively, patients are fed cream, with or without dyes such as Sudan black, to increase chyle flow and enhance visualization of the site of injury. The thoracic duct is then ligated above and below the injury; this may be performed by means of VATS on the hemithorax ipsilateral to the effusion.[57] Fibrin glue and talc pleurodesis may be used as adjuncts to ligation. Because there are usually multiple areas of injury and because the thoracic duct is friable by nature, surgical treatment is not

always successful. Continued nutritional management and reoperation may be required.

Cardiac Injury

Cardiac injuries may result from either blunt or penetrating trauma and involve the myocardium, coronary arteries, valves, or septum. Mortality rates range from 10% to 70% depending on presentation and mechanism of injury.[69–71]

Penetrating. Patients with penetrating cardiac injuries generally present in one of three ways. In approximately 20% of patients, the injury is clinically silent, at least initially, and is subsequently diagnosed at operation or on diagnostic imaging. In approximately 50%, there is evidence of pericardial tamponade, including one or more of the signs in Beck's triad (hypotension, distended neck veins, and muffled heart sounds). In the remaining patients, hemorrhagic shock develops after free bleeding from an atrial or ventricular wound into one or both hemithoraces.

Diagnosis of penetrating injuries to the heart often requires a high index of suspicion. The locations of entrance and exit wounds, the trajectory and path of the wounding object, and the locations of any retained missiles on radiographs are helpful in predicting heart injuries. Proximity wounds to the heart are defined as those that penetrate the chest wall in the area bounded superiorly by the clavicles, laterally by the midclavicular lines, and inferiorly by the costal margins. Any crossing of the anterior mediastinum by a missile or an instrument is also considered a proximity wound. Because cardiac injuries are present in 15%-20% of patients who present with proximity wounds, these injuries must be definitively excluded.

Physical examination is often unreliable in detecting pericardial tamponade. It is rare for all three signs in Beck's triad to be found; in fact, only about half of patients with tamponade show even two of the three. Moreover, detection of muffled heart sounds and distended neck veins amid the commotion typical of the trauma bay can be extremely difficult. Imaging studies may be helpful in this scenario.

As surgeons become more familiar with the use of ultrasonography in the trauma setting, two-dimensional surface echocardiography is gaining acceptance as a means of diagnosing cardiac injuries. When performed by appropriately trained surgeons, FAST detects blood within the pericardial sac with a sensitivity of 96%-100% and a specificity of 100%—results essentially equivalent to those achieved with a pericardial window.[7] In cases of concurrent laceration of the pericardial sac, pericardial ultrasound may not detect a cardiac injury because of associated decompression into the thoracic cavity.[72] If hemothorax is present, other diagnostic methods such as pericardial window are recommended.

The subxiphoid pericardial window remains the gold standard for diagnosis of cardiac injury. For otherwise stable patients with proximity wounds or suggestive signs and symptoms, a pericardial window should be considered when ultrasonographic findings are equivocal or when ultrasonography is unavailable. This procedure is usually performed in the OR with the patient under general anesthesia, often in combination with abdominal exploration (Fig. 27.5).

Some authorities advocate using pericardiocentesis to detect cardiac injuries, especially when rapid access to the OR, trauma surgeons, and anesthesiologists is not available. Drawbacks to this approach include the high rate of false positives and false negatives and the potential for iatrogenic cardiac injury. Furthermore, pericardiocentesis is of limited use in treating tamponade, because blood within the pericardial sac often is clotted and is not amenable to removal through a needle.

Surgical approach to penetrating cardiac injuries varies with mechanism of injury, patient physiology, and injury pattern.

A median sternotomy is a logical extension of a subxiphoid pericardial window and provides access to all four chambers of the heart. It is appropriate for most precordial stab wounds and some low-caliber gunshot wounds. Its main limitations are that it does not allow repair or cross-clamping of the descending aorta or examination or repair of the esophagus and bronchi. It also provides only limited exposure of the lower lobes of the lungs and the hemidiaphragms. A left thoracotomy is appropriate for patients who may require cross-clamping of the thoracic aorta and for those with suspected cardiac injuries in conjunction with other complex thoracic visceral injuries. Only occasionally is a right thoracotomy required; this incision generally does not provide adequate exposure of the heart.

Atrial wounds are generally amenable to early control by finger pressure or by exclusion with a vascular clamp and simple oversewing. Right or left ventricular free wall injuries away from the coronary arteries may be treated by applying digital pressure over the entrance wound for hemostasis, then placing horizontal mattress sutures under the wound, reinforced with an epicardial continuous suture along the site of injury. All left ventricular wounds should be repaired with felt-pledgetted or pericardial-pledgetted sutures. Many right ventricular stab wounds can be closed primarily without pledgets if the sutures are tied accurately.

Injuries near coronary arteries must be closed without incorporating the coronary artery in the suture. This can be accomplished by placing horizontal mattress sutures lateral and deep to the coronary artery across the cardiac laceration. If the sutures are tied with careful attention to the function of the myocardium distal to the injury and equally careful attention to the electrocardiogram, the laceration can be closed without coronary artery occlusion and subsequent ischemia. With all penetrating cardiac wounds, it is important to recognize the possibility of associated intracardiac injuries.

Blunt. Blunt cardiac injuries range from disruption of myocardium, septa, or valvular structures to cardiac contusion. Both cardiac disruption (also known as cardiorrhexis) and cardiac contusion are common; the former is seen most often in patients who die at the scene, the latter in those who survive to reach the hospital. Blunt cardiac injury typically involves a direct blow to the chest, usually sustained in a motor vehicle collision or a fall. Cardiac injuries generally are associated with sternal or rib fractures, though they may occur in the absence of any chest wall fracture; sternal fractures do not predict the presence of blunt cardiac injury.

The diagnosis of myocardial contusion is elusive. Many tests have been proposed, but none have proved definitive, except for direct visualization of the heart at surgery or autopsy. For practical purposes, the clinically important sequelae of myocardial contusion are myocardial dysrhythmias and pump failure. Guidelines have been proposed that may facilitate the workup of this condition.

The EAST guidelines recommend 12-lead EKG as an initial screening test in those with mechanism for and suspicion of blunt cardiac injury. If this screening EKG is normal, no further workup is required. If the admission EKG is abnormal, the patient should be admitted for continuous EKG monitoring for 24–48 hours. If a patient is hemodynamically unstable or abnormal, echocardiography should be obtained (transthoracic echocardiography or transesophageal if transthoracic is suboptimal). There is no role for cardiac enzyme analysis or cardiac troponin assay in the setting of blunt cardiac injury. The latter test may detect myocardial injury, but this information does not complement ECG and echocardiographic findings and has no clinical utility. Similarly, there is no role for nuclear medicine studies.[73]

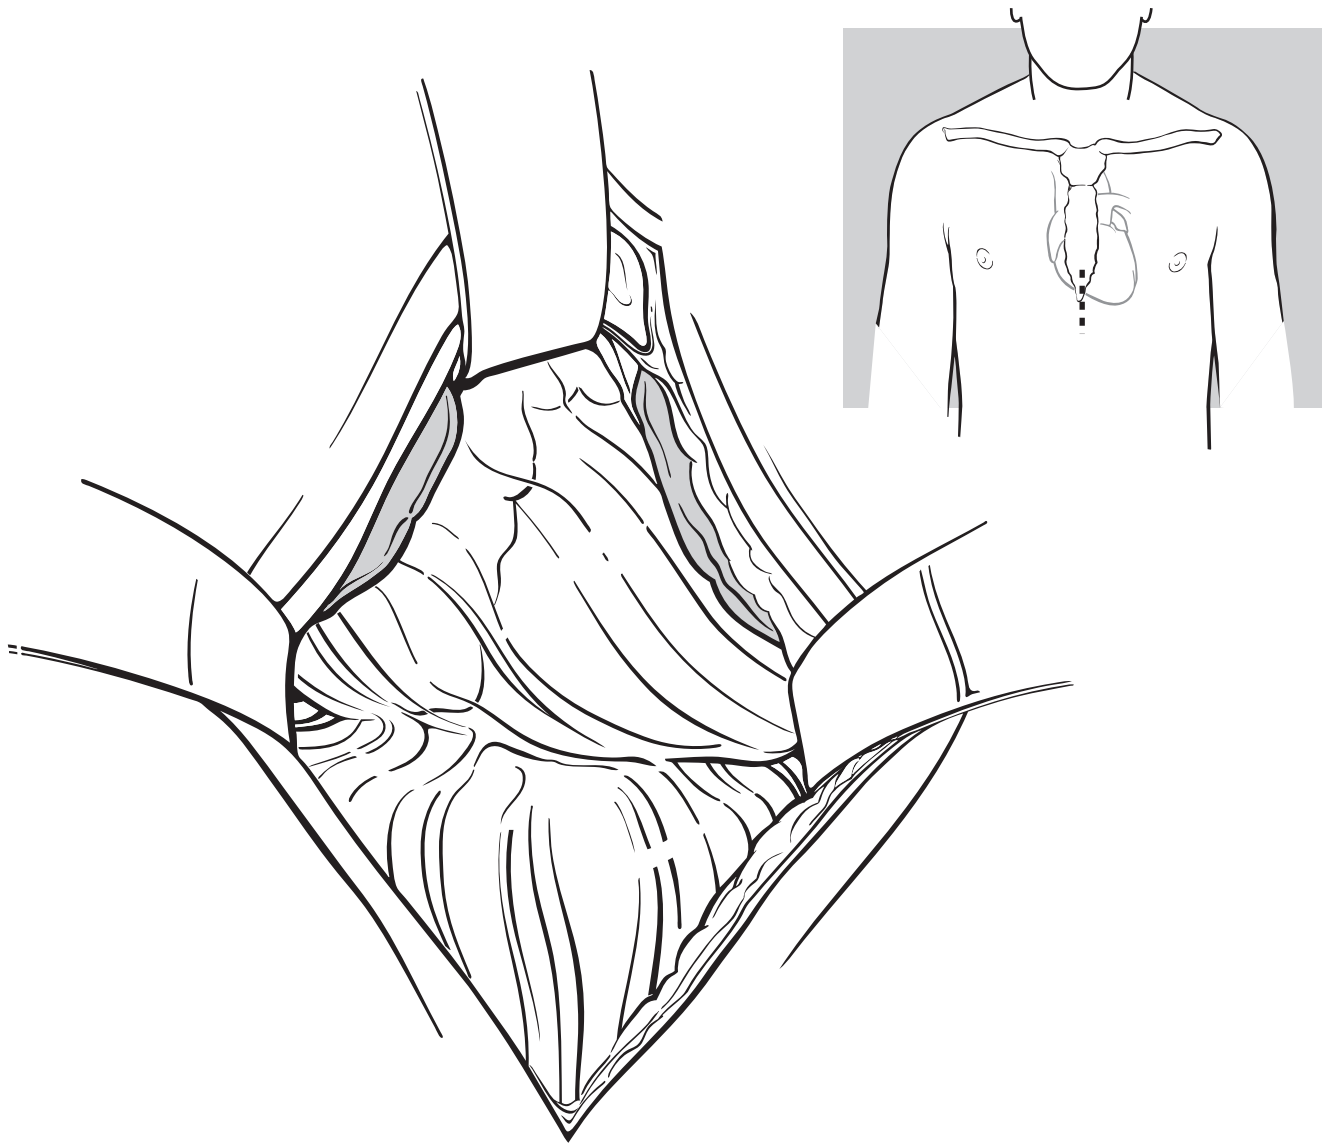
Pump failure associated with blunt cardiac injury is usually the result of right heart failure, because most hemodynamically


FIGURE 27.5. Subxiphoid pericardial window. The subxiphoid pericardial window remains the gold standard for diagnosis of cardiac injury.

major blunt cardiac injuries are caused by injury to the anterior right ventricular free wall. Treatment of right heart failure from blunt cardiac injury consists of inotropic support and reduction of right ventricular afterload. Dysrhythmias secondary to blunt cardiac injuries are treated in the same manner as dysrhythmias of any other etiology.

In the rare patient with cardiorrhexis who presents to the hospital with signs of life, the most common injury is right atrial perforation. Other lesions seen in patients with vital signs, in order of decreasing incidence, are left atrial perforation, right ventricular perforation, atrial septal perforation, ventricular septal perforation, coronary artery thrombosis, and valvular insufficiency (most commonly involving the tricuspid and mitral valves).[70,74,75] Principles of operative repair do not differ from those of penetrating cardiac trauma.

Blunt Aortic Injuries

Traumatic rupture of the aorta may account for as many as 10%-15% of all traffic fatalities, and the majority of such injuries are fatal at the scene. Traumatic disruption of the thoracic aorta results from rapid deceleration and is produced by a shearing effect caused by differences in the mobility of the aorta above and below a point where the vessel is fixed. Most thoracic aortic disruptions in survivors occur at the aortic isthmus just distal to the origin of the left subclavian artery, where the aorta is fixed to a substantial degree by the ligamentum arteriosum. Autopsy series reveal that as many as 40% of aortic injuries in nonsurvivors are not located at the isthmus, and the injuries tend to be complex.[76]

Suspicion of an aortic injury is most often triggered by abnormal findings on a chest radiograph in a patient with a high-speed mechanism of injury and multiple other injuries. Most patients show no signs or symptoms on physical examination, but some complain of interscapular pain or hoarseness. Others may exhibit a difference in blood pressure or pulse fullness between the upper and lower extremities or between the right and left upper extremities. Accordingly, the diagnosis is usually made radiographically.

Numerous radiographic signs of thoracic aortic disruption have been described, all representing hemorrhage within the mediastinum that alters or obliterates the shadows seen on a normal chest radiograph. Mediastinal widening is the most

frequent indicator. Other important signs are obscuration of the contour of the aortic knob, opacification of the aortopulmonary window, depression of the left mainstem bronchus, apical capping, deviation of the nasogastric tube, and displacement of the esophagus to the right. These signs may be present in any combination or may be entirely absent. Currently, thoracic CT is used liberally for diagnosis of thoracic vascular injuries. CT is used in virtually all patients with abnormal chest radiographs and in many patients with normal chest radiographs with a mechanism involving a high degree of energy transfer. CT findings that are suggestive of aortic injury include mediastinal hematoma, periaortic hematoma, intraluminal irregularity (intimal flap), acute coarctation, and abnormal aortic contour. Depending on the experience of the interpreting clinician, aortography may be eliminated in most of these patients before surgical repair; the sensitivity and specificity of CT in this setting approach 100%.[77–79] Aortography should continue to be used for equivocal cases or cases in which spiral CT is not available.

Essentially all aortic injuries associated with mediastinal hematomas should be repaired. Repair of these injuries, however, is less urgent than attainment of an adequate airway, control of external or cavitary hemorrhage, and evacuation of intracranial mass lesions. If there is active bleeding from a blunt aortic injury, it will be massive and the need for exigent and primary attention should be apparent; lesser amounts of bleeding from a chest tube often derive from associated injuries. If intra-abdominal bleeding is present, laparotomy is indicated before repair of the contained thoracic aortic injury and before aortography. Similarly, in patients with intracranial hemorrhage that necessitates operative evacuation, craniotomy should take precedence over repair of the contained thoracic aortic injury.

While one is temporizing, stringent efforts must be made to prevent hypertension and reduce shear forces across the injury, ideally by means of intravenous beta blockade. Esmolol, because of its short half-life, is the best agent to use in these patients, who are at risk for sudden hypovolemic episodes of hypotension. The goals of medical therapy are a heart rate lower than 100 beats per minute and a systolic blood pressure of approximately 100 mm Hg (in young and middle-aged patients) or 110–120 mm Hg (in elderly patients). With careful delayed operative management of aortic injuries, the risk of rupture is low but is not completely eliminated.[80,81]

Traditional repair techniques include exposure of the injury via left thoracotomy with direct repair or interposition graft placement. Although excellent results have been obtained with so-called clamp-and-sew techniques, most guidelines recommend use of some form of distal aortic perfusion using either left atrial–distal aortic bypass or partial cardiopulmonary bypass with femoral cannulation. With distal aortic perfusion, the risk of paraplegia is approximately 5% and is independent of clamp time; without distal aortic perfusion, ischemic times longer than 30 minutes are associated with an exponential rise in the incidence of spinal cord injury.

The use of endovascular stent grafting for repair of blunt aortic injury is increasing rapidly. Several reports have demonstrated success in the use of this technique.[82–84] Initial reports regarding the use of this technology report that advantages include a lower incidence of paraplegia, fewer respiratory complications, and lower mortality than the open approach to repair.[85–87] However, most studies examining this technique are single-institution and retrospective without long-term outcome data, and so interpretation of results should be approached with caution. There are limitations with the current level of stent graft technology, and device-related complications have been reported. However, the field of endovascular intervention is expanding rapidly, and indications for endovascular repair of blunt aortic injury are in evolution.

Great Vessel Injuries

Except for tears in the descending aorta, injuries to the thoracic great vessels, by any mechanism, are rarely seen in clinical practice; the best descriptions come from wartime and autopsy series. Diagnosis and management of these injuries cover a wide spectrum of possibilities, depending on mechanism of injury, presenting features, and associated injuries.

Penetrating Injuries. Penetrating thoracic great vessel injuries are usually obvious. The presence of an entrance wound at the base of the neck or in the chest should alert the clinician to this possibility. If the patient is in shock, urgent operation is required. If the patient's condition stabilizes with resuscitation, an arteriogram should be performed to localize the injury. Reports are emerging that Computed Tomography Angiography (CTA) may also be useful for delineation of these injuries.[16]

Exposure is most often obtained via a median sternotomy, with or without neck extension as needed for innominate, right subclavian, or carotid arterial injuries. Exposure of the left subclavian artery can be more difficult, even through a sternotomy with a trap-door extension. For isolated injuries to the proximal subclavian artery, a fourth-interspace left posterolateral thoracotomy is most useful. For injuries to the middle and distal thirds, supraclavicular incisions or deltopectoral incisions—or, occasionally, a combination thereof—are appropriate, provided that inflow control can be achieved. When inflow control is not attainable, as in cases involving injury at the thoracic outlet or the presence of a large hematoma, endovascular control of the proximal subclavian artery by means of a balloon catheter may be necessary. Moreover, there is a growing body of literature supporting endovascular management of great vessel injuries.[84,88–91] Endovascular repair may be considered in stable patients with arteriovenous fistula or pseudoaneurysm. Concerns with this modality primarily center on lack of data on long-term outcomes in a typically young patient population.

Most penetrating wounds of the middle and distal segments of the great vessels are amenable to lateral repair or end-to-end anastomosis; injuries involving greater tissue destruction usually prove fatal before the patient arrives at the hospital. The subclavian artery is a notable exception to this general rule, because the lack of elastic fibers in its tunica media makes it extremely friable. End-to-end anastomosis of an injured subclavian artery under any tension is doomed to failure. Accordingly, many subclavian injuries should be repaired with an interposition graft. Proximal injuries to the great vessels are best repaired by exclusion and bypass grafting with prosthetic material from the ascending aorta. Because bleeding is usually active, there is rarely enough time to arrange for cardiopulmonary bypass. Bypass is generally unnecessary, except in rare cases of associated ascending or aortic arch injury.

Blunt Injuries. Blunt injuries of the great vessels are typically the result of high speed and rapid deceleration. In postmortem examinations, pedestrians struck by motor vehicles have the highest rate of great vessel injuries. Patients with such injuries are rarely seen in the ED with signs of life.[88] Superior mediastinal hematoma is the most common finding during workup; its presence is an indication for further imaging with thoracic CT or angiography. Other presentations of blunt thoracic great vessel injury include dissection and thrombosis, which may be asymptomatic if localized to the proximal segments. Central neurologic injury may also be present, especially with carotid dissection. Associated stretch injury of the brachial plexus or the cervical nerve roots is common with subclavian artery injuries.

TRAUMA

Once the diagnosis is made, all great vessel injuries require intervention, typically surgical therapy. However, there are increasing numbers of reports describing successful endovascular treatment of these injuries in select patients. Small intimal defects found incidentally can sometimes be managed nonoperatively with repeat imaging and antiplatelet therapy. Surgery is contraindicated if neurologic injury is present, the injury is deemed nonsurvivable, or a common carotid dissection has extended into the distal internal carotid artery. As with blunt aortic injuries, the timing of surgery should be tailored to the treatment priorities mandated by the associated injuries. When time permits, proximal lesions are best managed with cardiopulmonary bypass and hypothermic circulatory arrest. Arranging for these techniques is mandatory with injuries involving the ascending aorta and the arch. Associated venous injuries are commonly encountered during exploration for great vessel arterial injury. If possible, they should be treated with lateral repair or patch venorrhaphy with pericardium or saphenous vein. However, ligation of these veins sometimes proves necessary and is generally well tolerated.

CONCLUSION

Thoracic trauma is a contributing factor in a majority of trauma-related deaths. With thorough physical examination and appropriate radiographic evaluation, the majority of these injuries can be identified and treated promptly. Most thoracic injuries do not require operative intervention; many may be treated with simple life-saving bedside procedures. However, when considering surgical intervention, many variables must be considered in this decision process, and each injury has unique issues to be addressed. Once the need for intervention is apparent, the critical decision for an appropriate surgical approach is based on a complete understanding of the location and nature of the injury.

TRAUMA

CHAPTER 28 ■ ABDOMINAL TRAUMA

JUAN ASENSIO, AURELIO RODRIGUEZ, GRACIELA BAUZA, T. VU, F. MAZZINI, F. HERRERIAS, AND ANDREW B. PEITZMAN

Evaluation and management of complex abdominal injury can challenge even the most seasoned surgeon, and missed abdominal injury remains a common cause of preventable morbidity and mortality. In the trauma patient, the abdomen is defined as the area between the nipples and the symphysis pubis. Because of the wide excursion of the diaphragm, penetrating injury at or below the nipple line (4th intercostal space) may involve the abdominal viscera. Understanding injury patterns increases the likelihood of timely diagnosis and treatment of injuries. The broad categories of abdominal injury are blunt injury and penetrating injury, with different injury patterns and different management and treatment. The paradigm shift to nonoperative management for blunt abdominal injury, and occasionally penetrating injury, has been made possible by the wide availability of computed tomography (CT) and a better understanding of the natural history of injury to the solid organs; spleen, liver, and kidney, specifically.[1]

INITIAL ASSESSMENT

The initial assessment of the trauma patient begins with the assessment of airway, breathing, and circulation. Based upon patient physiology on emergency department presentation, different levels of detailed examination and attention to life-threatening and non-life-threatening injuries may have occurred. Initial resuscitation of the trauma patient is discussed in Chapter 21, but for the purpose of this chapter, it is imperative to know that in a patient with potential abdominal injury, intravenous access should be supradiaphragmatic (i.e., subclavian, internal jugular, or antecubital fossa). In the patient with femoral intravenous access, potential abdominal vascular injuries such as liver, inferior vena cava (IVC), iliac arteries/veins, or aorta will result in fluid/colloid infusion into the abdominal compartment, creating further complications and ineffective resuscitation. In the patient with multiple gunshot wound (GSW) or stab wound (SWs) injuries, and high likelihood of both chest and abdominal injuries, intravenous access must be secured above and below the diaphragm.

Critically ill trauma patients are typically cold, coagulopathic, and acidotic; a lethal state referred to as the **triad of death**. Remember that trauma patients die from abnormal physiology. Do not focus on defining every anatomic injury in a critically ill trauma patient; the critical determination is the need for laparotomy.

BLUNT TRAUMA

Blunt mechanisms of injury include motor vehicle collision (MVC), motorcycle collision, pedestrians being struck, blast and crush injury, and fall from a height. Intra-abdominal injury in these scenarios results from compression and shearing forces on the tissues. Solid organ injury is most common: liver, spleen, kidney, or mesentery. Remember that seat belts not only save lives, but change injury patterns. Intestinal perforation or mesenteric injury is common in the restrained victim of MVC; present in 25% of patients with a lap belt mark.
